The Hydrogenation of Substituted Acetylenes with Raney Nickel[1]

BY KENNETH N. CAMPBELL AND MICHAEL J. O'CONNOR

Other workers have shown that the course of the catalytic hydrogenation of substituted acetylenes is profoundly influenced both by the nature of the substituents and by the catalyst employed. With platinum catalysts,[2] in general, there is no change in the velocity of hydrogenation when two atoms of hydrogen have been absorbed, while with the less active palladium catalysts,[2,3] there is frequently a great diminution in velocity, and it is possible to isolate the intermediate olefin in a pure state.

In this connection, it seemed of interest to study the catalytic hydrogenation of substituted acetylenes, using Raney nickel as the catalyst. Dupont[4] has made a similar study, which was, however, limited to 1-heptyne, phenylacetylene, 2-octyne and 1-methoxy-2-nonyne. He reported that the two monosubstituted acetylenes showed little or no change in velocity of reduction when one molar equivalent of hydrogen had been absorbed, but that the disubstituted ones did.

We have extended the investigation to include mono- and dialkylacetylenes, mono- and diphenylacetylenes, and phenylmethylacetylene, in order to determine the effect of substitution on the course of the reaction. We have found that all the acetylenes studied are readily reduced at room temperature, and pressures of three to four atmospheres, and that at the beginning, at least, the reaction is markedly exothermic.

Our results show a relation between the symmetry of the acetylene molecule and the course of the reduction. The reduction curves for the monoalkylacetylenes showed a slight change in slope at half reduction, while the dialkylacetylenes showed a more pronounced change in slope, which was particularly noticeable in the case of the symmetrical dialkylacetylenes. Phenylacetylene and phenylmethylacetylene, which are electronically the least symmetrical of the acetylenes studied, showed no change in slope in the reduction curve at half reduction. Diphenylacetylene, on the other hand, readily absorbed one molar equivalent of hydrogen, and the reaction stopped at this point, yielding isostilbene.

By stopping the reduction when one molar equivalent of hydrogen had been absorbed, it was possible to isolate the corresponding olefin in most cases. Raney nickel seems, therefore, to act catalytically similarly to palladium, and is easier to use. This appears to be a good method for preparing many pure olefins, with the double bond in a definite position, which are not readily obtainable by other methods. When the reduction is carried to completion, pure saturated hydrocarbons are obtained. Analyses made on the crude half-reduction products from the monoalkylacetylenes showed that less than 0.5% of acetylene remained. Since the acetylene used up accounts for practically all of the hydrogen absorbed, it is evident that very little saturated hydrocarbon was present. The physical constants of the 1-hexene and 1-heptene obtained by us compare favorably with those recorded in the literature. The method of analysis was not applicable to the products from the dialkylacetylenes, but since these showed a more pronounced change in slope in the reduction curve than did the monoalkylacetylenes, it is justifiable to assume that the olefins obtained are not appreciably contaminated by acetylenes or paraffins. Dupont[4] showed by means of Raman spectra that the olefins obtained by the half-reduction of 2-octyne and 1-methoxy-2-nonyne contained little or no unreduced acetylene.

No attempt was made in this work to establish the geometrical configuration of the olefins. Since Raney nickel seems to have a catalytic action similar to that of colloidal palladium, and since *cis* olefins are produced by the reduction of dialkylacetylenes with colloidal palladium,[3] it seems reasonable to assume that the olefins obtained in this study had the *cis* configuration. This is supported by the fact that isostilbene was obtained from the half-reduction of diphenylacetylene.

Following the work of Reasenberg, Lieber and Smith,[5] the promoting effect of small amounts of alkali and/or chloroplatinic acid on the catalytic reduction of amylacetylene and dibutylacetylene was investigated. When chloroplatinic acid and alkali were used together, reduction occurred more rapidly in the case of amylacetylene, but there was no significant change in the velocity of reduction of dibutylacetylene (see Fig. 2).

Experimental

Columns.—Unless otherwise noted, all distillations were made through a Fenske–Whitmore total-condensation, partial take-off column, packed with 3-mm. glass helices. The packed section was 12 mm. × 400 mm.

Monoalkylacetylenes.—These were prepared from the alkyl bromides and sodium acetylide in liquid ammonia by the modified Picon synthesis,[6] and purified by distillation through the column.

Dialkylacetylenes.—These were made from the alkyl bromides, sodamide and sodium acetylide by a modification of the procedure of Bried and Hennion.[7] In the case of the unsymmetrical dialkylacetylenes, the higher alkyl group was introduced first.

Arylacetylenes. (a) **Phenylacetylene.**—This was made by a modification of the method described by Vaughn, Vogt and Nieuwland.[8] Sodamide was prepared from 6 gram atoms of sodium in 2.5 liters of liquid ammonia, by the use of ferric nitrate as catalyst.[8] Three moles of finely powdered, dry, styrene dibromide was added, with vigorous mechanical stirring, to the sodamide solution as rapidly as the reaction permitted. Stirring was then continued for two to three hours, after which the mixture was hydrolyzed with ammonium hydroxide and distilled water, and extracted with ether. The ether solution was washed with 15% hydrochloric acid to remove suspended iron oxides and dissolved ammonia, and then with a dilute solution of sodium carbonate and finally with distilled water. The dried solution was distilled *in vacuo* through the column to give 161 g. (52.5%) of phenylacetylene, b. p. 75° (90 mm.). We found this procedure more convenient than that described in "Organic Syntheses."[9]

(b) **Phenylmethylacetylene.**—Two moles of phenylacetylene was added to a solution of 2.2 moles of sodamide in 2 liters of liquid ammonia. The solution was stirred for ninety minutes, and then 3 moles of dimethyl sulfate was added dropwise, with stirring, from a dropping funnel whose stem extended to the surface of the liquid ammonia. The mixture was stirred for about two hours, and was then worked up as described above. Fractionation of the product through the packed column gave 116 g. (50%) of phenylmethylacetylene, b. p. 113° (84 mm.).

(c) **Diphenylacetylene.**[10]—One mole of unsymmetrical diphenyldichloroethane[11] was added slowly to a solution of 3 moles of sodamide in 3 liters of liquid ammonia. The solvent was allowed to evaporate, and the solid residue was stirred with water to remove inorganic salts. The aqueous mixture was extracted with ether, the ethereal solution was washed with dilute hydrochloric acid, sodium carbonate solution and water. Distillation of the ether solution through a Claisen flask *in vacuo* yielded 142 g. (80%) of diphenylacetylene, b. p. 133° (8 mm.), m. p. 59°. The physical constants of the acetylenes used are recorded in Table I.

[a] Based on the alkyl bromide used. In the case of the dialkylacetylenes, the yield is based on the alkyl halide of higher molecular weight. [b] Prepared from acetone and hexynylmagnesium bromide. [c] These compounds have not been reported previously.

Complete Reduction of Acetylenes.—A mixture of 3 g. of Raney nickel, prepared by the method of Covert and Adkins,[12] 0.2 mole of substituted acetylene and 100 ml. of absolute methyl alcohol was shaken with hydrogen in an apparatus similar to that described by Adams.[13] Calibration of the apparatus with maleic acid showed that 0.1 mole of hydrogen corresponded to a change in pressure of 8.5 lb. (0.6 atm.). The initial hydrogen pressure was about 60 lb. per square inch (4 atm.). In all cases reduction was very rapid at first, and there was considerable liberation of heat. Reduction was usually complete in about thirty minutes. The saturated hydrocarbon was isolated by pouring the filtered solution into water, and distilling the dried organic layer through the packed

Ethylbenzene	84	136	745	1.4948	.8663	35.67	35.54

From the data obtained during the reduction (see Table III) curves were plotted showing moles of hydrogen absorbed against time in minutes. Typical curves are shown in Fig. 1. The curves obtained showed that for the symmetrical dialkylacetylenes and the acetylenic carbinol there was a sharp change in velocity at half reduction. The change in velocity was less marked, although still definite, with the unsymmetrical dialkylacetylenes and the monoalkylacetylenes, but in the case of phenylacetylene and phenylmethylacetylene there was no appreciable change in velocity at half reduction. The reduction of diphenylacetylene, which was carried out in benzene solution because the substance is not sufficiently soluble in methyl alcohol, stopped when one molar equivalent of hydrogen had been absorbed, and the product isolated was identified as isostilbene.

TABLE III

REDUCTION DATA FOR SUBSTITUTED ACETYLENES

Time, min.	Moles of hydrogen absorbed by acetylenes[a] Butyl	Et *n*-Am	Dipropyl	Phenyl	Phenyl-methyl	2-Me-2-hydroxy-3-octyne
1	0.047	0.059	0.035	0.035	0.118	0.024
2	.141	.150	.129	.071	.235	.090

[a] In each case 0.2 mole of substituted acetylene was used.

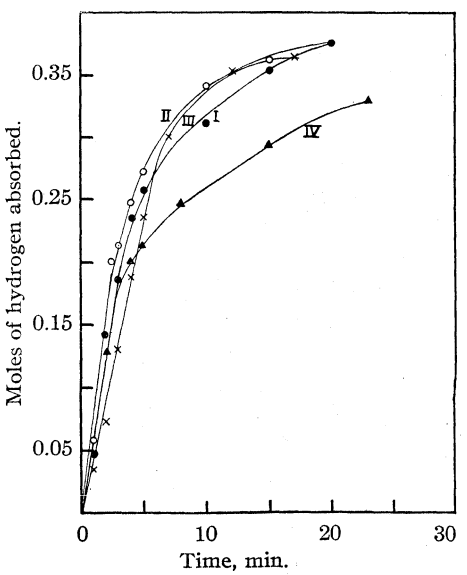

Fig. 1.—●, I, Butylacetylene; ○, II, ethyl-*n*-amyl-acetylene; ×, III, phenylacetylene; ▲, IV, dipropylacetylene.

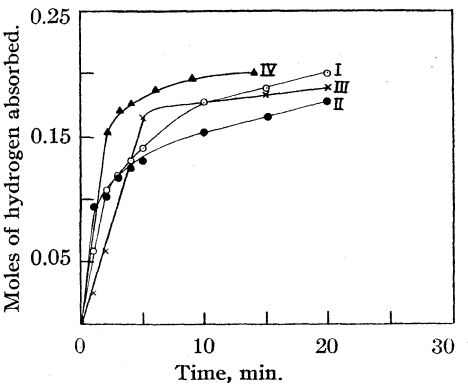

Fig. 2.—○, I, Unpromoted dibutylacetylene; ●, II, dibutylacetylene with alkali and chloroplatinic acid; ×, III, unpromoted amylacetylene; ▲, IV, amylacetylene with alkali and chloroplatinic acid.

Half Reduction of Acetylenes.—The half reductions of the substituted acetylenes were carried out as described above, except that the reaction was stopped when one molar equivalent of hydrogen had been absorbed. This usually required from two to five minutes, whereas in complete reduction the absorption of the second equivalent of hydrogen required fifteen to thirty minutes. Two 0.2-mole runs were combined, and the olefin isolated as described for the saturated hydrocarbons. The properties and yields of the olefins obtained are recorded in Table IV. In the case of styrene, the material tended to polymerize on distillation, and did not give satisfactory physical constants.

In order to determine whether appreciable amounts of substituted acetylene remained when one molar equivalent of hydrogen had been absorbed, analyses were made on the half reduction products of the monoalkylacetylenes. The methyl alcoholic solution from the reduction was filtered to remove the catalyst, diluted to 250 ml. with methyl alcohol and a 10-ml. portion taken for analysis. The sample was treated with 15 ml. of a 2% aqueous solution of silver nitrate, and the nitric acid liberated was titrated to the methyl red end-point with 0.05 *N* sodium hydroxide.[14] The results showed that, in general, at half reduction less than 0.5% of monoalkylacetylene was present before fractionation.

Effect of Promoters.—Following the work of Reasenberg, Lieber and Smith,[5] the promoting effect of alkali

(14) This method has been in common use in this Laboratory for several years.

TABLE IV

PHYSICAL CONSTANTS AND YIELDS OF OLEFINS

Olefin	Yield, %	B.p.,[a] °C.	Press., mm.	$n^{20}D$	d^{20}_4	MR_D Obsd.	MR_D Calcd.

[a] All boiling points except that for isostilbene were determined by means of the micro-Cottrell apparatus of Willard and Crabtree, *Ind. Eng. Chem., Anal. Ed.*, **8**, 79 (1936). [b] Schmitt and Boord, THIS JOURNAL, **54**, 751 (1932), record the following data: 1-hexene, b. p. 64° (760 mm.), $n^{20}D$ 1.3858, d^{20}_4 0.6732; 1-heptene, b. p. 95° (760 mm.), $n^{20}D$ 1.3999, d^{20}_4 0.6993. [c] These olefins have not been described previously.

and chloroplatinic acid were investigated in the reduction of amylacetylene and dibutylacetylene, as typical examples of mono- and dialkylacetylenes. In the case of amylacetylene, there was no promoting effect when chloroplatinic acid alone was used as promoter, but rather a slight retarding effect was noticed. When alkali and chloroplatinic acid were used together, there was some promotion observed (Fig. 2). In the case of dibutylacetylene, the use of alkali and chloroplatinic acid together resulted in no significant promotion (Fig. 2). The amounts of promoter, catalyst and unsaturated compound used were the same as in the work of Reasenberg, Lieber and Smith,[5] but the pressure was about four atmospheres, rather than one atmosphere.

TABLE V

ANALYTICAL DATA FOR THE NEW OLEFINS AND ACETYLENES

5-Undecene	85.62	14.38	85.73	14.57

Summary

1. The reduction of mono- and disubstituted acetylenes in the presence of Raney nickel has been studied, and a relation shown to exist between the symmetry of the acetylene molecule and the course of the reduction.

2. Several new olefins have been prepared by the half reduction of dialkylacetylenes. The half and complete reduction of acetylenes by means of Raney nickel is a feasible method of preparing certain olefins and saturated hydrocarbons.

The Conversion of Starch to Crystalline Dextrins by the Action of a New Type of Amylase Separated from Cultures of *Aerobacillus macerans*[1]

BY E. B. TILDEN AND C. S. HUDSON

It was first shown by Schardinger[2] that the cultivation of *Aerobacillus macerans* upon starch solutions produces a mixture of water-soluble dextrins, from which two distinct, non-reducing, crystalline compounds may be readily isolated. Subsequent work by other investigators has not demonstrated with certainty whether these crystalline dextrins represent comparatively simple components of starch itself, or whether they are formed as the result of synthetic activity of the living organism. In the latter case they would seem to be of little importance to the study of the constitution of starch. We now find, however, that when *Aerobacillus macerans* is grown for several weeks upon a potato medium, and the culture fluid is then filtered through a Berkefeld N filter to remove the microörganisms, the filtrate contains an enzyme which will produce the Schardinger dextrins from starch rapidly, and in greater yield than has been previously reported. We infer from this fact that the crystalline dextrins are components of the starch structure, or are closely related to such components.

During the course of the action of the enzyme upon starch there is no significant change in reducing power or optical rotation. In the present study, therefore, the progress of the reaction was followed by measuring the rapid and substantial decrease in viscosity, and also by means of a

(1) Publication authorized by the Surgeon General, U. S. Public Health Service.

(2) F. Schardinger, *Zentr. Bakt. Parasitenk.*, Abt. II, **22**, 98 (1908); **29**, 188 (1911).

simple microscopic test based upon Schardinger's observation that the crystalline alpha and beta dextrins form characteristic crystalline compounds with iodine. By the use of these tests it has been found that the activity of the culture filtrate is usually such that 0.5 ml. will convert 30 mg. of starch in a total volume of 1.5 ml. in thirty minutes at 40°. At 30° the digestion requires twice this period and at 20° four times; at 50°, however, the time taken for digestion is more than half that required at 40°, which indicates that some inactivation has occurred at the higher temperature. The enzyme is active, under the conditions employed, over a *p*H range of 5.6 to 6.4. It is precipitated along with other material by 37.5% acetone in the cold, and can be extracted from this precipitate with one-tenth the original volume of water. Considerable purification is thereby effected, and the activity of the enzyme is unimpaired.

Experimental

Microscopic Iodine Test.—To a drop of 0.1 *N* iodine solution on a spot plate is added 3 drops of the digest. A small quantity of the mixture is transferred with a platinum loop to a microscopic slide. The crystalline iodine compounds may begin to form at once near the edge of the drop, but the progress of the conversion is indicated from the quantity of these crystals that are observed after complete evaporation of the droplet on the slide. Under the microscope the crystals are seen to be a mixture of the green needles and dark blue hexagons characteristic of alpha dextrin, together with the brown prisms formed from beta dextrin. In control tests made upon digests of starch with other amylases, *e. g.*, that of *Aerobacillus polymyxa*, from which the main products are reducing substances, these crystalline iodine compounds were not formed, and the microscopic appearances were entirely different from those observed in the case of the *macerans* digests. This iodine test therefore seems to be specific for the products of the latter enzyme action.

Preparation of the Enzyme.—The potato medium consists of 100 g. of sliced raw potato and 10 g. of calcium carbonate per liter of water. After autoclaving for about an hour at 125° it is cooled and inoculated with a few drops of an active culture of *Aerobacillus macerans*. The new culture is allowed to develop for several weeks at 38°, and the fluid portion is then passed through a Berkefeld N filter. A sample of filtrate which had been kept sterile and cold retained much of its activity for a period of three months.

Details of an Experiment.—A paste containing 57.2 g. of potato starch (equivalent to 50 g. of anhydrous starch) in 2 liters of water was autoclaved at 125° for one hour, cooled to 40°, 100 ml. of a sterile culture filtrate was added under aseptic conditions, and the mixture was diluted with sterile water to give a starch concentration of 2%. The entire experiment was carried out at 40°. Preliminary tests had shown that under the conditions described the digestion should be complete in eight hours. A 250-ml. portion of the mixture was removed aseptically for use in obtaining data on the progress of the reaction, leaving 45 g. of starch in the main body of the solution which was to be used for isolation of the crystalline dextrins.

The change in viscosity was observed at 40° by means of an Ostwald viscosimeter which had an outflow time of ninety seconds for water at this temperature. The initial viscosity of the digest was assumed to be the same as that observed with a separate solution prepared from a culture filtrate which had been previously inactivated by boiling. The outflow time for this solution was 522 seconds, and by expressing viscosity in terms of the ratio t_s/t_w, where t_s is the outflow time for the digest sample, and t_w that for water, the initial viscosity of the digest was 5.80. In one hour the viscosity of the digestion mixture had dropped to 2.62, although the iodine test still showed a blue color, and no crystals were present. In two hours the viscosity was 1.95, the color with iodine was blue-violet, and a few crystals characteristic of Schardinger's iodine compounds had appeared. After four hours the viscosity was 1.11, the color with iodine was brownish-violet, and there was an abundance of the crystalline iodine compounds. By this time the solution had become water-clear, and its rotation in a 2-dm. tube was +8.4°. After six hours the viscosity had become constant at 1.02 and the rotation at +8.1°. The final specific rotation was therefore $[\alpha]_D$ +203°. During the next eight hours there was no change except in the color with iodine, which gradually became nearly a pure brown. Tests for reducing power were made at hourly intervals upon 5-ml. samples of the digest by means of the Shaffer–Hartmann microtechnique[3] and negligible values were obtained at all times. The final reducing power was found to be less than that of a 0.01% solution of glucose. The *p*H, which was initially 6.4, remained constant.

Isolation of the Crystalline Dextrins.—The procedure was that of Schardinger as modified by Lange,[4] who introduced trichloroethylene as a precipitating agent for the crystalline dextrins. The yield of crude product, calculated to the dry basis, was 18 g. or 40%. From this mixture the beta dextrin has been isolated and identified; the remaining material apparently consists largely of the alpha dextrin.

Summary

It is shown that the aqueous fluid from cultures of *Aerobacillus macerans* contains an enzyme which converts gelatinized starch to a high rotating ($[\alpha]_D$+203) mixture of non-reducing dextrins, of which the crystalline alpha and beta dextrins of Schardinger are components, without the production of maltose, glucose or other reducing sugar. We infer, therefore, that these dextrins are not products of the synthetic metabolism of

the organism but are either the true components of starch or are closely related to such true components. The research is being continued.

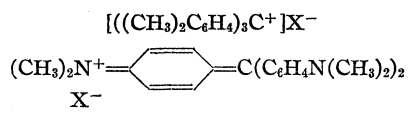
Triarylcarbinols. VII.[1] 4′-Dimethylaminobiphenyldiphenylcarbinol and its Relation to the Theory of Color of Dyes

BY AVERY A. MORTON AND WILLIAM H. WOOD

This paper is concerned with the structure of triphenylmethane dyes, particularly with the effect of a dimethylamino group substituted in the 4′-position of a biphenyl nucleus. It will be recalled that Dilthey[2] and Wizinger[3] have abandoned the conventional quinoid formula for dyes in favor of a carbenium, frequently called carbonium, structure in which the central carbon atom is given preference over nitrogen as the seat of basicity. Contrasting models for crystal violet are shown below.



The argument that the positions of nitrogen and carbon in the periodic table should favor a nitrogen base is met by claiming that the basic influence of the dimethylamino group is propagated through the benzene ring to a centrally located and basically enhanced carbon atom so that the latter becomes a superior base. In this scheme the coördinately unsaturated carbon atom is the chromophore which on conversion to the ionized state becomes colored. The dimethylamino group is the auxochrome.

We have applied this view to a system where the two competing, though vinylogously connected, points are separated by an additional phenyl nucleus in order to note, in a quantitative way, whether changes in basicity of the carbonium group are paralleled by changes in the properties of dyes. The sequence of reasoning underlying this work begins with the established fact that replacement of phenyl by a biphenyl nucleus enhances halochromism of triarylcarbinols and therefore by general opinion the basicity of the central carbon atom. This effect is well demonstrated with triphenyl- and trixenylcarbinol. While quantitative comparisons are difficult to make, the latter compound can be estimated qualitatively from colorimetric data of Ziegler and Boye[4] to be over five times stronger than triphenylcarbinol. Moreover, trixenylcarbinol becomes colored in sulfuric acid–acetic acid solution which is about one hundredth the concentration needed to produce color with triphenylcarbinol.[5] There is a definite shift in wave length from 414 to 542 mμ for the larger carbinol. As far as color can be used as the criterion of basicity there is no doubt but that substitution of phenyl by xenyl intensifies this property.

The second link in the chain of arguments is that substituents in the 4′-position of the biphenyl nucleus have their influence propagated through two phenyl nuclei, thus further enhancing the basicity of the central carbon atom. For example, trimethyltrixenyl- and trimethoxytrixenyl-carbinols previously[5] have been observed to show color in acid which is approximately one-tenth and one-hundredth, respectively, the strength needed for trixenylcarbinol. There is also a shift in wave length from 542 for the unsubstituted compound to 575 and 638 mμ for the two substituted compounds, respectively. The evidence is conclusive that there is a definite transfer of influence of substituents over two phenyl bridges and that marked changes in basicity of the central carbon atom can be observed. Indeed, as shown in competitive titrations, the basicity of trimethoxytrixenylcarbinol is not far below that of a dimethylamino group present in a compound of the triarylmethane type.

It then appears reasonable that a dimethylamino substituent in the 4′-position of a carbinol

which is stronger than triphenylcarbinol might, in the same manner, have an influence transported to the central carbon atom. If Dilthey's view is applicable to this case, the compound should be a dye, possibly more pronounced than the corresponding compound in the triphenylmethane series, but at least with some tendency in that direction. It scarcely would be expected that dye-like properties would be snuffed out entirely. The compound first intended for these tests was *tris*-[4′-dimethylaminobiphenyl]-carbinol, the trixenyl analog of crystal violet. The customary synthesis by sodium condensation applied to preparation of this compound led to an amorphous material which probably contained the desired compound but resisted efforts to purify and crystallize. A pure crystalline compound, however, resulted from the reaction between benzophenone, sodium and 4′-dimethylaminobromodiphenyl. The product, $(CH_3)_2NC_6H_4C_6H_4C(OH)(C_6H_5)_2$, 4′-dimethylaminobiphenyldiphenylcarbinol has one advantage, in that there is only one nitrogen competing against carbon for the anion. Its analog, dimethylaminotriphenylcarbinol, while not strictly a dye has many of the properties of dyes and is correctly considered the prototype of such substances. Unlike the simpler compound, however, the new product gave no color with dilute acids. Not only was it devoid of all properties remotely resembling a dye but the color of the carbinol was not realized until the basicity of the dimethylamino group had been neutralized completely. Moreover, the color of the carbonium salt was yellowish while that of the parent hydrocarbon was red, suggesting that the influence was that caused by a dimethylammonium salt in the 4′-position instead of the expected dimethylamino group. In this connection it is interesting to note that MacLean and Widdows[6] some years ago prepared dimethylaminocinnamyldiphenylcarbinol and found that it gave no color in dilute acids. Furthermore, the *tris*-[4′-dimethylaminobiphenyl]-carbinol, though a crude product, showed in titration experiments that the basicities of the dimethylamino groups were neutralized before any color of a carbonium salt appeared. Apparently no gradual loss of dye-like properties can be observed.

As far as these tests are concerned, there is no tendency toward formation of colors in dilute solution when the distance between the nitrogen atom and a central carbon atom is greater than one benzene ring. The principal seat of basicity in dimethylaminobiphenyldiphenylcarbinol is unquestionably on the nitrogen atom. This location is an eminently reasonable one, too, in all dimethylamino substituted triarylmethane compounds. In an energy transporting system of alternating single and double bonds such as are present in a phenyl nucleus, direction of movement of group influence can be either way. Enhanced basicity of a central carbon atom should accordingly increase the basicity also of the vinylogously connected nitrogen, so that maintenance of the vast natural superiority of nitrogen over carbon as a major sink for basicity of the molecule would thus be favored.

Approximate basicities of a number of amines and trixenylcarbinol have been made (see Table I). The method is not sensitive enough to catch fine differences but does reveal that the behavior of dimethylaminobiphenyldiphenylcarbinol toward perchloric acid is in accord with that expected of dimethylamino substituted compounds in general. The data also show that trixenylcarbinol is definitely stronger than such weak bases as acetamide or benzamide as contrasted with triphenylcarbinol which has been shown[7] to be weaker.

Though the main interest of this research was to test the effect of separating positions of possible basicity, several other interesting observations have been made. Of the three nitroanilines, the meta isomer is by far the strongest base, for it is the only one which can be titrated appreciably with trixenylcarbinol as an indicator. Another interesting point was the five-fold increase in yield of dimethylaminobiphenyl in a sealed tube methylation of the amine as the size of the tube was decreased by half.

Experiments

4′-Dimethylaminobiphenyldiphenylcarbinol.—A solution of 4 g. of 4-bromo-4′-dimethylaminobiphenyl and 2.6 g. of benzophenone in 50 ml. of thiophene-free benzene was refluxed on a steam-bath while 0.7 g. of sodium chips was dropped through a condenser over a three-hour period. The mixture was refluxed for fifteen hours longer and then decomposed with 25 ml. of water. After separation and concentration, the benzene layer was cooled in ice and the yellow amorphous precipitate filtered and dried. Attempts at crystallization were unsuccessful but the material sublimed as a white solid at 200° (0.5 mm.). Recrystal-

lization from alcohol gave fine needles melting at 177–178°; yield 2 g. or 36%; mol. wt. (Rast), 388, 415, 397 (calcd. 379); nitrogen analysis 3.63, 3.55%, calcd. 3.4%. The compound gave a strong red color in concentrated sulfuric acid and a yellow color in dilute solution of perchloric acid in glacial acetic acid. Observation of the light absorption in the Hardy Color Analyzer of the last solution showed the characteristic absorption of tertiary carbinols with a maximum value at 484 mμ.

Titration of the Carbinol.—Mallinckrodt 60% perchloric acid was treated with excess acetic anhydride and diluted with glacial acetic acid until the strength was 0.0421 *N*. The first drop of this solution added to a solution of 0.025 g. (0.000075 mole) of *p*-phenyltriphenylcarbinol[8] caused the appearance of a red color. With 0.028 g. (0.000074 mole) of 4′-dimethylaminobiphenyldiphenylcarbinol 1.9 ml. (0.000080 mole) of the standard acid solution was required before a permanent red color appeared. With 0.014 g. (0.000037 mole) the amount of standard acid required was 0.95 ml. or 0.000040 ml. A mixture of 0.19 g. (0.000057 mole) of *p*-phenyltriphenylcarbinol and 0.0214 g. (0.000057 mole) of 4′-dimethylaminobiphenyldiphenylcarbinol required 1.45 ml. (0.000061 mole) of standard acid. A similar mixture of 0.0182 g. (0.0000373 mole) of trixenylcarbinol and 0.014 g. (0.0000369 mole) of the same dimethylamino compound was neutralized by 0.9 ml. (0.000038 mole) of acid. In all these cases it is apparent that in the presence of 4′-dimethylaminobiphenyldiphenylcarbinol, halochromism is not displayed until enough acid has been added to neutralize the basicity of the dimethylamino group; in absence of this dimethylamino compound it can be observed with the first drop of acid.

TABLE I

In addition to the compounds listed, 2,6-dichloro-4-nitroaniline, diphenyl urea, acetamide, butyramide, benzamide, thiobenzamide, acetanilide, *p*-nitroacetanilide, benzanilide all gave the carbinol color (trixenylcarbinol as an indicator) with the first drop of perchloric acid solution.

Base	Quantity, g.	Moles × 10^5	Acid, ml.	Moles × 10^5

Titration of other Bases Using Trixenylcarbinol as an Indicator.—To ensure that results with the carbinol compound containing the dimethylamino group were not peculiar to this compound a number of bases were titrated in the same manner with 0.0421 perchloric acid in glacial acetic acid. The bases were Eastman Kodak Co. products used without any purification. Results are given in Table I. The series includes enough compounds to show the relative position of trixenylcarbinol as a base.

Titration of Dimethylaminobiphenyldiphenylcarbinol Using Trimethoxytrixenylcarbinol as an Indicator.—The dimethylamino compound 0.0188 g. (0.0000498 mole) in glacial acetic acid with 0.0181 g. (0.0000313 mole) of trimethoxytrixenylcarbinol required only 0.85 ml. (0.0000358 mole) of the standard perchloric acid solution before the blue color of the carbinol appeared. The result indicates that the trimethoxytrixenylcarbinol definitely competes with the dimethylamino compound for the acid and that transfer of group influence through two phenyl nuclei has been appreciable. Similar transfer of basic influence of the dimethylamino groups might therefore be expected.

Attempted Preparation of *tris*-(4′-Dimethylaminobiphenyl)-carbinol.—A solution of 8 g. of 4-bromo-4′-dimethylaminobiphenyl and 3.4 g. of diethyl carbonate in 50 ml. of thiophene-free benzene was refluxed while 2 g. of sodium chips was added over a period of forty-five minutes. After refluxing for sixteen hours longer the excess sodium was decomposed with alcohol and then with water. The mixture was filtered and the benzene layer treated with petroleum ether. A yellow amorphous solid was precipitated. Attempts to isolate a pure carbinol from this mass by crystallization, chromatographic adsorption on alumina, steam distillation to remove impurities, continuous extraction with petroleum ether and with ether, formation of salts with hydrochloric, sulfuric, and perchloric acids, and precipitation of the sodium carbinolate by either sodium or sodium alcoholate were all unsuccessful. The best material was obtained by dissolving the original yellow solid in concentrated sulfuric acid and diluting carefully with water until the sulfate of 4-bromo-4′-dimethylaminobiphenyl was precipitated. The filtrate was then neutralized with ammonia and a solid melting 160–183°, which could not be recrystallized from ether, alcohol or benzene, obtained. No color was observed in dilute acid solution. Titration of 0.0167 g. (equivalent to 0.000027 mole of the expected product) of this material with the standard perchloric acid solution showed that 1.6 ml. (0.000067 mole) could be added before a red carbonium salt color appeared. The product is obviously impure but it is apparent that the reaction produced no product which had any properties of a dye and that the carbinol color was not developed until after considerable neutralization of a stronger base had occurred.

Trixenylcarbinol.—Because so much difficulty was found in attempted syntheses of the above *tris* compound, a number of experiments were made to ensure that the best conditions for preparing the triarylcarbinols by the sodium condensation method were being applied. Best yields were secured when 19 g. of *p*-chlorobiphenyl and 5 g. of diethyl carbonate in 50 ml. of benzene were refluxed on a steam-bath while 5 g. of sodium (cut into chips 0.5 mm.

square and 2 mm. thick while kept under benzene in a beaker) were dropped through the condenser over a period of one-half hour. After twelve hours of refluxing the mixture was decomposed with water, the benzene layer was evaporated to 30 ml. and the carbinol precipitated with petroleum ether. The crude carbinol was then recrystallized either from xylene or alcohol after treatment with decolorizing carbon. Three experiments by this method gave 48, 48 and 47% yields, respectively, and a fourth, for some unexplained reason, gave 55%. Use of sodium sand instead of chips gave only 31%. Pieces of sodium 2–3 mm. in diameter and 2 cm. long produced only 39%. Activation of the chips with a little amyl alcohol before dropping through the condenser lowered the yield to 37%. Freshly distilled and excess diethyl carbonate did not improve the results.

4-Bromo-4′-dimethylbiphenyl.—Methylation of 4-amino-4′-bromobiphenyl (from reduction of the corresponding nitro compound by the method of García-Banús and Medrano[9]) was carried out in sealed tubes using 10 g. of the amino compound, 9 g. of methanol and 3 g. of concentrated hydrochloric acid. The tubes were heated to 140–150° for twelve hours and the products isolated in the conventional manner. The first two runs were made in Carius tubes about 66 cm. in length and gave yields of 0 and 9%. In the next three runs two of the tubes were only 43 cm., while a third was 66 cm. long. The batches were combined and gave an over-all yield of 28%. The final runs were therefore made in tubes only 36 cm. long and gave yields of 42, 44, 45, 42, and 45%. The length of the tube is limited by the volume of the reagent used. Seals of the short tubes must be well annealed in a luminous flame to prevent bursting at reaction temperatures.

Summary

4′-Dimethylaminobiphenyl has been prepared, its failure to have any properties resembling a dye noted, and the absence of any carbonium salt color until neutralization of the basic nitrogen atom observed. These results are not in accord with those predicted from the carbenium theory of triphenylmethane dyes.

Improved conditions for triarylcarbinol formation and for sealed tube methylation of an amine compound have been recorded.

Triarylcarbinols. VIII. Occurrence of Color with Trixenylcarbonium Salts

BY AVERY A. MORTON AND L. F. MCKENNEY

When trixenylcarbinol is dissolved in nearly dry acetic acid and the solution saturated with dry hydrogen chloride only a slight color is discernible. Upon adding a few drops of water a pronounced red color appears. By adding anhydrous calcium sulfate to the colored solution, the color gradually fades as would be expected if water were removed by the desiccant. It is apparent that water has played a definite part in production of color. Nor is the phenomenon limited to one reagent. Nitromethane, acetonitrile, formamide, urea, methanol, benzamide and many other compounds intensify color in the same way. In all cases intensity of color goes through a maximum as the quantity of agent is increased.

Formation instead of destruction of color with water is remarkable. The action is suggestive of complex formation though efforts to crystallize a complex from the strongly colored solution yielded the carbinol only and the position of the maximum absorption band was not displaced in the case of agents with which the color was intense.

The very weak acid, acetic, will not form a color with the carbinol unless the solution is heated. Nitric acid in acetic acid will produce a color with a few drops of nitromethane but not with water. With still stronger acids, sulfuric and perchloric, colored crystalline salts were obtained. In particular trixenylcarbonium perchlorate, $(C_6H_5C_6H_4)_3CClO_4HClO_4$, was a very stable compound, easily crystallized and purified. Upon electrolyzing a solution of this carbonium salt in nitromethane, nitrobenzene, or glacial acetic acid, the cathode rather than the anode portion became colorless. The same phenomenon was observed with an acetic acid solution of trixenylcarbinol to which a little sulfuric acid had been added, with a nitromethane solution of triphenylcarbonium perchlorate, $(C_6H_5)_3CClO_4$, and with nitromethane solutions of trixenylcarbonium sulfate, nitrate, and chloride. Furthermore, when a very dilute and colorless solution of trixenylcarbonium perchlorate in nitrobenzene was electrolyzed it was about the anode rather than the cathode that color reappeared.

Absence of color at the cathode cannot be due to a chemical reaction such as reduction since pure trixenyl- and triphenylcarbinols were recovered from the cathode compartment after electrolysis of the perchlorate salts in nitromethane. Were reaction at the cathode involved, there would of necessity have been decoloration at the anode due to migration of the supposedly colored cation away from that region. In spite of absence of color at the cathode it was found, in tests with the two perchlorate salts, that the bulk of the triarylcarbinol was isolated from that region. The whole behavior is in agreement with a view that the triarylcarbonium ion, or triarylcarbinol, is not capable of being colored if the perchlorate ion is removed by electrolysis and will appear colored once more when the ion is added.

The above phenomena were differentiated from those of the dye, crystal violet. Electrolysis was carried out in aqueous solution since conductance of this salt in nitromethane proved to be very poor. In this case the cation remained colored. It was deposited and reduced on the platinum anode. The reduced material was recovered and oxidized to reform the dye. Electrolysis of this material was typical of what might be expected. The ammonium ion, carrying the quinoid nucleus, was colored and was conveyed to the cathode compartment where it was reduced. The anode compartment became less colored from migration of the colored cations toward the cathode.

Experiments

Color Formation with Water.—The acetic acid was Mallinckrodt reagent grade which was found to have a melting point of 16.45° corresponding to about 0.1% water by weight. Trixenylcarbinol 0.115 g. (0.00024 mole) was dissolved in 200 ml. of acetic acid and the solution saturated with hydrochloric acid, prepared either from concentrated sulfuric acid and sodium chloride without any drying precautions or from aqueous concentrated hydrochloric acid dropped onto concentrated sulfuric acid, followed by drying over anhydrous aluminum chloride suspended on glass wool. In both cases the resulting acetic acid solution of the carbinol was faintly tinted. Addition of a few drops of water to such a solution caused it to become an intense red color. Samples for color analysis were made up by adding water to 25-ml. portions of the above solution. To maintain a constant volume, enough additional acetic acid was added to each sample to make the total volume equal to 30 ml. The intensity and position of the color band was determined in the Hardy color analyzer using the coördinates which correspond to absorption spectra measurements. The results are given in the table below. The quantity of water is corrected for the amount present in the acetic acid.

TABLE I

Water added, ml.	Acetic acid added, ml.	Total water present, mole	Color intensity[a] D at 542 mμ
0	5.0	0.0014	0.060
0.25	4.75	.0153	.140
0.50	4.50	.0292	.270
1.0	4.0	.0569	.325
2.0	3.0	.1124	.580
3.0	2.0	.1669	.260
4.0	1.0	.2234	.135

[a] D = density, T = transmitted light, $D = \log 1/T$.

The quantity of water plotted against the color intensity is a straight line up to maximum absorption. Beyond that point hydrolysis and precipitation occurred. The maximum absorption was at 542 mμ, a value agreeing well with that, 544, obtained by Burawoy,[1] who used a spectroscope with solutions of trixenylcarbinol and sulfuric acid in acetic acid.

Fading of Color with Calcium Sulfate.—A colored solution formed by dissolving trixenylcarbinol in glacial acetic acid, saturating with hydrogen chloride, and adding a few drops of water, was allowed to remain in contact with anhydrous calcium sulfate (the commercial grade known as Drierite was used). After eighteen hours the color had faded to a very light tint while an identical solution without calcium sulfate remained intensely colored. Addition of two drops of water to the solution which had stood over the drying agent restored the original red color. Tests with magnesium perchlorate and phosphorus pentoxide as desiccants were unsatisfactory because the soluble perchlorate and phosphoric acid themselves developed a color with the carbinol in absence of hydrochloric acid. Sodium sulfate was ineffective as a bleaching agent. The drying action of this last agent is known to be very considerably less than that of calcium sulfate.

Agents Producing Color.—Other compounds besides water have been found to cause a red color in the carbinol–hydrochloric acid–acetic acid solution. In Table II a list of these substances is given. The compounds are arranged in order of descending intensity of color. In the case of agents which imparted approximately equal intensity, the order is based on the moles of reagent required.

Ammonium acetate (ammonia), tetrachloroethane, ethyl iodide, iodobenzene, bromobenzene, phenol, anisole, phenetole, diphenyl ether, acetone, crotonaldehyde, ethyl benzoate, *sym*-trinitrobenzene, and nitrobenzene produced no color under the above conditions. Although small quantities of phenol and tetrachloroethane had no effect, addition of 0.002 g. of the carbinol to phenol or to tetrachloroethane as solvents caused an intense red color to appear.

Crystallization of the Carbinol from the Colored Solution.—The solubility of trixenylcarbinol in glacial acetic acid at room temperature was found to be 2.60 g. per liter. A solution of 0.4888 g. of the carbinol in 200 ml. of nearly dry acetic acid was saturated with dry hydrochloric acid and water added to produce a color. Upon standing crystals of carbinol precipitated from the strongly colored solution. Similar tests were made a number of times with identical results. The crystals were filtered, washed with anhydrous ether, and dried. The melting point varied from

200 to 201° as compared with the pure carbinol which melts at 206.5–207°.

Solutions of Trixenylchloromethane in Anhydrous Acetic Acid.—Trixenylchloromethane was prepared from the carbinol by reaction with acetyl chloride. The product was recrystallized from dry benzene until it was colorless. Its melting point was 193.0–193.5° with some decomposition. Dry acetic acid was prepared in four different ways to ensure that the color formed with trixenylchloromethane was not due to some impurity. By the first method 400 g. of reagent glacial acetic acid was kept over 50 g. of phosphorus pentoxide for twenty-four hours. It was then distilled through a 20-turn Davis column, all joints being of glass. The portion coming over at 118.4° was again treated with 50 g. more of the pentoxide after which it was distilled through the same column. By the second method, 700 g. of the acid (m. p. 15.65°) was refluxed with 28.3 g. of acetic anhydride and 14 g. of chromic oxide according to the method of Orton and Bradfield.[2] The acid was then distilled through the Davis column mentioned above. The fraction (200 ml.) boiling from 117.6 to 117.7° at 748 mm. was collected. Since both of the above fractions showed a pronounced red color when the chloro compound was dissolved in them, the refluxing with acetic anhydride was repeated in the absence of the chromic acid to ensure that no volatile chromyl compound had been formed. Glacial acetic acid, 700 g., was refluxed for twenty-four hours with 28 g. of acetic anhydride. The fraction which distilled at 118.4 to 118.6° was collected. To ensure further the absence of any inorganic compounds which might produce the color, a physical method of drying was employed. Reagent glacial acetic acid, 200 ml., and 200 ml. of anhydrous thiophene-free benzene were carefully fractionated through the column. A fraction, 100 ml., boiling at 117.8° (750 mm.) was collected and used. With all four samples of acetic acid a light to medium color was obtained when 0.002 g. of trixenylchloromethane was dissolved in 10 ml. of the acid.

Effect of Acetic Acid.—Trixenylcarbinol dissolved in glacial acetic acid was colorless when cold but strongly colored upon heating. The color disappeared when the solution was cooled.

Effect of Nitric Acid.—Trixenylcarbinol, 0.003 g., was dissolved in 15 ml. of glacial acetic acid. To this solution was added 6 drops of red fuming nitric acid (sp. gr. 1.6). No color developed. To 5-ml. portions of this solution were added, respectively, up to 10 drops of water and 1 ml. of nitromethane. The first caused no color while the second produced an intense red solution. Addition of 0.002 g. of the carbinol to concentrated nitric acid produced an intense red color.

Salts of Trixenyl- and Triphenylcarbinols.—Trixenylcarbinol, 1.1 g., was dissolved in 20 ml. of hot acetic anhydride and treated, a drop at a time, with 4 ml. of 60% perchloric acid. Beautiful green plate crystals separated immediately. The solution was cooled in an ice-bath, filtered, and the solid dried for twenty-four hours in an oven at 50–55° or until the analysis for acid content was constant. The yield varied from 80–86%. The analysis was carried out by boiling with standard caustic solution for ten minutes, followed by titration of the excess alkali. The organic matter recovered after this treatment was shown to be pure trixenylcarbinol by its melting point, 206.5–207°. The calculated for $(C_6H_5C_6H_4)_3CClO_4 \cdot HClO_4$ is 29.5% perchloric acid; found 29.6 and 29.7%. The crystals were stable in air and melted sharply at 219.5–220°. They dissolved slightly in benzene, forming colorless solutions which became colored on heating and colorless again on cooling.

Dark red crystals with green iridescence of trixenylcarbonium sulfate could be prepared by a similar reaction. They also could be obtained by cooling a hot solution of trixenylcarbinol in concentrated sulfuric acid. They were spread upon a tile and dried in a vacuum desiccator over solid sodium hydroxide. Because of their hygroscopic nature and the low volatility of sulfuric acid, the analysis was very unsatisfactory: calcd. for $(C_6H_5C_6H_4)_3CHSO_4 \cdot H_2SO_4$ 29.4% sulfuric acid, found 34 and 36%. Pure trixenylcarbinol was recovered as the organic portion from the analysis.

The nitrate was prepared by adding 1 g. of the carbinol to 20 ml. of fuming nitric acid, sp. gr. 1.6. After a half minute it was diluted with an equal volume of water and heated on a steam-bath. The red oil which rose to the top was removed. On cooling, it solidified to a red amorphous mass which reached a constant acid value of 21.3 and 21.4% nitric acid when kept in a vacuum desiccator over caustic. The theoretical for $(C_6H_5C_6H_4)_3NO_3 \cdot HNO_3$ is 21.2%. No nitration of the carbinol had occurred as shown by the melting point of the recovered material. From one preparation a few green (red by transmitted light) needle-shaped crystals of the nitrate salt were obtained which decomposed to a brown oil at 110°. The dark brown triphenylcarbonium perchlorate, prepared in the manner described for the trixenylmethyl compound,

(2) Orton and Bradfield, *J. Chem. Soc.*, 983 (1927).

analyzed within 0.1% of the theoretical for $(C_6H_5)_3CClO_4$ and showed all of the properties already reported by Hofmann[3] and co-workers.

Electrolysis of Trixenylcarbonium Perchlorate and other Salts.—Qualitative observations were made in a V-shaped 11 mm. i. d. tube with platinum electrodes. Solutions of the perchlorate salt were made by addition of a few crystals to anhydrous acetic acid, nitromethane, and nitrobenzene. Upon electrolysis of the resulting colored solutions the cathode compartment became colorless. For analysis of the two compartments a larger cell was made from 23 mm. i. d. tubing with vertical arms 24 cm. apart and 17 cm. high, and provided with a 20-mm. stopcock in the center and smaller cocks for draining the contents from around the platinum electrodes. The perchlorate salt, 150 mg., was dissolved in 130 ml. of Eastman Kodak Company pure nitromethane which had been twice redistilled to yield a fraction boiling at 101°. The current at the start was 14 ma. It rose rapidly to 18 and dropped slowly to 2 within two hundred and twenty minutes. The cathode compartment by that time was entirely colorless. The central stopcock was closed and 15 ml. each drawn off from around the cathode and the anode. The analysis was carried out by adding 5-ml. samples to 0.1 *N* alkali, extracting with ether and reëxtracting the ether layer with water to ensure removal of all of the perchlorate ions. Attempts to titrate the acid portion gave uncertain results because of the presence of traces of nitromethane. The ether layer was evaporated in a weighed beaker and dried to constant weight in an oven at 50–55°. The results are tabulated below.

Trixenylcarbinol	Milligrams per 5 ml. in samples 1 and 2		Average
From cathode compartment	7.3	7.5	7.4
From anode compartment	2.0	2.2	2.1
In original solution	4.0	4.4	4.2

Although the gain, 3.2 mg. around the cathode, was greater than the loss, 2.1 mg. about the anode, the evidence of transference of the carbinol toward the cathode is well beyond experimental error. The triarylcarbinol recovered from either compartment had a melting point of 206.5–207° identical with that of our purest samples. A mixed melting point showed no depression. When examined under the microscope the recovered crystals appeared to be entirely of one kind and identical with trixenylcarbinol.

A solution of 150 mg. of the perchlorate salt in 100 ml. of nitrobenzene had a strong purplish-red color. Upon dilution to one-fifth of this strength the color first appeared red and then turned colorless after a time. Upon electrolysis of this dilute solution a red color reappeared at the anode while the cathode portion remained colorless. Similar disappearances of color, possibly due to hydrolysis, were noted upon dilution of solutions in nitromethane and acetic acid.

Nitromethane solutions of the sulfate (1 mg. per 5 ml.), the chloride (6 mg. per 5 ml.), and the nitrate (12 mg. per 5 ml.) were electrolyzed in the V-shaped cell. In each case the cathode compartment became colorless.

Trixenyl- or triphenylcarbinol was electrolyzed in a solution of commercial glacial acetic acid, Mallinckrodt reagent grade, to which 3–4 drops of concentrated sulfuric acid were added. In both cases the solution became entirely colorless around the cathode.

Electrolysis of Triphenylcarbonium Perchlorate.—When the brown solution of 160 mg. of the perchlorate salt in 140 ml. of nitromethane was electrolyzed the cathode compartment became colorless as in the case of the trixenyl compound. The analysis was carried out in a similar manner and is recorded below.

Triphenylcarbinol	Milligrams per 5 ml. in samples 1 and 2		Average
From cathode compartment	6.9	6.1	6.5
From anode compartment	3.1	3.6	3.4
In original solution	4.0	4.4	4.2

The triphenylcarbinol recovered from the anode and the cathode was shown to be identical with an authentic sample by melting point, mixed melting point, and microscopic examination.

Electrolysis of Crystal Violet.—Solutions of crystal violet—approximately 2.5 mg. per 50 ml. of water—were electrolyzed in the large cell. After ten hours the cathode region was almost colorless and the anode section showed a considerable decrease in color intensity. Some colorless solid material which had been deposited on the platinum cathode was dissolved in hydrochloric acid and treated with lead dioxide. The blue color of crystal violet reappeared.

Summary

Addition of small amounts of water and some other compounds to a solution of trixenylcarbinol in glacial acetic acid saturated with hydrochloric acid causes formation of an intense red color.

Trixenylcarbonium perchlorate and triphenylcarbonium perchlorate have been prepared. Solutions of the former salt when subjected to electrolysis in organic solvents show disappearance of color around the cathode rather than in the anode compartment.

Monoalkyl Phthalates from Normal Aliphatic Alcohols

BY JAMES F. GOGGANS, JR., AND J. E. COPENHAVER

This work was undertaken because of the growing importance of the alkyl phthalates and the possibility of using them as checks for identification of alcohols, as well as to study the type of melting point curve given by these derivatives. Pickard and Kenyon[1] and others have prepared monoesters of the secondary alcohols for use in resolving their racemic mixtures, and some of the metallic salts of the monoesters have been patented for use in synthetic resins, yet very few of the normal monoesters have been described. The melting points and analyses are given in Table I and plotted in Fig. 1.

TABLE I

Ester	M. p. (corr.)	Acid number Calcd.	Found
Methyl[a]	82.4–82.7	311.5	313.1
Ethyl[b]	(47–48)	...	...
Propyl	54.1–54.4	269.6	270.3
Butyl	73.1–73.5	252.6	252.8
Amyl	75.4–75.6	237.6	237.0
Hexyl	24.6–25.4	224.3	222.9
Heptyl	16.5–17.5	212.4	211.8
Octyl	21.5–22.5	201.7	202.2
Nonyl	42.4–42.6	192.0	192.6
Decyl	37.8–38.0	183.2	182.7
Undecyl	43.8–44.1	175.2	175.2
Dodecyl	50.2–50.4	167.9	168.1
Tridecyl	52.4–52.7	161.1	160.2
Tetradecyl	59.8–60.0	154.9	154.6
Pentadecyl	60.3–60.5	149.1	148.9
Hexadecyl[c]	66.7–66.9	143.7	144.0
Heptadecyl	66.6–66.8	138.8	138.4
Octadecyl	72.4–72.6	134.1	133.4
Nonadecyl	70.8–71.0	...	...
Eicosyl	77.1–77.3	...	...

[a] Walker, *J. Chem. Soc.*, **61**, 717 (1892), gave m. p. 82.5°; Cohen, Woodroffe and Anderson, *ibid.*, **109**, 231 (1916); Kitamura, *J. Pharm. Soc. Japan*, **58**, 29–37 (1938), gave m. p. 82–82.5°.

[b] Amann, *Monatsh.*, **36**, 505–8 (1915), gave m. p. 47–48° after keeping at low temperature for a long time for crystallization.

[c] Willstätter, Mayer and Hüni, *Ann.*, **378**, 90 (1911), gave the m. p. as 61–62°.

Experimental

The method of preparation and purification of Pickard and Kenyon was followed with certain modifications. Esters from methyl through butyl were prepared by heating 4 g. of the anhydride with 1 g. of the alcohol at the reflux temperature for thirty minutes. From amyl to octadecyl, 0.5 g. of alcohol was heated with twice the required amount of anhydride at 105–110° for periods varying from thirty minutes to two hours, as the molecular weight of the alcohol increased. With nonadecyl and eicosyl, only 0.25 g. of the alcohol was used.

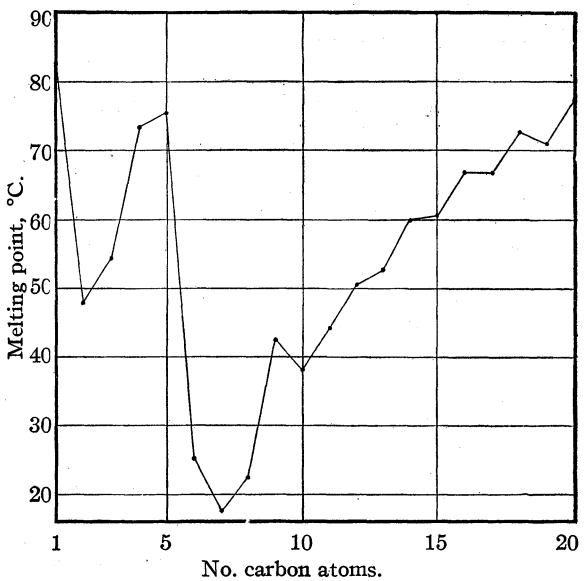

Fig. 1.—Melting points of the monoalkyl phthalates.

For purification, the reaction mass from methyl to hexyl was shaken with 25 cc. of benzene, filtered from excess anhydride and neutralized by dilute sodium carbonate, leaving the mixture slightly acid. The aqueous layer was extracted three times with 50-cc. portions of benzene to remove the unreacted alcohol and possible diesters. The esters were precipitated as colorless liquids or white crystalline solids from the water solution by dilute hydrochloric acid and crystallized three times from a mixture of 90% petroleum ether and 10% benzene.

As the sodium salts of the esters above octyl tend to form emulsions, the following procedure was used. The reaction mass was treated with 25 cc. of ether and filtered to remove the excess anhydride. After evaporating the ether, it was treated for forty-five minutes with 60 cc. of water, warming to 60–65° to hydrolyze any remaining anhydride. The dried residue was dissolved in 10 cc. of chloroform and filtered to remove any phthalic acid. The chloroform was evaporated under vacuum and the esters recrystallized three times from petroleum ether. It was found advantageous to use Dry-ice for cooling the solutions of the esters from hexyl through decyl, the solvent being removed by suction through a small tube tipped with porous alundum.

The melting points were taken, with mechanical stirring, in a 200-cc. bulb, fitted with a side-arm for the thermometer and melting point tube. Standard Anschütz ther-

(1) Pickard and Kenyon, *J. Chem. Soc.*, **91**, 2058–2061 (1907); **99**, 58 (1911); **103**, 1937 (1913).

mometers were used so the melting points may be regarded as corrected. The molecular weights were determined by titrating the esters, dissolved in 50% alcohol, with standard sodium hydroxide. The yields averaged from 35 to 50%.

Discussion

Due to the ease of hydrolysis and the time necessary at low temperature for crystallization, the ethyl ester was not isolated in pure enough form for analysis, hence Amann's value is used in the curve. The esters are white crystalline solids, having very definite melting points and soluble in organic solvents. There is sufficient variation in the melting points through dodecyl so that they could be used very satisfactorily as checks on the identification of the individual alcohols. It will be noted that up to decyl the melting points give a curious pattern and from this ester on, alternation gradually increases, both the odd and even ones forming smooth curves.

This problem was suggested by Dr. E. Emmet Reid, Research Adviser, University of South Carolina, and to him the authors wish to express their appreciation for assistance, and for the higher alcohols, the odd ones from undecyl to heptadecyl being those prepared by Meyer and Reid.[2]

Summary

The monoalkyl phthalates of the normal alcohols from methyl to eicosyl have been prepared and their melting points determined. A melting point curve is shown; it exhibits regular alternation above the decyl ester.

The Sterols of Alfalfa Seed Oil. I

BY L. CARROLL KING AND CHARLES D. BALL, JR.

1. Introduction

The fat constants and fatty acids of alfalfa seed oil have been studied by Jacobson and Holmes,[1] Schuette, Vogel and Wartinbee,[2] and by Schuette and Vogel.[3] As far as can be determined, there has been no previous account of an investigation of the unsaponifiable material from alfalfa seed oil.

About 4% of the oil which can be extracted from alfalfa seed with ethyl ether is unsaponifiable. This unsaponifiable portion consists of a crystalline substance or substances which represent about 35% of the total unsaponifiable, and of a clear, reddish, oily liquid which makes up the remainder.

The crystalline material consists primarily of a sterol very similar to or identical with the sterol isolated by Heyl, Wise and Speer[4] and Clenshaw and Smedley-MacLean[5] from spinach fat and later termed α-spinasterol by Hart and Heyl.[6] Simpson[7] in 1937 isolated α-spinasterol from senega root. The formula first assigned to α-spinasterol by Hart and Heyl[6] was $C_{27}H_{46}O$. Recent work by Larsen[8] on the completely reduced sterol, spinastanol, showed the latter to be identical with fucostanol and stigmastanol, for which the formula $C_{29}H_{52}O$ has been accepted. Since Larsen and Heyl[9] showed α-spinasterol to be doubly unsaturated, the formula for α-spinasterol, therefore, would be $C_{29}H_{48}O$.

The reddish oily fraction gives a positive Liebermann–Burchard reaction, but colors only the sulfuric acid layer in the Salkowski reaction. The Whitby B reaction[10] is positive. Further work on this material is in progress in this Laboratory.

2. Experimental

Extraction of Seed.—Ground alfalfa seed (*Medicago sativa* L.) was extracted continuously with hot diethyl ether. The extract was then filtered and the solvent distilled off in the presence of an atmosphere of carbon dioxide; yield 11.8% of a greenish oil which had an index of refraction of 1.4820 at 15°. The fat constants of this oil were in good agreement with those obtained by Jacobson and Holmes.[1]

Saponification.—To 100 g. of alfalfa seed oil was added 600 ml. of ethyl alcohol and 100 ml. of 50% potassium hydroxide. This mixture was refluxed for one hour,

cooled and exhaustively extracted with petroleum ether. The petroleum ether extracts were washed free from potassium hydroxide, using 10% alcohol. The solvent was then evaporated; yield 4 g. of unsaponifiable material.

Separation of Fractions.—The unsaponifiable fraction was taken up in 50 ml. of petroleum ether and allowed to stand. A slow growth of crystalline material took place. After one week this crystalline material was centrifuged, washed twice with petroleum ether, and recrystallized, once from petroleum ether and twice from absolute alcohol. The resulting crystals (Fraction I) were cholesterol-like plates and had a melting point of 164.4–164.8°. The mother liquor from Fraction I was reduced in volume to 25 ml. and allowed to stand. A second crop of crystals identical with Fraction I was obtained.

The mother liquor from the above fraction was placed in the icebox. A slow growth of crystalline material again took place. After two weeks this crystalline substance was separated. It was recrystallized once from petroleum ether and twice from absolute alcohol. The crystals (Fraction II) were elongated hexagonal plate-like structures, and had a melting point of 160–161°.

The mother liquor from the above fractions was evaporated to about 10 ml. and returned to the icebox for three weeks. The crystalline material, which grew slowly, was separated by diluting with cold petroleum ether and centrifuging. The substance was recrystallized once from petroleum ether and three times from absolute alcohol. The crystals (Fraction III) were elongated hexagonal plate-like structures and melted at 155–156°. No further crystalline material could be separated from the mother liquors. The reddish oil remaining weighed 2.6 g. and represented about 65% of the total unsaponifiable fraction.

Characterization of Fraction I.—The Liebermann–Burchard and Whitby B reactions were positive; the Salkowski reaction, negative. A series of esters of Fraction I was prepared. To prepare the acetate the sterol was refluxed in acetyl chloride until solution was effected, and for about ten minutes thereafter. The reaction mixture was cooled and then poured into water. The ester was then filtered off, washed with water and recrystallized twice from alcohol. The benzoyl ester, the *p*-nitrobenzoyl ester and the butyryl ester were prepared according to the procedure given by Hart and Heyl,[6] except that they were recrystallized from absolute alcohol. The phenylurethan was prepared by treating the sterol with phenyl isocyanate in petroleum ether solution. The product was recrystallized twice from absolute alcohol and once from ethyl acetate. Carbon and hydrogen determinations were run on the acetyl, the benzoyl and the *p*-nitrobenzoyl esters by the micro methods of F. Pregl.[11]

A summary of the constants and analyses of these compounds is given in Table I. The melting points of these derivatives checked quite closely with the corresponding derivatives for α-spinasterol cited by Sobotka.[12]

Bromination of Fraction I.—The sterol when dissolved in carbon disulfide and a solution of bromine in carbon disulfide added, gave only a soluble oil. Attempts to brominate in ether gave the same result. An attempt to brominate the acetate in ether solution also resulted in the formation of a soluble oil.

TABLE I

Compound	M. p., °C.	Analysis, % C Calcd.[a]	C Found	H Calcd.[a]	H Found
Sterol	164.4–164.8	84.4	83.0	11.7	11.7
Sterol acetate	180–181	81.93	81.84	11.01	11.21
Sterol benzoate	196–197	83.72	83.52	10.08	10.44
Sterol *p*-nitrobenzoate	211–213	77.00	76.34	9.26	9.49
Sterol phenylurethan	173–174				
Sterol butyrate	123–125				

[a] The required values are calculated from the formula $C_{29}H_{48}O$.

Mixed Melting Point Determinations.—A mixed melting point determination on Fraction I and α-spinasterol[13] gave no depression. The acetyl and *p*-nitrobenzoyl esters of α-spinasterol were prepared according to the same procedure used in preparing the corresponding esters of Fraction I. These compounds had the same melting points as the respective esters of Fraction I, and when corresponding esters from each source were mixed there was no melting point depression.

Preliminary work on Fractions II and III indicated that the crystalline substance in these fractions is also mainly α-spinasterol. However, the melting points of the derivatives corresponding to those for Fraction I were uniformly lower. Mixed melting point data indicated that other material contaminated the sterol. The Liebermann–Burchard, Whitby B, and Salkowski reactions were practically identical with those obtained for Fraction I. Further work on these fractions is in progress.

3. Discussion

A comparison of the melting point data, mixed melting point data, and analysis of the alfalfa seed sterol with that for the sterol reported by Heyl, Wise and Speer,[4] and later termed α-spinasterol by Hart and Heyl,[6] and by Larsen and Heyl[9] indicate that the alfalfa seed sterol is identical or very closely related to α-spinasterol. The observed and calculated values for the percentage of carbon in the free sterol leave something to be desired. However, it is interesting to note that if the data presented by Heyl, Wise and Speer[4] be calculated in the same manner as in the present work and not on the assumption of the presence of 1.0 molecule of water, their values for the percentage of carbon and percentage of hydrogen would be 83.2 and 11.7, respectively, agreeing closely with those reported in this paper. Further, the alfalfa seed sterol failed to give a crystalline bromide. The same observation was made

(13) We are indebted to Dr. Kolloff of the Upjohn Research Laboratories who very kindly supplied us with a specimen of α-spinasterol.

by Larsen and Heyl[9] and by Simpson[7] when they attempted to brominate α-spinasterol.

Summary

1. The unsaponifiable fraction of alfalfa seed oil has been separated into a crystalline substance and an oily mixture.

2. The crystalline substance is believed to be α-spinasterol.

EAST LANSING, MICHIGAN RECEIVED JULY 20, 1939

Porphyrin Studies. III.[1] The Structure of the Porphine[2] Ring System

BY PAUL ROTHEMUND

The importance of the porphine ring system is evident from the fact that it is the fundamental ring system of all the porphyrins. "Chlorins" are dihydroporphines, and the—thus far hypothetical—"Phorbine" ring, which is present in the chlorophylls, differs from chlorin only by the addition of an isocyclic ring in 6,γ-position.

Some time ago the author reported the synthesis of porphine by the interaction of pyrrole and formaldehyde.[3] It was found that many aldehydes can be condensed with pyrrole to yield porphines, in which the four *meso* (*ms*-) positions α, β, γ, and δ, carry the residue from the corresponding aldehyde as substituent. The reaction seems to be a general one of aldehydes, for more than 25 aliphatic, aromatic, and heterocyclic aldehydes gave positive results in this porphyrin formation. In this synthetic work a number of facts relating to the structure of the porphine ring have been observed.

In the second publication quoted above[3] it was mentioned that under certain conditions the reaction mixture from the porphine synthesis contained, in addition to porphine, a porphyrin with a hydrochloric acid number much lower than that of porphine. In comparison with porphine the two main absorption bands of this porphyrin were shifted about 100 Å. toward the red region of the spectrum. The new porphyrin formed only in small quantities, while porphine of hydrochloric acid number 3.3 was the main product. The hydrochloric acid number was 0.5, and the elementary analysis checked with that of porphine within the limits of analytical error. Each of the two porphyrins formed complex metal salts with magnesium ("phyllin"), iron ("hemin"), and copper. The low yields of the porphyrin with hydrochloric acid number 0.5 have prevented the preparation of complex metal salts other than the ones mentioned above so far, but from the component of hydrochloric acid number 3.3 the silver, zinc, cadmium, cobalt and nickel salt were prepared.

The direct determination of the molecular weight of the two porphyrins met with failure so far, but from analytical and spectroscopic data of the free compounds and of their metal complex salts, the author assumes that the new porphyrin isolated in the synthesis of porphine from pyrrole and formaldehyde is the isomer of porphine, and he suggests the term "isoporphine" for it. Two structural formulas may represent the difference in structure of the two compounds: formula I with hydrogen atoms linked to the nitrogen atoms in rings I and II (adjacent rings), and formula II, in which these hydrogen atoms are attached to nitrogen in rings II and IV (opposite rings).

There is, at present, no possibility of assigning one configuration absolutely to either compound, hence the use of the name porphine for structure I, and isoporphine for structure II is still arbitrary.

These structural formulas are drawn to show a double bond between carbon atom γ and the α carbon atom of ring IV (nomenclature of H. Fischer[4]). The presence of a double, not a single, bond between these carbon atoms has been postulated from physicochemical data by Stern.[5]

(1) Paper II, THIS JOURNAL, **58**, 625 (1936).

(2) In preceding papers we spelled "Porphin," because the term was introduced in this form into the chemical literature by H. Fischer for the—at that time hypothetical—fundamental ring system of porphyrins [H. Fischer and P. Halbig, *Ann.*, **448**, 193 (1926)]. Dr. Austin M. Patterson, member for the United States of the Committee on Organic Nomenclature of the International Union of Chemistry, and Chairman of the American Committee, recommended strongly to change the spelling in English to "Porphine," the final *e* signifying the basic character of the compound. He recommended further that the spelling of porphyrin be maintained.

(3) Rothemund, THIS JOURNAL, **57**, 2010 (1935); **58**, 625 (1936).

(4) Fischer, Halbig and Walach, *Ann.*, **452**, 268 (1927); Fischer, Moldenhauer and Süs, *ibid.*, **486**, 107 (1931).

(5) Stern and Wenderlein, *Z. physik. Chem.*, **A175**, 405 (1936).

The structures of porphine and isoporphine given above seem to be the best patterns not only for writing the formulas of nuclear-isomeric porphyrins, but also for the representation of the more complicated, partially hydrogenated compounds with porphine or isoporphine ring, as encountered in the chlorophylls and their derivatives.

Examples of this type of isomerism had been unknown so far. The author and his co-workers were, therefore, greatly interested in checking the synthesis of meso-(= α, β, γ, δ-)-tetrasubstituted porphines[3] with respect to a possible formation of two isomers. These syntheses yielded indeed in many cases two porphyrins with different hydrochloric acid numbers; their separation by fractionation with hydrochloric acid usually worked satisfactorily, and the isolated porphyrins showed characteristic differences in their spectra in ether.

The table gives some of the experimental results in abbreviated form; publication of the details will follow soon.[6]

TABLE I

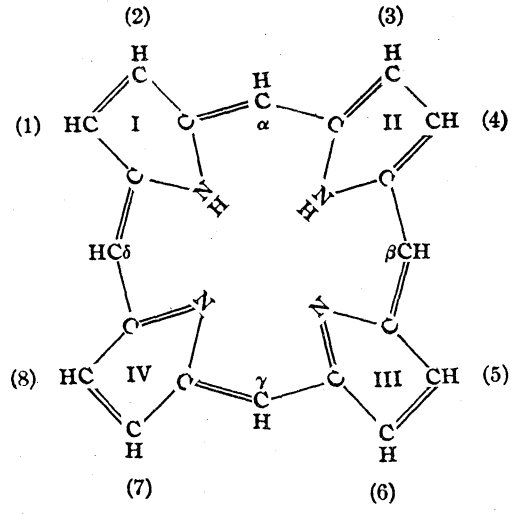
A question mark in a column indicates that the porphyrin has been found in the reaction, but that the purification has not been sufficient to determine its hydrochloric acid number.

Porphyrin	Hydrochloric acid number	
Porphine	3.3	0.5
$\alpha,\beta,\gamma,\delta$-Tetramethylporphine	0.5	0.075
$\alpha,\beta,\gamma,\delta$-Tetrapropylporphine	Near 8	2.3
$\alpha,\beta,\gamma,\delta$-Tetra-*n*-butylporphine	Near 14	7.0
$\alpha,\beta,\gamma,\delta$-Tetraisobutylporphine	?	5.2
$\alpha,\beta,\gamma,\delta$-Tetraphenylporphine	13.5	8.5
$\alpha,\beta,\gamma,\delta$-Tetrakis-3-methoxy-4-hydroxyphenylporphine	1.04	0.45
$\alpha,\beta,\gamma,\delta$-Tetrakis-*o*-hydroxyphenylporphine	15.7	?
$\alpha,\beta,\gamma,\delta$-Tetrakis-*m*-hydroxyphenylporphine	6.0	12.2
$\alpha,\beta,\gamma,\delta$-Tetrakis-*p*-methoxyphenylporphine	4	16.8

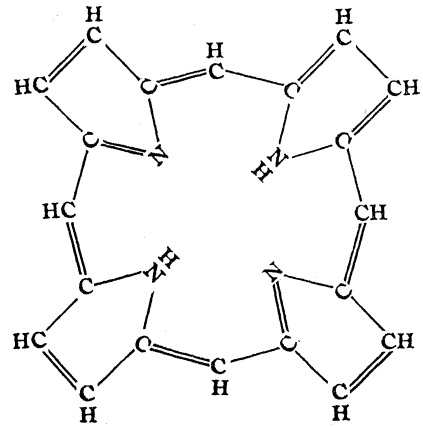
In Fig. 2 the absorption spectra of porphine, isoporphine and of their magnesium complex salts ("phyllins") are given diagrammatically. The characteristic spectroscopic differences are not very large, but they are sufficient to recognize an admixture of about 10 to 20% of one isomer to a solution of the other by visual spectroscopy.

The curve of the molecular absorption coefficient of porphine in ether solution throughout the visible region of the spectrum has been published

(6) Theses in partial fulfilment of the requirements for the degree of Doctor of Philosophy, Graduate School, The Ohio State University (of Th. Londergan, A. Menotti and J. Van Cleve).



Porphine



Isoporphine

Fig. 1.

by Dr. Albers and Dr. Knorr of this Laboratory.[7]

In accordance with the formulas in Fig. 1, we write the structures of the metal complex salts, *e. g.*, the phyllins, in the following manner (Fig. 3).

Haurowitz[8] could not find any connection between ion radius and absorption bands in porphyrins and their metal complex salts, and he concluded that a formula of type I (Figs. 1 and 3) with linkage of the metal to the nitrogen of adjacent rings, is improbable. He formulates the porphine ring as a biradical with ten conjugated double bonds. Stern[5] has set forth several objections to this assumption. It is hoped by the author of this paper that further studies, especially the comparative evaluation of absorption and fluorescence spectra, and the determination of the magnetic susceptibilities, of the porphines and the mesotetrasubstituted porphines will elucidate this matter. The röntgenographic investigation of these porphyrins and their com-

plex salts has been started by Professor Blake, Department of Physics, The Ohio State University.

In the issue of *Liebigs Annalen* of June 23, 1939, which has just been received, Helberger[9] described the synthesis of an isomer tetrabenzoporphine, which he named isotetrabenzoporphine. It was obtained from an oxygen-containing "Hydrogenation product 1," which in turn had been prepared by catalytic hydrogenation of *o*-cyanacetophenone. This isomer is especially interesting in connection with our synthesis of $\alpha,\beta,\gamma,\delta$-tetraphenylporphine, and $\alpha,\beta,\gamma,\delta$-tetraphenylisoporphine from benzaldehyde and pyrrole.[10]

(9) Helberger and Von Rebay, *Ann.*, **539**, 187 (1939). In the nomenclature given above (Fig. 1) Helberger's isotetrabenzoporphine would be called tetrabenzoisoporphine; we should like to suggest strongly the adoption of the latter name, *i. e.*, naming the fundamental rings porphine, and isoporphine, respectively, with the necessary prefixes. This method simplifies cataloging, and will avoid difficulties in cases of substances as mentioned in the table: $\alpha,\beta,\gamma,\delta$-tetraisobutylporphine, and its isomer $\alpha,\beta,\gamma,\delta$-tetraisobutylisoporphine.

(10) Reported at the 95th meeting of the American Chemical Society, Dallas-Fort Worth, Texas, April 19, 1938, by Rothemund and Menotti, and at the 49th Annual meeting of the Ohio Academy of Science in Cincinnati, Ohio, April 14, 1939, by A. Menotti. See also footnote 6.

Experimental[11]

For the experimental part reference is made to paper II.[1] The filling of the reaction tubes was the same; the sealed tubes were heated to 140–150° for twenty-four hours, and then worked up as described. Most of the isoporphine formed entered the 1% hydrochloric acid fraction (500 ml.), although a small amount was present in the 3% fraction, which was the main fraction for the isolation of porphine. From the 1% hydrochloric acid fraction isoporphine was transferred into 1 liter of ether by addition of saturated sodium acetate solution. The ether was washed with water to neutral reaction, and fractionated with 0.5% hydrochloric acid; the transfer from hydrochloric acid to ether was repeated for the purpose of further purification. After washing with water, and drying with sodium sulfate the ether was filtered and evaporated. The residue was dissolved in hot pyridine to make a saturated solution, and then ether was added, first drop by drop, and then in larger amount, until about ten times the volume of the original pyridine solution was obtained. Isoporphine crystallized in dark brown needles; its hydrochloric acid number was 0.5. It was soluble in pyridine, chloroform, or acetic acid; the solubility in pure ether was small, but ether containing acetic acid dissolved the substance much better. The substance did not melt, but decomposed upon heating above 250°.

(11) With the coöperation of Mr. B. Patterson.

Anal. Material recrystallized from pyridine–ether (1 vol. + 9–10 vols.) as described above, dried to constant weight over phosphorus pentoxide *in vacuo* at the temperature of boiling chloroform (drying pistol). Calcd. for $C_{20}H_{14}N_4$ (310.3): C, 77.40; H, 4.55; N, 18.05. Found: C, 77.5; H, 4.4; N, 17.7.

Magnesium Complex Salt of Isoporphine (Isoporphine Phyllin).—A solution of 6 mg. of isoporphine in 5 ml. of pyridine, 50 mg. of magnesium oxide, and 25 ml. of 30% methanolic potassium hydroxide were heated in a sealed tube for five hours to 150°. The solution was worked up exactly as described for the porphine phyllin.

Anal. Calcd. for $C_{20}H_{12}N_4Mg$ (332.6): C, 72.22; H, 3.64; N, 16.83; Mg, 7.31. Found: C, 72.0; H, 3.8; Mg, 7.3. (N not determined.)

The phyllin is not stable, when heated on a steam-bath with 5% hydrochloric acid. The complexly linked magnesium is eliminated and the free porphyrin regenerated.

Hemin and Copper Complex Salt of Isoporphine.—These two compounds were prepared analogously to the preparation of the corresponding porphine compounds.[3]

Anal. Calcd. for $C_{20}H_{12}N_4Cu$ (371.9): C, 64.59; H, 3.25; N, 15.06; Cu, 17.10. Found: Cu, 17.0 (digestion of the salt with concentrated sulfuric acid, evaporation of the acid and micro electrolysis of the weakly acid solution—Pregl's method—7 ml. electrolyte, 2.8 v., 35 ma., 50 min. boiling).

Anal. Calcd. for $C_{20}H_{12}N_4FeCl$ (399.6): C, 60.11; H, 3.03; N, 14.01; Fe, 13.96; Cl, 8.89. Found: C, 60.0; H, 3.2; N, 13.6; Cl (micro-Carius), 8.5.

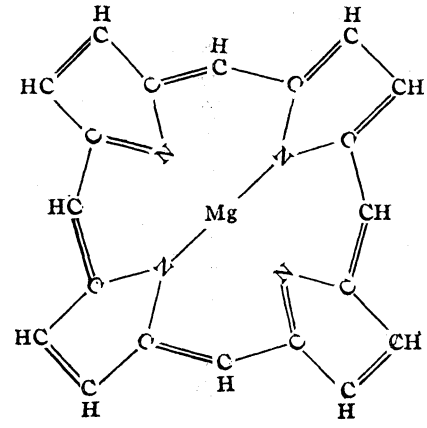
Porphine phyllin



Isoporphine phyllin

Fig. 3.

Summary

1. The low hydrochloric acid fraction of the porphine synthesis described previously yielded a new porphyrin of hydrochloric acid number 0.5.

2. Elementary analyses of this porphyrin and of some of its salts lead to the conclusion that this porphyrin is an isomer of porphine: "isoporphine."

3. The phyllin, hemin, and copper complex salt of isoporphine have been prepared.

4. The structures of the porphine and isoporphine ring are discussed.

5. A chart comparing the absorption spectra of porphine, porphine phyllin, porphine hemin, and porphine copper complex salt with those of isoporphine and its corresponding salts is presented.

6. The general synthesis for *meso*-tetrasubstituted porphyrins by the author was tested with respect to the possible formation of two porphyrins instead of one; cases in which two porphyrins have been found are given, and the hydrochloric acid numbers of the new porphyrins are listed.

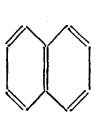
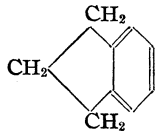
The Structure of Some Naphthalene, Hydrindene and Tetralin Derivatives

BY R. B. SANDIN AND T. H. EVANS[1]

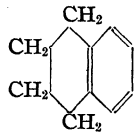
The problem which has to do with the fixation or the non-fixation of the Kekulé ring in such compounds as naphthalene has been attacked from numerous and different viewpoints.[2] There is much chemical evidence in favor of the idea that the double bonds of naphthalene are not free to migrate and that the Erlenmeyer formula (I) is



I



II



III

to be preferred.[3] The investigations of Fieser and Lothrop,[4] and Baker and Carruthers,[5] provide evidence of this kind. Also recently McLeish and Campbell,[6] working from the standpoint of the reactivity of the halogens in halogenated nitronaphthalene compounds, provide additional evidence in favor of the Erlenmeyer formula. Using Fuson's[7] theory of vinylogy, they have shown that the reactivity of the bromine atom in aromatic bromonitro compounds can be used to detect the presence and position of double bonds in bromonitro derivatives of naphthalene. They have also extended their work to derivatives of hydrindene and tetralin.

The authors of this paper call attention to another reaction which might prove of value in detecting ring stabilization and which, as far as the authors are aware, has never been used specifically for this purpose. The reaction involved is one studied by Nicolet[8] and co-workers. They showed that certain compounds containing bromine or iodine in the benzene ring could undergo hydrolysis in such a way that the halogen was replaced by hydrogen, the solution acquiring oxidizing properties as evidenced by the liberation of free halogen or by the formation of more highly halogenated derivatives. The halogen which reacted in this manner was always ortho or para to an amino or hydroxyl group. In studying the removal of such halogens it was found by Nicolet to be more convenient to perform the hydrolysis in the presence of stannous chloride in order to obviate effects due to resubstitution and oxidation. The important point in connection with the present work is that an arrangement in an aromatic compound of a bromine atom and an amino group in such a way that they are separated by a double bond or a conjugated system of double bonds, gives rise to a so-called "positive" bromine atom. This type of structure might also be added to the list of examples given by Fuson in his theory of vinylogy. A number of aminobromo derivatives of naphthalene have therefore been prepared and their behaviors examined with respect to an acid solution of stannous chloride at the boiling point. This work likewise has been extended to similar derivatives of hydrindene and tetralin. The measurements make no claim to accuracy, but are sufficient to show the relative reactivities of the bromine atom in the compounds examined. The results are found in Table I. The experimental details are given later in this paper.

Franzen and Staüble[9] have done considerable work on the effect of tin and hydrochloric acid and of an acid stannous chloride solution on brominated β-naphthols and β-naphthylamines. Their results are recorded in Table II.

If the Erlenmeyer formula for naphthalene is correct, the first three compounds in Table I should contain reactive bromines, whereas the bromine in 3-bromo-2-naphthylamine should be non-reactive. Also in 1,3-dibromo-2-naphthylamine the 1-bromo atom should be reactive, whereas the 3-bromo atom should be non-reactive. However, if there is no bond fixation, then the bromine in 3-bromo-2-naphthylamine should give rise to oxidizing properties and in the same way both bromines in compound (IV) should be substituted by hy-

VIII	5-Bromo-6-aminotetralin	1.0	60% removal of bromine
IX	5-Bromo-6-acetamidotetralin	2.0	85% of 6-aminotetralin, m. p. 34–5°
X	*o*-Bromoaniline	1.0	56% removal of bromine
	o-Bromoaniline	2.0	75% removal of bromine

TABLE II

Substance used	Conditions of hydrolysis	Result
1,6-Dibromo-2-naphthylamine	Stannous chloride and hydrochloric acid in alcohol; 21 hours	6-Bromo-2-naphthylamine
1,6-Dibromo-2-naphthylamine	Tin and hydrochloric acid	6-Bromo-2-naphthylamine
1,3,6-Tribromo-2-naphthylamine	Tin and hydrochloric acid	3,6-Dibromo-2-naphthylamine
3,6-Dibromo-2-naphthylamine	Tin and hydrochloric acid	Unchanged material
1,6-Dibromo-2-naphthol	Tin and hydrochloric acid	6-Bromo-2-naphthol
1-Nitro-3,6-dibromo-2-naphthol	Stannous chloride and hydrochloric acid	No bromine removed
1,3,6-Tribromo-2-naphthol	Tin and hydrochloric acid	3,6-Dibromo-2-naphthol
1,3,4,6-Tetrabromo-2-naphthol	Tin and hydrochloric acid	3,4,6-Tribromo-2-naphthol
3-Bromo-1-nitro-2-naphthylamine[20]	Tin and hydrochloric acid	3-Bromo-1,2-naphthylenediamine
1,3-Dibromo-2-naphthylamine[20]	Tin and hydrochloric acid; 2 hours	3-Bromo-2-naphthylamine

drogens under the experimental conditions. An examination of Table I definitely points to the Erlenmeyer formula for naphthalene possessing a double bond common to both rings. Attention is called to the high degree of reactivity of the bromine atom in a compound such as 1-bromo-2-naphthylamine and the extraordinary stability of the bromine atom in 3-bromo-2-naphthylamine.

Evidence in favor of the Erlenmeyer formula is also shown from the results presented in Table II. Here again we notice the persistence of the 3-bromo atom such as we have in 1,3,6-tribromo-2-naphthylamine. It might be expected that the 6-bromo atom should have been reactive, as the 6-bromo atom and the amino group are separated by a conjugated system of three double bonds. The fact that this bromine atom shows no reactivity is evidence that the double bond shared by the two rings does not function normally.[6,10]

In connection with the reactivity of the bromine atom in 1-bromo-2-naphthylamine, the proximity of the bromine atom to the adjoining aromatic ring may be of some importance. However, this effect is believed by the authors to be negligible. Franzen and Staüble,[9b] for example, have shown that when 1,3,4,6-tetrabromo-2-naphthol is reduced with tin and hydrochloric acid, the 4-bromo atom remains fixed.

Concerning the stability of the bromine atom in a compound such as 3-bromo-2-naphthylamine it is interesting to note that Nicolet[8e] gives as a possible mechanism for the elimination of a "positive" halogen from *o*-aminobenzene derivatives, first of all the formation of a quinoidal intermediate compound, and second a subsequent 1,3-elimination. On the basis of this conception it might be said that 3-bromo-2-naphthylamine is stable because the quinoidal intermediate is not produced. It is a known fact that 2,3-dihydroxynaphthalene does not yield a quinone on oxidation.[11] Evidently the two hydroxyls function independently and not as though they were connected by a double bond.

(10) Sampey, THIS JOURNAL, **49**, 2849 (1927).

(11) Marckwald, *Ann.*, **274**, 331 (1893); **279**, 1 (1894); Fries and Schimmelschmidt, *Ber.*, **65**, 1502 (1932); Fieser, THIS JOURNAL, **52**, 5219 (1930).

Regarding the structure of hydrindene and tetralin, Mills and Nixon[12] believe that there is bond fixation and give the structure (II) and (III) for these two compounds, respectively. The work of McLeish and Campbell confirms structure (II) for hydrindene derivatives as does also the earlier work of Fieser and Lothrop,[4b] Sidgwick and Springall,[13] and Baker.[14] Although the present work is not conclusive as far as hydrindene is concerned, any inference that might be drawn is in favor of structure (II) being the preferred structure. There is no doubt about the fact that the 6-bromo atom is remarkably reactive. In this respect it is similar to the bromine in 1-bromo-2-naphthylamine. Also the 4-bromo atom has a marked degree of stability although it is not completely unreactive. Similarly, McLeish and Campbell found that the bromine in 4-bromo-5-nitrohydrindene is very slightly reactive. Recently Fieser and Lothrop[2] have found that 5-hydroxy-6-methylhydrindene is capable of forming azo compounds in very weakly alkaline solutions. Also Baker[14] has shown that 5-hydroxy-4-acetylhydrindene is chelated to a certain degree. Finally, it is possible to make 4,6-dibromo-5-aminohydrindene[15] by direct bromination of 5-aminohydrindene. All these facts indicate (as Fieser and Lothrop[2] already have suggested) that the bonds in certain hydrindene derivatives are not fixed so rigidly that the 4–5 and 6–7 bonds cannot, under certain conditions, acquire double bond characteristics. In the authors' work the effect of the alicyclic ring is considered to be negligible, in view of the fact that 2-iodo-4-aminotoluene[3d] shows no evidence of "positive" iodine.

Concerning the structure of tetralin, the present work gives no definite information, since no 7-bromo-6-aminotetralin was available. The present results, however, do show a "positive" bromine in 5-bromo-6-aminotetralin. Contrary to the conclusions that might be drawn from this, McLeish and Campbell[6] found 6-bromo-5-nitrotetralin to be unreactive. Consistent with our results, Schroeter[16] and co-workers have reduced 5-bromo-6-hydroxy-7-nitrotetralin with stannous chloride and obtained a mixture of 5-bromo-6-hydroxy-7-aminotetralin and 6-hydroxy-7-aminotetralin.

For the sake of comparison, a study of the behavior of *o*-bromoaniline has been included. It will be noticed that the bromine reactivity in this case (two isomeric Kekulé or resonating forms) lies between the reactivity shown in the case of the bromine in 1-bromo-2-naphthylamine (the bromine and the amino groups separated by a fixed double bond), and the nonreactivity shown in the case of 3-bromo-2-naphthylamine (bromine and amino groups separated by a fixed single bond). Sampey,[10] working on the polarity of the carbon–halogen bond, has pointed out the remarkable reactivity of the halogens in ortho or para position to the hydroxyl group in halogen naphthols when the latter are treated with an acid stannous chloride solution. Under the same conditions, similar halogen phenols show little reactivity. Again, Hodgson and Leigh[17] call attention to the fact that the chlorine atoms in 2-chloro- and 4-chloronitrobenzenes are displaced much less easily by alkali than those in the corresponding chloronitronaphthalenes. Is it not possible that the difference in reactivity is connected with a stabilized structure for the naphthalene compounds?

Experimental Part

Preparation of Compounds.—1-Bromo-2-naphthylamine,[18] m. p. 63°, 4-bromo-1-naphthylamine,[19] m. p. 103°, and 2,4-dibromo-1-naphthylamine,[20] m. p. 118–119°, were prepared readily.

1,3-Dibromo-2-naphthylamine,[21] m. p. 119°, was prepared by the bromination of *p*-toluenesulfone-2-naphthalide, followed by hydrolysis with concentrated sulfuric acid. By the acid stannous chloride reduction of 1,3-dibromo-2-naphthylamine, there was obtained 3-bromo-2-naphthylamine, m. p. 169° (Consden and Kenyon[20] report 173°).

4,6-Dibromo-5-aminohydrindene,[15] m. p. 70–71°, was prepared by the bromination of 5-aminohydrindene.[14]

An 80% yield of pure 4-bromo-5-aminohydrindene, m. p. 54–55°, was obtained by reduction of 4,6-dibromo-5-aminohydrindene with stannous chloride and hydrochloric acid.

Anal. Calcd. for $C_9H_{10}NBr$: Br, 37.6. Found: Br, 37.3.

The time of reduction was thirty minutes. Longer periods gave a lowered yield. McLeish and Campbell[6] report a melting point of 50–51°. However, their compound was about 6% too high in bromine content and probably contained some unchanged dibromo compound.

5-Bromo-6-acetamidotetralin,[12,22] m. p. 126–127°, was prepared by the bromination of 6-acetamidotetralin in

glacial acetic acid. Acid hydrolysis of the preceding compound gave 5-bromo-6-aminotetralin, m. p. 52.5°.

Determination of Halogen Reactivity.—The method employed was somewhat similar to the one already used by Nicolet.[8] All the compounds were treated under as nearly the same conditions as possible, the only variable factor being the time. It was essential that the acid concentrations should be the same for all runs, since it is known that the rate of halogen removal is directly proportional to the acid concentration but is independent of the stannous chloride concentration.

In this work 0.02 mole of compound was dissolved in a boiling mixture of 25 cc. of glacial acetic acid and 20 cc. of concentrated hydrochloric acid. To this was added enough stannous chloride to give one mole of stannous chloride per gram atom of halogen in the compound being examined. The solution was then boiled in an all-glass apparatus under reflux for a suitable period of time. On boiling, some hydrogen chloride was lost. However, since all the experiments were carried on as nearly as possible under the same conditions, no attempt was made to avoid this loss. The reaction mixture subsequently was transferred to a beaker, treated with concentrated hydrochloric acid and cooled. The precipitated hydrochloric acid salt or stannichloride of the amine was filtered off and treated with sodium hydroxide. The liberated amine was either identified as such or as the acetyl derivative. Its weight was determined and sometimes also its halogen content. The mother liquor from the above amine hydrochloride was treated with sodium hydroxide and any precipitate produced was examined from the standpoint of identity, weight and halogen content.

Summary

Some brominated derivatives of α- and β-naphthylamine, 5-aminohydrindene and 6-aminotetralin have been examined from the standpoint of "positive" bromine content. It is believed that this reaction is useful in detecting double bond fixation. The results indicate that the structures of the naphthalene derivatives are based on the Erlenmeyer formula, and that the preferred structures for the hydrindene derivatives are based on the Mills and Nixon formula. No definite conclusion was reached regarding tetralin.

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY OF THE UNIVERSITY OF ALBERTA]

The Structure of Fluorescein, Sulfonefluorescein and Some of their Halogenated Derivatives

BY R. B. SANDIN, A. GILLIES[1] AND S. C. LYNN

Recently C. G. Le Fèvre and R. J. W. Le Fèvre[2] have determined the dipole moments of xanthone and some of its 2,7-disubstituted derivatives. They conclude that a nearly complete fixation of double and single bonds occurs in the xanthone skeleton (structure (I)). This is in accord with the theoretical prediction of Mills and Nixon:[3] "that fusion of a benzene ring with a 6-membered ring tends toward the stabilization in the former of that Kekulé individual which has a double bond between the points of attachment of the side nucleus."[4]

With the work of Le Fèvre and Le Fèvre in mind, it occurred to the authors of this paper that the xanthene dyes such as fluorescein and sulfonefluorescein and which in the lactoid modifications have a xanthone skeleton, might from a chemical standpoint show ring stabilization.[5]

The regulated dibromination of fluorescein has been examined and has been found to occur in the 4,5-positions.[6] This is contrary to what one would ordinarily expect from a consideration of a steric effect.[7] It is believed by the authors that this type of dibromination is an indication of ring stabilization. If the lactoid structure of fluorescein is assumed, then it is believed that structure (II) is the preferred structure. If, on the other hand, it is the quinoid form which is brominated, then it is assumed that either structure (IV) (two resonating negative ions) or structure (VI) (two

(3) Mills and Nixon, *ibid.*, 2510 (1930).

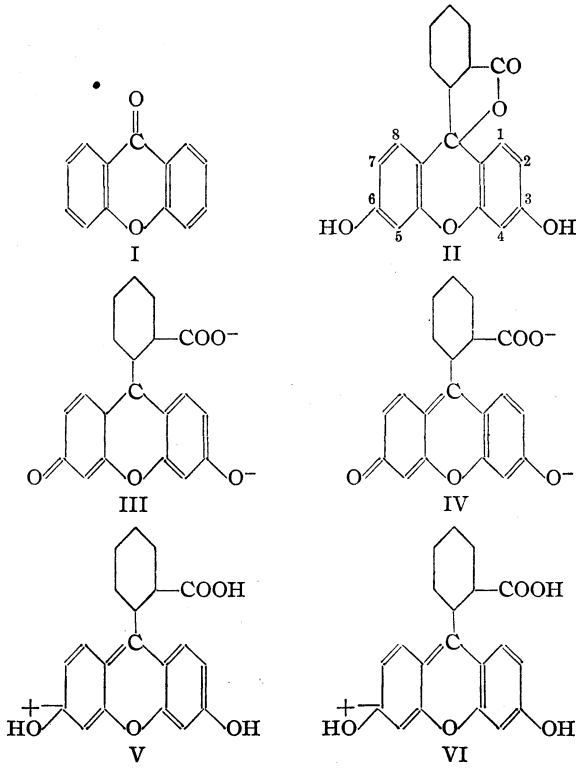
(4) In the case of tetralin, however, it has been found that tetralin, like all ordinary benzene derivatives, can react in both Kekulé forms. Fieser and Lothrop, THIS JOURNAL, **58**, 2050 (1936); Sidgwick and Springall, *J. Chem. Soc.*, 1532 (1936).

(5) For earlier work on the structure of fluorescein and sulfonefluorescein, see (a) Orndorff, Gibbs and Shapiro, THIS JOURNAL, **50**, 819 (1928); (b) Gibbs and Shapiro, *ibid.*, **50**, 1755 (1928); (c) Ramart-Lucas, *Compt. rend.*, **205**, 1409 (1937).

(6) Several text-books on organic chemistry give the structure of mercurochrome to be a mercurated dibromofluorescein in which the bromine atoms occupy the 2,7-positions. Orndorff and Hemmer, THIS JOURNAL, **49**, 1272 (1927), give the structure of dibromofluorescein as a 4,5-dibromo compound. However, Orndorff and Vose, *ibid.*, **46**, 1896 (1924), give a 2,7-structure for the dibromosulfonefluorescein and diiodosulfonefluorescein diacetates.

(7) That the structure of dibromofluorescein is a 4,5-dibromo one has also been shown by Harris, Marriot and Smith, *J. Chem. Soc.*, 1838 (1936). However, they gave no definite proof that the compound they obtained by the alkali fusion of dibromofluorescein was 2-bromoresorcinol which has a melting point of 102–103°. The melting point of 4-bromoresorcinol is almost identical with that of the 2-bromo compound, *viz.*, 103°.

resonating positive carbonium ions) represents the preferred structure. In the case of sulfonefluorescein, only dibromination occurs and again the structure has been shown to be a 4,5-dibromo structure. Since no tetrabromination of sulfonefluorescein takes place no matter how much bromine is used, it is conceivable that ring stabilization is much more pronounced in this case than in the case of fluorescein.



Hewitt and Woodforde[8] have shown that the dinitration of fluorescein occurs at the 4,5-positions, although previous workers had believed that nitration occurred at the 2,7-positions. More recently Ingraffia[9] has shown that fluorescein yields a benzenemonazofluorescein and a benzenebisazofluorescein when allowed to couple with a phenyldiazonium salt. He concludes that fluorescein has a lactoid structure and that the azo derivatives are 2,7-substituted derivatives. However, the authors of this paper believe that the azo derivatives must be 4,5-compounds because on reduction Ingraffia has found that the diaminofluorescein dihydrochloride produced is identical with that prepared from dinitrofluorescein. The authors of this paper also suggest that the structure (IV) (two resonating negative ions), as well as a fixed lactoid structure, will account for the formation of a bisazofluorescein.[10]

Some tetrahalogenated derivatives of fluorescein have also been examined from the standpoint of containing "positive" halogen.[11] Stannous chloride dissolved in hydrochloric acid, it is believed, can be used to detect bond fixation. For example, this reagent has no effect on 3-bromo-β-naphthylamine, whereas with the same reagent the bromine in 1-bromo-β-naphthylamine is very readily replaced by hydrogen. In the present work, tetrabromofluorescein dissolved in dioxane has been refluxed with excess stannous chloride hydrochloric acid reagent for as long as twenty-five hours and the 4,5-dibromo atoms are the only ones which are removed. A similar thing happens with 4,5-dibromo-2,7-dichlorofluorescein, from which only the two bromine atoms are removed. The results indicate that again there is the possibility of bond fixation in such a way that there is a double bond between the phenolic ring and the points of attachment of the side nucleus.

The authors wish to thank Mr. R. McKee for generous help in various phases of this work.

Experimental Part

Preparation of Compounds.—The fluorescein used in this work was prepared and purified according to Orndorff and Hemmer.[6] It was brominated to the dibromofluorescein stage according to Phillips,[12] purified through the diacetate and formed red plates, m. p. 285°. By using acetic anhydride and ethanol as a solvent for the purification of the dibromofluorescein diacetate, the present authors have obtained a melting point of 228–229°. Phillips[12] reports a melting point of 211°. The tetrabromination of fluorescein was carried out according to Orndorff and Hemmer.[6]

The preparation of 2,7-dichlorofluorescein was carried out according to Kolthoff, Lauer and Sunde.[13] It was purified through the diacetate (m. p. 237° from benzene). It was found best to hydrolyze the diacetate by heating it on a water-bath for several hours with 85% sulfuric acid. When alcoholic potassium hydroxide was used as the hydrolyzing agent, the dichlorofluorescein produced invariably had a low chlorine content, probably due to a hydrolytic breakdown of the dichlorofluorescein molecule itself. When dichlorofluorescein was brominated with

(9) Ingraffia, *Gazz. chim. ital.*, **62**, 781 (1932).
(10) The authors have found that only a diiodofluorescein (presumably 4,5-diiodofluorescein) is produced when an ammoniacal solution of fluorescein is treated with excess iodine dissolved in aqueous potassium iodide. Evidence has also been found that under similar circumstances 2,7-dichlorofluorescein forms a diiodo derivative, whereas 4,5-dibromofluorescein does not. This work is being done now and will be reported on later.

two moles of bromine, 4,5-dibromo-2,7-dichlorofluorescein was produced.

Anal. Calcd. for $C_{20}H_8Cl_2Br_2O_5$: AgCl + AgI, 41.3. Found: (Carius) 41.4.

Dibromosulfonefluorescein was prepared by the procedure of Orndorff and Vose.[6] No tetrabromination, using excess bromine, was found to occur.

2-Bromoresorcinol was prepared according to Rice[14] and melted at 100°.

4-Bromoresorcinol was made according to the procedure of Sandin and McKee[15] and melted at 100–102°.

3-Bromoresorcinol and 2-bromoresorcinol behave quite differently on sublimation. The latter sublimes much more readily than the former. Also the latter on sublimation tends to produce long needles, whereas the former sublimes to form colonies of small crystals.

Hydrolysis of Dibromofluorescein and Dibromosulfonefluorescein.—The directions of Harris[7] were followed and in both cases 2-bromoresorcinol was isolated and purified by sublimation. There was no depression of the melting point on mixing with synthetic 2-bromoresorcinol. However, when mixed with synthetic 4-bromoresorcinol, the melting point was as low as 75°.

Reduction of Tetrabromofluorescein and Dichlorodibromofluorescein.—To a solution of 50 g. of tetrabromofluorescein in 500 cc. of dioxane, 100 cc. of concentrated hydrochloric acid and 50 cc. of glacial acetic acid was added 150 g. of stannous chloride. The solution was refluxed for fifteen to twenty-five hours. At the end of about six hours, crystals of 2,7-dibromofluorescein began to settle out and the amount increased as the refluxing was continued. It was found that dibromofluorescein is much less soluble in dioxane than the tetrabromo compound. The reaction mixture was cooled, the crystals were filtered off and dissolved in dilute sodium hydroxide. The solution was filtered and the dibromo compound precipitated by the addition of hydrochloric acid. The freshly precipitated material was dark red in color. However, on heating on a water-bath for several hours the material became definitely crystalline and the color changed to a bright yellow. The appearance of the dibromofluorescein at this stage was very much like that of 2,7-dichlorofluorescein which has been digested with hydrochloric acid.

Anal. Calcd. for $C_{20}H_{10}O_5Br_2$: Br, 32.7. Found: Br (Carius), 31.8.

The diacetate was made by refluxing the dibromofluorescein with acetic anhydride. Crystallization of the diacetate from acetic anhydride gave the pure diacetate, m. p. 259° (with preliminary darkening of color).

Anal. Calcd. for $C_{24}H_{14}O_7Br_2$: Br, 27.9. Found: Br (Carius), 27.7.

The diacetate was hydrolyzed with 85% sulfuric acid by heating on the water-bath for several hours. The reaction mixture was diluted with water, the dibromofluorescein filtered off and washed thoroughly with hot water. It formed beautiful yellow crystals, m. p. 300–301°.

Anal. Calcd. for $C_{20}H_{10}O_5Br_2$: Br, 32.7. Found: Br (Carius), 32.6.

The above purified dibromofluorescein was hydrolyzed according to the procedure of Harris.[7] 4-Bromoresorcinol was isolated from the hydrolysis product and its identity established by carrying out mixed melting points with synthetic 2- and 4-bromoresorcinols. Moreover, on sublimation it behaved like the 4-bromoresorcinol. There was also isolated what is believed to be 2-(5′-bromo-2′,4′-dihydroxybenzoyl)-benzoic acid, m. p. 240–241° (with preliminary darkening of color and softening). Harris[7] and co-workers give the melting point of 2-(3′-bromo-2′,4′-dihydroxybenzoyl)-benzoic acid as 200° with softening at 187°.

Anal. Calcd. for $C_{14}H_9O_5Br$: Br, 23.7. Found: Br (Carius), 23.4.

The reduction of dichlorodibromofluorescein was carried out in the same manner. From the reaction mixture there was isolated nearly pure dichlorofluorescein.

Anal. Calcd. for $C_{20}H_{10}O_5Cl_2$: Cl, 17.8. Found: Cl (Carius), 17.5.

Fluorescein dissolved in glacial acetic acid was refluxed with stannous chloride and concentrated hydrochloric acid. At the end of fifteen hours the fluorescein was isolated almost quantitatively as the pure fluorescein diacetate. Evidently stannous chloride has a negligible effect on the conjugated system of double bonds as found in the quinoid modification of fluorescein.

Summary

1. Fluorescein and sulfonefluorescein have been dibrominated and the bromine atoms have been shown to occupy the 4,5-positions. Tetrabromofluorescein and dichlorodibromofluorescein have been reduced with stannous chloride and only the 4,5-dibromo atoms have been removed.

2. To explain these results it is suggested that these compounds have fixed structures according to the Mills and Nixon theory.

The Molecular Structure of Acetaldehyde

BY D. P. STEVENSON,[1] H. D. BURNHAM AND VERNER SCHOMAKER

Ackermann and Mayer[2] investigated the structure of acetaldehyde by the electron diffraction technique using 6.4 kilovolt electrons. Their photographs showed only two maxima and one minimum; hence it was necessary for them to assign very large uncertainties to their results. Since the distances they reported were considerably shorter than predicted by the covalent radius table,[3] it was decided that the structure of acetaldehyde should be reinvestigated using fast electrons.

Experimental.—Acetaldehyde was obtained by the acid depolymerization of Eastman Kodak Co. paraldehyde and also from a 95% solution of acetaldehyde in water (Eastman). In each case the acetaldehyde was distilled several times *in vacuo*, generous first and last fractions being discarded. From the purified liquid the vapor was allowed to expand into a carefully evacuated bulb which could be attached to the apparatus by means of a ground joint. In order to obtain completely satisfactory photographs, it was found necessary to have the vapor pressure in the sample bulb close to one atmosphere.

The Pasadena apparatus has been described by Brockway.[4a] The Princeton apparatus is similar to the Pasadena apparatus and has been used in other research.[4b] The wave length of the electrons was determined from transmission photographs of gold foil (a = 4.070 Å.), and it was approximately equal to 0.06 Å. for both the Pasadena and the Princeton photographs.

Interpretation.—Since the Pasadena and the Princeton photographs are identical both qualitatively and quantitatively, they will not be discussed separately.

The photographs showed six measurable maxima and minima. Two shelves were also present, the first preceding the first minimum and the second following the fifth maximum. They will be designated by the letters A and B, respectively. The fifth maximum and feature B resemble the maximum and shelf which appear on carbon dioxide photographs at the same value of s.[5] For the visual comparison of the photographs with the theoretical intensity curves, the most important characteristics of the photographs are that (1) the third minimum is deeper than either the second or fourth minimum, and (2) the third maximum is stronger than the fourth maximum. The measured $s\left(s_0 = \frac{4\pi}{\lambda}\sin\frac{\vartheta}{2}\right)$ values of the maxima and minima are given in the fifth column of Table I.

A radial distribution function[6] was calculated using the positions of both the maxima and minima. The coefficients were determined according to the method recommended by Schomaker.[7] These coefficients and the visually estimated intensities are given in columns 3 and 4 of Table I.

$$R(d) = \Sigma_n C_n \frac{\sin d\, s_n}{d\, s_n} \quad C_n = f(I_0, s_n) \qquad (1)$$

A plot of $R(d)$ against d is shown in Fig. 1. The maxima at 1.21, 1.51, and 2.33 Å. correspond to the carbon–oxygen and carbon–carbon bond distances and the non-bonded carbon–oxygen distance, respectively.

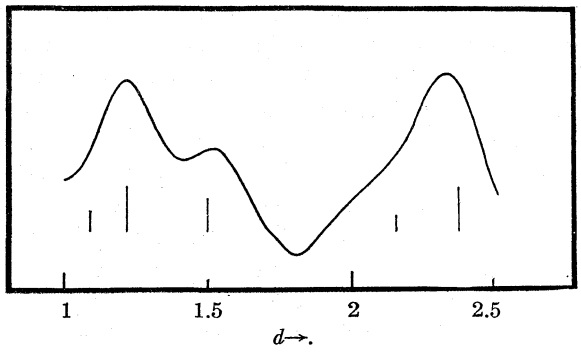

Fig. 1.—Radial distribution function, $R(d)$.

to carbon–carbon distance, and α, the carbon–carbon–oxygen angle. It was assumed that the hydrogen–carbon distance is equal to its value in methane, 1.09 Å., and that the configuration of the methyl group is tetrahedral.

In calculating the theoretical intensity curves it was found necessary to include temperature factors[4a] in the coefficients of the terms involving hydrogen–carbon distances as well as to take into account the effectively larger atomic scattering factor for electrons, $(Z - f)$, of hydrogen,[8] as compared with carbon and oxygen. The modified simple intensity formula thus had the following form

$$I(s) = 6\frac{\sin 1.54s}{1.54s} + 3.75\frac{\sin 1.09s}{1.09s}e^{-a_1s^2} + 3.75\frac{\sin 2.16s}{2.16s}e^{-a_1s^2} + 8\frac{\sin (C\text{–}O)s}{(C\text{–}O)s} + {}^{c}_{i}8\frac{\sin (C\text{–}O)s}{(C\text{–}O)s}$$

$$a_1 = 0.0022,\ a_2 = 0.0043 \quad (2)$$

The a's are equal to half the mean square of the change in the distance between the hydrogen and the carbon atoms due to the vibrations of the molecule. They were evaluated from the known stretching and bending frequencies of ethane. The method used in their calculation will be discussed in detail by one of us.

It was further found that the terms involving the methyl–hydrogen to oxygen distances and the carbonyl–hydrogen distances could be omitted from the intensity formula without affecting its form or the positions of its maxima or minima.

Nineteen curves were calculated using equation (2). Some of these are shown in Fig. 2. The parameter ρ was varied from 1.30/1.54 to 1.22/1.54 and α from 112 to 127°. All models with ρ greater than 1.26/1.54 could be eliminated because for them the second minimum is deeper than the third and because feature B appears as a small maximum closer to the sixth than to the fifth maximum. For ρ less than 1.24/1.54 and α greater than 123°, the curves are unsatisfactory because the fourth minimum is too shallow and feature B does not have the appearance it has on the photographs. The curves calculated with α less than 119° and all values of ρ may be eliminated because feature B does not appear. Curves for α greater than 123° are unsatisfactory because

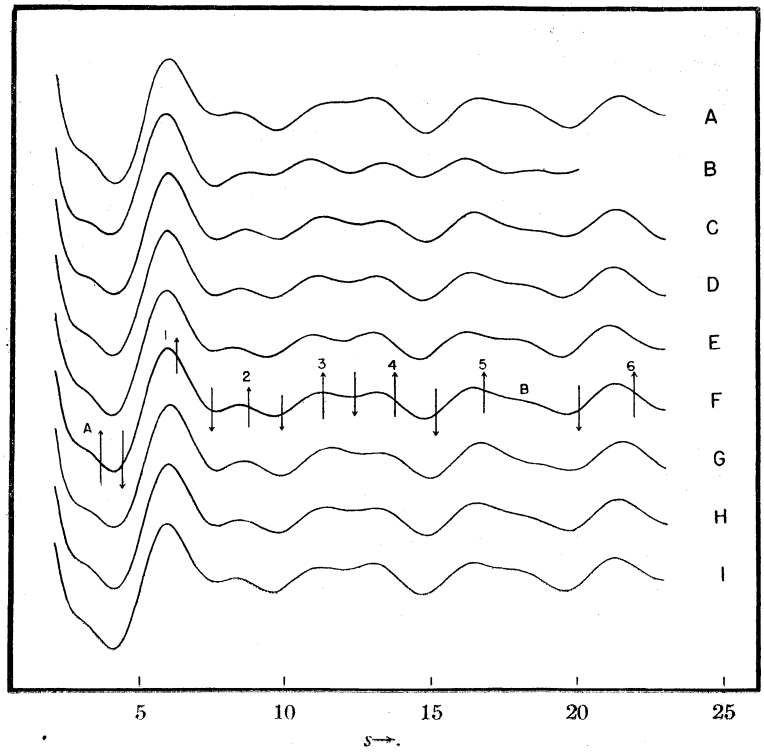

Fig. 2.—Theoretical intensity curves:

Curve A	ρ = 1.22/1.54, α = 121.6°
Curve B	ρ = 1.30/1.54, α = 121.6°
Curve C	ρ = 1.26/1.54, α = 119.3°
Curve D	ρ = 1.26/1.54, α = 121.6°
Curve E	ρ = 1.26/1.54, α = 124.5°
Curve F	ρ = 1.25/1.54, α = 121.6°
Curve G	ρ = 1.24/1.54, α = 119.3°
Curve H	ρ = 1.24/1.54, α = 121.6°
Curve I	ρ = 1.24/1.54, α = 124.5°

(8) L. Pauling and J. Sherman, *Z. Krist.*, **81**, 1 (1932).

B is too pronounced, appearing as a maximum rather than as a shelf following the fifth maximum. The curves calculated for $1.26/1.54 \geq \rho \geq 1.24/1.54$ and $119° \leq \alpha \leq 123°$ are qualitatively satisfactory. Quantitative comparison of the photographs with the curves calculated within the satisfactory ranges of ρ and α all give 1.22 Å. for the carbon–oxygen bond distance, 2.38 Å. for the non-bonded carbon–oxygen distance, and from 1.49 to 1.51 Å. for the carbon–carbon distance. Column 7, Table I gives a typical example of this comparison. Although the model with $\rho = 1.22/1.54$ and $\alpha = 119.3°$ cannot be eliminated, its curve is not so satisfactory as the curves for models with larger values of ρ inasmuch as the fourth minimum is too shallow and the fourth maximum is too weak.

Our final results for the structure are C–C = 1.50 ± 0.02 Å., C–O = 1.22 ± 0.01 Å., C–O = 2.38 ± 0.01 Å., C–H = 1.09 Å. (assumed), and the angle C–C–O = 121 ± 2°.

Discussion.—In a recent communication[9] it was reported that the carbon–oxygen distance in formaldehyde is 1.21 ± 0.01 Å. and this distance has been found to be 1.20 ± 0.02 Å.[10] in glyoxal; thus, with our results for acetaldehyde there are three determinations of the length of the carbon–oxygen double bond giving an average of 1.21 ± 0.02 Å.

Infrared and Raman spectra[11] studies of allene and ethylene yield 1.330 Å. for the length of the carbon–carbon double bond. This value has been confirmed recently by a new electron diffraction investigation of ethylene.[12] Thus, taking the carbon–carbon distances as standards, the subtrabend in Pauling's[13] rule for obtaining double bond distances from single bond distances is 1.540[14] − 1.330 = 0.21 Å. The carbon–oxygen single bond distance has been found to be 1.42 ± 0.02 Å. in dimethyl ether,[4a] *t*-butyl alcohol,[15] and *cis*-butene oxide,[4a] 1.43 ± 0.02 Å. in paraldehyde[4a] and *trans*-butene oxide,[4a] 1.44 ± 0.02 Å. in α-methylhydroxylamine,[4a] 1.46 ± 0.04 Å. in 1,4-dioxane,[4a] and 1.41 ± 0.02 Å. in methyl alcohol.[5]

(9) D. P. Stevenson, J. E. LuValle and V. Schomaker, THIS JOURNAL, **61**, 2508 (1939).

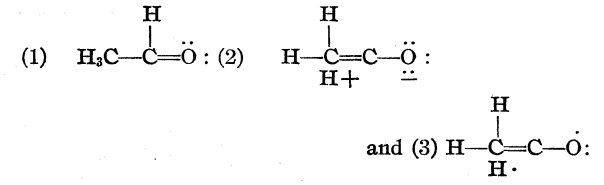
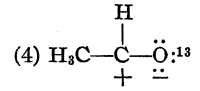
(14) The carbon–carbon distance in diamond; *cf.* "Strukturbericht."
(15) J. Y. Beach and D. P. Stevenson, THIS JOURNAL, to be published.

Taking 1.42 Å. as the most likely value for the carbon–oxygen single bond distance (small weight may be attached to values found in the cyclic molecules since their complexity makes reliable determination of individual distances exceedingly difficult), the expected carbon–oxygen double bond distance becomes 1.42 − 0.21 = 1.21 Å., in exact agreement with the average found from formaldehyde, glyoxal, and acetaldehyde.

The shortening of the carbon–carbon distance to 1.50 Å. from the covalent value of 1.54 Å. is probably due in part to resonance of the type suggested by Pauling, Springall, and Palmer,[16] for methylacetylene and methyl cyanide, the resonating structures being



and in part to the formal charge effect,[17] resulting from resonance with



However, it is difficult to estimate the relative contributions of the double bond character and of the formal charge.

If the increase of the R–C–O bond angle in going from formaldehyde[9] (120°) to acetaldehyde (121°) is real, it may be interpreted as indicating a greater amount of *p* orbital in the carbon–carbon bond than there is in the corresponding carbon–hydrogen bond.

The agreement with our values of the results of Ackermann and Mayer,[2] C–C = 1.51 ± 0.05 Å., C–O = 1.20 ± 0.05 Å., and the angle C–C–O = 122 ± 5° is remarkable inasmuch as Ackermann and Mayer determined the three parameters from but three measurements.

Summary

From electron diffraction photographs of acetaldehyde the value 1.50 ± 0.02 Å. has been found for the carbon–carbon distance, 1.22 ± 0.02 Å. for the carbon–oxygen distance, and 121 ± 2° for the carbon–carbon–oxygen angle. It is suggested that in general the covalent carbon–

(16) L. Pauling, H. D. Springall and K. J. Palmer, *ibid.*, **61**, 927 (1939).
(17) N. Elliott, *ibid.*, **59**, 1380 (1937).

oxygen double bond distance is about 1.21 Å. instead of 1.24 Å. The structure of acetaldehyde is discussed briefly in terms of resonance among several valence-bond structures.

The Heat of Combustion of *cis*- and *trans*-Azobenzene[1]

BY R. J. CORRUCCINI AND E. C. GILBERT

In making theoretical calculations of bond energies, Pauling[2] called attention to the unsatisfactory character of the data on the heat of combustion of azobenzene, and a redetermination of this quantity was undertaken in this Laboratory. While the investigation was still in the early stages, Hartley[3a] reported the preparation of the compound in the two isomeric forms, *cis*- and *trans*-, theoretically to be expected but previously never isolated. The two forms exist in equilibrium in solution, transition to the *cis* form being favored by sunlight. In the solid form the *cis* isomer is reported to be stable. In all previous work with azobenzene, therefore, the possibility exists that undetermined percentages of the two forms may have been present.

With this knowledge at hand the standard methods of purification were modified to take advantage of Hartley's findings in order that the two separate isomers might be prepared in the pure state, and the heat of combustion determined for each. In addition these results permit a new approach to the determination of the heat of transition, which has been measured by Hartley[3b] by another method.

The Calorimeter.—The calorimeter system and its calibration have been described previously in detail.[4] The heat of combustion of the *trans* isomer was measured before certain structural changes had been made in the system and hence the energy equivalent was somewhat different from that described in the reference cited. At the time of the work on *trans*-azobenzene the energy equivalent of the calorimeter (without the charge) was found to be 2507.6, 2507.5, 2506.9 (2505.4), 2507.9, 2507.1, with a mean value of 2507.4 ± 0.4 cal. deg.$^{-1}$. For the combustion of *cis*-azobenzene the calorimeter equivalent was that for which details are given,[4] 2550.0 ± 0.2 cal. deg.$^{-1}$.

The results of this paper are given in conventional calories calculated from international joules by dividing by the factor 4.1833[5] and are referred to the standard temperature of 25° in the same manner as previously.[4]

Preparation of Compounds.—Hartley[3] has shown that the formation of the *cis* form is favored by solar radiation, and that, being more polar, this form is consequently more soluble in polar solvents, this preferential solubility being the basis of the separation of the two forms.

Various samples of azobenzene were therefore recrystallized from aqueous ethanol and methanol, and from benzene and chloroform, all in very dim light. All the samples melted at 68.0–68.1° (by the capillary tube method) against a thermometer calibrated by the Bureau of Standards, and were combined for a final recrystallization from aqueous acetone. Any possible small amount of the *cis* form present originally should have been converted due to the temperature effect, or left in solution, it being thirty times as soluble in water as the *trans*-azobenzene. The product was dried in the dark over phosphorus pentoxide and melted at 68.1°. The minimum time for drying of these samples before combustion was eight days.

For the preparation of *cis*-azobenzene the most recent method of Hartley was used.[3b] A saturated solution of azobenzene in glacial acetic acid (500 cc.) was insolated for several hours in bright sunlight, keeping it in an ice-bath to reduce the temperature. This precaution was found to be imperative though not mentioned by Hartley. From this point all operations were carried out in the darkroom. Four hundred fifty cc. of water was added to precipitate the major portion of the *trans*-azobenzene and the solution filtered. The filtrate was diluted further with 500 cc. of water and extracted with chloroform. The extract was washed with water and evaporated immediately with reduced pressure. The products from several exposures were united and recrystallized twice more from petroleum ether (b. p. 40–60°) at temperatures from 20 to −10°, each time being washed with liberal portions of the solvent. The melting point of the compound measured by the "dip" method used by Hartley was 71.6°, slightly above the m. p. (71.4°), previously reported for the substance. The

compound was kept in the dark over phosphorus pentoxide for four days with no observable change in the m. p., and seven determinations of the heat of combustion were then made. One was discarded because of carbon formation.

The remainder of the compound was then again recrystallized from petroleum ether, no change being observed in the m. p. It also was dried for four days over phosphorus pentoxide in a refrigerator and two more combustions made.

Checking against possible loss due to volatility, a standard sized sample was found to lose only *ca.* 0.02 mg. in weight per hour, which is therefore negligible, since the combustion always followed weighing within less than this interval of time.

Results

The results for the combustion of *trans*-azobenzene are given in Table I, and for *cis*-azobenzene in Table II. The "precision error" of the determinations has been calculated by the method of Rossini.[5] For the *trans* form the accuracy uncertainty assigned to the heat of combustion of the standard benzoic acid (39 e) by the Bureau of Standards is 0.023%. The calibration error "*c*" of the first calorimeter was 0.015% and the reaction error "*b*" for the combustion of *trans*-azobenzene was 0.01%. The resulting accuracy error was 0.03%.

TABLE I

THE ISOTHERMAL HEAT OF COMBUSTION OF *trans*-AZOBENZENE AT 25°

Energy equivalent of the calorimeter 2507.4 ± 0.4 cal. deg.$^{-1}$

True mass of sample, g.	Corr.[a] temp. rise, deg.	Total heat evolved, cal.	Cal. from HNO_3	$-\Delta U_B/m$, cal. g.$^{-1}$	Dev. from mean

.72857[c]	2.4407	6233.4	12.5	8538.4	+1.0
.71989[c]	2.4105	6156.3	11.9	8535.2	−2.2
			Mean =	8537.4	±1.2

[a] Corrected for heat of stirring, evaporation, etc., and for the energy of ignition of the iron wire. [b] Not used in obtaining the mean. [c] These samples were recrystallized once more than the first six samples.

Similarly for the *cis*-azobenzene, the calibration error "*c*" was 0.006% and the reaction error "*b*" 0.014%. Including with these a reasonable allowance of 0.03% for possible lack of purity of the *cis* form, the accuracy uncertainty for this isomer becomes ±0.04%. The question of the purity is obviously an important one. The only criterion available to us was the m. p., which is obviously not of the same order of accuracy as the heat measurements. However, the fact that repeated crystallization failed to change either the m. p. or the heat of combustion gives reasonable confidence in the purity of the compound. Swietoslawski and Bobinska report[7] that their azobenzene was prepared by vacuum distillation and melted at 68.35–68.40°. Samples prepared in our laboratory by this method (three distillations *in vacuo*) melted at 68.1°, the temperature which we obtained for pure *trans*-azobenzene prepared by crystallization. As a further check, all of the *cis* residues which had been through several additional steps of treatment in their preparation were reconverted to the *trans* by heating to 135° for fifteen minutes, at which temperature the *cis–trans* transition is instantaneous.[3b] The *trans*-azobenzene thus formed likewise showed the original melting point of 68.1°.

From $-\Delta U_B$, the heat evolved in the bomb process per gram formula weight, $-\Delta U_R$, the decrease in energy for the combustion reaction at the standard state as defined by Washburn[6] was calculated. In doing this it was assumed that the nitrogen produced in the combustion may be treated as if it were oxygen. $-\Delta H_R$, the heat evolved in the isothermal process in the standard state at constant pressure was also calculated. These results for *trans*-azobenzene are shown in Table III where are also collected the results of other investigators. It seems apparent that in the most recent work, that of Swietoslawski and Bobinska,[7] the azobenzene must have been essentially the pure *trans* form. Since this work

(6) Washburn, *Bur. Standards J. Research*, **10**, 544 (1933).

(7) Swietoslawski and Bobinska, *Roczniki Chem.*, **9**, 723 (1929).

was done before the Washburn corrections were available, and with different conversion units, etc., quantitative comparison is difficult. The value reported by Swietoslawski to the Bureau of Standards is different from that in his published work.

TABLE III

COMPARISON OF DATA ON *trans*-AZOBENZENE

Stds.; see Kharasch, *Bur. Standards J. Research*, **2**, 425 (1929). [e] Heat evolved at constant pressure without Washburn correction to standard reference state.

The comparative results for the two pure forms from the present work are shown in Table IV. From them may be obtained $-\Delta H$ for the transition *cis* → *trans* at 25°. This amounts to 9.9 kcal. mole^{-1} or 54 ± 4 cal. g.$^{-1}$. Hartley[3b] has found by another method 65 ± 4 cal. as the mean of three determinations. Finally, also, $-\Delta H°_{298.16}$, the heat of formation of the compound, may be calculated using 68,318.1 cal. mole^{-1} as $-\Delta H°_{298.16}$ for water and 94,030 cal. mole^{-1} for carbon dioxide.[8] These results are shown in Table IV.

TABLE IV

SUMMARY OF DERIVED DATA ON *cis*- AND *trans*-AZOBENZENE AT 25°

Substance	*trans*-Azobenzene	*cis*-Azobenzene
Mol. wt.	182.21	182.21
$-\Delta U_B$ kcal. mole^{-1}	1545.7 ± 0.3[a]	1555.6 ± 0.2[a]

$-\Delta H_R$	1545.6 ± .4[b]	1555.5 ± .6[b]
$-\Delta H°_{298.16}$	−75.65	−85.55

[a] Precision uncertainty. [b] Accuracy uncertainty.

Summary

1. The isothermal heat of combustion of *cis*- and of *trans*-azobenzene has been determined for 25° and constant pressure.

2. The heat of formation for each has been calculated.

3. The heat of the transition *cis* → *trans* has been calculated.

[A CONTRIBUTION FROM THE MORLEY CHEMICAL LABORATORY, WESTERN RESERVE UNIVERSITY]

Fluorination of Phosphorus Trichloride[1]

BY HAROLD SIMMONS BOOTH AND ABE ROSCOE BOZARTH[2]

This investigation is a continuation of the studies by this Laboratory on the fluorination of non-polar inorganic halides.[3-8] Booth and Swinehart[3] reported the action of antimony trifluoride in the presence of a catalyst on phosphorus trichloride to give a smooth evolution of gases of unknown composition. The only chlorofluoride of phosphorus reported in the literature is PF_3Cl_2 prepared by Moissan.[9]

The generator used in the preliminary study was similar to that shown in Fig. 1A except that the generator head was attached directly to the flask, without a fractionating column. About 200 g. of reagent grade phosphorus trichloride was placed in the flask, the catalyst was added and powdered sublimed antimony fluoride was fed in, as needed for a smooth reaction, by means of the screw solid feed C, at room temperature. (Approximately two cubic centimeters of the catalyst, $SbCl_5$, per 100 g. of PCl_3 was found to be an optimum amount.) With tap water in the generator head, (H), (+15°) the product was largely PF_3, a small amount of PF_2Cl and very little or no $PFCl_2$.

On the assumption that the fluorination of phosphorus trichloride is stepwise, the application of precise control to the operating variables ought to lead to improvements in the yields of chlorofluorides. In a stepwise reaction probability of excessive fluorination should be a minimum when the reaction zone (generator flask A, Fig. 1A), is maintained at such a temperature that the unfluorinated liquid will be gently boiling and refluxing at the pressure maintained in the system, since then a fluorinated product would immediately distil out of the reaction zone as soon as it was formed, due to its lower boiling point.

The apparatus shown as Fig. 1A was constructed so as to attain this end. The reaction flask A was a two-liter,

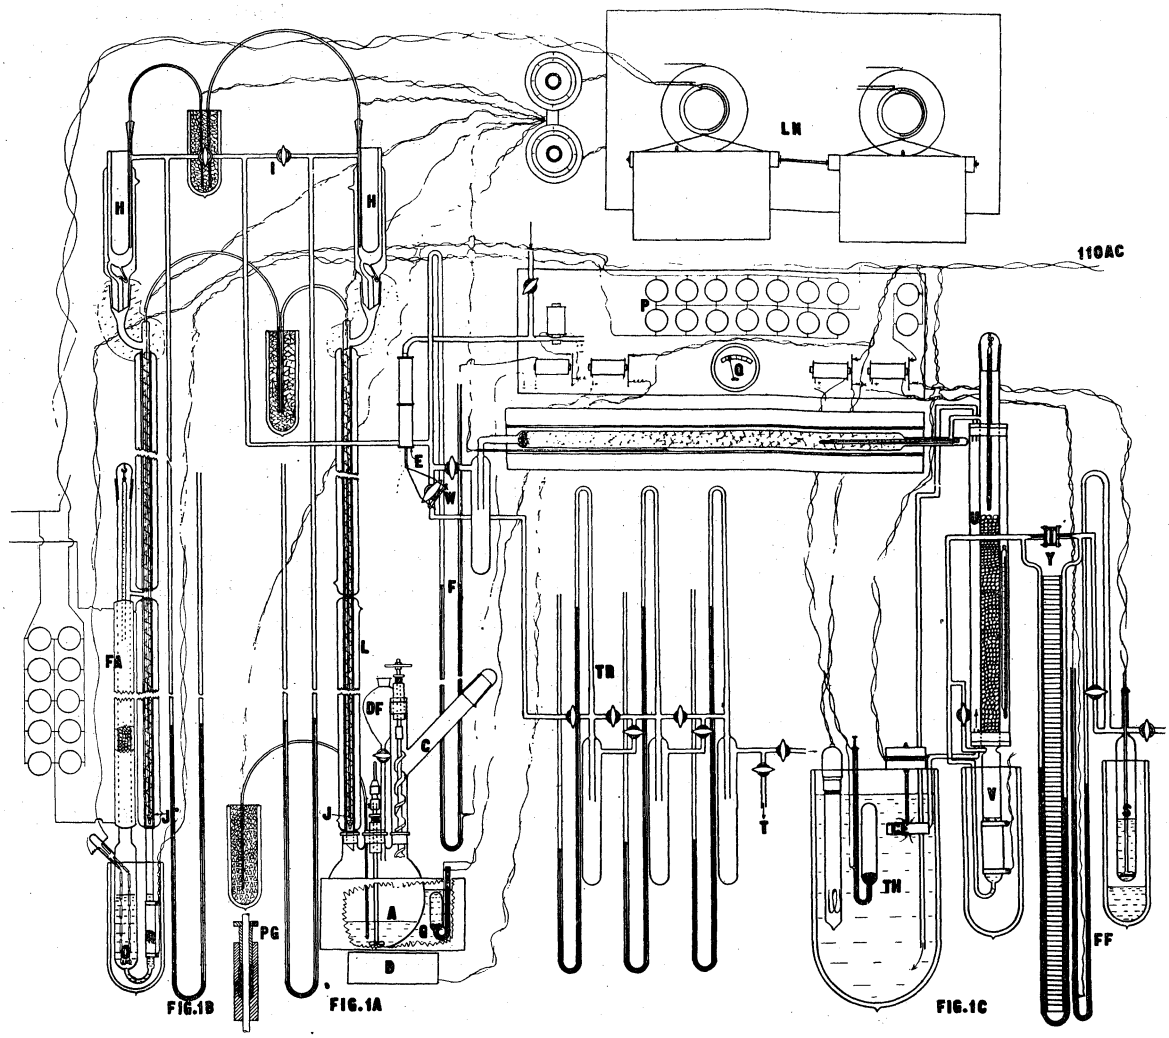

Fig. 1.

Pyrex, three-necked flask. Stirring was accomplished by a brass double-blade propeller which was rendered vacuum-tight at the point of entrance by a gland packed with commercial graphited string packing and lubricated with vacuum pump oil (shown in detail as PG). The temperature of the reaction flask above room temperature was maintained by a thermostatically controlled water-bath heated by an electric heater D, and below room temperature by a thermostatically controlled acetone-bath similar to that used for vapor pressure measurements and controlled either by liquid air or carbon dioxide snow cooling, as described by Booth and Bozarth.[10]

The fractionating column L was identical with that used and already described by the authors[10] except that it was made twice as high to improve the separation. A two-junction thermocouple inserted from the column top through the hollow center tube of the column indicated the temperature of the column bottom at J. A constant temperature was maintained in the still head H either by suitable fixed temperature refrigerants such as tap water, liquid ammonia, carbon dioxide snow wet with acetone, or by automatic thermostatic control with either liquid air or carbon dioxide cooling.[10]

The gaseous product was removed automatically at a constant system pressure by the compressed air operated automatic stopcock W (Fig. 1A) which opened whenever the mercury thread in manometer F completed the relay circuit.

The general method of adjusting the operating variables of the improved generator was as follows.

The bath G (Fig. 1A) was adjusted to the temperature at which fluorination took place. The manometer contact in F (with stopcock I open) was adjusted so as to contact the mercury and thus to open the automatic stopcock to the traps TR, at a pressure equal to the vapor pressure of the unfluorinated halide at the temperature of the reaction flask. A suitable refrigerant was placed in the head (H) or it was thermostatically controlled so as to maintain the head at the temperature at which the desired chlorofluoride had a vapor pressure equal to the op-

[a] The generator flask was not heated at the end of the fluorination to break up the loose addition compound probably formed between SbF_3 and $PFCl_2$, which probably accounts for the loss of some of the $PFCl_2$.

erating pressure. In the first studies upon an unknown gas this latter value must be approximated by means of the Swarts[11] rule and the Clapeyron equation.

The system was evacuated thoroughly and the halide added through the dropping funnel DF without breaking the vacuum. If the halide did not reflux after equilibrium was attained, the temperature of the bath G was increased until it did. The catalyst was then added through DF and allowed to mix well with the halide.

The reaction between phosphorus trichloride and antimony pentachloride is exothermic and the mixture had to be cooled to operating temperature before adding the antimony trifluoride. The contact in manometer F was adjusted until it was about 4 mm. above the mercury. A small amount of antimony trifluoride was fed in. As soon as the fluorination began the lower boiling fluorination product which is fractionated out formed a "gas block" in the still head H and raised the pressure and so caused the automatic stopcock W to open momentarily to remove the accumulated gaseous product. The stopcock I was opened until it allowed the gas to pass each time the automatic stopcock opened with a minimum fluctuation in generator pressure. As soon as the system settled down to equilibrium the temperature of the reaction zone, column bottom and still head, was determined. If the column bottom temperature (at J) was lower than the reaction zone temperature, the temperature of the bath about the flask had to be increased until the column bottom temperature reached a maximum which corresponded closely to the reaction zone temperature at the beginning of the fluorination. Under these conditions only pure unfluorinated halide returned to the reaction zone.

Fluorinations which are comparatively rapid such as fluorination of phosphorus trichloride do not lend themselves to the preparation of the difluoro compound exclusively directly from the unfluorinated halide. Any accumulation of the monofluoro is rapidly fluorinated so that the product is a mixture of the difluoro derivative and the completely fluorinated product. This is due to the fact that the threshold fluorinating temperature lowers with the replacement of each chlorine atom by fluorine in covalently unsaturated non-polar halides.

Table I shows the average data obtained for two runs fluorinating phosphorus trichloride with the conditions controlled to favor $PFCl_2$, two runs fluorinating $PFCl_2$ under conditions favoring PF_2Cl and one run fluorinating PF_2Cl to PF_3. The product condensed in each case was 50 to 75% the product desired, which was the opposite of the yields obtained without precise control, in which the product was 75–90% PF_3 (Table II).

TABLE II

FLUORINATION OF PHOSPHORUS TRICHLORIDE WITHOUT PRECISE CONTROL

Reaction zone at room temp.; press. 760 ± 20 mm.; PCl_3 used, 450 g.

Run	Vol. of catalyst, cc.	Distillation analysis of product, % $PFCl_2$	PF_2Cl	PF_3
VIII	5	16.7	32.0	51.5
IX	10 dropped in	19.8	6.2	74.0
X	20 added at start	0	25.0	75.0
XI	20 at start, total of 60	0	16.7	83.3
XII	1 at start	0	5.88	94.0
XIII	10 at start	8.33	25.0	66.7

Whereas phosphorus trichloride fluorinated smoothly at a temperature of +40° and 250 mm. pressure, $PFCl_2$ can be fluorinated at an equal rate at −13° and 250 mm. pressure; furthermore, it is even possible to fluorinate PF_2Cl to PF_3 at the low temperature of −50 to −55° and 720 mm. pressure. At +40° the rate of fluorination of $PFCl_2$ was quite rapid and that of PF_2Cl was very rapid, while the rate of fluorination of phosphorus trichloride was relatively slow. These facts explain both the difficulty of avoiding fluorination

(11) F. Swarts, *Bull. soc. chim.*, **35**, 1556 (1924).

beyond the first step even under controlled conditions, and the completeness of fluorination under uncontrolled conditions, due to increasing rate with increased fluorination.

Antimony trifluoride does not react with phosphorus trichloride to any appreciable extent in the absence of the catalyst ($SbCl_5$) at the temperatures maintained during this study.

Fluorination of Phosphorus Trichloride in the Vapor Phase by Solid Heated Calcium Fluoride

E. I. du Pont de Nemours and Company[12] have indicated that heated calcium fluoride may act as a fluorinating agent for organic halides in the vapor phase, producing chlorofluoro compounds from aliphatic chlorides.

An apparatus for the vapor phase fluorination of phosphorus trichloride by calcium fluoride was constructed of soda-lime glass as shown in Fig. 1B. The calcium fluoride furnace FA was a glass tube 1.6 cm. in diameter by 60 cm. long, wound with a thin layer of asbestos tape followed by no. 18 nichrome wire, three turns per inch, and then wrapped with heavy asbestos paper. The temperature was controlled by a split lampbank, one-half of which was controlled by the contacts of a recording controlling potentiometer.

C. P. precipitated calcium fluoride was formed into pellets about 0.5 cm. in diameter by a pharmaceutical pellet machine, and then dried at 125–150° before use.

The fluorination of a halide by this reaction was carried out as follows. The temperature of the furnace was indicated by a thermometer, at the exit end of the furnace. The halide was boiled at a constant rate by an internal coil heater O (fed by a constant current). The exit furnace gases passed into the middle of the fractionating column where the fluorinated product was separated from the unfluorinated. The still-head temperature in H was adjusted so as to correspond to the boiling point of the product desired at the pressure maintained in the system. The contact in the manometer F was adjusted so as to make contact and so to open the automatic stopcock W, whenever the pressure rose slightly due to accumulation of fluorinated product in the still head. A thermocouple at J at the column bottom indicated the temperature of the liquid returned to the boiling ampoule O. By controlling the heat input to the auxiliary heating coil, R, the column bottom temperature could be maintained identical with the temperature of the pure halide at the pressure maintained in the system. Under these conditions no fluorinated substance was being returned to the reaction zone and consequently recirculated through the furnace to be further fluorinated.

Although it was not tried, it seems perfectly feasible, by this method, to convert $PFCl_2$ over mainly to PF_2Cl by proper adjustment of operating variables.

(12) French Patent 730,874, May 23, 1932, "Perfectionnements a la Fabrication des Hydrocarbures Acyclique Fluors."

Reaction between Phosphorus Trichloride and Phosphorus Trifluoride at High Temperature

It was thought that perhaps at higher temperatures phosphorus trichloride and phosphorus trifluoride might react to give the equilibrium, $PF_3 + PCl_3 \rightleftarrows PF_2Cl + PFCl_2$. Since we started our experiments, T. Mitobedzki[13] has described a similar reaction for the preparation of the bromochlorides of phosphorus.

The apparatus finally developed is shown as Fig. 1C. The PF_3 was condensed into ampoule S. It was then melted and a Dewar one-third full of liquid air was placed around the ampoule (but not in contact with it). A small heating coil in the liquid phosphorus trifluoride (boiling point −101°) heated it much faster than it cooled, so that the pressure was raised rapidly to 720 mm. When the pressure reached 720 mm. the mercury in manometer FF made contact, closing a relay circuit which interrupted the heating current. The net result was that phosphorus trifluoride was fed at constant pressure (±2 mm.). The rate of flow of the phosphorus trifluoride was indicated by a sharp-edged orifice flow meter Y. The orifice was a thin platinum sheet with a perfect hole 0.013 mm. in diameter drilled in the center. The platinum plate was clamped between two glass flat joints as indicated. A constant flow was obtained by maintaining a constant pressure drop across the orifice. Since the ampoule S was automatically kept at constant pressure and the pressure on the other side of the orifice was kept constant by the contacting manometer F which operated the automatic stopcock W, a constant pressure drop and therefore a constant flow was maintained through the system.

The phosphorus trifluoride was saturated with phosphorus trichloride by being bubbled through the phosphorus trichloride in ampoule V, heated by a coil of nichrome wire fed by a constant current. The temperature of the jacket U was adjusted to that temperature at which phosphorus trichloride has a vapor pressure equal to one-half the total pressure in the system. The mixture leaving the saturator under these conditions contained a one to one molal ratio of phosphorus trifluoride to phosphorus trichloride. A centrifugal pump, CE, pumped water, maintained at constant temperature, from the bath TH through the jacket U. The reaction tube was made of glass, and the furnace temperature was controlled by a recording, controlling potentiometer, LN.

Preliminary runs in a smaller and less refined apparatus showed that at around 230–250° no appreciable reaction occurs; at 500° reaction takes place but phosphorus deposits and probably silicon fluoride is produced by a reaction analogous to that indicated by A. Simon[14,15] between silica and phosphorus trifluoride,

$$4PF_3 + 3SiO_2 \longrightarrow 3SiF_4 + 3O_2 + 4P$$

When the furnace temperature approximated 400° no phosphorus deposited, indicating little or no reaction with the glass tube. Under these con-

(13) T. Mitobedzki, *C. A.*, **27**, 475 (1933).

(15) Simon, German Patent 131,414 (1900).

ditions approximately 30% conversion of phosphorus trifluoride was obtained per pass.

Two runs at 500° in the apparatus just described gave considerable phosphorus and etching. The product, moreover, upon distillation, yielded a constant boiling fraction, probably consisting of SiF_4 and PF_2Cl, as analysis showed a mean value of 14.1% chlorine (calcd. for PF_2Cl, 34%). We were able to purify the $PFCl_2$ fraction and the molecular weight of the product coming from the still gave a mean value of 122, which is in accord with 121.8 found for the calcium fluoride reaction product and the theoretical molecular weight, 121.5. Between 350 and 400° it is possible to get mainly the equilibrium

$$PCl_3 + PF_3 \rightleftharpoons PF_2Cl + PFCl_2$$

At the temperature at which the equilibrium shifts appreciably to the right (400°), other products such as POF_3 and SiF_4 are formed. It was soon found that PF_2Cl readily forms constant boiling point mixtures with POF_3, etc., which are difficult to separate and identify, as their molecular weights are close. Considerable time also is required to attain equilibrium in this reaction. Hence, as a method of preparation this method is of little value.

The possibilities of using a Pyrex or metal tube and a catalyst suggested themselves but they were not tried since the Swarts reaction and the calcium fluoride reaction had been simultaneously modified and improved by precise control so as to produce mainly $PFCl_2$ and PF_2Cl.

Purification

The gases were purified by fractional distillation in an automatic column and their physical properties determined as described by Booth and Bozarth.[10]

Analysis

One hundred-cc. sample bulbs, filled to not over 700 mm. pressure, were weighed against counterpoises. The samples were absorbed at once (to minimize reaction with the stopcock grease) into a sodium hydroxide solution containing 100% excess sodium hydroxide, by placing the lower stopcock tube under the caustic and opening the cock. The gas is absorbed rapidly, the caustic rushing into the bulb with the evolution of heat. The solution was allowed to stand in the bulbs for two to three hours to ensure complete reaction.

The chlorine was determined gravimetrically with the following precautions. The samples were diluted to 200 cc. and acidified with nitric acid and then 30 cc. of concentrated nitric acid was added. It was found that in the presence of this amount of nitric acid the phosphite did not reduce the silver in the cold. If the concentration of nitric acid was too low, boiling immediately threw down metallic silver.

The phosphorus content was determined by oxidation with excess standard iodine solution and back titration of the excess with sodium thiosulfate, according to the method of Rosenheim and Pinsker.[16] The presence of fluorine was established qualitatively. The analytical results are recorded in Table III.

Physical Constants and Properties

After preliminary separation of the generation product, each fraction was purified carefully by the distillation technique already described. Finally a middle portion of a fraction coming from the still at constant still-head temperature and constant molecular weight was collected separately. This sample was used for measurement of the physical constants.

$PFCl_2$, Monofluorodichlorophosphine is a colorless gas which can be condensed to a colorless sparkling liquid and frozen to a clear white solid. This substance yields twig-like crystals upon freezing. Table IV gives the physical constants of $PFCl_2$.

$PFCl_2$ hydrolyzes in moist air and is hydrolyzed by water, but does not fume. It is absorbed very rapidly by sodium hydroxide solution with the evolution of heat. The compound appears to be stable: approximately 50 cc. of liquid $PFCl_2$ was stored under pressure in a sealed

(16) Rosenheim and Pinsker, *Z. anorg. allgem. Chem.*, 64, 333 (1909).

glass tube for ten months. At the end of this time the liquid was homogeneous and no excess pressure above that of the vapor pressure of $PFCl_2$ had developed.

PF_2Cl, Difluoromonochlorophosphine is a colorless gas which can be condensed to a colorless sparkling liquid and frozen to a white solid.

This gas tends to form difficultly separable mixtures with SiF_4 and POF_3. The molecular weights of SiF_4 (104.06), POF_3 (104.03) and PF_2Cl (104.48) are so near that indication of precise separation by means of the density balance becomes impossible. It was found that the PF_2Cl produced by high-temperature fluorination with calcium fluoride could not be rendered completely pure by repeated distillation, as evidenced by low analytical results and molecular weights.

TABLE V

PHYSICAL CONSTANTS OF PF_2Cl

Vapor pressure PF_2Cl, $\log p_{mm.} = 7.043 - (939.7/T)$

Temp., °C.	Press. obsd., mm.	Press. calcd. from equation	Deviation, mm.

−46.20	798.4	800.0	1.6
−42.22	934.4	940.6	6.2

Normal boiling point	−47.3 ± 0.05°
Latent heat of evaporation	4200 cal./g. mole
Trouton's constant	19.1
Melting point, prepared by fluorination of $PFCl_2$ by Swarts reaction	−164.8 ± 0.2°
Molecular weight	105.5

By avoiding leaks and by careful drying, the Swarts reaction yielded samples of PF_2Cl which could be purified to yield a pure fraction for melting point, vapor pressure, and analysis. The physical constants of PF_2Cl are given in Table V.

PF_2Cl hydrolyzes in moist air and water less rapidly than $PFCl_2$ but does not fume. It is absorbed very rapidly by sodium hydroxide solution with the evolution of heat. When stored as a liquid at −78° over long periods it appears to be stable.

PF_3, Trifluorophosphine.—This gas was prepared first by Moissan.[9] It is a colorless gas which can be condensed to a liquid, and frozen to a white solid. It is prepared best by dropping solid antimony fluoride into 200 g. of vigorously stirred phosphorus trichloride and slowly adding the catalyst. Every precaution must be taken to keep the partially fluorinated products in the reaction zone. The product is 80–90% trifluorophosphine (see Table II). A large sample was precisely distilled and the middle portion of the pure fraction used for measurement of the physical constants (Table VI).

Molecular weight	89.0 (this study); 87.2 (Moissan); 88.0 (theory)

Trifluorophosphine hydrolyzes very slowly in air and when pure it is odorless in toxic concentrations. This property of trifluorophosphine makes it hazardous to handle since any leaks are not detected readily until the operator begins to feel the effects. Its symptoms are a sharp pain in the chest cavity upon inhalation of a deep breath. There is a pronounced rise in body temperature, vomiting is induced in some cases, and the victim feels very weak for several hours. (These are the authors' experiences.) Very small concentrations will cause the sharp chest pain. Trifluorophosphine is absorbed rapidly by sodium hydroxide with the evolution of heat.

Critical Constants

These physical constants were measured by means of the apparatus and improved technique developed in this Laboratory.[17] The critical temperature was taken as that temperature at which the meniscus disappeared from the tube without rising or falling. The temperature above that of the room was maintained by resistance knife heaters; below room temperature by a new method using dry-ice as described by Booth and Bozarth.[10]

Considerable difficulty was encountered while measuring the critical constants of $PFCl_2$. Due to the high critical temperature the sample would liquefy in the upper part of the Cailletet tube exposed to the room. When the pressure was further increased so as to force the sample into the cell the liquid would wet the walls of the capillary and tend to come back past the mercury so that the sample could not be readily forced into the cell without mercury going into the cell also. In contact with mercury at the critical temperature this gas decomposed probably forming halides of mercury and leaving a deposit of yellow phosphorus. By careful manipulation of one sample mercury was kept out of the cell. In this case slight decomposition also was noted; a light brown film, probably elemental phosphorus, was formed. One sample was held at the critical temperature for five and one-half hours; a 2.3° rise in the critical temperature and a 0.94 atm. rise in the critical pressure was noted, simultaneously with the formation of a brown film on the walls of the cell. Table VII lists the critical constants found for this series.

Reaction of the Fluorination Products with Chlorine.—Chlorine was mixed with one of the chlorofluorides of phosphorus at the entrance of an empty tube 2.0 cm. in diameter and 40 cm. long. The fluoride gas was fed into the reactor tube at constant rate by a gas feed identical with that described in Fig. 1C. It was found that the reaction would not start in a clean glass apparatus but the presence of a single crystal of iodine immediately catalyzed the reaction. The reaction of PF_2Cl and chlorine is evidently exothermic since the chlorination tube warmed to 80–100° whereas the reaction between $PFCl_2$ and chlorine is not as exothermic since the reaction tube temperature remains unchanged. PF_3 and chlorine do not combine readily in the presence of iodine. If, however, the reaction tube is radiated with a carbon arc, rapid reaction takes place to form PF_3Cl_2. Preliminary experiments indicate that Moissan's value for the boiling point of PF_3Cl_2 given as −8.0° is incorrect; the correct value probably lies in the range 0 to 10°.

The products obtained by chlorination of $PFCl_2$ and PF_2Cl, probably $PFCl_4$ and PF_2Cl_3, are unstable liquids having the respective vapor pressures 275 mm. at 75–80° and 387 millimeters at 32°. $PFCl_4$, which decomposes in about thirty hours at 25°, yields as decomposition products a white solid, probably PCl_5, and a colorless gas, probably PF_5. PF_2Cl_3 does not decompose as rapidly; a white solid was apparent after standing for twenty-four hours and decomposition was complete in about six days. Moissan found that PF_3Cl_2 decomposed at 200° to form a white solid, PCl_5, and a gas, PF_5.

Summary

An apparatus and technique applicable to the controlled fluorination of inorganic halides is demonstrated.

The chlorofluorides of phosphorus have been prepared by three methods: (1) The Swarts reaction between PCl_3 and SbF_3 in the presence of $SbCl_5$ as a catalyst. (2) The calcium fluoride reaction, a gas–solid reaction between PCl_3 vapor and hot solid CaF_2. This is the first time to our knowledge that this reaction has been applied to the preparation of chlorofluorides from inorganic halides. (3) The reaction between PCl_3 and PF_3 in a hot tube. This method is unsatisfactory as a method of preparation due to side reactions with the glass to form POF_3 and SiF_4 which are extremely difficult to remove from PF_2Cl by distillation.

Two new gases ($PFCl_2$ and PF_2Cl) were obtained and PF_3 was restudied, using improved technique, with melting and boiling points as follows:

	M. p., °C.	B. p., °C.
$PFCl_2$	−144.0 ± 0.2	13.85 ± 0.05
PF_2Cl	−164.8 ± .2	− 47.3 ± .05
PF_3 (ours)	−151.5 ± .2	−101.15 ± .05
Moissan	−160	− 95

$PFCl_2$, PF_2Cl and PF_3 react with chlorine to produce pentavalent chlorofluorides. $PFCl_2$ and PF_2Cl yield liquid products which are unstable, decomposing at room temperature into PCl_5 and PF_5.

Phosphorus trifluoride when pure is odorless in toxic concentration and therefore care must be exercised in its manipulation.

The critical temperatures and pressures for PF_3, PF_2Cl and $PFCl_2$ have been determined.

The Fluorination of Phosphorus Tribromide[1]

BY HAROLD SIMMONS BOOTH AND SPENCER G. FRARY

The successful controlled partial fluorination of phosphorus trichloride[2] led us to study the fluorination of phosphorus tribromide by similar methods.

A preliminary generation was made using 36 cc. of C. P. phosphorus tribromide with 3 cc. of bromine as a catalyst. The fluorinator was immersed in a Dewar of water heated to +80°. Sublimed antimony trifluoride[3] was added gradually by a screw feed while the pressure was maintained at 20 mm. of mercury by the pressure regulator. Under these conditions the tribromide refluxed in the column with no refrigerant needed in the stillhead. Fractional distillation[4] of the products obtained by generation at −20° and under 220 mm. pressure yielded PF_3, HCl and HBr in small amounts, PF_2Br, and small amounts of HF. The still residue contained $PFBr_2$ and PBr_3. Since these conditions favored the production of $PFBr_2$, the pressure was raised to about 250 mm. With the same temperature in the fluorinator and ice in the head there was no refluxing of either PBr_3 or $PFBr_2$. The products of this fluorination were 10 cc. of $PFBr_2$, an equal amount of liquid PF_2Br and approximately 30 cc. of liquid PF_3, along with a little HBr and HF due to hydrolysis.

Later, when larger amounts of PF_2Br were needed in order to obtain a good fractional separation and purification, it was found that the yields obtained at 80 and 90° were poorer than those at higher temperatures. With the temperature of the fluorinator at 170°, the yield of partially fluorinated products was doubled.

The Fluorination of Monofluorodibromophosphine by Antimony Trifluoride and Bromine.—Booth and Bozarth[2] have shown that the fluorination of phosphorus trichloride with antimony trifluoride and antimony pentachloride as catalyst is a stepwise reaction and that the intermediate $PFCl_2$ can be fluorinated readily under proper control to PF_2Cl, but that the fluorination threshold temperature lowers with each fluorine atom introduced.

Fluorination of monofluorodibromophosphine was tried first at room temperature and at about 200 mm. absolute pressure. The heat of reaction raised the temperature to such an extent that PF_3 was the only product obtained.

The reaction was slowed by cooling the fluorinator to 0° and by reducing the pressure to 20–30 mm. While the product was chiefly PF_2Br, only about 25% of the material was converted. Warming the fluorinator increased the yield but increased the percentage of the trifluoride at the same time.

Hence the fluorination of phosphorus tribromide by antimony trifluoride and antimony pentachloride is likewise stepwise and closely resembles that of phosphorus trichloride.

Fluorination of Phosphorus Tribromide Using Calcium Fluoride.—On account of the successful fluorination of phosphorus trichloride with calcium fluoride by Booth and Bozarth,[2] it was decided to try fluorinating the tribromide with calcium fluoride pellets. The apparatus was similar to that used in the fluorination of phosphorus chloride except that a vertical condenser cooled with

tap water was used to condense the unreacted tribromide. The pressure was kept at about 2 cm. and the ampoule heated to 130–140° by an oil-bath to circulate tribromide vapor rapidly. The tube containing the pellets was heated to about 200°. The reaction proceeded very slowly, twenty-four to thirty-six hours of continuous operation being required to obtain 30 cc. of liquid product. This on distillation yielded 15 cc. of PF_3, 10 cc. of $PFBr_2$ and 5 cc. of PF_2Br, showing that the products were the same as those obtained by the reaction with antimony trifluoride and bromine.

Separation and Identification of the Products of Fluorination of Phosphorus Tribromide.—Since the products of the fluorination ranged in boiling point from −101 to +170°, they easily were roughly separated preliminarily.

The liquid $PFBr_2$ was redistilled several times in a small all-glass column at atmospheric pressure, and a small amount transferred to the isoteniscope for a vapor pressure[5] determination. Samples also were taken for analysis, vapor density, melting point and specific gravity determinations as described previously in publications from this Laboratory.

The fraction containing the PF_2Br was returned to the gas fractionating column and purified by repeated distillation at high reflux ratio at 200 mm. pressure.

Analysis.—Samples for analysis were condensed in weighed bulbs of 2-cc. capacity, attached to the apparatus by conical joints. The bulbs were sealed off at a constriction in the connecting tube and both portions again weighed. The sample, weighing about 2.5 g., was then frozen with liquid air, the tube broken, and dropped into an excess of sodium hydroxide solution in a stoppered 250-cc. Erlenmeyer flask and allowed to stand for twenty-four hours to ensure complete hydrolysis.

Phosphorus was determined by oxidizing the phosphite with an excess of standard iodine solution and back-titrating with sodium thiosulfate according to the method of Rosenheim and Pinsker.[6] Bromine was determined volumetrically by the Volhard method. Fluorides do not interfere with this determination if sufficient ferric nitrate is added to form the colorless complex ferric fluoride with all the fluorine. Since we have no satisfactory method for the determination of fluorine in the presence of phosphites, it was obtained by difference, but its presence was established qualitatively.

TABLE I

ANALYSES

	$PFBr_2$ Found	$PFBr_2$ Calcd.	PF_2Br Found	PF_2Br Calcd.

−15.3	779	787	8

The liquid density of $PFBr_2$ was determined in a special pycnometer by the method used by Booth and Herrmann for SO_2ClF.[7]

The vapor density of the PF_2Br was determined by a gas density balance as usual. The $PFBr_2$ was condensed in small bulbs and its vapor density determined in a regular Victor Meyer apparatus, using mercury in a gas buret to measure the volume.

Since these compounds are unstable and react

The Chemical Properties of the Phosphorus Bromofluorides.—The two bromofluorides condense to clear colorless liquids freezing to white crystalline solids. They fume in air to a greater extent than do either the tribromide or the trifluoride and have a sharp odor. They hydrolyze readily to form phosphorus, hydrobromic and hydrofluoric acids. They react with excess bromine to produce reddish-brown solids which presumably are PBr_4F and PBr_3F_2. These latter are quite unstable and on warming liberate bromine; they were not studied further.

PBr_2F is relatively stable and can be distilled at atmospheric pressure. However, on standing, it very slowly decomposes into PF_3 and PBr_3.

$$3PBr_2F \longrightarrow PF_3 + 2PBr_3$$

It reacts with mercury forming halides of mercury and free phosphorus.

PF_2Br is somewhat less stable than $PFBr_2$ and difficulty was encountered in obtaining it pure. The chemical analysis showed high phosphorus and low bromine, indicating contamination with PF_3. Distillation at low pressure from the column directly into the analysis bulbs and vapor pressure apparatus was necessary in order to obtain samples that gave the results shown in Table III.

If it is allowed to stand at low temperatures as a liquid, part of it decomposes to the fluoride and bromide: $3PF_2Br \longrightarrow 2PF_3 + PBr_3$. When the mixture is transferred from the ampoule the fluoride distils over with the unchanged bromofluoride while the bromide remains behind, causing analyses to be low in bromine and high in phosphorus.

The following experiences suffice to reveal the instability of PF_2Br:

(1) A sample that froze at −133.8° was allowed to stand in the melting point apparatus for several days. It then froze at −144°.

(2) Fifteen cc. of the liquid PF_2Br was held in the column still-pot for ten days at dry-ice temperature (−78°). The pressure rose steadily to almost atmospheric at the end of that time. The sample was then distilled and about 1 cc. of liquid PF_3 and 0.5 cc. of PBr_3 were obtained. This agrees with the equation for the decomposition given above, and indicates a conversion of about 1.5 cc. or 10% in ten days or about 1% per day.

(3) A series of analyses to show how the composition changes is given in Table IV.

TABLE IV

Sample	(1)	(2)	(3)	(4)	(5)	(6)	Calcd.
Phosphorus	30.06	23.0	21.60	21.33	20.5	21.20	20.88
Bromine	29.20	51.33	52.10	53.10	53.8	53.2	53.66
Fluorine	40.74	25.67	26.30	25.57	25.7	25.60	25.46
%PF_2Br from Br content	54.4	95.6	97.1	99.0	100	99.2	

(1) Sample that had stood in the melting point cell for several days before being transferred to the sample bulb. A portion of sample was discarded before transferring to the analysis bulb as well as part of that transferred, to remove some of the PF_3.

(2) Sample that had stood in an ampoule for a short time. Sample taken after about one-third the contents of an ampoule had been removed.

(3) and (4) Samples that were distilled into an ampoule and then immediately transferred to the sample bulbs. About one-sixth of product discarded first.

(5) and (6) Samples distilled directly into analysis bulbs by distillation of middle fraction from column.

Summary

Fluorination of phosphorus tribromide both by the action of antimony trifluoride at 70 and 170° using bromine as a catalyst, and also in the vapor state by reaction with calcium fluoride at 140° yields two new compounds, dibromomonofluorophosphine and monobromodifluorophosphine, as well as phosphorus trifluoride.

Dibromomonofluorophosphine is a clear colorless liquid which boils at +78.4° and freezes at −115.0° to a white solid.

Monobromodifluorophosphine is a gas at ordi-

nary temperatures. It condenses to a colorless liquid boiling at −16.1° and freezes to a white solid at −135.8°.

Both of these compounds hydrolyze on contact with the moisture in the air, react with mercury, liberating phosphorus, combine with bromine to form unstable compounds, probably $PFBr_4$ and PF_2Br_3, and decompose slowly forming PF_3 and PBr_3 at dry-ice temperatures (−78°).

The Fluorination of Phosphoryl Trichloride

BY HAROLD SIMMONS BOOTH AND FREDERIC B. DUTTON[1]

Booth and Swinehart[2] have shown that antimony trifluoride in the presence of a catalyst such as antimony pentachloride causes the progressive fluorination of inorganic non-polar halides. The present investigation is a study of the fluorination of phosphoryl chloride. Phosphoryl trifluoride had been prepared, and its properties first described by Moissan[3] by sparking a mixture of phosphorus trifluoride and oxygen. It has been prepared since by a number of workers using different methods.[4] The intermediate chlorofluorides have not been described previously.

Preparation of Phosphoryl Chlorofluorides.—Phosphoryl trichloride was fluorinated by means of antimony trifluoride using antimony pentachloride as a catalyst, and by means of calcium fluoride pellets at elevated temperatures. The apparatus used in these experiments has been described by Booth and Bozarth.[5]

Fluorination with Calcium Fluoride.—Fluorination by means of calcium fluoride was effected by passing the vapor of boiling phosphoryl trichloride over calcium fluoride pellets contained in an electrically-heated glass tube. The gases on leaving the reactor were so separated in a fractionating column that any unreacted material was returned to the boiling chamber and the fluorinated products were removed continuously. A generation carried out at a pressure of 100 mm. and with the reactor column containing the calcium fluoride pellets held at a temperature of 200° yielded about 90% phosphoryl trifluoride and 10% of higher-boiling substances. A generation carried out at 150° yielded about 35% of the trifluoride, 25% difluoromonochloride, and 40% monofluorodichloride. A generation at 120° gave chiefly the trifluoride but soon stopped and could be continued only by raising the temperature.

Fluorination with Antimony Trifluoride.—Fluorination by means of antimony trifluoride was carried out by slowly adding resublimed, finely crystalline antimony trifluoride[6] to a mixture of 200 g. of phosphoryl trichloride and 50 g. of antimony pentachloride while the liquid mixture was stirred rapidly and maintained at a predetermined temperature. The volatile products of the reaction passed through a condenser which was cooled by running water at about 10°.

A generation carried out with the reaction flask at 75° and a pressure of 190–200 mm. yielded about 55% of phosphoryl trifluoride, 5% of difluoromonochloride and 40% of monofluorodichloride. Higher temperatures (up to the boiling point of phosphoryl trichloride) did not seem to alter the above ratio and lower temperatures increased the yield of the trifluoride at the expense of the other products. The fluorinated products were fractionally distilled in a column, rapidly at first, to effect rough separation of the components. Each component was then carefully refractionated two or more times until further fractionation produced no change in the melting point.

Identification of the Phosphoryl Fluorochlorides

Analysis.—Samples for analysis were condensed in heavy walled bulbs connected to the apparatus by flat-joint connections. After filling, the bulbs were sealed off, weighed, frozen, the necks broken and all dropped into half-normal alkali. The gases dissolved completely on warming. Chlorine was determined either gravimetrically or by the Volhard method, and phosphorus by precipitation as the phosphomolybdate and twice as magnesium ammonium phosphate before ignition to the pyrophosphate.

No particular difficulty was encountered in the analysis of phosphoryl monofluorodichloride or the difluoromonochloride, but phosphoryl trifluoride gave results at first 2–4% low and it was found necessary to evaporate the acidified sample to dryness in a platinum dish to decompose fluophosphates before proceeding with the analysis.

The gas densities of the phosphoryl trifluoride and difluoromonochloride were determined in a gas density balance as described by Booth and Bozarth.[5]

Physical Properties

Freezing Points.—Freezing points were determined as usual in this Laboratory in a cell containing a magnetic stirrer and a thermocouple, surrounded by two or three concentric glass jackets and finally a Dewar jar containing liquid air. The temperatures were measured by a three-junction thermocouple. The fixed junction was held at the temperature of melting ice and the cooling curves automatically recorded on a Leeds and Northrup Micromax recording potentiometer. Considerable difficulty was encountered in melting and freezing phosphoryl trifluoride. Moissan gave as the boiling point −40°, which is essentially correct, and as the melting point −65°, which is seriously in error. The best determination made in this investigation put the freezing point at −39.4°.[7] The vapor pressure of the solid at the melting point is 771 mm. The liquid has a tendency to superheat with the resulting sudden increase in pressure which either blows a manometer, breaks the apparatus, or both.

On several occasions, when phosphoryl trifluoride had been condensed with liquid air as the refrigerant and this was later changed to dry-ice, the ampoule or cell holding the trifluoride cracked. It was thought that this phenomenon might be the result of a conversion of one solid modification to another. An attempt was made to discover the presence of a transition point by studying the vapor pressure of the solid but it was found that phosphoryl trifluoride condensed with liquid air and then held in dry-ice required two or three days to come to equilibrium, rendering it impractical to make a series of observations of the vapor pressure of the solid at different temperatures.

A second attempt to locate such a transition point was made by the differential method.[8] About 15 cc. of liquid phosphoryl trifluoride was frozen in the bottom of a cell which contained a copper neutral body just above the frozen gas. Two thermocouple wells entered the cell, one terminating in the neutral body and the second at the center of the frozen gas. The entire cell was cooled to liquid air temperature and a warming curve taken. The temperature was observed on the recording potentiometer by means of a 3-junction thermocouple using dry-ice as the fixed junction. At the same time the differential temperature between the neutral body and the frozen gas was observed on a second recording potentiometer by means of a 3-junction thermocouple. The warming curve indicated a change in the rate of warming and the differential curve indicated a maximum at approximately −100°, but neither curve showed a "sharp break"; this indicates a slow transition from one form to another.

[a] Prepared by Swarts reaction; all others by reaction with calcium fluoride. Calculated values were determined by use of the equation $\log p = (-1618.23/T) + 7.8440$.

Vapor Pressure.—The vapor pressure data for phosphoryl monofluorodichloride, which is a liquid at room temperature, were determined in the isoteniscope described by Booth, Elsey and Burchfield.[9] The vapor pressure data for the gases phosphoryl difluoromonochloride and trifluoride were obtained by direct observation of the pressure of the respective liquids held in small glass bulbs, immersed in a thermostat. Temperatures were measured by a resistance thermometer calibrated by the U. S. Bureau of Standards.

(7) Dr. G. Tarbutton, Department of Chemical Engineering, Tennessee Valley Authority, Wilson Dam, Alabama, has found the freezing point of phosphoryl trifluoride to be −39.1°.

(10) H. S. Booth and C. F. Swinehart, THIS JOURNAL, **57**, 1337 (1935).

Chemical Properties.—The properties of the phosphoryl fluorochlorides lie between those of the trichlorides and the trifluorides, and are proportional to the fluorine content. They hydrolyze in moist air or water with increasing rapidity, although the hydrolysis of the compounds containing fluorine is complicated by the intermediate formation of fluophosphates.

[a] From a plot of the vapor pressure data. [b] Calculated by the Clausius–Clapeyron equation.

All four substances are colorless in all states. All three fluorination products have little or no action on nichrome and copper. The trifluoride and the difluoromonochloride have a slight tendency to discolor the surface of mercury after prolonged exposure. When dry, the gases do not attack glass, but no precautions in the way of preliminary drying were sufficient to prevent the formation of a white ring at the surface and a slight cloudiness in the bottom of the container whenever the material was condensed in glass. This is most marked with the trifluoride and the difluoromonochloride and is very slight with the monofluorodichloride.

Phosphoryl difluoromonochloride was passed over sodium amalgam both in the gaseous and liquid states, in an attempt to remove the chlorine and form a condensation product of the formula $(POF_2)_2$. The surface of the amalgam was discolored, but there was no further evidence of reaction in the range of 20–60°.

Summary

The fluorination of phosphoryl trichloride by the Swarts reaction, and in the vapor phase by calcium fluoride pellets, yields two gases, phosphoryl trifluoride boiling at −39.8° first described

by Moissan, phosphoryl difluoromonochloride boiling at 3.1° and a liquid, phosphoryl monofluorodichloride boiling at 52.9°. The freezing points, vapor pressure data, critical constants, gaseous and liquid densities have been determined and recorded along with a few of their chemical properties.

The Entropy of Cyanogen. Heat Capacity and Vapor Pressure of Solid and Liquid. Heats of Fusion and Vaporization

BY R. A. RUEHRWEIN AND W. F. GIAUQUE

This paper is a report on a low temperature calorimetric investigation on solid and liquid cyanogen, N—C≡C—N. The results have been used to calculate the entropy of the gas by means of the third law of thermodynamics and this value has been compared with one calculated from available molecular data. The two values agree within their respective limits of error.

The measurements were made in a calorimeter with the laboratory designation Gold Calorimeter III and temperatures were obtained by means of Standard Copper–Constantan Thermocouple W-25, both of which have been described previously.[1,2]

Preparation and Purity of Cyanogen.—Cyanogen was prepared by a method similar to one described by Cook and Robinson.[3] Silver cyanide was precipitated from a saturated silver nitrate solution by a slight excess of a 78% solution of potassium cyanide. The silver cyanide was filtered, washed free of excess cyanide and dried in an oven at 130° for twelve hours. The silver cyanide prepared in this way was a pale brown powder. It was then heated in a glass vessel and a temperature of approximately 380° was maintained.

The cyanogen, which was evolved steadily at a pressure of about half an atmosphere, was passed through two tubes containing phosphorus pentoxide and finally condensed in a bulb surrounded by liquid air but protected from it in case of breakage. The phosphorus pentoxide tubes were 3 cm. in diameter and 30 cm. long. The preparation system was evacuated to a pressure of 10^{-5} mm. before the cyanogen was generated; 180 cc. of liquid was prepared. The material was distilled twice, small end-fractions being discarded, and the solid was subjected to a high vacuum to remove any non-condensable gases; 135 cc. of liquid remained after this treatment.

From the effect of premelting on heat capacity measurements below the melting point the liquid-soluble solid-insoluble impurity was estimated to be 5 parts in 100,000 on a molal basis.

The Melting Point of Cyanogen.—A summary of the melting point investigation is given in Table I.

TABLE I

MELTING POINT OF CYANOGEN

0°C. = 273.10°K.

The Vapor Pressure of Cyanogen.—The vapor pressure was measured with a Société Génévoise cathetometer with a precision of 0.002 cm. It was used as a comparison instrument for a standard meter suspended between the arms of the manometer, which was protected by a case with uniform temperature. The standard acceleration of gravity was taken as 980.665 cm. sec.$^{-2}$ and the acceleration at this location as 979.973 cm. sec.$^{-2}$. Data given in the "I. C. T."[4]

In Table II the observations have been compared with values calculated from Equations 1 and 2. From Equation 2 the boiling point was found to be 251.95°K.

The vapor pressure of cyanogen has been measured by Terwen,[6] Perry and Bardwell,[7] and Cook and Robinson.[3] Taking pressures as a reference, Terwen's data correspond to temperatures about 0.2° below the present results over the liquid and most of the solid ranges; however, the deviation increases at lower temperatures to 1.3° below when the pressure is about 2 cm.

The results of Perry and Bardwell and the present work agree within a few hundredths of a degree in the liquid and upper solid range but the deviation gradually increases until the observed temperature is 0.8° below the temperature obtained in this research when the pressure was about 2 cm.

Cook and Robinson made only one vapor pressure measurement below the boiling point and the present work is in agreement with this observation within 0.01°.

The melting and boiling points are compared with the values obtained by previous observers in Table III.

TABLE III

245.27	251.95	This research

The Heat Capacity of Cyanogen.—The amount of cyanogen used for the heat capacity measurements was measured by condensing it in a steel bomb and weighing at room temperature. The bomb was equipped with a gas tight double seated valve and a ground glass joint through which it could be evacuated and filled. The bomb weighed 450 g. and had a capacity of 150 cc., a weight of 119.516 g., which is equivalent to 2.2980 moles of cyanogen, was used for the measurements.

The heat capacity observations are given in Table IV and are shown in Fig. 1. The value marked with an asterisk is high due to premelting. One international joule was taken as 4.1832 cal-

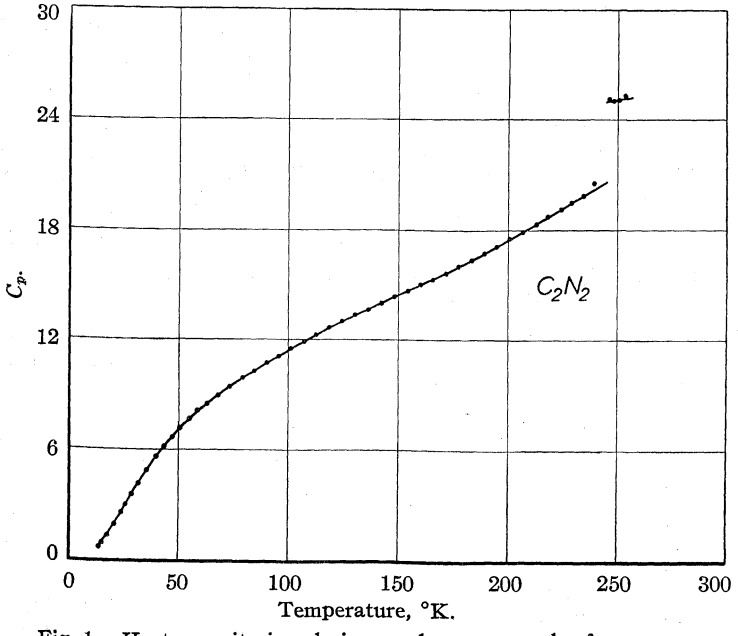

Fig. 1.—Heat capacity in calories per degree per mole of cyanogen.

ories in calculating energy. The calorimetric observations were corrected for vaporization into the small unoccupied volume in the calorimeter and the attached line. In making the correction the density of the liquid was taken from the work of Cook and Robinson[3] and the density of the solid was estimated with sufficient approximation for this small correction.

Heat capacity values taken from a smooth curve through the data are given in Table V. The curve should give the heat capacity to within 0.2% above 35°K. At 20°K. the error may be about 1% and at 15°K. as much as 5%.

The Heat of Fusion of Cyanogen.—A summary of the heat of fusion data is given in Table VI. The measurements were started a little below the melting point and ended somewhat above. A correction was applied for the $\int C_p \, d\,T$ and for the small amount of premelting that had occurred at the starting temperature due to the five thousandths of one mole per cent. impurity.

The Heat of Vaporization.—The heat of vaporization was measured by evaporating the cyanogen at constant pressure and absorbing the gas in a bulb containing 10 *M* sodium hydroxide. The absorption bulb had a small mercury trap. The rate of absorption of cyanogen in sodium hydroxide solution of lower concentration than 10 *M* was somewhat slow but the absorption was easily completed when the 10 *M* solution was used. The results are summarized in Table VII.

.21737	48	5576
	Mean	5576 ± 5
From vapor pressure equation 2, assuming a Berthelot gas		5624

The value of the heat of vaporization obtained from the vapor pressure observations and given in Table VII includes a gas imperfection correction of −151 cal. mole^{-1}. In obtaining the gas

imperfection, Berthelot's equation was used with $T_c = 401.4°K.$[10] and $P_c = 59.7$ atm.[10]

The value obtained from the vapor pressure measurements is given no weight in comparison with the direct calorimetric result.

The Entropy of Cyanogen.—A summary of the calculation of the entropy from calorimetric data is given in Table VIII. The correction for gas imperfection was calculated from the Berthelot gas expression

$$S_{ideal} - S_{actual} = 27\,RT_c^3P/32T^3P_c$$

The entropy of cyanogen gas has recently been calculated from molecular data by Stevenson,[11] who obtained 57.90 cal. deg.$^{-1}$ mole^{-1} at 298.1°K.

TABLE VIII

THE MOLAL ENTROPY OF CYANOGEN FROM CALORIMETRIC DATA

0–15°K. Debye function, $hc\nu/k = 118$	0.307
15–245.27°K., graphical	24.298
Fusion 1938/245.27	7.901
245.27–251.95°K., graphical	0.678
Vaporization 5576/251.95	22.131
Entropy of actual gas at boiling point	55.32 ± 0.1
Correction for gas imperfection	0.11
Entropy of ideal gas at 1 atm. and 251.95°K.	55.43 cal. deg.$^{-1}$ mole^{-1}

The moment of inertia, $I = 176 \times 10^{-40}$ g. cm.^{2}, is obtained from the electron diffraction measurements of Pauling, Springall and Palmer,[12] who find the C–C distance to be 1.37 Å. and the C–N distance 1.16 Å.

The fundamental frequency assignment was taken from the work and summary of Woo and Badger[13]: $\nu_1 = 860$, $\nu_2 = 2336$, $\nu_3 = 2150$, $\nu_4 = 230$, $\nu_5 = 512$ cm.$^{-1}$. ν_4 and ν_5 refer to deformation vibrations and have an *a priori* weight of 2. ν_5 is estimated from Raman observations on liquid cyanogen and ν_4 has not been observed directly, the 230 cm.$^{-1}$ value having been obtained from differences in ultraviolet bands. Unfortunately, ν_4 and ν_5 are the values of greatest importance in calculating the entropy. An error of 10 cm.$^{-1}$ in the 230 cm.$^{-1}$ value is equivalent to 0.15 cal. deg.$^{-1}$ mole^{-1} in the entropy. The symmetry number is 2.

The values are compared in Table IX.

(10) Pickering, *J. Phys. Chem.*, **28**, 97 (1924).
(11) Stevenson, *J. Chem. Phys.*, **7**, 171 (1939).
(12) Pauling, Springall and Palmer, THIS JOURNAL, **61**, 927 (1939).
(13) Woo and Badger, *Phys. Rev.*, **39**, 932 (1932).

The absolute entropy is obtained by adding R ln 9 = 4.366 cal. deg.$^{-1}$ mole^{-1}, the nuclear spin entropy, to the values given in column 4 of Table IX.

TABLE IX

COMPARISON OF ENTROPY VALUES FROM CALORIMETRIC AND FROM MOLECULAR DATA

Cal. deg.$^{-1}$ mole^{-1}.

	Calorimetric data		Molecular data	
T, °K.	Actual gas	Ideal gas	Less nuclear spin entropy	Absolute entropy
251.95	55.32	55.43	55.67	60.04
298.10	...	57.64	57.88	62.25

The agreement of the two entropy values is within the limit of error of the result based on molecular data. However, the agreement is sufficiently close to show that cyanogen approaches zero entropy as the absolute zero is approached.

Until a more complete investigation and analysis of the cyanogen band spectrum is available, the most reliable value of the entropy is the one based on the third law of thermodynamics, 57.64 cal. deg.$^{-1}$ mole^{-1} at 1 atm. and 298.1°K.

We thank Dr. T. M. Powell for assisting with the measurements.

Summary

The heat capacity of solid and liquid cyanogen has been measured from 15°K. to the boiling point.

The melting and boiling point temperatures were found to be 245.27 and 251.95°K., respectively (0°C. = 273.10°K.).

The heats of fusion and vaporization were determined by calorimetric observation to be 1938 and 5576 cal. mole^{-1}, respectively.

The vapor pressure of solid and liquid was measured and the data have been represented by the equations

Solid cyanogen 202 to 245.27°K. $\log_{10}P$(inter. cm. Hg) = $(-1795.9/T) - 0.001464T + 9.42442$

Liquid cyanogen 245.27 to 253°K. $\log_{10}P$(inter. cm. Hg) = $(-1525.7/T) - 0.0040842T + 8.96542$

The calorimetric data have been used to calculate the entropy of cyanogen gas and this value has been compared with one obtained from molecular data and it is found that the entropy of cyanogen approaches zero near the absolute zero of temperature.

Until more complete information concerning the vibrations of the cyanogen gas molecule is

available the most reliable value of the entropy of cyanogen is the calorimetric one, 57.64 cal. deg.$^{-1}$ mole^{-1} at 298.1°K. and one atmosphere. This value does not include the nuclear spin entropy.

The Decomposition of Some Iodonium Salts. Reactions with Mercury, Tellurium and Antimony

BY R. B. SANDIN, F. T. MCCLURE[1] AND F. IRWIN[2]

Recently H. J. Lucas and co-workers[3] have shown that di-*o*-tolyliodonium iodide decomposes at 155° into *o*-iodotoluene, uncontaminated by any isomeric product. They suggest that the mechanism involves a decomposition which proceeds through an intermediate, positively charged *o*-tolyl ion in which the positive charge is carried by a carbon atom. The positive *o*-tolyl ion then combines with the negative iodide ion of the iodonium salt to form a molecule of *o*-iodotoluene.

This plausible mechanism fits in with the fact that it is now known definitely that the I–I bond in diphenyliodonium iodide is an ionic, not a covalent, bond.[4] However, the authors of this paper became interested in the possibility that the decomposition of iodonium salts might, to some extent at least, be a non-ionic one and might proceed through the intermediate formation of free radicals. A non-ionic mechanism might explain the fact that the decomposition temperature of an iodonium salt depends upon the nature of the anion as well as the cation. For example, di-*o*-tolyliodonium bromide decomposes at 178°, the iodide at 155° and the sulfide at room temperature. If the decomposition involved only the positive ion, it is conceivable that the decomposition temperatures would lie closer together. Keeping the positive ion the same, we find roughly that the decomposition temperature of an iodonium salt varies directly with the electronegativity of the negative ion. Again, it is in a reaction such as this where one might look for the formation of free radicals. The latter are likely to be formed from those molecules which readily tend to undergo thermal self-decomposition at comparatively low temperatures (*e. g.*, explosives, endothermic compounds, etc.). Finally, the recent work of Waters[5] and co-workers on the decomposition reactions of the aromatic diazo compounds gave the present workers some hope in the idea that iodonium salts might behave similarly to diazonium salts.[6] Waters has shown that the diazonium chlorides can decompose by a non-ionic mechanism $(PhN_2)^+Cl^- \longrightarrow$ Ph-N=N-Cl $\longrightarrow$ Ph· + N_2 + ·Cl, giving transient free neutral aryl radicals which are identical in chemical behavior with the neutral alkyl radicals[7] which have been studied in the gaseous phase.

The authors of this paper have carried out the decomposition of diphenyliodonium chloride and sulfide and di-*p*-tolyliodonium chloride in the presence of mercury, tellurium and antimony. In all cases, reactions have occurred which suggest the intermediate formation of free aryl radicals. Similarly, Waters[5] has found that benzenediazonium chloride decomposes under acetone kept neutral with chalk, in such a way that mercury, tellurium and antimony are attacked. Waters concludes that in the reaction mixture the free phenyl radical has a transient existence and that the phenyl radical is formed by thermal or photochemical decompositions of organic molecules in the liquid phase as well as in the gaseous phase.[8]

In view of the results obtained, it seems especially tempting to assume that in the decomposition of an iodonium salt, part of it at least can decompose by way of a non-ionic mechanism. The assumption is made that in the iodonium salt the

(6) There is a fundamental relationship between diazonium salts and iodonium salts in that the former are quaternary ammonium salts (*i. e.*, fully substituted ammonium salts) and the latter are fully substituted derivatives of the hypothetical $(H_2I)^+X$.

central iodine atom is able, by expanding its valence shell, to act as an acceptor for the chloride or sulfide ion. Subsequent transformations of this complex result from the tendency of the central atom to revert to an octet. The following is suggested as a probable course of the reaction: $(C_6H_5)_2I^+ Cl^- \longrightarrow (C_6H_5)_2I \longleftarrow Cl \longrightarrow C_6H_5I + C_6H_5\cdot + \cdot Cl$. The expanded valence shell has been used to explain the marked difference in the mode of decomposition of the quaternary ammonium bases from the corresponding phosphonium bases. It also has been used in connection with the unusual reactions of, and formation of, the 2- and 3-covalent iodine compounds.[9]

The above conclusions of the authors are based largely upon the analogy between the reactions of iodonium compounds and the reactions of diazonium compounds studied by Waters and coworkers. Dr. H. J. Lucas of the California Institute of Technology has kindly drawn attention to the important role played by the metal in the decomposition reactions. He suggests the possibility of an intermediate, undissociated complex which decomposes at a lower temperature than the salt would otherwise. Such a reaction mechanism would not necessarily involve the formation of free radicals. On this basis also, the decomposition with and without a metal would not necessarily have to proceed via similar mechanisms.

Experimental Part

Preparation of Compounds.—Diphenyliodonium chloride and di-*p*-tolyliodonium chloride were prepared readily by a standard procedure.[3] It seems impossible to isolate an iodonium sulfide compound. Diphenyliodonium hydroxide, for example, when treated with sodium sulfide, produces a bright yellow precipitate (evidently the sulfide) which quickly decomposes into phenyl iodide and phenyl sulfide.[10] For that reason, in any of the decomposition reactions involving an iodonium sulfide salt, a more stable salt such as the chloride was mixed with sodium sulfide, or aqueous hydrogen sulfide, and to this mixture the necessary element such as mercury was added.

Diphenyltellurium dibromide, m. p. 200°, was made according to Krafft and Lyons.[11]

Triphenylstibinic sulfide, m. p. 119–120°, was made from triphenylstibinic chloride according to the procedure of Kaufmann.[12]

Reaction with Mercury.—Diphenyliodonium chloride (3.0 g.) was dissolved in 150 cc. of boiling *n*-propyl alcohol. To this was added about 2.0 cc. of mercury and the mixture was refluxed for about five hours. While the mixture was still hot it was filtered and, on cooling the filtrate, pure phenylmercuric chloride, m. p. 250°, crystallized out. The yield was 1.25 g. The same procedure carried out with the addition of finely divided calcium carbonate gave identical results. In the same manner, di-*p*-tolyliodonium chloride gave *p*-tolylmercuric chloride, m. p. 230°.

Changing the solvent from propyl alcohol to water did not seem to have any appreciable effect on the results. This seems peculiar, since one would expect a solvent such as water to favor an ionic decomposition. Waters[5] has found that the non-ionic decomposition of diazonium salts occurs best in such solvents as acetone and ethyl acetate.

Reaction with Tellurium.—Diphenyliodonium chloride was refluxed in an *n*-propyl alcohol solution with finely divided tellurium. After several hours the unchanged tellurium was filtered off and the filtrate evaporated to a small volume. On the addition of bromine, yellow crystals of diphenyltellurium dibromide, m. p. 199–200°, crystallized out. These crystals, mixed with a sample of synthetic material, produced no depression of the melting point. When water was used as a solvent, only once, out of several attempts, was enough diphenyltellurium dibromide obtained for a melting point determination. These results might indicate that an ionic decomposition occurs in a highly polar solvent such as water. It was also observed that when water was used as the solvent, finely divided tellurium speeded up the decomposition of the iodonium salt.

When a mixture of diphenyliodonium chloride dissolved in water, tellurium, ether and aqueous hydrogen sulfide, was shaken up in a flask for about an hour at room temperature, diphenyltellurium was again formed. The diphenyltellurium dissolved in the ether layer and was isolated as the yellow dibromide.

Similar results to the above were obtained when di-*p*-tolyliodonium chloride was used instead of the phenyl compound. Di-*p*-tolyltellurium was isolated as the yellow dibromide, m. p. 203–204°.

When a mixture of diphenyliodonium chloride and finely divided tellurium was heated in the dry condition in a testtube, diphenyltellurium dichloride, m. p. 158°, was formed. The tellurium had also the effect of lowering the decomposition temperature of the iodonium chloride.

Reaction with Antimony.—A solution of diphenyliodonium chloride in water was shaken up at room temperature with sodium sulfide, finely divided antimony and ether. The ether layer was separated, filtered and, on evaporating to dryness, beautiful crystals of triphenylstibinic sulfide, m. p. 119–120°, were left behind. They had a slight yellowish tinge and when mixed with a synthetic sample produced no depression of the melting point

Summary

1. Diphenyliodonium chloride and di-*p*-tolyliodonium chloride react with mercury in boiling *n*-propyl alcohol to produce phenyl and *p*-tolyl mercuric chloride. With tellurium they give diphenyltellurium and di-*p*-tolyltellurium. Di-

phenyliodonium sulfide decomposes at room temperature in the presence of tellurium and antimony to give diphenyltellurium and triphenylstibinic sulfide.

2. To account for these reactions, it is suggested that at least a part of the iodonium salt decomposes by way of a non-ionic mechanism.

Tyrosinase from the Wild Mushroom, *Lactarius Piperatus*

BY H. R. DALTON AND J. M. NELSON

Kubowitz[1,2] has shown that potato oxidase (tyrosinase) contains copper and that the activity of the oxidase toward catechol as the substrate is proportional to the metal content. After considerable purification a product was obtained which in the presence of acetone, at 0°, occurred in a globular form and contained 0.20% copper. Keilin and Mann[3] have also prepared a highly purified polyphenolase (*i. e.*, tyrosinase) from the common mushroom, *Psalliota campestris*, which had a copper content of 0.30% and an activity toward catechol proportional to the copper content.

The tyrosinase described in the present communication was prepared from the wild mushroom, *Lactarius piperatus*. Highly purified preparations from this source were found to contain 0.23% copper. The activity of these preparations toward catechol was also proportional to the copper content (see Fig. 1). The copper was

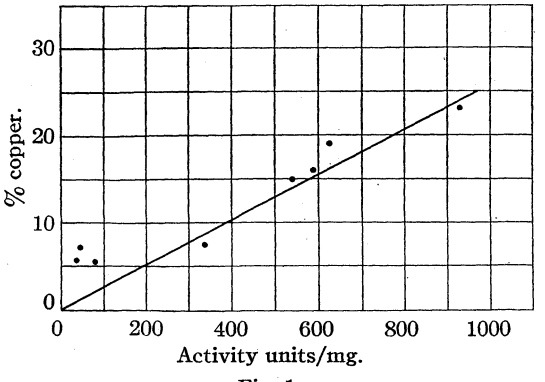

Fig. 1.

easily removed from the enzyme preparation by dilute acids just as Kubowitz noted in the case of the oxidase from potatoes. Contrary to the claims by Yakushiji[4] that the polyphenolase from *Lactarius piperatus* contains a hematin residue; the data in the table clearly show that the iron can be removed completely by one adsorption to kaolin. Only in the case of the two crude preparations, nos. 1 and 2, was iron found to be present and then only in very small amounts. It therefore appears that iron was present only as an impurity in the crude preparations.

Keilin and Mann[3] found no relationship between the activities of their oxidase preparations, from *Psalliota campestris*, toward the two substrates, *p*-cresol and catechol, and were inclined to attribute the activity toward *p*-cresol as involving the presence of some other factor in the reaction mixture. Likewise Adams and Nelson[8] were able to vary, in the case of the oxidase from *Psalliota campestris*, the ratio between the activities toward these two substrates. On the other hand, the last-mentioned investigators were unable by similar procedures, such as the use of various adsorbing materials, to alter the ratio of these two activities in the case of the tyrosinase from *Lactarius piperatus*. Further attempts in the present study to vary this ratio by treating the enzyme solutions with lead acetate and with silver acetate also were unsuccessful. All the preparations examined showed about 10 cresolase units to 1 catecholase unit.

The quantity of copper corresponding to one unit of cresolase is given in the table for several preparations. The rather crude preparations 1, 2 and 3 contain an appreciable quantity of undialyzable copper, which was also noticed by Keilin and Mann[3] in their crude preparations from *Psalliota campestris*, and hence show a high copper value per cresolase unit. Preparations 4 to 8 have lost this extraneous copper and the copper per cresolase unit reaches a constant value of approximately 0.0027 γ. These preparations represent enzyme in which all of the copper seems to be in an active form.

PREPARATION OF MATERIALS AND PROCEDURE (TABLE I)

Showing enzyme activity, dry weight per enzyme unit and copper content. All tyrosinase preparations obtained from *Lactarius piperatus*.

Prepn. 1.—Mushrooms dried by being spread out in the laboratory for several days. Broken up and water added—pressed in hydraulic press and the press juice dialyzed for forty-eight hours against water in a rocking dialyzer which kept the liquid in the cellophane sausage casing, continuously in motion.[5] *Prepn. 2.*—Prepn. 1 precipitated with 0.4 satd. ammonium sulfate, precipitate dissolved in water and dialyzed on rocker for forty-eight hours. *Prepn. 3.*—Prepn. 2 adsorbed to kaolin (*p*H 4.5), eluted with disodium phosphate (*p*H 8.4), treated with 0.3 satd. ammonium sulfate and precipitate discarded, made 0.6 satd. with ammonium sulfate and precipitate formed dissolved in water and dialyzed 48 hours on rocker. *Prepn. 4.*—Dried mushrooms treated with water, pressed and liquid made 0.6 satd. with ammonium sulfate, precipitate dissolved in water and enzyme material adsorbed to kaolin (*p*H 4.5), eluted with disodium phosphate (*p*H 8.4), reprecipitated with 0.6 satd. ammonium sulfate, precipitate dissolved in water, dialyzed fourteen hours on rocker followed by dialysis for twenty-four hours in a large bottle of glass distilled water in the icebox. *Prepn. 5.*—Dried mushrooms water pressed, precipitated with 0.6 satd. ammonium sulfate, dissolved in water, reprecipitated with 0.6 satd. ammonium sulfate, dissolved in water, adsorbed to kaolin (*p*H 4.5), eluted with disodium hydrogen phosphate (*p*H 8.4), reprecipitated with 0.6 satd. ammonium sulfate, dissolved in water, reprecipitated with 0.6 satd. ammonium sulfate, dissolved in water, dialyzed for forty-eight hours on rocker. *Prepn. 6.*—Enzyme material in Prepn. 5 adsorbed to kaolin (*p*H 4.8), eluted with disodium hydrogen phosphate (*p*H 8.4), precipitated with 0.4 satd. ammonium sulfate and precipitate formed discarded, solution remaining was made 0.6 satd. with ammonium sulfate and precipitate formed dissolved in water and dialyzed forty-eight hours on rocker. *Prepn. 7.*—Dried mushrooms, water added, pressed, precipitated with 0.6 satd. ammonium sulfate, dissolved precipitate in water, made 0.3 satd. with ammonium sulfate and precipitate discarded, remaining liquid made 0.6 satd. with ammonium sulfate and precipitate formed dissolved in water, adsorption to kaolin (*p*H 4.5), eluted with disodium hydrogen phosphate at *p*H 8.4, reprecipitated with 0.6 satd. ammonium sulfate, precipitate dissolved in water and enzyme material adsorbed to alumina (*p*H 6.5), eluted with disodium hydrogen phosphate (*p*H 8.4), dialyzed fourteen hours on rocker. This solution had only a slight brown color. *Prepn. 8.*—Dried mushrooms, water added, pressed, precipitated with 0.6 satd. ammonium sulfate, dissolved in water, precipitated with 0.2 satd. ammonium sulfate and precipitate discarded, solution made 0.5 satd. with ammonium sulfate, precipitate dissolved in water, adsorbed to bentonite (*p*H 4.5), eluted with disodium hydrogen phosphate (*p*H 8.4), precipitated with 0.6 satd. ammonium sulfate, dissolved in water, treated with alumina (*p*H 6.5) and portion not adsorbed set aside and marked A. Material adsorbed to the alumina was eluted with disodium hydrogen phosphate (*p*H 8.4) and precipitated with 0.6 satd. ammonium sulfate, dissolved in water and treated with alumina (*p*H 6.5) and solution containing portion of enzyme material which failed to adsorb added to A. Process repeated until 90% of the original enzyme material was recovered as material from portions not adsorbed to alumina. The combined solutions were made 0.6 satd. with ammonium sulfate, precipitate dissolved in small volume of water and treated with norite charcoal (*p*H 6.5), filtered, reprecipitated with 0.6 satd. ammonium sulfate, precipitate dissolved in 13 cc. of water (*p*H 6.7), dialyzed four days in large bottle (3 liters) of glass distilled water placed in refrigerator. Water was changed two times each day. The solution thus obtained was nearly colorless.

Enzyme activity was determined by means of the Warburg respirometer,[6] temp. 25°. Graubard and Nelson's[7] method as modified by Adams and Nelson[8] was used for determining units of enzymic activity toward both *p*-cresol and catechol as substrates. In each case one unit represents the amount of enzyme, measured under prescribed conditions, necessary to bring about an oxygen uptake of 10 cu. mm. per minute. Since the oxidations of the two substrates are distinctly different reactions[9] the two kinds of units must not be confused. For this reason the two enzymic actions have been termed for convenience, cresolase and catecholase activities.

Iron was determined by the *o*-phenanthroline method of Saywell and Cunningham.[10] No interference was observed by them from copper, aluminum and magnesium in a solution containing 1×10^{-5} mg. of iron to which had been added 2×10^{-5}, 1×10^{-4} and 1×10^{-4} mg. of copper, aluminum and magnesium, respectively. Copper was determined by the method of Warburg[11] as modified by Warburg and Krebs.[12] Each determination was made with enzyme containing sufficient copper to give a rate of oxygen uptake between 20 and 30 cu. mm. per ten minutes.

The purest enzyme preparation obtained contained 0.23% copper, possessed an activity of 1000 cresolase units per mg. dry weight and 0.0027 γ copper per cresolase unit.

Redfield[13] and Dhéré and Burdel[14] have found a similarity in the visible region of the spectrum

among a large number of bloods and solutions containing oxyhemocyanin. In general a rather strong band occurs in the region of 570 mμ. Since the hemocyanins are copper proteins like tyrosinase, purified preparations of the latter, from *Lactarius piperatus*, were examined by means of a Zeiss microspectroscopic ocular attached to a microscope, but no similar absorption could be detected in the visible region.

The preparations were also examined in a Hilger quartz spectrophotometer. The quartz cells used for holding the tyrosinase preparations were 1 cm. in depth. Figure 2 represents a curve plotted from data obtained. Dhéré[15] and Kubowitz[2] investigating the ultraviolet absorption spectrum of oxyhemocyanin obtained strong absorption bands in the region of 278 and 350

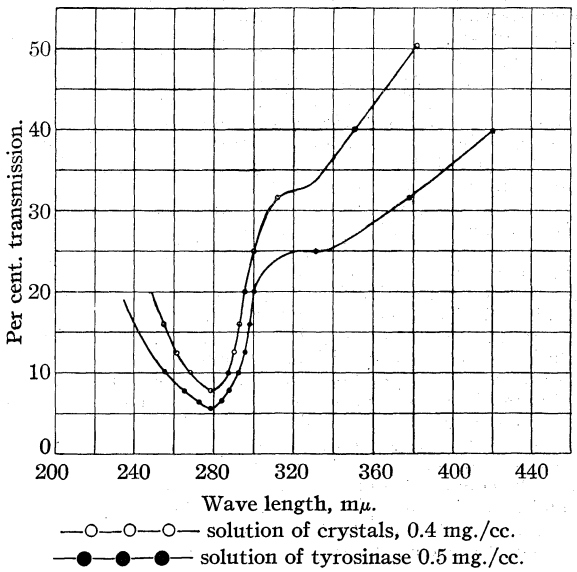

Fig. 2.—Shows the similarity between the absorption curves for a purified tyrosinase preparation and for a solution of the crystals. A weak absorption in the case of the enzyme solution exists in the region from 320 to 340 mμ. The absorption in this region in the case of the solution of the crystals is less pronounced, but when the low concentration of the crystalline material is taken into account, it will be found that the intensity is relatively about the same.

That the similarity of the two curves may be due to the enzyme solution containing uncrystallized material, corresponding to the crystals, can hardly be the case. As already stated in the text, not more than 10% of the dry weight in any purified preparation was obtained in the crystalline form. Assuming that Beer's law holds, it can be shown that these two curves are identical, and that it is unlikely that this would be the case if the crystals and enzyme material were not closely related.

mμ which are quite similar to the bands given by the *Lactarius piperatus* tyrosinase. The band at 278 mμ is due to protein.[15]

Ley and Hegge[16] in a study of copper amino acid showed that the band at about 385 mμ is due to copper. The band at about 330 mμ given by the tyrosinase preparations and the band at

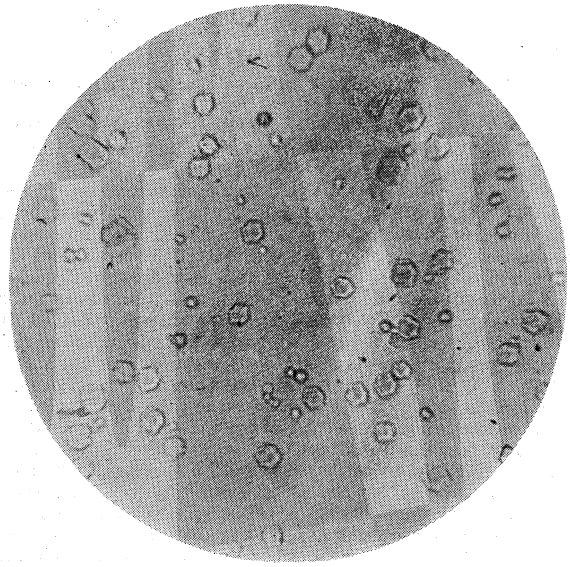

Fig. 3.

about 350 mμ for oxyhemocyanin are probably due to the copper in these complexes, their positions being shifted to some extent as a result of the influence of modifying groups. The failure of Ito[17] to find any indication of an absorption in this region for potato oxidase might be due to this absorption being much weaker than the protein band and likely to be hidden by the general absorption in this region.

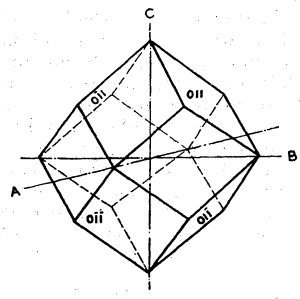

Fig. 4.

As has been stated in a previous communication,[18] a crystalline material was obtained from several preparations of tyrosinase from *Lactarius piperatus*. Rather crude preparations, as well as preparations purified as described in the legend of the table, yielded crystals. In no case, however, was more than 10% of the dry weight of a

purified enzyme preparation obtained in a crystalline form. The procedure followed in obtaining the crystals was similar to that usually employed for crystallizing hemocyanin,[19] *i. e.*, by adjusting the *p*H of the enzyme solutions, containing at least 1000 units of cresolase per cc., to about 4.8 by means of sodium acetate buffer and then adding ammonium sulfate until the solution became slightly cloudy. After standing for several hours crystals could be observed. Enzyme preparations which had been treated, in the course of purification, with lead acetate so far have not yielded any crystalline material by the above described procedure.

Since the previous communication it has been possible to obtain perfectly shaped crystals which belong definitely in the isometric system. Their shape is rhombic dodecahedric. They are usually found lying on their 011 faces and when thus viewed through the microscope show hexagonal shapes. Figure 3 is a photomicrograph of these crystals and Fig. 4 is a perspective diagram.

The crystals show thryxotropy, are colorless, stain well with methyl violet, and have an average size of approximately 0.010 mm. Analysis showed 0.25% copper and 13.6% nitrogen. Like solutions of the purified tyrosinase, solutions of the crystals showed no marked absorption in the visible spectrum, but did show an absorption curve similar to that of the enzyme in the ultraviolet (see Fig. 2).

The crystals are insoluble in dilute acids and salt solutions. When freshly prepared they are soluble in dilute alkali (*p*H 8) but become increasingly insoluble on standing. After standing for several weeks they become practically insoluble in 0.1 *M* sodium hydroxide.

The wash water from freshly prepared crystals, after the tenth washing by means of the centrifuge, still showed tyrosinase activity. This activity may possibly be due to enzyme from the concentrated mother liquor still adhering to the crystals. Against this possibility, however, might be mentioned that 3 mg. of crystals dissolved in 20 cc. of secondary sodium phosphate solution and having an activity of 4 cresolase units per cc. showed an increase in activity to 12 units per cc. after standing for three weeks.

Slight increases in activity on standing were also noticed in the case of some solutions of the tyrosinase preparations. The latter observation has been made also by Keilin and Mann[3] and, as they have suggested, may be due to the presence of a proenzyme, which by some unknown process may be activated. Results obtained in this study show that only about 15% of the copper in the crude preparations is in the active form. The remaining copper or at least part of it may be related to this inactive state of the enzyme.

The similarity in composition, spectra and tendency to slight increase in activity on standing, all point to a close relationship between the active enzyme and the crystals. The fact that inactive or only slightly active crystals were obtained from solutions of highly purified preparations in which all the copper appears to be in the active form (γ of copper per cresolase units, see table) suggests the two following possibilities. Either the enzyme becomes, for some unknown reason, inactive when it is crystallized, or an inactive form, such as a proenzyme, accompanies the enzyme as it is purified.

(19) C. Dhéré, *J. physiol. path. gén.*, **18**, 503 (1919).

Summary

1. A method is described for preparing highly purified preparations of tyrosinase from *Lactarius piperatus*.

2. The tyrosinase is shown to be a copper protein.

3. The purest tyrosinase preparation contained 0.23% copper and had a dry weight of one mg. per 1000 cresolase units and 0.0027 γ of copper per cresolase unit.

4. The iron present in the crude preparations of the enzyme can be removed by adsorption methods.

5. Purified enzyme preparations showed no definite absorption bands in the visible region of the spectrum, differing in this respect from the hemocyanins.

6. Two absorption bands were observed in the ultraviolet region: a band due to protein at 273 mμ and a band at about 330 mμ probably due to copper.

7. A crystalline material was obtained, from rather crude as well as from purified preparations of the tyrosinase, having a copper content of 0.25% and 13.6% nitrogen. The crystals were colorless and belonged to the isometric system. The average size was about 0.010 mm.

8. Solutions of the crystals were only slightly active toward *p*-cresol and catechol. This slight

activity showed a tendency to increase when the solutions were permitted to stand for some time. Certain solutions of the freshly prepared tyrosinase also showed this tendency to increase in activity on standing.

9. The ratio of activities of the tyrosinase preparations toward *p*-cresol and catechol could not be altered by various methods of purification, but always remained 10 to 1, respectively. The ratio of the two activities in the case of the solutions of the crystalline material was also 10 to 1.

10. Composition, similarity in absorption spectra, the slight increase in activity when solutions are allowed to stand, all point to a close relationship between the crystals and the highly purified tyrosinase preparations.

Sulfanilamide Derivatives. IV. N^1,N^4-Diacylsulfanilamides and N^1-Acylsulfanilamides[1]

BY M. L. CROSSLEY, E. H. NORTHEY AND MARTIN E. HULTQUIST

We have prepared an extended series of N^1-acylsulfanilamide derivatives[2] of the type  , as a continuation of our studies of N^1-substituted sulfanilamides. The scope of the work was extended to include examples where R was alkyl (from one to seventeen carbons in length), alkenyl, aryl, aralkyl, diaralkyl, aralkenyl, cycloalkyl, cycloalkenylalkyl and heterocyclic. Derivatives were also prepared from aliphatic dicarboxylic acids and aryl dicarboxylic acids. A few metanilamide derivatives were prepared, but these appeared to be of little therapeutic interest. X in the above formula was hydrogen, alkyl or a cation.

As intermediates in the preparation of many of the above, N^1,N^4-diacylsulfanilamides of the general formula,  , were synthesized. In these, R′ was usually a methyl group, but several compounds were prepared in which R′ was the same as R. This particular series was not extended since the pharmacological results were not encouraging.

Derivatives in which the N^4-nitrogen of the N^1-acylsulfanilamide was substituted by sulfanilyl- or sodium methylenesulfinate groups were also prepared.

Since inception of this work, the first members of both series have been mentioned. A diacetylsulfanilamide, melting at 240–242°, which from the method of preparation was probably impure N^1,N^4-diacetylsulfanilamide, was described by Scudi.[3] N^1-Acetylsulfanilamide has been described by M. Dohrn and P. Diedrich[4] and is being sold abroad under the name "Albucid" for use against gonorrhea.

Several methods of synthesis were employed, but the one most generally useful involved reaction between N^4-acetylsulfanilamide and an acyl halide in the presence of dry pyridine. This reaction proceeded smoothly, giving good yields of the N^1-acyl-N^4-acetylsulfanilamide. The N^4-acetyl group was then removed by boiling with a slight excess of aqueous sodium hydroxide, to give a solution of the sodium salt of the N^1-acylsulfanilamide, from which the free N^1-acylsulfanilamide was obtained by acidification. Other methods successfully used are given in the experimental part.

Attempts to prepare derivatives by reaction of dry N-acetylsulfanilyl chloride with several carbonamides in pyridine failed. The reason for such failure is not understood and is being investigated further.

N^1-Acyl-N^4-sulfanilylsulfanilamides were prepared by condensing an N^1-acylsulfanilamide with N-acetylsulfanilyl chloride in pyridine, followed by hydrolysis of the acetyl group with aqueous sodium hydroxide.

N^4-Sodium formaldehydesulfoxalate derivatives of N^1-acylsulfanilamides were prepared by warming equimolecular amounts of the starting materials in water until solution was complete, then evaporating to dryness *in vacuo*.

The compounds usually were obtained as white crystalline materials, although difficulty was met in crystallizing derivatives of unsaturated long chain acids. In many cases the products were first precipitated in sticky, amorphous form and then slowly crystallized. In the series of derivatives of fatty acids, the lower members were moderately water soluble. On ascending the series, the water solubility decreased and solubility in fat solvents increased. Water solubility of derivatives having chains of twelve carbons or more was less than 0.001 g./100 cc. All of the derivatives in which a hydrogen remained on the amide nitrogen formed very soluble

[a] Geneva names are given for acid radicals of six carbons and more because of confusion of their common names with the corresponding alkyl radicals. [b] Also exists in a form which starts melting at 115° and then changes to the higher melting form. [c] Prepared from stearic acid containing palmitic acid. [d] Softens and changes to high melting form at 130°, but melts immediately at 145°, then solidifies.

sodium salts, which were neutral for the lower members of the series, but became increasingly alkaline for the higher members. All of these compounds could be titrated quantitatively to a phenolphthalein end-point, however, while sulfanilamide itself cannot be so titrated, since its sodium salt is highly hydrolyzed at this *p*H.

In general, the derivatives could be hydrolyzed quantitatively to the organic acid and sulfanilamide (or sulfanilic acid) by boiling with alcoholic hydrochloric acid, or more rapidly by heating to 180–200° with 65% sulfuric acid.

The lower members of the series could be titrated quantitatively by diazotization of the N^4-amino group. The higher members were too insoluble in dilute mineral acids to be diazotized directly, but for purposes of analysis were hydrolyzed, by either of the above methods, to sulfanilamide (or sulfanilic acid) and then diazotized. Hydrolysis of the sample before diazotization also permitted nitrite assays of N^1,N^4-diacylsulfanilamides. Analyses by titration with sodium hydroxide and with sodium nitrite were regarded to be of more significance than fundamental analyses by microchemical methods as criteria of purity since presence of isomeric N^4-acylsulfanilamides could not be distinguished by combustion methods.

Alkylation of the N^1-nitrogen gave derivatives which no longer formed salts with cations. These had increased solubility in organic solvents. These derivatives were sensitive to hydrolytic agents and in this resembled the N^1-alkyldisulfanilamides.[5]

A partial rearrangement of certain of these derivatives has been observed. By heating N^1-dodecanoylsulfanilamide for twenty hours at 130–140°, the material darkened, and became semisolid. On dissolving the mixture in hot alcohol, addition of sodium hydroxide to *p*H 9.5, then diluting with water, N^4-dodecanoylsulfanilamide crystallized as fine needles, identified by melting point and inability to titrate with sodium hydroxide.

On boiling an aqueous solution of N^1-acetylsulfanilamide for two hours, small amounts of N^1,-N^4-diacetylsulfanilamide and sulfanilamide were identified. This suggests that two molecules of N^1-acetylsulfanilamide interact with formation of sulfanilamide and N^1,N^4-diacetylsulfanilamide. This interesting reaction will be investigated further.

Pharmacology.—The compounds of the present series have not been investigated in detail pharmacologically. Preliminary results are, however, of considerable interest and center chiefly on derivatives of long-chain fatty acids.

The N^1-acylsulfanilamides were part of our program on disulfanilamides, but the immediate emphasis on long-chain derivatives was due to a suggestion by Dr. D. A. Bryce, our medical director, that some combination of chaulmoogric acid and sulfanilamide might penetrate the tubercle of, and be effective against, tuberculosis. The sodium salt of N^1-chaulmoogrylsulfanilamide seemed to us to be the solution. Lack of chaulmoogric acid led to synthesis from other long-chain fatty acids. It then appeared that the free long-chain derivatives might be of more interest because of their probable fat solubility, and their possible penetration into the bacilli.

While the sodium salts of long-chain N^1-acylsulfanilamides are highly water soluble, they have the characteristics of soaps and are lytic in action. The free long-chain N^1-acylsulfanilamides are almost completely water insoluble, but are soluble in fats and fat solvents. Absorption of these by the oral route appears to be accelerated by administration of fats.

N^1-Dodecanoylsulfanilamide has been investi-

gated more fully than other members of the series. It appears to be equal or slightly superior to sulfanilamide, on an equal weight dosage, in experimental mice infections with various beta hemolytic streptococci. Cavies infected with a human strain of mycobacterium tuberculosis showed only localized lesions when treated with the drug. Animals treated with sulfanilamide showed moderate spread of the infection, while untreated controls developed generalized tuberculosis and died.

The pharmacological study has been made under the direction of D. R. Climenko. Further details are being published elsewhere.[6,7]

Experimental Part

General Methods of Synthesis. 1. Use of Acyl Halide in Pyridine.—This method was the most generally applicable and gave the best yields. It is illustrated by the following synthesis of N^1-dodecanoylsulfanilamide. A 1-

liter, 3-necked flask was equipped with a hook-type agitator and thermometer. Half of 257 g. (1.2 moles) of dry, finely pulverized N^4-acetylsulfanilamide was added with 250 cc. of dry pyridine. The agitator was started and the mixture heated to 90°. One-third of 219 g. (1 mole) of dodecanoyl chloride (boiling range 125–127°(7 mm.)) was added over five minutes, in portions, via a long-stemmed funnel (to prevent the acid chloride from coming into contact with the walls of the flask where it would have reacted with pyridine vapor to give highly colored impurities). The flask was cooled externally to prevent the temperature from exceeding 110°. The balance of the N^4-acetylsulfanilamide was then added, followed by the balance of the dodecanoyl chloride. The temperature was held at 100–110° for fifteen minutes to complete the reaction. The resulting pyridine solution was drowned in 1 liter of water and 250 cc. of concentrated hydrochloric acid. The product, which first separated as an oil, soon crystallized into soft pellets which were filtered and washed well with water. A portion of the crude N^1-dodecanoyl-N^4-acetylsulfanilamide was dissolved at *p*H 9 in water by addition of sodium hydroxide. The solution was treated with decolorizing carbon and the product reprecipitated by acidification. After three recrystallizations, N^1-dodecanoyl-N^4-acetylsulfanilamide was obtained, having the properties listed in Table IV.

The main portion of the crude material was dissolved in 600 cc. of water (to give approximately a 1 molar concentration) with addition of sodium hydroxide to a definite red spot test on phenolphthalein paper. A 1-cc. sample was taken, hydrolyzed by boiling with 5 cc. of concentrated sulfuric acid and 4 cc. of water for fifteen minutes, diluted with ice and water and titrated at 20° with 0.1 *N* sodium nitrite. For each equivalent in the alkaline solution indicated by the nitrite analysis, 1.4 moles of sodium hydroxide was added. The mixture was then boiled for one and one-half hours to hydrolyze the N^4-acetyl group. The hydrolyzed solution was diluted with an equal amount of water, neutralized to about *p*H 9 and treated with activated charcoal. The clarified liquor was acidified and the product obtained as a sticky oil which soon crystallized. It was recrystallized five times from toluene, using activated charcoal. 80% alcohol was used very satisfactorily for purification in other runs on this compound, and was the solvent most generally used for purification of other N^1-acylsulfanilamides. Average yield in these preparations based on the acid chloride was 60%.

2. Preparation from Acid Anhydrides.—This is illustrated by the preparation of N^1,N^4-diacetylsulfanilamide: 214 g. (1 mole) of N^4-acetylsulfanilamide was added gradually with agitation to 350 cc. of acetic anhydride heated at 70–80°. The mixture was then boiled for one hour. A thick slurry of crystals resulted which was drowned and washed well with water. The crystals were dissolved in 800 cc. of hot water by addition of sodium hydroxide to *p*H 8, treated with activated charcoal, cooled and a trace of N^4-acetylsulfanilamide removed by filtration. Crude N^1,N^4-diacetylsulfanilamide was precipitated by acidifying strongly with hydrochloric acid; yield after recrystallization was 60%.

Hydrolysis of the N^4-acetyl group was carried out by boiling one mole of the diacetyl derivative with 2.5 moles of sodium hydroxide in 1-liter water for one hour. The hydrolysate was neutralized to about *p*H 8 with hydrochloric acid and treated with activated charcoal while warm. The clarified solution on cooling and standing deposited a little sulfanilamide which was removed. The solution was acidified to about *p*H 4 and N^1-acetylsulfanilamide containing a little N^1,N^4-diacetylsulfanilamide crystallized. The mixture was warmed at 30–40° with 10% hydrochloric acid. The N^1-acetylsulfanilamide dissolved, while the N^1,N^4-diacetylsulfanilamide was insoluble and was removed by filtration. The filtrate was treated with activated charcoal, neutralized to *p*H 4 and N^1-acetylsulfanilamide crystallized on cooling. It was recrystallized from hot water, in which it was extremely

soluble at the boil, but only 0.9% at room temperature; the yield from N^1,N^4-diacetylsulfanilamide was 32%.

3. Preparation from N^1-Sodium-N^4-acetylsulfanilamide.—Anhydrous N^1-sodium-N^4-acetylsulfanilamide was prepared as follows. Crude N^4-acetylsulfanilamide paste was dissolved by addition of solid powdered sodium hydroxide to form a warm solution of N^1-sodium-N^4-acetylsulfanilamide. This was treated with activated charcoal, then cooled and crystallized. Large crystals formed containing much water of crystallization. These were filtered off and washed with a little ice water. The crystals were melted in a small amount of water and recrystallized to free from excess sodium hydroxide. As much of the adhering mother liquor as possible was removed by filtration, then by washing with very little ice water. The crystals were dried in a vacuum oven at not over 50° until practically anhydrous. Temperature was then raised to 60 to 70° until the product was anhydrous as indicated by hydrolysis of a sample to sulfanilamide and titration with sodium nitrite. The anhydrous material was finely ground and used in preparing various N^1-acylsulfanilamides, of which the following illustrates a method for the preparation of N^1-butyrylsulfanilamide: 236 g. (1 mole) of N^1-sodium-N^4-acetylsulfanilamide was suspended in 400 cc. of anhydrous dioxane; then 108 g. (1 mole) of butyryl chloride was added under agitation. When the reaction moderated, heat was applied to maintain a slow boiling for three hours under reflux condenser. The product was practically insoluble in the dioxane, was removed by filtration, and recrystallized twice from 70% alcohol. The N^4-acetyl group was hydrolyzed by the procedure described above for making N^1-acetylsulfanilamide.

Other solvents used for this method of preparation were xylene, pyridine and higher pyridine bases having a boiling range of 120 to 140°. Pyridine gave the most satisfactory results, since it had the ability to hold both the reactants and the final product in solution. Because the use of pyridine made unnecessary the preparation and drying of N^1-sodium-N^4-acetylsulfanilamide, this method was soon abandoned.

4. Reaction of N^4-Acetylsulfanilamide and an Acyl Halide in the Absence of Base.—Dry fusion of the N^4-acetylsulfanilamide with several acyl halides led in general to colored decomposition products along with the desired N^1-acetyl-N^4-acetylsulfanilamide. By use of inert solvents, fair yields were obtained in certain cases, as illustrated by the following method for preparing N^1-benzoyl-N^4-acetylsulfanilamide: 214 g. (1 mole) of dry N^4-acetylsulfanilamide, 141 g. of benzoyl chloride, and 700 cc. of toluene were agitated and heated under a reflux condenser for twenty hours. There was slow evolution of hydrogen chloride during this period. The toluene was evaporated and the residue dissolved in about 1 liter of water with sodium hydroxide to *p*H 9. The solution was treated with activated charcoal and a little unreacted N^4-acetylsulfanilamide removed. The solution was acidified, the crude product filtered off, and washed well with alcohol to remove benzoic acid. The product was recrystallized from 90% cellosolve giving 40% yield of N^1-benzoyl-N^4-acetylsulfanilamide.

5. Preparation of N^1-Alkyl-N^1-acylsulfanilamides.—Attempts to prepare N^1-alkyl-N^1-acylsulfanilamides by hydrolysis of the corresponding N^4-acetyl derivatives resulted in complete hydrolysis of the N^1-acyl group. Such derivatives were prepared successfully by starting with N-alkyl-nitrobenzenesulfonamides[8] which were acylated by the general procedure, then reduced using iron and acetic acid with addition of toluene. Metanilamide derivatives were made similarly.

Preparation of Acid Chlorides.—Chaulmoogryl chloride for N^1-chaulmoogrylsulfanilamide was prepared from ethyl chaulmoograte obtained through the courtesy of Professor Roger Adams of the University of Illinois. Eastman Kodak Co. technical chaulmoogric acid was found to have an iodine number approximately half of the theoretical value and could not be purified to give satisfactory starting material.

Long-chain acid chlorides from C_8 to C_{14} were prepared by converting technical lauric acid to the mixed acid chlorides with either thionyl chloride or phosphorus trichloride. The mixed acid chlorides were separated by fractionation through a 120-cm. packed column at 5–15 mm. pressure. The resulting acid chlorides had constants in close agreement with literature values.

Heterocyclic acids containing a nitrogen in the ring were converted to the acid chloride–hydrochlorides with thionyl chloride and isolated as solid products by evaporation of excess thionyl chloride. The condensation with N^4-acetylsulfanilamide was carried out in the presence of excess pyridine.

Summary

1. A large series of N^1-acylsulfanilamides was prepared from aliphatic, aromatic, heterocyclic and carbocyclic acids. As intermediates, N^1,N^4-diacylsulfanilamides were prepared in which the N^4-acyl group was usually acetyl. Salts of both series of compounds with various cations also were prepared.

2. Preliminary pharmacological results indicated that N^1-dodecanoylsulfanilamide was effective in mice against infections by beta hemolytic streptococci and arrested the spread of tuberculous infections in cavies.

Stigmasterol 22,23-Dibromide

BY ERHARD FERNHOLZ AND HOMER E. STAVELY

Stigmasterol possesses two double bonds, one in the ring system (5,6), the other in the side-chain (22,23). These differ in reactivity, and it is possible to add preferentially various reagents to one or the other. Bromine,[1] hydrogen bromide,[2] hydrogen chloride,[2] and perbenzoic acid[3] first react with the nuclear double bond, while catalytic hydrogenation leads primarily to the saturation of the side-chain.[4]

We have now succeeded in preparing a dibromide of stigmasterol in which the bromine is situated in the side-chain. Its acetate is obtained by removal of one mole of bromine from the tetrabromide with sodium iodide. Schoenheimer,[5] who first debrominated sterol bromides by this method, stated that the bromine atoms in the side-chain of stigmasterol tetrabromide do not react readily. However, it seems that no efforts were made to investigate the reaction products more thoroughly. The yield in which the new dibromide can be isolated depends to a great extent on the experimental conditions, and a comparatively small yield is obtained when the reaction is carried out in boiling solution as described in the literature.[5] The best yield (60%) is obtained by letting the reactants stand at room temperature for about twenty hours. It was not possible to replace sodium iodide by zinc dust, since even at room temperature in moist ether or in boiling alcohol the debromination did not stop at the dibromide but resulted in the formation of stigmasteryl acetate.

The new dibromide is remarkably stable and has a high melting point (212–213°). It resembles stigmasteryl acetate tetrabromide in this respect and is different from the 4,5-dibromide, which has a low melting point and cannot be recrystallized without decomposition. Although there was little doubt that we were dealing with the 22,23-dibromide and not a 5,6-dibromide isomeric with the one obtained by addition of one mole of bromine to stigmasteryl acetate, we made experiments to prove our supposition.

By saponification with methyl alcoholic potassium hydroxide stigmasterol 22,23-dibromide, m. p. 210°, was obtained without difficulties. The halogen in the side-chain was not noticeably attacked. This compound could be dehydrogenated by Oppenauer's method[6] and a ketone was obtained, m. p. 182–184°, which had an absorption spectrum with a maximum at 240 mμ (log E [molar] 4.08 in absolute alcohol)[7] characteristic for α,β-unsaturated ketones. This proves conclusively the anticipated structure of the new dibromide.

Treatment of the above ketone with zinc dust and acetic acid yielded a ketone of m. p. 125°, stigmastadienone. Under the name stigmastenone Marker and Wittle[8] have described a compound prepared from stigmasterol by catalytic dehydrogenation with copper. This compound correctly should be called stigmastadienone and should be identical with our compound; it melts, however, at 94° which is much lower. The preparation of stigmastadienone from stigmasterol by Oppenauer's method has been described in the patent literature[9] where a melting point of 107° has been recorded. We have prepared stigmastadienone by this method and the substance obtained had a constant melting point of 125°, and was identical with the stigmastadienone prepared from the dibromide.

Experimental

Stigmasteryl Acetate 22,23-Dibromide.—To 5 g. of stigmasteryl acetate tetrabromide in 75 cc. of benzene was added 3 g. of sodium iodide in 25 cc. of ethanol, and the mixture allowed to stand at room temperature for twenty hours. The mixture was then shaken with sodium sulfite to remove free iodine, washed with water, dried over sodium sulfate, concentrated, and filtered. The precipitate was crystallized from benzene–ethanol. The yield of pure acetoxy dibromide was 60%; fine needles, m. p. 212–213°, $[\alpha]^{25}D$ 30 (15.3 mg. in 2.0 cc. chloroform, 1-dm. tube, αD −0.23). Mixed m. p. with stigmasteryl acetate tetrabromide showed a depression of 20°.

(10) The micro-analyses reported in this paper were carried out by Mr. J. F. Alicino, Fordham University.

Two hundred milligrams of the product was debrominated with zinc dust and acetic acid. The bromine-free product had a m. p. of 138–139°; mixed m. p. with stigmasterol acetate gave no depression.

Runs on a larger scale gave poorer yields. A lower melting mixture was isolated from the mother liquor which was reconverted to stigmasterol tetrabromide and used over.

Stigmasterol 22,23-Dibromide.—One gram of stigmasteryl acetate 22,23-dibromide was refluxed with 5% potassium hydroxide in methanol for two hours. After addition of water it was extracted with ether, the ether washed, dried over sodium sulfate, evaporated to dryness and crystallized twice from benzene–ethanol; needles, m. p. 209–210°. Mixed melting point with the starting material gave a depression of 25°.

Anal. Calcd. for $C_{29}H_{48}OBr_2$: Br, 27.95. Found: Br, 27.65.

Stigmastadienone 22,23-Dibromide.—Three and six-tenths grams of stigmasterol 22,23-dibromide, 5 g. of aluminum *t*-butylate, 150 cc. of dry benzene, and 40 cc. of dry acetone were refluxed together overnight. The mixture was washed with dilute sulfuric acid, then with water until neutral, dried over sodium sulfate and evaporated to dryness in a vacuum. The residue was crystallized from acetone, giving 2.6 g. of material, m. p. 173–178°. After recrystallizing many times the m. p. became constant at 182–184°. $[\alpha]^{22}D$ +53° [18.8 mg. in 2.0 cc. chloroform, 1-dm. tube, αD +0.50°].

Anal. Calcd. for $C_{29}H_{46}OBr_2$: C, 61.05; H, 8.13. Found: C, 60.78, 60.87; H, 8.18, 8.11.

Stigmastadienone.—Two hundred milligrams of stigmastadienone 22,23-dibromide was heated on the steam-bath with 250 mg. of zinc dust and 10 cc. of glacial acetic acid for one hour, decanted from the zinc, water added and extracted with ether. The ether was washed with dilute sodium carbonate solution, then with water, dried over sodium sulfate, and evaporated to dryness. The residue was crystallized from ethanol.

The product had a melting range of 80–110° and was probably partially reduced. The semicarbazone was prepared by heating with semicarbazide hydrochloride and potassium acetate in boiling ethanol. It was recrystallized twice from chloroform–ethanol; crystals turned brown at 227°, m. p. 235–237°. The semicarbazone was decomposed by boiling with 3 cc. of 5 *N* sulfuric acid and 6 cc. of ethanol for two hours. Water was added and the precipitate filtered and crystallized from ethanol. The product weighed 45 mg.; narrow leaflets, m. p. 123–124°. After two more crystallizations from ethanol and decolorizing with norit the m. p. was constant at 124–125°.

Anal. Calcd. for $C_{29}H_{46}O$: C, 84.81; H, 11.29. Found: C, 84.80, 84.66; H, 11.24, 11.34.

Stigmastadienone from Stigmasterol.—A mixture of 5 g. of stigmasterol, 6 g. of aluminum isopropylate, 50 cc. of cyclohexanone and 150 cc. of toluene was refluxed for two hours and then poured into cold water. Concentrated hydrochloric acid was added and the aqueous layer discarded. The organic solvents were removed by steam distillation. The crude stigmastadienone was purified by crystallizing from ethanol; narrow leaflets, m. p. 125°, $[\alpha]^{25}D$ +63° (27.7 mg. in 2.0 cc. chloroform, 1-dm. tube, αD +0.87°).

Anal. Calcd. for $C_{29}H_{46}O$: C, 84.81; H, 11.29. Found: C, 84.78; H, 11.08.

A mixed m. p. with stigmastadienone prepared from the dibromide gave no depression.

Summary

Stigmasteryl acetate 22,23-dibromide has been prepared by the removal of one mole of bromine from stigmasteryl acetate tetrabromide.

The position of the bromine atoms has been established by conversion into a α,β-unsaturated ketone, stigmastadienone 22,23-dibromide.

The preparation of stigmastadienone from this dibromide and from stigmasterol has been described.

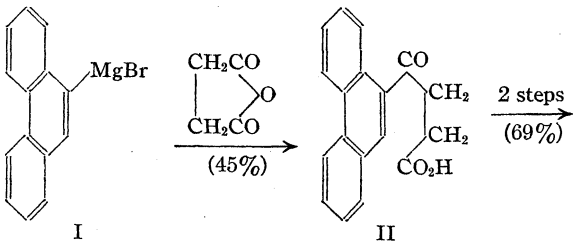
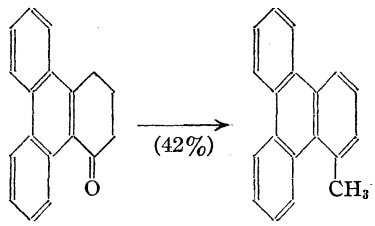
Methyl Homologs of Triphenylene

BY LOUIS F. FIESER AND LLOYD M. JOSHEL[1]

This work is an extension of investigations undertaken by the junior author in collaboration with Dr. M. S. Newman. Newman and Joshel[2] pointed out that, since the introduction of methyl groups in certain positions into the biologically



I II

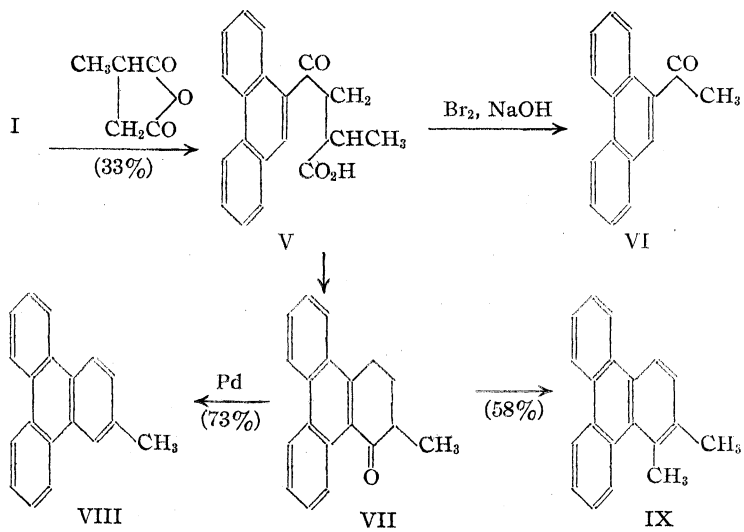


III IV

inactive 1,2-benzanthracene gives rise to powerfully carcinogenic hydrocarbons, it would be of interest to study the methyl homologs of all four of the tetracyclic aromatic hydrocarbons isomeric with 1,2-benzanthracene. The present research is devoted to a synthesis of the two monomethyl triphenylenes and of two of the fourteen possible dimethyl compounds of this series.

Since but little is known concerning the substitution reactions of triphenylene, and since the structures of homologs obtained in this way probably could be established most readily by synthesis, the choice in the present work fell on methods involving the synthetic construction of the tetracyclic system. A convenient approach to 1-methyltriphenylene (IV) already has been worked out by Bergmann and Blum-Bergmann,[3] who synthesized 1-keto-1,2,3,4-tetrahydrotriphenylene (III) by the condensation of 9-phenanthrylmagnesium bromide with succinic anhydride, reduction of the keto acid II and cyclization with phosphorus pentoxide in toluene. By introducing some modifications in these steps, for example by using anhydrous hydrogen fluoride for ring closure (87% yield), the ketone has been obtained in over-all yield of 31%. The ketone reacted readily with methylmagnesium chloride, and the crude carbinol on dehydration followed by dehydrogenation with sulfur was converted into 1-methyltriphenylene, which was purified through the picrate.

The 2-isomer was obtained in an analogous manner starting with methylsuccinic anhydride. The chief acidic product of the Grignard reaction was obtained in 33% yield and identified as having the structure V by a convenient method which was applied recently to an unmethylated product of the general succinoylation reaction.[4] The keto acid was brominated and the crude bromo derivative treated with alcoholic alkali, whereupon it underwent fission to 9-acetophenanthrene (VI). If the methyl group were in the alternate position adjacent to the carbonyl group the cleavage product would be 9-propiophenanthrene. The ketone



I V VI VIII VII IX

VII, obtained by reduction and cyclization with HF (92% yield), afforded 2-methyltriphenylene (VIII) by Clemmensen reduction followed by dehydrogenation with palladium charcoal. A more

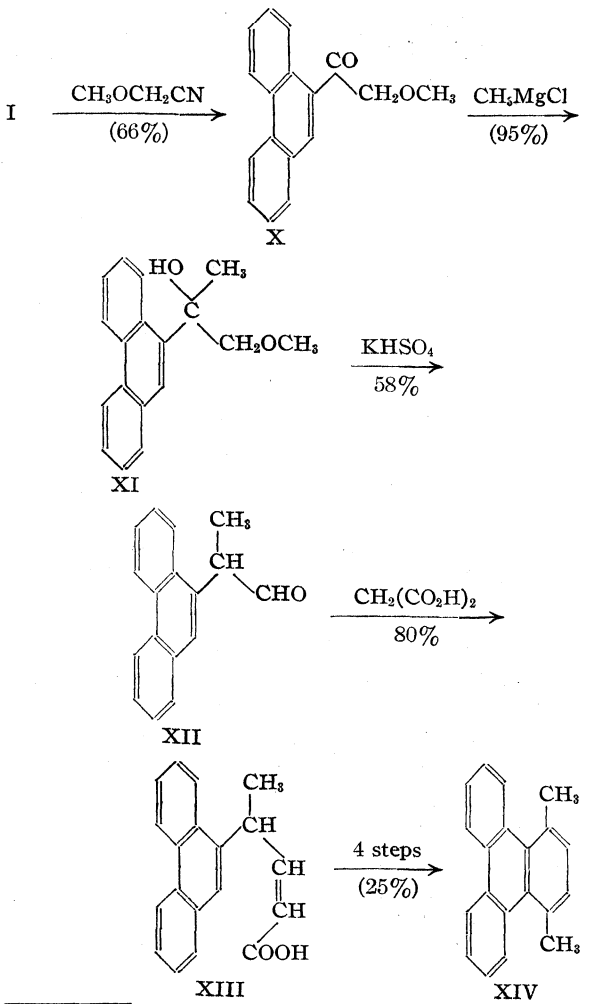
novel method of accomplishing this transformation was found in heating the ketone with palladium charcoal at 310°, whereby the aromatic hydrocarbon VIII was produced in excellent yield. By the Grignard process the ketone VII was also converted into 1,2-dimethyltriphenylene (IX), which bears some structural resemblance to 1,2,3,4-dibenzphenanthrene,[5] an active agent for the production of skin tumors.

In the triphenylene series the nearest approach to a structure analogous to that of the carcinogenic 10-methyl-1,2-benzanthracene is met with in the 1-derivative, and the 1,4-dimethyl derivative (XIV) would correspond to the potent 9,10-dimethyl-1,2-benzanthracene. In one attempt to obtain this hydrocarbon we tried to add the methyl Grignard reagent to the carbonyl group of β-(9-phenanthroyl)-propionic acid or its ester, but the experiments were all unsuccessful. Trial was also made of the reaction between 9-phenanthrylmagnesium bromide and the ethyl ester of levulinic acid, in analogy with a condensation reported by Grignard,[6] but the chief product was phenanthrene. A very satisfactory route to the desired hydrocarbon was then found in the utilization of the recently described method of preparing arylacetaldehydes.[7] α-(9-Phenanthryl)-propionaldehyde (XII) was obtained readily by the sequence of Grignard reactions indicated in the chart and dehydration of the resulting carbinol XI. Condensation with malonic acid gave an acid side chain of the required length, and the second methyl group was introduced after reduction and cyclization and the remainder of the process completed by the usual methods.

Tests for carcinogenic properties are being conducted in part by Dr. M. J. Shear and in part by Dr. Shields Warren.



(5) Hewett, *J. Chem. Soc.*, 193, 1286 (1936).

Experimental Part[8]

β-(9-Phenanthroyl)-propionic acid was prepared according to Bergmann and Blum-Bergmann[3] by the action of the Grignard reagent from 81 g. of 9-bromophenanthrene on 25 g. of succinic anhydride. On decomposition with acid part of the product separated in a crystalline condition and was collected by filtration; the rest was extracted from the organic layer with soda. The yield of material of m. p. 179.5–180.5° was 45%.

Treatment of the acid with methylmagnesium chloride in refluxing benzene–ether resulted only in the production of dark oils in the neutral fraction with invariable recovery of starting material.

The **methyl ester** was prepared by adding 21 g. of acid to 500 cc. of methanol containing dissolved hydrogen chloride, refluxing the suspension for four hours, during which time the solid dissolved, distilling about half of the solvent, and adding water. It crystallized from benzene–ligroin in colorless needles, m. p. 88.6–89.4° (21.5 g., 0.6 g. of good material from the mother liquor). Bergmann and Blum-Bergmann[3] report the m. p. 88°, using diazomethane.

Condensation of the ester with methylmagnesium chloride or iodide by the procedure found satisfactory in an analogous case[9] proved unsuccessful; about half of the ester was always recovered unchanged.

γ-(9-Phenanthryl)-butyric Acid.—The keto acid (10.5 g.) was refluxed for twenty-four hours with 30 g. of amalgamated zinc, 100 cc. of toluene, and 100 cc. of concentrated hydrochloric acid, added in portions; fresh zinc and acid were added and boiling continued for another day. On cooling, the product separated in a hard cake and this was collected together with the zinc and the

(9) Fieser and Johnson, THIS JOURNAL, **61**, 1647 (1939).

reduction product extracted with acetone (very little material was found in the toluene layer), giving 6.85 g. of acid, m. p. 172.8–174°, and 1.05 g. of slightly lower m. p.; yield 79% (compare 53–56% by the Wolff–Kishner method[3]).

1-Keto-1,2,3,4-tetrahydrotriphenylene (III) was prepared by treating 2.6 g. of the above acid with 25 g. of hydrogen fluoride at 0° for forty-five minutes, pouring the mixture onto ice and extracting with ether. Extraction with soda removed a small amount of starting material, and crystallization of the neutral fraction afforded 1.6 g. of ketone, m. p. 97–99°, and 0.5 g., m. p. 95–98° (87%, compare 68% with phosphorus pentoxide[3]). The m. p. of the first crop was not changed appreciably by two recrystallizations from methanol.

1-Methyltriphenylene (IV).—A benzene solution of 5.5 g. of the ketone III was added to the Grignard reagent from 1 g. of magnesium and excess methyl chloride, and after stirring at room temperature for one-half hour, refluxing for a like period, and standing overnight the mixture was worked up as usual. The neutral portion was heated with a crystal of iodine at 200–220° for one-half hour to effect dehydration, 0.75 g. of sulfur was added, and the oil was heated at 230° for one hour and at 230–250° for one-half hour. The distilled product was treated in benzene with 5 g. of picric acid and the once recrystallized picrate dissolved in benzene and passed through a tower of alumina. The hydrocarbon was obtained from benzene–alcohol as almost colorless needles, m. p. 92–93.5°; yield 2.3 g. (42.5%). Recrystallization gave a colorless product, m. p. 93.4–94.2°.

Anal. Calcd. for $C_{19}H_{14}$: C, 94.18; H, 5.82. Found: C, 94.19; H, 5.83.

The **picrate** crystallized from benzene as orange needles, m. p. 177.2–178.2°.

Anal. Calcd. for $C_{25}H_{17}O_7N_3$: N, 8.91. Found: N, 8.80.

α-Methyl-β-(9-phenanthroyl)-propionic Acid (V).—The Grignard reagent from 93.5 g. of 9-bromophenanthrene and 10 g. of magnesium in 250 cc. each of benzene and ether was added in the course of seventy-five minutes to a boiling solution of 37 g. of methylsuccinic anhydride in 250 cc. of ether; refluxing was continued for one-half hour and the mixture worked up the next day. Two crystallizations of the acid fraction from acetone–benzene gave 26 g. of small, colorless needles, m. p. 155–156°, and 4.8 g. of slightly lower melting material; yield 33%. The acidic material in the mother liquor was not investigated.

Anal. Calcd. for $C_{19}H_{16}O_3$: C, 78.06; H, 5.52. Found: C, 77.98; H, 5.75.

For proof of structure, 2.9 g. of V was treated in chloroform solution (50 cc.) with 0.5 cc. of bromine. The reaction seemed slow, but decoloration took place immediately on irradiation for a few seconds with ultraviolet light. The chloroform was evaporated and the remaining viscous oil was dissolved in 30 cc. of alcohol and treated with 5 g. of sodium hydroxide in 15 cc. of water. After twenty-four hours at room temperature the mixture was diluted with water and extracted with ether. The neutral fraction was distilled in vacuum and the 9-acetophenanthrene (0.5 g.) then crystallized from alcohol in long needles, m. p. 73–74°. Mosettig and van de Kamp[10] found the m. p. 74–74.5°; 9-propiophenanthrene[11] melts at 55–57°.

α-Methyl-γ-(9-phenanthryl)-butyric Acid.—The keto acid V (3.0 g.) was reduced by refluxing for twenty-four hours with amalgamated zinc (30 g.), toluene (40 cc.), and concentrated hydrochloric acid (100 cc.), added in portions. Crystallized from toluene–ligroin and then from benzene–ligroin the acid was obtained as colorless needles, m. p. 136.6–137.4°; yield 2.2 g. (77%).

Anal. Calcd. for $C_{19}H_{18}O_2$: C, 81.98; H, 6.52. Found: C, 81.84; H, 6.57.

2-Methyl-1-keto-1,2,3,4-tetrahydrotriphenylene (VII).—The above acid (20.7 g.) was cyclized with hydrogen fluoride (150 g.) and obtained as colorless needles, m. p. 85–86.5° (unchanged on recrystallization) from benzene–ligroin; yield 17.9 g. (92.5%).

Anal. Calcd. for $C_{19}H_{16}O$: C, 87.66; H, 6.20. Found: C, 87.69; H, 6.33.

2-Methyltriphenylene (VIII).—A mixture of 1 g. of the ketone VII and 0.1 g. of palladium charcoal was heated under nitrogen in a sealed tube at 300–310° for seven hours. The product was extracted with benzene and crystallized from benzene–alcohol, giving 0.68 g. (73%) of colorless needles, m. p. 102.6–103.6°.

Anal. Calcd. for $C_{19}H_{14}$: C, 94.18; H, 5.82. Found: C, 94.23; H, 5.88.

The **picrate** formed light orange needles from benzene–alcohol, m. p. 192.4–193°.

Anal. Calcd. for $C_{25}H_{17}O_7N_3$: C, 8.91. Found: N, 9.09.

4′-Keto-1,2,3,4-tetrahydro-3,4-benzpyrene gave no satisfactory reaction product when similarly treated.

2-Methyl-1,2,3,4-tetrahydrotriphenylene was prepared by Clemmensen–Martin reduction of VII (3 g.) as above; it crystallized from benzene–alcohol as colorless needles, m. p. 114–116° (2.2 g., 77.5%). A recrystallized sample melted at 116.2–116.8°.

Anal. Calcd. for $C_{19}H_{18}$: C, 92.63; H, 7.37. Found: C, 92.45; H, 7.42.

A 1.6-g. portion of the tetrahydride was heated with 0.16 g. of palladium charcoal under nitrogen at 215–230° for one-half hour and the temperature was then raised to 310° in the course of one and one-half hours, when nearly the calculated amount of hydrogen had been evolved. The product crystallized from benzene–alcohol as colorless needles, m. p. 104–105°, and gave no depression with the above sample of 2-methyltriphenylene; yield 1.3 g. (83%).

1,2-Dimethyltriphenylene (IX) was prepared from 1.4 g. of the ketone VII and excess methylmagnesium chloride, refluxing for three hours in benzene–ether and using ammonium chloride for decomposition. Following the procedure of Bachmann and Wilds,[12] the crude carbinol was heated under nitrogen with 150 mg. of palladium charcoal at 290–315° for one and one-quarter hours (80% of theoretical hydrogen evolution). The hydrocarbon was extracted with benzene and crystallized from benzene–alcohol, giving 0.8 g. (58%) of colorless needles, m. p. 86.8–87.4°.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.71; H, 6.29. Found: C, 93.58; H, 6.37.

The **picrate** formed orange needles, m. p. 154–155°, from benzene–alcohol.

Anal. Calcd. for $C_{26}H_{19}O_7N_3$: C, 64.33; H, 3.95. Found: C, 64.58; H, 3.97.

Methoxymethyl 9-Phenanthryl Ketone (X).—The Grignard reagent from 15.5 g. of 9-bromophenanthrene and 1.6 g. of magnesium was treated with 3.6 g. of methoxyacetonitrile in benzene and the mixture refluxed for one hour and decomposed with hydrochloric acid the next day. After steam distillation for one hour the product was taken up in ether and distilled, b. p. 220–225° (3 mm.). Two crystallizations from ether afforded 7.9 g. of colorless prisms, m. p. 67.2–68°, and 2.0 g. of material of m. p. 66.5–67.8° (66%).

Anal. Calcd. for $C_{17}H_{14}O_2$: C, 81.57; H, 5.64. Found: C, 81.94; H, 5.75.

Methylmethoxymethyl-9-phenanthrylcarbinol (XI) was prepared from 7.5 g. of X, treated in benzene with a solution of methylmagnesium chloride from 1.2 g. of magnesium. After one hour at room temperature and refluxing for three hours, decomposition was accomplished with ammonium chloride. The product distilled as a yellow glass, b. p. 192–195° (1 mm.), which solidified when rubbed with petroleum ether at −70° but melted below 0°; yield 7.6 g. (95%).

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81. Found: C, 81.23; H, 7.23.

α-(9-Phenanthryl)-propionaldehyde (XII).—On heating 31.5 g. of the carbinol XI with 3.5 g. of potassium bisulfate at 180° in a Claisen flask a vigorous reaction ensued and was over in about five minutes. The product was then distilled in vacuum and the resulting dark oil dissolved in 100 cc. of benzene and stirred overnight with 100 cc. of saturated sodium bisulfite solution. The crystalline addition compound was collected, washed with benzene, and decomposed by shaking with aqueous sodium carbonate solution and ether. Crystallization of the aldehyde from ether–petroleum ether gave 13.9 g. of colorless needles, m. p. 65.6–67.6°, and a second crop of 2.1 g., m. p. 65–67° (58%). A recrystallized sample melted at 66.2–67.2°.

Anal. Calcd. for $C_{17}H_{14}O$: C, 87.15; H, 6.02. Found: C, 87.23; H, 6.08.

γ-Methyl-γ-(9-phenanthryl)-crotonic Acid (XIII).—A solution of 15.6 g. of the aldehyde in 15 cc. of pyridine was treated with 10.4 g. of malonic acid and 5 drops of piperidine; on heating on the steam-bath the mixture rapidly turned yellow and evolved carbon dioxide, and after ten hours it was poured cautiously into dilute hydrochloric acid. The precipitated reaction product was washed with dilute acid and crystallized from acetone–benzene, giving 11.8 g. of colorless plates, m. p. 172–174°, and 3 g. of slightly less pure material (80.5%). Further purification raised the m. p. to 178.8–179.4° (softening at 173°).

Anal. Calcd. for $C_{19}H_{16}O_2$: C, 82.58; H, 5.84. Found: C, 82.67; H, 5.91.

γ-(9-Phenanthryl)-valeric Acid.—A suspension of 11.8 g. of the unsaturated acid XIII in 150 cc. of glacial acetic acid readily absorbed the calculated amount of hydrogen in the presence of 100 mg. of Adams catalyst. The reduced acid crystallized from benzene–ligroin to give 10.4 g. (87.5%) of colorless prisms, m. p. 83–85° (unchanged by further purification).

Anal. Calcd. for $C_{19}H_{18}O_2$: C, 81.98; H, 6.52. Found: C, 81.92; H, 6.61.

4-Methyl-1-keto-1,2,3,4-tetrahydrotriphenylene was prepared by cyclizing the acid (9.9 g.) with hydrogen fluoride (150 g.) at room temperature. After two hours the solution was poured onto ice and the precipitate coagulated by heating for a few minutes and then collected. Very little acid was removed by digestion with soda, and the neutral product on crystallization from benzene–ligroin gave 6.6 g. of the ketone as colorless prisms, m. p. 99–100.5°, and 1 g., 98.6–101° (82%).

Anal. Calcd. for $C_{19}H_{16}O$: C, 87.66; H, 6.20. Found: C, 87.74; H, 6.26.

1,4-Dimethyltriphenylene (XIV) was prepared from the ketone in 35% yield by the procedure described for the 1-methyl compound. The hydrocarbon crystallized from benzene–alcohol as colorless prisms, m. p. 108.4–109.2°.

Anal.[13] Calcd. for $C_{20}H_{16}$: C, 93.71; H, 6.29. Found: C, 93.62; H, 6.35.

The **picrate** crystallized from benzene in orange-red needles, m. p. 148.4–149.4°.

Anal. Calcd. for $C_{26}H_{19}O_7N_3$: N, 8.66. Found: N, 8.78.

Summary

In order to investigate the possibility that the introduction into triphenylene of suitably located alkyl groups might lead to carcinogenically active hydrocarbons, methods have been developed for the synthesis of the 1- and 2-methyl and the 1,2- and 1,4-dimethyl derivatives of this hydrocarbon. These homologs were obtained from the condensation products of 9-phenanthrylmagnesium bromide with succinic anhydride, methylsuccinic anhydride, or methoxyacetonitrile.

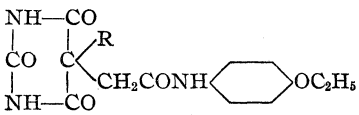
Alkylacetanilidobarbituric Acids. III. *p*-Ethoxy Derivatives

BY JOHN A. TIMM

The fact that the administration of mixtures or addition products of hypnotic and antipyretic substances produces an analgesic effect is well known.[1] This series of papers reports the preparation of 5-alkylbarbituric acids in which antipyretic and anesthetic groups replace the second hydrogen atom on the 5-carbon atom. Derivatives of acetanilide[2] and *p*-carbethoxyacetanilide[3] have been reported in the previous papers. The series has been extended in this paper to the preparation of 5-alkyl-5-*p*-ethoxyacetanilidobarbituric acids, *i. e.*, derivatives of the antipyretic, phenacetin



These derivatives, together with those reported in the first two papers of this series, are being tested pharmacologically. The results will be published elsewhere.

Experimental Part

Barbituric Acids Containing the *p*-Ethoxyacetanilido Group.—Equimolecular proportions of the appropriate 5-alkylbarbituric acid and *p*-ethoxychloroacetanilide,[4] a one and one-half molecular proportion of sodium acetate and a one-fourth molecular proportion of potassium iodide were dissolved in 70% alcohol by heating on a water-bath in a flask provided with a mechanical stirrer and a reflux condenser. The heating was continued for twenty-four hours. Crystals of the product separated during the course of the reaction. Approximately one-half of the alcohol was distilled off and the mixture cooled in an ice-bath. The products were recrystallized from absolute alcohol. They are white, crystalline solids which melt with decomposition. The usual difficulty was experienced in crystallizing the isopropyl derivative, which comes out of solution at first as a brown oil.

TABLE I

Barbituric acid, 5-*p*-ethoxyacetanilido-	Melting range, °C., with dec.	Yield, %	N Analyses, % Calcd.	Found	
5-Ethyl-	194–205	60	12.6	12.5	12.6
5-Isopropyl-	210–215	20	12.1	12.1	11.8

Fluorocarbons. The Reaction of Fluorine with Carbon

BY J. H. SIMONS AND L. P. BLOCK[1]

Carbon tetrafluoride has been obtained from the reaction of fluorine with carbon.[2] Ruff and Keim isolated hexafluoroethane from the reaction products and obtained small amounts of higher boiling material, which they assumed to be mixtures of higher molecular weight fluorocarbons, but in insufficient quantity to separate and isolate the compounds. Several difficulties are encountered in the study of this reaction. Frequent and sometimes violent explosions occur; and as the higher molecular weight compounds are produced in relatively small quantities, large amounts of reaction products are necessary in order to isolate them. Ruff, Bretschneider and Ebert[3] studied these explosions in detail and found a

(1) The authors gratefully acknowledge a grant from the American Academy of Arts and Sciences which aided in financing the preparation of these compounds.

white crystalline compound (CF) which exploded when heated. From the products of these explosions they obtained small quantities of higher boiling material. They suggest the possibility of the reaction proceeding smoothly with proper temperature control. We have attempted to do this without success. There is a short initial period before explosions begin but the amount of products that can be obtained in this time is very small.

Other reactions which might be expected to yield higher molecular weight fluorocarbons so far have produced only hexafluoroethane and tetrafluoroethylene. Fluorine has been caused to react with hydrocarbons[4] either pure or in solution in solvents such as carbon tetrachloride or dichlorodifluoromethane. Fredenhagen and Cadenbach and also Bigelow and Calfee have controlled the explosions frequent in these reactions by the use of a copper gauze catalyst. The reactions of fluorine with compounds of carbon and other halogens also have been studied.[5] The use of other fluorinating agents such as antimony trifluoride on such compounds is also possible but to replace the third halogen atom on a carbon atom is difficult although it may be accomplished in some cases.[6] Hexafluoroethane has been made by the electrolysis of trifluoroacetic acid,[7] and both hexafluoroethane and tetrafluoroethylene have been obtained by the passage of carbon tetrafluoride and dichlorodifluoromethane through an electric arc.[8] Swarts[9] assumed the formation of C_6F_6 and C_6F_{12} from the pressure effect and the proportion of hydrolysis products (CO_2, CO, HF, and CF_4) when hexafluoroethane was passed over a hot platinum wire. These effects could be explained equally well from the recorded leaks in his apparatus and the reaction of hydrogen fluoride with the glass vessel.

Preparation of Fluorocarbon Mixture.—We have been able to overcome the technical difficulties of the reaction of fluorine with carbon and have obtained about 150 cc. of liquid of molecular weight greater than 138. A preliminary report of this work has been published,[10] but we had only a small amount of material then and some of our reported data are in error due to incomplete separation.

A large and constant supply of fluorine was required. Different types of electrolyte cells were tried. The V-shaped cells[11] worked satisfactorily for a short time but the corrosion of the cell wall was excessive in long periods of operation. Cells operating at 70 to 100°[12] with an electrolyte of approximately the composition KF·2HF gave undue corrosion of the positive electrode whether this was nickel or graphite. The most rugged, simple, and generally satisfactory cell for long and constant use was a modification of the cell devised by one of the authors.[13] A description of this cell and the technique of its operation is given in the first volume of "Inorganic Syntheses."[14]

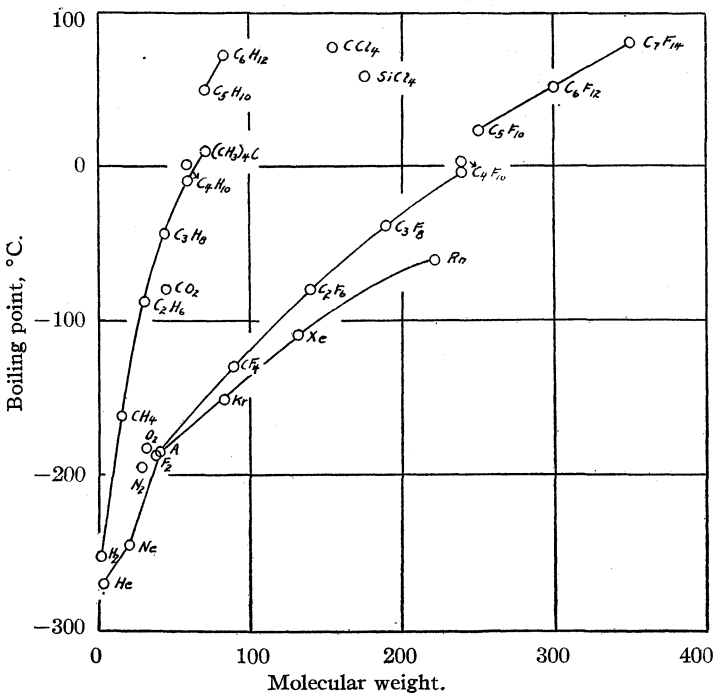

Fig. 1.

Four cells were employed. Two were kept in operation twenty-four hours a day with the operators working in shifts. The other two were either in reserve or in the process of regeneration, cleaning, or repair.

Several different kinds of carbon were used among which

were Norit and finely divided sugar charcoal. Neither the course of the reaction nor the products obtained appeared to be influenced by the kind of carbon used.

Both an elevated temperature and the addition of a mercury catalyst were employed. The reaction proceeded steadily and without explosions, when the reaction tube was heated to just below a dull red. An amalgamated copper tube was used in some of the earlier work, but it was found that about 1% of a mercury salt such as mercurous or mercuric chloride well mixed with the finely divided carbon was satisfactory. Copper gauze packed in the reaction tube in a manner similar to that found satisfactory for the direct fluorination of hydrocarbons did not prevent explosions. If, however, the gauze was amalgamated or if the carbon was mixed with a mercury catalyst no explosions occurred.

The fluorine, direct from the generator and without the removal of hydrogen fluoride, was passed through the copper tube containing the carbon and catalyst. The gaseous products were bubbled through traps containing sodium hydroxide solution and then collected over water. The gases were purified further by an additional passage through sodium hydroxide solution, then through concentrated sulfuric acid, and finally through phosphorus pentoxide.

The separations were made with the low temperature fractionating column described by one of the authors,[15] and the molecular weights determined in an all glass density balance a design of which has been published recently.[16] The vapor densities were checked by determinations made by the Dumas method. The two methods gave results in close agreement. The perfect gas law was assumed in those determinations. The liquid densities were determined by weighing known volumes in small sealed tubes. The freezing points were determined from warming curves, and the vapor pressures by direct measurement on a mercury manometer, while the material was warming slowly. The bulb, which served as a container, had an internal thermocouple and was surrounded by a heavy copper tube inside a vacuum flask. Three to five hours were required for the warming process. The thermocouples were made from calibrated copper and constantan wire and checked on the apparatus. The precision of the temperature measurements is better than one degree.

Analysis.—The constant boiling fractions of the fluorocarbons were analyzed by the following method. Two to three times the amount of sodium necessary for complete reaction was placed in a nickel boat. This was surrounded with a nickel tube and placed in a quartz tube which was sealed at one end. The open end of the quartz tube was sealed with a vacuum wax to a vacuum system. The air was exhausted and the tube baked out by heating strongly with a burner. An air-free sample of the fluorocarbon (0.5 to 1.0 g.) was weighed in a glass bulb. It was introduced into the vacuum system and condensed into a bulb which connected to the quartz tube. Upon evaporation it produced a pressure in the quartz tube. The quartz tube just below the nickel boat was then heated to a red heat with a gas burner. When the pressure was reduced to nearly zero by the reaction, the heating was stopped. When cold, air was admitted and the quartz tube removed. The excess sodium was removed by reaction with absolute alcohol and the sodium fluoride and carbon washed with alcohol onto a Gooch crucible. It was weighed, the sodium fluoride dissolved by washing with hot water, and it was weighed again. The carbon was burned by ignition and a final weight obtained.

This method was tried with a known sample of carbon tetrafluoride: F, calcd. 86.4%, found 86.1%; C, calcd. 13.6%, found 13.8%. With the higher boiling sample of C_4F_{10} an appreciable amount of sodium carbide apparently was formed. In this case the fluorine was determined by calcium fluoride precipitation. Fluorine also was determined by calcium fluoride precipitation for C_6F_{12}. In all samples the pressure fell to practically zero after reaction, which proved that the compounds did not contain hydrogen atoms in the molecules. The aqueous solution formed by dissolving the salt from the crucible was tested in every case with a silver nitrate solution. Only a trace of precipitate was formed in any sample. This proves that the compounds did not contain halogen other than fluorine, sulfur, etc.

Calcd. for C_3F_8: F, 80.85; C, 19.15. Found: F, 80.5; C, 19.9. Calcd. for C_4F_{10} (low boiling): F, 79.85; C, 20.15. Found: F, 80.5; C, 18.8. Calcd. for C_4F_{10} (high boiling): F, 80.5. Found: F, 78.8. Calcd. for C_5F_{10}: F, 76.0; C, 24.0. Found: F, 76.4; C, 24.2. Calcd. for C_6F_{12}: F, 76.0; C, 24.0. Found: F, 76.1; C, 24.6. Calcd. for C_7F_{14}: F, 76.0; C, 24.0. Found: F, 76.0; C, 23.1.

Results.—The results of our last preparation are given in the table. The first six fractions were obtained as constant boiling cuts. From a boiling temperature at atmospheric pressure of about 25°, there is a continuous rise of the boiling temperature as material is removed during distillation except for two temperatures, 51 and 80°, where constant boiling fractions are obtained. The molecular weights of the constant boiling fractions correspond with the formulas tentatively assigned. Apparently an homologous series of saturated fluorocarbons is formed in the reaction in addition to compounds not belonging to this series. Carbon tetrafluoride and hexafluoroethane are obtained in the largest amounts. Octafluoropropane with its long liquid range can be obtained fairly pure, and two fractions are separated which are apparently the two isomers of decafluorobutane. The determined molecular weight of the lower boiling was less than, and the higher boiling greater than, the theoretical. This is undoubtedly because, with only a small amount of material and a small difference in boiling temperature between the fractions, we crowded both fractions, leaving some lower boiling material in the lower and higher boiling in the upper. The

[a] Physical constants from Ruff, *Angew. Chem.*, **46**, 739 (1933). [b] We believe these compounds to be cyclic in structure, fraction number 6 is probably decafluorocyclopentane, number 7 is probably dodecafluorocyclohexane, and number 8 is probably also a derivative of a cyclic compound. [c] This mixture probably contains a variety of fluorocarbons containing from five to eight carbon atoms, inclusive. [d] This mixture probably contains fluorocarbons having from eight to twelve carbon atoms, inclusive. One-third of this mixture boiled between 95 and 105°, one-third between 105 and 120° and the remainder up to 160°. [e] A system of nomenclature for these compounds is desired. They are distinctly not derivatives of hydrocarbons as their properties show. To name them as such requires long names which will become even more cumbersome as more complex compounds with their isomers and substitution derivatives are made and isolated. The authors wish to suggest the following nomenclature: methfluorane, ethfluorane, ethfluorene, profluorane, bufluorane, cyclopentfluorane, methfluorylcyclohexfluorane, etc.

fraction boiling at 23° we have assumed to be decafluorocyclopentane. It has a much higher freezing point than the other fractions and appears to be mostly one compound. However, neither a sharp freezing point nor an entirely reproducible molecular weight could be obtained, and this latter was uniformly higher than the theoretical. As the saturated dodecafluoropentane isomers would boil at about the same temperature, it is assumed that the compound is contaminated with a small amount of them. If this is correct, then the higher fractions having constant boiling temperatures are probably either CF_3 derivatives of decafluorocyclopentane or dodecafluorocyclohexane and its trifluoromethyl derivative. The material from which no constant boiling fractions could be obtained is assumed to be a mixture of higher boiling fluorocarbons probably with many of the isomers present. This would be analogous to petroleum ether.

The substances are colorless and either odorless or very nearly so. They are very stable chemically. Many of the tubes containing these were sealed off while an appreciable pressure of the vapor existed inside. No trace of etching or carbonization could be observed in the Pyrex glass seal, which must have been at least 700°. The different fractions were tested for unsaturation with bromine in carbon tetrachloride solution, and no decolorization could be observed.

Discussion.—The formation of stable compounds of carbon and fluorine containing more than three carbon atoms per molecule indicates the possibility of the synthesis of a large number of similar compounds provided that methods can be discovered. Such compounds should be of considerable interest both theoretically and as useful substances.

To indicate the relatively low attractive force between the molecules of these compounds, a graph is shown in the figure. The molecular weight is plotted against the boiling point. On the same graph are represented the inert gases, the hydrocarbons, and a few other substances. The fluorocarbon curve does not lie greatly above the inert gas curve, whereas the hydrocarbon curve is very much higher. The fluorocarbons approach the inert gases in properties more closely than any other compounds. This curve also shows that we cannot be greatly in error in the formulas of these compounds. The three and four carbon compounds fall on a smooth curve with the previously known one and two carbon compounds. The three higher boiling compounds are slightly above this curve analogous to the positions of cyclopentane and cyclohexane relative to the hydrocarbon curve. The presence in

the molecules of these compounds of one or more hydrogen atoms would both lower the molecular weight and raise the boiling point due to the introduction of an electric moment. This would place the compounds far above the curve.

The authors wish to acknowledge gratefully the assistance in the preparation and separation of these compounds of the following Graduate Students at the Pennsylvania State College: R. L. Bond, J. W. Ford, R. E. McArthur, D. I. Randall, T. K. Sloat, and A. C. Werner.

Summary

A continuous reaction between fluorine and carbon without explosions has been accomplished.

Compounds corresponding in molecular weight to octafluoropropane, two isomers of decafluorobutane, decafluorocyclopentane, a dodecafluorohexane, and a tetradecafluoroheptane have been isolated in addition to carbon tetrafluoride and hexafluoroethane.

The properties of these compounds have been determined. A mixture of fluorocarbons boiling from 25 to 160° has been obtained.

The Action of *p*-Tolyl Isothiocyanate on Ethyl Acetonedicarboxylate

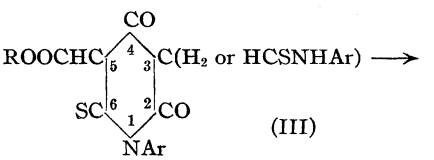
BY DAVID E. WORRALL

In connection with a study of the chemistry of isothiocyanates it seemed desirable to investigate their reactivity toward molecules containing two active methylene groups. Ethyl acetonedicarboxylate (I), a relatively common substance which contains such a system, was selected for this purpose. It quickly became apparent that this ester does not follow the pattern of substances previously studied,[1] but reacts in a highly characteristic manner.

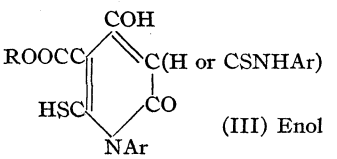
Through the sodium derivative I probably does form the expected thiotoluide, either with one or two equivalents of tolyl isothiocyanate. An additional reaction follows in which the elements of ethyl alcohol are lost. Ring closure suggests itself, particularly as the product contains a nucleus comparatively stable toward acid or alkali which remains intact through certain transformations. Sulfur is labile in the monosulfo derivative; therefore it is concluded that a piperidine ring is formed.

$$ROOCCH_2COCH(COOR)CSNHAr \longrightarrow OCCH_2COCH(COOR)CSNAr\ (II) + ROH$$

The same reaction takes place, using two equivalents of metal and isothiocyanate, although the second methylene group is converted into a thioamide producing III. Sulfur in the side chain is comparatively non-reactive. These pyridones are sufficiently acidic to decompose alkali carbonates forming salts stable toward acetic acid, thus functioning as hydroxypyridines. Because of the presence of tertiary nitrogen, isomerization is restricted to the introduction of two double bonds.



(III)



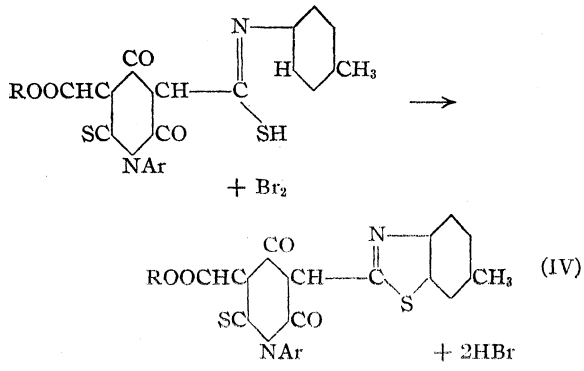
(III) Enol

II and III obviously form thio ethers with methyl iodide in alkaline solution, for the products contain inactive sulfur, whereas the parent substances readily lose this element. Hence one double linkage is located between positions 5 and 6 in the pyridine ring. Further alkylation is possible since the mono methyl ethers still are capable of forming metal derivatives. It is believed that these changes involve the shifting of hydrogen to position 4 rather than 2 which contains oxygen more completely neutralized. With dimethyl sulfate a third hydrogen, that attached to the amide nitrogen is replaced. Ethyltoluidine and a dimethylpyridine dicarboxylate, result from secondary reactions. The carbethoxy group is easily lost both with II and III.

II forms a stable bromine derivative. The methyl ether does likewise, therefore bromine is

(1) Worrall, THIS JOURNAL, **46**, 2834 (1924).

present at position 3. Although III also reacts spontaneously with bromine, liberating hydrogen bromide, the product (IV) contains no bromine and a pair of hydrogen atoms are missing from the molecule. The physical but not the chemical properties have altered considerably. IV is colorless, much less soluble in the usual organic solvents, and much higher melting than III. Sulfur is more mobile, but IV is still soluble in alkali and easily alkylated. The carbethoxy group is more readily hydrolyzed. One of the missing hydrogen atoms must have come from the substituted thioamide group; the other may have originated in either the aniline or the pyridone ring. Despite the fact that a similar reaction apparently takes place with an analogous compound prepared from methyl isothiocyanate,[2] the aniline ring probably is concerned in the reaction. Hugershoff[3] has shown that benzothioazoles result from the action of bromine on arylated thioureas. Moreover, the thioamide obtained by the addition of phenyl isothiocyanate to malonic ester reacts with bromine and definite proof has been found that the product is a thiazole.[2] Therefore, thiazole formation has been assumed here, a reaction in which intermediate bromine derivatives doubtless are formed.



(IV)

Experimental

1-*p*-Tolyl-2,4-dioxo-5-carbethoxy-6-sulfopiperidine.—To 0.25 g. mole of pulverized sodium suspended in ether was added cautiously one equivalent of I. A brisk reaction ensued, following which one equivalent of *p*-tolyl isothiocyanate was dropped into the clear ether solution. The pasty precipitate that formed was dissolved eventually in water containing crushed ice and slowly poured with stirring into cold dilute hydrochloric acid. A bulky solid separated, but on standing it changed into a compact, somewhat pasty mass that was digested with a small volume of cold alcohol; yield 14.3 g. The product was crystallized twice from alcohol, separating finally in bundles of colorless narrow plates, m. p. 174–175° dec.

Anal. Calcd. for $C_{15}H_{15}NO_4S$: C, 59.1; H, 4.9. Found: C, 59.0; H, 5.2.

II is soluble in aqueous sodium carbonate and is precipitated from the alkaline solution by hydrochloric acid, but not by acetic acid. An alkaline solution of II neutralized with acetic acid produces a blue green precipitate with ferric chloride. It is gradually decomposed by long heating with glacial acetic acid, slowly evolving hydrogen sulfide, the formation of which is speeded up by the presence of phenylhydrazine. In both reactions amorphous residues are produced.

1-*p*-Tolyl-2,4-dioxo-6-sulfopiperidine.—One gram of II heated for thirty minutes under a reflux condenser with concd. alcoholic potassium hydroxide was diluted with water, filtered and added dropwise with stirring to cold water containing hydrochloric acid. A bulky amorphous precipitate formed that was filtered with difficulty, thoroughly washed, and dried at room temperature. The resulting grayish powder was used directly for analysis m. p. 158–159°, dec.

Anal. Calcd. for $C_{12}H_{11}NO_2S$: C, 61.8; H, 4.7. Found: C, 61.4; H, 4.8.

1-*p*-Tolyl-2,4-dioxo-5-carbethoxy-6-sulfomethoxypiperidine.—To 2 g. of II dissolved in warm alcohol was added an excess of methyl iodide. A crystalline precipitate almost instantly formed in excellent yield.

Anal. Calcd. for $C_{16}H_{17}NO_4S$: C, 60.2; H, 5.3. Found: C, 59.9; H, 5.5.

It separates from alcohol as slender needles, m. p. indefinite with dec. above 250°. No hydrogen sulfide is liberated on heating with glacial acetic acid either alone or with phenylhydrazine, but the substance retains the property of dissolving in sodium carbonate solution. It forms a sparingly soluble salt with sodium hydroxide which can be recrystallized from a small volume of water. An analysis indicated the presence of one equivalent of sodium.

1-*p*-Tolyl-2,4-dioxo-3-bromo-5-carbethoxy-6-sulfopiperidine.—A small portion of II was brominated in glacial acetic acid, heated for a few minutes on a water-bath and recrystallized from alcohol, separating as tiny pale yellow needles, m. p. 238–239°, dec.

Anal. Calcd. for $C_{15}H_{14}BrNO_4S$: C, 46.9; H, 3.6; Br, 20.8. Found: C, 46.9; H, 3.4; Br, 20.9.

It still is soluble in sodium carbonate solution and reprecipitated unchanged by acid.

1-*p*-Tolyl-2,4-dioxo-3-bromo-5-carbethoxy-6-sulfomethoxypiperidine.—After bromination of the methyl ether of II the product obtained by pouring the mixture into water was recrystallized twice from a small volume of alcohol. Long colorless needles appeared which apparently contained alcohol of crystallization, as on drying at 100° a powder resulted; m. p. 165.5–166.5°.

Anal. Calcd. for $C_{16}H_{16}BrNO_4S$: Br, 20.1. Found: Br, 20.0.

1-*p*-Tolyl-2-oxo-4-methoxy-5-carbethoxy-6-sulfomethoxypiperidine.—A portion of II dissolved in sodium hydroxide solution was shaken with dimethyl sulfate. The

(2) Unpublished results.

(3) Hugershoff, *Ber.*, **36**, 3121 (1903).

product, insoluble in the alkaline solution, was crystallized from dilute alcohol, separating as slender silky needles, m. p. 166°.

Anal. Calcd. for $C_{17}H_{19}NO_4S$: C, 61.3; H, 5.7. Found: C, 61.1; H, 5.9.

This dimethyl derivative is not only insoluble in both aqueous sodium carbonate and sodium hydroxide but does not react with bromine.

1-*p*-Tolyl-2,4-dioxo-5-carbethoxy-6-sulfopiperidine-3-thioformo-*p*-toluide.—Using the customary technique, 0.1 g. mole of I was converted into the metal derivative with two equivalents of sodium. The second equivalent reacted slowly and incompletely even on the application of heat. The clear solution after several hours was poured from unchanged sodium into another flask containing two equivalents of tolyl isothiocyanate. A bulky solid separated after a time from the new mixture. The next morning the entire batch was mixed with ice water, the aqueous layer separated and run carefully with stirring into cold, well-diluted hydrochloric acid. The resulting flocculent precipitate coagulated on standing into a somewhat pasty ball-like mass. It was filtered and thoroughly washed with warm alcohol, yield 18 g.

Anal. Calcd. for $C_{23}H_{22}N_2O_4S_2$: C, 60.8; H, 4.9. Found: C, 61.0; H, 5.0.

III is practically insoluble in alcohol, but dissolves readily in benzene, separating from a mixture of these solvents as shining yellow needles, m. p. 182–184°, dec. It is easily dissolved by alkaline solutions, including concd. ammonia, from which the ammonium salt separates in a few minutes. No reaction takes place with hydroxylamine beyond partial hydrolysis of the ester group. Slow evolution of hydrogen sulfide occurs on long heating with glacial acetic acid. The substance is unchanged on long standing with dilute sodium hydroxide solution. Although unaffected by concd. hydrochloric acid, it is dissolved by cold concd. sulfuric acid, the solution acquiring a blue fluorescence on warming.

1-*p*-Tolyl-2,4-dioxo-6-sulfopiperidine-3-thioformo-*p*-toluide.—A solution containing 2 g. of III dissolved in concd. alcoholic potash was heated for an hour under a reflux condenser, diluted with water and carefully mixed with an excess of acid. The product separated from a large volume of alcohol as lustrous pale yellow irregular plates, m. p. 205–208°, dec.

Anal. Calcd. for $C_{20}H_{18}N_2O_2S_2$: C, 62.8; H, 4.7. Found: C, 62.6; H, 5.0.

It is less soluble than the parent substance in benzene, but more so in alcohol. It is soluble in sodium carbonate solution and reacts with bromine.

1-*p*-Tolyl-2,4-dioxo-5-carbethoxy-6-sulfomethoxypiperidine-3-thioformo-*p*-toluide.—On heating under a reflux condenser 5 g. of III suspended in alcohol containing methyl iodide, the solid rapidly disappeared. An excellent yield of bright yellow needles formed on cooling, m. p. 151–152°.

Anal. Calcd. for $C_{24}H_{24}N_2O_4S_2$: C, 61.5; H, 5.1. Found: C, 61.3; H, 5.1.

The methyl ether slowly dissolved by sodium carbonate solution is precipitated unchanged by acetic as well as by hydrochloric acid. It is readily dissolved by warm alcohol. No hydrogen sulfide is liberated on heating with glacial acetic acid either alone or with phenylhydrazine.

1-*p*-Tolyl-2,4-dioxo-5-carboxy-6-sulfomethoxypiperidine-3-thioformo-*p*-toluide.—A small portion of the monomethyl ether heated for an hour under a reflux condenser with concd. alcoholic potash was isolated in the usual manner. It crystallized from glacial acetic acid in the form of glittering yellow plates, m. p. 232–233° dec.

Anal. Calcd. for $C_{22}H_{20}N_2O_4S_2$: C, 60.0; H, 4.5. Found: C, 60.2; H, 4.6.

Hydrolysis but not decarboxylation took place.

1-*p*-Tolyl-2-oxo-4-methoxy-6-sulfomethoxypiperidine-3-thioformo-*p*-toluide.—The sodium derivative of the monomethyl ether of III was prepared using dilute sodium hydroxide and recrystallizing the colorless needles from a small volume of water. It was then heated to 100° in a sealed tube with alcohol containing methyl iodide for nearly two hours. On pouring the contents after cooling into water, an oil separated. This product dissolved in a small volume of warm alcohol formed tiny snow-white crystals, m. p. 153°.

Anal. Calcd. for $C_{22}H_{22}N_2O_2S_2$: C, 64.4; H, 5.4. Found: C, 64.1; H, 5.3.

It is insoluble in sodium hydroxide solution, and does not react with bromine.

1-*p*-Tolyl-2-oxo-4-methoxy-6-sulfomethoxypiperidine-3,5-dicarboxylate.—A suspension prepared by dissolving 4 g. of III in 150 ml. of warm dilute sodium hydroxide solution and then cooling was shaken with a few ml. of dimethyl sulfate. The sodium salt rapidly disappeared to be replaced by a precipitate that became increasingly pasty. Simultaneously a strong amine-like odor became noticeable. The product, heated on a water-bath for several hours, hardened into a crystalline mass that was repeatedly recrystallized from alcohol. Finally clusters of tiny colorless plates separated, m. p. 177–178°.

Anal. Calcd. for $C_{16}H_{15}NO_6S$: C, 55.0; H, 4.6. Found: C, 55.2; H, 4.7.

A qualitative test revealed the presence of sulfur. While insoluble in aqueous sodium hydroxide the substance is very soluble in alcoholic alkali, remaining in solution on mixing with a large volume of water. It is promptly precipitated from these solutions by acid. The original filtrate contained monomethyl-*p*-toluide, which was isolated by steam distillation from an alkaline mixture. The resulting oil dissolved in acid and formed a nitroso derivative with nitrous acid.

1-(1-*p*-Tolyl-2,4-dioxo-5-carbethoxy-6-sulfopiperidyl)-5-methyl-benzothiazole.—A molar equivalent of bromine was added to 5 g. of III suspended in a small volume of glacial acetic acid. The mixture, which immediately began to yield hydrogen bromide, was heated for an hour on a water-bath. The mustard colored product, practically insoluble in the common organic solvents, was thoroughly washed with warm alcohol; yield 4.3 g. By beating under a reflux condenser with glacial acetic acid, most of the color could be removed.

Anal. Calcd. for $C_{23}H_{20}N_2O_4S_2$: C, 61.1; H, 4.4. Found: C, 61.0; H, 4.3.

IV may be recrystallized in small quantities from nitrobenzene, or better still, aniline, as tiny feathery needles

m. p. above 300°. It is easily dissolved by ammonium hydroxide or concd. sulfuric acid, producing on warming with the latter a bluish fluorescence. Hydrogen sulfide is set free rapidly on heating the substance suspended in glacial acetic acid with phenylhydrazine.

1 - (*p* - Tolyl - 2,4 - dioxo - 5 - carboxy - 6 - sulfopiperidyl)-5-methylbenzothiazole.—IV dissolved quickly in cold ammonium hydroxide, a solution which was slowly run into a large volume of water containing an excess of hydrochloric acid. A bright yellow gelatinous precipitate formed. It was filtered with difficulty, washed thoroughly and dried at room temperature. The color darkened considerably, m. p. 260–261° with dec. and foaming.

Anal. Calcd. for $C_{21}H_{16}N_2O_4S_2$: C, 59.4; H, 3.8. Found: C, 59.4; H, 3.7.

The new substance is soluble in sodium carbonate solution.

1 - (*p* - Tolyl - 2,4 - dioxo - 5 - carbethoxy - 6 - sulfomethoxypiperidyl) - 5 - methylbenzothiazole.—On shaking an ammonia solution of IV with alcohol containing methyl iodide a precipitate quickly formed. The mixture, concentrated to a small volume by distillation, gave a quantitative yield of the product which was recrystallized from a large volume of alcohol. Pale yellow needles separated, m. p. 282–283°, dec.

Anal. Calcd. for $C_{24}H_{22}N_2O_4S_2$: C, 61.8; H, 4.7. Found: C, 61.7; H, 4.8.

The methyl derivative does not react with bromine or phenylhydrazine. On destructive distillation the gases blacken lead acetate paper and have a strong pyridine odor. It still is soluble in ammonia, but this is due to hydrolysis of the carbethoxy group, as an analysis of the product indicated. The product was isolated by precipitation with acid as a semi-gelatinous solid which did not discolor on standing, m. p. 260–261°, dec. The same substance was obtained by the action of concd. nitric acid or warm sulfuric acid.

Summary

It has been shown that ethyl acetonedicarboxylate reacts with one or two equivalents of *p*-tolyl isothiocyanate forming pyridones, which are soluble in alkali and are readily alkylated. An oxypiperidyl benzothiazole apparently results from the action of bromine on the pyridone containing a thioamide group.

Aromatic Amines and 3-Nitro-6-bromonitrostyrene

BY DAVID E. WORRALL AND JACK FINKEL

It has been shown previously[1] that while the additive capacity of nitrostyrene toward the so-called organic bases is comparatively weak and even more so as a rule when substituents are introduced, the nitration of 2-chloronitrostyrene produced an unsaturated compound in which this reactivity is somewhat strengthened. As we wished to determine whether its effect were general, the corresponding bromostyrene has been prepared. The two substances have almost identical chemical properties.

Experimental

α-Nitro-β-(2-bromophenyl)-ethylene (I).—This compound was obtained by the action of triethylamine[2] on bromobenzaldehyde[3] and nitromethane at 25 to 30°; yield, after steam distillation, approx. 60%. It crystallized from ligroin in bundles of yellow needles, m. p. 84°.

Anal. Calcd. for $C_8H_6BrNO_2$: C, 42.1; H, 2.6. Found: C, 42.1; H, 2.8.

α-Nitro-β-(6-bromo-3-nitrophenyl)-ethylene (II).—The product from the nitration of I, using fuming nitric acid, separated from alcohol as small pale yellow needles, m. p. 144–145°.

Anal. Calcd. for $C_8H_5BrN_2O_4$: C, 35.2; H, 1.8. Found: C, 35.1; H, 2.1.

A small portion on oxidation with potassium permanganate produced a substance that crystallized from water as long needles, m. p. 178–179°. It did not depress the melting point of an authentic sample of 6-bromo-3-nitrobenzoic acid prepared from *m*-nitrotoluene, thus indicating that the nitro group is para to the halogen.[4]

α-Bromo - α - nitro - β - (6 - bromo - 3 - nitrophenyl) - ethylene (III).—Five grams of II after bromination was mixed with warm alcoholic potassium acetate. The product crystallized from alcohol in yellow needles, m. p. 146–147°.

Anal. Calcd. for $C_8H_4Br_2N_2O_4$: C, 27.3; H, 1.1. Found: C, 27.6; H, 1.3.

The corresponding chlorine derivative was obtained as yellow needles, m. p. 140–141°.

N,N'-(α,α'-Di-(2-bromophenyl)-β,β'-dinitrodiethyl)-*p*-phenylenediamine.—A small portion of I dissolved in hot alcohol was mixed with one-half the equivalent amount of the base. The yellow crystals were washed with warm alcohol, m. p. 146–147°.

A similar addition product was obtained and analyzed, from III as brown crystals, m. p. indefinite. III, but not II, also formed an addition product with *p*-toluidine, yellow needles, m. p. 103–104°.

The same general procedure previously developed[1] was used in preparing the addition compounds which were obtained usually as yellow needles or narrow plates. The ammonia product was nearly colorless, while the benzidine and phenylenediamine compounds were orange in color.

Summary

3-Nitro-6-bromonitrostyrene has been prepared and also several derivatives. A number of addition products have been obtained with aromatic amines, including *o*- and *m*-anisidine.

MEDFORD, MASS. RECEIVED JULY 11, 1939

NOTES

The Non-interchange of Elementary Radiosulfur with Carbon Disulfide

BY ROBERT A. COOLEY, DON M. YOST AND EDWIN MCMILLAN

Radioactive sulfur (half life eighty to ninety days) finds important application as a tracer in chemical and biochemical investigations,[1] and at some stages in these studies it proves convenient to use carbon disulfide as a solvent for elementary sulfur. In order to be certain that this solvent can be used without danger of loss of the radioactive sulfur, it is necessary to show that there is no interchange between elementary sulfur and carbon disulfide. Judging from the nature and structure of carbon disulfide,[2] any appreciable interchange seems unlikely, but the great solubility of sulfur in carbon disulfide (50.49 g./100 g. carbon disulfide at 25°) suggests the possible rapid reversible formation of complex compounds that might make interchange possible.

The radiosulfur used was formed by bombarding a metal sulfide with 4 Mev. deuterons in the cyclotron at the University of California radiation laboratory. Elementary sulfur was obtained from the metal sulfide by dissolving it in hydrochloric acid and passing the hydrogen sulfide formed into a 1 *N* solution of potassium iodide saturated with iodine. After warming the resulting solution to volatilize the excess iodine, and to coagulate the very fine precipitate, the sulfur was collected as small globules on a sintered glass filter. An appreciable proportion of the sulfur obtained in this manner is in the amorphous (μ) form and is slow to dissolve in carbon disulfide. It has been found by Mr. J. B. Hatcher at this

(1) Borsook, Keighley, Yost and McMillan, *Science*, **86**, 525 (1937).

(2) Pauling, "Nature of the Chemical Bond," Cornell University Press, Ithaca, New York, 1939, p. 182.

Institute that heating the sulfur precipitate in an autoclave is not attended with losses and that it is thereby converted into a readily soluble form.

The exchange experiments were carried out in sealed U-tubes one leg of each containing a solution of about 3 mg. of radiosulfur in 300 mg. of C. P. carbon disulfide. The filled tubes were heated in a thermostat at 100° for forty-two to sixty-eight hours, and after the heating period about one-half of the carbon disulfide was caused to distil into the empty leg of the tube by cooling it with liquid air. The contents of the two legs were subjected to a Carius combustion, and the resulting sulfuric acid was then converted into dry lithium sulfate. Thin layers of the lithium sulfate, all of equal area, about 20 sq. cm., were prepared on metal plates for the measurement of the activity. Lithium rather than the more easily prepared barium sulfate was used in the radioactivity measurements because the barium absorbs the weak (107 Kev. maximum) beta radiation[3] of sulfur more extensively than does lithium. The thickness of the mounted lithium sulfate samples was >0.015 g./sq. cm. and was such that the beta particles from the bottom of a sample could not penetrate to the top and from there reach the electroscope chamber. This arrangement greatly simplifies the quantitative treatment of the results.

In our current experiments with radiosulfur it has been found possible to make the mounted samples of elementary sulfur by reducing barium sulfate to the sulfide with hydrogen at about 900°. Barium sulfide is then treated in the manner described above for the recovery of the sulfur. The reduction procedure was suggested to us by Professor J. E. Bell of this Institute, and the technique for its use was developed by Mr. J. B. Hatcher. Complete reduction of barium sulfate is not attained if the salt melts.

The activity of the lithium sulfate samples was measured with a lead shielded quartz fiber Lauritsen electroscope. A thin aluminum foil, 0.15 mg./sq. cm., served as the window on the ionization chamber. The background was about 0.001 div./min. and varied no more than 30% in a two-week period. By taking background readings immediately before and after readings with the samples, the activities of the latter were determined to ±0.0002 div./sec. The results, corrected for background, are shown in Table I. The same range of the electroscope scale was used throughout in determining the effect due to the background and to the samples, and therefore no correction for linearity of scale was required.

TABLE I

(3) W. F. Libby and D. D. Lee, *Phys. Rev.*, **55**, 245 (1939).

It is evident from the results that there is practically no interchange between sulfur and carbon disulfide even at 100°. The extent of any interchange must be less than 2%, that is, it must be less than the experimental error of the activity measurements. It is also clear that carbon disulfide may be used as a solvent for radiosulfur without fear of loss by interchange.

Note on the Formation of bis-(β-Diethylaminoethyl) Sulfide

BY ELTON S. COOK AND CORNELIUS W. KREKE

In an attempt to prepare β-diethylaminoethyl mercaptan from 1-bromo-2-diethylaminoethane hydrobromide and sodium hydrosulfide in the presence of sodium ethylate, Lischer and Jordan[1] obtained β,β′-diethylaminodiethyl disulfide. We have tried to prepare the mercaptan using sodium sulfide and hydrogen sulfide by a method based on that employed by Bennett[2] for the preparation of monothioethylene glycol. We did not obtain the desired mercaptan but isolated *bis*-(β-diethylaminoethyl) sulfide.

Experimental Part

1-Bromo-2-diethylaminoethane hydrobromide was prepared by heating redistilled β-diethylaminoethyl alcohol and 66% hydrobromic acid at 135° according to the method of Meyer and Hopff.[3] We found that 40% hydrobromic acid could not be used satisfactorily. The presence of a trace of free bromine greatly facilitated the reaction.

bis-(β-Diethylaminoethyl) Sulfide Dihydrochloride.—One hundred and fifty grams of sodium sulfide (Na_2S $9H_2O$) was heated to 130° for fifteen minutes and saturated with hydrogen sulfide. The solution was cooled to 60–65°, the passage of hydrogen sulfide being continued during the cooling. Then 10.2 g. of 1-bromo-2-diethylaminoethane hydrobromide was added slowly with stirring and the mixture was kept at 55° for fifteen minutes. The mixture was cooled and extracted immediately three times with 100-cc. portions of ether. The ether solution was dried over anhydrous sodium sulfate, the ether removed, and the dried oily residue was taken up in absolute ether. Dry hydrogen chloride was passed in and the dihydrochloride precipitated readily. It was crystallized from absolute alcohol by the addition of absolute ether:

Relations between Rotatory Power and Structure in the Sugar Group. XXXIV. The Possibility of Different Conformations of the Pyranoid Ring[1]

BY C. S. HUDSON

In a preceding article by Eugene Pacsu[2] he suggests that the exceptional character of the rotations of the α- and β-forms of substances having the pyranoid ring structure in the mannose series may be due to a difference in the conformation of the atoms forming the ring. I thank Dr. Pacsu, with whom I have conferred often during the progress of his research, for this opportunity to publish concurrently the reasons which have led me to take the same viewpoint on this question.

In 1930[3] I expressed the view that the exceptional character of these rotations indicated that the substances had different ring structures, and I assumed that the α-forms were of the furanoid and the β-forms of the pyranoid type. The experiments of Haworth and Hirst[4] and their collaborators, designed to test this view, yielded results which showed that it is not tenable and that the substances in question possess only the pyranoid ring. From then on I have searched for an explanation of these unusual rotations that would be compatible with a pyranoid ring structure. The discovery[5] of a crystalline molecular compound of the α- and β-forms of methyl xyloside suggested the possibility that some of the supposedly pure substances of the mannose series might be compounds of this nature, an hypothesis which easily could account for the exceptional rotations. Many efforts by various ways to separate α-methyl mannopyranoside into components and similar experiments on its tetraacetate and on the tetraacetate of β-methyl mannopyranoside, led to negative results; the hypothesis of the compound nature of any of these substances thus became very improbable but nevertheless the failures did not eliminate it as a possibility. Positive proof that they are true chemical individuals, not molecular compounds, was obtained in the course of experiments[6] on the oxidation of methyl glycosides by periodic acid; their exceptional rotations, as compared with those of their glucose analogs, are not attributable either to ring-size or to any lack of chemical individuality. As was pointed out some years ago,[7] there are several differences of rotation in the mannose pyranoid series that conform closely with analogous differences in the glucose series, provided one compares substances of α-classification only, or of β-classification only. Pacsu now finds similar relationships in the fructose and sorbose pyranoid series. It would seem therefore that the agreement of rotational differences within the α- or the β-series, when coupled with the known disagreement across an α–β pair, probably indicates differences in pyranoid ring conformation.

The Preparation of Seleno Ortho- and Meta-Cresols

BY DUNCAN G. FOSTER

In preparing a series of compounds for the measurement of vapor-phase absorption spectra it developed that the two compounds seleno *o*- and *m*-cresol, $CH_3C_6H_4SeH$, had never been described in the literature. The writer has prepared them by the standard method of treating the tolyl Grignard reagents with elementary selenium,[1] operating in a current of hydrogen. When hydrogen was not used no selenocresols were obtained, but only high-boiling selenides, which perhaps explains why they are not reported.

The compounds are colorless liquids when absolutely pure, but rapidly turn yellow on contact with the air. Direct analyses were found to be impracticable because their acid nature renders the Parr bomb method inapplicable and their instability and toxic properties make handling for carbon and hydrogen determinations difficult. For identification, they were converted to the acids $CH_3C_6H_4SeO_2H$[2] by dissolving in nitric acid and these compounds analyzed for carbon and hydrogen. This does not distinguish them from the ditolyl diselenides, which would behave in the same way, but the boiling points were much too low for them to have been diselenides. The copper salts were also prepared by standard means.[3] They were blue crystalline solids without m. p.

Note on the Preparation of *d*-Galacturonic Acid

BY IRA A. MANVILLE, FRANCIS J. REITHEL AND PAUL M. YAMADA

In a recent article[1] there was described a method for the enzymic preparation of *d*-galacturonic acid from polygalacturonic acid. We have had the pre-publication privilege of using this method for preparing the *d*-galacturonic acid necessary for our work on its nutritional significance. It was found in our laboratory that the method, though far superior to former methods in many respects, gave varying yields. Although this in no way detracted from the excellence of the method, it posed the question as to what factors should be considered in improving the yield.

First of all we tried different pectins. Of these, there seemed to be considerable variation even between "batches." Most satisfactory in our work was General Food's Certo Apple Pectin RX 1 or 2. California Fruit Exchange Citrus Pectin, Sample B-6712, also gave good results. We are not prepared to explain why these are better, but simply state the result of empirical observations and call attention to the importance of this detail.

Secondly, we found that in the preparation of pectic (polygalacturonic) acid, it was quite necessary for the best yield to remove the last trace of the calcium chloride which we used for controlling the swelling of the pectin. This was accomplished as follows. After swelling the pectin in alcohol and calcium chloride, adding sodium hydroxide, acidifying and washing (until no precipitate resulted upon the addition of sodium oxalate or five volumes of alcohol), the resultant pectic acid was suspended again in a volume of water equivalent to that of the alcohol. About half as much sodium hydroxide was added as before. It was then acidified and washed again. The pectic acid obtained has no contamination with pectin or calcium chloride. That the concentration of calcium chloride affects enzymic action is shown by the fact that addition of calcium chloride to the enzyme–pectic acid mixture will inhibit the action of the enzyme.

Thirdly, we found that of those preparations tried, only Röhm and Haas Pectinase 46 AP seemed to yield satisfactory results. This is the enzyme contained in the preparation used by Mottern and Cole.

Several other minor points should be mentioned. After enzyme action is complete, we find it advantageous to add the sulfuric acid before filtration. Further, it is often wise to work up the sludge from the alcohol precipitation by treating it with small amounts of sulfuric acid and carrying it on in the same manner as the original material.

By carefully observing all these points in technique, we have been able to obtain yields as high as 36% of the theoretical and have had no difficulty in obtaining a very pure product which, after recrystallization in the β-form from boiling absolute alcohol, has a melting point of 160°.

The purpose of this note is to aid those using

Sterols. LXXIV. Acetic Acid Derivatives of Estrone and α-Estradiol

BY RUSSELL E. MARKER AND EWALD ROHRMANN

Estratriene-1,3,5-one-17-oxyacetic acid-3 was first prepared by Ercoli and Mamoli[1] by treatment of estrone in aqueous potassium hydroxide solution with chloroacetic acid. In the present work the 3-oxyacetic acid derivatives of estratriene-1,3,5-one-17-ol-3 and of estratriene-1,3,5-diol-17(α),3 were prepared by the reaction of these substances with ethyl chloroacetate in the presence of an excess of an ethanolic solution of sodium ethylate. Estratriene-1,3,5-one-17-ol-3 was also caused to react in a similar way with α-chloropropionic acid to yield estratriene-1,3,5-one-17-oxymethylacetic acid-3. The acidic substances were characterized further by the formation of the methyl esters.

We wish to thank Parke, Davis and Company for their generous support and assistance rendered during the course of this work.

Experimental Part

Estratriene-1,3,5-one-17-oxyacetic Acid-3.—To a boiling solution of 1 g. of estrone in 40 cc. of absolute ethanol was added 3.5 cc. of ethyl chloroacetate and a solution of 600 mg. of sodium in 20 cc. of ethanol. The mixture was refluxed on the steam-bath for fourteen hours after which 2 g. of potassium hydroxide was added and the refluxing continued for one hour. The mixture was diluted with water and the clear solution acidified with hydrochloric acid. The white solid was taken up in ether and the ethereal solution washed with water and 5% sodium carbonate solution. Evaporation of the ether yielded approximately 150 mg. of unreacted estrone.

The sodium carbonate washing was acidified with hydrochloric acid and the white solid taken up in ether. Evaporation of the ether gave a product which crystallized from aqueous acetone as small white plates, m. p. 209–211°; yield, 750 mg.

Anal. Calcd. for $C_{20}H_{24}O_4$: C, 73.2; H, 7.4. Found: C, 73.5; H, 7.5.

When the reaction was carried out using equivalent amounts of sodium and ethyl chloroacetate, only a poor yield of the acid was obtained.

A solution of 50 mg. of the acid in 10 cc. of 80% ethanol was refluxed for one hour with 75 mg. of hydroxylamine hydrochloride and 100 mg. of sodium acetate. The product was crystallized from 80% ethanol to give white crystals of the **oxime**, m. p. 230–232° dec.

Anal. Calcd. for $C_{20}H_{25}O_4N$: C, 69.9; H, 7.3. Found: C, 70.0; H, 7.4.

The **methyl ester** was prepared by treating 150 mg. of the acid in ether–methanol solution with an excess of an ethereal solution of diazomethane. The product was crystallized from aqueous acetone as white crystals, m. p. 130–132°.

Anal. Calcd. for $C_{21}H_{26}O_4$: C, 73.6; H, 7.7. Found: C, 73.5; H, 7.8.

Estratriene-1,3,5-ol-17(α)-oxyacetic Acid-3.—This was prepared from estratriene-1,3,5-diol-3,17(α) as described for estratriene-1,3,5-one-17-oxyacetic acid-3. The product was crystallized from aqueous acetone to give white crystals, m. p. 182–184°.

Anal. Calcd. for $C_{20}H_{26}O_4$: C, 72.7; H, 7.9. Found: C, 72.6; H, 7.9.

Treatment of the acid in ether–methanol solution with diazomethane yielded the **methyl ester** which crystallized as white crystals from ether–pentane, m. p. 94–96°.

Anal. Calcd. for $C_{21}H_{28}O_4$: C, 73.2; H, 8.2. Found: C, 73.3; H, 8.1.

Estratriene-1,3,5-one-17-oxymethylacetic Acid-3.—This was prepared from estrone and α-chloropropionic acid as described for the preparation of estratriene-1,3,5-one-17-oxyacetic acid-3 except that about three times as much sodium was used. The product was crystallized from aqueous acetone as white crystals, m. p. 195–198°.

Anal. Calcd. for $C_{21}H_{26}O_4$: C, 73.6; H, 7.7. Found: C, 73.3; H, 7.7.

Treatment of the acid in methanol–ether solution with diazomethane yielded the **methyl ester** which crystallized from aqueous acetone as small white crystals, m. p. 137–139°.

Anal. Calcd. for $C_{22}H_{28}O_4$: C, 73.9; H, 7.9. Found: C, 74.1; H, 7.9.

tion with lanthanum nitrate[4]; the behavior of its aqueous iron or copper salt solutions in the presence of amyl alcohol or other immiscible solvents,[5] etc. However, when acetates or butyrates, or both, are also present, some or all of the foregoing tests become inconsistent and unreliable. It is true such mixtures may be analyzed, both qualitatively and quantitatively, with exceptional success by the use of the methods of C. H. Werkman and co-workers.[6] Unfortunately, these procedures require very careful manipulation and are rather time consuming.

A need for a rapid and reliable means of identifying propionates in the presence of the above-mentioned interfering ions was satisfactorily filled by the use of mercurous nitrate.

Mercurous propionate crystallizes in a well-defined form which is quite different from either mercurous acetate or butyrate. Further, it forms readily even when the latter substances are also present. Once one has become familiar with the crystalline characteristics of the pure salts and their mixtures, the possibility of error becomes insignificant. The authors testing numerous unknowns, obtained results which were correct in each and every case.

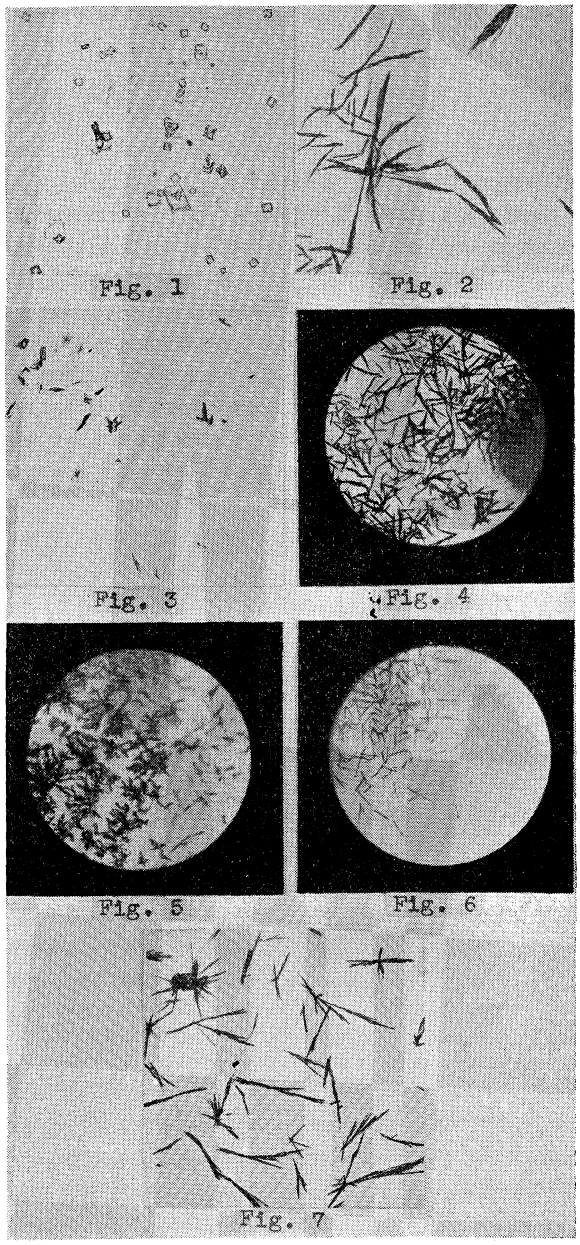
The accompanying photomicrographs illustrate the crystal structures involved. The entire method is brief, simple, and does not require undue care or technique.

In the accompanying photomicrographs the concentrations of the salts were as follows: for Figs. 1, 2 and 3, 2% solutions of the pure sodium salts were used; for the remaining four, equal amounts of 2% solutions of the sodium salts of the ions involved were taken.

Experimental.—A neutral hydrolysate or test solution is vacuum distilled to dryness. The residue is then acidified with concentrated phosphoric acid and the liberated acids are distilled off *in vacuo*. It is advisable to collect the distillate in an 8″ × 1″ (20 × 2.5 cm.) test-tube surrounded by an efficient freezing mixture (salt, 33; pulverized ice, 100; −21°). The test-tube may be connected to the side-arm of the flask by means of a bent piece of ordinary glass tubing. This delivery tube should dip to within 2.5 cm. of the bottom of the receiver.

A capillary introduced into the semi-solid distillate (when acetate is present) will withdraw several drops of acid. This is transferred to a glass slide and a drop of 5% sodium carbonate solution is added (care being taken that the mixture still reacts acid to litmus) and the whole is evaporated to dryness. The residue is dissolved in 2–4 drops of water, and a drop of a saturated solution of mercurous nitrate (acidified with nitric acid to prevent decomposition) is placed alongside, and is allowed to flow into the former. The precipitate is examined immediately with a microscope.

To obtain the photomicrographs, the following procedure was used: one drop of a 2% aqueous solution of sodium propionate (or acetate, or butyrate, or mixtures of any two or all three) was placed on a glass slide and diluted with 2–4



Mercurous salts: 1, acetate; 2, propionate; 3, butyrate; 4, acetate-propionate; 5, acetate-butyrate; 6, propionate-butyrate; 7, acetate-propionate-butyrate.

drops of water. A drop of the reagent was then allowed to flow into the test sample (magnification, 100 ×).

Discussion.—The distillation is employed to remove substances which may interfere with the analysis. It also serves to concentrate the acids present. Incidentally, too large an excess of acetic acid is conveniently and simultaneously frozen out.

If only the sodium salts of the acids involved comprise the test substance, the distillation may be dispensed with if one can be sure of at least 0.15 mg. of propionate in the test drop.

The method also may be used to identify either acetates or butyrates when they are present alone. As little as 0.15 mg. present in the test drop permits positive identification.

Formates tend to interfere with the analysis when the concentration is equal to or greater than either of the other anions. When smaller amounts are present, however, propionates may be identified although the crystal structure is slightly altered. Hence, if formates are indicated in a test solution (by the reduction of silver nitrate or mercuric chloride), it is advisable to destroy or otherwise remove them.

Attempts were made to employ other cations for the detection of the ions discussed under similar conditions. Thus, silver, bismuth, antimony, and lead salts of the acids were studied. Also, various cobaltammine complexes were tried. However, none of these were found to be completely suitable.

Acknowledgment.—The authors wish to express their thanks to Dr. W. Schmidt for permission to publish this paper. Thanks are also due to Mr. W. Pera for technical advice on photomicrography and to W. A. Hynes and L. K. Yanowski for supplying samples of the cobaltammine complexes.

Saponins and Sapogenins. XIV. The So-called Pyridazine Derivatives of Steroid Diones

BY C. R. NOLLER

The fact that the diketone obtained by the oxidation of chlorogenin[1] has been found to react with hydrazine to give a product the analysis of which checks that of a pyridazine derivative, has led Marker and Rohrmann[2] to postulate that the carbonyl groups of the diketone and hence the hydroxyl groups of chlorogenin occupy the 3,6-positions of the sterol nucleus. Several factors have led us to believe that this is not a likely structure for chlorogenin. Since tigogenin on oxidation gives gitogenic acid, one would expect chlorogenin, if it had the 3,6-formulation, to give digitogenic acid, which is not the case. Moreover, if oxidation opened ring I between C-3 and C-4, a β-keto acid would be formed or if ring I opened between C-2 and C-3 but the nuclear configuration were different, one would expect the ketodibasic acid to be isomerized readily by alkali since digitogenic acid readily is converted to digitoic acid, but the ketodibasic acid was recovered unchanged after alkaline saponification of the dimethyl ester. The opening of ring II between C-6 and C-7 on oxidation would not be expected since in the further oxidation of digitogenic acid ring II is opened between C-5 and C-6 to give a ketotribasic acid, oxydigitogenic acid. Finally the surface film of digitogenin appears to be unlike that of chlorogenin since the former contracts rapidly under pressure giving a solid condensed film which is partially collapsed[3] whereas chlorogenin gives a gaseous film which does not collapse until the pressure reaches 18 dynes per centimeter and which remains mobile even up to 32 dynes per centimeter.[4]

Because of the possibility of polymolecular condensation,[5] we have determined the molecular weight of the condensation product formed from hydrazine and the diketone from chlorogenin and have obtained values of 1410, 1980 and 2770 for three different preparations compared with a calculated value of 425 for a monomolecular pyridazine derivative. It is evident that the formation of condensation products with hydrazine does not prove that the hydroxyl groups of chlorogenin are in the 3,6-positions although the fact that the condensation products are polymolecular does not exclude these positions.

Since molecular weight determinations have not been reported for similar compounds from other steroid diones,[6] it seemed desirable to determine the molecular weight of a typical so-called pyridazine derivative such as that from choles-

tane-3,6-dione. A single preparation gave a value of 3000 compared with 396 for a monomolecular product. It is surprising that the fact has been overlooked that reaction with hydrazine cannot, in the absence of molecular weight determinations, be considered as proof or confirmatory evidence for the 1,4-diketone grouping since Fernholz[6] points out that a pyridazine from a 3,6-dione is possible stereochemically only if one of the double bonds is outside of the heterocycle. Moreover, Marker and Wittle[7] have objected to a deduction of others[8] based on "pyridazine" formation on the grounds that the pyridazine in question was probably a linear polymer.

The reaction with hydrazine of the diketone, m. p. 233–235°, from chlorogenin was carried out in the usual way.[2,6] Methyl alcohol was added to a boiling solution of the product in benzene and on cooling a pale yellow oil separated which solidified on rubbing with more methyl alcohol. Solution in benzene and precipitation with methyl alcohol was repeated three times. The product, which was amorphous, was dried at 130° and 3 mm. pressure. It turned a deep yellow at 240°, light brown at 270° and was a dark brown powder at 300°.

Anal. Calcd. for $C_{27}H_{40}O_2N_2$: N, 6.59. Found: N, 7.05, 6.89. When 0.1661 g. was dissolved in 1.889 g. of benzene, the freezing point was depressed 0.16°. Calcd. mol. wt., 425; found, 2770.

The mother liquors from the above preparation were concentrated, dissolved in benzene and precipitated by methyl alcohol. This product showed the same behavior on heating and was found to contain 6.82% nitrogen. When 0.0534 g. was dissolved in 1.247 g. of benzene, the freezing point was depressed 0.11°, indicating a molecular weight of 1981.

In another preparation a product with different properties was obtained although the conditions were to all outward appearances the same. This product was crystalline but showed the same behavior on heating as the previous products.

Anal. Calcd. for $C_{27}H_{40}O_2N_2$: C, 76.38; H, 9.49; N, 6.59. Found: C, 73.73, 73.80; H, 9.62, 9.22; N, 6.49, 6.84.

This crystalline product had only limited solubility in benzene and the solubility appeared to decrease with repeated crystallizations. This solubility behavior is different from that of all previously recorded products, which appear to be characterized by ready solubility in benzene.

In order to get sufficient material into solution for a molecular weight determination, it was necessary to warm the solution but there was no evidence that the material separated before freezing of the benzene took place. A depression of 0.15° was obtained when 0.0950 g. was dissolved in 2.290 g. of benzene, indicating a molecular weight of 1410. A micro Rast determination in camphor by Mr. L. H. Goodson gave a value of 894 for the molecular weight but decomposition of the compound was evident from the brown color of the solution.

A sample of cholestanedione-3,6, m. p. 169–171°, prepared by the method of Dane and Wang,[9] after reaction with hydrazine and purification from benzene and methyl alcohol, gave an amorphous product which darkened at 190° and melted to a red-brown liquid at 210–220°. Windaus[6] reported obtaining a crystalline product which sintered at 188°.

Anal. Calcd. for $C_{27}H_{44}N_2$: N, 7.06. Found: N, 6.72.

When 0.1235 g. was dissolved in 1.750 g. of benzene the freezing point was depressed 0.12°, indicating a molecular weight of 2999.

When 0.1040 g. of the diketone from chlorogenin was dissolved in 1.845 g. of benzene the freezing point depression was 0.69°, giving a molecular weight of 417 compared with a calculated value of 428.

Purification of *p*-Acetaminobenzenesulfonyl Chloride

BY L. H. PENCE AND H. C. WINTER

A convenient method for the purification of large quantities of *p*-acetaminobenzenesulfonyl chloride will be of interest to the many investigators engaged in the synthesis of sulfanilamide and related compounds.

The crude acid chloride obtained by the procedure described by Smiles and Stewart[1] in "Organic Syntheses" frequently may be employed in subsequent reactions without further purification; but they state that it must be used immediately after preparation, since it decomposes rapidly on standing. Once the sulfonyl chloride is purified, however, it may be kept indefinitely. According to their procedure recrystallization of the 90 g. of crude product from benzene yielded 70 g. of pure *p*-acetaminobenzenesulfonyl chloride melting at 149°. However, because of the slight solubility of the sulfonyl chloride in this solvent (2% hot and 0.5% cold), recrystallization from benzene has been reported[1] to be impractical for purifying more than a small amount at a time.

The following modification of the above procedure has been used in our laboratory and found to be much better adapted for the purification of large quantities of the compound from the standpoints of both time and convenience.

(1) Smiles and Stewart, *Org. Syntheses*, **5**, 3 (1925).

Dry acetanilide (67.5 g.) is added to freshly distilled chlorosulfonic acid (290 g.) in the usual manner. After the reaction mixture has been poured into crushed ice and water, the precipitated *p*-acetaminobenzene sulfonyl chloride is centrifuged and washed three times with water in the centrifuge. The damp, crude acid chloride is then dissolved easily in ether (1000 cc.), separated from the aqueous layer, and washed with water until the washings no longer give a test for sulfate ion. Four 50-cc. portions of water are usually sufficient. After drying the ethereal solution over anhydrous sodium sulfate for one hour,[2] and filtering, the ether is removed by distillation. When approximately 300 cc. of ether remains, the acid chloride begins to separate, and benzene (1000 cc.) is added. After cooling in the icebox the crystals are transferred to the filter, washed with benzene (200 cc.), and dried *in vacuo* at room temperature. The average yield of several preparations was 70 g. of the colorless crystals of *p*-acetaminobenzenesulfonyl chloride, melting at 149°. An earlier preparation (m. p. 147–148°) had the same melting point after standing for seven months.

(2) Longer drying may cause the acid chloride to crystallize out, as it is less soluble in anhydrous ether.

The Action of Titanium Tetrachloride on Benzylglucopyranoside Tetraacetates

BY E. V. PIEL[1] AND C. B. PURVES

Pacsu observed that in absolute chloroform solution titanium tetrachloride and a fully acetylated β-glycoside united to a less soluble, highly colored addition complex. The subsequent decomposition of this complex by water liberated the isomeric α-glycoside acetate in very high yield.[2] While using this reaction to prepare α- from β-benzylglucopyranoside tetraacetate, we noted that a small amount of starting material always could be recovered from the mother liquors of the product. As the yield of the crude, crystalline product was practically quantitative when the heating of the chloroform solution was not unduly prolonged, it was possible to follow the reaction by noting the amounts and the specific rotations of the various fractions (Table I). It was clear that the tetrachloride brought about an equilibrium containing the α- and β-forms of the acetylated glycoside in an approximate ratio of 9:1 and that this equilibrium could be experimentally reached from either side. Although colored addition compounds were formed with tetraacetyl β-methylfructopyranoside,[3] with sucrose acetate or triacetyl β-glucosan,[4] the original materials were recovered unchanged. In these cases the titanium tetrachloride compound initially formed was apparently too stable to rearrange in the experimental conditions.

(1) This article is based on a thesis submitted by Mr. Piel to the Faculty of the Massachusetts Institute of Technology in partial fulfilment of the requirements for the degree of S.B.

β, 20	150[c]	F(1)	14.5	141.6	90
		F(2)	2.7	21	
α, 14	75	F(1)	9.4	141.2	91[d]
		F(2)	2.1	58.5	

[a] As % of the total crystalline product. [b] At 21° instead of at the b. p. Equilibrium was not nearly reached. [c] Too prolonged heating caused slight decomposition and reduced the yield. Fractional recrystallization of F(2) gave 0.5 g. of the pure β-acetate with a rotation of −51.8° in chloroform. [d] The total yield was only 86%. F(2) gave 0.2 g. of pure β-acetate with the correct rotation.

Attention to technical details made the α-benzylglucoside acetate readily available from acetobromoglucose in an over-all yield of 60%, the β-benzyl acetate[5] being an intermediate step. This was greatly superior to the earlier yield (11%) obtained by converting acetobromo to acetoiodoglucose and condensing the latter with benzyl alcohol in quinoline.[6]

Experimental

All rotations were made with sodium light in a 2- or 4-dm. tube at 20 or 21°.

Acetobromoglucose.—A solution made from recrystallized glucose pentaacetate, 50 g., and glacial acetic acid nearly saturated with hydrogen bromide, 75 cc., was kept at room temperature for two hours.[7] Most of the solvent was recovered by evaporation, bath 60° (20 mm.), fortified with hydrogen bromide and used again. Traces were removed from the residual sirup by the addition and evaporation, under diminished pressure, of dry toluene.[8] The recrystallized product was 85–90%.

(8) *Cf.* Compton, THIS JOURNAL, **60**, 396 (1938).

Tetraacetyl - β - benzylglucopyranoside.—Acetobromoglucose, 110 g., redistilled benzyl alcohol, 265 cc., dry ether, 250 cc., and dry silver oxide, 60 g., were shaken together till the liquid was bromide free.[9] After filtration and evaporation of ether, the excess benzyl alcohol was recovered for the next run by distillation, bath 95–100° (0.1 mm.). A still head lagged with asbestos tape and at least 1 cm. in diameter, together with efficient cooling (ice water) of condenser and receiver, was necessary. The slightly impure product (75%) after complete purification from alcohol had specific rotations of −53.2° in chloroform and −46.7° in dioxane (*c*, 4.0).

Deacetylation gave pure β-benzylglucopyranoside, m. p. 122° (corr.), with rotations of −56.3° in water, −59.5° in dioxane (*c*, 2.0) and −57.6° in methyl alcohol (*c*, 1.5).

Tetraacetyl-α-benzylglucopyranoside.—The β-isomer, 20 g., titanium tetrachloride, 9 g. (1 mole), and pure chloroform, 200 cc., were heated under reflux for seventy-five minutes and the crude product was isolated by Pacsu's methods.[2] Recrystallization from 100 cc. of hot alcohol gave a first fraction of 15 g. and a second fraction, after dilution of the mother liquors with water, of 5 g., the rotations in chloroform being 141.5 and 38.3°, respectively. As those of the pure α- and β-isomers were 144.8 and −53.2°, the α-contents of the two fractions were 99 and 47%, corresponding to an average of 86% for the α-isomer. In a duplicate rearrangement of 153 g. of the β-tetraacetate, the second fraction, 15 g., was twice recrystallized from alcohol and gave 5 g. of the pure starting material with the correct levorotation of −52.8°. Other experiments are summarized in Table I.

Pure tetraacetyl-α-benzylglucopyranoside, m. p. 111°, had rotations of 144.8° in chloroform and 146.0° in dioxane (*c*, 2.5). Deacetylation gave the pure α-benzyl glycoside with rotations of 133.5° in water, 152° in dioxane (*c*, 2.5) and 150.3° in methyl alcohol, m. p. 122° corr.

(9) Such syntheses have been improved by the addition of Drierite [Kreider and Evans, THIS JOURNAL, **58**, 1661 (1936)].

Benzoylformic Acid from Styrene

BY CHARLES D. HURD, R. W. MCNAMEE AND FRANK O. GREEN

Oxidation of mandelic acid with potassium permanganate is the usual method[1] of synthesizing benzoylformic acid. Yields of 50 to 72% are attained. In place of mandelic acid it has been found that styrene (phenylethylene) may be oxidized in satisfactory yields to benzoylformic acid according to the equation

$$3C_6H_5CH{=}CH_2 + 8KMnO_4 \longrightarrow 3C_6H_5COCOOK + 8MnO_2 + 5KOH + 2H_2O$$

The commercial availability of pure styrene makes this an economical source of benzoylformic acid, whereas mandelic acid is much more expensive. It was established also that crude styrene, which was obtainable from "Drip Oil"[2] by fractional distillation, might be used also in this synthesis.

For some of the work, styrene was prepared by pyrolysis of cinnamic acid.[3] In other experiments, technical styrene[4] was used. This was vacuum distilled before use to remove the inhibitor (*p-t*-butylcatechol) and the polymers. From 3.5 g. of this distilled styrene, 8 g. of styrene dibromide, m. p. 72°, was obtained by reaction with bromine in carbon tetrachloride. The purity of this styrene, therefore, was at least 90%, and probably higher.

Styrene was concentrated from "Drip Oil"[5] for the oxidation experiments by fractionation through an efficient column. The fraction taken, b. p. 141–142°, was about one-half styrene because 2.78 g. of it yielded 3.56 g. of styrene dibromide.

Oxidation of Styrene of 90–100% Purity.—Eighteen grams (0.173 mole) of styrene and 9 g. (0.225 mole) of sodium hydroxide were shaken with 100 cc. of water in a 2-liter flask fitted with an air condenser. To this mixture was added in six portions a hot (70°) solution of 75 g. (0.474 mole) of potassium permanganate in 1500 cc. of water. After each addition the mixture was shaken vigorously for two minutes and cooled under the water tap so that the reaction temperature was kept at about 70°. When all the permanganate had been introduced, the excess was reduced with about 100 cc. of alcohol and the manganese dioxide filtered off and washed with water. The filtrate and washings were combined and evaporated down to 400 cc., then acidified with concentrated hydrochloric acid. The 1.5 g. of benzoic acid which separated was removed by filtration. When the addition of hydrochloric acid failed to precipitate any more benzoic acid the solution was extracted several times with ether. On evaporation of the ether, 20.4 g. of a light yellow liquid remained. This crude benzoylformic acid contained 2 to 3 cc. of water which made it quite insoluble in carbon disulfide. The water was removed by distilling with 7 cc. of toluene. An alternative procedure for removing the water was to dry the ether solution with calcium chloride. The residual acid, 18 g. (0.120 mole) or 69% yield, was dissolved in 30 cc. of carbon disulfide and the solution cooled with ice and salt. About 10 g. of crystals came down in the first crop and 5–6 g. in subsequent crops. Recrystallization gave 14.5 g. (0.096 mole) or 55% yield, of benzoylformic acid which melted at 59–61°.

Oxidation of Styrene of about 50% Purity.—A 26.5-g. fraction, b. p. 141–142°, obtained from drip oil, contained 13.3 g. (0.128 mole) of styrene. The quantities of other reagents were based on the styrene content; hence, 55.5 g. (0.351 mole) of potassium permanganate was used. The experimental details were the same as those outlined previously, but this time no benzoic acid separated after

concentration and acidification. The crude benzoylformic acid was a light yellow oil which weighed 12.6 g. It contained about 2 cc. of water which was removed as before. The crystalline benzoylformic acid obtained after purification weighed 7.5 g. (0.05 mole). This is a yield of 39%, based on the styrene content.

When drip oil fractions were taken which contained only 25% of styrene, oxidation to benzoylformic acid was not satisfactory.

COMMUNICATIONS TO THE EDITOR

THE ENTROPY AND HEAT CAPACITY OF PROPYLENE

Sir:

Recently[1] Powell and Giauque have published measurements of the heat capacity of solid and liquid propylene which enabled them to determine the entropy change from 0°K. to the boiling point. By comparing this result with an entropy value calculated statistically on the basis of certain assumptions, they concluded that in solid propylene there is random end for end orientation of the molecules. This does not seem very reasonable to us *a priori*, inasmuch as one end is flat (CH_2), the other round (CH_3); one leg is considerably longer than the other and less polarizable; and finally the molecule has an appreciable dipole moment.[2] Furthermore their statistical calculations were based on a set of frequencies

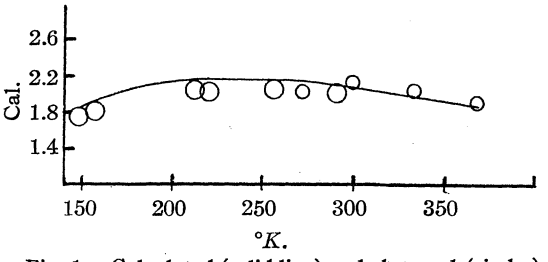

Fig. 1.—Calculated (solid line) and observed (circles) values of torsional heat capacity of propylene gas.

and a potential barrier hindering rotation of the methyl group (700 cal), published by one of us,[3] which are no longer acceptable. These frequencies were estimates obtained by comparison with other molecules, but on carrying the heat capacity measurements to higher temperatures it is found that the original set of frequencies would require a contribution from the internal torsional motion of the methyl group less than the classical value $\frac{1}{2}R$, which is not plausible. Furthermore, an experimental study of the infrared and Raman spectra and a normal coördinate analysis has since been carried out, which, although not yet complete, shows that the estimated frequencies were not satisfactory. The revised frequencies lower somewhat the vibrational entropy at the boiling point, but the main effect is to raise considerably the potential barrier necessary to account for the heat capacity of the gas.

Before the publication of the entropy data we had reached the conclusion that a barrier of about 2000 cal. best fitted the heat capacity measurements when the revised frequencies were used. We have therefore calculated both the entropy at the boiling point and the gaseous heat capacity over a range of temperatures, using a barrier of 2119 cal. and the following frequencies: 432, 580, 921, 940, 1000, 1022, 1100, 1111, 1297, 1399, 1445, 1468(2), 1647, 3000(6) cm.$^{-1}$. Moreover, this calculation was carried out by a method which takes into account the complete dynamics of the molecule, including the coupling of the angular momentum of the top and of the whole molecule. This more complete calculation gave results differing from the values of Pitzer[4] by as much as 19% of the difference between free and hindered rotation. The heat capacities calculated are compared with those observed[5] in Fig. 1. The entropy of the ideal gas at the boiling point (225.35°K.) is calculated to be 59.87 cal., compared with the experimental value of 59.93 cal.

obtained by assuming *no random orientation* in the solid. The agreement is well within the possible theoretical uncertainties and therefore we do not need, on the basis of the available evidence, to make the assumption that the third law breaks down for this substance.

Further details of the measurements on the heat capacities, on the study of the vibration frequencies, and on the method of calculating thermodynamic properties for molecules containing hindered rotators will be published separately. It should be noted that the vibration frequencies used herein are still provisional so that the value 2120 cal. for the potential barrier is not final; it does, however, correlate all the data now available. It further indicates that 59.93 E. U. is the proper value of the entropy at the boiling point.

A PHOTOCHEMICAL PRODUCTION OF REDUCING SUGARS FROM GLYCOSIDES BY ULTRAVIOLET LIGHT

Sir:

Ultraviolet light absorbed by fructosides and glucosides liberates reducing sugars.

A special arrangement of apparatus soon to be published in *Science* made it possible to illuminate aqueous solutions of these glycosides in thermostated quartz tubes where 11 or 12 cc. absorbed about 10^{19} photons of λ 254 mμ per minute. The light flux was measured with the uranyl oxalate actinometer. Portions of the solutions were kept in the dark at the same temperature as the illuminated portions and analyses were made on all portions at the same time and under the same conditions. The ml. of 0.002 *M* sodium thiosulfate entered as hypo in Table I represent the difference between Shaffer–Hartmann–Somogyi (S.–H.–S.) estimations on the dark and illuminated solutions, although the dark reaction was usually negligible. One ml. of hypo was equivalent to 5.6×10^{-5} g. of glucose or 6.1×10^{-5} g. of fructose acid which was reproduced to 0.1 ml. Professor C. B. Purves kindly supplied the glycosides as pure crystals.

Solutions were water white after these photolyses, but the solutions titrated with hypo were sometimes a light amber at the end-point as, for example, in Expts. 3 and 5. Also, strongly photolyzed solutions turned amber after a day or more in the dark at room temperature. The differences in the photochemical efficiencies of the α and β isomers are significant.

The change in the optical activity accompanying the formation of the reducing sugar was measured for solutions of β-benzylfructopyranoside. Rotations of the D lines of sodium were read to 0.02° in a four-decimeter tube at 21.5°.

In a typical experiment, a molar acetate solution at *p*H 3.5 contained 1.8016 g. of β-benzylfructopyranoside in 100 cc. The initial rotation of the solution was −9.45° and the change expected for complete hydrolysis was 5.1° to give a rotation of −4.35°. Three samples illuminated at 10° with light of λ 254 mμ gave observed rotations of −9.00, −8.77 and −8.56°, corresponding to 9, 14 and 18% hydrolysis; and the estimations of reducing sugar gave 9, 13.5 and 18% respectively. The corresponding percentages agree within the limits of error. The calculations based on the S.–H.–S. estimations assumed the

TABLE I

Typical data on glycosides at 0.02 *M* in water; temperature, 23°; volume illuminated, 11 cc.; *p*H of solutions not photolyzed, 6.2; light flux per minute, 8.6×10^{18} photons of λ 254 mμ.

Expt.	Glucopyranosides	*p*H after photolysis	Minutes photolyzed	Hypo, ml.
1	α-Phenyl	3.5	47	6 × 11/5 = 13.2
2	β-Phenyl	3.5	47	8.8 × 11/5 = 19.4
3	α-Benzyl	4.2	64	27.6 × 11/5 = 60.8
4	α-Benzyl	...	30	16.2 × 11/5 = 35.6
5	β-Benzyl	3.7	64	11.2 × 11/2 = 61.5
6	β-Benzyl	...	29	18.2 × 11/5 = 40.0
7	β-(β-Phenylethyl)	4.4	82	7.05 × 11/2 = 38.8
8	β-(β-Phenylethyl) Fructopyranoside	...	32	11.8 × 11/5 = 26.0
9	β-Benzyl	4.5	40	6.4 × 11/2 = 35.0

measured product to be fructose. In the dark reaction α changed to $-9.37°$. These experiments suggest that the main reaction in the photolysis gives the same products as hydrolysis by acids, where the change in α also agreed with the S.-H.-S. estimation of the amount hydrolyzed.

The photochemical efficiency of the measured reaction was independent not only of the light intensity when (5 to 700)10^{16} photons were absorbed per minute by 11 cc. of solution, but also of the *p*H—at least between 3.5 and 6.5. Gross quantum yields were independent of the initial concentration of glycoside but decreased as the liberated alcohol or phenol absorbed a larger fraction of the light incident on the solution.

THE STRUCTURE OF INSULIN

Sir:

As reported at the Baltimore meeting of the American Chemical Society, I have made an electron density projection of the insulin structure using Crowfoot's $hk \cdot O$ x-ray data [D. Crowfoot, *Proc. Roy. Soc.* (London), **A 164,** 580 (1938)] and assuming (incorrectly) that the true projection has a center of symmetry and that the structure proposed by Wrinch and Langmuir [D. M. Wrinch, THIS JOURNAL, **60,** 2005 (1938); *Science,* **88,** 148 (1938); *Nature,* **143,** 763 (1939); D. M. Wrinch and I. Langmuir, THIS JOURNAL, **60,** 2247 (1938); I. Langmuir and D. Wrinch, *Nature,* **142,** 581 (1938)] is a sufficiently close approximation for the determination of the signs of the structure factors. If the latter assumption is correct, the density at each point of the projection is a sort of average of that at the same point in the true structure and that at another point the same distance on the opposite side of the origin.

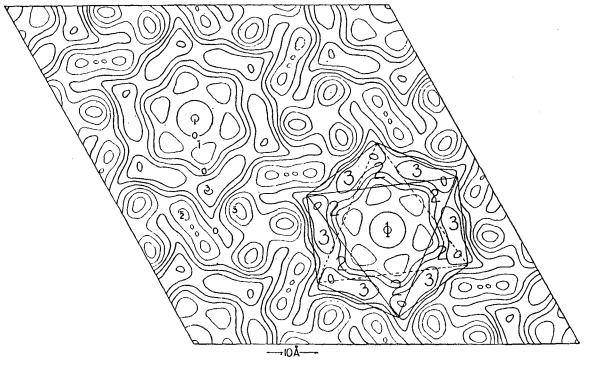

Fig. 1.—Election density projection on (0001), assuming a center of symmetry and that the structure factor signs are as calculated for simplified C_2 octahedron molecules, oriented as indicated.

This projection is here reproduced (Fig. 1), with a projection of Wrinch's "C_2 octahedron," oriented as she has assumed, superimposed. The numbers 1, 2 and 3 designate areas for which one would expect low, medium and high densities, respectively. With a slight change in orientation, the fit is not bad.

It would seem at first that this electron density projection lends support to the hypothesis of a cage or ring molecule or ion of about the size postulated by Wrinch. However, the chief features of the projection depend on the model assumed in deducing the signs of the structure factors. If, for this purpose, one postulates a molecule composed of six point atoms at corners of a regular octahedron, the resultant projection (Fig. 2) shows no indication of a cage structure.

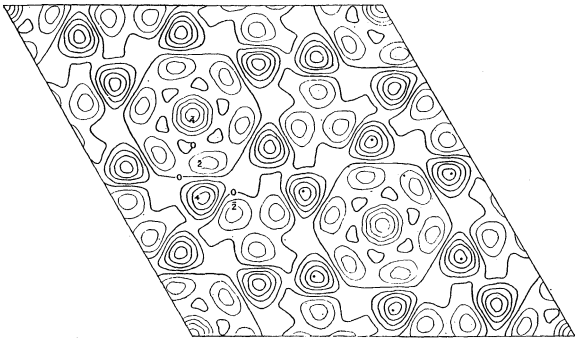

Fig. 2.—Same, except that the structure factor signs are assumed to be as calculated for molecules consisting of six point atoms, distributed as indicated by the dots.

Projections of this sort may prove useful in testing minor features of proposed structures and in suggesting modifications. For example, from Fig. 1 one can deduce that, if the structure contains cage ions even roughly resembling the C_2 cyclol model, the metal ions (Zn) are not at the midpoints of the centerlines joining adjacent cages.

CELLS WITHOUT TRANSFERENCE FOR *p*H DETERMINATION

Sir:

Although methods of routine *p*H-determination have developed rapidly during the last few years, cells with liquid junctions, abandoned in most research work long ago, are still in use. In order to eliminate this source of experimental and theoretical inconvenience Hamer[1] suggested cells of the type

$$H_2, H^+X^- + NaCl, AgCl,Ag$$

The concentration of the sodium chloride added to the solution must, of course, be known and allowed for in calculating the hydrogen ion activity.

For the same purpose we had examined cells of the type

$$H_2, H^+X^- + TlBr(satd.), AgBr, Ag$$

before we had knowledge of Hamer's paper. The solubility of thallous bromide (0.00257 mole per 1000 g. of water at 30°) is high enough to secure a definite potential not influenced by common impurities. On the other hand, the solubility is so low that the activity of the hydrogen ion is practically not altered and the liquid junction potential between a solution containing no thallous bromide and a solution saturated with this salt may be neglected safely. Even this liquid junction might be avoided by saturating with thallous bromide that portion also of the solution which is in contact with the hydrogen electrode.

The applicability of this type of cell is restricted, of course, to solutions which do not form any precipitate when saturated with thallous bromide and do not contain thallous or bromide ions in an amount comparable with the solubility of this salt. In such a case, however, another reference electrode of similar kind may be used, for instance, some organic zinc salt in connection with zinc amalgam or silver sulfate with silver etc.

Applying the usual formula one may obtain from the e. m. f. the quantity $a_{H^+}(\gamma_{Br^-}/\gamma_{Tl^+})^{1/2}$ which is in any case identical with the hydrogen ion activity as far as the principle of ionic strength is valid. In this respect too the method compares not unfavorably with others. This type of cells might prove the most convenient basis of *defining* the term "hydrogen ion activity," which is well known to be arbitrary to some extent.[2]

As we were compelled to interrupt our work on various methods of routine *p*H determination, we wish to offer this suggestion.

(1) W. J. Hamer, *Trans. Electrochem. Soc.*, **72**, 45 (1937).

(2) D. I. Hitchcock [THIS JOURNAL, **58**, 856 (1936)] suggested a different definition of *p*H on the basis of cells without liquid junction and discussed another suggestion made by Scatchard. The general idea of single ionic activities, introduced by Lewis and Randall, has been exhaustively discussed by E. A. Guggenheim (*J. Phys. Chem.*, **34**, 1758 (1930), and previous papers).

NEW BOOKS

Methodik der Hormonforschung. (Methods of Hormone Investigation.) By Dr. Phil. Habil. CHRISTIAN BOMSKOV. **Ovar (Follikelhormone, Gelbkörperhormon), Hoden, Hypophysenvorderlappen.** [Ovary (Follicular Hormone, Corpus Luteum Hormone), Testis, Anterior Pituitary.] Georg Thieme Verlag, Rossplatz 12, Leipzig C 1, Germany, 1939. xxix + 1016 pp. 274 figs. 18 × 27 cm. Price, RM. 89; bound, RM. 91.

The work under review forms a second instalment to the volume which bears the same title, noticed in these columns in September 1937 (p. 1771). In the author's view, the subjects here considered constitute the most modern and successful chapters of endocrinology. They are: estrogenic hormones (264 pages), hormones of corpus luteum (72 pages), androgenic hormones (202 pages), hypophyseal hormones (gonadotropic 280 pages, growth-stimulating 41 pages, thyreotropic 61 pages, lactogenic 23 pages, diabetogenic 7 pages, others of doubtful existence 22 pages). Of these, only the sex hormones at present offer extensive possibilities for chemical consideration.

As in the first volume, the author has performed his onerous task with conscientious thoroughness, and has prepared a survey notable for catholicity rather than critical selectivity. The compilation as a whole suffers at times from a certain lack of balance. For example, two whole pages are dedicated to a detailed description of Butenandt's procedure for the isolation of estrone from palm kernel oil, whereas reference to studies on the effects of sex hormones on the metabolism of cholesterol and of carbohydrate is dismissed in a few lines of literature citations, without a hint as to the nature of these effects.

Typographical errors are relatively scarce, but a few

stand out, particularly among the structural formulas of the androgens. In this connection the hope may be expressed that in future editions the systematic nomenclature of the steroids will be critically scrutinized for inconsistencies, and that the admirable stereochemical terminology proposed by Fieser[1] will be adopted.

However, in a work of this character, susceptibility to criticism of detail is inevitable, and investigators in the hormone field can only be grateful to the author for collecting in one place the wealth of detailed anatomical and physiological information otherwise obtainable only by wearisome search through a scattered literature. A smaller supplement is promised, which is to include "hormone-like" substances such as the anti-anemic principle of liver and the physiologically active compounds of the posterior lobe of the pituitary.

H. T. CLARKE

Ions, Electrons, and Ionizing Radiations. By JAMES ARNOLD CROWTHER, Sc.D., F.Inst.P., Professor of Physics in the University of Reading, Sometime Fellow of St. John's College, Cambridge. Seventh edition. Longmans, Green and Company, Inc., 114 Fifth Avenue, New York, N. Y., 1939. xi + 348 pp. 117 pp. 15 × 22.5 cm. Price, $4.00.

The titles of the different chapters are as follows: I, Introduction; II, The Passage of a Current through an Ionized Gas; III, The Properties of the Gaseous Ions; IV, The Charge on an Ion; V, Ionization by Collision—The Spark Discharge; VI, The Phenomena of the Discharge Tube; VII, Cathode Rays and Positive Rays; VIII, Emission of Electricity by Hot Bodies; IX, Photo-Electricity; X, X-Rays; XI, The α-Rays; XII, The β- and γ-Radiations; XIII, Neutrons, Positrons, Cosmic Radiation; XIV, The Physics of the Nucleus; XV, The Structure of the Atom; XVI, Radioactive Changes; XVII, Radium and its Products.

While the section on cosmic rays and the chapter on the nucleus have been rewritten and very considerably enlarged, it is to be regretted that this procedure has not been used in connection with the other chapters. The result is that many important general references to more recent literature have been omitted, and in some cases statements in one section, copied from previous editions, have not been modified to agree with those made in another section, which are based on the results of more recent investigations. This criticism applies especially to statements about the value of e, the charge on the electron.

The Bohr–Sommerfeld model of the atom is discussed in some detail, but in spite of the fact that the experiments on electron diffraction are mentioned (rather briefly, and not in the same chapter) the author has dismissed the wave mechanical treatment of atomic structure as "beyond the scope of this volume." A discussion of the "electron cloud" model would have added considerably to the value of the book, especially since it can be done without the use of any difficult mathematics. Furthermore, such a discussion would have helped to clarify the remarks on the wave mechanics interpretation of nuclear phenomena given in Chapter XIV.

Since the book is frankly intended to be an elementary introduction to the field of atomic physics, the author is to be commended for his clear and concise description of the methods used in the determination of fundamental physical constants and of the experiments upon which are based our present concepts in atomic physics. However, it would seem to the reviewer that the whole presentation could have been improved considerably by a rearrangement of the material. For instance, the chapter on atomic structure would logically follow that on X-rays. Moreover, certain sections in some chapters could have been inserted, with much better effect, in other chapters.

The binding and printing of the book are fine, and with the exception of inconsistencies in numerical values, mentioned above, there are very few misprints or errors, as far as the reviewer could find.

SAUL DUSHMAN

Pharmacie Galénique. (Galenic Pharmacy.) By A. GORIS and A. LIOT. Volumes I–II. Masson et Cie., Éditeurs, 120 Boulevard Saint-Germain, Paris VI, France, 1939. xvi + 1917 pp. Illustrated. 17 × 25 cm. Price, fr. 390; bound, fr. 450.

The comprehensive scope of this work can best be realized from the chapter headings, which are:

Vol. I. History of Pharmacy
- Medicaments, Aliments, Poisons, Selection and Preservation of Crude Drugs
- Composition of Vegetable Substances
- Assay of Drugs and Pharmaceutical Preparations
- Medicaments Prepared from Substances in their Natural State without any Previous Treatment
- Medicaments Obtained after Previous Treatment of the Crude Drugs
- Medicaments Obtained by Division
- Operations Employing Heat
- Operations Employing a Solvent

Vol. II. Medicaments obtained by Solution and Evaporation
- Soluble Ferments
- Organotherapy (Endocrine Glands)
- Vaccinotherapy
- Serotherapy
- Bacteriotherapy (fermented milk, yeast, etc.)
- Pharmaceutical Preparations Devised to Mask the Taste of the Medicaments Administered in Definite Dosage
- Medicaments to be Applied to the Mucous Membrane
- Medicaments for External Use
- Dressings (for wounds)
- Sterilization
- Disinfection
- Administration and Action of Medicaments, Incompatibilities
- Alteration and Preservation of Medicaments

From the above chapter headings it is readily seen that these volumes include much more than Galenical Pharmacy

which the title indicates. As stated in the preface, the authors have purposefully omitted bibliographies on the various subjects as the treatise is intended for students and pharmacists rather than the research worker.

The authors have drawn upon commercial pharmaceutical companies and hospitals for many of their illustrations of apparatus. Their illustrations (microscopic) of powdered vegetable drugs are excellent. The illustrations of the endocrine glands in color are also very good.

In general, the subject matter does not adhere as closely to the preparations of the Codex as seems to be the practice of most similar American texts in respect to the U. S. P. and N. F.

The presentation of the chemical relationship of various types of compounds is a very desirable feature. Thus the chemical similarity of the sex hormones, the chemical relation of vitamin A to carotene, the chemical formulas for the cardiac glycosides and the ergot alkaloids serve as examples. However, in the case of the last-named group of compounds, the discoverer of ergostetrine is given as John Hopkins instead of Marvin R. Thompson.

The discussion of the vitamins is excellent but may be criticized from the standpoint of not being entirely up-to-date. Thus no mention is made of vitamin B_6, or the identity of the pellagra-preventative factor with nicotinic acid. Under vitamin D, the reader is given the impression that irradiated ergosterol is practically the only source of this vitamin. No mention is made of the various dehydro derivatives of cholesterol which are now definitely known to have marked antirachitic properties.

The reviewer feels that these volumes furnish an excellent text for students of pharmacy and a good reference for practicing pharmacists with the exception of at least one phase of the subject, *viz.*, the vitamins, in which they are not up-to-date.

F. W. HEYL

Gärungschemisches Praktikum. (Experimental Fermentation Chemistry.) Second edition. By Dr. CONRAD BERNHAUER, Professor in the German University in Prague. Verlag von Julius Springer, Linkstrasse 22–24, Berlin W 9, Germany, 1939. xx + 317 pp. 40 figs. 14.5 × 22.5 cm. Price, RM. 15; bound, RM. 16.50.

Introduction of new material and new references has made the second edition 68 pages longer than the first. The main portion of the book consists of fifty-six fermentation experiments on yeasts, bacteria, and molds. Methods for isolation and quantitative determination of fermentation products and intermediary compounds are given. Qualitative and quantitative experiments on the alcoholic, lactic, propionic, butyl, and cellulose fermentations are included. Oxidative fermentations by the acetobacter group and by the molds are well covered. Directions are given for the isolation and culture of many of the organisms used. The probable mechanism of each of the fermentations also is discussed. The literature references are pertinent and fairly complete.

An introduction, a chapter on methods, and an appendix deal with general chemical and bacteriological methods and with industrial aspects of fermentation.

While the book as a whole contains much more practical information than any other work on fermentation of comparable size, it is, of course, not free from errors. Many of these obviously result from describing, as laboratory experiments, procedures which have been taken almost bodily from the literature and have not been tested as laboratory exercises. For example, on page 165 the directions for ether extraction of lactic acid say merely that 100 cc. of culture is to be extracted with ether. Only the well-informed reader will know the *p*H, method, and time of extraction. In the experiment on the ethyl alcohol–acetone fermentation (page 204) the reader is told to determine ethyl alcohol by oxidation to acetic acid, but nowhere in the book is such a method described.

In addition there are many cases where improper procedures are specified. A few examples will be given from the experiment on the acetone–butyl alcohol fermentation (Experiment 29). Fermentation gases for analysis are collected over carbon dioxide-saturated water. Since the fermentation gas contains approximately 40% hydrogen, roughly 40% of this dissolved carbon dioxide will be carried out by the evolved gases. In Experiment 29a, this error would make the apparent volume of carbon dioxide produced about 35% too high.

Acetylmethylcarbinol is determined on a distillate which contains only 80% of the total quantity of this product. The statement is made that under the conditions of the acetone determination, acetylmethylcarbinol reacts with 16 atoms of iodine, whereas the correct value is 6 atoms. In the exercise on isopropyl alcohol formation, grain mash is used as a medium. The reviewer knows of no isopropyl alcohol-forming organism that will grow well on such a medium.

The book is a valuable addition to the literature of fermentation, and presents in convenient form a large number of procedures and numerous references which should be very useful to the fermentation chemist. The experimental procedures given are reliable in outline, but the reader is cautioned against applying them without first consulting the original literature.

M. J. JOHNSON

Micromethods of Quantitative Organic Elementary Analysis. By JOSEPH B. NIEDERL, Ph.D., Associate Professor of Chemistry, and VICTOR NIEDERL, Teaching Fellow, New York University, Washington Square College. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1938. xvi + 267 pp. 53 figs. 15.5 × 24 cm. Price, $3.00.

The statement taken from the preface that "this book is primarily a laboratory manual for teaching and practicing the methods of quantitative organic microanalysis of pure organic compounds under ordinary laboratory conditions" makes clear the purpose of this book, and the following chapter headings will indicate its scope. The Microchemical Balance; Weighing on a Microchemical Balance; Miscellaneous Weighing Equipment; Miscellaneous Laboratory Utensils; Preparation and Weighing of a Sample for Analysis; Determination of Metals and Residues; Determination of Neutralization Equivalent; Volumetric Determination of Aminoid Nitrogen; Gasometric Determination of Nitrogen; Determination of Carbon and Hy-

drogen; Determination of Halogens; Determination of Sulfur; Determination of Phosphorus; Determination of Arsenic; The Determination of the Molecular Weight by (1) The Ebullioscopic Method (2) The Cryoscopic Method (3) The Vaporimetric Method and (4) The Osmotic Method; Determination of Alkoxy and Alkimide Groups; Determination of Acetyl Groups; Determination of Active Hydrogen; The Teaching of Quantitative Elementary Organic Microanalysis; Installation of a Laboratory for Organic Microanalysis; General Microchemical Literature and Calculations.

Organic microanalysts should be grateful to the authors for their inclusion and extension of the Nitrogen Reduction Table of Küster-Thiel. The measurement of nitrogen is often carried out above the temperature of 24°, the upper limit of the Küster-Thiel tables, consequently the extension of the table to 36° is particularly welcome.

The present book, together with the English translation of the latest edition of Pregl, should do much to spread the use of microanalytical methods in organic chemical laboratories.

The Oscillation Frequencies of Nitrites

BY DUDLEY WILLIAMS

In a recent article Penney and Sutherland[1] have surveyed the existing data on the vibrational frequencies of triatomic molecules and triatomic groups occurring in more complex molecules and have determined force constants and angles by the valence-force-field and central-force-field approximations. A comparison of results obtained through these approximations with the results obtained in cases where more detailed analyses were possible, showed that in the majority of cases the valence-force-field is more satisfactory than the older approximation involving central forces. Values for the angles as obtained by the valence-force method agreed with the accepted values to within 10%, while the discrepancies in the values obtained by the central-force method were sometimes larger.

However, in the case of the nitrite ion neither approximation gave satisfactory values for the force constants. It was found that the valence-force-field equation for the angle had no real solution. Although the central-force-field equations gave a reasonable value for the angle, they yielded improbable values for the force constants, the oxygen–oxygen force constant appearing larger than the nitrogen–oxygen force constants. Since the valence-force approximation gave satisfactory results for other triatomic systems with the same number of valence electrons, Penney and Sutherland suggested that further experimental work on the nitrites might be desirable.

(1) W. G. Penney and G. B. B. M. Sutherland, *Proc. Roy. Soc.* (London), **156**, 654 (1936).

It was the object of the present investigation to obtain additional data on the oscillation frequencies of the nitrites through a study of their infrared spectra in the region of the fundamentals. Previous studies of the infrared absorption of nitrites have been made by Maslakowez[2] and by Bailey and Thompson,[3] while Raman studies of nitrites have been reported by Langseth and Welles,[4] by Carrelli, Pringsheim and Rosen,[5] by Bar,[6] and by Dadieu, Jele, and Kohlrausch.[7] The results obtained by these authors are summarized in Table I.

The experimental methods employed in the present study are essentially the same as those reported previously.[8] Solutions of sodium nitrite and potassium nitrite (3 N) were studied and the results obtained are shown in Fig. 1. In this figure the "relative absorption factors" as defined in the previous article[8] are plotted as a function of wave length.

As one may see from the figure, three absorption maxima were observed in the spectrum of each nitrite. In the spectrum of sodium nitrite the positions of the maxima are 7.6, 8.2, and 13.3 μ, while the potassium nitrite bands appear at 7.7, 8.2, and 13.4 μ. The shapes of the absorption

TABLE I

PREVIOUS STUDIES OF THE NITRITE GROUP

Observed frequencies, cm.$^{-1}$	Compounds	Method	Observer
1380 1240	Potassium nitrite crystal	Infrared	Maslakowez
1330 1392 1127 and 1220 707 834	Sodium nitrite crystal	Infrared	Bailey and Thompson
1331 1240 813	Sodium nitrite solution	Raman	Langseth and Welles
2151 1303 785 696	Sodium nitrite solution	Raman	Carrelli, Pringsheim, and Rosen
1333	Powdered sodium nitrite	Raman	Bar
1324 1220 814 715 655 588	Sodium nitrite solution	Raman	Dadieu, Jele, and Kohlrausch

bands of the two solutions are similar except in the case of the low-frequency band. The sodium nitrite band at 13.3 μ has an asymmetry not observed in the corresponding potassium nitrite band; the reason for this difference is not clear. As the three bands shown are the only ones observed between 5 and 16 μ, it is assumed that they arise from fundamental vibrations of the nitrite group. The two sets of fundamentals arising in the crystal reported by Bailey and Thompson[3] apparently are replaced by a single set when the nitrite ion is in solution. The agreement between the present data and the infrared data of Bailey and Thompson seems better than the agreement between independent Raman investigations. Two Raman lines for solutions (814 and 655 cm.$^{-1}$) apparently have no counterparts in the infrared spectrum.

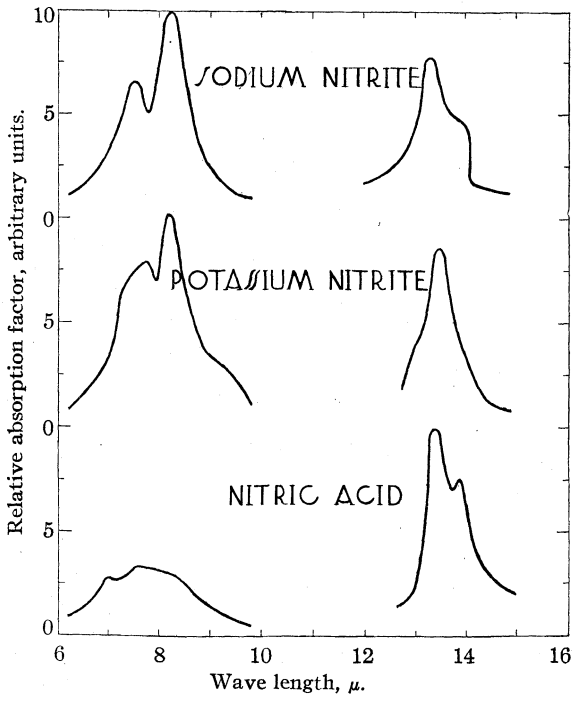

Fig. 1.

In assigning the observed frequencies to the normal vibrations of the nitrite ion there are essentially only two possible choices as it is probable that the lowest frequency arises from the "bending" vibration ν_2. Since the other frequencies are so nearly equal, there is no obvious choice for ν_1, the "central" vibration, and ν_3, the "nonsymmetrical" vibration. Therefore, it was decided to test both the assignments given below in the equations arising from the valence-force and central-force fields.

	ν_1	ν_2	ν_3
Assignment I	1320	750	1220
Assignment II	1220	750	1320

Frequencies are given in cm.$^{-1}$

The valence-force-field relations in the form used in the present work are

$$k_{NO} = mM\nu_3^2/(M + 2m\sin^2\alpha/2) \quad (1)$$

$$k_\alpha = m\nu_1^2\nu_2^2 d_{NO}^2 (M + 2m\sin^2\alpha/2)/\nu_3^2(M + 2m) \quad (2)$$

$$m(\nu_1^2 + \nu_2^2) = [k_{NO}(M + 2m\cos^2\alpha/2)/M] + [K\alpha(M + 2m\sin^2\alpha/2)/M\,d_{NO}^2] \quad (3)$$

where m is the mass of the oxygen atom, M is the mass of the nitrogen atom, α is the angle at the nitrogen, d_{NO} is the nitrogen–oxygen internuclear distance, and the k's are the indicated force constants. From these equations α can be determined by means of a cubic equation in the square of the sine of the half angle. When the observed frequencies are introduced, it is found that neither I nor II gives a real solution for the angle, a result indicating that the valence-force-field is an unsatisfactory approximation for the nitrite group. However, it was decided to assume angles of reasonable magnitude and use these in determining k_{NO} and k_α from (1) and (2). Since other similar groups were found by Penney and Sutherland[1] to have angles between 90 and 130°, these limiting angles were used. The value of 1.13 Å. for d_{NO} is taken from the X-ray data of Zeigler,[9]

(9) G. E. Zeigler, *Phys. Rev.*, **38**, 1040 (1931).

who gives 130° as the value for α in sodium nitrite crystals. The results obtained with the valence-force-field are shown below:

	Assumed angle	k_{NO} dynes/cm.	k_α dyne-cm./radian
Assignment I	90°	6.6×10^5	5.3×10^{-11}
	130°	4.8	7.4
Assignment II	90°	7.9	3.6
	130°	5.8	5.0

The values for k_{NO} are all considerably lower than the corresponding values for other comparable groups, while the values for k_α are all considerably higher. The use of Assignment II and 90° seems to give results more nearly similar to the values obtained for the other groups studied by Penney and Sutherland. However, since the equations yield no real values for α, little emphasis can be placed on this choice.

The central-force-field relations used in the present study are

$$k_{NO} = m\nu_3^2/[1 + (2m/M)\sin^2\alpha/2] \quad (4)$$

$$k_{OO} = mM\nu_1^2\nu_2^2[1 + (2m/M)\sin^2\alpha/2]/2\nu_3^2(M + 2m)\cos^2\alpha/2 \quad (5)$$

$$m(\nu_1^2 + \nu_2^2) = 2k_{OO} + k_{NO}[1 + (2m/M)\cos^2\alpha/2] \quad (6)$$

where the symbols have the same significance as in the first set of equations. When the Assignments I and II are introduced, it is found that I yields two real solutions for α, 86 and 100°, while II leads to no real solutions. Use of Assignment I with the two values for α leads to the following values for the force constants:

	Angle	k_{NO}, dynes/cm.	k_{OO}, dynes/cm.
Assignment I	86°	6.9×10^5	4.3×10^5
	100°	5.9	5.5

Since it is to be expected that k_{NO} is considerably greater than k_{OO}, the α value 86° seems to be the better choice.

Although 86 and 100° are the angles obtained from the central-force-field equations, the angle as determined from X-ray measurements[9] is 130°. Therefore a computation of force constants was made with this angle substituted in (4) and (5). The results are as follows:

	Assumed angle	k_{NO} dynes/cm.	k_{OO} dynes/cm.
Assignment I	130°	4.9×10^5	16.2×10^5
Assignment II[a]	130°	5.8	10.8

[a] When an angle of 90° is assumed, Assignment II gives the force constants: $k_{NO} = 8.0 \times 10^5$, $k_{OO} = 2.8 \times 10^5$ dynes/cm.

Since k_{OO} in each case is much larger than k_{NO}, it is believed that 130° is too large an angle, if the actual force field of the nitrite group at all resembles the central-force approximation. As stated above, Zeigler's X-ray studies were made with sodium nitrite crystals, and it is possible that the angle undergoes a considerable change when the salt is dissolved.

Summarizing the above results, one finds that neither assignment of frequencies is wholly satisfactory on the basis of a valence-force approximation, but that the assumption of an angle of 90° leads to more satisfactory values than the 130° angle obtained from X-ray measurements. With the central-force approximation, Assignment I gives 86° as the value of the angle. Force constants computed for this angle are satisfactory, whereas those based on an angle of 130° are unsatisfactory. Comparison of the force constant k_{NO} with the corresponding force constant of comparable molecules shows that it is relatively smaller, while the constant k_{OO} is relatively greater. Table II gives a comparison of nitrogen dioxide, the nitro group, and the nitrite ion.

TABLE II

CHARACTERISTIC FREQUENCIES, FORCE-CONSTANTS, AND VALENCE ANGLES IN NO_2 GROUPS

Group	ν_1 cm.$^{-1}$	ν_2 cm.$^{-1}$	ν_3 cm.$^{-1}$	α	k_{NO} 10^5 dynes/cm.	k_{OO} 10^5 dynes/cm.
Nitrogen dioxide	1370	640	1620	109°	9.78	3.15
The nitro group	1380	480	1560	106°	9.50	1.56
The nitrite ion	1320	750	1220	86°	6.87	4.31

The last curve in Fig. 1 represents the absorption spectrum of a 65% solution of nitric acid. One might expect the spectrum of this solution to show a marked similarity to the spectra of the nitrates reported previously.[8] Actually, the observed spectrum shows more similarity to the nitrite spectra than to those of other nitrates. Concentrated nitric acid solutions have a region of absorption extending from 6 to 9 μ, and there is evidence of several unresolved bands in this region. It is probable that a part of this absorption may arise from vibrations of the undissociated nitric acid molecule. Raman data which are in agreement with this hypothesis have been reported by Dadieu, Jele, and Kohlrausch,[7] who suggest that the nitric acid molecule has the form HO·NO_2, where the NO_2 group has inner vibrational frequencies of 454, 1300, and 1625 cm.$^{-1}$, the corresponding frequencies of nitro groups in ali-

phatic compounds being 480, 1380, and 1560 cm.$^{-1}$. If this interpretation is correct, the complex absorption bands observed near 13.4 μ may arise from an outer vibration involving OH and NO_2 groups. Although the spectrum of nitric acid has no direct connection with the nitrites, it was included in the present paper, since it can possibly be interpreted in terms of a related NO_2 group.

Summary

The infrared absorption spectra of sodium nitrite and potassium nitrite have been studied between 6 and 16 μ and absorption bands have been observed at 7.6, 8.2, and 13.3 μ. These bands are interpreted as arising from fundamental vibrations of the nitrite group. Force constants and valence angles of the nitrite group are computed by means of the central-force-field approximation. The valence-force-field proves to be an unsatisfactory approximation for the nitrites. The spectrum of nitric acid is discussed.

Viscosity Relationships of Aqueous Solutions of Sodium Oleate and Various Phenols

BY RALPH G. D. MOORE[1]

Weichherz and Saechtling[2,3] in a viscometric investigation of the system sodium oleate–phenol–water observed the occurrence of viscosity maxima at certain ratios of sodium oleate to phenol, indicating the formation of complexes between these substances. The authors did not consider them to be definite chemical compounds, but rather a loose association of the soap micelle with the phenol. The present paper presents a more extended study of this phenomenon, with the object of ascertaining how far it is characteristic of phenolic substances.

Attempted verification of some of Weichherz and Saechtling's results showed general qualitative agreement but considerable quantitative discrepancy, the present values for viscosities, especially in the region of lower water content, being without exception higher, sometimes of another order altogether. Comparison of the viscosities of solutions of sodium oleate prepared from oleic acid of varying degrees of purity (*cf.* Table II, expts. 1, 2, 3, 4) indicates that the cause of this lack of agreement lies in the relative degree of purity of the two specimens of sodium oleate in question, since Weichherz and Saechtling used Kahlbaum "reinst" (I), while the present author used samples (II) prepared from oleic acid which had been purified rigorously by a method analogous to that later described by Brown and Shinowara.[4] Illustrative of these discrepancies are the following examples.

Solutions of a concentration of 10% or higher in sodium oleate II were found to be metastable at 20°, slowly increasing in viscosity and finally crystallizing, in striking contrast to the reported investigations of Weichherz and Saechtling on solutions containing up to 30% sodium oleate. In a similar manner the viscosities obtained in the present investigation for the ternary system containing phenol were higher than the corresponding values of Weichherz and Saechtling, the former showing, for 90% water content, a maximum of over 1000 cp. at 20°, while in the case of the latter the value was about 17. For the system with 95% water the latter investigators could find no maximum, whereas in the present work the maximum at this concentration was well marked. In addition, the acid soap separation reported by the earlier investigators for this system was not observed, even after keeping the solution for several days. This heterogeneity was only observed (together with the absence of maxima in the viscosity isotherms) when the solutions containing 97% water were examined.

In order to determine whether the ability to cause maxima in the viscosity–concentration isotherms of sodium oleate solutions is a property common to all phenols, the following carefully purified materials have been examined: guaiacol, *p*-cresol, creosol, catechol, resorcinol, *p*-hydroxybenzyl alcohol, vanillyl alcohol, *o*-bromophenol.

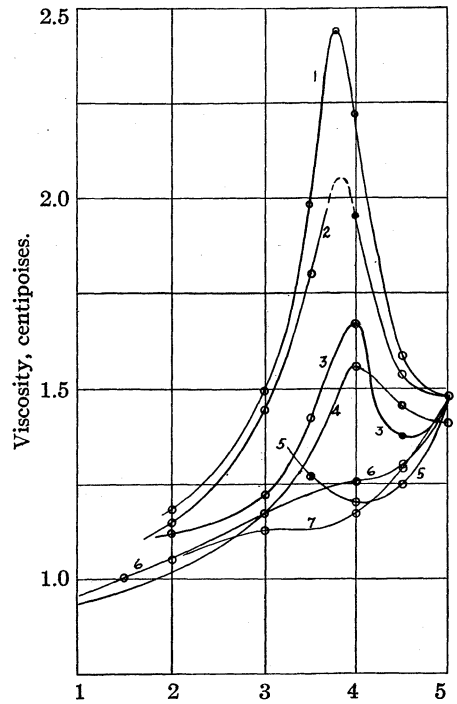
Percentage by weight of phenolic substance or sodium oleate.

Fig. 1.—Viscosity isotherms at 30° of sodium oleate–phenolic substance–90% water: 1, *p*-cresol; 2, creosol; 3, guaiacol; 4, phenol; 5, resorcinol; 6, vanillyl alcohol; 7, *o*-bromophenol; 8, catechol.



Percentage by weight of phenolic substance or sodium oleate.

Fig. 2.—Viscosity isotherms at 30° of sodium oleate–phenolic substance–95% water: 1, *p*-cresol; 2, creosol; 3, guaiacol; 4, phenol; 5, catechol; 6, vanillyl alcohol; 7, resorcinol.

In addition, a few measurements were made at critical concentrations on vanillin and *p*-hydroxybenzaldehyde. The results of this investigation are to be found in Table II. A comparison of the various substances is given in Figs. 1 and 2, in which the 30° isotherms are selected as being more accurate and eliminating to a large extent the difficulty occasionally encountered in obtaining equilibria at 20° within a reasonable time.

Of all the materials examined, *p*-cresol showed the most marked effect, maximum viscosity at 20° of the system containing 90% water being in the neighborhood of 100–200 poises. As shown by the curves for guaiacol and creosol the effect of introducing a methoxyl group ortho to the hydroxyl was very slight, shifting the position of the maximum slightly to the left of the maximum for the corresponding unmethoxylated phenol, but not affecting the height of the maximum to a very marked extent.

The above four substances produced outstanding effects on the viscosity of sodium oleate solutions containing both 90 and 95% water. In the case of the solutions containing 90% water the effect of catechol was of the same order, but the maximum caused by its isomer resorcinol was much smaller, besides being displaced toward the sodium oleate axis. The same was true for *o*-bromophenol. At 95% water content, on the other hand, none of these compounds caused a maximum in viscosity.

The other phenols investigated, such as vanillyl alcohol, *p*-hydroxybenzyl alcohol, vanillin and *p*-hydroxybenzaldehyde (Table II, expts. 98–102) showed no sign of a maximum even at 90% water content. It is thus clear that the property under investigation is not common to all substances containing a phenolic hydroxyl group.

Regarding the cause of the maxima, little can be added to the speculations of Weichherz and Saechtling.[2] An interesting comparison is obtained by an examination of the electrolytic dissociation constants of some of the phenols used, as given in the "International Critical Tables" (Table I). While complete agreement between the order of the constant and the occurrence and size of the viscosity maxima does not exist, it

appears that the greater the degree of electrolytic dissociation of the phenol, the less is the effect produced on the viscosity–concentration isotherms of sodium oleate–water systems.

TABLE I

ELECTROLYTIC DISSOCIATION CONSTANTS[5]

Substance (Order of decreasing effect on viscosity isotherms)	$K_{25°}$
Phenol	1.06×10^{-10}
p-Cresol	1.1×10^{-8}
Catechol	3.2×10^{-10}
Resorcinol	6×10^{-7}
(*o*-Chlorophenol	3.6×10^{-8})
p-Hydroxybenzaldehyde	1.63×10^{-6}
Vanillin	4.72×10^{-6}

This observation does not support the theory advanced by Weichherz and Saechtling, namely, that the formation of acid soaps, which in the more dilute solutions is preceded by the phenomenon of a maximum viscosity, is a minor cause of the latter. For if the effect produced varies *inversely* as the acidity of the phenols, other things being equal, the formation of acid soaps cannot be a contributory factor to the occurrence of maxima.

Since this work was carried out, an article has appeared by Angelescu and Ciortan[6] which describes the effect of the three isomeric cresols on the viscosity of sodium stearate solutions. The phenomena observed were similar to those which form the basis of the present paper, in that all three isomers caused maxima in viscosity which were affected greatly by the temperature. The authors correlate the observed phenomena with the dielectric constants and electric moments of the three cresols.

Experimental

Apparatus.—Few changes were made in the apparatus of Weichherz and Saechtling.[3] For the thermostat, manual control of electrolytic heating (1% lead acetate solution, lead electrodes) was used and found very satisfactory. Constancy of temperature to within 0.05° was not difficult to maintain during measurements. The thermometers used were graduated in tenths of degrees and calibrated by the Thüringische Landesamt für Mass und Gewicht (1928). The viscometers were of the Ostwald type, of sufficient range of flow time to permit rapid and accurate measurement of viscosities up to 100 cp.; in the following, all values for viscosity are relative to that of water at 20°. Densities were determined by means of a Westphal balance, the tube containing the solutions being jacketed with an electrically heated water-bath.

(6) Angelescu and Ciortan, *Kolloid Z.*, **82**, 164 (1938).

Preparation of Materials.—All compounds examined were purified rigorously by redistillation, recrystallization, or other standard procedures. In some cases it was necessary to resort to synthesis to obtain pure materials. A few of the more pertinent details are recorded below.

All oleic acid used was prepared from olive oil by saponification and subsequent partial purification by the lead salt–alcohol method.[7] Final purification was effected by repeated crystallization from a 30–40% solution in 95% ethanol at −30°. Raymond[8] used a similar procedure, and since completion of the present work the suitability of the method has been confirmed by the results of Brown and Shinowara.[4] After three or four recrystallizations the product was an oil with a very pale yellow tinge, m. p. 12–13°, which yielded on vacuum distillation a water-white material of the same m. p. While undoubtedly not 100% oleic acid,[9] this product probably was far purer than that used by Weichherz and Saechtling.[2,3]

The sodium salt, prepared by treating the acid with an equivalent amount of sodium, both first being dissolved in absolute ethanol, was stored in well-stoppered bottles in a desiccator after drying under reduced pressure at 60° over phosphorus pentoxide. Calculated for $C_{17}H_{33}COONa$: Na, 7.56. Found: Na, 7.49.

The *p*-hydroxybenzyl alcohol was obtained without difficulty from *p*-hydroxybenzaldehyde by application of the general method of Adams.[10,11]

Preparation of Solutions and Measurement of Viscosity.—After drying in the Abderhalden pistol under reduced pressure at 60° for at least twelve hours, over phosphorus pentoxide, the sodium oleate was weighed by difference into a stoppered Pyrex flask and dissolved in the calculated amount of air-free, doubly-distilled water at 50°. After the salt had dissolved the calculated amount of a phenol was added and the mixture kept at 50° until equilibrium was attained. Finally the solution, unless perfectly clear, was filtered by air pressure through a prewarmed Jena glass filter, placed in a stoppered flask in the thermostat, and allowed to remain there at 20°.

The usual precautions regarding choice of a viscometer were observed. If accurate filling at 20° was impracticable because of the high viscosity of the solution, it was carried out at 60°, making the necessary correction for difference in density. The mean of five measurements was recorded as the time of flow, except when this was impracticable due to extremely high viscosity. Readings were taken at 20, 30, 40, 60, and 80°, allowing a suitable interval before taking readings for the solution to reach thermal equilibrium. Density measurements were made on the balance of the solution over the same temperature range. To conserve space these values are not recorded with the rest of the data in Table II.

The writer wishes to express his appreciation to Professor H. Hibbert, in whose laboratories this work was carried out, for much helpful advice and criticism, and to acknowledge the assistance

[a] Expts. 1, 11 and 2, 12 were made, respectively, with two different lots of sodium oleate prepared from two lots of oleic acid purified by low temperature recrystallization. The material used in expts. 1 and 11 was used throughout Section A and in Section F, expts. 65–70 inclusive. All other expts. were carried out with the material used in expts. 2 and 12. [b] Sodium oleate was prepared from oleic acid purified by the Skellon barium salt method. [c] Sodium oleate was prepared from a sample of commercial acid.

of Mr. Q. P. Peniston in the preparation of some materials used.

Summary

1. Using a more rigorously purified sodium oleate, earlier observations on the occurrence of maxima in the viscosity of sodium oleate:phenol:water systems have been checked qualitatively but not quantitatively, the present results indicating the maxima to be even more pronounced than previously reported.

2. On extending the investigation to other phenolic substances it was found that not all produced such maxima in the viscosity of sodium oleate solutions. The effectiveness of *p*-cresol, guaiacol and creosol in this regard was of the same order as that of phenol, but in the case of catechol, resorcinol and *o*-bromophenol the maxima were not so marked or even, at lower concentrations of sodium oleate, non-existent. Vanillyl alcohol, *p*-hydroxybenzyl alcohol, vanillin and *p*-hydroxybenzaldehyde did not increase the viscosities of the solutions of sodium oleate examined.

3. Evidence is adduced against Weichherz and Saechtling's[2] theory that the formation of acid soaps is a minor cause of the observed maxima in viscosity.

The Degradation of Oriented Cellulose Structures by Polarized Ultraviolet Light

BY C. W. MASON AND F. B. ROSEVEAR[1]

Introduction

The photochemical changes produced in cellulose have received attention since Witz[2] in 1883 reported that cotton when exposed to light was changed, in part at least, to "oxycellulose." Although the exact nature of "oxycellulose" can only be inferred at present, and although some reported experiments may have been complicated by effects other than that of light, nevertheless, it appears that a certain portion of the ultraviolet region does produce physico-chemical changes in the cellulose structure.

The structure of cellulose shows very definite differences in properties, depending upon the direction considered. This is indicated macroscopically by its pronounced fibrous nature, microscopically by its strong double refraction, as well as the production of tiny fibrillae by mechanical treatment, and sub-microscopically by the X-ray deduction of its atomic arrangement.

It is reasonable to expect, then, that the anisotropic properties would include the photochemical

(2) Witz, *Bull. soc. ind. Rouen*, II, 190 (1883).

effect, providing the radiation can be rendered directional in those properties which have to do with its photochemical action.

A directional effect of this sort has been found with potassium nitrate and other nitrates. Narayanswamy and Krishnan[3] noted that in the photochemical breakdown of NO_3^- to NO_2^- in K, Na, NH_4, Sr, Ba, Cd, Pb, and Al nitrates, the rate of decomposition with plane polarized light was greater if the plane of vibration of the light was parallel to the plane of the NO_3^- groups.

The pleochroism of sodium nitrate and potassium nitrate in the ultraviolet, investigated earlier by Krishnan and Dasgupta,[4] supports the observations on decomposition. A selective absorption at about 3000 Å. occurs in solutions of sodium and potassium nitrates. With crystals and plane polarized light, this band is evident if the light is vibrating parallel to the plane of the NO_3 groups, while light vibrating perpendicular to the plane of the NO_3 groups is freely transmitted. A similar effect is noted at about 2600 Å.

Padoa[5] observed that the rate of photochemical decomposition of crystalline *o*-nitrobenzaldehyde, in polarized light, differs with the direction of vibration of the light. Weigert[6] found a similar effect, with tetrachloro-α-cetonaphthalene.

Experimental

I. Selection and Preparation of Cellulose.—Ramie was used, for X-ray evidence indicates that in ramie the molecular chains are not only parallel to each other, but essentially parallel to the fiber axis, rather than spiral as in many fibers.[7-10]

"Degumming" of ramie, following the mechanical "decortication," is accomplished commercially by a wide variety of methods,[11,12] so that even though some available samples of commercial ramie sliver gave a very low copper number, indicating high purity of their cellulose, it was thought best to follow a known procedure, as follows:

Raw, dried, decorticated ramie was: (1) extracted three times with boiling water; (2) refluxed for fifteen-minute periods with three changes of 1% sodium hydroxide; and (3) washed successively with water, 5:95 acetic acid, 1:99 acetic acid, 95% alcohol, absolute alcohol, and ether. The resulting product was free from the yellowish-brown color of the raw ramie. It showed a copper number of 0.10–0.12 as compared to a value of 0.08 for the commercial sliver.

II. Production of Plane Polarized Ultraviolet Light.—Preliminary exposures beneath ordinary glass, Pyrex, and vitreous silica, using Harrison's reagent[13] as a staining test, indicated that only the latter material had sufficient transmission (below 3300–3400 Å.) to permit marked degradation.

A. The Light Source.—The features of the quartz-enclosed mercury vapor arc as well as others are discussed in the First Report of the Committee on Photochemistry, National Research Council.[14] The mercury spectrum, while not continuous, has a rather large number of lines of high intensity distributed throughout the ultraviolet region. As the light source for the experiments, a Hanovia "Advanced Research Model" SC2601-A (110 volts, D.C.) quartz-enclosed mercury arc was used. This lamp gives an arc 6–7 cm. long and about 1 cm. in section.

Decrease in intensity of the arc with age was not found to cause trouble during the exposures. After some 1700 hours, the radiations still had a pronounced photochemical effect on cellulose, and the bulb showed no visible coating, or serious spectral alteration. The fact that the samples for light vibrating perpendicular and parallel to the fibers were run simultaneously renders unimportant any decrease other than a virtual elimination of the active wave lengths, and also any fluctuations in intensity.

B. The Polarizer.—Maximum cross section of the illuminating beam was necessary, to irradiate a quantity of fibers sufficient for analysis. For this and other reasons, polarizing prisms were inadequate; polarizing filters absorb ultraviolet completely.

The polarizer, based on the "pile of plates" principle, was constructed as follows. Two sets of eight polished vitreous silica plates (25 × 50 × 1 mm.) were cleaned carefully, piled face to face and the edges of the piles coated with warm "Piceine." This material when warmed was sufficiently fluid to adhere to the edges of the plates, without creeping between them, and on cooling served to hold the plates together, and to prevent reflection at their edges, because of its blackness and optical contact with the glass. When placed side by side, the two piles composed a reflector 50 × 50 × 8 mm., which was mounted in a duralumin frame so that the incident and reflected beams travelled parallel to the plane separating the two 8-plate halves of the polarizer.

It was found by measurement that the use of more than eight or ten plates added little to the quantity of reflected plane polarized light. A similar conclusion was reached regarding a "pile of plates" polarizer for microscopes.[15]

For the wave length range between 3400 Å. (the approximate upper limit of the spectral region active in degrading cellulose) and 2000 Å. (the approximate transmission limit of vitreous silica) the refractive index of vitreous silica varies from 1.479 to 1.547, corresponding to a variation in polarizing angle of only ±0.5°. By reflection at the polarizing angle of 56°, all wave lengths in the region will be almost completely polarized, over a 1° range.

Reasonably perfect and economical collimation was obtained by means of a set of narrow, flat, blackened, metal plates lying parallel to the length of the arc and to the direction of the desired light beam (see Fig. 1, p. 10). This produced three parallel channels for the light, 4 mm. wide and 120 mm. long, so that a ray of light from any point on the arc to the polarizing plates deviated not more than 2° from the desired 56° angle of incidence. A collimated beam of light 35 × 75 mm. in cross section was thus obtained.

Due to displacement by the multiple reflection, the polarized beam varies from a maximum intensity on one side, to minimum on the other. This non-uniformity and the difference in intensity between the center and the ends of the beam were taken into account by turning the exposure cell end for end each day, and also in the method of sampling.

III. Method of Exposure.—While the nature of the photochemical degradation of cellulose is by no means clear, it is also true that any observed degradation might be due in part to chemical influences, non-directional in effect.

Cunningham and Doree[16] found that ozone, when passed over cotton fabric, changed it into "oxycellulose." Oguri[17] exposed filter paper to light from a quartz mercury vapor arc, and found that the copper number was definitely lower when ozone was eliminated. Joachim-Henk,[18] and Barr and Hadfield[19] consider the presence of oxygen to be essential, and the action of ultraviolet light one of oxidation. Cunliffe[20] also showed the importance of oxygen and moisture.

Obviously, the *secondary* actions upon cellulose of ozone, hydrogen peroxide, acids, or other products would be wholly independent of the plane of vibration of the incident radiation, and if the primary action of light were to be studied, these complicating factors should be minimized.

An airtight cell, shown in Fig. 1, was used. A duralumin frame formed three chambers, each designed to take a 25 × 50 mm. vitreous silica slide as front window and a glass microscope slide as back window. In each chamber a glass plate carried a thin layer of parallel fibers of purified ramie, half oriented parallel to the vibration direction of the polarized light, and the other half perpendicular to the vibration direction. All the fibers were drawn over the ends or sides of the supporting plates and held in place at the back by a very small amount of glue. Sodium wire in each chamber served to remove oxygen, ozone, water, and carbon dioxide from the air left in the fibers and in the cell after sealing it, and also volatile reaction products of the degradation.

After extruding the sodium wire into each compartment the back windows of the cell were sealed with Apiezon-Q (Shell Oil Co.), a sealing plastic of very low vapor pressure, which can be used like putty. The tightness of these seals was indicated by the fact that during the runs of 500 hours or more, the only change in the sodium was some clouding of the surface; an excess of metallic sodium was present throughout the runs.

Before irradiation, two days' time was allowed for removal of the oxygen, carbon dioxide, and water from the air and fibers in the cell.

With this cell, it was found possible to irradiate a total sample of about 0.1 g., in layers only a few fibers thick.

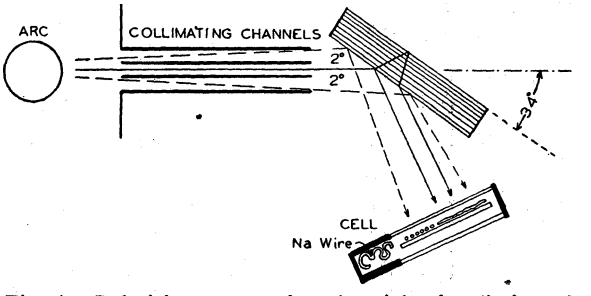

Fig. 1.—Polarizing system for ultraviolet irradiation of fibers.

The fibers present a series of parallel, roughly cylindrical surfaces, on each of which the beam is incident at every angle from perpendicular to grazing incidence. Penetration of light is less efficient than with a plane surface; with polarized light the penetration of light varies, depending upon whether the light vibrates parallel or perpendicular to the axis of the cylinders.

Elimination of reflection factors by immersion in a medium transparent to ultraviolet of appropriate refractive index would introduce prohibitive chemical complications. Consequently the fibers were exposed directly, and a correction computed as follows.

In the method of exposure used, light vibrating lengthwise of the fiber (n_γ) vibrates perpendicular to the "plane of incidence" (the plane containing the incident and refracted rays); light vibrating crosswise of the fiber (n_α) vibrates in the plane of incidence. The first case involves more loss by reflection.

For a plane surface, Fresnel developed mathematical expressions relating the quantity of incident, reflected and transmitted light for each case.[21–23] Vibrations perpendicular to plane of incidence:

$$b = -a\frac{\sin(i - r)}{\sin(i + r)}$$

$$c = 2a\frac{\cos i \sin r}{\sin(i + r)}$$

Vibrations in plane of incidence

$$b = -a\frac{\tan(i-r)}{\tan(i+r)}$$

$$c = \frac{2a\cos i \sin r}{\sin(i+r)\cos(i-r)}$$

Since light intensity is proportional to the square of the amplitude

$$I_a:I_b:I_c = a^2:b^2:(c^2 \tan i \cot r)$$

where a, b, and c are the amplitudes of the incident, reflected, and refracted beams, I_a, I_b, I_c the corresponding intensities, and i and r the angles of incidence and refraction, respectively. The term, tan i cot r, is applied to the refracted beam, to take into account the refractive index of the medium[21] (p. 93) which the light is entering.

For a *cylindrical* surface, i varies from 0 to 90° on either side of perpendicular incidence. Hence, by evaluating the term c^2 tan i cot r in terms of a^2 and summing over the angular range 0 to 90°, values for the intensity of refracted (penetrating) light, in terms of the incident intensity, are obtained.

For light vibrating perpendicular to the plane of incidence (n_γ)

$$I_c \text{ is proportional to } \int_0^{\frac{\pi}{2}} a^2 \frac{\sin 2i \sin 2r}{\sin^2(i+r)}\,di$$

For light vibrating in the plane of incidence (n_α)

$$I_c \text{ is proportional to } \int_0^{\frac{\pi}{2}} a^2 \frac{\sin 2i \sin 2r}{\sin^2(i+r)\sin^2(i-r)}\,di$$

These summations were evaluated graphically. The intensity terms were calculated for several angles of incidence, the values being recorded in Table I and plotted in Fig. 2.

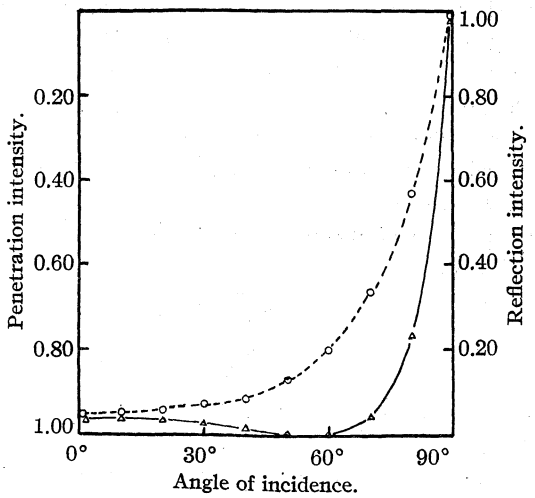

Fig. 2.—Intensity of penetration and of reflection of light, as a function of angle of incidence.

TABLE I

CALCULATED VARIATION IN INTENSITY OF REFRACTED BEAM WITH ANGLE OF INCIDENCE

i	I_c for light vibrating lengthwise (n)	I_c for light vibrating crosswise (n)
0°	0.952	0.956
10°	.948	.957
20°	.942	.963
30°	.930	.973
40°	.908	.984
50°	.870	.995
60°	.800	1.000
70°	.663	0.959
80°	.436	.765
90°	.000	.000

In calculating values for the first column, the refractive index used was $n_\gamma = 1.568$, for the second column, $n_\alpha = 1.530$, both values for 5893 Å. The corresponding refractive indices in the ultraviolet are not known, but the absorption spectrum of cellulose does not exhibit any marked bands that might indicate anomalous dispersion, and comparison of Fig. 2 with a similar published diagram for crown glass ($n = 1.523$)[24] will show that refractive index variations of the magnitude involved make practically no difference in the shape and position of the curves.

Since the value of (c^2 tan i cot r) for $i = 0°$ is indeterminate, it must be obtained from the relationship $a^2 = b^2 + c^2$ tan i cot r and Young's equation[21] (p. 352). No data on possible ultraviolet pleochroism of cellulose fibers have been determined, but even if this exists it is unlikely that the differences in the absorption coefficient for the two orientations would have sufficient influence on the reflection factor to render these curves inapplicable, especially since the absorption of cellulose is relatively low in the spectral region used.

If the total area of the graph represents one intensity unit of incident light, the curve divides this area into the relative amounts penetrating (above) and reflected (below). By planimetry the areas above the curves are: 0.77 for light vibrating parallel to n_γ, 0.91 for light vibrating parallel to n_α.

Thus, the fibers oriented parallel to the vibration direction of the incident light were penetrated by only 0.77/0.91 or 0.85 as much light as those lying perpendicular. The degradation values for fibers in the latter orientation were therefore reduced by the factor, 0.85.

(24) Hardy and Perrin, "Principles of Optics," McGraw-Hill Book Co., New York, N. Y., 1932, p. 28.

Actually, the effective penetration, for vibrations either crosswise or lengthwise of the fibers, is probably greater, because of imperfections in their assumed cylindrical surfaces, and because adjacent fibers may absorb some light that would otherwise be lost by the first reflection. The difference in penetration may therefore be somewhat less than the factor 0.85 indicates.

V. Determination of Amount of Degradation.—Of the common criteria for evaluating the degradation of cellulose, copper number was selected, as the most adaptable to the very small samples available.

A critical survey of methods up to 1931 is given by Burton and Rasch.[25] Doree[26] summarizes several methods which are in favor in the textile industry. Probably the most important variation from the original method is the elimination of strongly alkaline Cu^{++} solution containing tartrate, in favor of a solution made alkaline with Na_2CO_3–$NaHCO_3$ as proposed by Braidy[27] and Koehler and Marqueyrol.[28]

Amick[29] concludes that the copper number method for evaluating glucose is too much subject to variations in conditions to have any significance in expressing structural changes in glucose, but if conditions are fixed rigidly, analytical results can be duplicated.

Results on cellulose likewise can be duplicated if conditions are maintained comparable, but where variations in the history and condition of sample as well as differences in conditions of the experiments are introduced, absolute interpretations are not justified. The chief value of the copper number determination is in making comparisons of an empirical nature.

Heyes[30] gives a micro-method for copper number, which requires 0.25 g. By modifying the Heyes method, sufficiently accurate checks could be obtained on 0.01 g. of exposed ramie, permitting several determinations on the 0.1-g. samples.

The method finally adopted follows.

Solutions used were:

A. Carbonate-bicarbonate: 150 g. anhydrous sodium carbonate, 50 g. anhydrous sodium bicarbonate in 1 liter of solution.

B. Copper sulfate: 100 g. $CuSO_4 \cdot 5H_2O$, in 1 liter of solution.

C. Ferric sulfate: 4 g. $Fe_2(SO_4)_3$ and 100 cc. concd. sulfuric acid per liter of solution.

D. Sulfuric acid for washing: H_2SO_4:H_2O = 1090. (Solutions C and D as well as all distilled water used, were boiled free of air to minimize the possibility of oxidation of cuprous oxide.)

E. Standard potassium permanganate solution: approximately 0.004 *N*.

Such a low normality was chosen by experiment since it gave, for the sample weight used, the best compromise between a high buret reading and a sharp end-point. The solution was standardized against sodium oxalate, according to the method of Fowler and Bright.[31]

0.009–0.011 g. of the fibers in cuttings about 1 mm. long, were weighed into a dry 15 × 15 cm. test-tube; moisture "regain" was slight enough to be negligible. To this was added 10 ml. of digestion mixture (9.5 ml. solution A and 0.5 ml. of solution B) which had been preheated in a boiling water-bath for ten minutes previously. A stirring rod with a bent lower end, and short enough not to protrude, was inserted into each test-tube. A small glass crucible in the mouth of the tube served as a reflux condenser. The tube was supported in the boiling water-bath so that the digestion mixture was completely below the level of the liquid, and with the aid of forceps to grasp the rod, its contents were stirred gently (in order to avoid beating in air) every ten minutes for three hours.

Ten minutes before the close of the digestion period, the stirring rod was removed, and the carbonate adhering to it was washed into a sintered glass filtering funnel.

When the three-hour digestion was complete, the tube was cooled in cold tap water for five minutes, and the supernatant liquid poured into the filter funnel. The fibers were washed once with 3 cc. of distilled water, by decantation, and the washings added to the digestion liquor. To the washed fibers 1 ml. of ferric sulfate solution C was added, rinsing down the sides, and the tube of fibers was replaced in the water-bath for five minutes. During this time almost all of the digestion liquor was filtered with suction, leaving just enough in the funnel to cover the few fibers present. To the funnel, arranged over a filtering bell jar, and covered with a watch glass, was added 2 ml. of 10:90 sulfuric acid from a pipet. (It is important that all the residual alkali be destroyed by this step, as it was found that local neutralization of the next solution containing Fe^{++} ions precipitated ferrous hydroxide, which is very susceptible to oxidation.)

The Fe^{++}–Fe^{+++} solution was transferred to the funnel, and filtered into a 25-ml. Erlenmeyer flask under the bell jar; the fibers in the test-tube and funnel were washed with 1 ml. of ferric sulfate solution, then with three 2-ml. portions of 10:90 sulfuric acid, and finally with water.

Titrating was done promptly with the 0.004 *N* potassium permanganate, using a micro-buret with a drawn-out tip, which delivered a drop of 0.014 ml. volume.

The end-point is a colorless solution produced by neu-

(25) Burton and Rasch, *Bur. Standards J. Research*, **6**, No. 4, 603–19 (1931).

(31) Fowler and Bright, *Bur. Standards J. Research*, **15**, 493 (1935).

tralization of the faint blue color of the solution with the excess potassium permanganate. Further potassium permanganate produces a pink tint. Since all of these colors are very faint, the titration was carried out by artificial light with a Daylite glass filter, in a screened compartment. Comparison was made with distilled water containing one drop of potassium permanganate solution, and with an untitrated copper number solution. With such control, the end-point could be duplicated to plus or minus one drop (±0.014 ml.).

The ferric sulfate solution proposed by Heyes was too concentrated for this titration, masking the faint end-point with a yellow-green color. The solution used contained one-tenth as much ferric sulfate.

A micro-buret which did away with the troubles of lubricating a stopcock of small bore, and which delivered a drop of 0.014 ml. volume was improvised as follows. A 1-ml. graduated pipet was drawn out in a flame to a finer tip. This buret was then clamped vertically, a thin-walled rubber tube fixed to the upper end, and passed down to the desk top and under a weighted roller, by the movement of which liquid could be drawn up or expelled.

The blank for the determination was obtained on 10 cc. of digestion mixture without fibers, going through the actual procedure from the first filtration on. Three drops of potassium permanganate were required to produce the colorless end-point, this being equivalent to 0.04 ml., a value which was deducted from all final buret readings. On the basis of a 10-mg. sample, the blank was equivalent to a copper number of 0.11–0.12.

$$\text{Cu no.} = \frac{\text{ml. of } KMnO_4 \times \text{Normality} \times 0.0635}{\text{Weight of sample in grams}}$$

The accuracy obtainable is indicated by the following values on ramie sliver after exposure through vitreous silica, without the polarizer

15 hours: (at 15 cm. distance) 0.658, 0.637, 0.647, 0.555, 0.643.
10 hours: (at 15 cm. distance) 0.513, 0.580, 0.582.
7 hours: (at 5 cm. distance) 3.68, 3.58, 3.68.

Results

The first run of five hundred and thirty-five hours of irradiation, gave rather erratic results for the determination of copper numbers:

Vibrations lengthwise (n_γ)
0.316, 0.317, 0.254, 0.265, av. 0.29
Vibrations crosswise (n_α)
0.373, 0.269, 0.487, 0.257, 0.572, av. 0.39
Average, corrected by reflection factor 0.85 = 0.33

The inconsistency of these results is ascribed to poor samplings of the fibers, and to partial reoxidation of hydroxide as mentioned in the analytical procedure. In a second run, care was taken to avoid this by acidifying before adding Fe^{+++} solution to the cuprous oxide-stained fibers, and better mixing of the sample was obtained by agitating the cuttings of fibers by an air jet.

The second run, lasting eight hundred and forty hours, yielded more consistent copper numbers.

Vibrations lengthwise (n_γ)
0.37, 0.41, 0.33, 0.32, av. 0.36
Vibrations crosswise (n_α)
0.56, 0.67, 0.60, 0.49, 0.43, av. 0.55
Average corrected by reflection factor 0.85 = 0.47

Longer exposures, giving large copper numbers, would have emphasized the difference in degradation with orientation. (Measured by the amount of degradation, eight hundred and forty hours of exposure to the rather weak polarized light used was roughly equivalent to less than fifteen hours exposure to unpolarized light at 15 cm. distance.)

The exposed material might have been divided into fewer and larger samples for analysis, minimizing the error in the determination, but it was thought that, in view of the lack of high precision of the method, a larger number would be more significant, if they showed a consistent trend. This is certainly the case in the second run, for although the values show a considerable spread, none of the results for one orientation overlap those for the other, and the increase in copper number is roughly proportional to the longer time of irradiation.

The evidence presented for the greater photochemical degradation by light vibrating crosswise of the fibers, although definite, is only qualitative. The optical complexity of the specimen, so different from the transparent plane parallel surfaced ones ordinarily used in photochemical experiments, the non-uniform distribution of illumination and penetration, the probable presence of cellulosic material not oriented parallel in the fiber—all these factors would tend to minimize the difference of degradation for the two orientations, so that the observed difference of approximately 25% is far from insignificant.

Discussion

Photochemical action is initiated by absorption of light energy. For any substance, inorganic or organic, where absorption arises from the arrangement of atoms in a fixed structure such as a molecule or crystal lattice, the absorbed activating energy is very probably applied to deformation of this structure. If the light energy is polarized, the direction of maximum deformability should be that of strongest absorption, and of most pronounced photochemical action, as was found in the photolysis of inorganic nitrates.[2-4]

Cellulose is believed to be built up of "glucose residues," chained end to end by a hemiacetal

linkage, as in cellobiose. The molecules are arranged parallel to the fiber length; lateral spacings between chains are relatively great. In agreement with Wooster's[32] and Bragg's[33] generalizations, the highest refractive index is found for vibrations lengthwise of the chain structure. Greatest deformability, and the consequent maximum photochemical degradation, should take place crosswise of the chains, since their length and parallelism would prevent lengthwise deformation.

It is generally accepted that photochemical degradation of cellulose fibers results in shortened chain length with an increase in reducing and acidic properties due to the breaking of oxygen linkages, and a consequent increase in copper number. Comparisons of chain length by viscosity, etc., were not feasible on the small samples irradiated, but the chemical changes observed correspond to those to be expected from the above process, if the light energy by virtue of its transverse vibrations breaks some of the oxygen links in the cellulose chain.

The present work illustrates qualitatively the generalization that the properties of crystalline matter differ with direction, a factor that should never be ignored in dealing with ordered structures. With the recent development of methods for producing oriented aggregates of other long chain compounds such as oils, the study of the anisotropic photochemical properties of their molecules becomes possible.

Acknowledgment.—This work was carried out under a Fellowship supported by the Procter and Gamble Company. The authors are also indebted to E. B. Ashcraft for valuable advice.

Summary

Using a silica "pile of plates" polarizer, to give polarized ultraviolet light, parallel ramie fibers were irradiated, in a cell containing metallic sodium, to eliminate air or moisture that might cause secondary non-directional reactions. With light vibrating crosswise of the fibers, degradation was greater than with vibrations lengthwise, by about 25%, as measured by copper number determined on 10-mg. samples. From analogy with simpler compounds, it is concluded that photochemical degradation of cellulose chains is greatest if they are oriented so that the light energy vibrates in the direction in which they are most deformable.

A Simple Wet Combustion Method for the Determination of Carbon, Oxygen Equivalence and Empirical Formula by Iodic Acid Oxidation*

BY BERT E. CHRISTENSEN AND J. FRED FACER

More work pertaining to organic combustions has been described in the literature than perhaps any other single analytical procedure. The fact that so much attention has been devoted to this determination testifies to its importance. The problem of determining carbon and hydrogen has been approached in several ways.[1–6] In spite of all these developments there is still need for simpler techniques, less expensive equipment and methods by which the occasional determination can be made with some degree of ease.

A study of the means by which the above problem may be answered leads to one possibility, the wet combustion process. This would entail the measurement of "oxygen consumed" as an alternative for the determination of moisture. Dichromate and iodate have been cited as excellent reagents for this purpose. Of these iodate is outstanding[7] since little, if any, decomposition (unless carried out above 200°) or carbon monoxide formation accompanies its reduction.

A survey of the literature reveals that Strebinger[8]

was among the first to use iodate in this connection. He determined the oxygen requirement of an organic compound and from this and the known carbon and hydrogen content he calculated the percentage of oxygen in the compound. Later Stanek and Nemes[9] used this same reagent to determine not only the "oxygen consumed," but in addition the carbon dioxide evolved. The hydrogen content was calculated from the "oxygen consumed" plus other values by means of rather complicated equations.

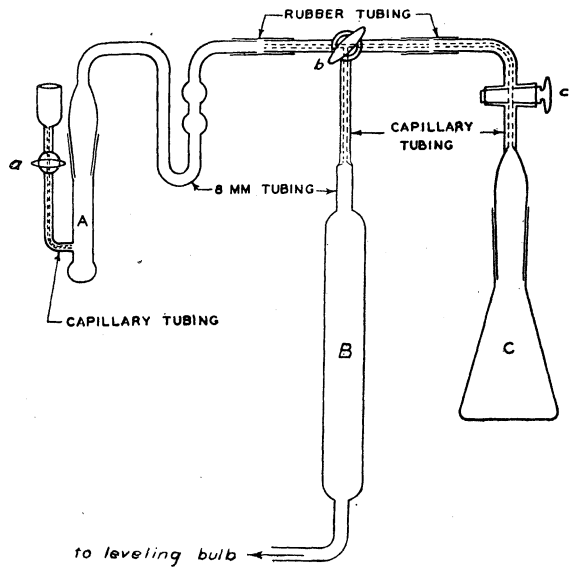

Fig. 1.

Williams[10] also has pointed out the importance of being able to determine the amount of oxygen required for complete combustion of organic material. He has developed this idea and in his paper on "Oxidation Equivalent Analysis"[11] describes a simple method for the determination of molecular structure based only on "oxygen consumed" and molecular weight data. The success of this method, however, hinges upon a fairly accurate means of obtaining the molecular or equivalent weight of the compound in question.

It was the opinion of the authors that the ideas presented by Williams could be much further utilized as a tool for the determination of molecular structure. Such an objective would only require the development of a simple procedure for the determination of carbon dioxide evolved from the reaction mixture. Due to the nature of the evolved gases (CO_2, I_2, Cl_2) it is apparent that a gravimetric method, such as described by Stanek and Nemes[9] for the determination of carbon dioxide, would not be as desirable as a volumetric procedure. For this reason a modified Pettenkofer method[12] using a volumetric principle was devised.

Apparatus.—This apparatus is illustrated diagrammatically in Fig. 1. The reaction vessel A (total volume 20 ml.) was constructed from no. 15 standard taper joint and a capillary stopcock. The gas reservoir B consisted of a three-way stopcock, a 100 ml. buret and a leveling bulb. Mercury was used as the confining fluid. The reaction flask for the analysis of carbon dioxide was designed from a 250-ml. Erlenmeyer flask, a no. 20 standard taper joint and capillary stopcock.

Procedure.—The conditions for iodate oxidation are described adequately in the literature.[8,9,11] The analysis as modified for measurement of carbon dioxide is very simple.

The reaction vessel is charged with 10–20 mg. of organic material[13] and sufficient potassium iodate to constitute approximately 100% excess[14] and the system flushed with carbon dioxide free air.

Closing capillary stopcock a, the three-way stopcock b is then opened so as to permit the flow of emitted gases into the gas reservoir which is maintained at a slight vacuum by means of the leveling bulb.

The carbon dioxide flask is then charged with 10 ml. of approximately 0.25 *N* barium hydroxide, partially evacuated, and then connected to the other arm of the three-way stopcock.

Three ml. of pure concentrated sulfuric acid (carbon free) are now introduced into the reaction vessel by means of the stopcock a. The charge is now ready for combustion.

By means of a phosphoric acid bath[15] the temperature of the reaction chamber is kept at approximately 190 ± 5° for twenty to forty minutes. The gases which are generated during this time pass through the U-tube containing approximately 1 ml. of concentrated potassium iodide solution, to the gas holder B. By operating stopcocks b and c the carbon dioxide is readily transferred to the reaction flask C.

At the end of the heating operation stopcock a is opened and 5 ml. of 50% sulfuric acid (to decrease the free air space) is introduced. The gas which has accumulated in gas reservoir B is then transferred to reaction flask C.

An Ascarite tower is now connected to the apparatus

(13) Samples such as hydroquinone which are rapidly oxidized in the cold by iodic acid can be treated successfully by first wetting the sample with a drop or two of 50% sulfuric acid before introducing the concentrated acid. The presence of a platinum boat in the reaction mixture should be avoided since it apparently catalyzes the decomposition of iodate.
(14) One milli-equivalent of oxygen will completely oxidize 2 mg. of paraffin, 7.5 mg. of glucose, or 4 mg. of benzoic acid. From the nature of an unknown compound one can approximate in most cases the iodate requirement with sufficient accuracy as to make a preliminary oxidation unnecessary.
(15) Christensen and King, *Ind. Eng. Chem., Anal. Ed.*, **9**, 194 (1936).

through stopcock a, and sufficient air (carbon dioxide free) is flushed through the system to sweep all the carbon dioxide into the evacuated flask C, bringing it to atmospheric pressure.

Determination of Carbon Dioxide.[16]—The flask C is now removed and allowed to stand for twenty minutes. Ten ml. of water and 5 ml. of acetone (to improve end-point) are then added and the excess barium hydroxide is *neutralized* to the thymol blue end-point. In order to give as sharp a change as possible 0.8 *N* hydrochloric acid is added at the rate of approximately one-half drop per second. When within about 0.3 to 0.4 ml. of neutrality, 0.05 *N* acid is used to establish the end-point. In case of oxidation of an unknown compound the 0.8 *N* hydrochloric acid required can be approximated sufficiently for this purpose so as not to introduce any complications.

To prevent the diffusion of air into the flask during titration, a rubber sheet (such as is used for dental dam) was fitted loosely over the mouth of the flask. The tip of the buret was inserted through a small hole in the rubber. This arrangement kept out the air without complicating the procedure whatsoever.

Having *neutralized* the excess barium hydroxide, the solution containing the barium carbonate precipitate is then made slightly acid to methyl red with a known amount of 0.05 *N* hydrochloric acid. In order to ensure removal of the last traces of carbon dioxide, the solution is boiled for five minutes. The amount of standard acid required to neutralize the barium carbonate can now be determined accurately by back titration with 0.05 *N* sodium hydroxide to the methyl red end-point. From these data the amount of carbon dioxide evolved can be computed.

Preliminary experiments using either carbon dioxide evolved from sodium carbonate or direct titration of solutions of sodium carbonate consistently gave high values for recovered carbon dioxide. This constant deviation was found to depend on quantity of precipitate and was thought to be due primarily to the apparent adsorption of barium hydroxide by the barium carbonate. In order to avoid using a blank, the hydrochloric acid was standardized with the carbon dioxide (evolved from either sodium carbonate or from the combustion of succinic acid) by means of the above procedure.

Determination of Oxygen Consumed.—The reaction vessel A is removed and the mixture transferred to a 1-liter Erlenmeyer flask, then diluted to approximately 100 ml. and steamed until disappearance of the iodine color. Sufficient sodium carbonate to neutralize about all but 1 ml. of the concentrated sulfuric acid is now added. Two grams of potassium iodide are introduced and the solution is then titrated with 0.1 *N* sodium thiosulfate. This measures the excess iodate.

The amount of iodate used was found to be consistently greater than the theoretical due to traces of organic matter in the sulfuric acid and to thermal decomposition. This necessitated the use of a blank which amounted to 0.90 mg.

(16) This procedure was later modified as follows: 10 ml. of standard barium hydroxide was measured by automatic pipet and introduced into vessel C. The amount of carbon dioxide absorbed was determined by titrating the excess barium hydroxide with 0.05 *N* hydrochloric acid to thymol blue end-point. The same precautions such as use of rubber sheet, acetone, etc., were taken here as in the case of the titration of barium carbonate.

Discussion and Results

The results of a number of typical runs are tabulated in Table I.

Calculation of Hydrogen.—Having determined both the percentage of carbon and the oxygen requirement of the compound, the percentage of hydrogen can be calculated readily from the equations of Strebinger

$$\% \text{ H} = \frac{(\%O_R + 100 - 11/3\% \text{ C})}{8.93}$$

where O_R is the oxygen requirement in grams per hundred grams of sample. With compounds containing other elements in addition to carbon, hydrogen and oxygen, these calculations can be applied to the residue after correcting for such elements.

Determination of the Empirical Formula.—From the above data it is possible to make some very interesting calculations. By way of illustration one may take a specific case in which the following designations can be used

$C_xH_yO_z$ = formula of unknown
M = molecular weight
N = number of atoms of oxygen required to oxidize one molecule of compound
E = grams oxidized by 1 gram atom of oxygen

then

$$M = \frac{12\,x}{\%\text{ C}} \qquad M = NE$$

$$NE = \frac{12\,x}{\%\text{ C}} \qquad \frac{N}{x} = \frac{12}{\%\text{ CE}} = R$$

$$N = Rx$$

Since N and x are integers, there must be one integer which multiplied by R will give the other integer. The possible integers (which fit this equation) can be ascertained rapidly with a slide rule.

Suppose that from the analysis of an unknown compound (benzoic acid) one obtains the following data: E = 8.12 (8.14 calcd.), % C = 69.3 (68.8 calcd.). Calculating the value of R we obtain 2.13. This would give x and N the possible integral values listed below.

x	N	M[17]
7	14.92	122
8	15.05	138
15	32.00	260

Which value of x, N and M is the correct one can be established readily by means of the Diophantine equations derived by Milne[10] in which

(a) $y = (6N - M + 22z)/2$
(b) $z = (M - 6N + 2y)/22$
(c) $x = (M - 2N - 18z)/8$

(17) M is always an even integer except in the case of odd molecules.

x, y, z, N and M are integral values. Below are listed the values of y and z derived from equations (a), (b), and (c).

Value of x	Corresponding value of z	Corresponding value of y
7	2	6
8	2.22	4
15	4.23	10

It is evident that the formula can be none other than $C_7H_6O_2$.

In certain cases where molecular weight is large or where considerable error is made in the determination of either E or percentage carbon, several *possible* solutions may be obtained. Even under these rather adverse conditions it is still possible to determine the correct formula. In such cases differences in chemical behavior, the determination of molecular or equivalent weights are a direct aid in determining the correct solution.

With the percentage carbon and "oxygen consumed" data it is also possible to ascertain the nature of the errors made during a determination (such as incorrect weights, wet or partially dehydrated samples, incomplete combustion) merely from the nature of carbon to oxygen ratios which are obtained.

Other Applications.—On many occasions it is only necessary to determine the percentage carbon to serve as a check on the purity of a preparation. For such purposes this method is especially adaptable, particularly on the micro scale. Furthermore, certain compounds which are not completely oxidized at 200° can be treated successfully at a higher temperature. In such cases

oxygen equivalent data may be obtained by the dichromate method.

Limitations.—The one limitation to this method is the use of iodic acid as an oxidizing agent. Not all compounds are completely oxidized by this reagent at 200°. The literature, however, reveals that a great many compounds can be oxidized successfully by iodic acid under conditions here specified.

In the case of compounds with high molecular weights, the determination of the molecular formula has the same limitations in accuracy as do the traditional combustion methods.

The question of compounds containing nitrogen, sulfur and halogens has not yet been investigated in this Laboratory. However, both Strebinger, and Stanek and Nemes have oxidized successfully a number of such compounds with iodic acid. It is the opinion of the authors that the presence of nitrogen, halogen, or sulfur in an organic compound which can be completely oxidized should offer no complications to the method here described.

When one considers (1) the simple apparatus, (2) adaptability of the procedure to intermittent operation, (3) the amount of information derived from a single analysis, and (4) rapidity of analysis (less than two hours), it is evident that this method offers at least a partial solution to an important organic technique.

Summary

A simple apparatus for the determination of oxygen equivalence and percentage carbon by means of iodic acid oxidation has been described.

A modification of the Pettenkofer method for the determination of carbon dioxide has been devised.

Equations have been derived by means of which the empirical formula of an organic compound can be established readily from the data supplied by the above method.

Fluorinated Aromatic Mercurials

BY MELVIN F. W. DUNKER AND EDGAR B. STARKEY

The preparation and properties of some fluorinated aromatic mercurials are described. These compounds have been tested for antiseptic activity and the results are reported in detail elsewhere.[1]

The direct mercuration of fluorobenzene by refluxing in glacial acetic acid with mercuric acetate yielded about 10% of *o*-fluorophenylmercuric chloride. The mercuration of *p*-fluorophenol with mercuric acetate in water at room temperature yielded a monomercurial assumed to have the mercury ortho to the hydroxyl since *p*-chlorophenol is reported to mercurate in that position.[2] The fluorophenylmercuric chlorides were prepared as shown by the equations below

$$O_2N{-}C_6H_4{-}NH_2 \xrightarrow[HNO_2]{HBF_4} O_2N{-}C_6H_4{-}N_2BF_4 \xrightarrow{\Delta}$$

$$O_2N{-}C_6H_4{-}F \xrightarrow[H_2 + Pd]{Sn + HCl\ or} F{-}C_6H_4{-}NH_2 \xrightarrow[HNO_2]{HBF_4}$$

$$F{-}C_6H_4{-}N_2BF_4 \xrightarrow[HgCl_2]{SnCl_2} F{-}C_6H_4{-}HgCl$$

While the replacement of the diazonium group with mercury does not always give yields which are entirely satisfactory, yet the compounds so prepared are generally obtained more pure, or in a form more easily purified, than when other methods are employed. This has been noted before.[3]

Experimental

Fluoronitrobenzenes.—The diazotization of *p*-nitroaniline as previously described[4] yielded the theoretical quantity of *p*-nitrobenzenediazonium fluoborate (ortho, 92%; meta, 92%). The decomposition of the diazonium fluoborate was carried out as described by Schiemann,[5] the same sand being used for repeated decompositions of the same diazonium compound. The decomposition of 1 mole of *p*-nitrobenzenediazonium fluoborate in 20-g. portions gave 82 g. of *p*-nitrofluorobenzene or 58% of the theoretical (ortho, 13%; meta, 43%).

Fluoroanilines.—The reduction of 100 g. (0.7 mole) of *p*-nitrofluorobenzene with tin and hydrochloric acid yielded 58 g. (75%) of *p*-fluoroaniline (ortho, 70%; meta, 89%).

(1) Accepted for publication in the *Journal of Bacteriology*.

(2) German Patent 234,851.

(3) Nesmejanow, *et al.*, *Ber.*, **62**, 1010 (1929); *ibid.*, **67**, 130 (1934).

(4) Dunker, Starkey and Jenkins, THIS JOURNAL, **58**, 2308 (1936).

(5) Schiemann and Pillarsky, *Ber.*, **62**, 3035 (1929).

The theoretical yield of *p*-fluoroaniline was obtained by the reduction of *p*-nitrofluorobenzene in 95% alcohol with hydrogen and palladium catalyst on charcoal.

Fluorophenylmercuric Chlorides.—The diazotization of the fluoroanilines gave the following yields of dry diazonium compounds: para, 86%; ortho, 70%; meta, 98%. The replacement of the diazonium group with mercury was carried out as described in an earlier paper.[4] *p*-Fluorophenylmercuric chloride was obtained in small glistening plates soluble in alcohol, acetone, glacial acetic acid, slightly soluble in benzene and insoluble in water. It was crystallized from hot glacial acetic acid and melted at 293–294°, decomposing slowly at the melting point (24% yield). *o*-Fluorophenylmercuric chloride was prepared similarly in 24% yield from *o*-fluorobenzenediazonium fluoborate. It was very soluble in alcohol and acetone and was recrystallized from ether, the crystals melting at 159–160°. *m*-Fluorophenylmercuric chloride was prepared in 28% yield from *m*-fluorobenzenediazonium fluoborate by the same procedure. Its solubility behavior was similar to that of the para isomer and its melting point 250–251° (all m. p. corrected).[6]

Anal.[7] Calcd. for C_6H_4ClFHg: Hg, 60.6. Found: Hg for ortho 60.5, 61.2; for meta 60.4, 60.9; for para 60.7, 60.8.

Mercuration of Fluorobenzene.—A mixture of 20 g. (0.21 mole) of fluorobenzene, prepared according to Balz and Schiemann,[8] 65 g. of mercuric acetate and 100 cc. of glacial acetic acid was refluxed for twelve hours. The cold reaction mixture was treated with dilute hydrochloric acid and then diluted with water to 700 cc. The white amorphous solid was filtered off and partially dried. The mixture was extracted with hot glacial acetic acid and the extractive, after crystallization from alcohol, gave 7 g. (about 11%) of needles melting at 156° and giving no depression of m. p. when mixed with a sample of pure *o*-fluorophenylmercuric chloride. The remainder of the white solid was amorphous, could not be separated into fractions by further crystallizations and melted over a wide range of temperature.

***p*-Fluorophenol.**—*p*-Fluorophenol was prepared from *p*-fluoroaniline in 40% yield as described by Rinkes[9] and also from *p*-phenetidine by introducing the fluorine according to the method of Schiemann and then deëthylating with aluminum chloride.[10]

Mercuration of *p*-Fluorophenol.—A solution of 13 g. (0.116 mole) of *p*-fluorophenol in 180 cc. of water was treated with a solution of 36 g. (0.113 mole) of mercuric acetate in 100 cc. of water acidulated with acetic acid. The mixture was allowed to stand for four days at room temperature and yielded 34 g. of crystals which were slightly soluble in benzene and water, soluble in acetone, alcohol and glacial acetic acid. When the compound was crystallized from glacial acetic acid, it melted at 193–194° with decomposition. A small amount (about 1 g.) of a dimercurial was formed which was not isolated in pure condition.

Anal. Calcd. for $C_8H_7O_3FHg$: Hg, 54.1. Found: Hg, 52.9, 53.1.

***p*-Fluorobenzoic Acid.**—*p*-Fluorotoluene was prepared from *p*-toluidine by the Schiemann method[5] in 70% yield. A yield of 58% of *p*-fluorobenzoic acid melting at 183–184° was obtained on oxidation with potassium permanganate. *p*-Fluorobenzoic acid was also prepared as described by Schiemann and Winkelmüller in 50% yield.[11]

Mercuration of *p*-Fluorobenzoic Acid.—The direct mercuration of *p*-fluorobenzoic acid as described under fluorobenzene gave a poor yield of a monomercurial. The mercurichloride was a white powder which could not be crystallized from alcohol, acetone or benzene. On heating, the mercurial slowly turned yellow above 230° and melted with decomposition at 239°.

Anal. Calcd. for $C_7H_4O_2ClFHg$: Hg, 53.5. Found: Hg, 53.4.

3-Nitro-4-fluorobenzoic Acid.—The nitration of *p*-fluorobenzoic acid by the method of Rouche[12] gave 3-nitro-4-fluorobenzoic acid, melting at 121–122° in 50% yield.

3-Amino-4-fluorobenzoic Acid.—The reduction of the above compound using hydrogen and palladium catalyst gave 11 g. (98%) of 3-amino-4-fluorobenzoic acid. Several crystallizations from boiling water (with charcoal) yielded tan needles. The free acid melted with decomposition at 182–183°. The hydrochloride crystallized from water in small white plates which began to darken at 215° and melted with decomposition at 240–243°. The acetylamino derivative also was prepared and obtained as white needles from water, melting with decomposition at 245–246° if heated rapidly to 240°. The acetylamino compound decomposed from 200° up if heated slowly.

Anal. Calcd. for $C_9H_8O_3FN$; N, 7.11. Found: N, 7.16, 7.23, 7.03; av., 7.14.

2-Fluoro-5-carboxybenzenediazonium Fluoborate.—The diazotization of 8 g. of 4-fluoro-3-aminobenzoic acid yielded 10 g. (77%) of cream-colored diazonium compound, decomposition point 185°.

4-Fluoro-3-chloromercuribenzoic Acid.—The replacement of the diazonium group with mercury as described[4] gave a poor yield of highly colored mercurial. However, by repeated solution of the compound in acetone and precipitation with petroleum ether, there was obtained a small amount of cream-colored amorphous powder melting at 240–241° with decomposition. The mixed melting point of this compound with the mercurial prepared by direct mercuration was 239° with decomposition.

As additional evidence that, in the mercuration of *p*-fluorobenzoic acid, the mercury entered the ring adjacent to the fluorine, the following is offered. The compound decomposed with effervescence at its melting point and a deposit of white needles which were identified as *o*-fluorophenylmercuric chloride (mixed m. p.) sublimed on the upper portion of the tube.

Summary

1. The three isomeric fluorophenylmercuric

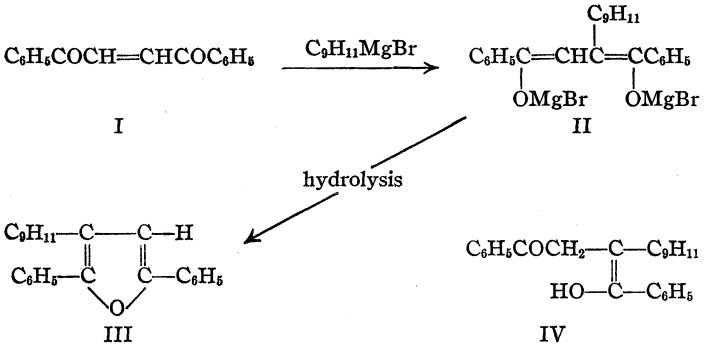
The 1,4-Diphenyl-2-mesityl 1,4-Diketones

BY ROBERT E. LUTZ AND CHARLES J. KIBLER

The preparation of this series of compounds was undertaken in order to study the effect of reactions of a mesityl group substituted directly at the ethylene linkage of the unsaturated 1,4-diketone system, and to determine the effect of this mesityl group on the tautomerism of the corresponding triketone enol and hydroxyfuranone.

The starting point in the synthesis was dibenzoylethylene, I. Mesitylmagnesium bromide adds to the unsaturated diketone readily, presumably through 1,4-addition followed by enolization at the remaining carbonyl, to give the dienolate II.[1] On hydrolysis 2,5-diphenyl-3-mesitylfuran, III, was formed exclusively and in good yield, with no indication of the formation of the expected and hoped for saturated diketone, $C_6H_5COCH_2CH(C_9H_{11})COC_6H_5$, which remains as yet unknown. This result is not particularly surprising, however, since it is known that phenylmagnesium bromide adds to dibenzoylstyrene with the formation of large amounts of the corresponding tetraphenylfuran along with the expected saturated diketone, tetraphenyl-1,4-butanedione.[1b,2] The mesityl group not only offers no hindrance to furanization but actually facilitates the reaction considerably. It seems very likely that the dienolic intermediate II on hydrolysis undergoes prompt ketonization at the unhindered enolic group to produce the monoenol, IV, with a normally reactive carbonyl now available for furan ring closure, and with the remaining and hindered enolic group, in the favorable configuration indicated, persisting long enough for reaction to be complete even under these mild conditions.



The unsaturated 1,4-diketone of this series, VI, is easily obtained by the nitric–acetic acid oxidation of the furan, III, and is assigned the *cis* configuration on the basis of this mode of preparation.[3] It is reduced easily by zinc and acetic acid, sodium hydrosulfite, and catalytic hydrogen; but the furan III was the only crystalline product obtained. In the catalytic hydrogenation an attempt was made to follow the course of the reaction. Piperidine was added in the hope that ketonization would be catalyzed with the production of the saturated diketone instead of the furan. A non-crystalline product was obtained which spontaneously on standing for eight days, or immediately when treated with acetic anhydride and sulfuric acid, gave the furan, and which very evidently contained the monoenol IV. Undoubtedly, then, the reduction was 1,6.

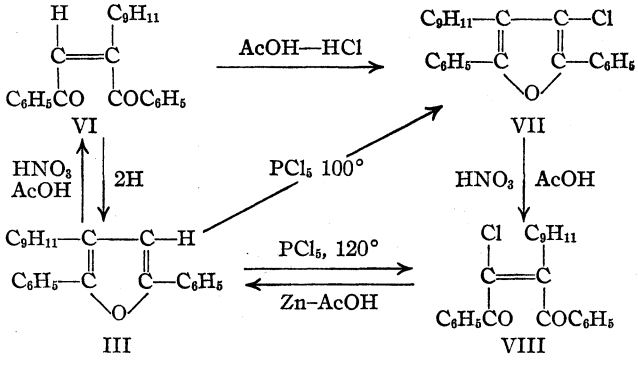
The unsaturated diketone VI reacts with dry hydrogen chloride in acetic acid to give the chlorofuran VII which is obtained also by direct chlorination of the furan III with phosphorus pentachloride at 100° (at a higher temperature, however, some of the unsaturated chloro diketone VIII is

(1) *Cf.* (a) Lutz and Tyson, THIS JOURNAL, **56**, 1341 (1934); (b) Lutz and Reveley, *ibid.*, **61**, 1854 (1939).

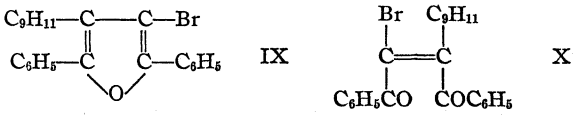
(2) Hahn and Murray, *ibid.*, **36**, 1484 (1914).

(3) *Cf.* (a) Lutz and Wilder, *ibid.*, **56**, 979 (1934); (b) Lutz, Tyson, Sanders and Fink, *ibid.*, **56**, 2679 (1934); (c) Lutz and Wilder, *ibid.*, **56**, 2145 (1934); (d) Lutz and Eisner, *ibid.*, **56**, 2698 (1934).

formed through the oxidizing action of the reagent[3c]). The nitric–acetic acid oxidation of the chlorofuran gives the unsaturated chloro diketone in good yield. This compound as would be expected is reduced by zinc and acetic acid to the furan III. The structures of these halogen derivatives are evident from their modes of formation and from their reactions as outlined in the diagram.

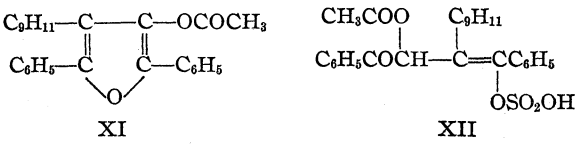


The bromofuran IX was obtained by reactions similar to those described above, from the furan III and phosphorus pentabromide, and from the unsaturated diketone VI and hydrogen bromide in acetic acid or phosphorus pentabromide. Oxidation of the bromofuran gives the unsaturated bromo diketone X which is reduced directly to the furan III by zinc and acetic acid.



In the reactions of diphenylmesitylfuran described above, it is noteworthy that halogenation occurs readily and only in the vacant β-position in the furan nucleus. Evidently the mesityl group does not hinder substitution or oxidative ring fission.

The unsaturated diketone VI reacts with acetic anhydride and sulfuric acid to give the acetoxyfuran XI, a reaction not easily carried out on types with mesityl groups in the terminal positions and directly attached to the carbonyl groups.[4] The mechanism of the reaction very probably involves 1,4-addition of acetic anhydride or its equivalent (such as a mixed anhydride, to give XII as intermediate) followed by furanization between the enolized group and the remaining and reactive carbonyl group.



In conclusion it may be stated that the substitution of mesityl in the 2-position on the chain of dibenzoylethylene and in the β-position of the furan nucleus has introduced no unexpected hindrance to typical reactions.

The synthesis and study of the triketone enolhydroxyfuranone tautomerism in this series is in progress.

Experimental Part

2,5-Diphenyl-3-mesitylfuran, III.—Seven grams of powdered dibenzoylethylene in 1-g. portions was added with efficient stirring to a solution of three equivalents of mesitylmagnesium bromide in 60 cc. of absolute ether. The reaction was immediate and vigorous. The resulting clear brownish solution was refluxed for fifteen minutes and decomposed in ice water acidified with hydrochloric acid. The product, isolated by extraction with ether, was digested with ethanol, the furan crystallizing in nearly pure condition in 65% yield. It crystallized from acetone as flat colorless needles melting at 157.5–158°.[5]

Anal. Calcd. for $C_{25}H_{22}O$: C, 88.7; H, 6.55. Found: C, 88.6, 88.8; H, 6.6, 6.7.

An attempt was made to show that the furan was not actually formed until after hydrolysis or partial hydrolysis by carrying out the reaction in the presence of an excess of iodine for the purpose of oxidizing the dienol as fast as it was liberated. Only the furan was obtained. This is without significance, however, since the rate of furanization is evidently unusually high and since one case is now known where a dienol, oxidizable by air, is rearranged instead into the saturated diketone when treated with iodine under conditions similar to those employed here (namely, the dienol formed in the catalytic reduction of the dimolecular alkaline condensation product of di-(trimethylbenzoyl)-ethylene[6]).

The furan reacted with three parts of phosphorus pentachloride when the two solids were fused together and heated at 100° for one hour. Largely unchanged material was obtained on hydrolysis of the reaction mixture, but a small amount of the chlorofuran VII was isolated upon fractional crystallization. In a similar experiment with heating for five minutes at 120°, followed by hydrolysis and fractional crystallization, again unchanged material was recovered together with a small amount of the chloro unsaturated diketone VIII. The furan reacted at room temperature with five parts of phosphorus pentabromide with the formation of a red oil which was allowed to stand

(4) *Cf.* Lutz and Wood, THIS JOURNAL, **60**, 229 (1938). 1,2,4-Trimesityl-2-butenedione-1,4 and 1,4-dimesityl-2-phenyl-2-butenedione-1,4 do not give acetoxyfurans under the usual conditions (Lutz and Kibler, papers to appear shortly).

(5) The melting points of all analytical samples are corrected.

(6) Lutz and Disque, unpublished results.

for twenty-five minutes. On hydrolysis and crystallization of the resulting solid product from ethanol, the bromofuran X was obtained in 64% yield.

cis-**1,4-Diphenyl-2-methyl-2-butenedione-1,4 (Dibenzoylmesitylethylene), VI.**—A suspension of 5 g. of diphenylmesitylfuran III in 25 cc. of concd. acetic acid, cooled to 10°, was treated with 20 cc. of a 1–3 mixture of concd. nitric and acetic acids, also cooled to 10°. The furan dissolved immediately with evolution of oxides of nitrogen. The solution was allowed to stand at 10° for one hour and was then decomposed in water. After several hours the coagulated product was filtered off and crystallized from ethanol, giving 4.3 g. (90%) of nearly pure material. It crystallized from ethanol or methanol as rectangular plates or rosets melting at 98.5–99.5°.

Anal. Calcd. for $C_{25}H_{22}O_2$: C, 84.7; H, 6.3. Found: C, 84.5; H, 6.3.

Sunlight was without action on the unsaturated diketone in ethanol solution or in chloroform containing iodine.

Reduction. (a) A mixture of 0.5 g. of the unsaturated diketone, an excess of zinc dust, and 50 cc. of concd. acetic acid was allowed to react in the cold and was then heated slowly to boiling. The furan III was the sole product isolated; yield 65%. Similar results were obtained when the zinc dust was added to a boiling solution of the unsaturated diketone in concd. acetic acid.

(b) A mixture of 0.5 g. of sodium hydrosulfite, 0.5 g. of the unsaturated diketone and 70% ethanol was refluxed for thirty minutes and diluted with water. Fractional crystallization from ethanol gave 0.2 g. of the furan and 0.15 g. of unchanged material.

(c) A solution of 0.5 g. of the unsaturated diketone in 70% ethanol with 0.1 g. of platinum oxide catalyst absorbed one molecule of hydrogen in fifteen minutes. Filtering and diluting with water and extracting with ether gave an oil which could not be induced to crystallize. A sample of the oil was treated with acetic anhydride containing a trace of sulfuric acid; on subsequent hydrolysis the product crystallized without difficulty and proved to be the furan. The oily product on standing for eight days deposited crystals of the furan which was identified.

4-Chloro-2,5-diphenyl-3-mesitylfuran, VII.—A solution of 0.7 g. of the unsaturated diketone VI in 20 cc. of concd. acetic acid was saturated at room temperature with dry hydrogen chloride. In a short time 0.42 g. of analytically pure chlorofuran VII crystallized as truncated prisms melting at 102.5–103.5°. On diluting the filtrate with water 0.15 g. of nearly pure furan was obtained; total yield 77%. Further crystallization of the main product did not change the melting point.

Anal. Calcd. for $C_{25}H_{21}OCl$: Cl, 9.5. Found: Cl, 9.6.

cis-**3-Chloro-1,4-diphenyl-2-mesityl-2-butenedione-1,4, VIII.**—A suspension of 0.15 g. of the chlorofuran VII in 2 cc. of concd. acetic acid was treated with 0.2 cc. of a mixture of 0.2 cc. of concd. nitric acid and 0.5 cc. of concd. acetic acid, at room temperature. After standing for ten minutes the furan dissolved and 0.1 g. of the unsaturated chloro diketone VII crystallized as thick hexagonal plates melting at 127.5–128°. Recrystallization from methanol and from ethanol did not change the melting point.

Anal. Calcd. for $C_{25}H_{21}O_2Cl$: C, 77.2; H, 5.46. Found: C, 77.2; H, 5.3.

Reduction to the furan III was effected quickly in the usual way by the action of zinc dust in boiling concd. acetic acid (one minute).

4-Bromo-2,5-diphenyl-3-mesitylfuran, IX.—To a solution of 0.5 g. of VI in 5 cc. of concd. acetic acid at room temperature was added slowly 2 cc. of a 30% solution of hydrogen bromide in concd. acetic acid. The product crystallized and after standing for five minutes the solution was partly diluted with water and the product crystallized from ethanol, giving 0.37 g. (65%) of nearly pure bromofuran IX. It was purified by further crystallizations from isopropanol; truncated prisms of melting point 126–127°.

Anal. Calcd. for $C_{25}H_{21}OBr$: C, 71.9; H, 5.1. Found: C, 72.1; H, 5.4.

In an alternative procedure 0.1 g. of VI was mixed thoroughly with 0.5 g. of phosphorus pentabromide and allowed to react for an hour, the temperature being maintained at 0°. Hydrolysis and crystallization from ethanol gave 0.07 g. of pure bromofuran.

cis-**3-Bromo-1,4-diphenyl-2-mesityl-2-butenedione-1,4, X.**—A solution of 0.3 g. of the bromofuran IX in 3 cc. of concd. acetic acid was treated with 1 cc. of a 1–3 mixture of concd. nitric and acetic acids at room temperature. After standing for fifteen minutes the product was precipitated with water and crystallized from ethanol; yield 95%. It crystallized from methanol as hexagonal plates melting at 103–104.5°. It was stable in the solid state in the dark but turned deep pink when exposed to light. Ethanol solutions appeared not to be affected by exposure to sunlight.

Anal. Calcd. for $C_{25}H_{21}O_2Br$: C, 69.3; H, 4.9. Found: C, 68.8, 69.5; H, 5.0, 5.2.

Reduction to the furan III was effected quickly by zinc dust and concd. acetic acid (one minute) in the usual way.

4-Acetoxy-2,5-diphenyl-3-mesitylfuran, XI.—A solution of 0.5 g. of VI in 10 cc. of acetic anhydride was treated with 10 drops of concd. sulfuric acid. Reaction was indicated by coloration and warming. After standing for five minutes and hydrolysis in ice water, the product was isolated by extraction with ether. It crystallized (cubic) from ethanol; yield, 0.44 g. (78%); m. p. 124.5–126.5°. It was not very stable and further crystallization by the ordinary methods lowered the melting point.

Anal. Calcd. for $C_{27}H_{24}O_3$: C, 81.8; H, 6.1. Found: C, 82.2, 82.1; H, 6.4, 6.5.

Summary

Mesitylmagnesium bromide adds 1,4 to dibenzoylethylene but gives diphenylmesitylfuran instead of the expected saturated diketone.

The unsaturated diketone was made by the nitric–acetic acid oxidation of the furan. Reduction of this gives the furan, even with catalytic hydrogen in 70% ethanol. It was converted into an acetoxyfuran.

The chloro and bromo derivatives of the furan and the unsaturated diketone are described.

The presence of the mesityl group does not hinder typical reactions.

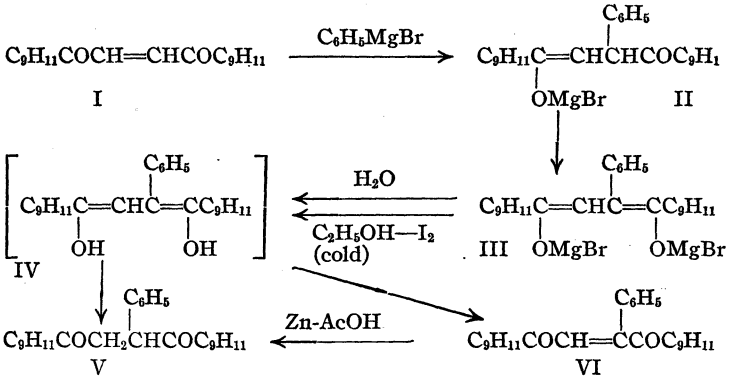
The 1,4-Dimesityl-2-phenyl 1,4-Diketones

BY ROBERT E. LUTZ AND CHARLES J. KIBLER

This series of compounds has been made in order to study the effect of terminal mesityl groups on the reactions of the saturated and unsaturated 1,4-diketone systems and on the ease of furan ring closure and ring fission. Interest centers in a comparison of the reactions of this series with, first, those of di-(trimethylbenzoyl)-ethylene, I, and, second, those of dibenzoylphenylethylene, $C_6H_5COCH{=}C(C_6H_5)COC_6H_5$. In the case of di-(trimethylbenzoyl)-ethylene the reactions of the conjugated systems are relatively unimpaired and like those of dibenzoylethylene itself, but of course the individual carbonyl group reactivities are lowered. In the case of dibenzoylphenylethylene, as compared with dibenzoylethylene, the full conjugated system is nearly as easily reduced, one α,β-unsaturated ketone system appears to react normally with the other definitely hindered, the ethylene linkage is unreactive as also is one of the carbonyls, but furan ring closure is if anything facilitated as also is the reverse reaction, oxidative fission of the furan ring.



1,4-Dimesityl-2-phenyl-1,4-butanedione, V, has been made from di-(trimethylbenzoyl)-ethylene, I, by 1,4-addition of phenylmagnesium bromide,[1] the reaction proceeding as indicated in the diagram through the monoenolate II to the dienolate III. The proof that the excess of phenylmagnesium bromide causes the enolization of II to III rests on the hydrolysis of the product under oxidizing conditions with the formation of the unsaturated 1,4-diketone, VI, which could only have been produced by oxidation of the dienol IV.[2] The reaction between the Grignard reagent and di-(trimethylbenzoyl)-ethylene, then, can be manipulated to give good yields of the unsaturated diketone, VI. Since the nitric–acetic acid oxidation method has proved to be useless in the case of 2,5-dimesitylfurans, this oxidation of the dienol becomes the logical preparative method.

Dibenzoylphenylethylene and dibenzoylmesitylethylene, whatever the method of synthesis, appear to have the *cis* configuration with respect to the aroyl groups, and are obtainable by the oxidation both of the corresponding furans and the dienols.[2,3] It is probable, therefore, that the unsaturated diketone under discussion, VI, is also *cis*.

Reduction of the unsaturated diketone proceeds easily with zinc and acetic acid to give the saturated diketone exclusively.

Furan ring closure from the saturated diketone, V, could not be brought about by the usual procedure using acetic anhydride and sulfuric acid. Since di-(trimethylbenzoyl)-ethane itself cannot be dehydrated under these conditions,[4] it might appear that ring closure by this method is to some extent hindered by the mesityl groups; however, di - (trimethylbenzoyl) - dimethylethane, $C_9H_{11}COCH(CH_3)CH(CH_3)COC_9H_{11}$, is furanized with extraordinary ease under comparable conditions.[5] It can only be said that the 1,4-dimesityl com-

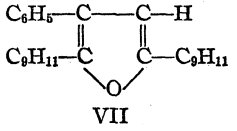
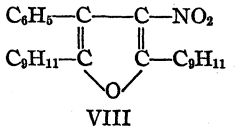
(5) Lutz and Taylor, *ibid.*, **55**, 1593 (1933).

pounds are less consistent in their behavior toward dehydrating agents than the 1,4-diketones with aryl groups which have no ortho substituents.

Furanization of the saturated diketone to VII was accomplished smoothly by the action of hydriodic acid at 150°, and also by the prolonged action of boiling acetic acid saturated continually with dry hydrogen chloride. The second of these procedures, which was only partially successful in the case of di-(trimethylbenzoyl)-ethane, proved to be very satisfactory here. It is worthy of note that the 2-phenyl group in V definitely has facilitated furan ring closure as do the 2-phenyl and 2-mesityl groups when substituted in dibenzoylethane.



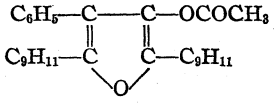
VII



VIII

Attempts to oxidize dimesitylphenylfuran, VII, using concentrations of the nitric–acetic acid reagent which are effective in the oxidation of various 2,5-diphenylfurans to the corresponding *cis* unsaturated 1,4-diketones, failed to open the furan ring; instead, substitution of one nitro group was the result. In view of the ease of nitration at the β-positions in dimesitylfurans and the relative unreactivity of the aryl nuclei,[6] the structure VIII has been assigned.

Attempts to convert the unsaturated diketone VI into the acetoxyfuran IX by the action of acetic anhydride or acetyl chloride and sulfuric acid failed, thus closing the door to one possible path for the preparation of the corresponding triketone enol, the synthesis of which is now being undertaken by other methods.



IX

Experimental Part

2,5-Dimesityl-3-phenylfuran, VII.—Attempts to dehydrate dimesitylphenylbutanedione V with acetic anhydride and sulfuric acid under a variety of conditions from 0° to the boiling point failed. Two methods were found, the best being presented under (a).

(a) A solution of 1.0 g. of V in 25 cc. of concd. acetic acid and 1 cc. of water was refluxed gently, dry hydrogen chloride being passed through the boiling solution for thirty hours. On cooling 0.53 g. of nearly pure furan crystallized and 0.34 g. was obtained by diluting the filtrate with water and recrystallizing. It was crystallized from concd. acetic acid; rectangular plates, m. p. 104–105.5° (corr.).

Anal. Calcd. for $C_{28}H_{28}O$: C, 88.4; H, 7.4. Found: C, 88.2; H, 7.7.

(b) A mixture of 0.2 g. of V and 1 cc. of hydriodic acid (sp. gr. 1.7, protected with hypophosphorous acid) was heated in a sealed tube at 145–150° for one hour. The resinous product crystallized from ethanol giving a 74% yield of the furan.

2,5-Dimesityl-4(?)-nitro-3-phenylfuran, VIII.—A suspension of 0.1 g. of dimesitylphenylfuran, VII, in 1 cc. of concd. acetic acid, supercooled to 10°, was treated with 0.4 cc. of a 1–3 mixture of concd. nitric and acetic acids. The temperature was maintained at 10° for one hour. The product began to separate within a few minutes. Filtration gave 0.07 g. of nearly pure nitro derivative. After two crystallizations from isopropanol it separated as cubic prisms melting at 164–165° (corr.).

Anal. Calcd. for $C_{28}H_{27}O_3N$: C, 79.0; H, 6.4; N, 3.3. Found: C, 78.9; H, 6.3; N, 3.36.

1,4-Dimesityl-2-phenyl-2-butenedione-1,4, VI.—Five grams of powdered di-(trimethylbenzoyl)-ethylene, I, was added in half-gram portions to 3 equivalents of phenylmagnesium bromide in 60 cc. of absolute ether with thorough and continued mechanical stirring. The reaction was immediate and vigorous, producing a clear brown solution. This was then refluxed for a few minutes, cooled to 0°, and added slowly over ten minutes to a vigorously stirred solution of 6 g. of iodine in 200 cc. of ethanol cooled in an ice-bath. The temperature of the mixture varied between 0 and 10°. Stirring was continued for ten minutes and water containing sodium bisulfite and acidified was added to destroy the excess of iodine. Extraction with ether and subsequent concentration to small volume produced 2.9 g. of pale yellow crystals; yield 46%. Repeated crystallization from ethanol gave truncated prisms melting at 109–110° (corr.).

Anal. Calcd. for $C_{28}H_{28}O_2$: C, 84.8; H, 7.1. Found: C, 84.7; H, 7.1.

Substitution of quinone for iodine in the above oxidation produced similar results.

Reduction by means of zinc dust and boiling concd. acetic acid in the usual way produced the saturated diketone in good yield.

Attempts to convert the unsaturated diketone into the acetoxyfuran under varied conditions failed. Using acetic anhydride and concd. sulfuric acid at temperatures up to 50°, no reaction occurred, and at higher temperatures up to 100° intractable resins were obtained. Using acetyl chloride instead gave similar results but at lower temperatures from 0 to 25°.

Summary

1,4-Dimesityl-2-phenyl-2-butenedione-1,4 is made by the reaction between phenylmagnesium bromide and di-(trimethylbenzoyl)-ethylene, followed by oxidative hydrolysis of the resulting dienolate.

(6) Lutz and Kibler, work on the nitration of the 2,5-dimesitylfurans, to be published shortly.

Dimesitylphenylfuran is made by dehydration of the saturated diketone. It is not oxidized by the nitric–acetic acid reagent.

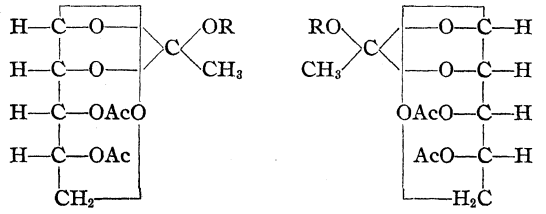
The Preparation of *d*- and *l*-Ribosidodihydroxyacetone Tetraacetates with an Orthoester Structure

BY CLARENCE W. KLINGENSMITH AND WILLIAM LLOYD EVANS

In a previous communication[1] the synthesis of the first pairs of disaccharide antipodes, β-*d*- and β-*l*-arabinosidodihydroxyacetone tetraacetates and β-*d*- and β-*l*-xylosidodihydroxyacetone tetraacetates, and the synthesis of the first disaccharide racemate, β-*d*,β-*l*-arabinosidodihydroxyacetone tetraacetate were reported. In this communication another pair of antipodes containing *d*- and *l*-ribose and dihydroxyacetone is reported. The behavior of this pair of ribose derivatives as well as the synthesis of methyl-*d*-riboside triacetate (II) with an orthoester structure by Levene and Tipson[2] indicates that the orthoester structures, (I) and (III), should be assigned to them.



I. R = $AcOCH_2COCH_2$-. III. R = $AcOCH_2COCH_2$-.
II. R = CH_3-.

In conformity to the nomenclature proposed by Haworth, Hirst and Stacy[3] for methylglycoside acetates with an orthoester structure, our compounds are named diacetyl *d*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate (I) and diacetyl *l*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate (III).

Methylglycoside acetates with an orthoester structure were first obtained by Fischer, Bergmann and Rabe,[4] and the nature of their structures was first explained by Bott, Haworth and Hirst[5] and independently by Freudenberg and Scholz.[6] This type of methylglycoside acetate has been obtained with rhamnose,[4,7] mannose,[5,8,9] lyxose,[10] maltose,[6,11] 4-[β-*d*-glucosido]-*d*-mannose,[12] ribose,[2] *d*-α-glucoheptose,[3] turanose,[13] fructose,[14] and talose,[15] and is characterized by (a) one acetyl group that is stable to alkaline hydrolysis and (b) extreme sensitivity to acids.

The orthoester structures of diacetyl *d*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate and diacetyl *l*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate differ from the orthoester structure of the methylglycoside acetates in that the acetoxyacetonyl group, $AcOCH_2COCH_2$-, of the former is substituted for the methyl group of the latter. The presence of the acetoxyacetonyl group made it impossible for us to demonstrate the stability of one acetyl group to alkaline hydrolysis in contrast to the removal of the other three normal acetyl groups. In an acetyl determination by the method of Kunz and Hudson,[16] diacetyl *d*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate gave a value that was 9.4% higher than the theoretical value for four groups or 46% higher than the theoretical value for three groups. Kreider and Evans[17] previously reported that the acetyl values of oligosaccharide acetates that contained dihydroxyacetone were about 10% high by the method of Kunz and Hudson. Bernier[18] also obtained high acetyl values with dihydroxyacetone monoacetate. These high values are in accord with

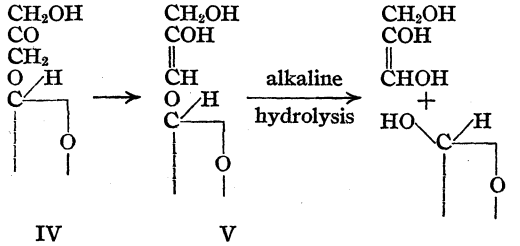
the work of Evans and Cornthwaite,[19] who found that dihydroxyacetone in alkaline solution was converted into lactic, acetic, and formic acids as well as other substances. The fact that our acetyl value by the Kunz and Hudson method was abnormally high for three groups can be accounted for on the basis of the findings of Gehman, Kreider, and Evans.[20] They presented evidence to show that the dihydroxyacetone portion of oligosaccharides (IV) containing dihydroxyacetone was susceptible to alkaline hydrolysis by virtue of their possible rearrangement to the enediol structure (V).

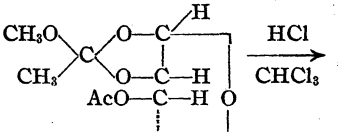


IV V

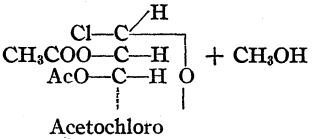
In an analogous manner, the *d*-ribose-1,2-ortho-3′-hydroxyacetonyl acetate (VI), formed by the removal of the three normal acetyl groups in the alkaline hydrolysis (Kunz and Hudson acetyl determination) of diacetyl *d*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate (I), may rearrange to the enediol structure (VII). This may then undergo alkaline hydrolysis to the trioseenediol (VIII), the precursor of lactic acid and *d*-ribose-1,2-orthoacetic acid (IX), which may suffer further hydrolysis to *d*-ribose (XI) by first rearranging to 2-monoacetyl-*d*-ribose (X).

The rearrangement of *d*-ribose-1,2-orthoacetic acid (IX) to 2-monoacetyl-*d*-ribose (X) is in harmony with the evidence presented by Pigman and Isbell[15] to show that orthoacid derivatives are unstable to alkali.

The behavior of diacetyl *d*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate and diacetyl *l*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate in dry alcohol-free chloroform containing dry hydrogen chloride was analogous to the behavior of the methylglycoside acetates with an orthoester structure. Isbell[12,15] observed that the rotations of 4-[β-*d*-glucosido]-methyl-*d*-mannoside heptaacetate and of methyl-*d*-taloside tetraacetate with orthoester structures changed rapidly in chloroform solution containing dry hydrogen chloride and that acetochloro-4-[β-*d*-glucosido]-*d*-mannose and acetochloro-*d*-talose were formed.



Methylglycoside acetate with an orthoester structure



Acetochloro derivative

A similar rotation change occurred with our ribose derivatives, (I) and (III), and evidence that the acetochlororiboses were formed was observed. Furthermore, the isomeric compound, the β-*d*-arabinosidodihydroxyacetone tetraacetate of Kreider and Evans,[1] which does not possess an orthoester structure, showed no reaction with hydro-

gen chloride in chloroform solution. Hence, it is concluded that the behavior of the ribose derivatives, (I) and (III), is to be attributed to an orthoester structure.

The possibility that diacetyl *d*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate and diacetyl *l*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate contain β-biosidic links was also eliminated by the fact that the calculated specific rotations of β-*d*-ribosidodihydroxyacetone tetraacetate (unknown compound) and β-*l*-ribosidodihydroxyacetone tetraacetate (unknown compound) are −112.3 and +112.3°, respectively, which are in complete disagreement with the observed specific rotations of −11.6 and +11.8°. These rotations were calculated from the value of A as given by Kreider and Evans[1] and from the value of B which was calculated from the rotatory values of the individual asymmetric carbon atoms of a pentose tetraacetate which were obtained by a method analogous to that of Isbell.[21]

A racemate, diacetyl *d,l*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate, also is described. Other compounds which are reported in the literature for the first time are *l*-ribose tetraacetate, *d,l*-ribose tetraacetate and acetobromo-*l*-ribose.

Experimental Part

Preparation of Known Starting Materials.—*d*- and *l*-ribose were prepared from *d*- and *l*-arabinose, respectively, according to the directions of Karrer, *et al.*[22] The *d*-ribose, which was recrystallized once from absolute ethanol, was acetylated by the procedure of Levene and Tipson[2] to *d*-ribose tetraacetate, m. p. 109.5–110.0° (corr.), $[\alpha]^{28}D$ −56.0° (*c*,[23] 3.0; pure chloroform). A product with these same constants was obtained by the acetylation of a sample of *d*-ribose that had been purified by conversion to *d*-ribose *p*-bromophenylhydrazone, m. p. 165.0–165.5° (corr.), and subsequent hydrolysis with benzaldehyde according to the procedure given by Karrer.[22] The values of *d*-ribose tetraacetate as reported by Levene and Tipson[2] are given here for comparison: m. p. 110°, $[\alpha]^{25}D$ −52.0° (chloroform). Acetobromo-*d*-ribose, m. p. 94.5–95.5° (corr.), $[\alpha]^{25}D$ −223.9° (*c*, 3.0; pure chloroform), was obtained from the tetraacetate according to the directions of Levene and Tipson.[2] The values of acetobromo-*d*-ribose as given in the literature[2] are presented here for comparison: m. p. 96°, $[\alpha]^{25}D$ −209.3° (*c*, 2; chloroform). Dihydroxyacetone monoacetate was prepared by the method of Fischer, Baer and Feldmann.[24] The silver carbonate was prepared as in the previous communication.[1] The Drierite used as the internal desiccant was finely powdered and preheated at 235° for two hours. The benzene used as the reaction medium and the solvent for the acetobromo riboses was thiophene-free, dried and distilled over sodium and preserved over Drierite.

***l*-Ribose Tetraacetate.**—This compound was prepared from *l*-ribose (once recrystallized from absolute ethanol), according to the procedure used by Levene and Tipson[2] in the preparation of *d*-ribose tetraacetate. After two recrystallizations from ethanol (95%), the melting point, m. p. 109.5–110.0° (corr.), and specific rotation, $[\alpha]^{30}D$ +56.0° (*c*, 3.5; pure chloroform), were constant. The yield of the pure crystalline product was 58% of the theoretical. The acetylation of a sample of *l*-ribose that was purified by conversion to *l*-ribose *p*-bromophenylhydrazone, m. p. 165.0–165.5° (corr.), and subsequent hydrolysis with benzaldehyde by the procedure of Karrer[22] gave a product with the same constants.

Anal. Calcd. for $C_5H_6O_5(COCH_3)_4$: acetyl, 12.58 ml. of 0.1 *N* NaOH per 100 mg. Found: acetyl, 12.60 ml.

***d,l*-Ribose Tetraacetate.**—Equal portions (200 mg.) of *d*-ribose tetraacetate and *l*-ribose tetraacetate were dissolved in warm ethanol (95%). Upon cooling the solution, crystallization took place. The product melted at 90.5° (corr.). The observed rotation in a 2-dm. micro polarimeter tube was ±0.0° (*c*, 2.4; pure chloroform). The melting point of each constituent taken separately was 109.5–110.0°, a mixed melting point of the two active isomers was 84.5–86.5° (corr.), and a mixed melting point of the racemic modification and a small amount of either active isomer was 88.0–90.0° (corr.). These facts seem to indicate that the racemic modification is a molecular compound.

Acetobromo-*l*-ribose.—This compound was prepared essentially according to the procedure of Levene and Tipson[2] for the preparation of acetobromo-*d*-ribose except that *l*-ribose tetraacetate was substituted for *d*-ribose tetraacetate. The yield was 69–75% of the theoretical based on the *l*-ribose tetraacetate as compared with the 60% yield reported by Levene and Tipson. This higher yield was attributed to the fact that the solution of the *l*-ribose tetraacetate in the acetic acid–hydrogen bromide reagent was allowed to stand at room temperature (20–25°) for two hours rather than for one hour. The product was recrystallized once from ether and petroleum ether: m. p. 94.5–95.5° (corr.), $[\alpha]^{23}D$ +224.8° (*c*, 3.1; pure chloroform).

Anal. Calcd. for $C_{11}H_{15}O_7Br$: Br, 23.58. Found: Br, 23.68.

Diacetyl *d*-Ribose-1,2-ortho-3′-acetoxyacetonyl Acetate.—This compound was prepared from acetobromo-*d*-ribose and dihydroxyacetone monoacetate essentially according to the directions of Kreider and Evans[1] for the preparation of β-*d*-arabinosidodihydroxyacetone tetraacetate. After the manner of Reynolds and Evans[25] the acetobromo-*d*-ribose was dissolved in benzene and dropped into the reaction flask over a period of forty-five minutes rather than adding the solid substance portion-wise. Iodine (1 mole) was used as a catalyst after the manner of Helferich, Bohm and Winkler.[26] The yield was 18–20%

(21) H. S. Isbell, *Bur. Standards J. Research*, **3**, 1041 (1929).

(22) P. Karrer, *et al.*, *Helv. Chim. Acta*, **18**, 1435 (1935).

(23) In this paper, *c* represents the concentration in grams per 100 ml. of solution.

(24) H. O. L. Fischer, E. Baer and L. Feldmann, *Ber.*, **63**, 1732 (1930).

(25) D. D. Reynolds and W. L. Evans, THIS JOURNAL, **60**, 2559 (1938).

(26) B. Helferich, E. Bohm and S. Winkler, *Ber.*, **63**, 990 (1930).

of the theoretical based on the acetobromo-*d*-ribose. The crude product was recrystallized to constant melting point and rotation by dissolving in pure chloroform or benzene, decolorizing with Carboraffin, evaporating to a thin sirup and adding 10–15 volumes of dry alcohol-free ether. It crystallized in needle-like clusters; m. p. 97.0–98.0° (corr.), $[\alpha]^{24}D$ −11.6° (*c*, 1.8; pure chloroform).

Anal. Calcd. for $C_8H_{10}O_7(COCH_3)_4$: acetyl, 10.26 ml. of 0.1 *N* NaOH per 100 mg. Found: acetyl (Freudenberg[27]), 10.25 ml.

This substance was soluble in chloroform, acetone, and benzene; moderately soluble in alcohol; and slightly soluble in ether and water. It was very sensitive to hydrogen chloride in chloroform solution. When 0.2075 g. was dissolved in 15.08 ml. of dry alcohol-free chloroform containing 0.011 g. of dry hydrogen chloride, the first rotation observed in a 2-dm. tube six minutes after dissolution was −3.03°. On the basis of a specific rotation of −11.6°, the initial rotation in chloroform alone was calculated to be −0.32°, indicating that a very rapid rotation change had taken place. No further change in rotation was observed even after standing for fifteen minutes. The hydrogen chloride was then removed from the solution by shaking with silver carbonate, after first adding a few grams of powdered Drierite to remove the water formed by the neutralization reaction. The solid materials were removed by filtration. Upon evaporating the solvent from the filtrate a sirup was obtained which could not be brought to crystallization. The sirup gave a positive test for halogen and evolved acid fumes after standing several weeks at room temperature which indicated the presence of acetochloro-*d*-ribose.

Diacetyl *l*-Ribose-1,2-ortho-3′-acetoxyacetonyl Acetate.—This compound was prepared and purified in exactly the same manner as the *d*-isomer except that acetobromo-*l*-ribose was substituted for acetobromo-*d*-ribose: yield, 18–20% of the theoretical, m. p. 97.0–98.0° (corr.), $[\alpha]^{25}D$ +11.8° (*c*, 3.2; pure chloroform). It crystallized in needle-like clusters.

Anal. Calcd. for $C_8H_{10}O_7(COCH_3)_4$: acetyl, 10.26 ml. of 0.1 *N* NaOH per 100 mg. Found: acetyl (Freudenberg[27]), 10.10 ml.

This substance was soluble in chloroform, acetone, and benzene, moderately soluble in alcohol, and slightly soluble in ether and water. The behavior of this compound in chloroform solution containing hydrogen chloride was analogous to the *d*-isomer. When 0.5211 g. was dissolved in 25.72 ml. of dry alcohol-free chloroform containing 0.162 g. of dry hydrogen chloride, the first rotation observed in a 4-dm. tube five minutes after dissolution was +9.45°. On the basis of a specific rotation of +11.8°, the initial rotation in chloroform alone was calculated to be +0.95°, indicating that a rapid rotation change had occurred. After removing the hydrogen chloride and the solvent as described in the case of the *d*-isomer, a sirup was obtained which could not be brought to crystallization. The sirup gave a positive test for halogen and evolved acid fumes after standing for a few weeks. The behavior of this sirup was indicative of the presence of acetochloro-*l*-ribose.

Diacetyl *d,l*-Ribose-1,2-ortho-3′-acetoxyacetonyl Acetate.—Equal portions (52 mg.) of the two isomers were dissolved in benzene and evaporated to a thin sirup. Upon adding a large volume of anhydrous ether, crystallization took place. The product melted at 124.5–125.0° (corr.). The melting point of the constituents taken separately was 97.0–98.0°. The observed rotation in a 2-dm. micro polarimeter tube was ±0.0° (*c*, 1.7; pure chloroform). These facts indicate that a true racemate was formed.

Acknowledgment.—The authors wish to thank H. J. Dauben, who prepared a large part of the *l*-ribose that was used in this work.

Summary

1. The preparation of the following pair of disaccharide antipodes in crystalline condition is described: diacetyl *d*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate and diacetyl *l*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate. The racemate, diacetyl *d,l*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate is also described.

2. These are the first examples of orthoester derivatives which contain a group other than the methyl and ethyl groups as a part of the ortho structure.

3. A possible explanation for the high acetyl values of diacetyl *d*-ribose-1,2-ortho-3′-acetoxyacetonyl acetate by the Kunz and Hudson method is presented.

4. *l*-Ribose tetraacetate and acetobromo-*l*-ribose are reported for the first time. The racemate, *d,l*-ribose tetraacetate, is described.

Monoalkyldioxanes

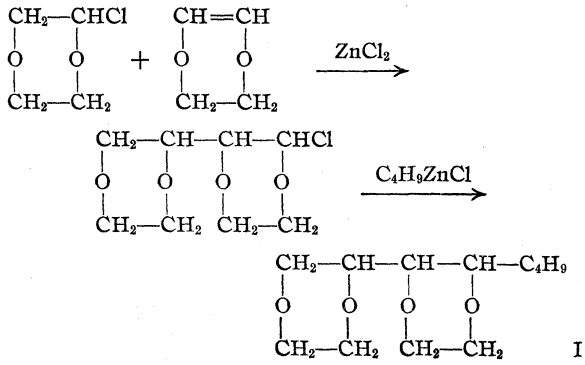
BY R. K. SUMMERBELL AND R. R. UMHOEFER

Methods of synthesizing dialkyl-, diaryl-, and monoaryldioxanes have been reported previously.[1,2] The analogous method is applied here to the problem of the monoalkyldioxanes. Variations in the procedure indicate the best yields to be obtained by adding pure monochlorodioxane to the Grignard solution.

In the previous work on dialkyldioxanes,[2] it was found advantageous to treat the Grignard reagent with zinc or cadmium chlorides before carrying out the reaction with the 2,3-dichlorodioxane. As there is little possibility of a dehalogenating side reaction, no advantage was anticipated in the present case, and none was found.

Because of the tendency of monochlorodioxane to decompose on standing, it was always freshly prepared before each reaction. Monochlorodioxane is best made by adding dry hydrogen chloride to dioxene at 0° and distilling the resulting mixture. The yields of monochlorodioxane are lowered by using benzene or ethyl ether as solvents. The conversion of dioxene to monochlorodioxane seems to be incomplete, even with the use of excess hydrogen chloride, since slight amounts of dioxene are recovered on distillation of the reaction product.

A mixture of dioxene and monochlorodioxane, in the presence of polymerizing catalysts, when treated with a Grignard reagent yields, besides the expected alkyldioxane, a small amount of a solid product. No solid by-product was obtained in cases where the monochlorodioxane was distilled before the reaction with the Grignard reagent or when the polymerizing catalysts were omitted. The compound obtained by the use of the butyl Grignard reagent in the presence of zinc chloride had the empirical formula $C_{12}H_{22}O_4$. As the compound is without any very reactive functional groups, the four oxygen atoms are probably constituents in two dioxane rings. From these data formula I, 2-butyl-3-dioxanyldioxane, can be advanced as the possible structure of the compound. As acyl halides[3] and α-chloroethers[4,5] in the presence of catalysts may be added to ethylenic hydrocarbons, the probable mechanism by which the 2-butyl-3-dioxanyldioxane is formed is shown by the equation.



I

Additional evidence for the structure of the solid has been secured by similarly preparing the corresponding by-product 2-ethyl-3-dioxanyldioxane with the use of the ethyl Grignard reagent.

A New Synthesis of Substituted Dioxanes.—Another synthesis of substituted dioxanes was suggested by the fact that β-chloroethyl ether is converted to dioxane when heated with 5% sodium hydroxide at 200°,[6] or by other reagents.[7]

This method has been applied in synthesizing ethyldioxane from β-chloroethyl β-bromo-α-ethylethyl ether. A mixture of equivalent amounts of acetaldehyde and ethylene chlorohydrin was treated with dry hydrogen chloride at 0° to form β-chloroethyl α-chloroethyl ether.[8] This ether when brominated according to the method of Boord[9] yielded β-chloroethyl α,β-dibromoethyl ether. The reaction of this substance with ethylmagnesium bromide resulted in the desired β-chloroethyl β-bromo-α-ethylethyl ether. When this ether was treated with 10% potassium hydroxide at 200° for three and one-half hours, a 17% yield of ethyldioxane was obtained. By varying the starting materials and Grignard reagents used, this appears to be a general method for the synthesis of many other substituted dioxanes.

Properties of the Monoalkyldioxanes.—The homologous series of the monoalkyldioxanes

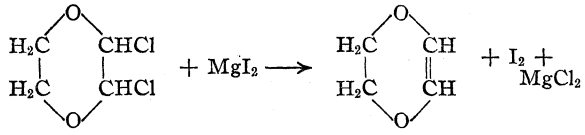
exhibits a uniform variation in physical properties. However, the relationship of refractive index and density appears to be uncommon,[10] in that the slope of the plot of refractive indices of the monoalkyldioxanes, against density, is negative. Methyldioxane, as is dioxane itself, is infinitely soluble in water. Ethyldioxane dissolves to a considerable extent and propyl and butyldioxanes are not appreciably soluble. The lower members of the series have a characteristic, slightly displeasing, ethereal odor. The unpleasantness of the odor increases with higher members of the series.

Dioxane forms addition products with picric acid[11] and hydroquinone[12] which can serve as derivatives. The action of these reagents was tried on the monoalkyldioxanes, but in no case was it possible to isolate an addition compound.

A New Preparation of Dioxene.—Previously dioxene has been prepared only by the action of aliphatic Grignard reagents on 2,3-dichlorodioxane.[2] The reaction of light metals with 2,3-dichlorodioxane was found by Böeseken[13] to result only in tar. He also noted in the reaction of 2,3-dichlorodioxane with sodium iodide in boiling acetone that free iodine was liberated and a precipitate of sodium chloride formed, but he was not able to isolate dioxene.

As the reaction of inorganic iodides on α,β-dihalogen compounds is a method of obtaining double bonds under mild conditions,[14] it seemed desirable to apply this procedure to the synthesis of dioxene. It has been found that a mixture of magnesium and magnesium iodide in dry ether dehalogenates 2,3-dichlorodioxane to yield dioxene. This combination is useful because magnesium iodide is appreciably soluble in ether.



$$Mg + I_2 \longrightarrow MgI_2$$

Furthermore magnesium reacts with the liberated iodine to reform magnesium iodide. The formation of dioxene probably occurs through the intermediate formation of 2,3-diiododioxane.[15]

The use of the combination of magnesium and magnesium iodide in anhydrous solvents as a dehalogenating agent for α,β-dihalogen compounds holds many possibilities of being applicable to those compounds which may be decomposed under more vigorous conditions.

Experimental

Monoalkyldioxanes.—The properties and analyses of the monoalkyldioxanes are given in the tables.

Allyldioxane.—The procedure that has given the most satisfactory yields of the monoalkyldioxanes was that used in synthesizing allyldioxane. This method will be given in detail.

The allyl Grignard reagent was prepared from 181.5 g. (1.5 moles) of allyl bromide, 36.4 g. (1.5 moles) of magnesium and 600 cc. of dry ether.[16]

The monochlorodioxane was prepared by conducting, with stirring, 2.4 moles of dry hydrogen chloride into 51.6 g. (0.6 mole) of dioxene at 0°. The resulting mixture, on fractional distillation, yielded 50 g. (68.5%) of monochlorodioxane, b. p. 57–65° (25 mm.).

The monochlorodioxane was then added dropwise to the allylmagnesium bromide solution. The reaction mixture was stirred for one-half hour after all the monochlorodioxane had been added. Then excess Grignard reagent was hydrolyzed by slowly adding iced, dilute hydrochloric acid and the ether layer was separated, dried over sodium sulfate, decanted and then fractionally distilled. The fraction which distilled at 148–157° was collected as allyldioxane; yield, 37.8 g. (72.5%). The material was refluxed over sodium for several hours and fractionally distilled twice, b. p. 156–158° (corr.) at 747.6 mm.; d^{20}_4 0.937; $n^{20}D$ 1.4442.

The monoalkyldioxanes were purified by distillation from metallic sodium through a 40-cm. Podbielniak type column. In most cases the refractive indices of the first

and last portions of the distillate were the same. The allyldioxane, in contrast to the other alkyldioxanes, decomposed considerably when refluxed with sodium. The solid decomposition products were shaken with dilute sodium hydroxide and benzoyl chloride, extracted with ether, and, after drying over sodium sulfate, the ether was allowed to evaporate. A small amount of crystals formed on the side of the beaker and a viscous oil remained on the bottom. The crystals were collected and recrystallized three times from dilute alcohol, m. p. 70°. A mixed melting point with authentic ethylene dibenzoate was at 70–71°. This indicates ethylene glycol to be a reaction product of allyldioxane and sodium.

Reaction of Monochlorodioxane with Butyl Grignard Reagent Using Zinc Chloride.—The Grignard reagent was prepared from 205 g. (1.5 moles) of butyl bromide, 36.4 g. (1.5 moles) of magnesium and 700 cc. of dry ether. To this Grignard reagent was added 204 g. (1.5 moles) of anhydrous zinc chloride dissolved in 300 cc. of dry ether. The mixture was then refluxed for one hour on a water-bath kept at 40°.

The monochlorodioxane was prepared by dissolving 51.6 g. (0.6 mole) of dioxene in 100 cc. of dry benzene and passing into the solution at 0° 1.5 moles of dry hydrogen chloride. The solution was allowed to stand for three hours at room temperature, the color changing from colorless to yellow. Then excess hydrogen chloride was removed under the reduced pressure of the water pump.

The solution of monochlorodioxane was added dropwise to the organometallic mixture at 0°. The reaction mixture was allowed to stand at room temperature for ten hours, and was then refluxed on a water-bath for six hours. The flask was cooled in an ice-bath, and cold water slowly added to the reaction mixture. The precipitate that formed was dissolved by adding dilute sulfuric acid and the ether layer was then separated, dried over sodium sulfate, decanted and fractionally distilled. A fraction which distilled at 40–65° at 18 mm. was collected. The liquid residue which remained solidified on cooling. The fraction of butyldioxane was distilled twice from sodium: yield, 9.5 g. (11%); b. p. 178.2–179.2° (corr.) at 735 mm.; d^{20}_4 0.932; $n^{20}D$ 1.4336.

2-Butyl-3-dioxanyldioxane.—The solid residue from the first distillation of butyldioxane was extracted with petroleum ether, treated with norite and the solvent evaporated. The crystalline residue (1 g.) was recrystallized from dilute alcohol, needles, m. p. 101–102°. The solid was insoluble in water and was not affected by dilute hydrochloric acid or dilute sodium hydroxide. It dissolved in concentrated sulfuric acid without darkening. The material was recovered unchanged after being dissolved in acetyl chloride for one-half hour. The molecular weight, determined by the cryoscopic method using benzene, was found to be 242.

Anal. Calcd. for 2-butyl-3-dioxanyldioxane ($C_{12}H_{22}O_4$): C, 62.61; H, 9.56; mol. wt., 230. Found: C, 62.38, 62.29; H, 9.47, 9.39.

A number of experiments were tried in attempts to increase the yield of the solid compound. Aluminum chloride and zinc chloride were used as catalysts with mixtures of monochlorodioxane and dioxene before the reaction with butylmagnesium bromide. Benzene and carbon disulfide were employed as solvents in the preparation of monochlorodioxane. In most cases a small amount of the solid was obtained. However, the polymerizing agents tended to lead to the formation of tars. A later experiment using magnesium bromide as the catalyst in the synthesis of 2-ethyl-3-dioxanyldioxane appeared to be more satisfactory.

2-Ethyl-5-dioxanyldioxane.—Approximately 0.28 mole of dry hydrogen chloride was bubbled into a solution of 12 g. (0.14 mole) of dioxene and 200 cc. of dry benzene. The resulting mixture was allowed to stand at room temperature for four and one-half hours after adding 7.4 g. of dioxene and a solution of magnesium bromide prepared from one-half gram of bromine in 5 cc. of ether and excess magnesium. Excess hydrogen chloride was then removed from the colorless, turbid solution under the reduced pressure of the water pump.

To this solution was added a filtered Grignard reagent prepared from 64.8 g. of ethyl bromide, 14.4 g. of magnesium and 300 cc. of ether. After standing overnight, excess Grignard reagent was hydrolyzed by slowly adding dilute hydrochloric acid. The ether layer was separated, dried over sodium sulfate and fractionally distilled. A 3.6-g. fraction of ethyldioxane which distilled at 100–138° was collected. The residue (9.5 g.) did not crystallize on standing for several days in the refrigerator. It formed a glass on cooling with dry ice. The material was then heated in a bath at 150° under 20 mm. pressure. About 1 g. of distillate (ethyldioxane) was obtained. The residue contained a few crystals after standing for several days in the refrigerator. The mixture was dissolved in petroleum ether and decanted from some insoluble, colored tar. The petroleum ether was then evaporated and the residue warmed under reduced pressure to remove all the petroleum ether. The material did not crystallize on standing two weeks in the refrigerator. It was then vacuum distilled (1 mm.). The distillate formed an oily mass of crystals after several days. The crystals were filtered, and crystallized twice from dilute methanol: yield 0.5 g., m. p. 97.5°.

A mixed melting point with the solid from the butyldioxane synthesis (m. p. 102°) showed a large depression. The material is slightly soluble in water and easily soluble in organic solvents.

Anal. Calcd. for 2-ethyl-3-dioxanyldioxane ($C_{10}H_{18}O_4$): C, 59.40; H, 8.97. Found: C, 59.41; H, 9.02.

Ethyldioxane from β-Chloroethyl β-Bromo-α-ethylethyl Ether

α-Chloroethyl β-Chloroethyl Ether.—This ether was prepared according to the procedure of Grignard and Purdy[8] by conducting approximately 4 moles of dry hydrogen chloride into a mixture of 88 g. (0.67 mole) of paraldehyde and 161 g. (2 moles) of ethylene chlorohydrin at 0°. The yield of crude, dry α-chloroethyl β-chloroethyl ether was 227 g. (79%).

β-Chloroethyl α,β-Dibromoethyl Ether.—The crude α-chloroethyl β-chloroethyl ether (227 g. or 1.58 moles) was cooled to 0° in an ice-bath and 254 g. (1.58 moles) of bromine added in small portions over a period of two and one-half hours. The reaction product was then placed under reduced pressure to remove hydrogen chloride.

The material, yellow in color, separated into two layers on standing. The small top layer appeared to be water; yield, 420 g. (99%).

One-half, 210 g., of the β-chloroethyl α,β-dibromoethyl ether on distillation yielded a 154 g. (73%) fraction which distilled at 110–113° (12 mm.). This material was without color but turned light yellow on standing a short time. It fumed in air. A portion of the material was redistilled, b. p. 108° (12 mm.).

Anal. Calcd. for $C_4H_7OClBr_2$: total halogen, 73.33. Found: total halogen, 73.55.

β-Chloroethyl β-Bromo-α-ethylethyl Ether.—The unpurified β-chloroethyl α,β-dibromoethyl ether (210 g., 0.79 mole) was added during one hour to a solution at 0° of ethylmagnesium bromide prepared from 108.9 g. (1 mole) of ethyl bromide, 24 g. of magnesium and 450 cc. ether. The reaction mixture was stirred for one-half hour at room temperature. Then excess Grignard reagent was destroyed by slow addition of dilute hydrochloric acid and the ether layer was removed and dried over calcium chloride. After standing for two days the solution had a deep green color. The ether was then removed on a water-bath and the liquid residue vacuum distilled. A 42.5 g. (25%) fraction was obtained which distilled at 92° (12 mm.). The distillate was at first colorless but soon turned pink in color. After standing for two days it became dark amber in color.

A portion of the material was redistilled. A fraction which distilled at 92–93° (12 mm.) was colorless and remained so on standing; d^{20}_4 1.388; $n^{20}D$ 1.4770.

Anal. Calcd. for $C_6H_{12}OClBr$: total halogen, 53.55. Found: total halogen, 54.10.

Ethyldioxane.—Thirty grams of β-chloroethyl β-bromo-α-ethylethyl ether was refluxed for twenty-six hours with 30 g. of potassium hydroxide and 270 cc. of water. At the end of that time a test for halogen was obtained from the aqueous portion; however, a considerable amount of insoluble material remained. The mixture was divided into two equal portions. One portion was heated at 200–205° (bath temp.) in a monel metal bomb for one and one-half hours. The dark turbid solution was then extracted four times with a total of 150 cc. of ether. The combined ether extracts were dried over sodium sulfate and fractionally distilled. Eight-tenths gram (10%) of ethyl dioxane was obtained, b. p. 132–136°.

The other portion of the dihalogen ether and potassium hydroxide mixture was heated at 200–205° (bath temp.) for three and one-half hours. After working up the product as before, 1.4 g. (17%) of ethyldioxane was obtained, b. p. 132–136°.

Dioxene.—The reaction was carried out in a three-necked, five-liter flask equipped with a dropping funnel, bulbed condenser fitted with a calcium chloride tube and a mercury-sealed Hershberg stirrer.[17] In the flask were placed 82.6 g. (3.4 moles) of magnesium turnings and 1200 cc. of dry ether. Then 91.5 g. (0.4 mole) of iodine was added in small portions. The formation of the magnesium iodide occurred readily with the liberation of considerable amounts of heat. When the mixture became colorless, 314 g. (2 moles) of 2,3-dichlorodioxane mixed with 200 cc. of ether was added dropwise, with vigorous stirring, at such a rate that the color of the mixture due to the liberated iodine was never darker than light brown (nine hours). One-half hour after the addition of the last of the 2,3-dichlorodioxane, the mixture became colorless. It was then poured onto cracked ice and the ether layer separated, dried over sodium sulfate, decanted and fractionally distilled. A fraction which distilled at 93–95° was collected as dioxene: yield 84.3 g. (49%).

The synthesis of dioxene by this method has been carried out using varying proportions of magnesium iodide and 2,3-dichlorodioxane. Greater yields of dioxene were obtained with the use of larger amounts of magnesium iodide, and the reaction, particularly after a considerable amount of the 2,3-dichlorodioxane had been added, appeared to proceed more smoothly. In all cases the reaction proceeded at a decreasing rate. This is possibly due to coprecipitation of the iodide ion with the insoluble magnesium chloride. The effect of varying the ratio of magnesium iodide to 2,3-dichlorodioxane on the yield of dioxene is shown in the following table.

Ratio, moles iodine/ moles 2,3-dichlorodioxane	Yield, %
1:20	31
1:10	44
1:5	49

(17) Hershberg, *Ind. Eng. Chem., Anal. Ed.*, **8**, 313 (1936).

Summary

A series of monoalkyldioxanes has been prepared for the first time. The densities, refractive indices and boiling points vary in a uniform manner with increasing size of alkyl group. An uncommon relationship of refractive index and density exists for the series.

A solid by-product from the synthesis of the monoalkyldioxanes has been indicated to be the 2-alkyl-3-dioxanyldioxane. The mechanism for the formation and a method for the synthesis of the compounds are given.

A general method for the synthesis of substituted dioxanes by means of substituted β-halogenethyl ethers has been discussed. The procedure has been applied in the synthesis of ethyldioxane from β-chloroethyl β-bromo-α-ethylethyl ether.

A mixture of magnesium and magnesium iodide in dry ether has been found to be a new and excellent reagent for dehalogenating α,β-dihalogen compounds. It was used in the synthesis of dioxene from 2,3-dichlorodioxane.

Dioxadiene

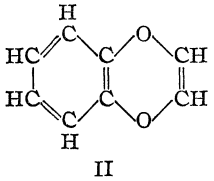
BY R. K. SUMMERBELL AND R. R. UMHOEFER

I. Introduction

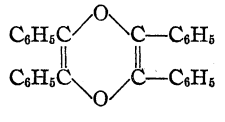
The synthesis of dioxene[1] and the subsequent investigation of its properties has shown this compound to differ in many respects from dioxane. Thus while dioxane is soluble in all proportions with water, dioxene is insoluble. The boiling point of dioxene is seven degrees below that of dioxane. Also the ability to form the unique addition products characteristic of dioxane is no longer evident. Consideration of the contrast in properties of these compounds has led us to synthesize dioxadiene (I), a compound with two double bonds.

Dioxadiene, although hitherto unknown, has long been listed in chemical abstracts under the name of Dioxin. It is used as the fundamental or parent nucleus for the cataloging of dioxane, dioxene, and their derivatives. The term dioxadiene has been proposed previously to designate the compound discussed here.[2,3]

Condensed forms of the dioxadiene nucleus such as benzodioxadiene (II)[4] and dibenzodioxadiene have long been known. Tetraphenyldioxadiene (III) is the only non-condensed derivative of dioxadiene that has been prepared and studied thus far.[3] The presence of so many phenyl groups, raising the molecular weight and modifying the properties of the double bonds, limits the usefulness of such compounds as material for the study of the dioxadiene nucleus.



II



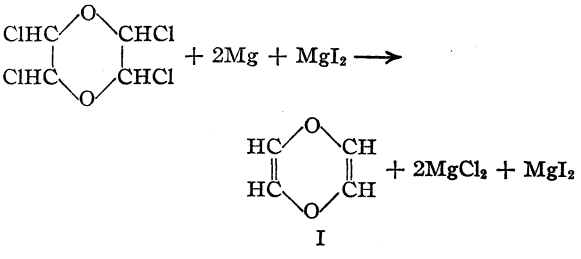
III

II. Synthesis of Dioxadiene

A new synthesis of dioxene from 2,3-dichlorodioxane using a mixture of magnesium and magnesium iodide in ethyl ether as a dehalogenating reagent has been reported.[6] An obvious extension of the method to the synthesis of dioxadiene would be the application of the same dehalogenating reagent to 2,3,5,6-tetrachlorodioxane.

Although dioxene is readily prepared from 2,3-dichlorodioxane, there is a considerable difference in reactivity of 2,3-dichlorodioxane and 2,3,5,6-tetrachlorodioxane. The dichlorodioxane is easily hydrolyzed in ten to fifteen minutes by heating with water, while the tetrachloro compound requires three or four hours for hydrolysis. No reaction could be observed when the symmetrical tetrachlorodioxane was treated with magnesium iodide dissolved in ethyl ether.

The reaction was modified by using the higher boiling *n*-butyl ether as a solvent. Because of the possibility that the dioxadiene would be polymerized at the high temperature required for the reaction, the apparatus was so arranged that the dioxadiene would distil from the reaction mixture as it was formed. The method produced yields of dioxadiene as high as 64% of the theoretical.



I

III. Physical Properties

An interesting physical property of dioxadiene is the boiling point, 75°, which is 26° less than that of dioxane. This large difference is found also in the furan series, where the boiling point of furan is 33° less than that of tetrahydrofuran. Vinyl ether shows a much smaller decrease in boiling point compared with ethyl ether. Correspondingly, a large difference exists between the calculated and observed values of the molar refractivity of both dioxadiene and furan. On the basis of these comparisons the unsaturation of dioxadiene is nearer to that of furan than that of vinyl ether.

Dioxadiene is insoluble in water. This may be explained by assuming that resonance involves the electron pairs of the oxygen so that they are

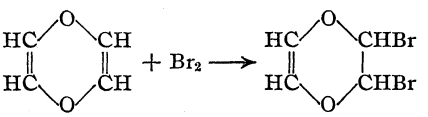
not available for hydrogen bond formation with the solvent.

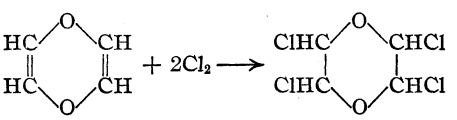
IV. Chemical Properties

The chemical properties of dioxadiene in general are those of an unsaturated ether. However, it shows a greater stability toward dilute acid solutions than other unsaturated ethers such as dioxene and vinyl ether.

Dioxadiene polymerizes in two to three weeks to a hard colorless solid which does not melt below 250°. The polymer is insoluble in water, benzene, dioxane and camphor and hence its molecular weight has not been determined. The polymerized material gave a slight reaction with bromine water. Dioxadiene reacts vigorously with bromine. When brominated in carbon tetrachloride solution, a solid crystalline product, containing two atoms of bromine, was obtained with practically no evolution of hydrogen bromide. The reaction is probably one of addition of bromine to only one of the double bonds. Dioxadiene



reacts with chlorine to form the symmetrical tetrachlorodioxane. This reaction is of importance, as it is an excellent proof of the structure of dioxadiene, since the derivative obtained by this reaction was one of the known isomers.



Hydrogen chloride adds to dioxadiene to form the 2,5-dichlorodioxane. Dioxadiene reacts readily with a solution of mercuric chloride to yield an amorphous solid of unknown structure. Analysis indicates the product to be a dimercury derivative. Slight color changes of doubtful significance were observed when dioxadiene was treated with maleic anhydride and with picric acid; however, no compounds could be isolated.

In all of the above reactions, dioxadiene has behaved in a manner to be expected of an unsaturated aliphatic compound where the unsaturation is conjugated to a limited extent. The name dioxadiene seems more appropriate than dioxin.

Attempts to prepare dioxadiene from more available intermediates were unsuccessful. These included the treatment of diglycolic acid anhydride and glycolide with zinc dust and the pyrolysis of the acetate of dimeric glycol aldehyde.

Experimental

Dioxadiene.—To 23 g. of magnesium turnings in 500 cc. of dry *n*-butyl ether in a one-liter, three-necked flask equipped with an efficient mercury-sealed stirrer connected with a condenser by a bent tube of large diameter, 80 g. of iodine was added in small portions. After all the iodine had reacted, the flask was immersed in an oil-bath and the latter heated to 140°. With good stirring, 35.5 g. of 2,3,5,6-tetrachlorodioxane (m. p. 141–142°) was added in 1–2 g. lots. The reaction was accompanied by vigorous ebullition of the mixture, resulting in the distillation of the dioxadiene along with a considerable amount of *n*-butyl ether. After about 100 cc. of distillate had been collected, 100 cc. of *n*-butyl ether was added to the reaction flask. When all the tetrachlorodioxane had reacted, the bath temperature was raised to 155° and an additional 25 cc. of distillate collected; time, one and one-half hours. The distillate (300 cc.), slightly colored with iodine, was distilled from an ordinary distilling flask and the low boiling fraction (up to 115°) was fractionated through a 40-cm. Podbielniak type column. An 8.4 g. (64%) fraction was obtained, b. p. 73–78°. In another preparation of dioxadiene under the same conditions, a 48% yield was obtained. However, all the material distilled at a constant boiling point of 75° at 746 mm.; d^{20}_4 1.115; $n^{20}D$ 1.4350; *MR*, calcd. 20.84; found, 19.66.

Anal. Calcd. for $C_4H_4O_2$: C, 57.12; H, 4.76. Found: C, 57.18; H, 4.94.

Reaction of Dioxadiene with Bromine.—To a solution of 1.18 g. (0.0142 mole) of dioxadiene in 15 cc. of dry carbon tetrachloride at 0° was added slowly 2.28 g. (0.0142 mole) of bromine dissolved in 10 cc. of carbon tetrachloride. The dioxadiene readily reacted with the bromine. No further reaction of the dioxadiene with bromine occurred when an additional small quantity of the bromine solution was added. This was indicated by the persistence of the bromine color. The carbon tetrachloride was removed in a vacuum desiccator, and the crystalline residue was recrystallized from petroleum ether as needles, m. p. 55–57°; yield 2.98 g. (87%). After another recrystallization from petroleum ether, the material melted at 58°. The compound decomposed over a period of several weeks when exposed to the atmosphere.

Anal. Calcd. for $C_4H_4O_2Br_2$: Br, 65.55. Found: Br, 65.97.

Symmetrical Tetrachlorodioxane.—A solution of 1.3 g. of dioxadiene in 40 cc. of dry carbon tetrachloride was saturated with chlorine at room temperature. After evaporation of the carbon tetrachloride from a water-bath, the residue (0.5 g.) was crystallized three times from methyl alcohol: needles, m. p. 139–140°. A mixed melting point with 2,3,5,6-tetrachlorodioxane (m. p. 142–143°) melted at 139–140.5°.

Anal. Calcd. for $C_4H_4O_2Cl_4$: Cl, 62.81. Found: Cl, 62.35.

2,5-Dichlorodioxane.—Approximately 0.35 mole of dry hydrogen chloride was passed into a solution of 4.9

g. of dioxadiene and 5 cc. of dry carbon tetrachloride. Some solid separated during the reaction. After the carbon tetrachloride was removed in a vacuum desiccator, the residue was warmed with petroleum ether and the solution decanted from some insoluble material. The petroleum ether solution on cooling deposited needle-like crystals of 2,5-dichlorodioxane, m. p. 117–118°.[7] The material decomposed on standing. It was readily hydrolyzed by water and the solution yielded the *p*-nitrophenylosazone of glycol aldehyde when treated with *p*-nitrophenylhydrazine; m. p. 300° (uncorr.).

Mercuration of Dioxadiene.—A solution of 1 g. of dioxadiene in 5 cc. of alcohol was added to 71.5 cc. of a cold solution which contained 3.22 g. of mercuric chloride and 6.23 g. of sodium acetate–$3H_2O$. A white precipitate formed immediately. After standing overnight in a refrigerator, the solid was filtered and washed with water several times. The material after air drying weighed 3.28 g. The theoretical yield for a disubstituted compound is 3.30 g. The product showed no definite melting point, and was insoluble in alcohol, dioxane, benzene or a mixture of alcohol and acetic acid. The material was washed several times more with water and dried in a desiccator.

Anal. Calcd. for $C_4H_2O_2Hg_2Cl_2$: Hg, 72.39. Found: Hg, 71.56, 70.11.

(7) 2,5-Dichlorodioxane, needles, m. p. 118–119°, has been isolated as a product of the chlorination of dioxane by L. Rochen of this Laboratory. It is an unstable solid easily hydrolyzed by water.

Summary

1. Dioxadiene has been prepared for the first time.

2. The physical and chemical properties have been studied. These indicate that the unsaturation is modified to a marked extent by conjugation with the ether oxygens.

Sterols. LXXV. Cholesterol Derivatives

BY RUSSELL E. MARKER AND EWALD ROHRMANN

The present work is a continuation of a previously reported investigation[1] on 7-keto-cholesterol derivatives. In the previous work it was observed that 7-ketocholesteryl chloride upon catalytic hydrogenation in acetic acid solution gave a mixture of products from which cholestyl chloride was isolated. Indications of the presence of 7-hydroxycholestyl chloride were also obtained.

We have now observed that when the hydrogenation of $\Delta^{5,6}$-unsaturated 7-keto compounds is conducted in a neutral medium with Adams catalyst the essential product is a saturated 7-keto compound. This selective reduction of the ethylenic linkage most probably is due to the slightly hindered nature of the carbonyl group at C-7.

The catalytic hydrogenation of 7-ketocholesteryl chloride in neutral solution with Adams catalyst yielded 7-ketocholestyl chloride identical with that prepared previously by the oxidation of crude 7-hydroxycholestyl chloride.[1] A similar reduction of 7-ketocholesteryl acetate gave 7-ketocholestyl acetate evidently identical with the product which Windaus and Kirchner[2] obtained by the hydrogenation of 7-ketocholesteryl acetate with palladium catalyst in an acidic medium. When the hydrogenation of 7-ketocholesteryl acetate was carried out in acetic acid solution with Adams catalyst followed by alkaline hydrolysis of the reduction products, 7-hydroxycholestanol was obtained. This was identical with the product obtained by the reduction of 7-ketocholestanol with aluminum isopropylate. Mild oxidation of this diol with chromic anhydride yielded 7-ketocholestanone first reported by Windaus and Kirchner.[2]

Dimroth and Trautmann[3] reported the preparation of $\Delta^{5,6}$-cholestenol-7 by the reduction of $\Delta^{5,6}$-cholestenone-7 with aluminum isopropylate. No analytical data were given on their product which melted at 93–94°. The substance was reported to yield a benzoate, m. p. 108–109°. We have prepared $\Delta^{5,6}$-cholestenol-7 by the reduction of 7-hydroxycholesteryl chloride with sodium and amyl alcohol. The product, m. p. 106°, gave a benzoate, m. p. 147°. Bromination of the substance followed by mild oxidation with chromic anhydride and subsequent debromination gave $\Delta^{5,6}$-cholestenone-7 of m. p. 126°, while catalytic hydrogenation in neutral medium gave cholestanol-7.

It is improbable that our $\Delta^{5,6}$-cholestenol-7 differs from that of Dimroth and Trautmann in the configuration of the hydroxyl group as in both

cases the hydroxyl group was formed by reduction of a carbonyl group with aluminum isopropylate, a reaction which appears to give largely one isomer at C-7. It is possible that the two benzoates may be polymorphic forms.

In the present paper we are also reporting the incidental preparation of 3-acetyl-4-hydroxycholesterol which was prepared by the oxidation of cholesteryl acetate with selenium dioxide.[4-7] The substance was obtained in two polymorphic forms.

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part

7-Ketocholestyl Chloride.—A mixture of 1.6 g. of 7-ketocholesteryl chloride, 400 mg. of Adams catalyst and 120 cc. of ether was shaken with hydrogen at 3 atmospheres pressure for four hours at 25°. The product was crystallized from acetone as thick white prisms, m. p. 136–138°. This gave no depression with an authentic sample of 7-ketocholestyl chloride.

Anal. Calcd. for $C_{27}H_{45}OCl$: C, 77.1; H, 10.7. Found: C, 77.1; H, 10.5.

The substance gave an **oxime** which crystallized from aqueous ethanol, m. p. 152–154°.

Anal. Calcd. for $C_{27}H_{46}OClN$: C, 74.35; H, 10.6. Found: C, 74.35; H, 10.7.

Hydrogenation of the Acetate of $\Delta^{5,6}$-Cholestenol-3(β)-one-7.—A mixture of 5 g. of the acetate, 500 mg. of Adams catalyst and 150 cc. of ether was shaken with hydrogen at 3 atmospheres pressure for seven hours at 25°. The mixture was filtered, the filtrate evaporated and the residue crystallized from acetone–methanol to give white plates, m. p. 147–148°.

Anal. Calcd. for $C_{29}H_{48}O_3$: C, 78.3; H, 10.9. Found: C, 78.4; H, 10.6.

Hydrolysis of the resulting acetate of cholestanol-3(β)-one-7 by refluxing with an excess of ethanolic potassium hydroxide gave a product which crystallized from acetone–methanol as white plates, m. p. 128–130°, solidifying almost at once and remelting at 157–159°.

Anal. Calcd. for $C_{27}H_{46}O_2$: C, 80.5; H, 11.5. Found: C, 80.8; H, 11.7.

The hydrolysis product gave an **oxime** which crystallized from aqueous ethanol as fine white needles, m. p. 232–233°.

Anal. Calcd. for $C_{27}H_{47}O_2N$: C, 77.6; H, 11.3. Found: C, 77.2; H, 11.5.

Cholestanediol-3(β)-7(α). (a) By Hydrogenation of 7-Ketocholesteryl Acetate.—A mixture of 5 g. of 7-ketocholesteryl acetate, 500 mg. of Adams catalyst and 150 cc. of glacial acetic acid was shaken with hydrogen at 3 atmospheres pressure at room temperature for fourteen hours. The mixture was filtered and the filtrate evaporated *in vacuo*. The residue which would not crystallize was hydrolyzed with ethanolic potassium hydroxide and the product crystallized from acetone to give white plates, m. p. 164–166°.

Anal. Calcd. for $C_{27}H_{48}O_2$: C, 80.1; H, 11.95. Found: C, 80.2; H, 11.9.

The filtrate containing crude 7-hydroxycholestanol was evaporated to dryness and the crystalline residue dissolved in 125 cc. of glacial acetic acid. To this solution was added 2 g. of chromic anhydride in 20 cc. of 80% acetic acid. After standing at room temperature for two hours the solution was diluted with water and the precipitated solid taken up in ether. The ethereal extract was washed with sodium carbonate solution and the ether evaporated. The residue was crystallized from acetone as white needles, m. p. 186–187°.

Anal. Calcd. for $C_{27}H_{44}O_2$: C, 80.9; H, 11.1. Found: C, 81.2; H, 11.2.

(b) By Aluminum Isopropylate Reduction of the Acetate of Cholestanol-3(β)-one-7.—A mixture of 1.2 g. of cholestanol-3(β)-one-7 acetate, 1.5 g. of aluminum isopropylate and 40 cc. of dry isopropyl alcohol was refluxed on the steam-bath for fourteen hours. Most of the solvent was distilled off over a period of three hours. The residue was diluted with water and the precipitate extracted with ether. The product crystallized from acetone as white plates, m. p. 163–165°. It gave no depression with the product of the catalytic hydrogenation of 7-ketocholesteryl acetate.

$\Delta^{5,6}$-Cholestenol-7.—To a boiling solution of 3 g. of 7-hydroxycholesteryl chloride was added 6 g. of sodium over a period of four hours. The mixture was then cooled, diluted with ether and washed well with water. The ether and amyl alcohol was evaporated on the steam-bath. The residual oil which would not crystallize was sublimed in high vacuum. The material distilling at 130–160° was crystallized from acetone to give 800 mg. of thick white prisms, m. p. 105–106°.

Anal. Calcd. for $C_{27}H_{46}O$: C, 83.9; H, 12.0. Found: C, 83.9; H, 12.0.

When treated with benzoyl chloride in pyridine at room temperature for two days the product yielded a benzoate which crystallized from methanol as white needles, m. p. 145–147°.

Anal. Calcd. for $C_{34}H_{50}O_2$: C, 83.2; H, 10.3. Found: C, 83.1; H, 10.1.

Hydrogenation of $\Delta^{5,6}$-Cholestenol-7.—A mixture of 400 mg. of $\Delta^{5,6}$-cholestenol-7, 500 mg. of Adams catalyst, 50 cc. of ether and 25 cc. of absolute ethanol was shaken with hydrogen at 45 pounds (3 atm.) pressure for ninety minutes. The mixture was filtered, the filtrate diluted with water and the ether layer separated. The ether was evaporated and the residue crystallized from ethanol to give white needles, m. p. 115–117°. This gave no depression with an authentic sample of cholestanol-7, m. p. 116–117°.

$\Delta^{5,6}$-Cholestenone-7.—To a solution of 500 mg. of $\Delta^{5,6}$-cholestenol-7 in 5 cc. of ether was added a slight excess of bromine in 2 cc. of glacial acetic acid. No crystalline bromide was obtained. The solution was diluted with

water, extracted with ether and the ether evaporated at room temperature. The residue was dissolved in 10 cc. of benzene. To this solution was added a solution of 500 mg. of chromic anhydride in 15 cc. of 80% acetic acid, and the mixture stirred for five hours at room temperature. The benzene layer was washed with water and the solvent evaporated. The residue was dissolved in 20 cc. of glacial acetic acid and the solution heated on the steam-bath for thirty minutes with 2 g. of zinc dust. The solution was decanted into water and the precipitated solid extracted with ether. After washing with dilute sodium carbonate solution the ether was evaporated and the residue crystallized from acetone to give white needles, m. p. 125–126°.

Anal. Calcd. for $C_{27}H_{44}O$: C, 84.3; H, 11.5. Found: C, 84.3; H, 11.7.

3-Acetyl-4-hydroxy-cholesterol.—A mixture of 50 g. of cholesteryl acetate in 250 cc. of benzene was oxidized with a solution of 20 g. of selenium dioxide in 500 cc. of 98% acetic acid as described in a previous paper for sitosteryl acetate. The product was crystallized from acetic acid and after treatment with Norite it was crystallized from methanol to give white needles, m. p. 163–165°.

Anal. Calcd. for $C_{29}H_{48}O_3$: C, 78.3; H, 11.1. Found: C, 78.2; H, 10.9.

The acetic acid filtrate from the above initial crystallization upon standing deposited pale tan plates. After treatment with Norite and crystallization from methanol–ether the product formed white plates, m. p. 189–191°. The mixture with the product of m. p. 163–165° melted over an intermediate range of 163 to 184°.

Anal. Calcd. for $C_{29}H_{48}O_3$: C, 78.3; H, 11.1. Found: C, 78.3; H, 11.0.

Both polymorphic forms yielded the diacetate of 4-hydroxycholesterol, m. p. 162–163°, on refluxing with acetic anhydride. Hydrolysis of both forms with ethanolic potassium hydroxide yielded 4-hydroxycholesterol, m. p. 174–175°.

Summary

Reduction of 7-ketocholesterol derivatives with hydrogen and Adams catalyst in neutral medium tends to reduce the ethylenic linkage, yielding a saturated 7-keto compound.

$\Delta^{5,6}$-Cholestenol-7 has been prepared by the reduction of 7-hydroxycholesteryl chloride with sodium and amyl alcohol.

The preparation of 4-hydroxycholesteryl acetate by the oxidation of cholesteryl acetate with selenium dioxide is reported.

The Photolysis of Azomethane and of Azomethane–Acetaldehyde Mixtures

BY FRANCIS E. BLACET AND ALVIN TAUROG

Several investigators are in agreement that at elevated temperatures the thermal[1,2] and photochemical[3,4] decomposition of acetaldehyde involves the reactions

$$CH_3 + CH_3CHO \longrightarrow CH_4 + CH_3CO \quad (1)$$
$$CH_3CO + M \longrightarrow CH_3 + CO + M \quad (2)$$

However, the evidence for these reactions in room temperature photolysis is indirect,[5] being based upon analyses of decomposition products, and is opposed by the experimental proof that CH_3CO is fairly stable[6] below 60°, as well as by a rather high calculated minimum value of 17 kcal. for the energy of activation of reaction 2.[7] By mixing azomethane and acetaldehyde vapors at room temperature, and irradiating the mixture with λ 3660 Å., which is not absorbed by the aldehyde but which dissociates azomethane to give free methyl radicals,[8] the present authors have obtained additional information which pertains to this mechanism. A brief study has been made also of the gaseous decomposition products and the quantum yield of azomethane photolysis.

Experimental Method

Azomethane was obtained by preparing dimethylhydrazine dihydrochloride after the manner of Hatt[9] and oxidizing this with cupric chloride by the method suggested by Jahn.[10] This oxidation process was found to be definitely superior to the potassium chromate method of Thiele.[11] Ramsperger's procedure[12] was followed in purifying the azomethane.

Radiant energy was obtained from a high pressure mercury arc and a quartz monochromator. The gas train was similar to that which has been described[13] except that a second storage reservoir and mercury trap was added to accommodate the azomethane. This reservoir was pro-

tected from the light of the room, and was kept at −80° to diminish photodecomposition of the vapor by stray light and to reduce the vapor pressure enough to allow mercury traps of moderate length to be used.

The gaseous decomposition products were determined by the Blacet–Leighton method of microanalysis. Residual azomethane vapor in the gas was removed with a sintered glass bead containing 12 *N* hydrochloric acid, followed by solid potassium hydroxide. The alkali also removed residual acetaldehyde. Fuming sulfuric acid was used to test for unsaturated hydrocarbons, silver oxide for carbon monoxide, copper oxide and potassium hydroxide at approximately 300° for hydrogen, and saturated hydrocarbons were removed by combustion with a hot platinum coil.[14] The percentage nitrogen was calculated from the difference in volume of a sample taken for analysis and the sum of the volumes of the other gases found present.

Quantum yields for pure azomethane decomposition were determined in essentially the same manner as previously described for aldehyde photolysis[13] except that calculations were made in two different ways, one based on the pressure change in the system and the other based on the free nitrogen produced in the reaction. Special care was taken to exclude atmospheric nitrogen from the reaction system and the storage reservoirs by flushing them with carbon dioxide several times and evacuating by means of a Toepler pump. Possible residual carbon dioxide was removed from the gaseous decomposition products in the same operations which took out the excess azomethane. All photochemical experiments were performed at 30° and with the wave length 3660 Å.

The absorption spectrum of azomethane vapor was taken using a model E-316 Hilger spectrograph and a hydrogen discharge as the radiation source.

Experimental Results

The azomethane made by the cupric chloride method was water white in the liquid state. A column of the vapor 40 cm. in length, having a pressure of 300 mm. at 22.5°, gave continuous absorption between λ 3020 and 3850, with a maximum at 3380 Å. A second region of continuous absorption began at λ 2570 and extended to shorter wave lengths. In agreement with Ramsperger,[15] no discontinuous absorption was observed at lower pressures.

In a Paneth type experiment azomethane was found to remove tellurium mirrors readily when irradiated with λ 3660.[16]

Azomethane.—The apparatus used in this work was equipped with thermopile and galvanometer for energy measurements and although the primary object of the investigation was to study azomethane–acetaldehyde mixtures, a few quantum yield determinations of pure azomethane photolysis were made. This seemed especially worth while since the two previous quantum yield studies are in disagreement: Ramsperger[15] having reported a value of approximately 2 while Forbes, Heidt and Sickman[17] have given yields approaching unity as a maximum. In both of these cases quantum yields were based upon the experimental fact that the pressure after the complete thermal decomposition of azomethane was 2.04 times the original pressure.

In Table I are the results of analyses of the non-condensable gas produced in several runs on azomethane which differed from one another only in initial pressure. The percentages given represent the average of 2 or 3 separate analyses which differed in most cases by 5–10% from the mean value. Tests for unsaturated hydrocarbons with fuming sulfuric acid gave an average reduction in volume of less than 0.3%. No evidence for propane was found.

TABLE I

ANALYSES OF NON-CONDENSABLE PRODUCTS FROM AZOMETHANE

Pressure, mm.	% hydrogen	% methane	% ethane	% nitrogen
13	1.5	9	40	49
31	2.5	4	39	54
32	0.5	3	40	56
49	2.0	7	33	57
57	2.0	7	38	53
80	3.0	9	32	56
Average %	1.9	6.5	37	54

Quantum yields, Φ, were determined in the four cases listed in Table II. The run at 13 mm. should be discounted with respect to the others since at very low pressures experimental errors may be very large. The third column in this table gives the yield calculated from the pressure change in the reaction system assuming the overall reaction

$$(CH_3)_2N_2 + h\nu \longrightarrow C_2H_6 + N_2 \qquad (3)$$

The yield in the fourth column was calculated from the nitrogen produced, the assumption be-

ing that one molecule of nitrogen was formed per decomposition process irrespective of secondary reactions.

Azomethane-Acetaldehyde Mixtures.—The first few runs in which the azomethane pressure was about one-half to one-third the acetaldehyde pressure gave no carbon monoxide in the photolysis products. However, by going to lower ratios appreciable amounts of carbon monoxide were found as shown in Table III. The percentages given are of the non-condensable gas in each case. Complete analyses of the gas were not made in these experiments.

7.5	487	11.6	3.0
3.0	503	14.3	2.2

Discussion of Results

Azomethane Photolysis.—The removal of tellurium mirrors in the Paneth experiment indicates that some free radicals are produced at room temperature when azomethane is irradiated with λ3660; however, the experiments were qualitative and do not exclude the possibility of partial dissociation directly into stable molecules. The formation of radicals in the thermal dissociation had previously been demonstrated.[18,19]

The average of 54% nitrogen in the non-condensable gases formed in the photolysis of azomethane is in excellent agreement with 54.7% reported by Burton, Davis and Taylor.[8] These authors have explained this high percentage by assuming that methyl radicals produced thus

$$(CH_3)_2N_2 + h\nu \longrightarrow 2CH_3 + N_2 \qquad (4)$$

may react with additional azomethane to give condensable products in some such manner as the following

$$CH_3 + (CH_3)_2N_2 \longrightarrow (CH_3)_2N_2CH_3 \qquad (5)$$
$$CH_3 + (CH_3)_2N_2CH_3 \longrightarrow (CH_3)_2N_2(CH_3)_2 \qquad (6)$$

The methane percentage is also in qualitative agreement with that reported by these authors. Although no completely satisfactory mechanism has been given for the formation of this hydrocarbon, the over-all reaction

$$2CH_3 + 2(CH_3)_2N_2 \longrightarrow 2CH_4 + (CH_3N_2CH_2)_2 \qquad (7)$$

should be mentioned as a type of process which might occur in competition with reactions 5 and 6. Davis, Jahn and Burton[20] have found that nitric oxide greatly diminishes the amount of hydrocarbons produced in azomethane photolysis. They interpret this to mean that reaction 3 does not occur to an appreciable extent and have suggested that the large amount of ethane production in the absence of nitric oxide is the result of some process which follows reaction 5. If such a mechanism were to occur, one would expect the free methyl to attack the azomethane itself giving C_2H_6 and CH_3N_2. Since CH_3N_2 is unstable[8] and dissociates immediately after formation to give CH_3 and N_2 the net result would be a chain process for which there is no photochemical evidence at room temperature.

The possibility that reaction 3 would occur in the absence of, but not in the presence of, nitric oxide should not be ignored. If azomethane remains activated for an appreciable length of time before dissociating, as indicated by the work of Forbes, Heidt and Sickman,[17] it is conceivable that it would react directly with nitric oxide, thus partially suppressing both reactions 3 and 4. The initial nitric oxide pressures in the above-mentioned experiments varied from 9.9 to 20.5 mm. The small but definite percentage of hydrogen found is difficult to account for without postulating the formation of an equivalent amount of unsaturated hydrocarbons. It is possible that these were formed but escaped detection by dissolving in the 12 *N* hydrochloric acid used to remove the excess azomethane.

The evidence indicates that the quantum yield of azomethane decomposition calculated from the free nitrogen formed in the process is more reliable than the one calculated from a pressure increase in the system. If the low value obtained at 13 mm. pressure may be discounted, the yield is unity within experimental error over the pressure range 49 to 80 mm. at 30°. This is in accord with the conclusions reached by Forbes and his collaborators,[17] in spite of the fact that the two methods of arriving at the value of unity are not entirely consistent with each other.

It is interesting to note that if one assumes both

(18) Leermakers, THIS JOURNAL, **55**, 3499 (1933).
(19) Rice and Evering, *ibid.*, **55**, 3898 (1933).
(20) Davis, Jahn and Burton, *ibid.*, **60**, 10 (1938).

primary processes given above and reactions 5, 6 and 7 as the only secondary reactions which occur, he can show from the percentages of methane, ethane and nitrogen given in Table I that the quantum yield given from pressure increase should be approximately 74% of that calculated from the nitrogen. Experimentally, the last three values of Table II give an average for the pressure method which is 71% of the nitrogen method. The small amount of hydrogen was ignored in this calculation.

The Photolysis of Azomethane–Acetaldehyde Mixtures.—Table III shows that under the proper experimental conditions azomethane will photosensitize the decomposition of acetaldehyde. It is probable that this process is initiated by free methyl radicals as indicated in reaction (1). The fact that the percentage of carbon monoxide is not appreciable until the ratio of acetaldehyde to azomethane is of the order of 10 to 1, is an additional indication that free methyls react with azomethane and that the energy of activation of this process is less than that for the aldehyde reaction. Such a conclusion is in accord with the low hydrocarbon to nitrogen ratio discussed above and also explains the failure of Burton, *et al.*,[8] to detect carbon monoxide in a similar experiment with a mixture of azomethane and acetaldehyde since the molecular ratio used by them was approximately 1 to 1. The hydrogen percentages found are somewhat erratic; nevertheless, they lead to the conclusion that this gas comes from the azomethane and not from the acetaldehyde. All of these results are consistent with reactions (1) and (2). At the same time it must be recognized that others have presented strong objections to reaction (2) as a room temperature process and it is possible that carbon monoxide was produced by reactions not considered in this discussion.

Summary

1. The quantum yield of azomethane decomposition by λ 3660 Å. at room temperature and in the pressure range 49 to 80 mm., has been found to be unity when calculated on the basis of the number of molecules of free nitrogen formed per quantum absorbed. Quantum yields calculated on the basis of pressure increase in the reaction system averaged 0.75. The nitrogen method is considered more reliable.

2. Analyses of the gaseous photodecomposition products of azomethane gave an average of 1.9% hydrogen, 6.5% methane, 37% ethane and 54% nitrogen. A mechanism is suggested which would account for all gases except the hydrogen.

3. It has been shown by the detection of carbon monoxide that azomethane will photosensitize the decomposition of acetaldehyde when the ratio of acetaldehyde to azomethane is greater than 10 to 1. This is interpreted as meaning that free methyl radicals produced in the photolysis of azomethane will react with either azomethane or acetaldehyde, preferably with the former.

The Contact Potential of an Iodine Film on Tungsten

BY M. J. COPLEY AND R. W. SPENCE[1]

Monomolecular films of oxygen and of hydrogen on metals have been widely investigated, but little information is available about the properties of halogen films. Van Pragh[2] exposed a platinum surface to iodine vapor, noted its effect on the accommodation coefficient of argon on platinum, and concluded that, at a pressure of 0.027 mm., an iodine film is formed below 1565°K. Glockler and Calvin[3] in their determination of the electron affinity of iodine from thermionic data taken in the presence of iodine vapor, found no evidence of adsorption of iodine on tungsten at temperatures above 2000°K. with pressures as high as 10^{-4} mm. Hendricks, Phipps and Copley[4] measured the degree of surface ionization taking place when molecular rays of the potassium halides impinged upon a hot tungsten filament. The course of the ionization curves showed that, at temperatures below 1600°K., for the specific rate of arrival (4.3×10^{13} molecules

cm.$^{-2}$ sec.$^{-1}$) used in their experiments, surfaces were formed having work functions considerably higher than the work function of clean tungsten. They suggested that these high work function surfaces were due to adsorbed films comprised of halogen atoms. In the case of potassium iodide the work function of the WI surface was determined as 5.27 volts.

In order to learn more about the properties of an iodine film on tungsten, its contact potential relative to clean tungsten has been determined. The contact potential method[5-9] of studying adsorbed films on metallic surfaces makes use of the infra-saturation current from a hot filament to the clean and to the coated metal. If A and B are two filaments, A at a constant elevated temperature and B cold, the current between the two filaments is determined by their potential difference. At small positive potentials, within the infra-saturation region, the current varies as the $^3/_2$ power of the potential and hence is very sensitive to voltage changes. If the current-volts characteristic of the system is measured with filament B clean, then measured again with filament B coated, and the current in each case plotted against the voltage, the second curve, while parallel to the first, is displaced along the voltage axis. The magnitude of this displacement represents the contact potential difference between the clean and the coated surface.

Experimental

The apparatus used in making the contact potential measurements is shown in Fig. 1. A and B were aged

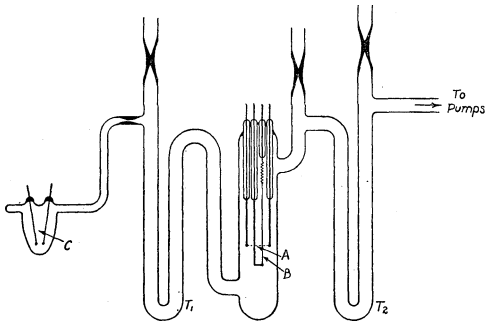

Fig. 1.—Diagram of contact potential cell.

tungsten filaments, 3.4 and 5.6 cm. in length, respectively, and both 0.00767 cm. in diameter, mounted at right angles to one another in a Pyrex glass tube. The vertical filament was kept taut by a tungsten spring attached to its upper end. No spring was used with the horizontal filament, but when the filament was spot-welded onto the leads, the leads were pinched together slightly to keep it under tension. This arrangement of the filaments[8] ensured that practically all the current measured flowed from a short section at the center of the hot filament to the cold filament; thus the electron source was homogeneous and nearly equipotential.[8] T_1 and T_2 were liquid air traps to freeze out iodine and mercury. The system was evacuated by means of two mercury vapor pumps (not shown in figure) in tandem and was pumped continuously during a run. Carefully purified thallous iodide was used as a source of iodine. It was placed in the electrolytic cell C and after fusion electrolyzed by means of two platinum-tipped tungsten electrodes sealed through the glass wall.

In order to obtain a vacuum sufficiently good to ensure clean surfaces, it was found necessary to give the system a thorough bake-out. This was accomplished by surrounding the entire system, with the exception of the pumps and the electrolytic cell C, by a furnace maintained at 500° for a period of twenty-four to forty-eight hours. Meanwhile the electrolytic cell containing the thallous iodide was hand torched. During this torching the thallous iodide was distilled repeatedly from the cell into the side tube where it was fused and allowed to run back. After such a bake-out, when the filaments had been flashed, the electron emission from the hot filament to the cold filament would usually remain constant for an hour, even without liquid air around the contact potential cell. It was extremely important to have such a high vacuum, since surrounding the contact potential cell with liquid air invariably introduced fluctuations in the galvanometer circuit.

The emission current was measured by the electrical circuit shown in Fig. 2. The currents for heating and flashing

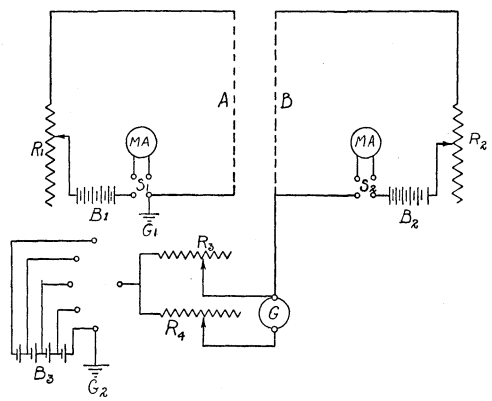

Fig. 2.—Electrical circuit for contact potential measurements.

the filaments were supplied by storage batteries B_1 and B_2, and were adjusted by the rheostats R_1 and R_2. The resistance boxes R_3 and R_4 constituted a shunt arrangement for the galvanometer G. Potentials between the two filaments were obtained from the bank of 2-volt storage cells B_3. The contact potential cell was surrounded by a shield of copper gauze to eliminate anomalous effects.

The apparatus was checked by measuring the contact potential of a WO film relative to clean tungsten. In

making this measurement the filaments were flashed at 2700°K. and readings were taken of the infra-saturation current at voltages ranging from 0 to 8 volts. The emitter filament was kept at 2350°K. and the collector filament at room temperature. After the current-volts characteristic had been measured for the clean collector, air was admitted into the system through a capillary while the collector filament was kept at 1200°K. After the excess air had been removed, the emitter filament was flashed at 2700°K. and then adjusted at 2350°K. and the current-volts characteristic again was measured. The two sets of data when plotted gave curves which were closely parallel; however, the one for the WO surface was shifted along the voltage axis in the positive direction. Several determinations gave values for the contact potential ranging from −1.70 to −1.73 volts, in excellent agreement with the values reported by Reimann[7] and by Bosworth and Rideal.[8]

The procedure for obtaining the W–WI contact potential was identical with that outlined above for determining the W–WO contact potential. To form an iodine film, the thallous iodide was electrolyzed and the iodine caught in liquid air trap T_1; then it was allowed to vaporize from this trap and come in contact with the filaments. It was found necessary, in order to obtain a film showing a maximum contact potential, to hold the collector filament at an elevated temperature; 1000°K. was finally adopted.

Results

Figure 3 shows a plot of current versus volts for a typical run. The base curve for the clean tungsten could be duplicated in different runs, even when the vacuum had been broken in the intervening time, if a satisfactory baking-out process was again given to the system. The two curves in every case were very nearly parallel, particularly in the range 4 to 8 volts. The values obtained for the contact potential in twelve separate determinations were, respectively: −0.94, −0.90, −0.88, −0.90, −0.95, −0.93, −0.93, −0.88, −0.95, −0.87, −0.91, and −0.91 with an average value of −0.91 volt.

As stated in a previous paragraph it was necessary to keep the collector filament at 1000 to 1200°K. during the exposure to the iodine vapor. When the collector filament was kept at room temperature during the coating process and the contact potential determined, a value of −0.42 volt was obtained. This difference is presumably due to the formation of a molecular rather than atomic film. Attempts to activate such a molecular film by flashing to 1000°K. or above always gave a value of the contact potential lower than −0.91 volt, indicating some evaporation of the iodine. This behavior of iodine is different from that observed by Reimann[7] for oxygen with tungsten. He found that the value of the W–WO contact potential was the same whether the temperature of the filament during the exposure to oxygen was room temperature or any other temperature for which the film was stable. An attempt was made to obtain more information on this point by admitting air with the collector filament cold; in every case a value in the neighborhood of −0.85 volt instead of −1.70 volts was obtained. It should be pointed out, however, that Reimann formed his WO surfaces with pure oxygen evolved from heated barium peroxide which was present in the contact potential cell.

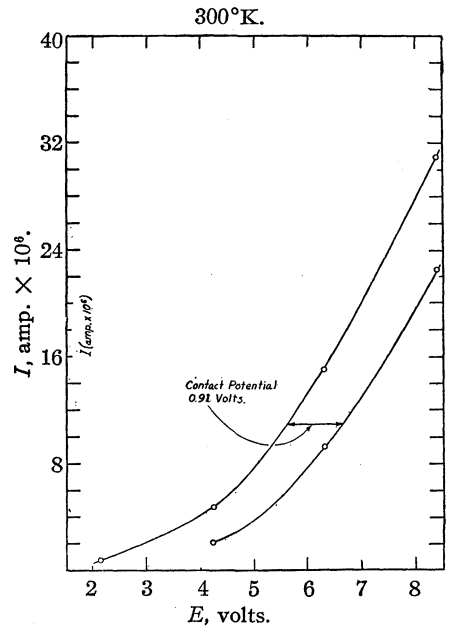

Fig. 3.—Current–volts characteristics of W and of WI surfaces.

If an iodine film was heated to 1250°K. for several minutes between contact potential measurements, the second determination was always low. This indicates that at 1250°K. the rate of evaporation of an iodine film is noticeable. At 1500°K. the rate of evaporation is rapid; however, to remove the last trace of iodine and duplicate the current-volt characteristic of clean tungsten it was necessary to flash to 2000°K.

Eckart[10] has shown that the contact potential difference between two surfaces is

$$V_{12} = \varphi_1 - \varphi_2 \qquad (1)$$

where φ_1 and φ_2 are, respectively, the work function of the clean and coated surfaces. Hence using 4.52 volts for the work function of clean tungsten and 0.91 volt, the average value for

(10) Eckart, *Z. Physik*, **47**, 38 (1928).

V_{12}, we obtain for φ_2 a value of 5.43 volts. This value for the work function of a WI surface is in satisfactory agreement with the value 5.27 volts calculated from surface ionization measurements by Hendricks, Phipps and Copley,[4] since their result was obtained by extrapolating data taken over a short temperature range.

The large negative value of the W–WI contact potential suggests that the adsorbed iodine atoms on the surface are highly polarized. Thus on the surface of the coated filament there is an electrical double layer with the negative ends of the dipoles facing out. The dipole moment μ of the adsorbed atoms may be estimated by the formula

$$\mu = V_{12}/2\pi\ \sigma \qquad (2)$$

where V_{12} is the contact potential and σ is the concentration of atoms per cm.^{2}. Assuming that the measurements have been made on a complete monolayer and that the lattice structure is the same as for a cesium film,[11] σ may be taken as 4.8×10^{14} atoms cm.$^{-2}$. Substituting in equation (2) gives a value of 1.0 Debye units for μ.

Summary

Evidence is presented that iodine forms a stable film on tungsten. Above 1250°K. the film evaporates at a noticeable rate, but flashing to 2000°K. is required for its complete and rapid removal.

The contact potential difference at room temperature between a clean tungsten surface and an iodine-coated tungsten surface was found to be −0.91 volt. The magnitude of the dipole moment of the adsorbed atoms in the complete film is estimated as 1.0 Debye unit.

Activity Coefficients in Concentrated Aqueous Solutions of Strong Electrolytes Described by a Formula Containing the Mean Ionic Diameter as Single Parameter. I. Theory and Application to the Alkali Chlorides, Bromides and Iodides[1]

BY PIERRE VAN RYSSELBERGHE AND SYLVAN EISENBERG

I. Introduction

If one wishes to represent the activity coefficient of a strong electrolyte by means of a formula valid at all concentrations, from infinite dilution to saturation, it is usually assumed necessary to introduce two parameters: the mean ionic diameter or distance of closest approach between a positive and a negative ion, a, and a coefficient B which, multiplied by the first power of the concentration C, gives a term representing, in a purely empirical manner, the effect of repulsive forces. The corresponding formula is associated with the names of Hückel[2a] and Harned,[2b] and can be written as follows, in the case of one single electrolyte being present

$$\log f_{\pm} = -\frac{z_+z_-\epsilon^2\kappa}{2DkT(1+\kappa a)} + BC \qquad (1)$$

in which $f_{\pm}$ is the mean rational activity coefficient of the ions, z_+ and z_- are the absolute values of the valences of the positive and of the negative ions, ϵ is the elementary charge of positive electricity, D is the dielectric constant of the solvent, k is Boltzmann's constant, T is the absolute temperature, κ is defined by the formula

$$\kappa = \sqrt{\frac{4\pi n\epsilon^2(\nu_+{z_+}^2 + \nu_-{z_-}^2)}{DkT}} \qquad (2)$$

in which n is the number of molecules of salt per cc., ν_+ and ν_- the numbers of positive and negative ions corresponding to one molecule of salt. The reciprocal of κ is often designated as the *radius of the ionic atmosphere.* The number n and the concentration C are connected by the formula

$$C = n \times 1000/N \qquad (3)$$

in which N is Avogadro's number.

For aqueous solutions of uni-univalent electrolytes at 25°, formula (1) can be transformed into the following

$$\log_{10} f_{\pm} = -0.5059\,\frac{\sqrt{C}}{1+\frac{a}{3.042}\sqrt{C}} + BC \qquad (4)$$

in which a is expressed in Ångströms.[3]

(2) (a) E. Hückel, *Physik. Z.*, **26**, 93 (1925); (b) H. S. Harned, Chap. XII of Taylor's "Treatise on Physical Chemistry," 2d ed., pp. 797, *et seq.*, D. Van Nostrand and Co., New York, 1931, where earlier references will be found.

(3) The numerical values of the constants used are: $\epsilon = 4.770 \times 10^{-10}$, $\pi = 3.1416$, $N = 6.064 \times 10^{23}$, $D = 78.54$, $k = 1.371 \times 10^{-16}$, $T = 298.1$, $\log 10 = 2.3026$.

The first term on the right of formula (1) or (4) represents the decrease in thermodynamic activity due to the electrostatic interactions between ions, while the second term, in which the empirical constant B is positive, represents the combined effect of short-range repulsive forces between ions, interaction between ions and solvent, possible departure from complete dissociation at high concentrations, variation of dielectric constant with concentration, deviations from spherical symmetry for the ions, etc. The first term results from the Debye–Hückel theory; the second one corresponds, at least in some respects, to the van der Waals forces between molecules of gases or liquids. Therefore, we shall designate these terms as Debye–Hückel (D. H.) and van der Waals (W.) terms, respectively. When the W. term becomes larger than the D. H. term as concentration rises, the repulsive forces outweigh the electrostatic attractions between ions and their atmospheres, and the activity coefficient becomes larger than unity. In an interesting discussion of the properties of concentrated electrolytes, Onsager[4] suggests expressing the W. term as an ordinary covolume correction of van der Waals, which amounts to considering the repulsive forces as having a potential equal to zero at all distances r larger than a from the center of each ion and rising suddenly to infinity at $r = a$. Onsager states that the values of a to be introduced in the W. term "need not agree exactly with those that are used in computing the coulomb energy, because the picture of 'hard billiard balls' is certainly too simple." He states, however, that "there seems to be a fairly close correspondence. A more complete study of this question might be worth while; it would show to what extent the thermodynamic functions of different electrolytes form a one-parameter family in regard to their dependence on the concentration, and give us more detailed information about the short-range forces." The present work is an answer to this query. The first step is to establish as correct an expression as possible for the W. term, taking into account excluded spheres, overlapping of such spheres, etc. Both the D. H. and the new W. terms are then expressed in terms of the same a and the activity coefficient is represented by a *one-parameter* formula. The theory leading to the new expression for the W. term is given in the next section. The resulting formula is then applied to a systematic interpretation of the activity data of the alkali chlorides, bromides and iodides. Other salts will be studied in subsequent communications.

(4) L. Onsager, *Chem. Rev.*, **13**, 73 (1933).

We should note here that a remarkable attempt at setting up a one-parameter formula is Guggenheim's[5] modification of Brönsted's specific interaction theory, in which the D. H. term contains the same a (3.08 Å. at 0°) for all electrolytes, and the W. term is linear in the concentration, the coefficient being the parameter and representing the specific interaction between positive and negative ions. This formulation is satisfactory at ionic strengths lower than 0.1 and the parameter has the interesting property of conserving its value in all mixtures where the corresponding pair of ions is present.

II. The van der Waals or Covolume Terms in the Activity Coefficient of a Strong Electrolyte

The problem before us is to compute the partition function representing the mutual exclusion from certain portions of space of a mixture of N_α molecules of one kind and N_β molecules of another kind. The diameters of these ions are, respectively, D_α and D_β. The problem is extremely complicated and, as noted by Fowler,[6] several solutions to be found in the literature are entirely fallacious. In the second edition of his "Statistical Mechanics," Fowler gives a solution due to Ursell,[7] which supersedes all previous ones. Ursell's theory is quite general and can be applied to a mixture of any number of kinds of molecules. He treats completely the case of two kinds and finds for the partition function [$B(T)$ in Ursell's notation]

$$Z = V^{N\alpha+N\beta}Y \qquad (5)$$

with

$$\log Y = -\frac{1}{V}\left\{N_\alpha^2\left(\frac{2}{3}\pi D_\alpha^3\right) + N_\alpha N_\beta\left(\frac{4}{3}\pi D_{\alpha\beta}^3\right) + N_\beta^2\left(\frac{2}{3}\pi D_\beta^3\right)\right\} - \frac{1}{V^2}\left[\frac{5}{16}N_\alpha^3\left(\frac{2}{3}\pi D_\alpha^3\right)^2 + 4\pi^2 N_\alpha^2 N_\beta D_\alpha^3\left\{\frac{2}{9}D_{\alpha\beta}^3 - \frac{1}{8}D_{\alpha\beta}^2 D_\alpha + \frac{1}{144}D_\alpha^3\right\} + \frac{5}{16}N_\beta^3\left(\frac{2}{3}\pi D_\beta^3\right)^2 + 4\pi^2 N_\alpha N_\beta^2 D_\beta^3\left\{\frac{2}{9}D_{\alpha\beta}^3 - \frac{1}{8}D_{\alpha\beta}^2 D_\beta + \frac{1}{144}D_\beta^3\right\}\right] \qquad (6)$$

In this formula $D_{\alpha\beta}$ is the sum of the radii of the two kinds of molecules. We thus have

$$D_{\alpha\beta} = (D_\alpha + D_\beta)/2 \qquad (7)$$

(5) E. A. Guggenheim, *Phil. Mag.*, [7] **19**, 588 (1935).

(6) R. H. Fowler, "Statistical Mechanics," 2nd edition, Cambridge University Press, 1936, pp. 241 *et seq.*

(7) H. D. Ursell, *Proc. Camb. Phil. Soc.*, **23**, 685 (1927).

In applying this result to electrolytes we shall assume that

$$D_\alpha = D_\beta = D_{\alpha\beta} = a \qquad (8)$$

a being the distance of closest approach which also appears in the D. H. term. If N is the number of molecules of salt in the volume V we have

$$N_\alpha = \nu_+ N \qquad N_\beta = \nu_- N \qquad (9)$$

Taking (8) and (9) into account, formula (6) becomes

$$\log Y = -\frac{N^2}{V}(\nu_+ + \nu_-)^2\left(\frac{2}{3}\pi a^3\right) - \frac{5}{16}\frac{N^3}{V^2}(\nu_+ + \nu_-)^3\left(\frac{2}{3}\pi a^3\right)^2 \qquad (10)$$

Let

$$v = \frac{4}{3}\pi a^3 \qquad (11)$$

represent the volume of the sphere of protection of an ion. Formula (10) becomes, making $\nu_+ + \nu_- = \nu$

$$\log Y = -\frac{\nu^2 N^2}{2V}v - \frac{5\nu^3 N^3}{64V^2}v^2 \qquad (12)$$

or, expressing it in terms of the total number of ions present, $N_i = N_\alpha + N_\beta = \nu N$

$$\log Y = -\frac{1}{2}\frac{N_i^2}{V}v - \frac{5}{64}\frac{N_i^3}{V^2}v^2 \qquad (13)$$

The corresponding contribution to the Helmholtz free energy of the ions in the solution is

$$F_{iw} = -kT\log Y = N_i kT\left[\frac{1}{2}\frac{N_i}{V}v + \frac{5}{64}\left(\frac{N_i}{V}\right)^2 v^2\right] \qquad (14)$$

On account of the practical incompressibility of solutions, F_{iw} can be assumed equal to the corresponding Gibbs free energy G_{iw} which is such that

$$G_{iw} = N_i \Delta\mu_{iw} = N_i kT\log f_{\pm w} \qquad (15)$$

in which $\log f_{\pm w}$ corresponds to the van der Waals term in $\log f_\pm$. From (14) and (15) we deduce

$$\log f_\pm = \frac{1}{2}\frac{N_i}{V}v + \frac{5}{64}\left(\frac{N_i}{V}\right)^2 v^2 \qquad (16)$$

or, in terms of the molar concentration C and Avogadro's number N

$$\log f_\pm = \frac{1}{2}\nu v N C \times 10^{-3} + \frac{5}{64}v^2\nu^2 N^2 C^2 \times 10^{-6} \qquad (17)$$

Expressing a in Ångström units we have, when $\nu = 2$

$$\log_{10} f_\pm = 1.10313 \times 10^{-3} a^3 C + 8.7564 \times 10^{-7} a^6 C^2 \qquad (18)$$

The complete formula for the activity coefficient of a uni-univalent strong electrolyte in aqueous solution at 25° is thus

$$\log_{10} f_\pm = -0.5059\frac{\sqrt{C}}{1 + \frac{a}{3.042}\sqrt{C}} + 1.10313 \times 10^{-3} a^3 C + 8.7564 \times 10^{-7} a^6 C^2 \qquad (19)$$

Such a formula may be expected to hold for values of a large enough to make the approximations involved in the derivation of the D. H. term acceptable. For uni-univalent electrolytes a should be larger than 2.

It is interesting to note that if formula (14) is applied to imperfect gases one finds that the correction to be added to the pressure $P = NkT/V$ is given by

$$P_w = -\frac{\partial F_w}{\partial V} = \frac{NkT}{V}\left[\frac{1}{2}\frac{N}{V}v + \frac{5}{32}\frac{N^2}{V^2}v^2\right] \qquad (20)$$

Introducing the van der Waals covolume b

$$b = 4N \times \frac{4}{3}\pi\left(\frac{a}{2}\right)^3 = \frac{1}{2}Nv \qquad (21)$$

we find

$$P_w = \frac{NkT}{V}\left[\frac{b}{V} + \frac{5}{8}\left(\frac{b}{V}\right)^2\right] \qquad (22)$$

This formula gives precisely the first two terms derived by Boltzmann[8] by taking account of the possibility of more than two of the spheres of force surrounding the molecules intersecting one another.

III. Remarks Concerning the Dependence of Activity Coefficients on the Mean Ionic Diameter

We have drawn a set of standard curves corresponding to our formula (19) for round values of a ranging from 2 to 6 Å. in steps of 0.5 Å. These curves have been used in one of our methods of determining a empirically for various salts, as is explained in another section of this paper. It is interesting, at this place, to report the theoretical values of the concentration C for which $f_\pm$ is a minimum and those for which it has reached again the value *one*. These concentrations have been read from our standard curves and are reported in Table I.

TABLE I

CONCENTRATIONS AT WHICH $f_\pm$ IS A MINIMUM AND CONCENTRATIONS AT WHICH $f_\pm$ IS EQUAL TO UNITY, FOR VARIOUS VALUES OF THE IONIC DIAMETER a. (1–1 ELECTROLYTES)

a, Å.	C, moles/liter for $f_\pm$ minimum	C, moles/liter for $f_\pm = 1$
2.0	7.9	21.3
2.5	4.0	16.2
3.0	1.4	10.3
3.5	1.0	5.8
4.0	0.64	3.2
4.5	.36	2.0
5.0	.30	1.2
5.5	.20	0.81
6.0	.14	0.56

(8) L. Boltzmann, "Vorlesungen über Gastheorie," 1896, Vol. II, § 51; see J. H. Jeans, "The Dynamical Theory of Gases," Cambridge University Press, 3rd ed., 1921, p. 133.

In view of the often expressed opinion that constants or parameters in the various equations for activity coefficients should be determined from data corresponding to rather low concentrations, we wish to indicate that the activity coefficient is a rather insensitive function of the parameter a at low concentrations, particularly for small values of a, but that at high concentrations it becomes a very sensitive function of a.

We have of course

$$\frac{\mathrm{d}\log f_{\pm}}{\mathrm{d}\log a} = \frac{\mathrm{d}f_{\pm}}{f_{\pm}} \Big/ \frac{\mathrm{d}a}{a} \cong \frac{\Delta f_{\pm}}{f_{\pm}} \Big/ \frac{\Delta a}{a} \qquad (23)$$

Let us consider $\Delta a = 0.5$ Å. with $a = 2$ Å. We have then $\Delta \log f_{\pm} = \log f_{\pm}(2.5) - \log f_{\pm}(2.0)$. The percentage variation of a is 0.5/2.25 or 22%. The corresponding variations of $\log f_{\pm}$, calculated according to our formula (19), are reported in Table II. In the same manner we have calculated the variations of $\log f_{\pm}$ corresponding to $\Delta a = 0.5$ Å. with $a = 4$ Å. In this case the percentage variation of a is 12%. The variations of $\log f_{\pm}$ are reported in the second half of Table II. These figures are very illuminating and show that, if one uses a formula with a as single parameter, the choice of the best empirical value for this parameter should be based, to a large extent, on data at high concentrations. We have devised, for this purpose, a method derived from the theory of least squares. Another striking proof of the lack of sensitivity of $f_{\pm}$ toward a change in a in the dilute range is that afforded by the curves of Fig. 1 which represent the variation of $\log f_{\pm}$ with a for various round concentrations. It will also be shown in another section of this paper that, when a has been determined from data in the concentrated range, very accurate values of $f_{\pm}$ can be calculated for the dilute range, while the opposite procedure in which a values are derived from data in the dilute range gives sometimes very erratic results.

IV. Determination of the Mean Ionic Diameter by the Method of Least Squares

The first step in the determination of the parameter a of a given salt consists of solving the seventh-degree equation in a corresponding to our formula (19) for some particular concentration. Only one of the solutions of this equation has physical significance and is considered as a first approximation to the exact value of a. We then calculate, for a series of round concentrations from 0.1 molar up to 4 or 5 molar, the residuals v_i defined by

$$v_i = \log \bar{f}_i - \log f_i + (\partial \log f_i/\partial \bar{a})\,\Delta\bar{a} \qquad (24)$$

in which f_i is the activity coefficient calculated by our formula (19) for the approximate value $\bar{a}$ of a, $\bar{f}_i$ is the experimental activity coefficient and $\Delta\bar{a}$ the correction to be applied to $\bar{a}$. We then calculate the sum

$$S = \sum_{i=1}^{i=r} v_i^2 \qquad (25)$$

r being the number of experimental points considered, and we minimize it by the condition

$$\partial S/\partial \Delta\bar{a} = 0 \qquad (26)$$

from which we deduce

$$\Delta\bar{a} = \frac{\sum_{i=1}^{i=z} (\log f_i - \log \bar{f}_i) x_i}{1.539 \sum_{i=1}^{i=r} x_i^2} \qquad (27)$$

where x_i is given by

$$x_i = C_i \left[\frac{1}{(3.042 + \bar{a}\sqrt{C_i})^2} + 2.150 \times 10^{-3}\bar{a}^2 + 0.3413 \times 10^{-5}\bar{a}^{-5} C_i \right] \qquad (28)$$

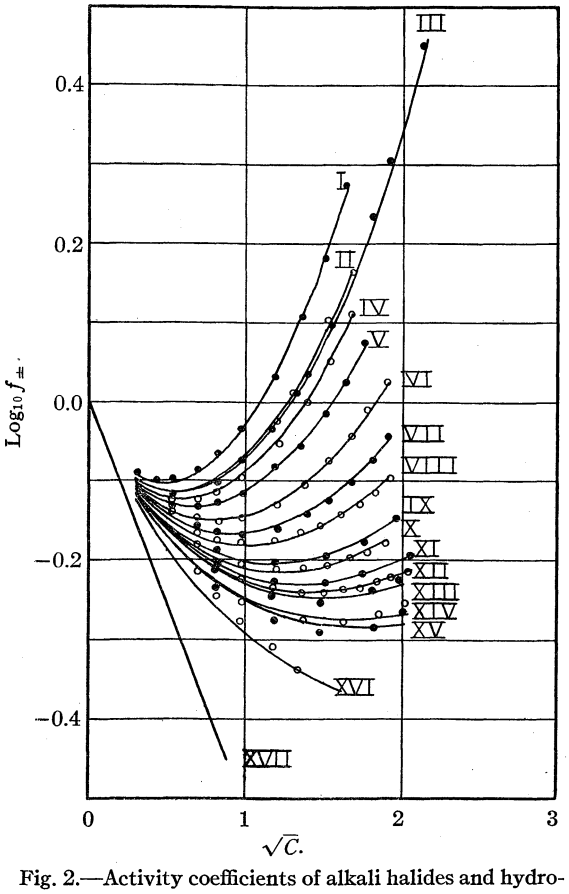

Fig. 2.—Activity coefficients of alkali halides and hydrochloric acid. The solid lines represent predicted values. The open circles represent experimental points for the even numbered salts. The solid circles represent experimental points for the odd numbered salts: I, LiI; II, LiBr; III, HCl; IV, LiCl; V, NaI; VI, NaBr; VII, NaCl; VIII, KI; IX, KBr; X, KCl; XI, RbCl; XII, RbBr; XIII, RbI; XIV, CsCl; XV, CsBr; XVI, CsI; XVII, Debye–Hückel limiting slope.

V. Application of the Theory to the Alkali Chlorides, Bromides and Iodides

The activity data used for our calculations are those of Robinson.[9] The activity coefficients γ corresponding to molalities m are converted into the rational ones $f_\pm$ by the well-known formula

$$\log f_\pm = \log \nu + \log (1 + 0.018\, \nu m) \qquad (29)$$

and the molalities are transformed into volume concentrations by means of the density data. The weighted a's obtained by the method described above for the chlorides, bromides and iodides of lithium, sodium, potassium, rubidium and cesium in aqueous solution at 25° are given in the second column of Table III. On Fig. 2 we give the $\log f_\pm$ curves corresponding to these weighted a's, and the experimental $\log f_\pm$'s, indicated by circles, are seen to be in close agreement with these curves except in the case of cesium bromide and cesium iodide, for which appreciable departures occur.[10] It is to be noted that, particularly in the case of cesium iodide, with $a = 2.067$ Å., we are in a range of a values to which the Debye–Hückel theory is not strictly applicable. Improvements would probably be noticed if the Debye–Hückel term in our formula (19) were corrected according to the methods suggested by Bjerrum[11a] and by Gronwall, La Mer and Sandved.[11b]

Besides the a's calculated by the method of least squares, we have also determined, for a number of round concentrations ranging from 0.1 to 4–5 molar, the a's which give exact agreement with the theory. For this purpose we have used the curves of Fig. 1 from which the a's are directly read. They are reported in the third column of Table III (average values and average deviations). The results are indeed remarkable, with the sole exception of those for cesium iodide. In the last column of Table III we give the sums of the standard ionic radii for the crystals on the basis of Pauling's[12] data. We notice that, for the salts of lithium and sodium,

(9) R. A. Robinson and D. A. Sinclair, THIS JOURNAL, **56**, 1830 (1934); R. A. Robinson, *ibid.*, **57**, 1161 (1935); see also O. Redlich and P. Rosenfeld, activity data in Landolt–Börnstein-Roth Tables, Dritter Ergänzungsband, Verlag von Julius Springer, Berlin, 1936, pp. 2138–2171.

(10) We also give on Fig. 2 the curve for hydrochloric acid, which almost coincides with that for lithium bromide. This case will be analyzed further in another communication.

(11) (a) N. Bjerrum, *Det. Kgl. Danske Vidensk. Selsk. Math.-fysik. Medd.*, VII, No. 6 (1926); (b) T. H. Gronwall, V. K. La Mer and K. Sandved, *Physik. Z.*, **29**, 358 (1928).

(12) L. Pauling, "The Nature of the Chemical Bond," Cornell University Press, Ithaca, N. Y., 1939, p. 338.

the a's in solution are larger than the sums of the standard crystalline radii, undoubtedly on account of hydration, which is relatively more important for the lithium than for the sodium salts. With the potassium salts, a in solution is practically equal to the sum of radii in the crystal, while for the rubidium and cesium halides, the a's in solution are smaller than the sums of the standard crystalline radii.

TABLE III

MEAN IONIC DIAMETERS OF THE ALKALI CHLORIDES, BROMIDES AND IODIDES IN AQUEOUS SOLUTION AND SUMS OF THE STANDARD CRYSTALLINE RADII

Salts	a least squares, Å.	a for exact agreement, Å.	Sums of ionic radii in crystal, Å.

KI	3.551	3.67 ± 0.13	3.499
RbCl	3.061	3.07 ± 0.03	3.290
RbBr	2.980	3.00 ± 0.03	3.435
RbI	2.914	2.92 ± 0.03	3.652
CsCl	2.719	2.65 ± 0.07	3.462
CsBr	2.653	2.58 ± 0.07	3.607
CsI	2.067	2.26 ± 0.23	3.824

It seems reasonable to assume that the ions of the three potassium salts are unhydrated, or practically so, and that they can come into exact contact without deformation, since the differences $a - b$, in which b designates the sum of the standard ionic radii, are 0.081, 0.018 and 0.052 Å. for the chloride, bromide and iodide, respectively. It is then also logical to assume, at least as a working hypothesis, that the three halide ions are unhydrated in all these alkali halide solutions. Subtracting from the a's the standard crystalline radius of the negative ion we get the figures of the second column of Table IV.

We see that the resulting radii for Li^+ in the three halides are practically the same, showing that the amount of hydration, which can be characterized by the quantity

$$h_+ = a - (r_+ + r_-) \qquad (30)$$

given in the third column of Table IV, is constant for the three salts. We have a similar situation for the Na^+ ion. The h_+'s values for K^+ can probably be neglected, as assumed above. For the three rubidium salts we get negative values of h_+, but the differences $a - r_-$ are all positive.

TABLE IV

IONIC RADII OF THE POSITIVE IONS IN SOLUTIONS OF THE ALKALI CHLORIDES, BROMIDES AND IODIDES

Salts	$a - r_-$, Å.	$a - (r_- + r_+)$, Å
LiCl	2.738	2.131
LiBr	2.787	2.180
LiI	2.896	2.289
NaCl	1.921	0.963
NaBr	2.038	1.080
NaI	2.140	1.182
KCl	1.412	0.081
KBr	1.349	.018
KI	1.383	.052
RbCl	1.255	− .229
RbBr	1.029	− .455
RbI	0.746	− .738
CsCl	.913	− .743
CsBr	.702	− .954
CsI	− .101	−1.757

This could be explained by assuming that, at closest approach, the positive and negative ions penetrate each other, the center of the positive ion being outside the negative one. The difference represents the distance between the center of the positive ion and the surface of the negative one. We have the same situation with cesium chloride and cesium bromide, but with cesium iodide $a - r_-$ is negative, showing that, on the basis of the above suggestion, the center of the positive ion is now inside the negative ion, at 0.101 Å. from the surface of the latter. We have represented on Fig. 3 the variation of a with the

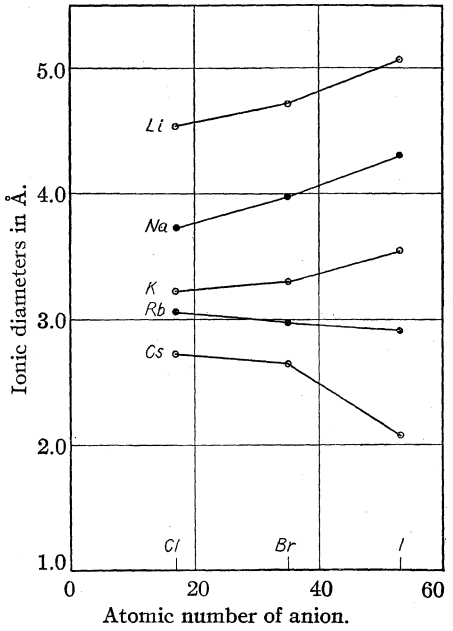

Fig. 3.—Ionic diameters of alkali salts in aqueous solutions plotted against the atomic number of the anion.

atomic number of the negative ion for each alkali metal and on Fig. 4 the variation of a with the atomic number of the positive ion for each halogen.

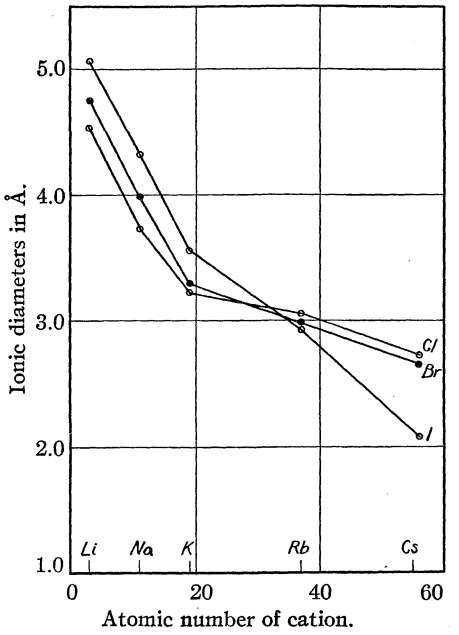

Fig. 4.—Ionic diameters of alkali salts in aqueous solutions plotted against the atomic number of the cation.

VI. Activity Coefficients in the Dilute Range. Concluding Remarks

We have calculated the activity coefficients of 0.001 and 0.01 molar solutions of the fifteen halides using the weighted a's of Table III, which were all determined from data at concentrations larger than 0.1 molar. For eight of the salts experimental values are available and the agreement is surprisingly good, as shown in Table V. As noted above already, the reverse procedure, by which a would be calculated from these data in the dilute range, gives erratic results (a becoming sometimes as large as 7 Å.). Inspection of Fig. 1 and our remarks of section III should make this point perfectly clear.

TABLE V

We wish to point out that our one-parameter formulation leads to better agreement with the data than the interesting but more complicated treatment proposed by Scatchard.[16] We believe that the effect of the ionic charges on the dielectric constant of the solution and the other interactions analyzed by Scatchard are implicitly contained in our equation and that they all affect the value of a. Scatchard uses the ionic radii corresponding to the crystal lattices reported by Pauling in 1928,[17] and it should be pointed out that these values are somewhat smaller than the corrected ones recently published by Pauling.[12] It also should be noted that our treatment constitutes, at least for the salts discussed in the present paper, a definite improvement on the only other one-parameter treatment so far proposed, namely, that of Guggenheim,[5] whose range of applicability is limited by an ionic strength of 0.1.

We already have obtained a number of promising results with other 1–1 electrolytes and with some 2–1, 2–2 and 3–1 electrolytes, as well as with some non-electrolytes, which appear to follow our equation (19) when the electrostatic term is left out. These results and other work at present in progress will be reported in subsequent papers.

Summary

1. The problem of expressing the activity coefficients of strong electrolytes as functions of a single parameter, the distance of closest approach between positive and negative ions or mean ionic diameter, is stated.

2. The van der Waals or covolume terms in the activity coefficient formula are derived on the basis of a theory due to Ursell. A term proportional to the volume concentration and to the cube of the distance of closest approach, and another one proportional to the square of the vol-

ume concentration and to the sixth power of the distance of closest approach, are added to the Debye–Hückel expression for the logarithm of the activity coefficient.

3. It is shown that only at high concentrations do the activity coefficients become sufficiently sensitive functions of the distance of closest approach to make the determination of this parameter really precise.

4. The determination of this parameter by the method of least squares is described.

5. The theory is applied to the alkali chlorides, bromides and iodides with remarkable success. A set of mean ionic diameters is obtained, and various remarks as to the extent of hydration, penetration of ions at contact, etc., are derived from a comparison of these diameters with the sums of the standard crystalline radii.

6. Activity coefficients in 0.001 and 0.01 molar solutions are calculated with the weighted mean ionic diameters obtained at high concentrations. In eight cases out of fifteen comparison with experimental values is possible and shows more than satisfactory agreement.

The Bromination of 4-Phenylphenyl Acetate

BY STEWART E. HAZLET AND HARRY A. KORNBERG

In previous reports it was shown that although the bromination of 4-phenylphenol results in substitution at a position ortho to the hydroxyl group, when the benzenesulfonate[1] or the benzoate[2] of the phenol is brominated, the substitution occurs at the position in the molecule most remote from the ester linkage (*viz.*, *p'*). The study of the introduction of bromine into the esters of 4-phenylphenol has been extended now to 4-phenylphenyl acetate, which is analogous to the benzenesulfonate and the benzoate previously considered.

It was suggested in an earlier report[2] that perhaps steric hindrance is responsible for the change in directive influence when hydroxyl is modified to benzenesulfonyloxy or benzoyloxy. In the work here reported (see Chart I for the outline) the hydroxyl of 4-phenylphenol (I) was replaced by the acetyloxy group. On the basis of the calculations of Latimer and Porter[3] the acetyloxy group of compound II should possess the same residual charge as the benzoyloxy group in one of the compounds previously studied. The acetyloxy group is, however, much smaller than the benzoyloxy group and should be expected to exert less steric effect. Therefore it was considered possible that the bromination of 4-phenylphenyl acetate (II) might result in substitution in a position ortho with respect to the acetyloxy group. This was realized; it was found that the first bromine atom to enter 4-phenylphenyl acetate (II) gave rise to 2-bromo-4-phenylphenyl acetate (IV). Furthermore, under conditions only slightly different from those used in the preparation of compound IV and in the earlier studies,[1,2] a second atom of bromine entered the ester molecule (II) in the same relative position as in the case of the phenol (I), *viz.*, the second ortho position; thus 2,6-dibromo-4-phenylphenyl acetate (VI) was formed.

A bromine substitution product of compound II, 4-(4-bromophenyl)-phenyl acetate (IX), isomeric with compound IV obtained by direct bromination of the acetate (II) was prepared by the acetylation of a phenol (VIII) of known structure. The two isomers had distinctly different physical properties.

The experimental steps and the proofs of structure of the compounds are outlined in Chart I, and the details of procedures are given in the Experimental Part.

Experimental Part

4-Phenylphenyl Acetate (II).[4]—This compound was prepared in almost quantitative yield by gently refluxing for three hours one mole of 4-phenylphenol (I) and 0.25 mole of anhydrous sodium acetate in an excess of acetic anhydride. The reaction mixture was allowed to cool, poured into ten volumes of water, and permitted to stand overnight. The ester was collected by filtration and recrystallized from methanol. The colorless, irregular crystals melted between 87 and 88°.

2-Bromo-4-phenylphenyl Acetate (IV).—Fifteen grams of 4-phenylphenyl acetate (II) was dissolved in 30 ml. of

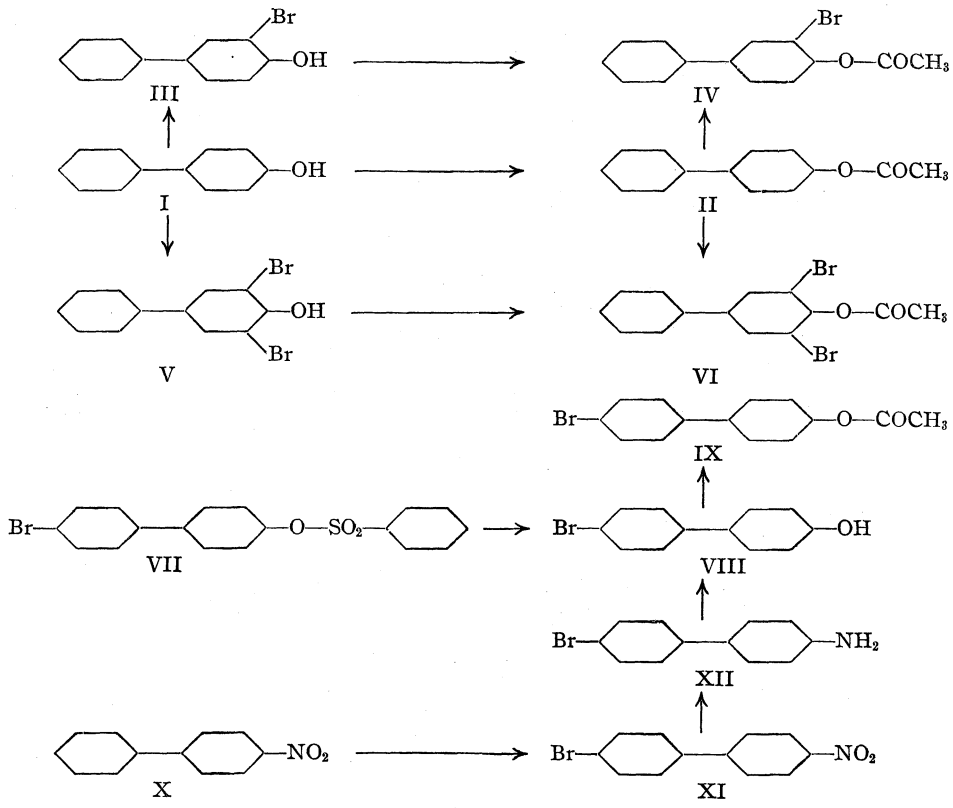

CHART I

glacial acetic acid. The mixture was stirred vigorously and was heated to 100 ± 2° in an oil-bath. A trace of iron powder was added, and then 6 ml. of bromine (approximately 1.5 moles) was added dropwise over a period of thirty minutes. The heating and stirring were continued for ten hours. Upon pouring the cooled mixture into 400 ml. of water, a dark brown viscous mass separated. After adding an excess of sodium carbonate solution, the mixture was extracted with ether. The viscous liquid (23.1 g.), which was obtained from the ether solution, was dissolved in boiling methanol. Upon cooling, a brown solid separated. Ligroin[5] was used for recrystallizations. The product (11.7 g., 57% yield) was obtained as elongated hexagonal plates; m. p. 74–75°.

This compound (IV) was also prepared from 5 g. of 2-bromo-4-phenylphenol (III)[2] in 20 ml. of acetic anhydride; 0.25 mole of anhydrous sodium acetate was added. The mixture was heated for five hours on a steam-bath, cooled, and poured into 300 ml. of cold water. The crude product (4.7 g.) represented a 90% yield. After treatment with Norite and two recrystallizations from methanol, the product was obtained as colorless hexagonal plates; m. p. 74–75°.

Anal. Calcd. for $C_{14}H_{11}O_2Br$: Br, 27.5. Found: Br, 27.6.

When equal amounts of the two samples prepared by the different methods were mixed, there was no depression of the melting point.

(5) The boiling range of the ligroin used in all of the experimental work was from 90 to 120°.

2,6-Dibromo-4-phenylphenyl Acetate (VI).—Fifteen grams of 4-phenylphenyl acetate (II) was treated as in the bromination described above except that 8 ml. of bromine (approximately 2 moles) was used, the temperature of the oil-bath was 110 ± 2°, and the time of the reaction was eight hours. The product was recovered as indicated in the case of the monobromo compound (IV). The yield of the crude material was only 40% (14.8 g.), and after several treatments with Norite and recrystallizations from ligroin, the colorless irregular crystals obtained (4.2 g.) represented only a 16% yield; m. p. 81–83°.

Anal. Calcd. for $C_{14}H_{10}O_2Br_2$: Br, 43.3. Found: Br, 43.4.

A second method was also used for the preparation of this compound (VI). To 0.8 g. of 2,6-dibromo-4-phenylphenol (V)[2] in 20 ml. of acetic anhydride, 0.5 g. of sodium acetate was added. The mixture was gently refluxed for two hours, cooled, poured into 200 ml. of water, and allowed to stand overnight. After filtration, treatment with Norite, and recrystallization from ligroin, the product was obtained in almost quantitative yield as irregular crystals which melted between 81.5 and 83°.

Anal. Calcd. for $C_{14}H_{10}O_2Br_2$: Br, 43.3. Found: Br, 43.7.

A mixture of equal amounts of this compound prepared by the two different methods melted from 81 to 83°.

4-(4-Bromophenyl)-phenyl Acetate (IX).—4-Phenylnitrobenzene (X) was converted to 4-(4-bromophenyl)-nitrobenzene (XI),[6] the nitro compound was reduced to 4-

(6) Le Fèvre and Turner, *J. Chem. Soc.*, 2041 (1926).

(4-bromophenyl)-aniline (XII),[7] and the amine converted to 4-(4-bromophenyl)-phenol (VIII).[7] The crude product so obtained was refluxed with an excess of acetic anhydride and 0.25 mole of anhydrous sodium acetate for two hours, and the product (IX) was recovered in the usual manner. A mixture of ligroin and benzene was used for recrystallizations. The product was obtained as colorless irregular plates; m. p. 128–129°. On the basis of the amount of compound X used, the yield was low.

Anal. Calcd. for $C_{14}H_{11}O_2Br$: Br, 27.5. Found: Br, 27.2.

A sample of 4-(4-bromophenyl)-phenol (VIII) obtained by the hydrolysis of 4-(4-bromophenyl)-phenyl benzenesulfonate (VII)[1] was also used for the preparation of this compound (IX). The yield of the crude acetate (IX) corresponded to 92% on the basis of the benzenesulfonate used. The m. p. 128–129° was the same as for the product described above, the crystals were similar, and a mixture of samples of the two preparations melted between 128 and 129°.

(7) Bell and Robinson, *J. Chem. Soc.*, 1127 (1927).

Summary

1. Although the bromination of 4-phenylphenyl benzenesulfonate or 4-phenylphenyl benzoate yields the 4-(4-bromophenyl)-phenyl ester, the introduction of bromine into 4-phenylphenyl acetate results in substitution in the ortho position (or positions) with respect to the acetyloxy group. The behavior of the acetate, therefore, is analogous to that of 4-phenylphenol.

2. These results are in keeping with a previous suggestion that steric effects may determine the positions taken by substituents entering an ester molecule.

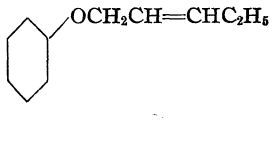
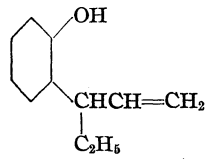
The Rearrangement of Phenyl Allyl Ethers. III. The Synthesis of α-(ortho-Methoxyphenyl)-propionic Acid

BY WALTER M. LAUER AND LOUIS I. HANSEN[1]

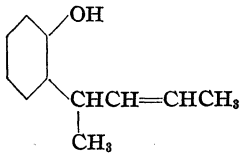
The rearrangement of γ-ethylallyl phenyl ether (I) yields both o-(α-ethylallyl)-phenol (II), and o-(α,γ-dimethylallyl)-phenol (III).[2]



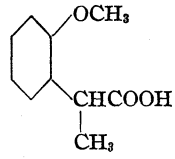
I



II



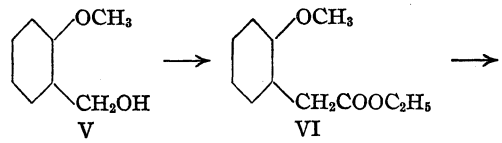
III



IV

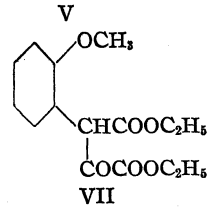
The structure of the abnormal rearrangement product (III) is based upon several lines of evidence which need not be considered here. However, one method of approach which was used involves the conversion of this abnormal rearrangement product into α-(o-methoxyphenyl)-propionic acid (IV). This acid has not been described previously. Therefore, it was the purpose of the present study to synthesize this acid and to compare it with the product obtained by the degradation of the abnormal rearrangement product (III).

A number of promising syntheses were studied and the desired acid was prepared in two independent ways. The synthetic product proved to be identical with that obtained from the abnormal rearrangement product. An outline of the most satisfactory synthesis follows

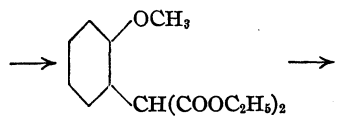


V

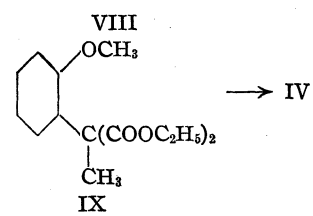
VI



VII



VIII



IX

IV

The corresponding compounds in the para series were also prepared.

(1) Abstract of Ph.D. thesis, submitted to the University of Minnesota, March, 1938. Paper III, THIS JOURNAL, **58**, 1392 (1936).

(2) Lauer and Filbert, THIS JOURNAL, **58**, 1388 (1936); Hurd and Puterbaugh, *J. Org. Chem.*, **2**, 381 (1938).

In addition, α-(*o*-methoxyphenyl)-butyric acid was synthesized, since this acid is related to the normal rearrangement product (II), in the same way that α-(*o*-methoxyphenyl)-propionic acid is related to the abnormal rearrangement product (III).

Experimental

***o*-Methoxybenzyl alcohol** (V) (b. p. 130–131° at 15 mm.) was prepared from *o*-methoxybenzaldehyde according to the excellent procedure of Davidson and Bogert[3] using a crossed Cannizzaro reaction.

The α-naphthylurethan (m. p. 135–136°) was prepared.[4]

***o*-Methoxybenzyl chloride** was prepared by saturating a solution of 112 g. of *o*-methoxybenzyl alcohol in 500 ml. of benzene with dry gaseous hydrogen chloride according to the directions of Pschorr[5]: yield, 112 g. (88%); b. p. 104–105° at 10 mm.

***o*-Methoxybenzyl cyanide** was obtained by refluxing the chloride (85 g.) in acetone (900 ml.) with a concentrated aqueous solution containing potassium cyanide (80 g.).

Ethyl *o*-methoxyphenylacetate (VI), (b. p. 137–138° at 13 mm.).—A mixture of *o*-methoxybenzyl cyanide (104 g.), alcohol (104 ml.) and a solution of potassium hydroxide (46 g.) in water (50 ml.) was refluxed for ten hours. The reaction mixture was then poured into water, cooled and filtered, and extracted with ether. The aqueous alkaline solution was warmed on the steam-bath to remove the ether and some of the alcohol. Acidification with 10% sulfuric acid produced an oil (100 g.) which solidified on standing. Crystallization from a petroleum ether–ether mixture yielded the pure acid, m. p. 123–124°. The *o*-methoxyphenylacetic acid was esterified.

Diethyl *o*-Methoxyphenylmalonate (VIII).—Absolute alcohol (172 ml.), in a three-necked flask fitted with a mercury-sealed stirrer, reflux condenser and dropping funnel, was treated with sodium (5.64 g.). After the reaction mixture had cooled to 60°, freshly distilled ethyl oxalate (35.8 g.) was added rapidly with vigorous stirring. The addition of the ethyl ester of *o*-methoxyphenylacetic acid (47.5 g.) followed. Stirring was discontinued and the reaction mixture was then poured into a beaker. The sodium salt crystallized out after standing at room temperature for several hours. The thick paste was stirred thoroughly with dry ether (200 ml.) and then filtered. The *o*-methoxyphenyl oxalacetic ester was liberated from its sodium salt with dilute sulfuric acid and then extracted from the aqueous solution with ether. The combined ether extracts were dried over sodium sulfate. After the ether had been removed by distillation, the residual oil was heated by means of a metal or oil-bath. The pressure was reduced to approx. 15 mm. and the temperature was raised gradually to 125°, at which temperature the evolution of carbon monoxide began. The temperature was then increased slowly to 175° and maintained approximately four hours until the evolution of carbon monoxide was complete. The distillate combined with the residue in the distilling flask yielded diethyl *o*-methoxyphenyl malonate (36 g., b. p. 162–164° at 4.5 mm.) upon distillation under reduced pressure.

Anal. Calcd. for $C_{14}H_{18}O_5$: C, 63.2; H, 6.8. Found: C, 63.8; H, 7.2.

Diethyl Ester of *o*-Methoxyphenylmethylmalonic Acid (IX).—Sodium (1.3 g.) was dissolved in absolute alcohol (15.5 g.) contained in a three-necked flask fitted with a mercury-sealed stirrer, reflux condenser and dropping funnel. Diethyl *o*-methoxyphenylmalonate (15 g.) was then added slowly with cooling. The reaction mixture was allowed to remain in an ice-bath for two hours after the addition of the ester. At the end of this period the reaction mixture was heated in a steam-bath and methyl iodide (8.4 g.) was added dropwise. The reaction mixture was heated under reflux until it became neutral to litmus, and then poured into water. The oily layer was separated and the aqueous layer extracted with ether. The combined ether extracts were then dried over sodium sulfate. Distillation yielded a product (12.5 g.) boiling at 152–153° under a pressure of 2.8 mm.

The unmethylated malonic ester was separated from the methylated ester by means of fractional hydrolysis at room temperature with a dilute solution (4.5%) of potassium hydroxide. After the ether solution of the mixture of esters had been shaken with the alkali for a period of six hours, the aqueous layer was acidified with dilute hydrochloric acid. Extraction with ether yielded a solid which, upon crystallization from a mixture of ether and petroleum ether, melted at 137.5–138° with decomposition. Decarboxylation gave *o*-methoxyphenylacetic acid (m. p. 123–124°).

A second treatment of the ether solution with dilute potassium hydroxide at room temperature for a four-hour period did not yield any isolable acid. The ether solution upon distillation gave an oil (b. p. 150–151° at 2.6 mm.) which solidified (m. p. 42–43°).

Anal. Calcd. for $C_{15}H_{20}O_5$: C, 64.29; H, 7.14. Found: C, 64.14; H, 7.15.

Hydrolysis and Decarboxylation of the Diethyl Ester of *o*-Methoxyphenylmethylmalonic Acid.—A solution of the pure ester (2 g.) in alcohol (15 ml.) was refluxed for one hour with a slight excess of potassium hydroxide solution (10%). The reaction mixture was then poured into water and acidified with dilute hydrochloric acid. Extraction with ether gave a solid which, upon crystallization from a mixture of ether and petroleum ether, melted at 148.5–149° with decomposition.

Anal. Calcd. for $C_{11}H_{12}O_5$: C, 58.9; H, 5.4. Found: C, 58.6; H, 5.8.

Decarboxylation was accomplished by refluxing the dibasic acid in xylene for two hours. After the xylene was removed by distillation under reduced pressure, an oil which solidified remained. Crystallization from a mixture of ether and petroleum ether yielded the desired monobasic acid of m. p. 101–102°.

A mixed melting point taken with the acid prepared by the degradation of the abnormal rearrangement product (III) showed no depression.

α-(*o*-Methoxyphenyl)-butyric acid was prepared by the ethylation of diethyl *o*-methoxyphenylmalonate using ethyl iodide. The procedure was similar to that used for

(3) Davidson and Bogert, THIS JOURNAL, **57**, 905 (1935).

methylation. Diethyl *o*-methoxyphenylethylmalonate is a solid of m. p. 66–67°.

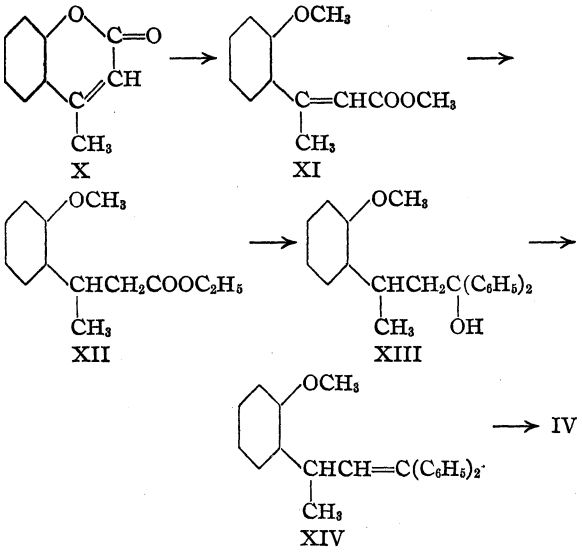
Anal. Calcd. for $C_{16}H_{22}O_5$: C, 65.3; H, 7.5. Found: C, 65.0; H, 7.5.

Hydrolysis and decarboxylation yielded the solid α-(*o*-methoxyphenyl)-butyric acid (m. p. 56–57°; b. p. 165–166° at 10 mm.).

Anal. Calcd. for $C_{11}H_{14}O_3$: C, 68.0; H, 7.2. Found: C, 67.5; H, 6.9.

The physical properties of a few of the para compounds are: (a) ethyl *p*-methoxyphenylacetate, b. p. 148–150° at 14.5 mm.; (b) diethyl *p*-methoxyphenylmalonate, b. p. 161–162° at 3 mm., $n^{20}D$ 1.4988; (c) diethyl *p*-methoxyphenylmethylmalonate, b. p. 160–161° at 3.5 mm., $n^{20}D$ 1.4990. (*Anal.* Calcd. for $C_{15}H_{20}O_5$: C, 64.3; H, 7.1. Found: C, 63.9; H, 7.0); (d) *p*-methoxyphenylmethylmalonic acid, m. p. 149.5–150°. (*Anal.* Calcd. for $C_{11}H_{12}O_5$: C, 59.0; H, 5.4. Found: C, 59.1; H, 5.4); (e) α-(*p*-methoxyphenyl)-propionic acid, m. p. 56–57°.

A second but less satisfactory synthesis of α-(*o*-methoxyphenyl)-propionic acid made use of the following series of reactions



4-Methylcoumarin (X), prepared according to the directions of Stoermer and Sandow,[6] was converted to the **methyl ester of *o*-methoxy-β-methylcinnamic acid (XI)** using the procedure of these same investigators. Difficulty was experienced in the catalytic reduction of XI, consequently the ester was hydrolyzed to the acid by means of alcoholic potassium hydroxide.

Reduction of *o*-methoxy-β-methylcinnamic acid to the corresponding saturated acid was accomplished by the use of sodium amalgam. The unsaturated acid (18 g., 0.09 mole) was dissolved in 100 cc. of water containing sodium hydroxide (3.68 g., 0.09 mole). To this solution 4% sodium amalgam (150 g.) was added over a period of six hours, maintaining a temperature of 50° throughout. After twelve hours, reduction was complete. The filtered aqueous solution was then acidified with 10% sulfuric acid and extracted with ether. The combined ether extracts, after drying with sodium sulfate, yielded an oil which was distilled under reduced pressure (b. p. 172° at 9 mm.). After standing at room temperature for approximately one month, the product finally solidified (m. p. 49–50°).

Anal. Calcd. for $C_{11}H_{14}O_3$: C, 68.14; H, 7.23. Found: C, 68.26; H, 7.25.

Ethyl *o*-methoxy-β-methylhydrocinnamate (XII) (b. p. 153–154° at 9 mm.) was prepared by refluxing the saturated acid with absolute ethyl alcohol in the presence of a small amount of concd. sulfuric acid.

The conversion of the ester to the **carbinol XIII** was brought about in the following manner. To a solution of the Grignard reagent prepared from phenyl bromide (54.2 g.) and magnesium (8.3 g.) and ether (1500 cc.) was added an ether solution of the hydrocinnamate (29 g.). The rate of addition of the ester was regulated so that the reaction mixture refluxed slowly. After the addition of the ester, the mixture was refluxed for an additional two hours. The ether was then removed by distillation and the residue was heated on the steam-bath for one hour. The reaction mixture was decomposed with ice and sulfuric acid, and then extracted with ether. The combined ether extracts were washed with water and after the ether was removed, the residue was steam distilled to remove the diphenyl. The residual oil in the distilling flask was then taken up in ether and dried. The product (35 g.), which was obtained after the removal of the ether, did not crystallize.

The carbinol XIII was dehydrated in accordance with the procedure of Schlenk and Bergmann[7] by refluxing with acetic anhydride. The yellow oil which resulted from this dehydration could not be crystallized but was oxidized directly.

Oxidation of XIV.—A solution of XIV (2 g.) in acetic acid (15 ml.) was placed in a bath at 50–60°. To this solution was added dropwise chromic acid (1.5 g.) dissolved in water (3 ml.) and acetic acid (6 ml.). After oxidation was complete, the reaction mixture was steam distilled. Benzophenone was isolated from the steam distillate. The contents of the distilling flask were then subjected to extraction with ether, and the ether extract was shaken with a 5% solution of sodium carbonate. The alkaline aqueous extract, after acidification with sulfuric acid (10%), produced an oil, which upon distillation at reduced pressure yielded a crystalline solid (m. p. 101–102°). This solid proved to be the desired acid IV.

Summary

α-(*o*-Methoxyphenyl)-propionic acid has been synthesized in two different ways. It is identical with the product previously obtained by the degradation of the abnormal rearrangement product of γ-ethylallyl phenyl ether. This synthesis therefore supplies evidence of the correctness of the structures which have already been assigned to the abnormal rearrangement product of γ-ethylallyl phenyl ether and to its degradation product.

The Rearrangement of Phenyl Allyl Ethers. IV. An Examination of the Pyrolysis Product of Phenyl Allyl Ether for Evidence of Para Rearrangement

BY WALTER M. LAUER AND ROBERT M. LEEKLEY

The para rearrangement of phenyl allyl ethers, while not as common as ortho rearrangement, has nevertheless been observed. For example, Claisen and Eisleb[1] obtained methyl 2-hydroxy-3-methyl-5-allylbenzoate by heating methyl 2-allyloxy-3-methylbenzoate and recently Mumm and his co-workers[2] have studied the para rearrangement of substituted allyl ethers of this same methyl *o*-cresotinate. That para rearrangement is not confined to cases in which both ortho positions are blocked becomes apparent from a study by Staudinger of the rearrangement of γ,γ-dimethylallyl *o*-anisyl ether. The rearrangement product upon methylation and subsequent degradation yielded veratric acid.

In view of these facts it was considered advisable to reëxamine the pyrolysis of phenyl allyl ether for evidence of para rearrangement. The results of this study show that no appreciable amount of *p*-allylphenol is formed.

Although Claisen has shown conclusively that the product obtained by the pyrolysis of allyl phenyl ether is *o*-allylphenol, the methods which were used were such that a small amount of *p*-allylphenol in the rearrangement product might have escaped detection. In the present investigation a method sufficiently sensitive for the detection of even a small amount of *p*-allylphenol was used. *o*-Allylphenol and *p*-allylphenol are not easy to separate, but the corresponding hydroxybenzaldehydes are easily separated, since salicylaldehyde forms a copper derivative but *p*-hydroxybenzaldehyde does not. If a mixture of the two aldehydes is treated with a solution of copper acetate, the salicylaldehyde is precipitated as the copper derivative and the *p*-hydroxybenzaldehyde may be removed by extraction with ether. This method was tested with known mixtures of the two aldehydes, and in one of these tests seventy milligrams of *p*-hydroxybenzaldehyde was recovered from a mixture that contained 10 g. of salicylaldehyde and 100 mg. of *p*-hydroxybenzaldehyde. The rearrangement product obtained by the pyrolysis of allyl phenyl ether was converted to the corresponding hydroxybenzaldehyde by isomerization with potassium hydroxide followed by ozonolysis.

No trace of *p*-hydroxybenzaldehyde could be found in the salicylaldehyde produced from the rearrangement product. It was therefore concluded that if any *p*-allylphenol was formed by the rearrangement of allyl phenyl ether, it must be in very small amount.

This conclusion was confirmed in other ways. A sample of *o*-allylphenol which had been prepared by the decarboxylation of 3-allyl-4-hydroxybenzoic acid was compared with one prepared by the rearrangement of allyl phenyl ether. There were no significant differences in refractive indices or in melting points of the crude phenylurethans between the two samples.

Experimental

***o*-Allylphenol** (b. p. 110–113° at 23 mm.; $n^{20}D$ 1.5453) prepared by the rearrangement of allyl phenyl ether, was isomerized to *o*-propenylphenol by means of methyl alcoholic potassium hydroxide according to the procedure of Claisen.[3] Completeness of isomerization was established by means of a quantitative determination of the —CH=CHCH$_3$ group using mercuric acetate.

The ozonide, prepared in ethyl acetate from 14 g. of propenylphenol was decomposed by reductive cleavage according to the method of Hahn and Wassmuth.[4] Acetaldehyde was identified as one of the cleavage products by means of its dimethone (m. p. 138.5–140°).

The residue, after removal of the ethyl acetate and the acetaldehyde, was shaken with a saturated solution of sodium bisulfite. The bisulfite addition product, washed with ether, was decomposed with dilute sulfuric acid. Extraction with ether, followed by removal of the ether, yielded a residue which was treated with copper acetate. The copper derivative of salicylaldehyde weighed 7.86 g. and the residue of ether-soluble material weighed 301 mg. The ether solutions of the several components indifferent to the copper acetate treatment were combined. Salicylic acid was identified, but no phenylhydrazone precipitated after treatment with phenylhydrazine hydrochloride and sodium acetate, even though the addition of a small amount of *p*-hydroxybenzaldehyde produced an immediate precipitate.

Separation of Salicylaldehyde and *p*-Hydroxybenzaldehyde.—A mixture containing salicylaldehyde (10 g.) and *p*-hydroxybenzaldehyde (0.1 g.) was shaken for three

(1) Claisen and Eisleb, *Ann.*, **401**, 21 (1913).
(2) Mumm and Möller, *Ber.*, **70**, 2214 (1937).
(3) Claisen *Ann.*, **418**, 69 (1919).
(4) Hahn and Wassmuth, *Ber.*, **67**, 696 (1934).

hours with ether (50 ml.) and a saturated aqueous copper acetate solution (150 ml.). After the mixture had been allowed to stand overnight, it was filtered. The precipitate, washed with ether, weighed 9.65 g. The filtrate was extracted, first with the ether that had been used to wash the precipitate, and then twice with fresh ether. The combined ether extracts were concentrated to 50 ml. and then shaken with more of the saturated copper acetate solution (100 ml.). The precipitate after washing with ether weighed 2.1 g. The filtrate was again extracted with ether and the extract treated with copper acetate as before. This time 0.7 g. of copper derivative was obtained, making a total of 12.45 g. (99.5%). The filtrate from the last crop of copper derivative was extracted with ether. The ether extract yielded 71 mg. (71%) of pure *p*-hydroxybenzaldehyde (m. p. 115–116.5°) after suitable treatment.

Pyrolysis of Ethyl *p*-Allyloxybenzoate.—One-half hour at 230–250° converted the ethyl *p*-allyloxybenzoate to ethyl 3-allyl-4-hydroxybenzoate (m. p. 77–78° after crystallization from benzene), in 89% yield.

Hydrolysis and Decarboxylation of Ethyl 3-Allyl-4-hydroxybenzoate.—Hydrolysis was accomplished by boiling for three hours with 2 *N* sodium hydroxide. Crystallization from a mixture of ether and petroleum ether yielded the acid of m. p. 127–128°; yield 85%. Decarboxylation of the acid (8 g.) by heating with quinoline (10 g.) yielded *o*-allylphenol (b. p. 93–94° at 8 mm.; $n^{20}D$ 1.5450).

Pyrolysis of *p*-Allyloxybenzoic Acid.—*p*-Allyloxybenzoic acid (m. p. 162–163°, Claisen reported 162°) was obtained by the hydrolysis of its ethyl ester. This acid (10 g.) was heated with quinoline (10 g.) and a trace of copper powder for eight hours at 200–210°. The pyrolysis product was dissolved in a mixture of ether and petroleum ether (1:2), extracted three times with dilute sulfuric acid, once with water, and five times with aqueous sodium hydroxide (10%). The alkaline extract was acidified and then extracted with ether. The ether extract yielded on distillation a 60% yield of *o*-allylphenol (b. p. 97–98° at 11 mm., $n^{20}D$ 1.5452).

Phenylurethan of *o*-Allylphenol.—This derivative was prepared from each of the three samples of *o*-allylphenol in exactly the same way. A mixture of the phenol (340 mg.), phenyl isocyanate (240 mg.) and a trace of dry pyridine was heated for one hour at 100°. The phenylurethan was extracted from diphenylurea with boiling petroleum ether (b. p. 90–100°). The phenylurethan obtained from the petroleum ether was then placed in a vacuum desiccator. The melting point of the derivative was taken without further purification.

The melting points of the phenylurethans were as follows: (1) from *o*-allylphenol prepared by decarboxylation of 3-allyl-4-hydroxybenzoic acid, m. p. 103.5–104.5°; (2) from *o*-allylphenol obtained by the pyrolysis of allylphenyl ether, m. p. 103.5–104.5°; (3) from *o*-allylphenol obtained by the pyrolysis of *p*-allyloxybenzoic acid, m. p. 104–105°. One crystallization of the phenylurethans was sufficient to raise the melting point to 106–107° (Claisen reported 106.5° as the m. p. of the pure compound) in each case.

Summary

The pyrolysis product of allyl phenyl ether was examined for evidence of para rearrangement. The rearrangement of this ether proceeds without the formation of any appreciable amount of *p*-allylphenol, however.

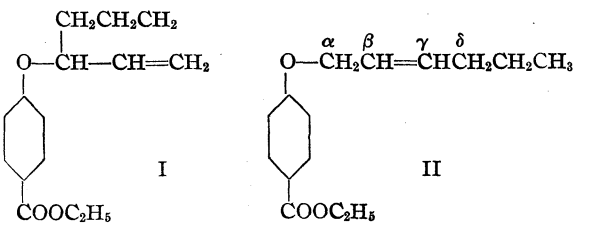
The Rearrangement of Phenyl Allyl Ethers. V. The Isomeric Ethyl *p*-(α- and γ-Propylallyloxy)-benzoates

BY WALTER M. LAUER AND ROBERT M. LEEKLEY[1,2]

The substituted allyl ethers of ethyl *p*-hydroxybenzoate lend themselves admirably to rearrangement studies since both the ethers and their rearrangement products are converted to solid acids by hydrolysis. This circumstance makes possible a more precise study of the nature of the rearrangement products. Furthermore, since the para position is blocked by the carbethoxyl group the possibility of para rearrangement is eliminated. In view of these facts, the isomeric ethers, ethyl *p*-(α-propylallyloxy)-benzoate (I) and ethyl *p*-(γ-propylallyloxy)-benzoate (II) were chosen for investigation.



Several years ago, it was reported[3] that rearrangement of γ-ethylallyl phenyl ether leads to *o*-(α,γ-dimethylallyl)-phenol. That *o*-(α-ethylallyl)-phenol was also formed during this rearrangement was demonstrated by Hurd and Pollack.[4] The formation of *o*-(α-ethylallyl)-

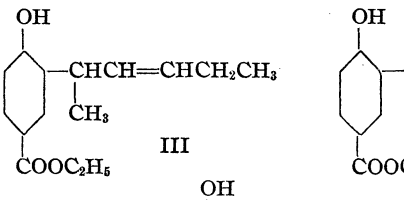
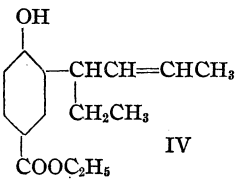
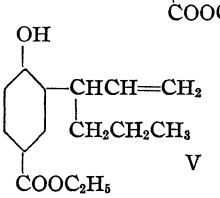
phenol involves the usual transposition from the α- to γ-carbon atom of the unsaturated chain, whereas the formation of the abnormal rearrangement product, *o*-(α,γ-dimethylallyl)-phenol, requires a migration of the aromatic residue to either the β- or δ-carbon atom. A choice between these two possibilities should be feasible in the case of II, for if a shift to the β-carbon occurs, the abnormal rearrangement product should be III, while a shift to the δ-carbon should lead to structure IV for the abnormal rearrangement product.



III



IV

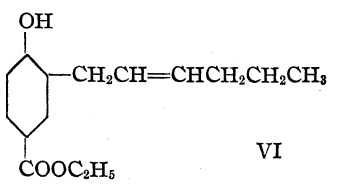


V

The present work demonstrates that ethyl 3-(α-methyl-γ-ethylallyl)-4-hydroxybenzoate (III) results along with the normal rearrangement product, ethyl 3-(α-propylallyl)-4-hydroxybenzoate (V). Therefore, at least in this case, it must be concluded that a β (or ϵ) and not a δ shift is involved in the formation of the abnormal rearrangement product.

Ethyl *p*-(α-propylallyloxy)-benzoate (I) was obtained, along with its isomer, ethyl *p*-(γ-propylallyloxy)-benzoate (II), by the action of 3-chloro-1-hexene on ethyl *p*-hydroxybenzoate. This mixture of esters, which consisted of approximately 75% of the α-substituted allyloxy isomer, upon hydrolysis yielded the corresponding acids, which were separated by fractional crystallization. The lower melting acid, upon ozonolysis gave formaldehyde, and on esterification yielded the desired ethyl *p*-(α-propylallyloxy)-benzoate.

Rearrangement of the ester (I) produced the normal rearrangement product, ethyl 3-(γ-propylallyl)-4-hydroxybenzoate (VI).



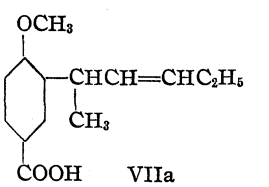
VI

The structure of the rearrangement product (VI) was established in the following way. Methylation followed by hydrolysis yielded a 3-hexenylanisic acid, which upon ozonolysis gave butyraldehyde. Furthermore, the rearrangement product did not reduce a hot mercuric acetate solution, but did so after isomerization with a strong potassium hydroxide solution which is known to convert allylbenzenes into propenylbenzenes.

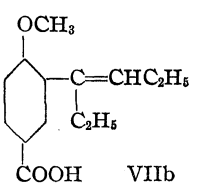
Ethyl *p*-(γ-propylallyloxy)-benzoate (II) was prepared from 1-chloro-2-hexene and ethyl *p*-hydroxybenzoate. This reaction occurred without an α-γ-transposition since a freezing point curve indicated that the product did not consist of a mixture of esters. Hydrolysis of the ester yielded *p*-(γ-propylallyloxy)-benzoic acid, which was in turn reduced to *p*-(*n*-hexyloxy)-benzoic acid. The saturated acid, which was obtained in the above manner, was found to be identical with a sample prepared from *n*-hexyl bromide and ethyl *p*-hydroxybenzoate.

A mixture of rearrangement products was obtained by the pyrolysis of ethyl *p*-(γ-propylallyloxy)-benzoate. This mixture was methylated and then hydrolyzed to produce two 3-hexenylanisic acids, which were separated by fractional crystallization.

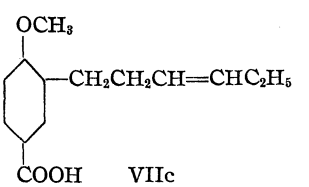
The lower melting acid was shown to be 3-(α-methyl-γ-ethylallyl)-4-methoxybenzoic acid, VIIa. The structure was proved in the following way. Ozonolysis produced propionaldehyde. There are only three possible 3-hexenylanisic acids which contain a continuous six-carbon chain from which propionaldehyde could be formed. These three compounds possess the structures, VIIa, VIIb and VIIc.



VIIa



VIIb



VIIc

Of these three structures VIIb was eliminated since the acid did not reduce mercuric acetate. If structure VIIc were the correct one, 3-(*n*-hexyl)-anisic acid would be formed by catalytic reduc-

tion. Actually, the hexylanisic acid which was formed by reduction was not identical with the sample prepared by the reduction of 3-(γ-propylallyl)-anisic acid. Therefore the lower melting of the two 3-hexenylanisic acids which were derived from the rearrangement products was 3-(α-methyl-γ-ethylallyl)-4-methoxybenzoic acid, VIIa.

The higher melting isomeric 3-hexenylanisic acid was 3-(α-propylallyl)-4-methoxybenzoic acid, since ozonolysis produced formaldehyde.

The rearrangement of ethyl p-(γ-propylallyloxy)-benzoate (II), therefore, leads to two rearrangement products. In order to estimate the relative amounts of these two products, the original mixture of pyrolysis products was ozonized. The dimethones of the volatile aldehydes were separated by fractional crystallization. On the basis of this rather inaccurate method it was estimated that the ratio of abnormal to normal rearrangement product was approximately two to one.

Experimental

p-(α-Propylallyloxy)-benzoic Acid.—A solution of ethyl p-hydroxybenzoate (55 g.) in acetone (200 ml.) was placed in a flask fitted with a reflux condenser, a dropping funnel and a mercury-sealed stirrer. Anhydrous potassium carbonate (50 g.) was then added and the reaction mixture was refluxed gently on the steam-bath while 3-chloro-1-hexene (39.5 g.; b. p. 63–64° at 110 mm.; $n^{20}D$ 1.4310) was added. The reaction mixture was heated under reflux with stirring for twelve hours. After this period most of the acetone was removed by distillation. Enough water to dissolve the salt was added and the product was extracted with ether (150 ml. total). Petroleum ether (100 ml.) was then added to the ether extract and the acidic components were removed by extraction with four portions of aqueous sodium hydroxide (5%). After most of the solvent had been removed by distillation, the product was heated on the steam-bath under diminished pressure for several hours. During this time 3-chloro-1-hexene (13 g.) distilled. The residue which did not distil at 12 mm. at the temperature of the steam-bath was distilled in a Hickman still. Three fractions were collected (b. p. 105–106° at approx. 0.05 mm.) and their refractive indices determined: (1) $n^{20}D$ 1.5150; (2) $n^{20}D$ 1.5162; (3) $n^{20}D$ 1.5173. The drift in the refractive index was considered to be an indication that the product was not a single compound.

Fraction 1 was hydrolyzed with methyl alcoholic potassium hydroxide (25%). The substituted benzoic acid, crystallized twice from a mixture of benzene and petroleum ether, melted at 138–139°. It was shown to be p-(γ-propylallyloxy)-benzoic acid.

The mother liquor from the first crystallization was evaporated to dryness and the residue crystallized from petroleum ether alone. Recrystallization from dilute methyl alcohol yielded a solid of m. p. 76–77°, which proved to be p-(α-propylallyloxy)-benzoic acid. This compound showed unusual behavior when melted. If the melted sample was chilled, it immediately solidified to an allotropic form, melting at 35–38°, which could again be transformed to the higher melting variety.

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.91; H, 7.27. Found: C, 71.14; H, 7.80.

Ozonolysis of p-(α-Propylallyloxy)-benzoic Acid.—The ozonide, prepared in ethyl bromide solution from the acid (230 mg.), was decomposed according to the method of Whitmore.[5] Formaldimethone (150 mg.; m. p. 187–188.5°) was obtained.

Ethyl p-(α-Propylallyloxy)-benzoate.—The dried (at 60°) silver salt, was converted to the ethyl ester by means of ethyl iodide in dry ether. The ester (b. p. 95–97° at 0.5 mm., $n^{20}D$ 1.5130) was distilled in a Hickman still.

Anal. Calcd. for $C_{15}H_{20}O_3$: C, 72.53; H, 8.12. Found: C, 72.76; H, 8.21.

Pyrolysis of Ethyl p-(α-Propylallyloxy)-benzoate.—The ester (9.1 g.) began to boil at 220° under 40 mm. pressure, but as the rearrangement proceeded the temperature of the liquid rose gradually to 246°. Further heating was not accompanied by any boiling point increase.

The rearrangement product was dissolved in petroleum ether (40 ml.) and extracted with aqueous sodium hydroxide (5%). The alkaline extract was acidified with dilute sulfuric acid and the phenolic product was extracted with ether. Evaporation of the ether extract produced a solid which upon crystallization from petroleum ether melted at 75–76.5°.

Anal. Calcd. for $C_{15}H_{20}O_3$: C, 72.53; H, 8.12. Found: C, 72.49; H, 8.08.

This rearrangement product, ethyl 3-(γ-propylallyl)-4-hydroxybenzoate did not reduce mercuric acetate in glacial acetic acid.

3-(γ-Propylallyl)-4-methoxybenzoic Acid.—Ethyl 3-(γ-propylallyl)-4-hydroxybenzoate (920 mg.) was added to a solution of sodium methoxide (25 ml. of methyl alcohol containing 200 mg. of metallic sodium). Dimethyl sulfate (2 ml.) was then added and the reaction mixture was refluxed for forty-five minutes. The reaction mixture was again refluxed after the addition of aqueous sodium hydroxide (20 ml., 20%). Dilution of the reaction mixture with water (100 ml.) followed by acidification with dilute sulfuric acid yielded the solid acid (650 mg.); m. p. 107–108°, after crystallization from dilute methyl alcohol. This compound did not reduce a hot solution of mercuric acetate in glacial acetic acid.

Anal. Calcd. for $C_{14}H_{18}O_3$: C, 71.75; H, 7.75. Found: C, 71.73; H, 7.89.

Ozonolysis of 3-(γ-propylallyl)-4-methoxybenzoic acid produced butyraldehyde which was identified as the dimethone (m. p. 131.5–133.5°).

3-Hexyl-4-methoxybenzoic Acid.—The saturated acid (m. p. 113.5–114°) was prepared from 3-(γ-propylallyl)-4-methoxybenzoic acid by catalytic reduction using a palladium (on calcium carbonate) catalyst.

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.14; H, 8.54. Found: C, 70.95; H, 8.68.

(5) Whitmore, THIS JOURNAL, **54**, 3711 (1932); **56**, 180 (1934).

3-(1-Hexenyl)-4-hydroxybenzoic Acid.—Ethyl 3-(γ-propylallyl)-4-hydroxybenzoate (1.75 g.) was heated for one hour at 155–160° with potassium hydroxide (4 g.) and water (2 ml.). The reaction mixture was then dissolved in water and acidified. Ether extraction yielded the crude product (1.2 g.) which after several crystallizations from benzene melted at 134–135°.

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.91; H, 7.27. Found: C, 70.57; H, 7.65.

A precipitate was formed when a few drops of a solution of mercuric acetate in glacial acetic acid were heated with several crystals of 3-(1-hexenyl)-4-hydroxybenzoic acid.

Ethyl *p*-(γ-Propylallyloxy)-benzoate.—Ethyl *p*-hydroxybenzoate (55 g.) dissolved in acetone (200 ml.), was placed in a flask fitted with a dropping funnel, a reflux condenser, and a stirrer. Anhydrous potassium carbonate (50 g.) was added and the reaction mixture was refluxed gently while 1-chloro-2-hexene (39.5 g.) was added slowly through the dropping funnel. After the reaction mixture was stirred under reflux for twelve hours, most of the acetone was distilled off. Enough water to dissolve the salt was added and the resultant solution was extracted with ether. Petroleum ether was added to the ether extract and acidic impurities were removed from the non-aqueous extract with sodium hydroxide (5%). Distillation using a Hickman still yielded a pure product (45 g., b. p. 115–116° at 0.2 mm., $n^{20}D$ 1.5197, m. p. 14.1°).

Anal. Calcd. for $C_{15}H_{20}O_3$: C, 72.53; H, 8.12. Found: C, 72.78; H, 8.13.

***p*-(γ-Propylallyloxy)-benzoic Acid.**—Hydrolysis of the ester (twenty-five minutes with 5 ml. of 25% methyl alcoholic potassium hydroxide) yielded the salt, which was dissolved in water and converted to the free acid with dilute sulfuric acid. Crystallization from benzene and petroleum ether gave a product which melted at 139.5–140.5°. It was identical with the *p*-(γ-propylallyloxy)-benzoic acid which was obtained as a side-product in the preparation of *p*-(α-propylallyloxy)-benzoic acid.

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.91; H, 7.27. Found: C, 70.64; H, 7.17.

The reduction product, ***p*-hexyloxybenzoic acid** melted at 104.5–106.5°.

p-Hexyloxybenzoic acid was also prepared by the action of *n*-hexyl bromide on a solution of ethyl *p*-hydroxybenzoate in alcoholic sodium ethoxide. After hydrolysis with methyl alcoholic potassium hydroxide and acidification with dilute sulfuric acid, the acid was obtained. Purification yielded a product (m. p. 105.5–107°) which was identical with that obtained by the reduction of the *p*-(γ-propylallyloxy)-benzoic acid.

Anal. Calcd. for $C_{13}H_{18}O_3$: C, 70.23; H, 8.17. Found: C, 70.28; H, 8.16.

Pyrolysis of Ethyl *p*-(γ-Propylallyloxy)-benzoate.—The ester (56 g.) was heated to boiling (213–241°) at 40 mm. pressure for a period of one and one-half hours. A petroleum ether (b. p. 60–68°) solution of the rearrangement products was extracted with sodium hydroxide (5%). The alkaline solution was then acidified with dilute sulfuric acid and extracted with ether. Distillation of the ether extract yielded a colorless, viscous oil (53 g., $n^{20}D$ 1.5367, b. p. 183–188° at 5 mm.). This oil did not reduce a hot solution of mercuric acetate in acetic acid. On standing for about one month, a sample of the pyrolysis product partially solidified. The mixture of isomeric phenols was analyzed.

Anal. Calcd. for $C_{15}H_{20}O_3$: C, 72.53; H, 8.12. Found: C, 72.61; H, 8.11.

Ozonolysis of the pyrolysis product yielded formaldehyde and propionaldehyde, identified as formaldimethone and propionaldimethone, respectively.

3-(α-Propylallyl)-4-methoxybenzoic Acid and 3-(α-Methyl-γ-ethylallyl)-4-methoxybenzoic Acid.—The rearrangement product (26 g.) of ethyl *p*-(γ-propylallyloxy)-benzoate was dissolved in a solution of sodium ethoxide, and methylated with dimethyl sulfate. A mixture of hexenylanisic acids (m. p. 104–114°) was obtained in almost quantitative yield.

The two hexenylanisic acids were separated by fractional crystallization. Dilute methyl alcohol, dilute acetic acid and petroleum ether were used as solvents, but petroleum ether was found to be the most suitable for purification of the higher melting isomer. The higher melting (m. p. 142.5–143.5°) component, **3-(α-propylallyl)-4-methoxybenzoic acid,** was obtained in pure form after twenty-one crystallizations. This product did not reduce a hot mercuric acetate solution.

Pure **3-(α-methyl-γ-ethylallyl)-4-methoxybenzoic acid** was isolated from the petroleum ether mother liquors. The mother liquors richest in the more soluble fraction were evaporated to dryness and the residues combined and recrystallized from dilute acetic acid until there was no further change in melting point (m. p. 113–114°). 3-(α-Methyl-γ-ethylallyl)-4-methoxybenzoic acid did not reduce mercuric acetate.

Anal. Calcd. for $C_{14}H_{18}O_3$: C, 71.75; H, 7.75. Found: C, 71.45; H, 8.00.

Ozonolysis of 3-(α-methyl-γ-ethylallyl)-4-methoxybenzoic acid, yielded propionaldehyde, which was identified as the dimethone (m. p. 153.5–154.5°; m. p. reported 155°)[6] and its anhydride (m. p. 142–143°; m. p. (Vorländer) 142–143°; m. p. (Klein and Linser) 148°).[7]

Ozonolysis of 3-(α-propylallyl)-4-methoxybenzoic acid yielded formaldehyde which was identified as formaldimethone (m. p. 188–189°).

3-(1-Methylamyl)-4-methoxybenzoic acid (m. p. 125–126°) was prepared by the catalytic reduction of 3-(α-methyl-γ-ethylallyl)-4-methoxybenzoic acid using a palladium catalyst (on calcium carbonate).

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.14; H, 8.54. Found: C, 70.85; H, 8.86.

3-(1-Ethylbutyl)-4-methoxybenzoic acid (m. p. 145–146°) was obtained by the catalytic reduction of 3-(α-propylallyl)-4-methoxybenzoic acid.

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.14; H, 8.54. Found: C, 70.94; H, 8.70.

Hydrolysis of Rearrangement Product of Ethyl *p*-(γ-propylallyloxy)-benzoate.—A solution of sodium hydroxide (5.3 g.) and the rearrangement product (13.1 g.)

(6) (a) Klein and Linser, *Mikrochemie*, Pregl Festschrift, 204, 1929; (b) Kao and Yen, *Science Repts. Natl. Tsing Hua Univ.*, Series A, **1**, 185 (1932).

in water (100 ml.) was refluxed for one hour. Acidification produced an oil which finally solidified. The higher melting isomer, 3-(α-propylallyl)-4-hydroxybenzoic acid (m. p. 133–134°), was obtained in pure form by a series of crystallizations from benzene and petroleum ether.

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.91; H, 7.27. Found: C, 71.01; H, 7.15.

All attempts to isolate the more soluble isomer in pure form were unsuccessful.

Methylation of 3-(α-propylallyl)-4-hydroxybenzoic acid with dimethyl sulfate gave a 97% yield of 3-(α-propylallyl)-4-methoxybenzoic acid (m. p. 142–143°).

Anal. Calcd. for $C_{14}H_{18}O_3$: C, 71.75; H, 7.75. Found: C, 71.45; H, 7.55.

Summary

The rearrangement of the isomeric ethyl p-(α- and γ-propylallyloxy)-benzoates has been investigated, with the following results.

Ethyl α-propylallyloxybenzoate undergoes rearrangement to form ethyl 3-(γ-propylallyl)-4-hydroxybenzoate, whereas ethyl γ-propylallyloxybenzoate gives two rearrangement products, namely, ethyl 3-(α-propylallyl)-4-hydroxybenzoate and ethyl 3-(α-methyl-γ-ethylallyl)-4-hydroxybenzoate.

The formation of this latter rearrangement product constitutes an additional example of an abnormal phenyl allyl ether rearrangement and supplies evidence for the view that in the case of an abnormal rearrangement, the aromatic residue becomes attached to the β-carbon atom, while the normal rearrangement leads to a transposition of the aromatic residue to the γ-carbon atom.

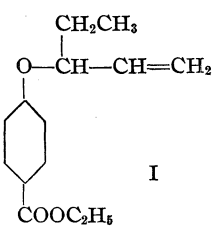
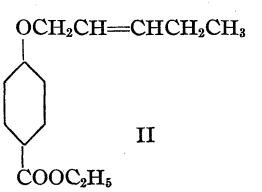
The Rearrangement of Phenyl Allyl Ethers. VI. The Isomeric Ethyl p-(α- and γ-Ethylallyloxy)-benzoates

BY W. M. LAUER AND H. E. UNGNADE[1]

Certain phenyl allyl ethers upon rearrangement lead to products which one would not expect on the basis of the rearrangement pattern outlined by Claisen. Such so-called abnormal rearrangement was first observed several years ago in the case of γ-ethylallyl phenyl ether.[2] The preceding paper in this series[3] furnishes an additional example, namely, ethyl p-(γ-propylallyloxy)-benzoate. Since in this latter case it was possible to effect a separation of derivatives of the normal and abnormal rearrangement products, a similar study of the behavior of the lower homolog, ethyl p-(γ-ethylallyloxy)-benzoate, II, was undertaken. The isomeric compounds, ethyl p-(α-ethylallyloxy)-benzoate, I, and ethyl p-(α,γ-dimethylallyloxy)-benzoate, III, were also prepared and investigated.

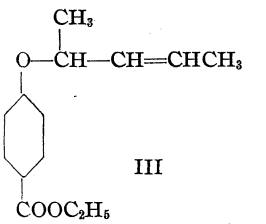


I

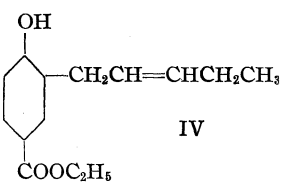


II

Ethyl p-(α-ethylallyloxy)-benzoate, I, on pyrolysis yielded the normal rearrangement product, IV, together with a small amount of 1,3-pentadiene and ethyl p-hydroxybenzoate. That the rearrangement product is the normal one is indicated by the fact that the corresponding substituted anisic acid yielded propionaldimethone on ozonolysis.

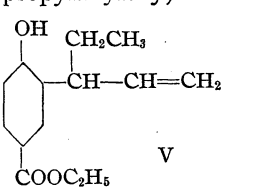


III

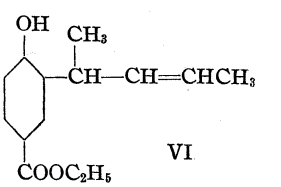


IV

Ethyl p-(γ-ethylallyloxy)-benzoate, II, gave both normal and abnormal rearrangement products, V and VI, thus paralleling the behavior of the previously reported case of ethyl p-(γ-propylallyloxy)-benzoate.



V



VI

3-(α-Ethylallyl)-4-methoxybenzoic acid, derived from the normal rearrangement product, V, was

(1) Abstract of Ph.D. thesis submitted November, 1938.
(2) Lauer and Filbert, THIS JOURNAL, **58**, 1388 (1936).
(3) Lauer and Leekley, *ibid.*, **61**, 3043 (1939).

obtained in pure form by fractional crystallization. Repeated attempts to isolate the corresponding derivative of the abnormal rearrangement product, VI, were unsuccessful. However, there can be little doubt of its presence since ozonolysis of the pyrolysis product always yielded formaldimethone and acetaldimethone.

Ethyl *p*-(α,γ-dimethylallyloxy)-benzoate, III, on pyrolysis yielded 1,3-pentadiene and ethyl *p*-hydroxybenzoate, in amounts which corresponded to slightly more than 50% cleavage of the phenyl ether. Methylation of the rearrangement product, followed by hydrolysis, yielded a product which upon crystallization showed the properties of a mixture. Ozonolysis of this mixture gave acetaldimethone and a small amount of formaldimethone. If ozonolysis can be relied upon, then it must be concluded that ethyl *p*-(α,γ-dimethylallyloxy)-benzoate, III, also yields an abnormal as well as a normal rearrangement product.

Experimental

Ethyl *p*-(α-Ethylallyloxy)-benzoate (I) was prepared from 3-chloro-1-pentene (31 g., b. p. 48–48.5° at 150 mm., $n^{20}D$ 1.4258) and ethyl *p*-hydroxybenzoate (49.2 g.) in the presence of acetone (150 g.) and potassium carbonate (41 g.). The combined ether–petroleum ether extracts were shaken three times with aqueous sodium hydroxide (10%), dried over potassium carbonate, and distilled in a Hickman still; fraction 1, b. p. 89–90° at 0.1 mm. (11.5 g.); fraction 2, b. p. 90–95° at 0.1 mm. (2 g.); residue 2.5 g.

Hydrolysis of fraction 1 with potassium hydroxide (30 g.) in methanol (90 g.) for a period of twenty minutes gave a mixture of acids upon acidification with sulfuric acid. Fractional crystallization from benzene, petroleum ether, aqueous methanol, and aqueous ethanol finally yielded the pure ***p*-(α-ethylallyloxy)-benzoic acid,** m. p. 108–109°, since ozonolysis yielded formaldimethone.

Hydrolysis of fraction 2 and the residue gave only *p*-(γ-ethylallyloxy)-benzoic acid (m. p. 156.5–157.5°).

Pure *p*-(α-ethylallyloxy)-benzoic acid (1.36 g.) was converted to the ethyl ester (1.40 g.), through the silver salt. The ethyl ester gave a negative phenol test.[4]

Pyrolysis of Ethyl *p*-(α-Ethylallyloxy)-benzoate.—The ethyl *p*-(α-ethylallyloxy)-benzoate (1.40 g.) began to boil at 200° at 40 mm. After one hour of heating the boiling point remained constant at 236°.

The small amount of material which collected in the trap was treated with bromine at the temperature of liquid air. The reaction mixture was then allowed to come to room temperature and the excess bromine removed under diminished pressure. The crystalline product weighed 200 mg. and was identified as 1,2,3,4-tetrabromopentane (m. p. 113–114°, yield 8.6%). A petroleum ether (b. p. 60–68°) solution of the main rearrangement product was shaken with aqueous sodium hydroxide (5%). The alkaline solution after acidification with dilute sulfuric acid was extracted with ether. Evaporation of the ether yielded a residue which was heated with a sodium hydroxide solution (5%) for one hour. Acidification gave 0.86 g. of rearrangement product, melting at 101–102° after crystallization from petroleum ether.

The rearrangement product, dissolved in alcoholic sodium ethoxide, was *methylated* with dimethyl sulfate (1.1 g.), and then converted to the methoxy acid (0.65 g.). Two crystallizations from dilute methyl alcohol and one from petroleum ether yielded a pure product (m. p. 117–117.5°, 200 mg.). The **3-(γ-ethylallyl)-4-methoxybenzoic acid** obtained in this manner did not reduce mercuric acetate nor did it give a positive phenol test.

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.90; H, 7.27. Found: C, 70.73; H, 7.62.

Ozonolysis of 3-(γ-Ethylallyl)-4-methoxybenzoic acid.—One hundred and ten milligrams in ethyl bromide (60 ml.) at 0°, followed by reductive cleavage, gave a dimethone (110 mg.) which proved to be propionaldimethone (m. p. and mixed m. p. 151–151.5°). The dimethone was converted to its anhydride by heating with glacial acetic acid containing a small amount of sulfuric acid. After one crystallization from petroleum ether, the anhydride melted at 139–140°. Mixed with the anhydride obtained from an authentic specimen of propionaldimethone, the melting point showed no change.

Ethyl *p*-(γ-ethylallyloxy)-benzoate (II) was obtained by refluxing a mixture consisting of *p*-hydroxybenzoic ester (61.6 g.), potassium carbonate (64 g.), acetone (200 ml.) and 1-chloro-2-pentene (40 g.). The major portion of the acetone was removed under diminished pressure and water in sufficient quantity to dissolve the solids was then added. Extraction with an ether–petroleum ether mixture gave an extract, which in turn was extracted three times with aqueous sodium hydroxide, and dried. Distillation in a Hickman still yielded pure ethyl *p*-(γ-ethyallyloxy)-benzoate (b. p. 108–109° at 0.1 mm.; freezing point 34.1°; 41 g.).

Anal. Calcd. for $C_{14}H_{18}O_3$: C, 71.75; H, 7.75. Found: C, 71.64; H, 7.61.

Hydrolysis of the phenyl ether (20 g.) gave a practically quantitative yield of *p*-(γ-ethylallyloxy)-benzoic acid (m. p. 157–158°).

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.87; H, 6.84. Found: C, 69.53; H, 6.79.

Reduction of *p*-(γ-ethylallyloxy)-benzoic acid with hydrogen and platinum oxide in methanol yielded *p*-(*n*-amyloxy)-benzoic acid (m. p. 123–124°). Admixing with an authentic specimen of this saturated acid produced no change in the melting point.

Ozonolysis of *p*-(γ-ethylallyloxy)-benzoic acid at 0° in ethyl bromide and ethyl acetate, followed by decomposition of the ozonide, yielded propionaldimethone (m. p. and mixed m. p. 149–150°). Conversion of the dimethone to its anhydride by heating in glacial acetic acid containing sulfuric acid gave a product which after crystallization from petroleum ether melted at 140–141°. An authentic specimen of propionaldimethone produced an anhydride melting at the same temperature.

Pyrolysis of ethyl *p*-(γ-ethylallyloxy)-benzoate (40.5 g.) was carried out at a pressure of 40 mm. The temperature

(4) Folin and Ciocalteu, *J. Biol. Chem.*, **73**, 627 (1929).

rose from 195 to 233° and then remained constant. The liquid air trap collected pentadiene (0.13 g., 13.3% yield), which on bromination yielded 1,2,3,4-tetrabromopentane (m. p. 113.5–114.5°).

The main product was shaken with aqueous sodium hydroxide and low-boiling petroleum ether. The alkaline solution on acidification gave a solid product (39.88 g.), which showed a negative test with mercuric acetate. All attempts to separate this mixture of phenols failed. Similarly, attempts to separate the products of hydrolysis were unsuccessful.

Methylation of the Pyrolysis Product.—The mixture of phenols (38 g.), dissolved in sodium methoxide, was treated with dimethyl sulfate (48 g.). After most of the methanol was distilled off the residue was refluxed with aqueous potassium hydroxide (10%). Acidification produced the methoxy acids.

Repeated crystallization yielded only one *pure* fraction, which proved to be 3-(α-ethylallyl)-4-methoxybenzoic acid (m. p. 164.5–165.5°).

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.91; H, 7.27. Found: C, 70.84; H, 7.52.

Many impure fractions possessing a crystal form differing from that of 3-(α-ethylallyl)-4-methoxybenzoic acid were obtained, but, unfortunately, only 3-(α-ethylallyl)-4-methoxybenzoic acid was obtained in pure form.

Ozonolysis of a sample (500 mg.) of 3-(α-ethylallyl)-4-methoxybenzoic acid gave formaldimethone (m. p. 186–188°, 200 mg.), but ozonolysis studies on the mixture of pyrolysis products always yielded formaldimethone and acetaldimethone, which were separated and identified. Pyrolysis therefore yielded both 3-(α-ethylallyl)-4-methoxybenzoic and 3-(α,γ-dimethyallyl)-4-methoxybenzoic acid.

Ethyl p-(α,γ-Dimethylallyloxy)-benzoate, III.—4-Chloro-2-pentene (23.5 g.) was added slowly to a mixture of potassium carbonate (35 g.), ethyl p-hydroxybenzoate (37.5 g.) and acetone (150 g.) and then refluxed for nine hours. Ether extraction of the aqueous solution yielded the ethyl ester of p-(α,γ-dimethylallyloxy)-benzoic acid (b. p. 108–114° at 0.1 mm.; 16.5 g.).

Anal. Calcd. for $C_{14}H_{18}O_3$: C, 71.75; H, 7.75. Found: C, 71.77; H, 7.75.

Hydrolysis of the ester III (3 g.) gave p-(α,γ-dimethylallyloxy)-benzoic acid (melting point 131–132°; 2 g.).

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.87; H, 6.84. Found: C, 69.97; H, 7.04.

Ozonolysis of ethyl p-(α,γ-dimethylallyloxy)-benzoate (400 mg.) followed by reductive cleavage yielded acetaldimethone (300 mg.).

Pyrolysis of the ether, III (10 g.), at 40 mm. pressure was carried out between the temperatures of 208 and 223° for a period of one hour. Penta-1,3-diene (b. p. 41–42°, 1.4 g., 58.5% yield) collected in the liquid air trap. Bromination of this diene yielded 1,2,3,4-tetrabromopentane (m. p. 113–114°).

Anal. Calcd. for $C_5H_8Br_4$: C, 15.47; H, 2.08. Found: C, 15.49; H, 2.14.

The maleic anhydride addition product (m. p. 61–62°) was also prepared.

The liquid pyrolysis product was treated with aqueous sodium hydroxide (5%) and petroleum ether. The petroleum ether solution yielded only a small amount of a pale yellow oil which was not investigated. The aqueous alkaline layer was acidified and extracted with ethyl ether. The ether extract yielded p-hydroxybenzoic acid (2.7 g.) identified as the ethyl ester (m. p. 115°), and an oil (4.4 g.) which did not crystallize. The oil was saponified. **Methylation** with dimethyl sulfate followed by saponification with aqueous sodium hydroxide (10%) yielded an acid upon acidification with dilute sulfuric acid. After four crystallizations the melting range was 128–132°, and it was concluded that the product was a mixture. The mixture was analyzed.

Anal. Calcd. for $C_{13}H_{16}O_3$: C, 70.90; H, 7.27. Found: C, 70.73; H, 7.62.

The mixture (100 mg., m. p. 128–132°) obtained by methylation was ozonized at 0° in ethyl bromide. Reductive cleavage yielded volatile aldehydes which were converted to their dimethones (150 mg.). After five crystallizations two pure dimethones were obtained, namely, formaldimethone and acetaldimethone, although the amount of formaldimethone was very small (7 mg.).

Summary

The rearrangement of the isomeric ethyl p-(α- and γ-ethylallyloxy)-benzoates has been investigated, with the following results.

Ethyl α-ethylallyloxy-benzoate yields ethyl 3-(γ-ethylallyl)-4-hydroxybenzoate upon rearrangement, whereas ethyl γ-ethylallyloxybenzoate gives two rearrangement products, namely, ethyl 3-(α-ethylallyl)-4-hydroxybenzoate and ethyl 3-(α,γ-dimethylallyl)-4-hydroxybenzoate.

A study of the rearrangement of ethyl α,γ-dimethylallyloxybenzoate has furnished some evidence that the normal rearrangement product may be accompanied by an abnormal one.

Ethers of *p*-Hydroxybenzoic Acid as Derivatives for the Identification of Alkyl Halides

BY W. M. LAUER, P. A. SANDERS, R. M. LEEKLEY AND H. E. UNGNADE

The authors have had occasion to prepare a number of ethers of *p*-hydroxybenzoic acid during the last few years. These derivatives have much to recommend them for identification purposes, even though there are already several different types of derivatives which are useful for the identification of alkyl halides.[1]

A procedure which is suitable for the preparation of small amounts of the ethers follows. A solution of metallic sodium (0.2 g.) in absolute alcohol (5 ml.) is prepared in a 25-cc. Erlenmeyer flask fitted with a reflux condenser. Ethyl *p*-hydrobenzoate (1 g.) is dissolved in the alcoholic solution of sodium ethoxide and then the alkyl halide (1 ml.) is added. After refluxing for one-half to one hour, a considerable portion of the alcohol is removed by distillation and the residue is treated with water to dissolve the precipitated sodium halide. The aqueous solution is then extracted with ether and the ether extract is shaken with three portions (5 ml. each) of aqueous sodium hydroxide (10%). The ether solution is concentrated and a saturated solution (5 m.) of potassium hydroxide in methyl alcohol is added. The reaction mixture is heated for approximately ten minutes. The precipitated potassium salt is then dissolved in water and the solution acidified (congo red) with dilute sulfuric acid. Extraction with ether yields the *p*-alkoxybenzoic acid, which is crystallized from a suitable solvent. In a number of cases benzene or mixtures of benzene and petroleum ether were used.

Several substituted *p*-allyloxybenzoic acids are included in the following table. It is a well-known fact that certain substituted allyl halides undergo the α,γ-transposition upon ether formation, yielding mixtures of isomeric products. Several mixtures of this kind were separated, but usually such separations are quite difficult. This, of course, is not true in the case of allyl chloride and α,γ-dimethylallyl chloride, which give *p*-allyloxybenzoic acid and *p*-(α,γ-dimethylallyloxy)-benzoic acid, respectively.

Unfortunately several of the *p*-alkoxybenzoic acids possess melting points which show only a slight difference. The same situation exists in the case of some of the other types of derivatives in common use for characterization purposes. A mixed melting point determination renders identification certain, however. It should be noted that *p*-(*n*-alkoxy)-benzoic acids exhibit mesomorphism.[2] Thus *p*-(*n*-butoxy)-benzoic acid, upon melting at 147–148° changes to a cloudy viscous liquid which exists over a definite temperature range. The cloudy liquid clears sharply at 160° and this temperature appears to be as characteristic of the substance as the transition at 147–148°.

TABLE I

MELTING POINTS OF ETHERS OF *p*-HYDROXYBENZOIC ACID

Ether	M. p., °C.
Methyl	180–182[a]; 184[b]

Synthetic Glycerides of Unsaturated Fatty Acids. I. Mono- and Trilinolein

BY HOWARD C. BLACK AND CHARLES A. OVERLEY

Glycerides of known constitution of the saturated fatty acids have been prepared by Fischer[1] and King[2] in high degrees of purity. However, the synthesis of pure glycerides of unsaturated acids has been complicated by the difficulty encountered in preparing the acid chlorides of such acids.

In the present paper a new method for the synthesis of unsaturated glycerides is proposed. It consists of the preparation of glycerides from the acid chlorides of bromine addition products of unsaturated fatty acids and subsequent removal of the bromine to yield the unsaturated glycerides. Linoleic acid has been selected for the initial work because of the ease of preparation and purification of its crystalline tetrabromide. Also recent work has shown quite definitely that the debromination of the tetrabromide yields only the natural linoleic acid.[3,4] In addition, linoleic esters are of interest because of their biological importance.[5] The acid chloride of the tetrabromo derivative of linoleic acid was prepared in crystalline form. From it the mono- and triglycerides were prepared according to the methods of Fischer as described by King and debrominated to yield mono- and trilinolein, respectively.

Experimental

Tetrabromostearic acid was prepared by bromination of the acetone-soluble fraction[4] of cottonseed oil fatty acids. The method of Rollet[6] as modified by McCutcheon[3] was employed, m. p. 115.5°.

9,10,12,13-Tetrabromostearoyl Chloride.—Eighty grams of tetrabromostearic acid in a round-bottomed flask under reflux condenser was placed in an oil-bath at 120°. When the acid had melted 15 g. (1.2 mole) of thionyl chloride was added in small portions through the condenser over the period of an hour. Only slight darkening occurred. It was allowed to cool to room temperature and stand overnight. The oil was taken up in 250 ml. of anhydrous petroleum ether and placed at −26° for several hours. The shiny, white plates which separated were filtered in the freezer and washed with cold petroleum ether until most of the excess thionyl chloride was removed. The product was carefully dried *in vacuo:* yield 78.0 g.; m. p. 59.5–60.0°; total halogen as Br, 59.92; calcd., 60.28. The m. p. was not changed by subsequent recrystallizations from anhydrous ether or petroleum ether. In comparison to other aliphatic acid chlorides this product is quite stable.

Mono-(9,10,12,13-tetrabromo)-stearin.—To a cold mixture of 10.0 g. (0.075 mole) of acetoneglycerol and 9.6 g. (0.075 mole) of quinoline in a glass-stoppered Erlenmeyer flask was added in small portions with cooling and shaking 45 g. (0.073 mole) of 9,10,12,13-tetrabromostearoyl chloride dissolved in 20 ml. of dry chloroform. The mushy mixture was allowed to stand for forty-eight hours at room temperature. The material was then taken up in 150 ml. of cold ether and washed successively several times with cold 0.5 *N* sulfuric acid, saturated sodium bicarbonate solution and water. After being dried over anhydrous sodium sulfate the ether solution was allowed to stand at −26°. The gummy precipitate was filtered and recrystallized from 1:1 ether–petroleum ether at −26°: yield 35.5 g.; m. p. 51.5–52.0°. The monoglyceride was liberated from the acetone condensation product by dissolving 35 g. of the latter in 300 ml. of ether, cooling in an ice-bath and adding 300 ml. of cold concentrated hydrochloric acid in portions with vigorous shaking. The mixture was let stand overnight at −26° and the semicrystalline solid filtered and washed free of chlorides with cold water. It was dried *in vacuo* and recrystallized from 500 ml. of ether at 0°. The product appeared as plates when examined under the high power microscope: yield 26 g.; m. p. 101.5–102.0°; Br, 47.60, calcd., 47.45.

Tri-(9,10,12,13-tetrabromo)-stearin.—To a cold mixture of 2.2 g. (0.024 mole) of glycerol and 9.6 g. (0.075 mole) of quinoline in a glass-stoppered Erlenmeyer flask was added with shaking and cooling 45 g. (0.073 mole) of 9,10,12,13-tetrabromostearoyl chloride in 30 ml. of dry chloroform. The semisolid mass was let stand at room temperature for two days and taken up in 600 ml. of ether and washed successively with 0.5 *N* sulfuric acid, saturated sodium bicarbonate solution and water. The ether solution was dried over anhydrous sodium sulfate and placed at 0°. The crystals which separated appeared to be needles under low power and long thin plates under high. They were recrystallized from ether: yield 30.5 g.; m. p. 81.0–81.5°; Br, 51.97, calcd., 52.18.

Debromination of Mono-(9,10,12,13-tetrabromo)-stearin.—This was carried out by treating 20-g. lots of the tetrabromo derivative with 20 g. of 30-mesh zinc and 50 ml. of anhydrous alcohol. The zinc had been washed with dilute hydrochloric acid, then with water and carefully dried. The flask was gently warmed in a water-bath until the beginning of the vigorous exothermic reaction, which was controlled by cooling the flask with ice. Finally the alcohol was refluxed for half an hour and the zinc removed by filtration. The flask and zinc were washed with 150 ml. of anhydrous petroleum ether. The filtrate and washings were washed several times with water and finally dried over anhydrous sodium sulfate and evaporated *in vacuo*. The nearly colorless oil was taken up in 30 ml. of a 1:1 ether–petroleum ether mixture and let stand at −26° overnight. Shiny crystals separated.

(4) Riemenschneider, Wheeler and Sando, *J. Biol. Chem.*, **127**, 391 (1939).
(5) Burr and Burr, *ibid.*, **86**, 587 (1930).
(6) Rollet, *Z. physiol. Chem.*, **62**, 410 (1909).

After being filtered and dried they melted to a colorless viscous oil at room temperature: yield 8.9 g.; iod. value 142.1; calcd. for monolinolein 143.3; sap. value 158.5, calcd. 158.3; $n^{20}D$ 1.4758; m. p. determined by placing a drop in an ordinary m. p. tube and letting stand in a beaker of alcohol at −26° for several hours and then warming slowly, 14.0–15.0°. When the debromination was carried out with 0.4 *N* alcoholic hydrochloric acid, 0.5 g. of an oil was isolated from the filtrate; iod. value 158.3; sap. value 178.0; $n^{20}D$ 1.4636.

Debromination of Tri-(9,10,12,13-tetrabromo)-stearin.—This was carried out as described for the monoglyceride. The product did not crystallize at −26°. It had the following constants: iod. value 171.2; calcd. for trilinolein 173.3; sap. value 191.2, calcd. 191.5; $n^{20}D$ 1.4709; m. p. determined as above, −5.0–4.0°. Nothing distilled when the oil was heated to 250° in a vacuum of 0.5 mm.

Rebromination of the Linoleins.—Three grams of trilinolein dissolved in 50 ml. of petroleum ether took up bromine at 20° to yield 4.5 g. of gummy material which could not be crystallized. Three grams of monolinolein was dissolved in 50 ml. of petroleum ether and bromine dissolved in petroleum ether added at 20° with stirring; 2.5 g. of gummy material separated, m. p. 92–95°. Recrystallization from ether yielded crystals melting at 101.5–102.0°, mixed m. p. with mono-(9,10,12,13-tetrabromo)-stearin, 101.5–102.0°. An oil which could not be crystallized was isolated from the filtrate.

Saponification of the Linoleins and Rebromination of the Acid.—Six grams of each of the glycerides was let stand overnight with 75 ml. of 5% alcoholic sodium hydroxide and the fatty acids isolated by acidification and extraction with petroleum ether. Five grams of acid from each of the glycerides was brominated in 80 ml. of petroleum ether at 20°, yielding 4.5 g. of crystals melting at 115.5°. Likewise 5 g. of linoleic acid obtained by debromination of tetrabromostearic acid was brominated to yield 4.5 g. of crystals melting at 115.5°; mixed m. p. with the tetrabromide of the acid isolated from the linoleins 115.5°.

Discussion

The advantage of the present method for preparation of unsaturated glycerides is that the double bonds are protected from polymerization and oxidation until the final step, thus yielding the glycerides with a minimum amount of impurities. The method is limited to the glycerides of the unsaturated fatty acids, the bromine derivatives of which yield the natural acids on debromination. That the unsaturated glycerides synthesized in this case very probably contain the natural linoleic acid is indicated by the identity of the tetrabromides of the acid isolated from the glycerides with the tetrabromide of natural linoleic acid. The yields of solid tetrabromide obtained on bromination of the acids isolated from the glycerides agree with those reported for the bromination of natural linoleic acid.[3,4] At least the position of the double bonds has not been shifted and it is unlikely that *cis–trans* isomerization has occurred since several investigators have shown that the acid regenerated by debromination of the solid tetrabromo derivative is identical with natural linoleic acid.[3,4,6,7,8] There is no reason to assume that debromination of the acid radical in the glycerides should produce a different configuration than debromination of the free acid.

When the debromination was carried out in neutral solution there was no evidence of interesterification, but when alcoholic hydrochloric acid was used with the monoglyceride a small amount of material with constants corresponding roughly to those of ethyl linoleate was isolated. Attempts to carry out the debromination in certain other solvents were unsuccessful.

Rebromination of the unsaturated glycerides produced the anticipated results. When linoleic acid is brominated, approximately a 50–50 yield of solid and liquid tetrabromide is obtained.[3,4] There is no reason to assume that the bromination of linoleic glycerides should proceed differently. Indeed, bromination of monolinolein yielded a 40–45% yield of the solid bromo monoglyceride, as well as some oily material. Since no homogeneous product could be isolated from the bromination of trilinolein, it is reasonable to assume that both the liquid and solid derivatives of the fatty acid radicals were formed. Suzuki[9] has reported the isolation of the bromine addition products of several triglycerides from fish oils. He did not report a derivative of trilinolein and only a few addition products of mixed glycerides of linoleic acid.

Summary

A new method for the synthesis of unsaturated glycerides has been proposed. It consists of the preparation of glycerides from acid chlorides of bromine addition products of unsaturated fatty acids and subsequent removal of the halogen to yield the unsaturated glycerides. The method has been applied to mono- and trilinolein.

In addition to mono- and trilinolein, 9,10,12,13-tetrabromostearoyl chloride and mono- and tri-(9,10,12,13-tetrabromo)-stearin have been synthesized.

Erythrina Alkaloids. VI. Studies on the Constitution of Erythramine

BY KARL FOLKERS AND FRANK KONIUSZY

The isolation and characterization of a new alkaloid, erythramine, from the seeds of *Erythrina sandwicensis* Deg. and *Erythrina subumbrans* (Hassk.) Merrill has been described.[1] The microanalyses on the crystalline erythramine base, hydriodide, hydrobromide, and the hydrochloride showed that erythramine has the empirical composition $C_{18}H_{21}NO_3$. The present paper reports the results of our studies of its constitution.

A Friedrich determination showed that one methoxy group is present, and that there is no group attached to the nitrogen atom. A Kuhn–Roth carbon-methyl determination gave a negative result. The presence of a methylenedioxy group was shown by hydrolysis with sulfuric acid and reaction of the formaldehyde with the added phloroglucinol. It follows that all three oxygen atoms of erythramine exist in ether linkage. This conclusion was confirmed by a lack of reaction between erythramine and acetic anhydride or with benzoyl chloride.

Methyl iodide reacted with the base to yield a crystalline erythramine methiodide; therefore, erythramine is a tertiary base. The negative methylimide group determination limits the probable alkaloidal formulations of the tertiary nitrogen to either a $-\overset{|}{C}=N-$ linkage of a ring or a ring system with the nitrogen atom common to two nuclei.

The presence of a methylenedioxy group presupposes the presence of one benzenoid nucleus.[2] Catalytic hydrogenation with Adams platinum catalyst under two atmospheres pressure resulted in the formation of a dihydroerythramine. This absorption of only two atoms of hydrogen was all that could be brought about, and considering the usual stability of alkaloidal oxygenated benzenoid nuclei to hydrogenation under such conditions, it seemed evident that the unsaturation of erythramine consisted of one benzenoid nucleus and one ethylenic double bond.

If the tertiary nitrogen atom were in the form of a $-\overset{|}{C}=N-$ linkage of a ring, then the hydrogenation would have produced a secondary nitrogen atom and dihydroerythramine would be a secondary base. However, a dihydroerythramine methiodide was readily formed, and this substance eliminates the formulation of the tertiary nitrogen atom of erythramine as a part of a $-\overset{|}{C}=N-$ linkage. These data lead to the formulation of the tertiary nitrogen atom of erythramine as being common to two nuclei. In this connection it is to be noted that three stages of Hofmann degradation proved that two other *Erythrina* alkaloids, α- and β-erythroidine, possessed tertiary nitrogen atoms common to two nuclei of the ring system.[3]

From this information concerning the nature of the three oxygen atoms, the nitrogen atom, and the unsaturation of erythramine, it has been deduced that this alkaloid possesses four nuclei, exclusive of the methylenedioxy bridge, which in all probability are six-membered rings.

It is now of interest to consider the relationship of alkaloids of known structure which have been isolated from species of genera belonging to the same subfamily, *Papilionaceae*, of the family *Leguminosae* to which the genus *Erythrina* belongs. From plants of this subfamily, the only alkaloids of known structure are represented by the "lupin" alkaloids, sparteine, and the related lupanine, anagyrine, cytisine, lupinine, matrine, and by the indole alkaloid, physostigmine. Although the "lupin" alkaloids possess a nitrogen atom common to two nuclei, they also possess a second nitrogen atom (except lupinine) so that there is this fundamental difference from erythramine and erythroidine ($C_{16}H_{19}NO_3$).[3,4] The subfamily, *Papilionaceae*, is quite large, and of the above alkaloids of known structure, only physostigmine is obtained from species of the genus *Physostigma* which is in the same tribe, *Phaseoleae*, with the genus *Erythrina*. The magnitude of even the tribe *Phaseoleae* is evident since forty-eight genera have been assigned to it by Bentham. Again, physostigmine possesses two nuclear nitrogen atoms and differs in other respects

from erythramine. Thus, erythramine or α- and β-erythroidine cannot be compared readily with any of the alkaloids of known structure derived from plants of the same tribe or of a related tribe as the genus *Erythrina*. Furthermore, the indole character of hypaphorine, which has been found to occur[1] in many species of *Erythrina*, is not necessarily translatable into the properties of the accompanying erythramine.

One of the oldest known relationships between physiological action and chemical constitution is that of the curare action of quaternary ammonium compounds, as discovered by Crum-Brown and Fraser. Although erythramine is a tertiary base, it causes a selective and strong curare-like action at the threshold dose of 7 mg. of the hydrobromide per kilogram of frog. Dr. Klaus Unna, of the Merck Institute of Therapeutic Research, found that the synthetic quaternary erythramine methiodide was one-fifth as active as the tertiary base. Hydrogenation of erythramine to its dihydro derivative decreased the curare-like activity to about one-thirtieth of that for the natural alkaloid.

Further insight on the constitution of erythramine will be described by experiments made on another new *Erythrina* alkaloid, erythraline, which is very closely related to erythramine.

Experimental Part

Functional Groups of Erythramine.—A sample of erythramine hydriodide (m. p. 249°; $(\alpha)_D$ + 220°) from *Erythrina sandwicensis* Deg. was used.

Anal. Calcd. for $C_{18}H_{21}NO_3 \cdot HI$: C, 50.60; H, 5.15. Found: C, 50.66; H, 5.13. The micro Friedrich determination showed: OCH_3, 7.17%; N-CH_3, negative. Calcd. for one OCH_3, 7.26%.

In three separate test-tubes were placed 20-mg. samples, respectively, of erythramine base, hydrastine base, and hydrocotarnine base; the fourth tube was a blank. In each of the four tubes were added 5 ml. of 40% sulfuric acid and 60 mg. of phloroglucinol. When all had dissolved, the tubes were heated in a beaker of boiling water for twenty minutes. Erythramine, hydrastine, and hydrocotarnine each gave a heavy red precipitate of a phloroglucide while the blank remained colorless. Thus, erythramine contains a methylenedioxy group.[5] The methoxy and methylenedioxy groups account for the three oxygen atoms in the molecule and are in agreement with the failure of erythramine to react with acetic anhydride or benzoyl chloride.

Stability of Erythramine.—The free base cannot be stored satisfactorily under ordinary conditions because of progressive decomposition. Small samples were kept in evacuated vials at dry-ice temperature. When the free base was required, it generally was obtained from the hydriodide just before the experiment.

Erythramine hydrohalide salts were stable either dry or in solution.

The stability of erythramine in alkaline solution was tested as follows. A quantity of 106 mg. of pure erythramine hydriodide was dissolved in 30 ml. of water, heated to 100° on the steam-bath, and when 1 ml. of 5% sodium hydroxide was added, white globules of insoluble erythramine base formed. After the addition of 1.5 ml. of ethanol to cause homogeneity, the solution was refluxed for two hours. The cooled solution was diluted to 50 ml. and extracted with chloroform. The yield of base (gum) after solvent removal was 74 mg. (99.9%). It was converted to the hydrobromide, which had the established properties.

Purity of Erythramine.—It was found essential that erythramine hydriodide show a melting point of 245° (slow bath) or 249° (normal bath) and an optical rotation of +220–221° before use. In one instance, a sample of hydriodide showing m. p. 241–242° (slow bath) and $(\alpha)_D$ +219° would not yield crystalline dihydroerythramine hydriodide after hydrogenation. The same sample yielded a hydrobromide which melted at 204–205° instead of the established 228°.

Erythramine Methiodide.—A quantity of 200 mg. of erythramine base was dissolved in 1.5 ml. of absolute methanol and treated with 1 ml. of redistilled methyl iodide. The solution was warmed on the steam-bath and then concentrated until the volume was 1.5 ml. After standing overnight at 10°, a crystalline methiodide derivative separated as yellowish-white gleaming platelets; m. p. 96–98°, $(\alpha)^{28}_D$ +176°, C = 0.355, H_2O.

Anal. Calcd. for $C_{18}H_{21}NO_3 \cdot CH_3I$: C, 51.69; H, 5.48. Found: C, 51.61; H, 5.22.

Dihydroerythramine Hydriodide.—In the first experiment, erythramine hydriodide (322.5 mg.) in 50 ml. of water could not be hydrogenated with Adams platinum catalyst (25 mg.) at atmospheric pressure.

When 814 mg. of erythramine base was dissolved in 50 ml. of water containing 2 ml. of concentrated hydrochloric acid, and hydrogenated over 100 mg. of Adams platinum catalyst at two atmospheres pressure, the absorption of hydrogen stopped (one mole) after one hour. After filtration, the solution was made alkaline with sodium bicarbonate and extracted ten times with chloroform. Distillation of the solvent yielded 820 mg. of gum. This was treated with 348 mg. of sodium iodide in 5 ml. of absolute ethanol, and acidified with acetic acid. A first crop of 622.4 mg. of dihydroerythramine hydriodide was obtained. After crystallizations from absolute ethanol, the melting point was constant at 214–215° with decomposition. Analyses made on this material after drying at 25° *in vacuo* indicated non-stoichiometric solvation. Therefore, the salt was dried at 140° and 2 mm. for two hours: $(\alpha)_D$ 0°; C = 0.500, H_2O.

Anal. Calcd. for $C_{18}H_{23}NO_3 \cdot HI$: C, 50.35; H, 5.63. Found: C, 50.28; H, 5.48.

Dihydroerythramine Base.—When 100 mg. of dihydroerythramine hydriodide was dissolved in water, treated with sodium bicarbonate, extracted with chloroform, etc., 53.5 mg. of a colorless gummy base was obtained.

(5) Gadamer and Winterfeld, *Arch. pharm.*, **262**, 601 (1924).

This was dissolved in 5 ml. of dry ethyl ether and then treated with 10 ml. of petroleum ether. After filtration to remove flocculent material, the filtrate was concentrated by gentle warming to a volume of *ca.* 2 ml. The concentrate was cooled in an ice-bath and the sides of the flask were scratched. Tiny white crystals separated, which melted at 89–90°.

Anal. Calcd. for $C_{18}H_{23}NO_3$: C, 71.75; H, 7.69. Found: C, 71.82; H, 7.60.

Dihydroerythramine Hydrobromide Monohydrate.—A quantity of 99 mg. of pure dihydroerythramine hydriodide yielded 64 mg. of gummy base by the usual procedure. It was dissolved in 1 ml. of absolute ethanol, treated with 0.3 ml. of 40% hydrobromic acid, and a little dry ether was added. After filtration of flocculent precipitate, the solution was allowed to stand overnight at 10°. The hydrobromide (34 mg. yield) melted constantly at 240° after recrystallization from ethanol. For analysis, the salt was dried at 25° *in vacuo*.

Anal. Calcd. for $C_{18}H_{23}NO_3 \cdot HBr \cdot H_2O$: C, 54.00; H, 6.54. Found: C, 54.26; H, 6.04.

Drying of 5 mg. of this monohydrate at 140° and 2 mm. for two hours caused a decrease in weight of only 0.04 mg. (0.8%). The anhydrous hydrobromide could not be obtained. Longer drying periods initiated thermal decomposition.

Dihydroerythramine Methiodide Hemihydrate.—A quantity of 52 mg. of dihydroerythramine base was dissolved in 1 ml. of methanol and 1 ml. of redistilled methyl iodide. Ethyl ether was added to the point of turbidity. Crystals of the methiodide separated after refrigeration overnight; m. p. 160–161°. The substance was dried at 78° and 2 mm. for two hours before analysis.

Anal. Calcd. for $C_{18}H_{23}NO_3 \cdot CH_3I \cdot {}^1/_2H_2O$: C, 50.45; H, 6.01. Found: C, 50.61; H, 6.13.

This substance could not be dehydrated at 140° *in vacuo* without decomposition.

Acknowledgment.—We wish to express our appreciation to Mr. B. A. Krukoff for his advice on botanical matters and to Mr. Douglass Hayman and Mr. Wilhelm Reiss for their coöperation in performing the microanalyses.

Summary

Erythramine, which has the empirical composition $C_{18}H_{21}NO_3$, contains one methoxy group and one methylenedioxy group. The nitrogen atom is tertiary and in all probability is common to two nuclei of the molecule. The unsaturation consists of one benzenoid nucleus and one ethylenic double bond. The molecule appears to contain four six-membered nuclei exclusive of the methylenedioxy bridge.

Erythramine methiodide was about one-fifth as active and dihydroerythramine was about one-thirtieth as active as the natural erythramine for curare-like action in frogs.

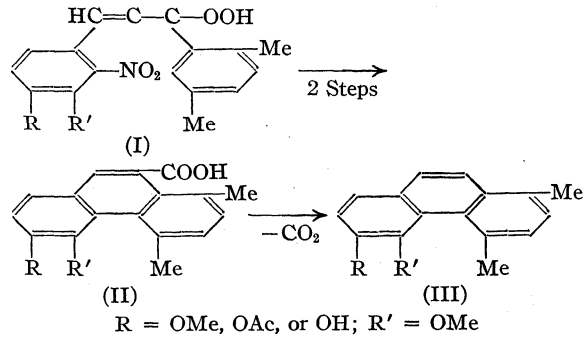
The Synthesis of Some New 1,4-Dimethylphenanthrenes Structurally Related to Morphol

BY JACK TARKINGTON CASSADAY[1] AND MARSTON TAYLOR BOGERT

In a recent communication,[2] we described the preparation of 1,4-dimethyl-6,7-dihydroxyphenanthrene from *p*-xylylacetic acid and 6-nitroveratraldehyde by the Pschorr reaction. The work recorded in the present paper consists of the extension of that investigation by substituting 2-nitroveratraldehyde and 2-nitroacetovanillin for the 6-nitroveratraldehyde, resulting in the production of the 5,6-dimethoxy and 5-methoxy-6-hydroxy derivatives of 1,4-dimethylphenanthrene, and their 10-carboxylic acids.

In the case of the 1,4-dimethyl-5,6-dimethoxyphenanthrene, or 1,4-dimethyl-5-methoxy-6-hydroxyphenanthrene, the methoxyl groups could not be hydrolyzed by the process which proved effective with the 6,7-dimethoxy isomer,[2] or by any of the other methods used. This is in agreement with the experience of other investigators. Pschorr and Sumuleanu[3] found it impossible to demethylate 3,4-dimethoxyphenanthrene. Mo-



R = OMe, OAc, or OH; R′ = OMe

(3) Pschorr and Sumuleanu, *Ber.*, **33**, 1810 (1900).

settig and Burger[4] were unsuccessful in their attempts to demethylate either a 3-methoxyacetylphenanthrene or the corresponding carboxylic acid.

The 5-methoxy-6-hydroxy derivative was prepared primarily because it carried its hydroxyl group in the position which Eddy's investigations[5] have shown to be most favorable for the development of analgesic properties. Unfortunately, however, it was not appreciably soluble in water.

Both of the above compounds (III) are closely related structurally to morphol (3,4-dihydroxyphenanthrene), and to methylmorphol (3-methoxy-4-hydroxyphenanthrene), a degradation product of the alkaloid codeine.

It may be recalled that morphol has a stronger analgesic action than 3-hydroxyphenanthrene.

Acknowledgments.—We are indebted to the Ella Sachs Plotz Foundation and to the National Academy of Sciences for financial assistance in the purchase of the chemicals and apparatus required for this investigation. Our thanks are due also to Mr. Saul Gottlieb, of these Laboratories, who carried out the necessary microanalyses.

Experimental

2-Nitroveratraldehyde was prepared by the method of Slotta and Lauersen,[6] but the introduction of nitrogen during the methylation of the acetovanillin was found unnecessary, and a simple 3-necked flask was employed instead of their more elaborate apparatus. The process of Pschorr and Sumuleanu[7] proved much less satisfactory, because of the formation of a mixture of isomers in the nitration of the acetovanillin.[8]

α-(*p*-Xylyl)-2-nitro-dimethylcaffeic Acid (I).—A mixture of 32.4 g. of potassium *p*-xylylacetate, 33.5 g. of 2-nitroveratraldehyde, and 285 g. of freshly distilled acetic anhydride, in a 3-necked flask equipped with a mechanical stirrer and mercury seal, a reflux condenser carrying a calcium chloride guard tube, and a thermometer, was stirred for eight hours at 105–110°. Excess of acetic anhydride was hydrolyzed by the addition of hot water, maintaining the temperature of the mixture below 120°. It was then poured into very dilute hydrochloric acid containing cracked ice. After standing for a few minutes, the supernatant solution was decanted from the tarry precipitate and fresh water added, under which the tar became crystalline more quickly. One crystallization from dilute acetic acid gave a 67% yield of the product sought, sufficiently pure for reduction to the amino acid. Five additional crystallizations from the same solvent resulted in white crystals, m. p. 205.5–206.5° (corr.).

Anal. Calcd. for $C_{19}H_{19}O_6N$: C, 63.9; H, 5.3; N, 3.9. Found: C, 64.3; H, 5.6; N, 4.0.

α-(*p*-Xylyl)-2-nitro-3-methoxy-4-acetoxycinnamic Acid (I).—Application of the above process to a mixture of 35 g. of potassium *p*-xylylacetate, 33 g. of 2-nitroacetovanillin prepared as described by Slotta and Lauersen,[6] and 250 g. of acetic anhydride, gave a 50% yield of pale tan acid, m. p. 202.5–203.5° (corr.), pure enough for reduction to the amino acid. After two recrystallizations from glacial acetic acid, in one of which Norite was used, the acid was obtained in crystals of a pale greenish tint, m. p. 211–214° (corr.).

Anal. Calcd. for $C_{20}H_{19}O_7N$: C, 62.3; H, 4.9; N, 3.6. Found: C, 62.3; H, 5.1; N, 3.7.

α-(*p*-Xylyl)-2-amino-dimethylcaffeic acid was prepared by reduction of the nitro acid with ferrous sulfate and ammonium hydroxide essentially as described for the 6-amino isomer in our previous paper[2]; yield, 61–67% of a light gray crude acid, m. p. 110–113° (corr.). No appreciable amount of acetic acid could be left in the amino acid, or it turned black on drying. Attempts to purify further this gray crude failed, and an analytically pure amino acid was not secured.

Hydrochloride.—This was prepared easily by dissolving the amino acid in dilute alcohol containing a little hydrochloric acid, recrystallizing the product from the same solvent, and drying the crystals in an evacuated desiccator. When left in an oven at 110°, the compound decomposed partially.

Anal. Calcd. for $C_{19}H_{21}O_4N\cdot HCl$: C, 62.7; H, 6.1. Found: C, 62.4; H, 6.2.

α-(*p*-Xylyl)-2-amino-3-methoxy-*p*-coumaric acid was prepared similarly from the nitromethoxyacetoxy acid. There was obtained an 80% yield of the crude acid, as a pale yellow solid, m. p. 198.5–200° (corr.), pure enough for cyclization. Six recrystallizations from 95% alcohol gave lemon colored needles, m. p. 203–204° (corr.).

Anal. Calcd. for $C_{18}H_{19}O_4N$: C, 69.0; H, 6.1. Found: C, 68.8; H, 6.2.

It will be observed that in this reduction the acetyl group of the initial nitro acid was hydrolyzed off. Pschorr[9] had a similar experience in the reduction of the α-phenyl-2-nitro-3-methoxy-4-acetoxycinnamic acid.

1,4-Dimethyl-5,6-dimethoxyphenanthrene-10-carboxylic Acid (II).—This was secured from the corresponding aminodimethylcaffeic acid by following the directions for the preparation of the 6,7-dimethoxy isomer,[2] except that potassium hydroxide was found preferable to ammonium hydroxide for solution of the 10-carboxylic acid prior to its precipitation by dilute hydrochloric acid. The yield of crude acid, pure enough for decarboxylation, was 50%. By redissolving in dilute potassium hydroxide, reprecipitating in dilute hydrochloric acid containing ice, recrystallizing twice from dilute alcohol, decolorizing with Norite, and three recrystallizations from 95% ethanol, it was obtained in white crystals, m. p. 180.5–181.5° (corr.).

Anal. Calcd. for $C_{19}H_{18}O_4$: C, 73.5; H, 5.8. Found: C, 73.7; H, 6.0.

(4) Mosettig and Burger, THIS JOURNAL, **55**, 2981 (1933).

(6) Slotta and Lauersen, *J. prakt. Chem.*, [2] **139**, 220 (1934).
(7) Pschorr and Sumuleanu, *Ber.*, **32**, 3405 (1899).
(8) Raiford and Stoesser, THIS JOURNAL, **50**, 2556 (1928).
(9) Pschorr, *Ber.*, **33**, 1822 (1900).

Attempts to hydrolyze the methoxyl groups of this compound by the action of hydrobromic or hydriodic acid proved futile. Only black tars resulted, which gave no color reactions with ferric chloride. Nor could any pure acetyl derivatives be secured from them.

1,4 - Dimethyl - 5 - methoxy - 6 - hydroxyphenanthrene-10-carboxylic Acid (II).—Following the same procedure, 17.5 g. of the crude α-(*p*-xylyl)-2-amino-3-methoxy-*p*-coumaric acid gave a 47% yield of the crude phenanthrenecarboxylic acid, sufficiently pure for decarboxylation. No satisfactory solvent was found for further purification of this crude acid. Recourse was had therefore to acetylation.

Acetate.—A mixture of 1.765 g. of the crude acid, 0.882 g. of fused sodium acetate, and 15 cc. of acetic anhydride, was refluxed for two hours, the excess of acetic anhydride then hydrolyzed by the addition of hot water, and the mixture poured into 100 cc. of water and ice. The gummy solid which separated was removed, dissolved in acetic acid, and the solution placed in a refrigerator. After 2–3 hours, crystals separated, which were recrystallized thrice, once using Norite. White blades were thus obtained, m. p. 170.5–171.5° (corr.).

Anal. Calcd. for $C_{20}H_{18}O_5$: C, 71.0; H, 5.3. Found: C, 71.2; H, 5.4.

From 120 g. of 2-nitroacetovanillin and 80 g. of potassium phenylacetate, Pschorr[9] obtained only 3 g. of 5-methoxy-6-hydroxyphenanthrene-10-carboxylic acid.

1,4-Dimethyl-5,6-dimethoxyphenanthrene (III).—When a mixture of 5 g. of the 10-carboxylic acid with 1 g. of dry copper powder was distilled at a pressure of 25 mm., a thick red oil was obtained, which was easily crystallized from 95% ethanol; yield, 47%; m. p. 71.5–72.5° (corr.). After four recrystallizations from the same solvent, the product formed white crystals, m. p. 73.5–74° (corr.), insoluble in alkali.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.2; H, 6.8. Found: C, 81.2; H, 7.0.

The carboxylic acid could not be decarboxylated by refluxing with quinaldine and basic copper carbonate.

This compound is a homolog of dimethylmorphol. Attempts to hydrolyze the methoxy groups by hydrochloric, hydrobromic, or hydriodic acid, resulted in tars, which gave an intense green-red fluorescence in most organic solvents tried. Neither an acetate nor a picrate could be isolated in crystalline form. One sample of the dimethoxy compound was heated in a sealed tube for sixteen hours at 200° with alcoholic potassium hydroxide, following the technique of Campbell, Dodds and Lawson,[10] but the product gave no ferric chloride color reaction, and no pure compound could be isolated.

1,4-Dimethyl-5-methoxy-6-hydroxyphenanthrene (III) was prepared by distilling a mixture of 7 g. of the 10-carboxylic acid (II) with 1.4 g. of dry copper powder at 25 mm. pressure and crystallizing the resultant viscous yellow oil from alcohol; yield 42%; m. p. 133–134° (corr.). After two recrystallizations from alcohol, the compound appeared as white crystals, m. p. 136.5–137° (corr.).

Anal. Calcd. for $C_{17}H_{16}O_2$: C, 81.0; H, 6.4; MeO, 12.3. Found: C, 81.2; H, 6.6; MeO, 11.0.

These crystals were soluble in cold olive oil, acetone or alkali, as well as in warm glycol.

In another run, 8 g. of the crude carboxy acid yielded 2.9 g. of the crystalline 1,4-dimethyl-5-methoxy-6-hydroxyphenanthrene.

In Pschorr's experiments[9] on the decarboxylation of 2 g. of 5-methoxy-6-hydroxyphenanthrene-10-carboxylic acid, he obtained only an oil, from which he prepared 0.3 g. of the 5-methoxy-6-acetoxyphenanthrene.

Efforts to hydrolyze the methoxyl group of the above (III) with either hydrobromic or hydriodic acid gave much the same results as with the 1,4-dimethyl-5,6-dimethoxyphenanthrene, and proved equally futile.

Summary

1. 1,4 - Dimethyl - 5,6 - dimethoxyphenanthrene and 1,4-dimethyl-5-methoxy-6-hydroxyphenanthrene have been synthesized from *p*-xylylacetic acid and 2-nitroveratraldehyde or 2-nitroacetovanillin. It is planned to investigate their analgesic properties.

2. The successful cyclization of 2-amino-3-methoxy-*p*-coumaric acid by the Pschorr reaction was accomplished without blocking the free hydroxyl group.

3. The methoxyl groups in 1,4-dimethyl-5,6-dimethoxyphenanthrene, or 1,4-dimethyl-5-methoxy-6-hydroxyphenanthrene, could not be hydrolyzed by any of the methods tried.

The Application of the Pschorr Reaction to alpha-(para-Xylylene)-2,5-di-(6′-amino-dimethylcaffeic Acid). The Synthesis of 9,10-Dimethyl-2′,3′,6′,7′-tetramethoxy-1,2,5,6-dibenzanthracene

BY JACK TARKINGTON CASSADAY[1] AND MARSTON TAYLOR BOGERT

Akin and Bogert[2] were unsuccessful in their attempts to hydrolyze the methylenedioxy groups of 9,10-dimethyl-2′,3′,6′,7′-di-(methylenedioxy)-1,2,5,6-dibenzanthracene to the corresponding tetrahydroxy compound.

We have therefore carried out the synthesis of the analogous tetramethoxy derivative (VI), and endeavored to hydrolyze its methoxy groups but, although evidence was secured of its probable presence, we were unable to isolate the tetrahydroxy derivative (VII) in purity.

We were led to undertake this synthesis because it has been shown in a recent paper[3] that, while the methylenedioxy groups of 1,4-dimethyl-6,7-methylenedioxyphenanthrene could not be hydrolyzed by any of the methods employed,[2] the analogous 6,7-dimethoxy derivative gave a 35% yield of the pure dihydroxy compound when refluxed with a mixture of glacial acetic and hydrobromic acids. Since this 6,7-dihydroxy derivative possessed appreciable solubility in water, it was hoped that the solubilities of the analogous tetrahydroxydibenzanthracene (VII) would also prove favorable for pharmacological testing. 9,10-Dimethyl-1,2,5,6-dibenzanthracene[2] is cancerigenic. It is therefore a matter of some importance to discover what activity, if any, its tetramethoxy and tetrahydroxy derivatives possess.

In applying the Pschorr reaction to the amino-caffeic acid (II), the amino groups were replaced by hydroxyls (III) when sodium nitrite, sulfuric acid and copper powder were used. Similar results have been reported by Cook,[4] and by Mayer and English.[5]

Dropping sulfuric acid (23%) into a solution of the amino acid, potassium hydroxide, and sodium nitrite,[6] or using isoamyl nitrite and 10% alcoholic hydrogen chloride,[7] failed to accomplish the desired cyclization. Mixtures of unidentifiable products resulted in all cases. Only when dioxane was employed as the solvent, with isoamyl nitrite, sodium hypophosphite, and copper powder, was the cyclization achieved satisfactorily. Pyridine could not be substituted for the dioxane. The dihydroxy acid (III) was decarboxylated by dry distillation at 2–3 mm. pressure, and the tetramethoxy acid (V) by digestion in quinaldine with basic copper carbonate.

The hydrolysis of the tetramethoxy derivative (VI), and of its dicarboxylic acid (V), was sought by various methods, but none proved satisfactory. The most promising seemed to be the use of hydrobromic and hydriodic acids. No pure tetrahydroxy derivative was isolated, although some alcoholic extracts of the products gave green color reactions with ferric chloride, and a tetraacetate was obtained, but not in sufficient amount to saponify successfully.

Great difficulty was experienced in securing satisfactory analytical figures for several of these polycyclic compounds, especially the nitro derivatives, but whether this was due to inadequate purification, or to combustion troubles, was not clear. Similar difficulties have been reported by Gulland and Virden,[8] Kondo and Ochiai,[9] Cook,[4,10] Akin and Bogert,[2] Hewett,[11] and others.

Acknowledgments.—Our grateful thanks are due to the Ella Sachs Plotz Foundation and to the National Academy of Sciences for the financial aid which made this investigation possible. We are under obligations also to Mr. Saul Gottlieb, of these Laboratories, who conducted the microanalyses of our difficultly combustible products.

Experimental

α-(*p*-Xylylene)-2,5-di-(6′-nitro-dimethylcaffeic Acid) (I).—By digestion of a mixture of 59 g. of potassium *p*-xylylene-2,5-*bis*-acetate[2] and 86.4 g. of 6-nitroveratraldehyde[3] in 400 g. of acetic anhydride, and pouring the mixture into an excess of very dilute hydrochloric acid, a crystalline mass was secured, which was washed with acetone or methanol, to remove unaltered initial materials and tar.

Two washings with 300-cc. portions of acetone left the crude product as a pale tan solid, which decomposed between 295 and 310°, and was practically insoluble in methanol, ethanol, ether, dioxane, chloroform, acetic acid, acetone, benzene, or other solvents tried. The yield was 85%. Boiling the product for five hours with methanol and sulfuric acid had little esterifying effect, and most of the initial nitro acid was recovered unchanged. The compound therefore was dissolved repeatedly in alkali, precipitated by dilute hydrochloric acid, then washed thrice with hot acetone and dried. Pale yellow crystals were thus obtained, which darkened and decomposed above 300°.

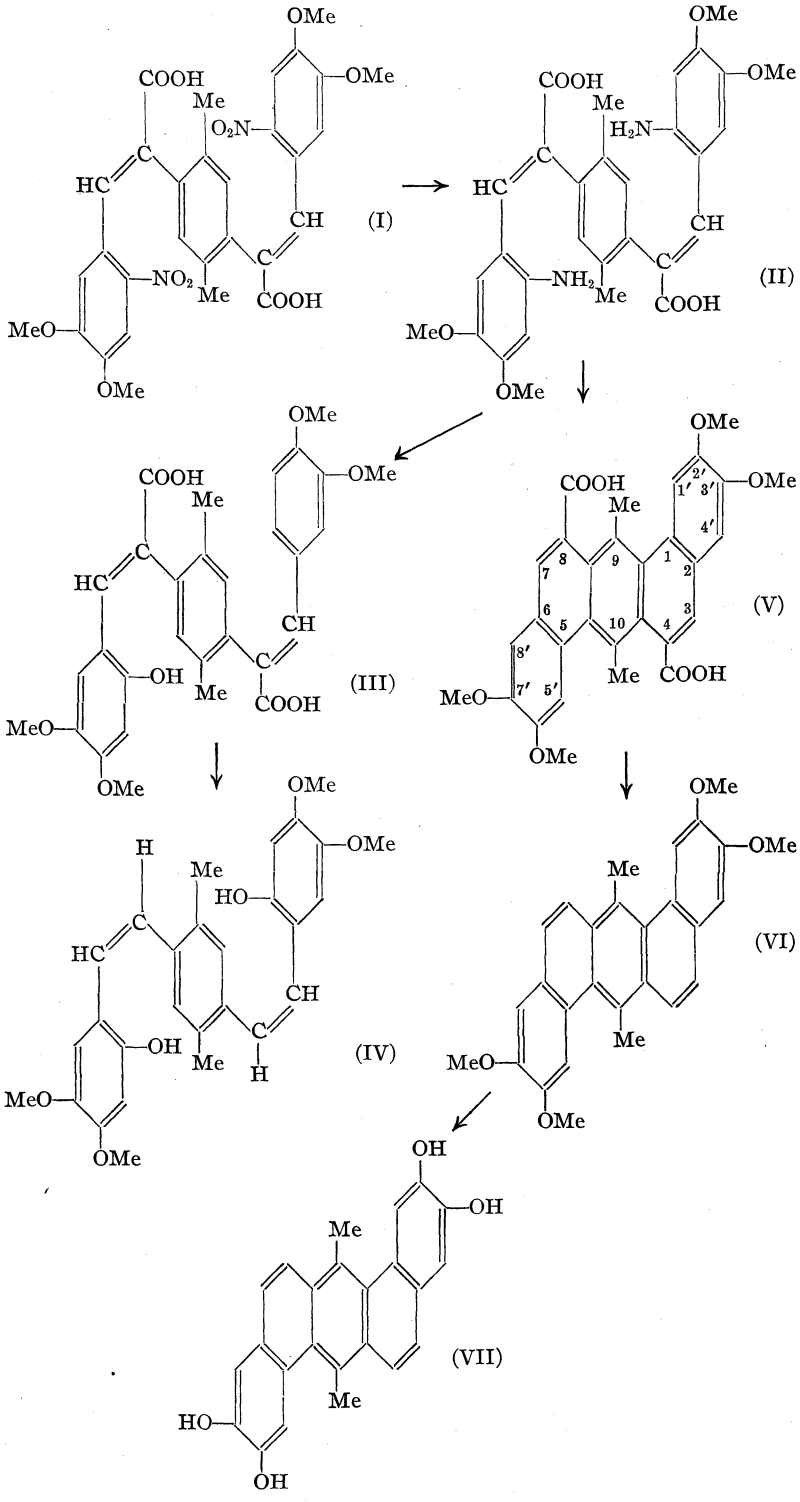
Anal. Calcd. for $C_{30}H_{28}O_{12}N_2$: C, 59.2; H, 4.6. Found: C, 58.5; H, 4.8.

α - (*p* - Xylylene) - 2,5 - di - (6′ - amino-dimethylcaffeic Acid) (II).—A hot solution of 30 g. of the crude nitro acid (I) in 85 cc. of ammonium hydroxide and 340 cc.. of water was added to a boiling solution of 173 g. of ferrous sulfate heptahydrate in 30 cc. of ammonium hydroxide and 715 cc. of water. During the next hour, 300 cc. of ammonium hydroxide was added. The solution was then precipitated by acetic acid, the mixture heated to boiling, cooled and filtered. The yield of crude amino acid so obtained varied from 50 to 60%. As in the case of the antecedent nitro acid (I), no suitable solvent could be found by which to purify the crude acid. Purification through the hydrochloride or acetyl derivative was also unsatisfactory. It was treated, therefore, as the crude nitro acid, *viz.*, by repeated solution in alkali and precipitation with acetic acid, followed by washing with alcohol and drying. The pale yellow crystals thus secured decomposed above 300°.

Anal. Calcd. for $C_{30}H_{32}O_8N_2$: C, 65.7; H, 5.8. Found: C, 65.4, 65.2; H, 6.2, 5.9.

Diazotized and coupled with "H" acid, the amino acid gave a deep purple solution.

FLOW SHEET



α - (*p* - Xylylene) - 2,5 - di - (6′ - hydroxy - dimethylcaffeic Acid) (III).—To an aqueous solution containing 1.42 g. of sodium nitrite and 2.5 g. of potassium carbonate, there was added 6.8 g. of the amino acid (II), and the resulting solution was run slowly into 100 cc. of ice-cold sulfuric acid (5 *N*), some drops of octyl alcohol being used to check foaming. After stirring for a few minutes, copper powder was added and the stirring continued for four hours, keeping the temperature at 0–5°. The mixture was transferred to a glass-stoppered bottle and shaken for fifteen

hours at laboratory temperature. The solid was removed, dissolved in sodium carbonate solution, and reprecipitated with dilute hydrochloric acid; yield, 6.2 g. This material was dried, extracted in a Soxhlet with 150 cc. of methanol for eight hours, the extract concentrated to 25 cc., and the solute precipitated by gradual addition of water; yield, 66%. After two recrystallizations from dilute methanol, a pale brown solid was obtained, which decomposed at 245–255°.

Anal. Calcd. for $C_{30}H_{30}O_{10}$: C, 65.5; H, 5.5. Found: C, 65.4; H, 5.6.

The compound contained no nitrogen, and gave no coupling reaction with "H" acid. The hydroxyl groups could not be methylated with methyl sulfate. Cook[4] has reported a similar failure to esterify the phenolic hydroxyls of an analogous compound by use of this same methylating agent.

2,5 - Di - (2' - hydroxy - 4',5' - dimethoxystyryl) - *p*-xylene (IV).—The dihydroxy acid (III) was distilled at 3 mm. pressure from a flask immersed in a metal bath the temperature of which was above 360°. The first receiver was surrounded by ice water, and this was followed by two traps in acetone–"Dry-ice" baths. A pale yellow sublimate collected in these traps, which were removed from the cooling baths and allowed to warm up to laboratory temperature before admitting air to restore the atmospheric pressure. The sublimate could then be shaken out of the traps without the use of any solvent. It decomposed between 55 and 60°, and became gummy in the presence of moisture. Three runs were made, the result being the same in all three.

Anal. Calcd. for $C_{28}H_{30}O_6$: C, 72.7; H, 6.5. Found: C, 73.1; H, 6.8.

9,10 - Dimethyl - 2',3',6',7' - tetramethoxy - 1,2,5,6-dibenzanthracene-4,8-dicarboxylic Acid (V).—To a solution of 20 g. of the amino acid (II) in 335 cc. of dioxane, there was added 11.1 cc. of sulfuric acid followed by 22 cc. of carefully purified isoamyl nitrite. After two hours of stirring at room temperature, the diazo solution was stirred into a solution of 138 g. of sodium hypophosphite in 138 cc. of water and containing some copper powder, keeping the temperature at 45–55°. After all the diazo solution had been run in, the temperature of the mixture was raised to 80°. The yield of crude product was 90%. This was washed with boiling acetic acid (8 cc. per g.). There remained a 59% yield of pale tan dicarboxylic acid (V), which decomposed at about 296° (±4°), and was pure enough for conversion into the tetramethoxydibenzanthracene (VI). Crystallized thrice from acetic acid, it formed white crystals, which decomposed at 315–317° (corr.). A second lot was crystallized six times from acetic acid and dried at 110° for eight hours. In the following analyses, the first figures were obtained with the first lot, the second ones with the second lot.

Anal. Calcd. for $C_{30}H_{26}O_8$: C, 70.0; H, 5.1. Found: C, 69.5, 69.6; H, 5.9, 6.1.

When the compound was boiled with methanol and sulfuric acid for five hours, it was recovered unchanged.

9,10 - Dimethyl - 2',3',6',7' - tetramethoxy - 1,2,5,6-dibenzanthracene (VI).—A mixture of 11 g. of the crude dicarboxylic acid (V), 2.2 g. of basic copper carbonate, and 66 cc. of freshly distilled quinaldine, was refluxed for six hours at 250°, cooled, and extracted with 700 cc. of ether. The ether extract was washed twice with dilute hydrochloric acid, once with dilute potassium hydroxide, and finally with water. Ethanol was added and the ether distilled off. The solid which separated, when crystallized from alcohol, formed pale yellow crystals, insoluble in alkali; yield 25–30%. Its solutions exhibited a pale blue fluorescence. After two more crystallizations from alcohol, the crystals melted at 137–138° (corr.).

Anal. Calcd. for $C_{28}H_{26}O_4$: C, 78.9; H, 6.1; mol. wt., 426. Found: C, 78.1, 78.5; H, 6.9, 7.3; mol. wt. (Rast, average), 441.

Dry distillation of the dicarboxy acid (V) with copper powder alone failed to yield any appreciable quantity of the decarboxylated compound (VI).

Attempts to Obtain the 9,10-Dimethyl-2',3',6',7'-tetrahydroxy-1,2,5,6-dibenzanthracene (VII).—Many experiments were carried out with both the tetramethoxydibenzanthracene (VI) and its dicarboxylic acid (V), to hydrolyze their methoxyl groups, but they were uniformly unsuccessful and no analytically pure tetrahydroxy derivative (VII) could be isolated from the black tars which were formed in most cases. Hydrochloric, hydrobromic, and hydriodic acids were the attacking reagents, as well as potassium hydroxide, and the evidence for the presence of the tetrahydroxy derivative seemed strongest when hydriodic acid was used upon either (V) or (VI). Alcohol extracts of some of these tarry products, especially those obtained with hydriodic acid, gave green color reactions, like catechol, with ferric chloride. Two typical experiments follow.

A mixture of 1 g. of (V) or (VI) with 15 cc. of hydrobromic acid (48%) and 30 cc. of glacial acetic acid was refluxed for one to two hours. Poured into water, the black liquid gave a gray flocculent precipitate, which was removed, washed and dried, giving 0.8 g. of a black powder.

A mixture of 2 g. of (V) or (VI) with 10 cc. of hydriodic acid (sp. gr., 1.7) and 20 cc. of acetic acid was refluxed for three hours and the solution poured into water. The precipitate which separated was exceedingly difficult to filter and was therefore washed with water by decantation and siphoning, until the washings were no longer colored and the solid was pale gray. By centrifugation, a gray jelly was obtained, which dried to a dark gray powder, which always gave a characteristic green ferric chloride test in alcoholic solution.

Tetraacetate.—The black powder (0.8 g.), obtained above by the action of hydrobromic acid upon (V) or (VI), was refluxed for two hours with acetic anhydride (5 cc.) and fused sodium acetate, and the crude product crystallized thrice from a mixture of ethanol and ethyl acetate. A pale tan powder resulted, which decomposed at 300–350° without melting, and could not be distilled under reduced pressure.

A similar compound was obtained by the action of acetic anhydride upon the dark gray product of the action of hydriodic acid upon (V) or (VI). Attempts to saponify this to the tetrahydroxy compound proved fruitless with the minute amount of material at our command.

In the following analyses, the first figures are for the hydrobromic acid product, the second for the hydriodic acid product.

Anal. Calcd. for $C_{32}H_{26}O_8$: C, 71.4; H, 4.8. Found: C, 71.2, 71.1; H, 5.7, 5.8.

Summary

1. 9,10 - Dimethyl - 2′,3′,6′,7′ - tetramethoxy-1,2,5,6-dibenzanthracene, and its 4,8-dicarboxylic acid, have been prepared by the Pschorr reaction from *p*-xylylene-*bis*-(acetic acid) and 6-nitroveratraldehyde.

2. In the diazotization of the intermediate aminodimethylcaffeic acid, cyclization results only when dioxane is used as the solvent. In aqueous solutions, the amino groups are replaced by hydroxyls.

3. Attempts to prepare the corresponding tetrahydroxydibenzanthracenes by hydrolysis of the methoxyl groups proved unsatisfactory.

4. The dibenzanthracene and its dicarboxylic acid were synthesized for testing as possible carcinogens.

The Nitration of Diphenyliodonium Nitrate

BY R. B. SANDIN, F. T. MCCLURE[1] AND F. IRWIN[2]

The nitration of diphenyliodonium nitrate has been the subject of considerable research.[3] It is an interesting problem, from the standpoint of the influence of groups present in the benzene ring, on the course of further substitutions. According to Vorländer, Robinson, Ingold and others,[4] the most strongly meta-directing groups are the positive poles directly attached to the benzene ring. For example, phenyltrimethylammonium nitrate is nitrated exclusively in the meta position.[5] In this case the orienting group is $-N(CH_3)_3^+$. Again, a group may be meta-directing because the group as a whole carries a permanent dipole as in NO_2. On the other hand, ortho–para orientation is associated with those radicals which lose electrons to the ring as in the case of the methyl group, or which carry unshared pairs of electrons so that conjugation with the double bonds of the ring is possible as in NH_2.[6]

The nitration of a compound such as diphenyliodonium nitrate might be expected to be similar to the nitration of phenyltrimethylammonium nitrate, since the orienting group is $-IC_6H_5^+$. Vorländer[3a] in his work showed that meta-nitration did take place. By repeated crystallization of the reaction product he isolated pure di-*m*-nitrophenyliodonium nitrate. This gave *m*-iodonitrobenzene and *m*-nitrophenol (free from *o*-derivative) with sodium hydroxide. Any *p*- or *o*-compound may thus have been separated. On reading Vorländer's experimental work, the reader might draw the conclusion that nitration occurs almost exclusively in the meta position. Regarding the nitration, Vorländer has this to say: "*p*-Nitro-phenol ist vielleicht in spuren, *o*-Nitrophenol überhaupt nicht vorhanden, ... *o*-Nitro-phenol war nicht einmal durch seinen Geruch nachzuweisen." The experimental work which Vorländer reports gives no indication of ortho–para nitration.

However, the iodine atom in $-I(C_6H_5)_2^+$ has unshared electrons and is at the same time the positive end of a dipole. On the basis of unshared electrons one might expect the formation of some ortho and para derivatives along with the meta compound. Meta-directing groups usually do not contain unshared electrons in the shell of the atom which is directly joined to ring carbon.[7]

There is also another difference between phenyltrimethylammonium nitrate and diphenyliodonium nitrate to be considered. Since the positive electricity resides at the nucleus of the charged atom, the amount of damping action arising through the passage of the effect, through the

(7) Vorländer, *Ber.*, **58B**, 1893 (1925), has shown that $-IO_2$ in which the iodine atom has unshared electrons is meta-directing. Recently, Masson, Race and Pounder, *J. Chem. Soc.*, 1669 (1935), have nitrated iodoxybenzene and have obtained about 99.5% meta-nitration.

successive shells of electrons belonging to the charged atom itself, would be smaller for the former than for the latter compound. On this basis it might be expected that the iodonium compound would show weaker *m*-reactivity.

It was in connection with a study of phenyl derivatives of several elements occupying consecutive or adjacent positions in the periodic table that Challenger and Rothstein[3b] carried out the nitration of diphenyliodonium nitrate. They carried out the nitration under the conditions followed by Vorländer. The composition of the resulting iodonitrobenzenes was determined by thermal analysis and the nitrophenols simultaneously produced were not examined. Their results showed a para-nitration which varied from 14 to 20.2% (average 17.5%). They also definitely isolated *p*-iodonitrobenzene. However, they say that "a method whereby both the nitrated phenyl groups were obtained as halogenonitrobenzenes would have been preferable."

It was with the object of trying to confirm the results of Challenger, especially from the standpoint of the more desirable procedure which he mentions, that the authors of this paper have reëxamined the nitration of diphenyliodonium nitrate. In the authors' procedure the nitrated material was isolated as the nitrated iodonium iodide, which was then caused to rearrange into a mixture of iodonitrobenzenes. Both phenyl groups were therefore isolated as halogenonitrobenzenes. The mixture was examined from the standpoint of thermal analysis and also any *p*-iodonitro-benzene was very readily isolated from the mixture because of its limited solubility in ethanol.

The work of the present authors confirms the work of Challenger. Thermal analysis indicates a minimum of 18.5% of para nitration. At least 10% of the reaction mixture can be isolated as pure *p*-iodonitrobenzene and by taking into consideration the solvent effect of the ethanol, the amount of para-nitration can be shown to be at least 14%.

In the rearrangement of the nitrated iodonium iodide, it is believed that it is quite safe in assuming that the meta nitrated material will yield a *m*-iodonitrobenzene, the para nitrated material a *p*-iodonitrobenzene, and so on. In support of this there is the work of Lucas and co-workers[8] which shows that the decomposition of di-*o*-tolyliodonium iodide produces only *o*-iodotoluene and not a mixture of iodotoluenes. Moreover, the authors have not been able to detect the formation of any *p*-iodonitrobenzene as a result of the decomposition of pure di-*m*-nitrophenyliodonium iodide.

(8) Lucas, Kennedy and Wilmot, THIS JOURNAL, **58**, 157 (1936).

Experimental Part

Preparation of Materials.—A method similar to that of Lucas[8] and co-workers was followed for the preparation of the iodonium salts. The reaction between iodosobenzene and iodoxybenzene in the presence of a small amount of silver oxide was found to take place very readily and in a relatively short period of time. Diphenyliodonium nitrate was prepared by adding potassium nitrate to the aqueous extract produced in the above reaction. Care was taken to keep the volumes of solution as small as possible because of the solubility of the iodonium nitrate. The latter compound finally was crystallized several times from water, from which it separated in a pure condition.

Di-*m*-nitrophenyliodonium iodide was made similarly from *m*-nitroiodoxybenzene and *m*-nitroiodosobenzene. In this case, however, the yields were relatively small and the reaction required a longer period of time. The iodide was produced by adding potassium iodide to the aqueous extract of iodonium base. The salt was purified by crystallizing from water, in which it is difficultly soluble. It was shown to be pure by analysis. Vorländer[3a] reports that di-*m*-nitrophenyliodonium iodide melts at 142–144°. The authors have found that the melting point is 158–159°. It should be mentioned here that, usually, by the melting point of an iodonium salt is meant the decomposition temperature, and at this temperature very often the products are in a liquid condition.

Nitration of Diphenyliodonium Nitrate and Decomposition of the Nitrated Iodonium Iodides.—Ten grams of diphenyliodonium nitrate was added during five minutes to 50 cc. of nitrating mixture (130 cc. of concentrated nitric acid, 327 cc. of concentrated sulfuric acid), kept cool in an ice–water mixture. The reaction mixture was allowed to stand for about thirty minutes at room temperature, after which it was poured into 1 liter of a mixture of crushed ice and water. The mixture was heated until all of the precipitate had dissolved. Potassium iodide was then added to the clear solution and the very insoluble iodonium iodide was formed. After cooling to room temperature the iodide was filtered off by suction and washed with small quantities of cold water. After air drying, the yield of nitrated iodonium iodide was found to vary from 13.4 to 14.2 g.

The decomposition of the compound was effected by immersing a 250-cc. flask, containing the compound, in a glycerol-bath heated to the required temperature. The rearrangement also could be brought about by holding the flask directly in the low flame of a Bunsen burner. The rearrangement was practically instantaneous and was accompanied by the liberation of some iodine. The main reaction proceeds as follows: $(m\text{-}O_2NC_6H_4)_2I_2 \longrightarrow 2m\text{-}O_2NC_6H_4I$.

The rearranged product in some cases was treated directly in the flask with enough boiling ethanol to bring about complete solution. It was filtered immediately and on cooling the filtrate, almost pure *p*-iodonitrobenzene

separated out. A second crystallization from ethanol usually gave crystals melting at 171–172°. The yield of pure *p*-iodonitrobenzene was determined and an estimation of the amount remaining in the solvent was made. For this purpose the solubility in 95% ethanol at 25° was taken as 0.76 g. in 100 cc. of solution. There was also taken into consideration a loss due to a side reaction which liberates iodine. This sometimes was as high as 9%. On this basis, then, the amount of para nitration was calculated to be about 14%.

When the rearranged product was examined from the standpoint of thermal analysis it was first of all shaken up with a dilute solution of sodium thiosulfate. The iodine-free mixture was then extracted with chloroform, the chloroform solution was separated, washed with water, dried and evaporated to dryness. The melting point of the residue was determined and from the tables given by Challenger and Rothstein[3b] the amount of para nitration was calculated to be 19%. In this work it was assumed that no ortho compound was present,[3b] and no attempt was made to fractionate the material prior to a melting point determination.

Pure di-*m*-nitrophenyliodonium iodide was treated according to a procedure similar to the above, and no *p*-iodonitrobenzene could be detected.

Some typical experiments are recorded in Tables I and II.

TABLE I

Experiment	I	II
Yield of nitrated iodonium iodide, g.	13.4	14.2
Yield of *p*-iodonitrobenzene, g.	1.20	1.34
p-Iodonitrobenzene remaining in solvent, g.	0.60	0.45
Loss due to iodine liberation, g.	0.16	0.16
p-Nitration, %	14.6	13.9

TABLE II

Experiment	III	IV
Yield of nitrated iodonium iodide, g.	13.4	13.7
M. p. of rearranged material	88°	89°
p-Nitration, %	18.5	19.0

Summary

Diphenyliodonium nitrate has been nitrated and the work of Challenger and Rothstein, which shows that a considerable amount of para nitration occurs along with meta nitration, has been confirmed.

The Dipole Moments and Structures of Ozone, Silicobromoform and Dichlorogermane

BY GEORGE L. LEWIS AND CHARLES P. SMYTH

The structures of the molecules of the three inorganic substances, ozone, silicobromoform and dichlorogermane contain contributions from several forms among which resonance exists. It has seemed desirable to investigate the relation of each of these structures to its dipole moment.

The dipole moments were obtained in the usual manner from the dielectric constants ϵ and the densities d of solutions of the substances in non-polar solvents by means of the equations

$$P_{12} = \frac{\epsilon - 1}{\epsilon + 2}\frac{c_1M_1 + c_2M_2}{d}$$

and

$$P_2 = \frac{P_{12} - P_1}{c_2} + P_1$$

in which P_{12} is the polarization of the mixture, and c_1 and c_2, M_1 and M_2, and P_1 and P_2 are, respectively, the mole fractions, molecular weights and polarizations of the individual components, the subscript 2 referring to the polar substance. The values of P_∞ obtained by extrapolating the $P_2 - c_2$ curves to infinite dilution are used to calculate the dipole moment μ by means of the equation

$$\mu = 0.0127 \times 10^{-18}\sqrt{(P_\infty - MR_D)T}$$

in which MR_D is the molar refraction for the D sodium line and T is the absolute temperature.

Preparation of Materials

Heptane.—Material from the American Petroleum Corporation was used without purification, d^{25}_4 0.67958, $n^{25}D$ 1.38428.

Carbon Tetrachloride.—Purification of this solvent was carried out by standard methods:[1] d^{25}_4 1.58431, $n^{25}D$ 1.45717, ϵ^{25} 2.223.

Oxygen.—Tank electrolytic oxygen was passed through concentrated sulfuric acid and over phosphorus pentoxide and condensed by means of liquid air: $d^{-192.5}_4$ 1.1937, $\epsilon^{-192.2}$ 1.505.

Ozone.—A solution of ozone in liquid oxygen was prepared by passing a stream of purified oxygen through an ozonizer and condensing the product directly in the dielectric cell or the pycnometer surrounded by liquid air. The concentration of the solution was determined by allowing the liquid to evaporate through neutral potassium iodide solution in three gas washing bottles in series into a large aspirator bottle. The volume, measured within 0.1%, was then used to determine the total number of moles of oxygen plus ozone; the mole fraction of ozone was determined iodimetrically with sodium thiosulfate.

Silicobromoform.—A pure specimen of silicobromoform was given us by Professor W. C. Schumb of the Massachusetts Institute of Technology.

(1) Williams and Krchma, THIS JOURNAL, **48**, 1888 (1926).

Dichlorogermane.—About 1 cc. of dichloromonogermane was prepared by Messrs. S. R. Ginsburg and A. J. Grossman by a method outlined elsewhere.[2] Because of its instability, the material was not of a high degree of purity. It was kept in a sealed tube under its own pressure immersed in liquid air until the solutions in carbon tetrachloride were made up.

Experimental Methods

The dielectric constants were measured at a frequency of 520 kilocycles with a crystal-controlled heterodyne beat apparatus described elsewhere,[3] an accuracy of 0.05% being attained. The densities at 25° were measured with an Ostwald–Sprengel pycnometer. After being suspended in the constant temperature kerosene bath for twenty minutes, the pycnometer was set to the mark in the customary manner, removed from the bath, rinsed with distilled ether, wiped with a clean handkerchief, and weighed. Densities were reproducible to ±0.00001. For measurements of the density of liquid oxygen and oxygen solutions of ozone, the pycnometer used was a glass bulb with a very fine capillary opening. The volume of the bulb was determined by weighing full of mercury and was corrected for change with temperature. The weight of the liquid was determined from the volume of gas formed on evaporation just as in the determinations of the concentrations of the solutions. The density of the liquid oxygen could be reproduced to 0.001.

The solutions of silicobromoform and dichlorogermane were made up in an atmosphere of carbon dioxide by the simple device of placing dry-ice on the bottom of a large can, placing a glass-stoppered weighing flask containing a weighed amount of solvent upon a platform just above the dry-ice, holding the tube containing the active substance near the bottom of the can when opening it and immediately adding the active solute to the weighed solvent without removal from the can. Decomposition in the dilute solutions thus prepared was too slow to affect the accuracy of the measurements.

TABLE II

MOLAR REFRACTIONS, POLARIZATIONS AND DIPOLE MOMENTS

Substance	MR_D	$P_\infty(t°)$	$\mu \times 10^{18}$
O_3	7.6	26 (−192.4°)	0.49
$SiHBr_3$	33	46 (25°)	.79
GeH_2Cl_2	21.8	123 (25°)	2.21

Experimental Results

The dielectric constants, densities and polarizations are given in Table I. Table II lists in the second column molar refractions, calculated from the refractive index of gaseous ozone given by "International Critical Tables," and calculated for silicobromoform from the atomic refractions given by Eisenlohr[4] and for dichlorogermane from the atomic refractions obtained from Landolt–Börnstein and from the data of Miller.[5] The succeeding columns give the polarization at infinite dilution P_∞ with the corresponding temperatures in parentheses and the dipole moments.

Discussion of Results

The three solutions of ozone in liquid oxygen were the most concentrated directly obtainable with the ozonizer employed. Extrapolation of their values of P_2 gives $P_\infty = 31$, but they are so close together that, in view of the small moment of the molecule, their differences from one another and from the true value of P_∞ are probably within the experimental error. The value 26 is, therefore, taken as being within two units of the correct value. If 31 is used instead of 26, the moment comes out higher by only 0.07. The temperature at which these measurements were made was so low as to raise a question of the necessity of applying the usually negligible quantum theory correction to the polarization. However, the probable moments of inertia of the molecule proved to be so large as to render the correction negligible. The molar refraction 7.6 calculated for gaseous ozone at 0° and 760 mm. seems a little high as compared to the value 4.05 calculated for gaseous oxygen under similar conditions from the refractive index in Landolt–Börnstein, but, even if the value were as low as 6.0 instead of 7.6, the moment would be raised only to 0.51. It is interesting to note that the polarization 3.86 found for liquid oxygen, which agrees closely with the values found by Kanda,[6] is lower than the value 4.01 calculated for MR_D from the refractive in-

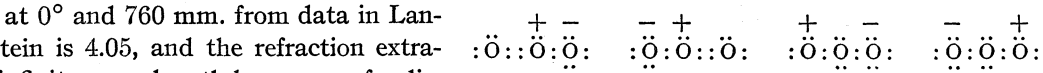
dex and density of liquid oxygen given by Landolt–Börnstein. The value of MR_D calculated for the gas at 0° and 760 mm. from data in Landolt–Börnstein is 4.05, and the refraction extrapolated to infinite wave length by means of a dispersion formula is 3.96. The same dispersion in the liquid would give $MR_\infty = 3.92$, which differs from the polarization 3.86 by no more than the uncertainty arising from the experimental errors in both figures. It is evident that not only is the dipole moment of the oxygen molecule zero but also the atomic polarization $P_A = P - MR_\infty$ is so small as to differ from zero by less than the experimental error. A very small atomic polarization is characteristic of small molecules.

The small but finite moment found for the ozone molecule shows that the symmetrical triangular structure  , in which each oxygen is linked by a single bond to the two other atoms in the molecule, is impossible as this structure would have zero moment. It also shows the impossibility of a linear molecule in which a central oxygen is joined by identical bonds to one on each side of it. The infrared spectrum[7] has been interpreted as indicating a triangular molecule, the angles of the triangle varying somewhat with the interpretation. The best results seem, however, to point to a molecule in which two atoms are bound to a central atom with an obtuse angle between the two bonds. Benedict[8] even went so far as to calculate the angle as 122° and the bond distance as 1.29 Å. This bond distance value is close to that for the single oxygen–oxygen bond[9] 1.32 Å., while the distance should probably be close to and slightly less than the double bond distance 1.14 Å. This cannot, therefore, be regarded as a satisfactory determination of the bond angle.

The natural expectation that the structure of ozone should be more or less analogous to that of sulfur dioxide is strengthened by the spectroscopic investigations. Electron diffraction[10] shows the sulfur dioxide molecule to be a triangle with the O–S–O angle 124 ± 15° and the sulfur–oxygen separation 0.05 Å. less than the sum of the covalent radii for a double bond. A larger O–O–O angle might be expected in the ozone molecule because of the smaller size of the central atom. The electronic structures which seem likely to contribute to the ground state of the molecule are the following



The first two structures, in which each atom has its complete octet of electrons, should make the largest contribution. All these structures are bent, the O–O–O angle being not less than 120°. The dipole moment should arise wholly from the first two structures and should be in the line bisecting the O–O–O angle, as the components of all the moments perpendicular to this line should cancel out. The moment of the molecule is the resultant of two equal moments in the two O–O bonds, that is, $2m\cos(\Theta/2) = 0.49$, where Θ is the O–O–O angle. If $\Theta = 120°$, $m = 0.49$, and, if $\Theta = 170°$, $m = 3$, which is about the size of the ordinary semi-polar bond between atoms of different elements[11] and identical with that between sulfur and oxygen.

The nitrogen–oxygen bond in the nitro group, which consists of equal contributions from a double bond form and from a single semi-polar bond form has a moment 3.3. On the other hand the molecule of nitrogen dioxide has been found to have a small moment like that of ozone, Williams, Schwingel and Winning[12] reporting a value 0.51 at 23.4°, which decreased with rising temperature, and Schultz[13] finding a constant value 0.29. The nitrogen dioxide molecule, although it possesses one less electron, presumably has a triangular structure somewhat similar to that of ozone and, like ozone, the resultant of contributions from different forms. The resultant of the moment of these bonds would be in the line bisecting the O–N–O angle. The small difference in electronegativity between nitrogen and oxygen seems to have little effect upon the moment. The identity of the two bonded atoms might be expected to reduce the polarity of a semi-polar bond between them as compared to that of a bond between two atoms of different electronegativities, but the effect of electronegativity difference between the elements upon the moment of a semi-polar bond between them has thus far been obscured by the uncertainties of the bond moments. The dipole moment does not prove that the O–O–O angle is wider than 120°, but places the probable limits at 120 and

160°. It thus may be concluded that the ozone molecule is a triangular structure consisting of contributions from different forms. The two oxygens linked to the central atom form an angle of, perhaps, 140°. The two oxygen–oxygen bonds would then be expected to have lengths of about 1.13 Å. and moments not far from 0.7.

The low moment found for silicobromoform, $SiHBr_3$, is consistent with the low values for the chlorosilanes found by Brockway and Coop in the vapor state[14] and published after our measurements had been carried out. The value of $SiHBr_3$, 0.79, is lower than the moment of $SiHCl_3$, 0.85, just as that of $CHBr_3$,[15] 0.99, is lower than that of $CHCl_3$, 1.05, but the exact differences are uncertain because of solvent effect. Brockway and Coop have pointed out that the reduction of moment in the di- and trichlorosilane molecules because of mutual induction between the dipoles is less than in the corresponding carbon compounds because the larger size of the silicon separates the dipoles more. Although the moment of silicobromoform is smaller than that of bromoform, the difference is relatively smaller than that between methyl chloride and monochlorosilane. This same dependence of induction upon the size of the central atom has been observed[2] recently in the cases of mono and dichloro compounds of carbon, silicon, germanium and tin in extension of relations previously noted.[11]

The moment of dichlorogermane, 2.20, is larger than that of methylene dichloride, 1.56, and much larger than that of dichlorosilane, 1.17, but much smaller than the moment of $(C_2H_5)_2SnCl_2$, 3.85, which should be close to the tin analog of these other compounds. If Müller's empirical equation for solvent effect[16] applies to GeH_2Cl_2 as it does to CH_2Cl_2, a gas value 2.34 may be calculated for GeH_2Cl_2, which, for our present considerations, is not a material alteration from the solution value. The increase in moment with increase in the size and positive character of the central atom when the individual dipoles have their positive ends toward the latter has been observed before.[11,17] The sharp decrease from the carbon to the silicon compound in the cases of CH_2Cl_2 and SiH_2Cl_2 and $CHBr_3$ and $SiHBr_3$ as well as in the other chlorosilanes must arise in part, at least, from a resonance which involves contributions from forms containing positive halogen linked by a double bond to the central atom. This involves a shortening of the silicon–halogen bond below the sum of the single covalent bond radii of the two atoms, which amounts to 7.0% in $SiHCl_3$ and 7.4% in $SiCl_4$, as compared to 0% in CCl_4, 5.9% in $GeCl_4$, and 3.8% in $SnCl_4$. The percentage lowerings are calculated from the bond radii given by Pauling[9] and the interatomic distances summarized by Brockway.[14,18] They indicate clearly that the contribution of the doubly-bonded form, which, through having a positive charge on the halogen, lowers the total dipole moment of the molecule, is greatest in the silicon compounds. This would tend to make the moments of the silicon compounds have minimum values, but the difference between the bond shortenings in the two tetrachlorides appears too small to account wholly for the large difference in moment between the silicon and the germanium compounds. Undoubtedly, the more electropositive character of the germanium contributes largely to the difference.

Summary

The dipole moment of ozone has been measured in solution in liquid oxygen. It indicates that the molecule is a bent structure with a very obtuse angle between the bonds of two oxygens attached to a central atom. These two identical bonds have some polar character as a result of resonance among forms containing semi-polar bonds.

The moments of silicobromoform and dichlorogermane, measured in heptane and carbon tetrachloride solutions, respectively, show that silicon compounds tend to have minimum moments in the group of carbon, silicon, germanium and tin compounds, which, otherwise, increase in the order named.

The Dipole Moments and Structures of Certain Nitro Compounds and Amines

BY GEORGE L. LEWIS AND CHARLES P. SMYTH

The dipole moments of trinitromethane or nitroform, tetranitromethane and nitrogen pentoxide have been determined with the object of studying the molecular structures and the interactions of immediately adjacent nitro groups. A brief account is included in this paper of the determination and interpretation of the moments of cyclohexylamine and morpholine. The moments were obtained with the apparatus and methods previously described.[1,2]

Preparation of Materials

Benzene.—Benzene was purified as in the work previously described.[1]

Carbon Tetrachloride.—Carbon tetrachloride was purified as in the work previously described.[2]

Tetranitromethane.—Tetranitromethane, prepared according to the method of Chattaway[3] by the action of virtually dry nitric acid on acetic anhydride, was dried over anhydrous sodium sulfate and distilled in an all-glass apparatus under reduced pressure at 35°; $n^{25}D$ 1.43822; d^{25}_4 1.62294.

Nitroform.—This compound was prepared according to the method of Hantzsch and Rickenberger[4] by the acidification with concentrated sulfuric acid of $KC(NO_2)_3$, which was formed by the action of alcoholic potash upon tetranitromethane; m. p. 19°.

Nitrogen Pentoxide.—The method of preparation was essentially that of Russ and Pokorny.[5] Fuming nitric acid was mixed with an equal volume of concentrated sulfuric acid and distilled from it into phosphorus pentoxide, which was kept at about −20° and stirred until the mixture had the consistency of a paste. The resulting nitrogen pentoxide was sublimed in a stream of ozonized oxygen and collected along with oxygen and ozone in a tube immersed in liquid air. Upon warming after removal from the liquid air, the oxygen and ozone evaporated, leaving the white solid.

Cyclohexylamine.—Material from Merck and Company was distilled, dried over calcium chloride and then sodium, distilled onto fresh sodium in an atmosphere of nitrogen, and redistilled: b. p. 133.8°; d^{25}_4 0.86253.

Morpholine.—Material very kindly given us by the Carbide and Carbon Chemical Corporation was dried over calcium chloride and then over sodium, distilled onto fresh sodium in an atmosphere of nitrogen, and redistilled. The middle fraction was retained and measured without further purification; b. p. 128.7°; $n^{25}D$ 1.45227; d^{25}_4 0.99619.

Experimental Results

The dielectric constants ϵ and densities d of the solutions containing mole fraction c_2 of the polar solute and the polarizations P_2 of the polar solute are given in Table I, while the molar refractions MR_D, the polarizations P_∞ obtained by extrapolating the P_2–c_2 curves to infinite dilution, and the dipole moments μ are listed in Table II.

The molar refractions were calculated for tetranitromethane and morpholine from the refractive indices and densities herein reported and that for nitrogen pentoxide as the refraction of N_2O_4 plus half that of O_2 obtained from data in Landolt–Börnstein. The molar refraction of cyclohexylamine was calculated from similar data in Landolt–Börnstein and that of nitroform was the value of von Auwers and Harres.[6]

Discussion of Results

Tetranitromethane was measured because, although two previous investigators had found moments for it in solution so small as to be indistinguishable from zero, absorption measurements[7] and X-ray analysis of the crystal[8] had been interpreted as indicating that it was not a symmetrical molecule but actually trinitromethyl nitrite. Mark and Noethling assumed a linear nitrite structure, which now seems highly improbable. After the measurements in the present paper had been carried out, a determination in the vapor state was published indicating a moment indistinguishable from zero. The results of these measurements are summarized in Table III.

TABLE III

DATA ON TETRANITROMETHANE

Investigators	Temp., °C.	MR_D	P_∞	$(\mu \times 10^{18})$	Solvent
Williams[9]	25	31	32.5	0.2	C_6H_6
Weissberger and Sängewald[10]	25	35.3	36.2	.19	CCl_4
Coop and Sutton[11]	81.8	36.0	38.6	.39	Gas
Lewis and Smyth	25	31.72	41.7	.71	CCl_4

As Coop and Sutton say that the polarization may be "somewhat greater than the above value, but not by more than 3 cc.," and, as our value may be as much as 1 cc. high, the agreement is satisfactory. The value of Weissberger and Sängewald is also low by probably no more than the experimental error. Coop and Sutton's value of the molar refraction was taken as the average of the value of Weissberger and Sängewald, which may have a considerable error because of being determined in dilute solution, and of a value privately communicated to them by M. W. Lister. The value 31.72 determined in the present work agrees closely with that of von Auwers and Ottens[12] 31.44 and is higher than the sum 29.4 of the refractions of four alkyl nitro groups and one carbon atom taken from Landolt–Börnstein. The value 31.7 is, therefore, to be regarded as the molar refraction. This leaves a difference between the polarization and the refraction of about 10 cc., which would give a moment 0.7.

The moment of the symmetrical tetranitromethane molecule should, of course, be zero, while that of trinitromethyl nitrite would depend upon rotation around the single O–N bond of the nitrite group and would vary from 3.4 to 0 with variation in the position around this bond. Complete freedom of rotation would give a moment 2.4, but repulsion within the molecule should make the general region of the zero moment position more probable, which would mean an average moment possibly less than 1.0. The possibility that the tetranitromethane is really trinitromethyl nitrite is not wholly excluded if the moment is as large as 0.7. However, measurements on nitrobenzene in the vapor state[13] gave an atomic polarization 6 for nitrobenzene as compared to 1.0 for fluorobenzene and 1.8 for chlorobenzene, and similar measurements on nitromethane[14] gave an atomic polarization 6.1 as compared to 1.2 for phosgene and 0 for hydrogen cyanide obtained at the same time and small values for the alkyl halides obtained at other times. The large errors which commonly accumulate in atomic polarization values make any discussion of it necessarily approximate, but it would appear that a large atomic polarization may be associated with the nitro group. If the atomic polarization of two mononitro compounds is 6, it would not be surprising for a molecule containing four nitro groups to have an atomic polarization of 10. It seems reasonable, therefore, to attribute the difference between the polarization and the refraction to atomic polarization and report the moment as zero and the molecule, therefore, as the symmetrical tetranitromethane and not trinitromethyl nitrite. A determination of structure by the electron diffraction method just published[15] obtains the interatomic distances to be expected on the assumption of a symmetrical tetranitromethane. Before leaving the subject of tetranitromethane, attention should be directed to the somewhat unusual

occurrence of a minimum in the density–concentration curves in the very dilute region of its solutions in carbon tetrachloride.

No account of atomic polarization has been taken in the calculation of the moment of nitroform in Table II. The addition of 8 cc. to the refraction, a maximum value for atomic polarization, would lower the moment by only 0.07. The solvent effect has presumably already lowered it by more than this from its true gas value. The ratio of the value 2.71 to the solution value of nitromethane is 0.85, while the ratio of the chloroform moment to that of methyl chloride is 0.56. If there were no inductive action between neighboring dipoles, the moments of the mono- and the tri-substituted molecules should be equal as required by their tetrahedral structures. The lowering of the moment by induction is much less in nitroform than in chloroform, for not only is the ratio of the tri- to the mono-substituted compound 0.85 as compared to 0.56, but the absolute lowering is only 0.5 as compared to 0.8. The total polarizability of the nitro group is slightly greater than that of chlorine as shown by its refraction of 6.7 as compared to 5.97, but its polarizability per atom and per displaceable electron is only a little more than a third of that of chlorine and that for the chlorine electrons. In some positions of the nitro groups as they rotate around the C–N bonds, an oxygen of one nitro group may come very close to that of another with a considerable resultant lowering of the N–O dipole moments, but if, as it was found necessary to assume in the electron diffraction investigation of tetranitromethane[15] and as should be equally probable here, the nitro groups are undergoing rotatory oscillation about the C–N bonds in such a way as to keep the oxygen–oxygen repulsions minimized as far as possible, the oxygens are somewhat removed from neighboring dipoles and the inductive effects should be smaller than those in chloroform. The smaller reduction in dipole moment is thus accounted for.

The nitrogen pentoxide molecule should consist of two nitro groups attached to a central oxygen. A rather early electron diffraction investigation[16] indicated a symmetrical molecule with a 180° valence angle for the central oxygen. As this structure would have zero moment, the considerable moment 1.39 given in Table II shows it to be impossible. Evidently, the molecule is bent and a very rough value of the oxygen valence angle may be calculated from the group and bond moments involved. If from the solution value of nitromethane 3.2, the approximate moment of the H–C bond 0.3 is subtracted, a moment 2.9 is obtained for the nitro group. If induction reduces this by 10% as compared to the 15% reduction in nitroform, the group moment is 2.6. This moment in each half of the molecule is opposed by the N–O bond moment, which is about 0.3.[17] The moment of each half of the molecule is, therefore, 2.3, acting approximately in the direction of the oxygen valence bonds. The moment of the molecule as a whole should, therefore, be $2 \times 2.3 \cos(\theta/2) = 1.39$, where θ is the oxygen valence angle. This gives $\theta = 145°$, which seems rather large. However, electron diffraction[18] gives an oxygen valence angle 100° in OF_2 and 115° in OCl_2, in which latter molecule the repulsion between the two attached atoms should be larger. Calculation of the dimensions of the OCl_2 and $O(NO_2)_2$ molecules shows that, for a given oxygen valence angle, steric repulsion between the two nitro groups must be much greater for certain positions in the rotation of the groups about their bonds to the central oxygen than the repulsion between the two chlorine atoms. Thermal oscillation around these bonds should, therefore, tend to widen the oxygen valence angle and may be sufficient to account for the large value 145° estimated approximately. It should be remarked that the bond moment calculated from the moment and valence angle of the OCl_2 molecule was consistent with other indications of its size.[19] Neglect of atomic polarization in calculating the moment of nitrogen pentoxide presumably raises its value somewhat, but the presence of impurity due to decomposition of the unstable substance tends to compensate for this. It is thus clearly established that the molecule is bent, but the angle of bending is only very approximately estimated.

The moment of cyclohexylamine 1.32 is 0.2–0.3 higher than those of secondary alkyl amines, about the same size as those of the primary alkyl amines, and smaller than those of the aryl primary amines as would be expected. Its behavior is thus normal.

The moment of morpholine 1.58 in Table II is slightly higher than the value 1.48 recently pub-

lished by Partington and Coomber,[20] which does not affect its interpretation. The dioxane molecule, which has two possible forms, a Z-shape and a U-shape, has been shown by its moment[21,22] to exist almost wholly in the Z-form. Similarly, the moment found for morpholine, which has two possible Z-forms and four possible U-forms, agrees well with the identical values calculated for the two Z-forms. Our reasoning has agreed with that of Partington and Coomber in leading to the conclusion that the morpholine molecule exists primarily in its Z-forms, although the presence of U-forms is not entirely excluded.

Summary

The dipole moments of tetranitromethane, nitroform and nitrogen pentoxide have been determined in carbon tetrachloride solution and those of cyclohexylamine and morpholine have been measured in benzene solution. Tetranitromethane is concluded to have a large atomic polarization but zero dipole moment, which means that it is not trinitromethyl nitrite as sometimes suggested. The moment of nitroform is consistent with its tetrahedral structure, inductive effects in the molecule being smaller than those in chloroform, probably because of the lower polarizability of the atoms and of a staggering of the nitro groups in their rotation around their bonds to the central carbon atom. The moment of cyclohexylamine is of the same size as those of the primary alkyl amines, as it should be. The moment of morpholine shows that it exists primarily in the Z- or chair-shaped forms of the molecule.

Allylic Rearrangements. IX. The Isolation and Rearrangement of Primary and Secondary Pentenyl, Hexenyl and Heptenyl Bromides[1,2]

BY WILLIAM G. YOUNG, LAWRENCE RICHARDS AND JULIAN AZORLOSA

In the first paper[3] of this series it was recognized for the first time that the so-called crotyl bromide was actually a mixture of primary and secondary butenyl bromides which were far more mobile than previously suspected. Although they could be separated by low-temperature fractional distillation, they rearranged even at room temperature to an equilibrium mixture. Later papers[4] have pointed out that studies involving the formation or reaction of these butenyl bromides must take into consideration the possibility of an allylic rearrangement during the reaction, and also a thermal rearrangement after the products are formed. Since other alkenyl bromides have been prepared and used in the synthesis of many types of compounds without recognition by investigators of the need for carefully controlled conditions, there exists, therefore, a need for a careful and extended study of the alkenyl bromides, their equilibria and reactions.

It is the purpose of this paper to discuss the separation and thermal rearrangement of the primary and secondary pentenyl, hexenyl and heptenyl bromides. A separation of the hexenyl bromides[5a] and the synthesis of several pure primary alkenyl bromides[5b] have been reported, but it will be shown that sufficient precautions were not used in the isolation of the pure compounds.

Experimental Part

Preparation of Materials

Alkylvinylcarbinols.—The ethyl, propyl and butylvinylcarbinols used as a source of the desired vinyl bromides were prepared in 60% yields by the action of the appropriate Grignard reagent on acrolein according to the method of Delaby[6] as modified by Prévost.[7]

(1) This work was accomplished with the aid of a grant from the Board of Research of the University of California.

(2) The terms primary alkenyl and secondary alkenyl bromides are used to designate the two allylic isomers, R—CH=CHCH$_2$Br and R—CHBrCH=CH$_2$ respectively. Accordingly, the terms primary pentenyl, hexenyl and heptenyl bromides refer to 1-bromo-2-pentene, 1-bromo-2-hexene, and 1-bromo-2-heptene, respectively. Similarly, secondary pentenyl, hexenyl and heptenyl bromides refer to 3-bromo-1-pentene, 3-bromo-1-hexene, and 3-bromo-1-heptene, respectively.

Alkenyl Bromide Mixtures.—The pentenyl, hexenyl and heptenyl bromide mixtures used in this work were prepared by the action of a mixture of 240 ml. of 48% hydrobromic acid and 24 ml. of 95% sulfuric acid on one mole of the appropriate alkylvinyl carbinol for two days at room temperature. The bromides were all washed with dilute bicarbonate solution, then with water and dried over calcium chloride before distillation. The yields varied from 75–90% for different runs.

Fractional Distillations of the Bromide Mixtures.—All distillations were conducted at pressures of 1–5 mm. The 80-cm. fractionating columns were packed with glass helices and were surrounded with an appropriate thermostated liquid, when the distillation temperature was appreciably below room temperature. All materials were stored in a refrigerator at −15 to −20° between distillations, and the various fractions were collected in receivers maintained at −78° during the distillations to avoid the thermal rearrangements which were known to occur even at room temperatures with the butenyl bromides.[3] Since the bromide mixtures, as prepared, contained 80–90% of the primary alkenyl bromides, these isomers were readily isolated by low temperature fractionations. The criteria of purity of the isolated compounds were the constancy of the refractive indices upon repeated distillation and the agreement of the Carius analyses with the theoretical values.

The isolations of the secondary alkenyl bromides involved what may be described as a three-stage process. In the first stage, the secondary forms, present as 10–20% of the original bromide mixtures, were removed by fractionation and stored until sufficient amounts had been collected for the third stage. In the second stage, the mixtures almost completely freed of their secondary bromides were heated until equilibrium had been established. These rearranged mixtures were then treated as in the first stage. In the case of the pentenyl bromides, the first and second stages were combined by slowly fractionating at a distillation head temperature of 70–80°. The process in this case was continuous since the secondary isomer was re-formed by rearrangement in the boiler as rapidly as it was removed at the top of the column. In the third stage, the accumulated mixtures rich in the secondary forms were fractionated as practised in the isolation of the primary alkenyl bromides. The physical properties of the bromides prepared by the method described above are listed in Table I. See the discussion of results for explanation of difficulty encountered during the isolation of the secondary heptenyl bromide.

Determination of Physical Properties.—Refractive indices were determined with the aid of a Zeiss–Abbe refractometer with water-jacketed prisms and the D sodium line as a light source. The alkenyl bromides have been found to attack optical glass and slowly deposit a hard white film upon the surface of the prism of the refractometer. Consequently, small glass cells containing the alkenyl bromides were fastened to the prism face with α-bromonaphthalene while the measurements were taken.

Densities were determined with a 10-ml. cone-shaped pycnometer having a thermometer ground in the neck. All density measurements were made at 25.00°, and the values were corrected to vacuum. As a precautionary measure the samples were checked with a refractometer before and after the densities were taken.

Boiling points were determined by rapidly distilling small amounts of the pure bromides at reduced pressures through a small Vigreux type column. The refractive indices were determined before and after the distillations in order to show that no rearrangements had occurred during the distillations.

The pure compounds were analyzed for bromine by the method of Carius.

Composition of the Equilibrium Mixtures at 100°.—Small samples of each pure bromide were sealed in dry test-tubes and heated at 100° in a steam-bath until no changes were observed in the refractive indices. The primary and secondary alkenyl bromides rearranged to the same refractive indices, showing that equilibria were established. This required from one to eight hours depending on the alkenyl bromide and the particular sample being rearranged. Except in the case of the heptenyl bromides (see below) the composition of each equilibrium mixture (Table III) was determined from the refractive index of the mixture and the refractive index of each pure isomer. The assumption was made that the refractive indices are additive for each of the isomeric pairs and the validity of this assumption which had been tested in the case of the butenyl bromides[3] was also demonstrated for mixtures of the two pentenyl bromides (see Table II).

Estimation of the Composition of the Heptenyl Bromide Equilibrium Mixture.—Although only the primary heptenyl bromide has been isolated in a pure state and hence data are not available to

TABLE III

COMPOSITION OF THE ALKENYL BROMIDE EQUILIBRIUM MIXTURES AT 100°

Alkenyl bromides	$n^{25}D$ at equilibrium	% primary bromide
Butenyl[2]	1.4767	85.5
Pentenyl	1.4747	80.1
Hexenyl	1.4742	85.8
Heptenyl	1.4737	Estimated 89.0

calculate the composition of the heptenyl bromide equilibrium mixture, nevertheless it has been possible to *estimate* the composition by two independent methods. It had been noticed that the conversion of methyl,[4c] ethyl[8] and propyl[8] vinylcarbinols into bromide mixtures using standard method VI[4c] (phosphorus tribromide + pyridine at −75°) gave approximately 47% primary bromide. Hence, the assumption could be made that 47% primary heptenyl bromide would be produced using the same standard method on butylvinylcarbinol. The bromide mixture, thus prepared, possessed refractive indices $n^{25}D$ 1.4691 and 1.4690 for two different preparations. After rearrangement at 100° these preparations came to equilibrium at $n^{25}D$ 1.4736 and 1.4738, respectively. Consequently we know that these preparations which contained 47% primary bromide increased on an average of 0.00465 refractive index unit in rearranging to equilibrium. The change in composition which will cause a change of 0.00465 refractive index unit was determined by recording the observed difference between the refractive indices of the primary and secondary butenyl, pentenyl and hexenyl bromides shown in Table I, and extrapolating to get the difference for the heptenyl system. Knowing that this difference of 0.0110 unit equals 100% change in composition, we find that the change of 0.00465 unit during rearrangement of the bromide mixture represented an increase of 42% in primary bromide content. Since the mixture started with 47% primary bromide, the equilibrium mixture must have approximately 89% primary bromide. In view of the fact that a similar calculation based on data obtained upon conversion of the primary heptenol into bromide mixtures by standard method VI gave the same value for the composition of the heptenyl bromide equilibrium mixture, we feel justified in using this estimate until it has been possible to isolate the pure secondary heptenyl bromide and thus get a more direct evaluation of the composition of the equilibrium mixture.

Mobility of the Alkenyl Bromides.—The absolute mobilities or rates of rearrangement of the alkenyl bromides have not been determined. The rearrangements are very sensitive to minute traces of catalytic substances and it has been impossible to obtain reproducible results. Qualitative observations have indicated that at 100° the order of decreasing mobility is: butenyl, hexenyl, pentenyl, and heptenyl, respectively.

Discussion of Results

Separation of the Alkenyl Bromides.—Careful and repeated fractional distillation at low temperatures has resulted in the isolation of the pure primary and secondary forms of the pentenyl bromides (1-bromo-2-pentene and 3-bromo-1-pentene), and the hexenyl bromides (1-bromo-2-hexene and 3-bromo-1-hexene). In the case of the heptenyl bromides, the pure primary form (1-bromo-2-heptene) was obtained, but the pure secondary form (3-bromo-1-heptene) has not yet been isolated. This is due to the fact that the primary heptenyl bromide could readily be isolated in quantity by low temperature fractional distillation of a bromide mixture. However, in an attempt to produce the secondary isomer continuously by high temperature fractionation (above 100°) of a mixture rich in the primary form as had been done with the butenyl and pentenyl bromides, the mixture lost hydrogen bromide, forming some heptadiene, although this fact was not apparent at the time. Consequently, the fraction which was thought to be mainly secondary bromide was later found to be low in bromine content and to contain some heptadiene (see Table I). Likewise the refractive index of this fraction was lower than anticipated for the secondary isomer, $n^{25}D$ 1.4560 to 1.4600. From our knowledge of the other secondary alkenyl bromides the 3-bromo-1-heptene would be expected to have a value of $n^{25}D$ 1.4637. A new supply of material must be synthesized before another attempt can be made to purify this bromide.

Previous Preparations of the Alkenyl Bromides.—The pentenyl, hexenyl and heptenyl

CALCULATION OF COMPOSITION OF ALKENYL BROMIDES PREVIOUSLY DESCRIBED BY OTHER INVESTIGATORS

Bromide	Investigator	Refractive index, n_D	Calcd. composition % prim.	% sec.	Notes
Butenyl	Delaby and Lecomte[5b]	1.4815 (16°)	87.0	13.0	Although reported as pure primary bromide, this is the equilibrium mixture
Pentenyl	Hurd and McNamee[10b]	1.4757 (21°)	73.5	26.5	
Pentenyl	Hurd and Pollock[10c]	1.4654 (20°)	2.0	98.0	Frac. 1
		1.4769 (20°)	78.2	21.8	Frac. 2. Ozonization gave 18.5% secondary and 81.5% primary
	Delaby and Lecomte[5b]	1.4731 (20°)	53.0	47.0	Reported as the pure primary isomer
Hexenyl	Van Risseghem and Gredy[5a]	1.4657 (20°)	3.7	96.3	Reported to be pure secondary bromide
		1.4777 (20°)	93.3	6.7	Reported to be pure primary bromide
		1.4744 (21°)	72.4	27.6	Reported to be equil. mxt. from 30 dist. of *s*-bromide (see Table III)
		1.4750 (21°)	76.8	23.2	Reported to be equil. mxt. from 22 dist. of prim. bromide (see Table III)
	Hurd and Parrish[10a]	1.4715 (26°)	69.4	30.6	
	Delaby and Lecomte[5b]	1.4778 (16°)	79.0	20.9	Reported as the pure primary isomer
Heptenyl	Hurd and Parrish[10a]	1.4693 (24°)	51.0	49.0	
	Delaby and Lecomte[5b]	1.4760 (17°)	59.0	41.0	Reported as the pure primary isomer

bromides have been synthesized many times for one purpose or another but in most cases the investigator was unaware of their mobility and hence thought that only one product, the primary isomer, $R-\underset{H}{\overset{H}{C}}=\underset{H}{\overset{H}{C}}-CBr$ reported by Bouis,[9] was present. Fortunately, in a few cases sufficient data have been given so that we can use our refractive index data and calculate the composition of the materials reported. Table IV contains this information. Van Risseghem and Gredy[5a] have reported the separation of the primary and secondary hexenyl bromides (1-bromo-2-hexene and 3-bromo-1-hexene). If they had not underestimated the mobility of the bromides and as a result used too high a distillation temperature (50–60°) they would have made a successful separation. Actually their primary bromide contained 6.7% of the secondary isomer and the secondary bromide contained 3.7% of the primary form. Their attempt to attain equilibrium by repeated distillation at 100° in a sealed tube could not possibly give an equilibrium mixture. Judging from our experience the bromides are mobile enough so that the secondary form would be continually formed in the boiling liquid to replace the secondary form which is removed in excess in the vapor. Hence the final distillate would of necessity contain more secondary bromide than that present at equilibrium, regardless of the number of distillations performed. Moreover, the composition probably would depend upon the conditions maintained during the last distillation rather than on the previous distillations. Their secondary hexenyl bromide after thirty distillations ($n^{21}D$ 1.4744) was actually 72.4% primary bromide instead of the 85.8% called for by our equilibrium measurements and the 90–95% which they report. Likewise, their primary bromide after twenty-two distillations ($n^{21}D$ 1.4750) contained 76.8% primary bromide in place of the 90–95% which they reported. It should be noted that these two products contained far more secondary bromide than these authors report by Raman measurements and that they differ in composition by 5%, although they were reported to be identical in composition.

The results by Hurd and co-workers[10] are of particular interest because they offer a comparison of refractometry and ozonolysis methods of analysis. The approximate agreement observed in the case of the pentenyl bromides is gratifying, especially since there seems to be complete disagreement between our results and those obtained from Raman and infrared absorption measurements. For example, Delaby and Lecomte[5b] have synthesized bromides from the alkylvinylcarbinols and claim to obtain only pure primary bromides. However, analysis of their results using refractive index data shows that in every case their product was a mixture of both the primary and secondary bromides. In order to justify our confidence in the refractive index method of analysis,

(9) Bouis, *Bull. soc. chim.*, [4] **41**, 1160 (1927).

(10) (a) Hurd and Parrish, THIS JOURNAL, **57**, 1732 (1935); (b) Hurd and McNamee, *ibid.*, **59**, 104 (1937); (c) Hurd and Pollock, *J. Org. Chem.*, **3**, 565 (1939).

it should be recalled that a mixture of butenyl bromides comparable to that reported by Delaby and Lecomte was actually fractionated[3] at low temperatures into fractions comparable in size to those expected from refractive index analysis.

Further confirmation of the above conclusions has been obtained in this Laboratory[8] from experiments on the *controlled* conversion of alkylvinylcarbinols into bromides with phosphorus tribromide. In each case approximately 47% secondary bromides was present.

Summary

Several pure primary and secondary alkenyl bromides of the type R—C(H)=C(H)—CBr(H)(H) and R—C(H)(Br)—C(H)=CH(H) (R = Et to Bu) have been isolated for the first time.

The isomeric bromides have been rearranged at 100° to equilibrium mixtures the compositions of which have been determined.

The refractive index method of analysis of alkenyl bromide mixtures has been tested further with pentenyl bromide mixtures.

Conflicting reports in the literature concerning the composition of bromides made from alkylvinylcarbinols have been discussed and corrected values calculated.

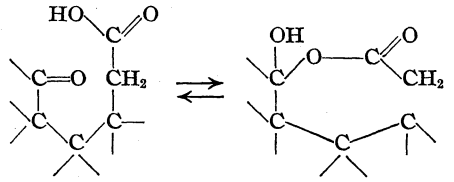
Cerin and Firedelin. V. A Study of Friedonic Acid[1]

BY NATHAN L. DRAKE AND JOHN K. WOLFE[2]

Friedonic acid, a monobasic keto acid, is produced from friedelin by vigorous oxidation.[3] The acid is esterified readily, but neither free acid nor ester yields the ordinary derivatives of a carbonyl compound. However, the fact that the acid can be reduced both by sodium and alcohol and by hydrogen in the presence of a catalyst to an hydroxy acid which spontaneously undergoes inner esterification to yield a lactone, make it clear that friedonic acid is a keto acid and not an hydroxy acid. It is the purpose of this paper to present additional evidence of the presence of a carbonyl group in friedonic acid, and to show the relation of carbonyl to carboxyl.

From the reaction products of one of many routine oxidations of friedelin was isolated a substance, isomeric with friedonic acid, which melted at 126–127°. The same compound had been isolated earlier by Campbell,[4] but never in quantity sufficient to warrant further investigation. We have found that this product, which is unaffected by dilute sodium hydroxide in the cold, can be converted into a methyl ester identical with the methyl ester of friedonic acid, and that friedonic acid, when allowed to stand at room temperature for some time in alcoholic solution containing sodium ethoxide, is converted in part into this same compound (m. p. 126–127°). We shall call this substance "isomer A." The possibility that this substance is an hydroxylactone formed by interaction of the carboxyl and carbonyl of friedonic acid has been considered



Such a formulation would account for the fact that both isomer A and friedonic acid yield the same methyl ester, and that isomer A cannot be titrated with alkali in the cold, but does give normal values of saponification equivalent. The failure of "isomer A" to take up alkali in the cold makes it very unlikely that stereoisomerism only is involved in the difference between friedonic acid and this isomer. However, our ignorance of a suitable method of preparing the substance has rendered further work upon it impossible. Our supply of this material has been limited to several grams obtained for some unknown reason during a routine preparation of friedonic acid, and a very small amount formed by the action of sodium alkoxide on friedonic acid as mentioned above.

(1) Presented before the Division of Organic Chemistry at the Baltimore meeting of the Amercian Chemical Society, April, 1939.
(2) From the Ph.D. dissertation of John K. Wolfe.

(4) Campbell, Thesis, U. of Md., 1936.

We have attempted again and again to produce isomer A, but all experiments, except the one mentioned above from which only a very small quantity of product was isolated, have failed. When isomer A was treated with methylmagnesium iodide[5] in the "Grignard machine," 0.58 mole of methane was evolved, and 3.0 moles of reagent consumed. A similar experiment with friedonic acid resulted in the liberation of 1.57 moles of methane and the consumption of 4.15 moles of reagent. The methyl ester of friedonic acid liberated 0.52 mole of methane and consumed 3.0 moles of reagent. Apparently enolization of a carbonyl group of methyl friedonate is responsible for the evolution of methane when this substance is treated with methylmagnesium iodide, and the results obtained with isomer A would lead one to conclude that the same carbonyl group is present in this substance. This situation would not be possible in the "hydroxylactone" formula.

The possibility that isomer A is the lactone of an hydroxy keto acid also has been considered, but the practically quantitative formation of methyl friedonate from it definitely eliminates this possibility.

When friedonic acid is treated with acetic anhydride a mixed anhydride results. It was hoped that this reaction might yield the acetyl derivative of the "hydroxylactone" from which gentle hydrolysis or alcoholysis might form isomer A. However, treatment of the mixed anhydride with 70% ethanol regenerates friedonic acid. An attempt was made to prepare a similar mixed anhydride from isomer A, but the substance was recovered unchanged from the reaction mixture.

In order to obtain additional evidence supporting the presence of a carbonyl function in friedonic acid, its absorption spectrum in the near ultraviolet was determined.[6] A decided maximum of absorption (log ϵ = 1.55) was found at 2900 Å. Many alicyclic ketones show absorption in this range.[7] Conjugation of a double bond with the unsaturation of the carbonyl group causes a shift of the characteristic carbonyl absorption into the neighborhood of 2500 Å. (log ϵ = 4.1). The observed absorption spectrum of friedonic acid confirms our earlier belief that the acid is not an α,β-unsaturated ketone.

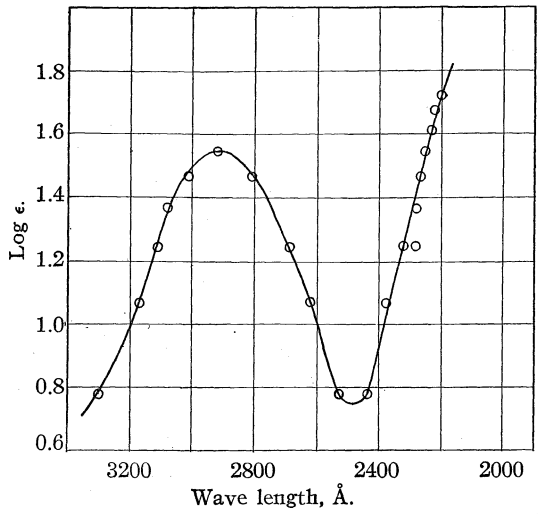

Fig. 1.—Absorption spectrum of friedonic acid, 1% in cyclohexane.

When friedonic acid was heated to a temperature about 40° above its melting point in an atmosphere of nitrogen, a new product was formed by elimination of water and loss of carbon dioxide. Quantitative determination of the water and carbon dioxide formed showed that approximately one mole of each was produced per mole of acid. The product, norfriedelene, gave a strong test for unsaturation using tetranitromethane, and absorbed one mole of hydrogen to yield norfriedelane which gave no color with tetranitromethane. In keeping with its unsaturated character, norfriedelene reacted with one mole of perbenzoic acid in chloroform and was transformed into an epoxide. These transformations are quite comparable to the behavior of 12-ketocholanic acid, which when heated to 300° loses water and carbon dioxide to yield dehydronorcholene.[8] Apparently the condensation involves the α-methylene group of friedonic acid; the subsequent decarboxylation, characteristic of α,β-unsaturated acids,[9] produces norfriedelene.

Oxidation of norfriedelene by means of potassium permanganate in glacial acetic acid according to Wieland[10] produced a new acid ($C_{29}H_{48}O_3$), norfriedonic acid, a keto acid differing from friedonic acid by methylene group and by its ability to form the usual derivatives of the carbonyl group. The lactone of the related hydroxy acid was obtained earlier directly from friedelin.[3] The

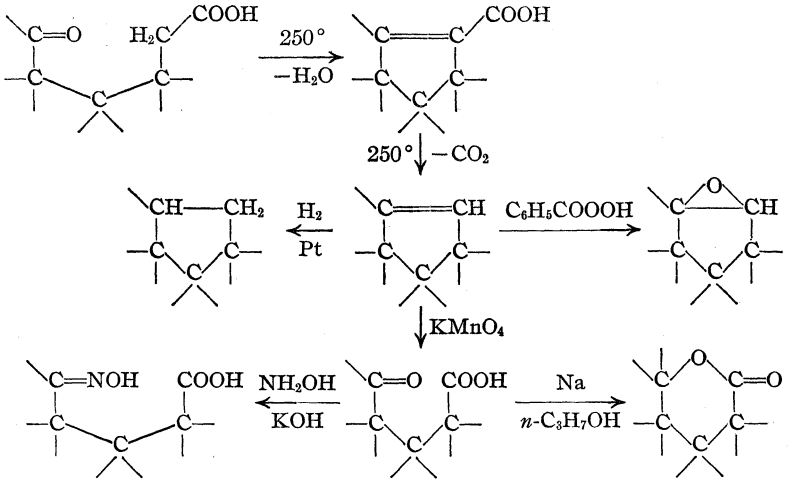
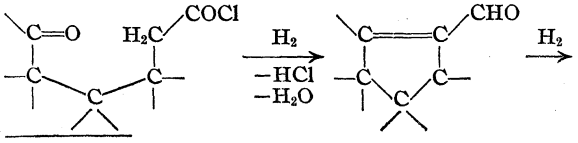
(10) Wieland and Wiedensheim, *Z. physiol. Chem.*, **186**, 229 (1930).

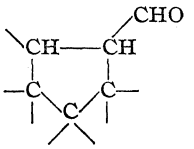
fact that carbonyl derivatives are readily obtained both from norfriedonic acid and its methyl ester indicates very clearly that some interaction of carbonyl and carboxyl groups is responsible for the failure of friedonic acid (and methyl friedonate) to yield such derivatives. The pyrolysis of friedonic acid and the other reactions given above can be represented



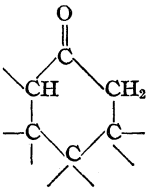
Friedonic acid yields a non-crystalline acid chloride when treated with thionyl chloride. Reduction of the acid chloride in xylene by hydrogen in the presence of a palladium–barium sulfate catalyst[11] produced a substance $C_{30}H_{50}O$, isomeric with friedelin. This new substance differs markedly from friedelin in regard to the reactivity of its carbonyl group. A 2,4-dinitrophenylhydrazone formed readily and the compound gave no test for unsaturation with tetranitromethane. This new substance also differed from friedelin by being easily oxidized to an acid containing the same number of carbon atoms and only two oxygen atoms. The isomer of friedelin must, therefore, be a saturated aldehyde, formed by a process quite analogous to the one involved in the production of norfriedelene from friedonic acid. Reduction of the double bond first formed may take place before production of the aldehyde, but more likely involves 1,4-addition to the α,β-unsaturated system in the aldehyde first produced. The formation of this aldehyde, norfriedelanylformaldehyde, can be represented



(11) Rosenmund, *Ber.*, **54**, 437 (1921).



From the data presented above and in earlier papers, it seems reasonable to conclude that friedonic acid is an epsilon-keto acid whose carbonyl group is highly sterically hindered, and that friedelin must contain the unit of structure



Experimental

Preparation of Friedonic Acid.—The procedure employed in oxidizing friedelin to friedonic acid was much the same as that used in earlier work.[3] The oxidation mixture was heated under reflux for ten hours, and at the end of that time concentrated to about one-fifth of its original volume. Five volumes of water was then added to the boiling solution, and the resulting precipitate was filtered hot, washed thoroughly with water, and dried in a desiccator over potassium hydroxide to constant weight; yield, 24.5 g. of light green solid from 24 g. of friedelin. The crude acid was pulverized and shaken well with 800 ml. of cold ethyl ether. The residual friedelin was filtered off, washed with ether, and used again without purification in a subsequent oxidation; yield, 8.0 g. of friedelin. The ethereal solution was extracted repeatedly with 10% sodium hydroxide until no more sodium salt precipitated in the aqueous layer. The precipitated sodium salt was returned to the separatory funnel and washed twice with ether. When the resultant emulsion was centrifuged three layers were produced; the upper ethereal layer was decanted, and the lower green aqueous layer poured off through holes punched in the compact intermediate layer of sodium salt. A suspension of the sodium salt was then acidified with concentrated hydrochloric acid in a separatory funnel and separated from the aqueous layer by extraction. The ethereal solution was then evaporated to dryness, the gummy residue taken up in 25 ml. of 95% ethanol, seeded with a few crystals of friedonic acid and cooled in the icebox overnight; yield of crude friedonic acid, 7.3 g. (m. p. 196–198°). Recrystallization of the crude acid from ethanol yielded 6.0 g. of pure acid which crystallized as colorless needles having parallel extinction and melted at 205–207°. The ethereal solution from which the acid was originally extracted was combined with that obtained during centrifugation, washed free from sodium hydroxide and evaporated to dryness. The solid residue was diluted with alcohol and filtered; the product was nearly pure friedelin (3.5 g.). Of the 24 g. of friedelin sub-

jected to oxidation, 11.5 g. was recovered, 12.5 g. oxidized, and 6.0 g. of friedonic acid obtained (48% yield).

Isomer A.—Friedonic acid (0.2 g.) was dissolved in 25 ml. of ethyl alcohol, containing 1 g. of dissolved sodium, and was allowed to stand at room temperature for forty-eight hours. The mixture was acidified, diluted with water, and filtered. On recrystallization of the solid from ethyl alcohol, 0.1 g. of friedonic acid was obtained. The filtrate from the crystallization was evaporated to dryness and triturated with a little ethyl alcohol in the cold. The undissolved crystals were filtered and recrystallized from ethyl alcohol; a small quantity of a nicely crystalline substance melting at 126–127° was obtained. When treated with 0.02 *N* sodium hydroxide this product showed no acidic properties. A mixed melting point with the substance obtained from friedelin by oxidation showed no depression.

Anal. Calcd. for $C_{30}H_{50}O_3$: C, 78.54; H, 11.00. Found: C, 78.49, 78.65; H, 11.09, 11.08.

Methyl Friedonate.—One gram of friedonic acid (m. p. 205–207°) was dissolved in 50 ml. of methyl alcohol containing 0.1 g. of dissolved sodium. Five ml. of methyl sulfate was added and the mixture refluxed for one and one-half hours. Half of the solvent was evaporated, the mixture diluted with 100 ml. of water, and extracted twice with ether. The solid obtained by the removal of the ether was recrystallized from methyl alcohol, from which it formed silky needles, which after several recrystallizations melted at 157–158°.

Anal. Calcd. for $C_{31}H_{52}O_3$: C, 78.75; H, 11.09; methoxyl, 6.56. Found: C, 78.58, 78.87; H, 11.08, 11.22; methoxyl, 6.58, 6.52.

Methyl friedonate also was prepared from sodium friedonate by the action of methyl iodide, and from friedonic acid by use of diazomethane. Melting points and mixed melting points of all samples were the same.

Reduction of Friedonic Acid. Friedololactone.—Friedonic acid (0.5 g.) was hydrogenated in glacial acetic acid in the presence of Adams platinum catalyst. Twelve hours were required to complete the reduction. The catalyst was filtered off and the resulting solution was diluted with water (100 ml.). The jelly-like precipitate was filtered, dried, and recrystallized from ethyl acetate to a melting point of 308–312°. This product showed no depression in melting point when mixed with friedololactone previously obtained.[3]

Methyl Friedonate from "Isomer A."—One gram of "isomer A" (m. p. 126–127°) when treated with sodium methoxide and dimethyl sulfate in the same manner as friedonic acid above, yielded a product which after several recrystallizations from methyl alcohol melted at 157–158°. A mixed melting point with methyl friedonate prepared from pure friedonic acid showed no depression.

Norfriedelene.—Friedonic acid (2.93 g.) was heated in an atmosphere of nitrogen for two and one-half hours at 250°. The water and carbon dioxide evolved were collected and weighed in absorption tubes. The melt was cooled and the solid material obtained recrystallized three times from an ethyl acetate–benzene mixture to a constant melting point of 228.5–230°. The product, of which 1.82 g. was obtained, gave a yellow color with tetranitromethane, showing the presence of unsaturation.

Anal. Calcd. for $C_{29}H_{48}$: C, 87.79; H, 12.21. Found: C, 87.75, 87.94; H, 12.28, 12.26.

Norfriedelane.—One-half gram of norfriedelene was hydrogenated in ethyl ether–ethyl acetate solution in the presence of 0.1 g. of Adams platinum catalyst. After five hours the hydrogenation was complete; the solvent was removed and the product recrystallized from benzene to constant melting point. Norfriedelane gave no color with tetranitromethane and melted at 220–221°; it crystallized as colorless needles having a slight oblique extinction (about 3.2°).

Anal. Calcd. for $C_{29}H_{50}$: C, 87.36; H, 12.65. Found: C, 87.41, 87.44; H, 12.79, 12.82.

Norfriedonic Acid.—Two grams of powdered norfriedelene, 3 g. of powdered potassium permanganate, and 120 ml. of glacial acetic acid, previously distilled from chromic anhydride, were stirred vigorously for eight hours at room temperature. Five grams of sodium bisulfite was added and the mixture diluted with 400 ml. of water. The acid was extracted with ether and converted into sodium salt by addition of 10% sodium hydroxide. The mixture was centrifuged, separated, and the sodium salt acidified with hydrochloric acid. After several crystallizations from ethyl alcohol, 0.75 g. of acid melting at 215–217° was obtained. The residues from crystallizations contained 0.95 g. of amorphous material which could not be induced to crystallize.

Anal. Calcd. for $C_{29}H_{48}O_3$: C, 78.31; H, 10.89. Found: C, 78.20, 78.27; H, 11.02, 11.03.

Norfriedonic acid crystallizes in the form of colorless needles having parallel extinction.

Methyl Norfriedonate.—Esterification of norfriedonic acid by dimethyl sulfate and alkali and by diazomethane yielded a product which melted at 166–167°.

Anal. Calcd. for $C_{30}H_{50}O_3$: C, 78.54; H, 11.00; mol. wt., 458. Found: C, 78.52, 78.63; H, 10.87, 10.94; $-OCH_3$, 6.87, 6.78; mol. wt. (from $-OCH_3$), 452, 458.

Norfriedololactone.—Norfriedonic acid (0.1 g.) was dissolved in 10 ml. of *n*-propanol; the mixture was refluxed and 0.05 g. of sodium added. After cooling, the mixture was diluted with 30 ml. of water and made acid to Congo red with concd. hydrochloric acid. The white precipitate was filtered and recrystallized from ethyl acetate; 10 mg. of a product melting at 288–290° was obtained. This product showed no depression in melting point when mixed with norfriedololactone obtained in earlier work.[3]

The Oxime of Norfriedonic Acid.—Norfriedonic acid (0.25 g.) and 0.15 g. of hydroxylamine hydrochloride were dissolved in 10 ml. of ethyl alcohol. A solution of 0.15 g. of potassium hydroxide in 5 ml. of ethyl alcohol was added and the mixture was refluxed for thirty minutes. The resulting mixture was diluted with water (25 ml.) and acidified with 10% sulfuric acid. The solution was extracted twice with benzene and ethyl alcohol mixture (90–10). The solvent was removed and the solid residue recrystallized from a benzene–ethyl alcohol mixture (50–50). The oxime (0.22 g.) melted at 270.5–273°, and crystallized as colorless needles having parallel extinction.

Anal. Calcd. for $C_{29}H_{49}O_3N$: C, 75.75; H, 10.73. Found: C, 75.94, 75.93; H, 10.83, 10.90.

The Oxime of Methyl Norfriedonate.—Methyl norfriedonate (0.2 g.) and 0.15 g. of hydroxylamine hydrochloride were dissolved in 5 ml. of pyridine and allowed to stand at room temperature for twenty-four hours. The mixture was then diluted with water, filtered, and washed well with water. The product (0.17 g.) was recrystallized from methyl alcohol. The oxime melted at 193–195°, and crystallized in the form of colorless prisms having parallel extinction.

Anal. Calcd. for $C_{30}H_{51}O_3N$: C, 76.04; H, 10.86. Found: C, 75.93, 75.85; H, 11.01, 10.72.

The 2,4-Dinitrophenylhydrazone of Methyl Norfriedonate.—Methyl friedonate (0.2 g.) was dissolved in 5 ml. of ethyl cellosolve and 0.12 g. of 2,4-dinitrophenylhydrazine dissolved in 5 ml. of cellosolve was added to this solution; two drops of concd. hydrochloric acid was then added and the mixture refluxed for five minutes. The solution was allowed to stand overnight to complete crystallization, and the product formed was recrystallized from ethyl alcohol–benzene mixtures; it (0.15 g.) melted at 233–234°, and formed bright yellow prisms having oblique extinction.

Anal. Calcd. for $C_{36}H_{53}N_4O_6$: C, 67.62; H, 8.38. Found: C, 67.36; H, 8.40.

Norfriedelanylformaldehyde (I).—One gram of friedonic acid and 5 ml. of thionyl chloride were heated to reflux on a steam-bath for about thirty minutes. Excess thionyl chloride was removed *in vacuo* and the residue was placed in a desiccator over potassium hydroxide for forty-eight hours; the acid chloride could not be induced to crystallize. Xylene (15 ml.), previously dried over sodium, was added along with 2 g. of palladium–barium sulfate catalyst[11] and hydrogen was passed through the mixture at 150° for seven hours during which time 1 g. of fresh catalyst was added; the hydrogen chloride evolved was collected and titrated with 0.05 *N* sodium hydroxide. The quantity of hydrogen chloride produced was approximately 85% of that calculated for one mole per mole of substance. The solvent was removed under reduced pressure, and the partially crystalline mass was treated with ethyl acetate. After several recrystallizations from ethyl acetate, 0.20 g. of a substance which melted at 222–225° and crystallized in the form of colorless prisms having a slight oblique extinction (extinction $\angle$ *ca.* 19.4°) was obtained. From the mother liquors 0.3 g. of friedonic acid was recovered via its sodium salt.

Anal. Calcd. for $C_{30}H_{50}O$: C, 84.43; H, 11.82. Found: C, 84.51, 84.66; H, 11.80, 12.10.

The Oxime of I.—Prepared in the usual way, this oxime was purified by several recrystallizations from ethyl acetate. It separates from ethyl acetate in the form of very small colorless crystals which melt at 255–259°.

Anal. Calcd. for $C_{30}H_{51}NO$: C, 81.57; H, 11.65. Found: C, 81.50, 81.64; H, 11.62, 11.54.

The 2,4-Dinitrophenylhydrazone of I.—Fifty mg. of I was dissolved in 5 ml. of ethyl cellosolve and mixed with a solution of 25 mg. of 2,4-dinitrophenylhydrazine in 5 ml. of ethyl cellosolve. One drop of concd. hydrochloric acid was added and the mixture refluxed for fifteen minutes during which time yellow needles separated from the mixture. After several recrystallizations from benzene 36 mg. of substance melting with decomposition at 312–314° was obtained. This material crystallized as bright yellow needles having parallel extinction.

Anal. Calcd. for $C_{36}H_{54}N_4O_4$: C, 71.26; H, 8.97. Found: C, 71.13, 71.21; H, 8.84, 8.85.

Norfriedelanylformic Acid.—To 0.3 g. of I dissolved in 50 ml. of glacial acetic acid at 100° was added a solution of 60 mg. of chromic anhydride dissolved in 30 ml. of acetic acid. The mixture was then evaporated to 20 ml. total volume and diluted with 50 ml. of water. The crystals formed were filtered, dried, dissolved in ether, and the ethereal solution extracted twice with 10% sodium hydroxide solution. The aqueous layer was centrifuged and acidified with hydrochloric acid. The solid formed was filtered and recrystallized from glacial acetic acid. The product was an acid (0.22 g.), which crystallized in the form of long colorless needles having parallel extinction and melted at 307–308°.

Anal. Calcd. for $C_{30}H_{50}O_2$: C, 81.37; H, 11.39. Found: C, 80.90, 81.10; H, 11.40, 11.46.

Methyl Norfriedelanylformate.—Norfriedelanylformic acid (0.04 g.) was dissolved in 10 ml. of methyl alcohol containing 0.05 g. of dissolved sodium. One ml. of dimethyl sulfate was added. The mixture was refluxed for one-half hour and crystals formed from the boiling mixture. The cooled mixture was filtered, and the crystals dried and recrystallized from a mixture of pyridine and methyl alcohol. Twenty-five mg. of methyl ester melting at 230–231.5° was obtained. This substance crystallizes in the form of very thin plates having parallel extinction.

Anal. Calcd. for $C_{31}H_{52}O_2$: C, 81.51; H, 11.49. Found: C, 81.15; H, 11.47.

Summary

1. An isomer of friedonic acid, called for the present "isomer A," has been isolated and its conversion to methyl friedonate described.

2. Pyrolysis of friedonic acid has been shown to result in the production of an unsaturated hydrocarbon, norfriedelene, which has been hydrogenated to norfriedelane.

3. Oxidation of norfriedelene was found to yield norfriedonic acid, a monobasic keto acid of which carbonyl and carboxyl derivatives have been made.

4. Reduction of friedonyl chloride has been shown to result in the formation of an aldehyde isomeric with friedelin. The aldehyde has been oxidized to the corresponding acid.

5. Friedonic acid is apparently an epsilon-keto acid containing a highly blocked carbonyl group.

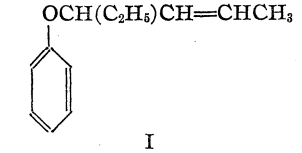
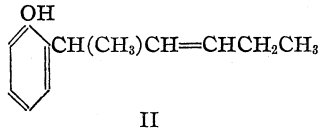
The Chemistry of Vitamin E. XIX. Alkenylation of Phenol with 4-Chloro- and 4-Bromo-2-hexene; Rearrangement of the Phenyl Ether[1]

BY LEE IRVIN SMITH, HERBERT E. UNGNADE, WALTER M. LAUER AND ROBERT M. LEEKLEY

α-Ethylcrotyl phenyl ether (I) was obtained by Hurd and Cohen[2] by action of 4-chlorohexene-2 upon an acetone solution of phenol in the presence of potassium carbonate.



I

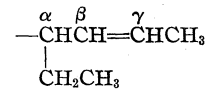


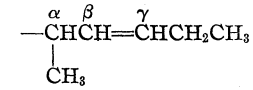
II

When distilled under reduced pressure, the ether partially rearranged into a phenol which was regarded as *o*-(α,δ-dimethylcrotyl)-phenol, II.

Incidental to the synthesis and examination of substances related in structure to the tocopherols, we have repeated the synthesis of the ether I and have determined the structures of two of the by-products formed along with the ether I. The ether was prepared both from 4-chloro- and 4-bromohexene-2 and phenol under varied conditions. The product was always a mixture, which consisted of the ether I along with mono- and dialkenylphenols. The disubstitution product was formed in fairly large amounts when equimolecular proportions of the phenol and halide were used, but the amount of this could be diminished by using an excess of phenol. The mixture was separated readily by extracting the monoalkenylphenol with aqueous alkali, followed by extraction of the dialkenylphenol with Claisen's alkali.[3] The phenyl ether which was not extracted by the alkali was purified by high vacuum distillation, for only under these conditions could it be obtained free from phenolic impurities. The ether was found to undergo rearrangement even at 100° at a measurable rate: at this temperature, 0.88% of the ether rearranged in twenty-four hours, while at 120°, rearrangement proceeded to the extent of 9.6% in twenty-four hours. These results support the observation of Hurd and Cohen[2] that the ether rearranges during distillation.

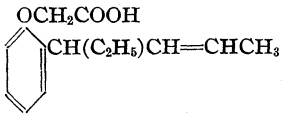
In order to ascertain whether or not the various products were homogeneous, the phenyl ether, monoalkenylphenol and dialkenylphenol were ozonized. Reductive cleavage of the ozonides gave mixtures of aldehydes in each case and it therefore appears that the compounds are not pure. All of them are probably mixtures of α,γ-allylic isomers containing the following groupings



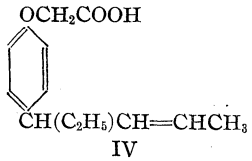


Oxidation of the ether likewise led to a mixture of phenoxy acids; a mixture also resulted on reduction to the saturated ether, the constants of which differed somewhat from those given for 3-phenoxyhexane by Hurd and McNamee.[4] Cyclization of the mixture of monoalkenylphenols with pyridinium chloride gave an alkali-insoluble product which was a mixture, probably of isomeric chromans.

The monoalkenylphenol portion was converted to aryloxyacetic acids by reaction of their sodium salts with ethyl bromoacetate. From the mixture of aryloxyacetic acids so obtained, there was isolated, after many crystallizations, small amounts of two pure isomeric acids, $C_{14}H_{18}O_3$, one melting at 95.2–96° and the other at 110–110.5°. These acids both gave acetaldehyde and small amounts of formaldehyde upon ozonolysis; it appeared therefore that both contained the α-ethylcrotyl group and hence the isomerism did not lie in the nature, but rather in the position, of the side chain. If so, one acid must be the ortho compound III, and the other the para compound IV.



III



IV

Acting upon this assumption, the unsaturated

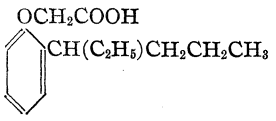
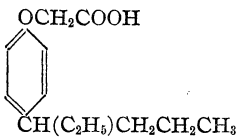
acids III and IV were reduced to the saturated acids, and these two saturated acids, V and VI, were synthesized.



V



VI

The synthetic acids were identical with the acids obtained from the monoalkenylphenols; it follows therefore, that among the monoalkenylphenols obtained by action of a 4-halo-2-hexene and potassium carbonate upon phenol in acetone there are two which contain the α-ethylcrotyl group in the *o*- and *p*-positions, respectively, to the hydroxyl group. These results, however, are not sufficient to map the course of the reaction beyond the data given, for the acids III and IV were obtained only in small amounts and it is certain that other substances were present in the monoalkenylphenol portion of the reaction product.

The dialkenylphenol portion of the product was also a mixture. In view of the complexity of the monoalkenylphenol mixture, the dialkenylphenol portion must be very complicated indeed. No pure compounds were isolated from this mixture but because of its complex nature and because our interest lay more in the monoalkenylphenols and the cyclic compounds derived from them, not a great deal of work was done upon it. The components of the mixture were, however, all 2,6-dihexenylphenols, because the mixture was insoluble in aqueous alkali, soluble only in Claisen's alkali, was phenolic, and could not be rearranged by heating. The insolubility in aqueous alkali eliminates a 2,4-dialkenylphenol, for these are completely soluble. The constituents of the mixture, therefore, must be related as stereoisomers, or allylic isomers, or both.

All of the products obtained from the reaction between phenol and the unsaturated halides were tested by Dr. H. M. Evans for vitamin E activity.[5] The phenyl ether I, as well as the monoalkenylphenols and the isomeric cyclic compounds derived from them, were inactive in 50-mg. doses. The dialkenylphenol, however, was active when fed at this level.

Experimental Part[6]

Hexene-2-ol-4.—The procedure given by Hurd and Cohen[2] was followed, 3 moles of ethylmagnesium bromide being added to 2 moles of crotonaldehyde. This resulted in a decrease of secondary products. The yield was 128–133 g., b. p. 60–60.5° under 21 mm., 64–65° under 25 mm.; $n^{20}D$ 1.4345–1.4346.

4-Chloro-2-hexene.—The alcohol (132 g.) containing anhydrous sodium sulfate (50 g.) was cooled in ice and salt and dry hydrogen chloride was passed into it. When saturated, the mixture was allowed to stand for several hours at 0°, when it was again saturated with the gas, increasing the weight a total of 53.5 g. The mixture was allowed to stand overnight at 0°. Water was added, the oily layer was separated, washed with water, then with dilute bicarbonate and dried over potassium carbonate. Fractionation of this oil gave 111 g. of product boiling at 66–67° under 110 mm.; $n^{20}D$ 1.4385; $n^{20}D$ 1.4382 for a specimen prepared from the alcohol and phosphorus pentachloride.

4-Bromo-2-hexene.—The alcohol (42 g.) and aqueous hydrobromic acid (250 g., 40%) were allowed to stand, with frequent shaking, for twenty-four hours. Water was added and the oil worked up as described for the chloro compound above. Fractionation under 20 mm. pressure gave 7 g. of the monobromo compound, b. p. 35–39°, and 30 g. of the dibromo compound, b. p. 90–110°. Although the yield was poor, the product, contrary to the statement of Hurd and Puterbaugh,[2b] could be obtained this way. The procedure used for the chloride was not tried for preparation of the bromide, but in view of our success with this method generally for converting allylic alcohols to halides[7] we believe that a good yield of the bromide could be obtained using gaseous hydrogen bromide at 0°. However, it remains to be established whether or not this bromide (and also the chloride) is a pure substance or a mixture of allylic isomers.

Phenyl α-Ethylcrotyl Ether I (and Allylic Isomer).—Phenol and potassium carbonate were placed in a flask equipped with an efficient reflux condenser. The halide was added to the cooled (0°) mixture, which was then refluxed until a negative Beilstein test was obtained. Water and petroleum ether were added, and the aqueous layer was removed and extracted with petroleum ether. The combined organic layers were extracted several times with aqueous sodium hydroxide (10%) and then with Claisen's alkali. The residual petroleum ether solution was washed with water and dried over potassium carbonate. After removal of the solvent, the ether I was distilled under high vacuum. The phenols in the aqueous alkaline extraction were precipitated by passing carbon dioxide into the solution. These were removed by ether extraction. The extracts were dried over potassium carbonate, the solvent was removed and the residue was distilled. The Claisen's alkali extracts were diluted with water, acidified with sulfuric acid and extracted with ether. After drying over sodium sulfate the ether was removed and the residue was distilled. The results of several experiments are given in Table I, and the properties of the compounds are given in Table II.

Cyclization of the Monoalkenylphenols.—The monoalkenylphenol fraction (6 g.) was refluxed with pyridinium chloride (1 g.).[8] The initial b. p. was 222°; after sixty

TABLE I

RESULTS OF ALKENYLATION EXPERIMENTS

Phenol, g.	Halide, g.	K_2CO_3, g.	Acetone, cc.	Time, hrs.	Phenyl ether	Products, g. Mono alkenyl-phenol	Di-alkenyl-phenol
8.0	(Cl) 10	11.7	20	4	5.0[a]	..	..
5.0	(Br) 7	7.3	16	8	6.0[a]	..	..
183.0	(Cl) 229	268.0	200	8	60.0[a]	45	48
94.0	(Cl) 111	140.0	150	24	47.0	22	5

[a] Part of the ether was lost in these experiments by rearrangement during distillation. Thus, the 60 g. of ether in run 3 (distilled under 18 mm. pressure), was accompanied by 45 g. of high boiling material (b. p. 128–168° under 18 mm.) which contained 13 g. of alkali soluble phenol, b. p. 129–132° under 15 mm., $n^{20}D$ 1.5292. The alkali insoluble remainder of the 45 g. was redistilled; this gave 15 g. of the ether and 13 g. of the higher boiling, alkali insoluble, rearrangement product.

TABLE II

PROPERTIES OF ALKENYLATION PRODUCTS

Compound	B. p., °C.	p, mm.	$n^{20}D$
Phenyl ether I[a]	103 –106	13	1.5059
	116 –120	18	1.5054
	34.5– 35.5	10^{-5}	1.5053
Monoalkenylphenols	135 –137	10	1.5296
	141 –144	12	1.5299
Dialkenylphenols[b]	169 –170	9	1.5220
	175 –179	11	1.5224
	60	10^{-6}	1.5225

[a] The pure phenyl ether shows 0.9 mole of active hydrogen in the Grignard machine. This is probably due to cleavage by the Grignard reagent: see Lüttringhaus, *et al.*, *Ber.*, **71**, 1673 (1938). The authors are indebted to W. W. Prichard for this analysis.

[b] d^{20}_{20} 0.9394; *MR* calcd., 82.31; found, 83.83. *Anal.* Calcd. for $C_{28}H_{26}O$: C, 83.72; H, 10.08. Found: C, 83.62; H, 9.93. The density and refractive index values of this dihexenylphenol as functions of the temperature lie closely on straight lines.

minutes the b. p. dropped to 216° and remained constant. The product boiled at 106–108° under 10 mm.; $n^{20}D$ 1.5225. It was insoluble in alkali.

Conversion of the Monoalkenylphenols to Aryloxyacetic Acids.—The monoalkenylphenol fraction (3.391 g.) and ethyl bromoacetate (5 cc.) were added to a solution of sodium ethoxide (0.45 g. of sodium in 20 cc. of ethanol). The mixture was refluxed for six hours. Aqueous sodium hydroxide (10 cc., 25%) was added and the mixture was refluxed for four hours longer. The alcohol was distilled out under reduced pressure and the solid residue removed and dissolved in water. Addition of acid precipitated the aryloxyacetic acids (4.340 g.). These did not reduce mercuric acetate in hot acetic acid, hence the double bond had not shifted toward the ring.

The mixture of acids was fractionally crystallized alternatively from petroleum ether and from aqueous acetic acid. After many crystallizations (approximately 30) small amounts (80–100 mg.) of two pure acids were obtained. These were III and IV, melting at 110–110.5° and 95.2–96°, respectively.

Anal. Calcd. for $C_{14}H_{18}O_3$: C, 71.80; H, 7.69. Found (III, m. p. 110–110.5°): C, 71.93; H, 7.99. Found (IV, m. p. 95.2–96°): C, 71.84; H, 7.99.

Ozonolysis.—The acid III (20 mg.) in chloroform (60 cc.) was ozonized at 0°. The ozonide was reductively cleaved using essentially Whitmore's method[9] and the volatile aldehyde was distilled into aqueous dimethone solutions (1%). The crude precipitate (35 mg.) was crystallized first from aqueous ethanol and then from petroleum ether. The bulk of the product was acetaldehydedimethone, m. p. 138–139°; mixed m. p. with an authentic specimen (m. p. 140–141°), 139–140°. A small amount (about 1 mg.) of formaldehydedimethone, m. p. 168–170°, also was obtained. Acid IV (20 mg.) was similarly treated; the crude dimethone weighed 35 mg. and it consisted almost entirely of acetaldehydedimethone, m. p. 138.5–139.5°; mixed m. p., 139.5–140.5°. A trace of formaldehydedimethone, m. p. 178–180°, was also obtained.

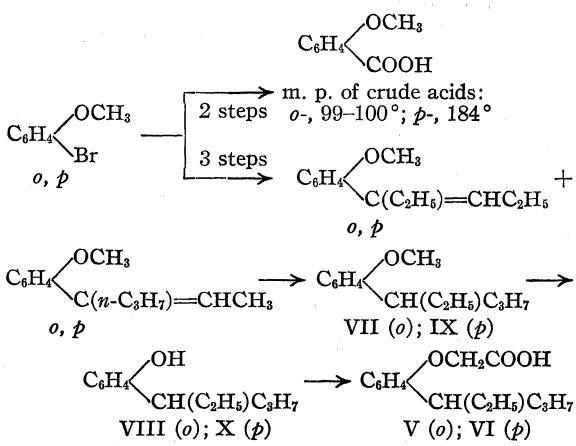
Reduction.—The pure acid III, m. p. 110–110.5°, (85 mg.) was reduced in absolute ether using a platinum oxide catalyst. After removal of the catalyst, the solvent was evaporated. The crystalline residue was taken up in ether and extracted with aqueous sodium bicarbonate (10%). Acidification of the aqueous layer precipitated ***o*-(3-hexyl)-phenoxyacetic acid** (V). After several crystallizations from petroleum ether, the acid melted at 65–66° although not sharply. Unfortunately there was insufficient material for further purification. The synthetic acid (see below) when first obtained melted at 65°; when completely purified, it melted sharply at 75–76°. The isomeric acid IV, m. p. 95.2–96° (120 mg.) was catalytically reduced in methanol using a platinum oxide catalyst. The product, an oil, was the methyl ester of the reduced acid. This was hydrolyzed by warming it for thirty minutes with aqueous sodium hydroxide (5 cc., 10%) and ethanol (5 cc.). Acidification of the mixture produced an oil which was removed by ether extraction. The ether solution was extracted with sodium bicarbonate; acidification of the bicarbonate solution precipitated ***p*-(3-hexyl)-phenoxyacetic acid** (VI) which was recrystallized from petroleum ether. It melted at 81–82°; when mixed with the synthetic acid (m. p. 82–83° see below) it melted at 81–83°.

Synthesis of *o*- and *p*-(3-Hexyl)-phenoxyacetic Acids. (V and VI.)—Since these acids were *o,p*-isomers, it was very important that the two bromoanisoles, *o*- and *p*-, be absolutely pure and not contaminated with each other. *o*-Bromophenol, prepared according to "Organic Syntheses"[10] from phenol, was converted into *o*-bromoanisole,

(9) Whitmore, THIS JOURNAL, **54**, 3711 (1932); **56**, 180 (1934).
(10) *Org. Syntheses*, **14**, 15 (1934).

but this product gave, via carbonation of the Grignard reagent, an *o*-anisic acid most of which melted at 92°, but which did not melt completely even at 105°. Recrystallization from petroleum ether did not give a product with a better m. p. Accordingly, it was decided to synthesize *o*-bromoanisole by a method involving intermediates the purity of which could be checked at each step. The routes from the bromoanisoles to the acids V and VI involved the same steps; these are shown in the chart.

SYNTHESIS OF *o*- AND *p*-(3-HEXYL)-PHENOXYACETIC ACIDS V AND VI



Ortho Series (experimental by H. E. UNGNADE)

***o*-Nitroanisole** (150 g.) in ethanol (100 cc.) was reduced with hydrogen (1200 lb. (80 atm.) pressure) at 100° in the presence of Raney nickel. The yield of ***o*-anisidine,** b. p. 100–101° under 9 mm., was 102 g. This anisidine gave an acetyl derivative which, without purification, melted at 85–86°.[11] The anisidine was converted to *o*-bromoanisole through the Sandmeyer reaction, according to the procedure of "Organic Syntheses"[12]; the yield of *o*-bromoanisole, b. p. 214–215°, was 100 g. One gram of this material was converted to the Grignard reagent, which was then carbonated. The crude *o*-anisic acid so produced melted at 99–100°.[13]

Hexanol-3.—To a Grignard solution prepared from ethyl bromide (93.8 g.) and magnesium (20.6 g.) was added purified butyraldehyde (62 g.). The product, isolated and purified in the usual way, boiled at 132–135° and weighed 40 g.

Hexanone-3.—The hexanol (40 g.) was oxidixed by dropping it, with stirring, into sodium dichromate (81.6 g.) in sulfuric acid (68 g.) and water (400 cc.) at such a rate that the temperature was maintained at 50–55°. The upper layer was separated, the aqueous layer was extracted with ether and the ether extract was combined with the organic layer. The solution was washed with sodium hydroxide solution (10%), then once with water and finally with calcium chloride solution. After drying over calcium chloride, the ether was removed and the residue fractionated. The main fraction (34 g.) was hexanone-3, b. p. 121–123.5°.

3-(*o*-Methoxyphenyl)-3-hexanol and *o*-Hexenylanisoles.—*o*-Bromoanisole (56 g.) was converted into the Grignard reagent, and to this was added hexanone-3 (30 g.) in ether. The product was isolated in the usual way, but the carbinol was not purified. Instead, it was distilled at atmospheric pressure with sulfuric acid (2 drops). The distillate was washed with sodium carbonate, then with water, and dried over calcium chloride. Fractionation gave 40 g. of a mixture of ***o*-hexenylanisoles** boiling at 120–125° under 14 mm.

***o*-(3-Hexyl)-anisole, (VII).**—The unsaturated anisole mixture (40 g.) was reduced in methanol (100 cc.) by hydrogen (42 lb. (3 atm.) pressure) in the presence of a platinum oxide catalyst. The product (37 g.) boiled at 104–105° under 9 mm.

Anal. Calcd. for $C_{13}H_{20}O$: C, 81.42; H, 10.41; *MR* calcd., 60.3. Found: C, 81.38; H, 10.77. $n^{20}D$ 1.4975–1.4976; d^{20}_{20} 0.9242; *MR* found, 60.8.

***o*-(3-Hexyl)-phenol, (VIII).**—The methoxy compound VII (10 g.), hydriodic acid (32 g., d. 1.50), acetic acid (70 cc.) and acetic anhydride (5 cc.) were refluxed for two hours. The mixture became homogeneous after an hour and a half. The cooled mixture was made alkaline with aqueous sodium hydroxide, and the phenol was liberated by passing a stream of carbon dioxide into the alkaline solution. The mixture was extracted with ether, the extract was thoroughly washed with water and dried over magnesium sulfate. After removal of the ether, the residue was distilled. The phenol VIII (5 g.) boiled at 109–111° under 10 mm. It was colorless, possessed a faint aromatic odor and was fairly soluble in 5% aqueous alkali.

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.89; H, 10.18; *MR* calcd., 55.8. Found: C, 80.27, 80.10; H, 9.55, 10.22; $n^{20}D$ 1.5099; d^{20}_4 0.9531; *MR* found, 55.8.

***o*-(3-Hexyl)-phenoxyacetic Acid (V).**—Ethyl bromoacetate (5 cc.) was added to a solution of the phenol VIII (3.56 g.) in sodium ethoxide (0.46 g. of sodium in 20 cc. of absolute ethanol). Following the procedure described above for the phenol mixture, the acid V (m. p. 65° after one crystallization) was isolated. Crystallized several times from petroleum ether, it melted at 75–76°.

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.19; H, 8.48; neut. equiv., 236. Found: C, 70.81; H, 8.69; neut. equiv., 239.

Para Series (experimental by R. M. LEEKLEY)

***p*-Bromophenol** was prepared according to "Organic Syntheses"[12] (p. 123) and was converted to *p*-bromoanisole by a procedure also given in "Organic Syntheses"[12] (p. 50). A small amount of the ***p*-bromoanisole** was converted to the Grignard reagent and the latter was carbonated. The crude *p*-anisic acid so obtained melted at 184°.[14]

3-(*p*-Methoxyphenyl)-3-hexanol and *p*-Hexenylanisoles.—*p*-Bromoanisole (40 g.) (0.25 mole) in ether (150 cc.) was converted into the Grignard reagent, and to this was added hexanone-3 (20 g., 0.20 mole) in ether (50 cc.). The product was isolated in the usual way and, after re-

(11) Kaufmann, *Ber.*, **42**, 3482 (1909), gives the m. p. as 87–88° after purification.

(12) "Organic Syntheses," Coll. Vol. I, John Wiley & Sons, Inc., New York, N. Y., 1932, p. 131.

(13) Claisen, *Ann.*, **418**, 87 (1919), gives the m. p. as 100–101° after purification.

(14) Oppenheim and Pfaff, *Ber.*, **8**, 893 (1875).

moval of the solvent, a drop of sulfuric acid was added and the residue distilled under atmospheric pressure. The distillate was again distilled from a drop of sulfuric acid, the second distillate was dried over calcium chloride and redistilled under 15 mm. pressure. The portion boiling at 125–130° (23 g.) was a colorless, mobile liquid, $n^{20}D$ 1.5223, consisting of the *p*-hexenylanisoles.

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.04; H, 9.54. Found: C, 82.04; H. 9.52.

***p*-(3-Hexyl)-anisole (IX).**—The above hexene (9.9 g.) in methanol (100 cc.) was reduced with hydrogen (45 lb. (3 atm.) pressure) in the presence of 0.2 g. of palladized calcium carbonate (5% palladium). The catalyst was removed, most of the methanol was evaporated and the residue was washed with water. The oil was separated with a little ether, dried over calcium chloride, and distilled. The hexane (5.4 g.) boiled at 125–125.5° under 15 mm., $n^{20}D$ 1.4988.

Anal. Calcd. for $C_{13}H_{20}O$: C, 81.18; H, 10.49. Found: C, 81.51; H, 10.12.

***p*-(3-Hexyl)-phenol (X).**—The *p*-methoxy compound IX (16.5 g.), acetic acid (40 cc.) and constant boiling hydriodic acid (60 cc.) were refluxed for three and one-half hours. The mixture was made alkaline with aqueous sodium hydroxide (25%) and the alkaline solution was saturated with carbon dioxide to liberate the phenolic product. The mixture was extracted with ether and the ethereal solution was dried over magnesium sulfate. After removal of the ether, the residue was distilled under reduced pressure (14 mm.) from a flask with a short neck. The distillate then was redistilled. The fraction boiling at 134–145° under 14 mm. solidified to a mushy solid which melted slightly above room temperature. It was almost colorless and weighed 5 g.

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.83; H, 10.18. Found: C, 80.51; H, 9.87.

***p*-(3-Hexyl)-phenoxyacetic Acid (VI).**—Ethyl bromoacetate (5 g.) was added to a solution of the phenol X (3.56 g.) in sodium ethoxide (0.46 g. of sodium in 20 cc. of absolute ethanol). Using the procedure described above for handling the phenol mixture, the ethereal solution of acid VI was extracted with saturated sodium bicarbonate. Acidification of the bicarbonate solution produced an oil which solidified when rubbed with a glass rod. The solid was removed and crystallized from petroleum ether, then from dilute acetic acid, and again from petroleum ether. At this point the product weighed 280 mg., but it was not analytically pure. Three more crystallizations from petroleum ether (b. p. 90–100°) gave a product which melted at 82–83°. When mixed with the acid VI (m. p. 81–82°) obtained from the monoalkenylphenol mixture the substance melted at 81–83°.

Anal. Calcd. for $C_{14}H_{20}O_3$: C, 71.19; H, 8.48. Found: C, 71.10; H, 8.63.

Summary

1. Phenol in the presence of potassium carbonate and acetone reacts with 4-chloro- and 4-bromohexene-2 to give mono- and diallylation products as well as a phenyl ether.

2. All of these products are mixtures.

3. The monoalkenylphenol portion of the reaction product contains ortho and para α-ethylcrotylphenol. These phenols were isolated as the corresponding aryloxyacetic acids, which were reduced to the 3-(*o*- and *p*-carboxymethyl)-hexanes, and the structures of these were proved by synthesis.

4. The diallylation product consisting of 2,6-diallylated phenols showed vitamin E activity in 50-mg. doses. The phenyl hexenyl ether, the mono allylated phenols, and the cyclized products derived from them, showed no vitamin E activity.

The Odor of Alkoxy Diphenyls

BY C. M. BREWSTER AND IVAN J. PUTMAN, JR.

In a study of the osmophoric properties of ethers it seemed of interest to examine alkyl ethers of the hydroxy-diphenyls, as few compounds of this class have been prepared or studied, and the substitution of a phenyl radical for a nuclear hydrogen atom might be expected to weaken the strong odor of the mononuclear phenolic ethers.

Durrans[1] in his extensive survey of the odors of organic compounds stated that while etherification nearly always produces compounds of pleasant aromatic odor, the replacement of the hydroxyl hydrogen by an alkyl group may or may not strengthen the odor. In methyl *p*-tolyl ether, for example, the odor is strengthened, but in eugenol methyl ether the introduction of the same alkyl group markedly weakens the odor. We have found little difference in intensity of odor between the alkyl ethers and the unsubstituted phenols in the present series of compounds.

(1) Durrans, *Perf. Ess. Oils Rec.*, **10**, 104–136 (1919).

The most unusual fact in connection with the odor of these ethers is that in each case the ortho compound is stronger in odor than the para, although even with the ortho ethers the odor is faint, whether examined at room temperature or heated to 100°. This is contrary to the results summarized by Durrans, who found that in most instances the para ether has the stronger odor.

Unsaturation in the substituted alkyl group does not seem to be of great importance; a slight strengthening of odor was noted in the allyl ethers, without appreciable change in character.

There is no marked difference in procedure in making the ethers described in this paper, except that the reactions take place more slowly and with greater difficulty than in forming the mononuclear ethers,[2] which is to be expected from the greater molecular weight. When a third phenyl group is introduced, as in the benzyl ether of *p*-hydroxydiphenyl, the reactivity is increased since the radical has the effect of an alkyl group.

Experimental

2-Diphenyl-propyl Ether.—A mixture of 15 g. of *o*-hydroxydiphenyl and 3.8 g. of sodium hydroxide was refluxed on a water-bath with 85 cc. of acetone[3] for one hour. Fifteen grams of propyl bromide was added in small portions, and the mixture gently refluxed for six hours. Soon after addition of the propyl bromide a granular precipitate of sodium bromide began to separate. At the end of the reaction the solvent was removed by distillation, and the yellow liquid dissolved in ether, washed twice with water, and the ether solution dried with sodium sulfate. The ether solution was refluxed with activated carbon for one hour, filtered, the ether distilled off and the residual oil fractionated *in vacuo*. The water-white liquid has a faint aromatic odor, b. p. 303°; yield from 15 g. of the phenol, 17 g.

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.85; H, 7.60. Found: C, 84.48, 84.52; H, 7.65, 7.67.

The methyl ether of *o*-hydroxydiphenyl was prepared by the same method, using methyl iodide as the halide. The colorless oil has a faint, slightly pungent fruity-aromatic odor; b. p. 288°. Borsche and Scholten[4] used methyl sulfate; they give the b. p. as 274°; yield from 10 g. of the phenol, 9 g.

The ethyl ether of *o*-hydroxydiphenyl was prepared easily by the method which we used for the propyl ether; the halide used was ethyl bromide. Hönigschmid[5] used a somewhat different procedure; our simpler method gives an equally pure product, m. p. 34°. The odor of the crystals is faint and aromatic, resembling that of the methyl ether, but somewhat sweeter and more flower-like; yield from 10 g. of the phenol, 9 g.

2-Diphenyl-isopropyl Ether.—Ten grams of *o*-hydroxydiphenyl and 2.5 g. of sodium hydroxide were refluxed in 75 cc. of acetone for one hour, then 15 g. of isopropyl bromide was added in small portions, and the reaction mixture gently boiled for six hours. To determine the progress of the reaction, a few drops were removed, the solvent evaporated, the residue shaken with dilute sodium hydroxide and ligroin, and the alkaline layer acidified. The product when refined and fractionated *in vacuo* was a water-white liquid of faint aromatic odor, b. p. 315–317°, with slight decomposition at this temperature; yield from 10 g. of the phenol, 10 g.

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.86; H, 7.60. Found: C, 84.72; H, 8.13.

2-Diphenyl-allyl Ether.—Following the procedure for the propyl ether, allyl bromide was used and almost immediately after the addition of the first portion the solution became cloudy and sodium bromide began to separate. After three hours of refluxing the reaction was complete. The product when purified and fractionated *in vacuo* gave a colorless liquid which has the same pleasant odor as the propyl ether; slightly stronger, but weaker than the ethyl ether. The boiling point is 312°, with slight darkening which begins about 280°. There is no marked change or further decomposition even when the ether is held for one hour at a temperature above 280°. Auwers and Wittig[6] obtained a less stable ether from *o*-hydroxydiphenyl, sodium ethylate and allyl bromide, for when heated to 250° they obtained a green colored oil with bluish fluorescence, and proved that their ether had undergone the Claisen shift. From 12 g. of the phenol we obtained a yield of 13 g. of the ether.

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.67; H, 6.72. Found: C, 85.39; H, 6.79.

2-Diphenyl-benzyl Ether.—When benzyl chloride was condensed similarly, the yield was about 25%, even after refluxing the mixture for six hours. The unchanged benzyl chloride was distilled off, and the residue washed repeatedly with 25% aqueous sodium hydroxide to remove unchanged *o*-hydroxydiphenyl. The pale yellow liquid was dissolved in ether and refluxed with activated carbon; the filtrate was deep orange but on evaporation of the ether and continued drying at 55°, it became light yellow again. It is a nearly colorless, viscous liquid which boils with slight decomposition at 324°; yield, from 12 g. of the phenol, 4 g. At room temperature the compound is practically odorless, but when heated to 100° it has a pleasant nut-like odor.

Anal. Calcd. for $C_{19}H_{16}O$: C, 87.65; H, 6.20. Found: C, 87.46; H, 6.26.

4-Diphenyl-ethyl Ether.—The reaction mixture was prepared and refluxed as for the ortho compound; changes in appearance during the reaction were the same. Acidification of the filtrate gave no precipitate of *p*-hydroxydiphenyl; the yield was nearly quantitative; minute white

(2) We obtained only small yields when alcohol was used as solvent, although with mononuclear phenolic ethers this solvent is quite satisfactory.

(3) Claisen and Eisleb [*Ann.*, **401**, 29 (1913)] recommended the use of acetone as solvent in the preparation of ethers. If a higher boiling point solvent is necessary, methyl ethyl ketone is to be preferred.

(4) Borsche and Scholten, *Ber.*, **50**, 601 (1917).

(5) Hönigschmid, *Monatsh.*, **22**, 569 (1901).

(6) Auwers and Wittig, *J. prakt. Chem.*, **108**, 99–112 (1924).

leaflets from alcohol, m. p. 76°. The compound is odorless; yield from 12 g. of the phenol, 11 g.

Anal. Calcd. for $C_{14}H_{14}O$: C, 84.58; H, 7.36. Found: C, 84.26; H, 7.16.

The methyl ether of *p*-hydroxydiphenyl, first prepared by Werner,[7] was obtained in nearly quantitative yield, using methyl iodide as the halide, m. p. 90°. The very minute water-white granular crystals have no odor.

4-Diphenyl-propyl Ether.—Propyl bromide was condensed with *p*-hydroxydiphenyl as in the preparation of the ortho ether. The product when purified and crystallized from alcohol gave white leaflets, m. p. 76–77°. It is difficultly soluble in petroleum ether; yield from 10 g. of the phenol, 9 g., odorless.

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.85; H, 7.60. Found: C, 84.62, 84.71; H, 7.55, 7.60.

4-Diphenyl-isopropyl Ether.—Isopropyl bromide was used as the halide. The reaction in acetone took place more slowly than in the case of the ortho ether. Dull white needles were obtained from slow evaporation of an alcoholic solution, and hexagonal leaflets from more concentrated solutions; m. p. 73°, odorless; yield from 10 g. of the phenol, 4 g.

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.85; H, 7.60. Found: C, 84.51; H, 7.66.

4-Diphenyl-allyl Ether.—Large transparent leaflets from alcohol; m. p. 86–87°, odorless; yield from 12 g. of the phenol, 14 g. The melted crystals show a slight darkening when heated to 290°, but there is no further decomposition when maintained at or above this temperature for one hour.

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.67; H, 6.72. Found: C, 85.43; H, 6.79.

4-Diphenyl-*n*-butyl Ether.—Butyl bromide was used as the halide. The filtrate on acidification gave negligible quantities of unchanged *p*-hydroxydiphenyl; large white leaflets from alcohol; m. p. 74–75°, odorless; yield from 10 g. of the phenol, 13 g.

Anal. Calcd. for $C_{16}H_{18}O$: C, 85.67; H, 6.72. Found: C, 85.43; H, 6.79.

4-Diphenyl-benzyl Ether.—Using benzyl chloride as halide, the odorless ether was obtained in nearly quantitative yield; from 12 g. of the phenol, 18 g. of the ether was prepared; heavy white plates from alcohol, m. p. 136°.

Anal Calcd. for $C_{19}H_{16}O$: C, 87.45; H, 6.20. Found: C, 87.35, 87.65; H, 6.25; 6.20.

We were not successful in preparing the *s*-butyl, *t*-butyl or *n*-amyl ether by this method using acetone as solvent, nor by trials with copper as catalyst, nor with benzene as solvent. However, preliminary trials with reagents heated in sealed tubes have been attended with some success and will be reported on later.

Summary

Several new alkyl ethers of *o*- and *p*-hydroxydiphenyls have been prepared by a simplified method. The ortho ethers possess a fragrant odor, but the para ethers are odorless.

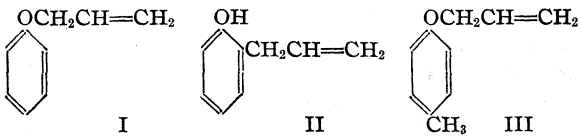
The Claisen Rearrangement. I. A Kinetic Study of the Rearrangement of Allyl *p*-Tolyl Ether in Diphenyl Ether Solution

BY JOHN F. KINCAID AND D. S. TARBELL

The rearrangement of allyl aryl ethers, illustrated by the conversion of allyl phenyl ether (I) to *o*-allylphenol (II), has been investigated extensively since its discovery by Claisen,[1] and numerous features of the reaction mechanism have been established. The object of our work is to make a kinetic study of the rearrangement of allyl ethers of various types to obtain further information about the Claisen rearrangement. We wish to report a study of the kinetics of the rearrangement of allyl *p*-tolyl ether (III) in diphenyl ether solution at 214.7, 200.6, and 185.8°. At the second temperature the effect of acids, bases, and oxygen on the rate was studied, and the rate of the rearrangement of the pure liquid allyl *p*-tolyl ether was measured at the two lower temperatures.



I II III

Experimental

Preparation of Materials

Allyl *p*-tolyl ether was prepared by the method of Hurd and Yarnall,[2] using Eastman redistilled *p*-cresol, allyl bromide, and sodium hydroxide in aqueous acetone solution. The reaction mixture was worked up by the procedure referred to, and in addition the ether was washed several times with sodium hydroxide solution to remove unreacted cresol. The product was distilled through a modified Widmer vacuum-jacketed column at 4 mm. and

(1) Claisen, *Ber.*, **45**, 3157 (1912).

(2) Hurd and Yarnall, THIS JOURNAL, **59**, 1686 (1937).

bath temperature of 110–115°, b. p. 65 ± 1°, due to pressure fluctuations, d^{35}_4 0.9494. A blank determination showed that this sample contained 0.5% of its rearrangement product or an equivalent amount of acetylatable material. Some of the rate runs were made with a sample of ether prepared in a similar manner containing 1.8% of rearrangement product, but proper corrections were applied in both cases.

Diphenyl ether (Dow technical grade) was stirred overnight with sodium wire while being heated on the steam-bath and the precipitate filtered off; treatment with another batch of sodium gave no appreciable reaction. The material was then stirred with mercury to remove sulfur compounds, but this appeared to be unnecessary, as no darkening of the metal occurred. After removing the mercury by filtration, the diphenyl ether was washed with dilute hydrochloric acid, sodium hydroxide solution, water, dried with calcium chloride, followed by solid potassium hydroxide, and distilled in a nitrogen atmosphere, some samples being distilled at atmospheric pressure, and some in vacuum. A blank determination on this ether showed no acetylatable material present within the experimental error.

The fact that different samples of allyl *p*-tolyl ether and diphenyl ether gave identical values for the rate constant was shown by values of k of 8.03×10^{-5} for a new solution, compared to 8.13×10^{-5} for the stock solution with which most of the runs at 200° were made.

Dimethylaniline was distilled with acetic anhydride, washed free of acid with sodium carbonate solution and water, dried over potassium hydroxide and distilled, b. p. 192–192.5°. A blank determination showed no acetylatable material present.

Method of Analysis.—The reaction was followed by a modification of the Verley and Bölsing[3] method for determining phenols, which consists in the quantitative acetylation of the phenol by a mixture of acetic anhydride and pyridine, followed by the determination by titration of the unused acetic anhydride. An amount of the reaction mixture containing from 0.2 to 0.4 g. of the rearrangement product was weighed into a 50-cc. iodine flask, 2 cc. of an approximately 2 molar solution of acetic anhydride in pyridine was pipetted in, and the mixture heated for an hour on the steam-bath. In order to obtain consistent results, it was found necessary to put a liquid seal of mercury around the stopper, and the stopper was held in place by rubber bands. After cooling, the contents of the flask were transferred to a beaker containing 100 cc. of water, using carbon tetrachloride to rinse the flask, and the acetic acid titrated with 0.2 *N* alkali with vigorous stirring. Since it was impossible to use indicators in the presence of the organic liquids, the titrations were carried out with a Beckmann *p*H meter to a *p*H of 8.6. Analyses of known mixtures showed the average deviation to be about 1%, and the error in analysis was very rarely as great as 2.5%. Runs in which the mixture was heated longer than an hour showed that no appreciable percentage of the ether rearranged on heating for an hour at 100°.

Experimental Procedure.—Preliminary experiments showed that considerable material was lost by evaporation when the rearrangement reaction was carried out in glass-stoppered flasks at 200°, so that the rate constants for longer runs were as much as 25% low. Consequently, the data given below were obtained by a procedure in which each sample was placed in a glass tube, the tube cooled in an ice-bath, and sealed off after being evacuated by an oil pump. In a trial experiment in which a tube containing a one molar solution was pumped out with an oil pump for thirty minutes at room temperature, the constant was only 4% lower than that obtained by the usual technique. Therefore the loss by evaporation during the evacuation of the tubes under the conditions used was negligible. Runs were carried out by completely immersing the sample in a well-stirred oil thermostat, kept constant to 0.1° by a mercury thermoregulator and relay. Constancy of the thermostat temperature was checked by a thermometer reading to 0.1°, and the temperature at each setting of the thermostat was determined by a one-junction copper–constantan thermocouple which was calibrated against the melting point of tin. The temperatures are estimated to have an absolute accuracy of ±0.3°, and to have a relative accuracy of ±0.1°.

The time necessary for the sample to come to the bath temperature after its immersion, estimated from blank experiments, was found to be about two hundred seconds,[4] and this was subtracted from all the observed times of reaction. This figure, although not known very accurately, is important only for the shorter runs.

Isolation of the Product of the Rearrangement.—Forty grams of allyl *p*-tolyl ether was heated in sealed tubes without solvent for thirteen hours at 200°, and analysis in the usual way showed that 97.7% (average of two analyses) of the theoretical amount of the rearrangement product was present. The product (40.3 g.) was distilled in a nitrogen atmosphere through the modified Widmer column at a pressure of two to three mm. and distillation temperature ranging from 68.7 to 73.7°. Each fraction was analyzed in duplicate for phenolic hydroxyl and the molecular weights calculated are given in the table.

RESULTS OF FRACTIONATION

Fraction	Wt., g.	Mol. wt.[a]
1	1.3	151.3
2	16.5	149.2
3	13.1	150.8
4	3.4	148.1
5 (Residue)	2.4	

[a] Molecular weight of 2-allyl-4-methylphenol, 148.2.

Fraction 5 was transferred to a 5-cc. Claisen flask and redistilled, getting 0.8 g., b. p. 76–87° at 2 mm., molecular weight 162.6, and 1.55 g. of undistillable material. The 3.6 g. of material not accounted for was held up in the Widmer column, and evidently was mainly the normal rearrangement product, since fraction 4 had the correct molecular weight. The possibility that the undistillable part of fraction 5 was formed during the distillation rather than during the rearrangement was eliminated by redistilling fractions 1, 2, 3, and 4 under the same conditions, when no non-volatile residue was found.

Effect of Oxygen on the Rearrangement.—Four tubes were prepared to contain varying amounts of air and oxy-

(3) Verley and Bölsing, *Ber.*, **34**, 3354 (1901).

(4) MacDougall, Lauer and Spielman [THIS JOURNAL, **55**, 4089 (1933)] used a correction of three minutes in a similar case.

gen, and the rate measured at 200.2°. Tube 1 contained 1 atm. of pure oxygen, tube 2 was evacuated and sealed by the usual method, tube 3 was alternately frozen and melted two times under vacuum to remove all dissolved gases, and tube 4 had air bubbled through it for thirty hours before being evacuated and sealed as usual. The rate constants after being corrected to 200.6° for the four samples were 7.87, 7.48, 7.41, and 7.89, each multiplied by 10^{-5}. The allyl *p*-tolyl ether employed in these experiments had been freshly distilled to remove any traces of peroxide. While these results indicate that the rate of the rearrangement is not appreciably affected by the presence of oxygen, the occurrence of some side reaction under these conditions is indicated by the yellow color of the reaction mixture. Runs carried out with the usual technique were colorless even after the heating had been continued until the rearrangement was virtually complete.

Experimental Results

TABLE I

FIRST ORDER RATE CONSTANTS AT 200.6°

The results of runs performed at the three temperatures are tabulated in Tables I to III. The first order rate constants k were calculated from the usual equation

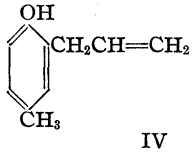
$$k = (1/t)\ 2.303 \log x_0/x \qquad (1)$$

in which x_0 is the initial percentage of reactant and x is the percentage of reactant remaining at time t (in seconds). The results show that the reaction is strictly unimolecular over the range of temperature and concentration studied; at 200.6° the concentrations measured cover a nearly five-fold range, from 4.77 to 22.81% (approximately 0.3 to 1.5 molar), in addition to the measurements on the pure liquid. The first order "constants" for the pure liquid (Tables I and II) show a marked increase as the reaction proceeds, but the initial rate in the pure liquid extrapolates to the same value as in solution. It should be emphasized that the use of equation (1) in this case leads to rate constants for the longer runs which

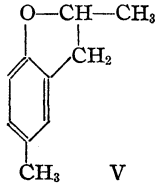
are much too low since a constant value for k is assumed in the integration leading to equation (1). Actually the rate of the rearrangement of the ether in the presence of 80% of 2-allyl 4-methylphenol is more than four times as great as it is at the beginning of the reaction, although the rate constants for 80% reaction given in Tables I and II are only about double the initial values.

The effect of dimethylaniline on the rate is of interest because Claisen[5] stated that better yields were obtained in some cases of the rearrangement when a basic solvent was used, and dimethylaniline is frequently employed as solvent when the reaction is carried out on a preparative scale. As the data in Table I show, 10% of dimethylaniline has no appreciable effect on the rate of the rearrangement.

It seemed likely that the upward drift of the rate constants in the pure liquid was due to the catalytic effect of the phenol formed acting as an acid. To test the possibility that the reaction was acid catalyzed, a run was made using as solvent a 0.81% solution of acetic acid in diphenyl ether, but the rate was not affected appreciably (Table I). The possibility of error due to isomerization[6] of the 2-allyl 4-methylphenol (IV) formed by rearrangement to a coumarane derivative V by the acid present was eliminated by trial runs



IV

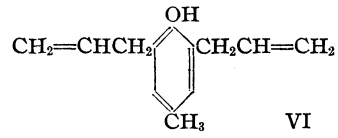


V

with known amounts of the phenol. An attempt to measure the effect of a stronger acid, chloroacetic, failed, because runs with known samples showed the analytical method was not reliable in the presence of chloroacetic acid; the results indicated qualitatively that there was no striking increase in the rate, however.

The rate of rearrangement is not affected by the presence of air or oxygen, as is clear from runs described in the experimental part.

To find whether side reactions take place during the rearrangement, the isolation of the products of the reaction described in the experimental part was carried out. The results show that less than 1% of 2,6-diallyl-4-methylphenol (VI) was



VI

formed, which Hurd and Yarnall[2] isolated in a few per cent. yield from the rearrangement of allyl p-tolyl ether carried out at higher temperature. We obtained 4% of non-volatile rearrangement product, possibly analogous to the dimer[7] isolated from the rearrangement of allyl phenyl ether. The rest of the material isolated, amounting to 87%, was pure rearrangement product, and the material not accounted for which was held up in the still was probably mainly the same thing. Since polymerization should be less important during rearrangement in solution than in the pure liquid, it seems safe to conclude that in solution the reaction is at least 95% quantitative.

Discussion

The energy of activation, ΔE, for the reaction was computed from the mean values of the rate constants for the 14% (1 molar) solutions at the three temperatures. The constants of the Arrhenius equation, $k = A \exp(-\Delta E/RT)$, were found to be 1.60×10^{11} sec.$^{-1}$ and 33.1 kcal./mole for A and ΔE, respectively. These quantities may be interpreted with the aid of the equation due to Eyring[8] for the absolute rate of any reaction

$$k = (kT/h)\,\kappa \exp(\Delta S^{\ddagger}/R) \exp(-\Delta E^{\ddagger}/RT) \quad (2)$$

Here k is Boltzmann's constant, h is Planck's constant, κ is the transmission coefficient and $\Delta S^{\ddagger}$ and $\Delta E^{\ddagger}$ are the entropy and energy of activation, respectively. Following the usual practice of assuming that κ equals unity, we find that $\Delta S^{\ddagger}$ equals -8.1 e. u./mole at 200°, *i. e.*, the activated complex is poorer in entropy by 8.1 units than the normal reactant molecule.

Two structures for the activated complex seem possible. The γ carbon atom on the allyl group might be expected to start to form a bond with the carbon atom ortho to the oxygen simultaneously with the breaking of the carbon–oxygen bond. A second mechanism is one in which the slow step is the breaking of the carbon–oxygen bond, the allyl group being split off as a radical or positive ion, although any mechanism in which the allyl group is ever free seems inconsistent

with the findings of Hurd and Schmerling,[7] who rearranged a mixture of allyl ethers without finding mixed products. The ring closure mechanism would be expected to involve a considerably larger entropy decrease than is observed here, while in the absence of strong solvation effects the second mechanism should involve an entropy *increase* on the formation of the activated complex. Since it seems impossible to prove the exact mechanism from the data available at present, further discussion will be deferred until later papers of this series.

Summary

1. The rate of the rearrangement of allyl *p*-tolyl ether in diphenyl ether solution has been measured at 214.7, 200.6, and 185.8°, the reaction being followed by determination of the phenol formed by quantitative acetylation with pyridine and acetic anhydride.

2. Over this temperature range and for a five-fold change in concentration the reaction is unimolecular, and the initial rate of the rearrangement in the pure liquid is the same as in solution.

3. The rate is not appreciably affected by the addition of 10% of dimethylaniline, 1% of acetic acid, or by the presence of air or oxygen.

4. The energy of activation is 33.1 kcal./mole, the data for the one normal solutions being represented by the expression $k = 1.60 \times 10^{11} \exp(-33.1/RT)$.

5. The rearrangement has been shown to be at least 95% quantitative at 200° in solution.

Sulfonation Reactions with Sulfuryl Chloride

BY M. S. KHARASCH AND ALICE TANNER READ[1]

Introduction

In a recent paper[2] chlorination reactions with sulfuryl chloride were discussed, and it was shown that many types of organic molecules can be chlorinated with this reagent by the use of a peroxide catalyst. If the mechanism which was postulated for that reaction is correct, namely, a chain reaction involving the formation of chlorine atoms and SO_2Cl free radicals, then sulfonation as well as chlorination should take place, by the direct action of the SO_2Cl radical on the hydrocarbon, *i. e.*, sulfuryl chloride should, under the proper conditions, be a sulfonating as well as a chlorinating agent. Although no sulfonation products are isolated from the peroxide-catalyzed reaction, even when the sulfuryl chloride is added slowly (a procedure which minimizes any inhibitory effect of sulfuryl chloride itself), other catalysts have been found which, in the light, give both sulfonated and chlorinated products, the proportion of each being dependent upon the type of catalyst and the conditions used. With the exception of peroxides, which yield only the chlorinated hydrocarbons both in the dark and in the light, none of the catalysts investigated were very active in complete darkness. If the reaction were allowed to continue for some time, a small yield of chlorinated product could be obtained, but in no case did we obtain in the absence of light more than a trace of sulfonated product.

Discussion

Since a free-radical mechanism has been demonstrated in the addition of mercaptans to unsaturated molecules in the presence of oxygen,[3] the mercaptan type of compound seemed a likely catalyst for reactions with sulfuryl chloride. A number of such compounds were tried in preliminary test-tube experiments and found to be effective in starting the reaction. The most promising of these were studied on a larger scale with cyclohexane, which was selected as a suitable hydrocarbon because all the hydrogen atoms in this molecule are equivalent, and the products, cyclohexyl chloride and cyclohexylsulfonyl chloride, are easily separated and identified. In all the reactions in which the mercaptan type of catalyst was used, sulfonation as well as chlorination took place. In order to ascertain the op-

timum conditions for sulfonation, the effects of light, oxygen, sulfur dioxide, water, and concentration of sulfuryl chloride were investigated. The results are given in Table I.

Since even under the optimum conditions the mercaptan-catalyzed reaction gave low yields of cyclohexylsulfonyl chloride, other catalysts for the reaction were sought. In preliminary experiments, a number of anthroquinonesulfonic acids were found to initiate the reaction in the light, but were without effect in the dark. Of these, the potassium salt of anthraquinone-1-sulfonic acid was tried on a larger scale with cyclohexane and gave a 64% yield of the chloride and 4% of the sulfonyl chloride.

Many types of organic nitrogen compounds were tried as catalysts, and in all cases sulfonation as well as chlorination was obtained, except in the presence of those compounds which are bromination and oxidation inhibitors (diphenylamine, *p*-phenylenediamine, etc.) in which case either no reaction at all, or a small amount of chlorination, took place (Table I). Of all the catalysts studied, by far the most effective for sulfonation are the aromatic nitrogen ring compounds, the pyridines and quinolines. With these catalysts, under the proper conditions, the extent of chlorination is greatly reduced and good yields of cyclohexylsulfonyl chloride are obtained.

In Table II are given the results of experiments with hydrocarbons other than cyclohexane. In all aliphatic or aromatic compounds with an aliphatic side-chain, sulfonation in the aliphatic part of the molecule took place. A notable exception is toluene. Attempts to prepare benzylsulfonyl chloride from toluene and sulfuryl chloride, using optimum conditions for sulfonation, and operating at a low temperature (55–60°), were unsuccessful. However, that sulfonation of aliphatic side-chains is possible by this method, is demonstrated by the formation of phenethylsulfonyl chloride in small yields from ethylbenzene,

TABLE II

REACTIONS BETWEEN SULFURYL CHLORIDE AND HYDROCARBONS

[a] Yields are based on the sulfuryl chloride added. [b] The potassium salt was used. The reaction was carried out in strong light. [c] The reaction was carried out in strong light at the boiling point of the hydrocarbon, 99°. [d] The reaction was carried out in strong light; the temperature was kept between 60 and 70°. [e] Benzene was used as a solvent; the reaction was carried out in strong light and the sulfuryl chloride was added dropwise. [f] The reaction mixture was refluxed in strong light.

and of fair yields of 2-phenyl-2-methyl propylsulfonyl chloride from *t*-butylbenzene.

It is fairly well established that in the peroxide-catalyzed chlorinations with sulfuryl chloride the aliphatic side-chain of the aromatic hydrocarbon is always the point of attack. We now find the same is true of sulfonation reactions with this reagent. Heretofore, sulfuryl chloride has been used in conjunction with halogen carriers, as an agent for chlorination, and with the aid of aluminum chloride for sulfonation of aromatic nuclei. The above experiments indicate that when the reaction takes place through a free radical mechanism, the aliphatic type of molecule is attacked much more readily than the aromatic. This brings out the striking difference between reagents which can share an electron pair, and act exclusively upon the aromatic nucleus, and reagents, such as atoms and free-radicals, which preferentially attack aliphatic molecules. In this connection it should be noted that benzene, itself, is attacked by sulfuryl chloride in strong light when a catalyst is used, but the only product obtained is hexachlorobenzene. However, when an equimolecular mixture of benzene and cyclohexane is allowed to react with sulfuryl chloride under the same conditions, the benzene is not attacked and good yields of cyclohexylsulfonyl chloride are obtained.[4]

An examination of the foregoing tables discloses the fact that the catalyst, more than any other one factor, determines the course of the reaction. Under similar conditions of light and low sulfuryl chloride concentration, peroxides, as already has been stated, give chlorination exclusively; anthraquinonesulfonic acids give almost entirely chlorination; mercaptans and organic nitrogen compounds give chlorination and sulfonation in varying amounts, the best yields of sulfonation product being obtained with the aromatic nitrogen ring compounds. With any one catalyst, the most favorable conditions for sulfonation are strong light and a low concentration of sulfuryl chloride in the reaction mixture at any one time. Oxygen, which might be expected to inhibit chlorination, inhibits both reactions in diffused light, and has no appreciable effect in strong light, except in the case of the pyridine type of catalyst, where chlorination is somewhat inhibited, but the yield of cyclohexylsulfonyl chloride is not increased. Sulfur dioxide, which, in excess, favors sulfonation when a mixture of sulfur dioxide and chlorine is used as the sulfonating agent,[5] has no effect with sulfuryl chloride in strong light, and inhibits both chlorination and sulfonation in diffused light. The effect of temperature can be seen in the experiments with *n*-heptane (Table II); when the reaction is carried out at the boiling point of the hydrocarbon the proportion of heptylsulfonyl chloride is considerably less than when the temperature is kept at 70°. This is accounted for readily by the fact that sulfuryl chloride is largely dissociated at temperatures above its boiling point, into sulfur dioxide and chlorine[6] and, consequently, some of the reaction takes place through the action of molecular chlorine, rather than through a free-radical mechanism.

(4) With 2-mercaptothiazoline as a catalyst, the yield of sulfonation product was greatly increased by the use of benzene as a solvent, instead of excess cyclohexane, but the effect of benzene as a diluent was not appreciable when the reaction was catalyzed by pyridine.

(5) Reed, U. S. Patent 2,046,090; Kharasch and Alsop, unpublished work.

(6) Trautz, *Z. Elektrochem.*, **14**, 534 (1908).

Although the number of compounds sulfonated by this method is not large, there is little doubt that the reaction is quite general for aliphatic hydrocarbons, and has been extended to alkyl halides and many other types of molecules. Since sulfuryl chloride can now be used either as a sulfonating or a chlorinating agent with aliphatic compounds, it should prove a useful reagent in organic chemistry. The primary purpose of the present investigation, however, was to demonstrate that sulfonation should and does take place when sulfuryl chloride reacts with aliphatic hydrocarbons through a free-radical mechanism.

Experimental Part

The cyclohexane (0.5 mole) and sulfuryl chloride (0.25 mole) were introduced into a 125-cc. round-bottomed flask connected by a ground-glass joint to a Hopkins-type condenser, and brought to a gentle reflux. A small amount of catalyst (0.02–0.12 g.) was added, and the reaction mixture was heated over a low flame until no more gas was evolved. The progress of the reaction was followed by means of a bubble counter attached by a rubber tube to the top of the condenser. No attempt was made to trap any of the reactants swept over with the gases, and in cases where oxygen or sulfur dioxide was bubbled through the mixture during the reaction, the losses were appreciable. After the reaction was complete, the mixture was filtered through a glass-wool plug, and the excess cyclohexane was removed by distillation through an indented column 45 cm. long. The solution was then transferred to a 50-cc. Claisen flask, and the rest of the distillation was carried out at reduced pressure. Cyclohexyl chloride was identified by its boiling point, and cyclohexylsulfonyl chloride by its boiling point and anilide.

The experiments in which the sulfuryl chloride was added slowly, or in which gases were passed through the solution, were carried out in a 125-cc. round-bottomed flask into which was sealed a capillary delivery tube reaching to the bottom of the flask and sealed to a wide neck which held a dropping funnel and gas delivery tube. The flask was connected to the condenser by a ground-glass joint.

The source of illumination was a 2000-watt lamp placed about twelve inches (31 cm.) from the reaction flask. The cyclohexane used was Eastman Kodak Co. practical grade, dried over sodium. The sulfuryl chloride was obtained from the Hooker Electrochemical Company and was not purified further.

The identification of *n*-heptylsulfonyl chloride, and phenethylsulfonyl chloride was made by conversion to the amides.

Summary

1. Simultaneous chlorination and sulfonation of aliphatic hydrocarbons with the aid of sulfuryl chloride, a catalyst, and light is recorded.

2. It is shown that aromatic nitrogen ring compounds when used as catalysts in this reaction, favor the formation of the aliphatic sulfonyl chlorides.

3. The mechanism of the reaction is discussed.

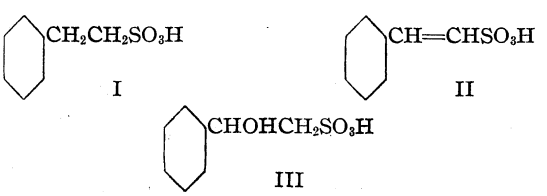
The Peroxide Effect in the Addition of Reagents to Unsaturated Compounds. XXIII. The Reaction of Styrene with Bisulfite

BY M. S. KHARASCH, REMSEN TEN EYCK SCHENCK AND F. R. MAYO

A recent paper from this Laboratory discussed the addition of bisulfite to various olefins.[1] The unique behavior of styrene suggested further study of this reaction.

The Interaction of Styrene and Bisulfite

The formation, by the oxygen-catalyzed reaction between ammonium bisulfite and styrene, of benzoic acid, 2-phenylethanesulfonic acid (I), and 2-phenylethylenesulfonic acid (II) has been confirmed qualitatively. The material isolated in greatest amount, however (about 65% of the total yield in most instances), was found to be not II, as observed by the workers cited, but a new compound, 2-hydroxy-2-phenylethanesulfonic acid (III). This substance, on treatment with phosphorus pentachloride and then with ammonia, loses the elements of water to form the same amide as II, and can be identified in a mixture of the two only by fractional crystallization of the sodium or potassium salt from dilute alcohol. It is not surprising that the previous workers in the field did not suspect its presence since they for the most part converted the crude salts directly into amides without previous puri-



(1) Kharasch, May and Mayo, *J. Org. Chem.*, **3**, 175 (1938); a summary of the earlier literature is given in this article.

fication. The few attempts that were made to work up the products by crystallization from water as the barium salts met with no success, since striking solubility differences between the various components do not exist under such circumstances.

The extent to which styrene will react with bisulfite, and hence the efficiency of the process, has been found to depend somewhat on the *p*H of the original aqueous salt solution, provided no further additions of material capable of altering the hydrogen ion concentration are made during the course of the reaction. The addition occurs, furthermore, under more extreme conditions of acidity and alkalinity than was formerly believed; such variations, however, are ineffective in causing appreciable changes in the ratio of products formed.

A small but reproducible variation in the proportion of the final products has been observed between two main classes of bisulfites: salts of the ammonium group, including all the alkylamines tested, give rise to somewhat greater amounts of the substitution product (II) at the expense of the addition product (I) than do those of the alkali metals. A number of examples of each type are given in Table I. The anomalous behavior of dimethylanilinium sulfite is probably attributable to the effect of the strongly electronegative phenyl radical, but confirmation of this hypothesis was hindered by the inability of diphenylamines, because of their greatly lowered base strength, to form sulfites at all. Much the same sort of difficulty was encountered in an attempt to relate the variations between ammonium and alkali metal salts to base strength—the alkaline earths, for instance, form water-insoluble sulfites. Dimethylaniline possesses the additional peculiarity of furnishing extraordinarily high yields, apparently as a result of its properties as a mutual solvent together with its ability, when present in excess, to keep the solution at all times very close to neutrality. The behavior of pyridine, which has similar characteristics, was found to be practically identical.

The rate of reaction was found to be effectively independent of the salt employed, but to be closely related to the oxygen concentration. Only the roughest of quantitative observations were made, but even these sufficed to indicate that the speed at which oxygen is consumed increases with its partial pressure. Conversely, the over-all yield of organic sulfonates shows an inverse relationship to the oxygen tension. Increasing oxygen pressure, furthermore, results in favoring the substitution reaction, where it occurs to any appreciable extent, as with the ammonium group of salts already referred to, at the expense of the addition reaction. The small amounts of substitution encountered in the use of alkali metal bisulfites are independent of oxygen concentration, as is the ratio of hydroxysulfonate (III) in all oxygen-promoted experiments. The yield of the latter, in fact, remained substantially constant regardless of any alteration of experimental conditions.

The possible effect of bisulfite concentration was investigated in one experiment conducted according to the method of Kolker and Lapworth,[2] as amended by Ashworth and Burk-

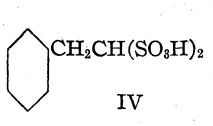
hardt[3] to include styrene. The use of $M/6$ bisulfite solution in place of the usual $M/1$, in a procedure precluding rate comparisons, gave the same products in about the customary yield.

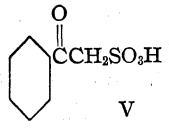
Replacement of oxygen by nitrite or perdisulfate ion as reaction promoter results in complete suppression of the substitution reaction, the proportion of both the addition product and the hydroxysulfonate being at the same time slightly increased. Over-all yields are here to some extent influenced by the rate at which the oxidant is introduced, but even when the latter is added at the minimum convenient speed they are no better than those resulting from use of oxygen at one atmosphere pressure.

Nitrate ion has been found to be of very slight value as an oxidant in bisulfite additions in comparison with the three foregoing materials. The observable effect, in fact, readily may be ascribed not to the nitrate itself but to the few per cent. of nitrite generally present as impurity in nitrates.

Since we have been totally unable to convert any of the three major products into any other by any means comparable to conditions existing during the reaction or the subsequent isolation of the resulting sulfonates, we have concluded that each is a primary reaction product. For instance, a pure sample of each of the three compounds in turn was treated first with hot acid, then with hot alkali, and finally with sodium bisulfite and oxygen. With one exception the starting materials were in every case recovered unchanged, and in that single instance not one of the previously known substances but a new compound was obtained. Specifically, the action of bisulfite and oxygen upon the substitution product results in the addition of another molecule of bisulfite to the double bond with the production in good yields of 2-phenylethane-1,1-disulfonic acid (IV). From the fact that this compound is never formed during treatment of styrene with bisulfite, even in those experiments in which subsequent analysis shows the unsaturated acid to have been present, it is evident that its formation is prevented by the presence of excess styrene.



IV



V

It was anticipated after discovery of the hydroxysulfonate (III) that benzoylmethanesulfonic acid (V) might also logically be included among the products of the reaction, as a result of further oxidation of the former substance. No trace of it, however, has thus far been isolated. It furthermore has been observed in this connection that the hydroxy compound, in view of its structure as a water-soluble secondary alcohol, is surprisingly resistant to oxidation. It is stable to both acid and alkaline permanganate in the cold, and even at 90–100° the oxidation is relatively slow.

This observation was made the basis of an attempt to determine yields of unsaturated sulfonate without separation of the crude mixtures into their components. Accurately weighed samples were treated with cold neutral permanganate in excess, the solution freed from precipitated manganese dioxide, and added to excess acid potassium iodide solution. By titrating the liberated iodine with thiosulfate a measure of the unreacted permanganate was obtained. Under such conditions the substitution product is quickly and completely oxidized. The reaction, however, does not follow any predictable stoichiometric course, and as a result it is necessary to standardize the permanganate against a sample of unsaturated sulfonate or sulfonamide of known purity rather than against any of the usual inorganic standards. As a further qualification, it was found that while pure hydroxysulfonate (III) is not attacked by the oxidizing agents employed, it does react to a varying extent when present in a mixture of products and thus leads to extremely inconsistent results. Its removal is very conveniently effected, fortunately, leaving only addition and substitution products in the remainder. These are nearly impossible to separate, but since the former, unlike the hydroxy derivative, is uniformly inert, assay of the latter with permanganate standardized as described gives highly reproducible results.

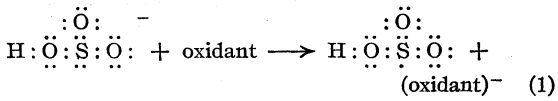
Mechanism

The data herein presented are entirely in accord with the thesis of Kharasch, May, and Mayo[1] that the reaction proceeds through a free-radical intermediate. The evidence for this hypothesis lies in the facts that reagents capable of oxidizing bisulfite are necessary for any interaction to occur and that the products (aside from the benzoic acid arising probably from the direct oxidation of styrene) are exclusively those ac-

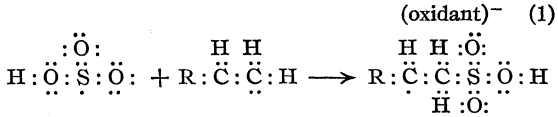
(3) Ashworth and Burkhardt, *J. Chem. Soc.*, 1791 (1928).

countable for by "abnormal" addition to the double bond. Our observations furthermore provide a more quantitative basis for the conclusion that the favored reactions between bisulfite and styrene are unlike those which occur with other olefins in that chains are apparently not important in this particular case. It is true that a chain reaction best accounts for the simple addition products (I), but this class of compound, which constitutes the main product of most unsaturated hydrocarbons, is formed to only a very limited extent from styrene. Reference to the footnotes to Table I will show the comparatively large amounts of oxidant consumed in the addition of bisulfite to the latter olefin, indicating a stoichiometric rather than a chain reaction. In addition, the proportion of sulfite lost as sulfate is not compatible with a self-propagating reaction.

The first steps, wherein a bisulfite free radical, produced by the oxidant[4] capturing an electron from a bisulfite ion, is absorbed by a styrene molecule, have previously been postulated by Kharasch, May, and Mayo.[1] They are reproduced below as equations 1 and 2.



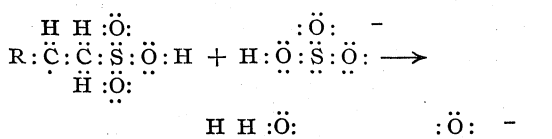
(1)



(2)

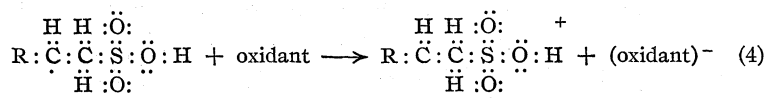
The resulting free-radical complex is then subject to three types of further change, each giving rise to a different product.

1. The simplest case is that in which a hydrogen atom is acquired by collision with another bisulfite ion, as in equation 3, with the formation of 2-phenylethanesulfonic acid and regeneration of sulfite-ion free radical.

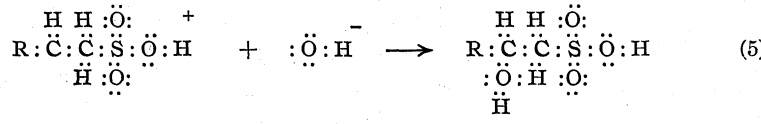


(3)

2. The intermediate may collide with the oxidant and in doing so lose to the latter its unpaired electron. The positively charged molecule thus created readily combines with a negative ion from the solution to form 2-hydroxy-2-phenylethanesulfonic acid.

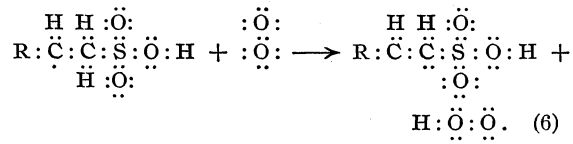


(4)



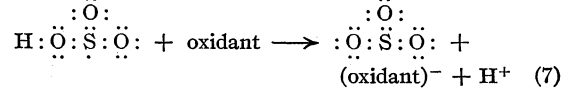
(5)

3. The third type of impact, that which is responsible for the substitution reaction and the formation of 2-phenethylenesulfonic acid, occurs only in the presence of oxygen. For this reason the nature of the oxidant in equation 6 is specified.



(6)

Finally, bisulfite free radicals are transformed to sulfate by a second collision with oxidant, before they can effect combination with styrene, as in equation 7.



(7)

The loss of the second electron to the oxidant has been written, when it takes place (reactions 4 and 6), as a separate step for several reasons. In the first place the removal of both charges at once from sulfite ion results in molecular sulfur trioxide, which in aqueous solution would at once stabilize itself as totally unreactive sulfate ion. Furthermore, if it were possible for sulfur trioxide to exist in dilute solution long enough for it to share the free-electron pair of styrene, the ensuing formation of hydroxysulfonates would be a general property of bisulfite addition instead of being peculiar to styrene, as observed. Lastly, the method employed permits each equation to follow in simple sequence from a common foundation, whereas the introduction of a two-electron transfer would require the retention of both species of inorganic free radical.

It is significant that the apparent relative stabilities of the substituted ethanesulfonate

(4) The term "oxidant" as used in this paper refers to any molecule, atom or free radical capable of accepting an electron or a hydrogen atom from either bisulfite ion, bisulfite free radical, or the organic free-radical complex.

free radicals fall in the same order as those of the corresponding substituted methyl free radicals. The latter, arranged according to increasing ability to independent existence, are methyl, phenylmethyl, diphenylmethyl, and triphenylmethyl. Of the former, the alkylethanesulfonate free radicals are relatively short-lived and are the most reactive with the result that practically every collision with bisulfite is effective, and the products are mainly simple addition compounds. Arylethanesulfonate free radicals, on the other hand, are probably of much greater stability. Reaction of these with bisulfite may be assumed to require an appreciable activation energy. Consequently, fruitful impacts are largely with the oxidant and lead to substitution or the introduction of hydroxyl groups in a large proportion of the intermediate free radicals. The observed phenomena thus follow predictions based on consideration of the probable electron patterns as defined by the theory of electronegativity.[5]

Experimental

Materials.—Styrene, obtained through courtesy of Bakelite Corp., was used both as received (containing small amounts of hydroquinone) and freshly distilled *in vacuo*. No difference between the two kinds was perceptible in any bisulfite addition. Baker monohydrated ammonium sulfite of 71% purity and General Chemical Co. ammonium bisulfite solution, 25% sulfur dioxide, were employed, together with Merck Reagent sodium bisulfite and Mallinckrodt Analytical sodium sulfite, anhydrous, assaying 79% sodium bisulfite and 86% sodium sulfite, respectively. Ethylenediamine sulfite was prepared by diluting the Eastman Kodak Co. Technical base (60% $(CH_2NH_2)_2$ in water) with two volumes of alcohol and saturating with sulfur dioxide. The granular white precipitate, after collection on a filter, an alcohol and ether wash, and air-drying, melted at 176°. Iodine titration of a sample for sulfur dioxide showed the material to be 99% pure $(CH_2NH_3)_2SO_3$. The yield was nearly quantitative. Concentrated stock solutions of substituted ammonium bisulfites were made up by absorbing the maximum of sulfur dioxide in 25–35% solutions of base in water as supplied by Commercial Solvents Corp. Pyridine was diluted with one-fourth its weight of water and sulfur dioxide introduced until its concentration was approximately molar. This reagent was used without further dilution. Dimethylaniline was suspended in water and treated with sulfur dioxide until the mixture became homogeneous. More water was added to the resulting solution to reduce its sulfite content to molar before use.

Procedure for Reaction

Buffered solutions of highly reproducible *p*H for oxygen-promoted runs were prepared by mixing weighed quantities of sulfite and bisulfite, or of solutions of bisulfite and free base, and diluting until molar in total sulfurous acid salts. Reaction was carried out on a high-speed shaker in ordinary round-bottomed flasks with wired-in rubber stoppers, pierced by inlet tubes leading to a graduated reservoir of pure oxygen collected over water. The oxygen tension in the atmosphere over the reaction mixture in the vessel was fixed by using the undiluted gas, air, or a mixture of air with four volumes of nitrogen. In any case the concentration of the promoter was automatically kept constant by replacement with pure oxygen from the reservoir as fast as consumed. Over-all pressure was maintained at atmospheric within narrow limits by never permitting the water level to rise far inside the cylinder. Back diffusion was negligible because of the steady flow of oxygen into the flask. Oxygen runs were continued until iodine titration of an aliquot showed that only a negligible quantity of bisulfite remained, or until extreme *p*H changes greatly reduced the rate of reaction.

Solutions of bisulfite alone were used in nitrite-catalyzed, of sulfite alone in persulfate-catalyzed additions. The sole change necessary in the apparatus was substitution for the gas inlet tube of two stopcocks. Air was displaced from the flask and liquid by passing in carbon dioxide rapidly for fifteen to twenty minutes before shaking was commenced and excluded thereafter, within the limitations of the method, by introducing the oxidant through the stopcocks. The oxidant was added as a 2.5–5 *M* solution at the rate of 10 mmole. per mole of sulfite or bisulfite every half-hour. Samples for assay of unreacted sulfite were withdrawn in a capillary pipet from time to time by the same route without permitting ingress of appreciable oxygen. This type of run was stopped when the sulfite concentration had fallen to such a point (0.15 *M*) that fresh portions of oxidant caused a much smaller drop in the reducing power of the solution than at the start of the experiment.

The proportion of styrene present was in all instances the same: mole for mole with the total sulfurous salts. Since even at best a large part of the latter are oxidized to sulfate, the styrene is always actually in excess.

Among the solvents tested, two, 95% alcohol and liquid ammonia, failed to produce any evidence of reaction whatever. Dimethylaniline was the base employed in the former trial, and in the latter the solvent itself functioned as proton acceptor. This second run was made by bubbling through air under stirring in place of the usual technique of shaking in a closed system. The action of nitrite on either of these mixtures was not investigated. Water proved to be a generally reliable medium. The most desirable results were obtained in 80% aqueous pyridine, in which a much more nearly homogeneous solution is attainable than with water. Even under high oxygen pressures the ratio of sulfonate to sulfate formed in such a run is unusually favorable.

Analysis of Reaction Mixture.—Completed reaction mixtures were separated and the aqueous portion clarified by ether extraction or filtration through a little carbon. After potentiometric *p*H determination and iodine titration of an aliquot to measure the unused sulfite, the salt solution was evaporated to dryness in an open dish on the steam-bath: directly if from an oxygen- or persulfate-sodium sulfite addition, and after mixing with 0.55 mole of sodium carbonate for every gram atom of

(5) Kharasch and Reinmuth, *J. Chem. Educ.*, **8**, 1703 (1931); Kharasch and Flenner, THIS JOURNAL, **54**, 674 (1932).

nitrogen contained if from any other type, whether the nitrogen as originally added was contained in the base or in nitrite or nitrate ion (which are reduced by bisulfite to ammonia or hydroxylamine). Heating of the residue, when nitrogen was present, was continued as long as escape of any ammoniacal fumes could be detected. Small variations in this procedure were desirable in several special cases: for instance, pyridine was not evaporated off freely but was recovered by distilling from the salts *in vacuo*, after addition of aqueous sodium carbonate solution to cause separation of excess styrene. Dimethylaniline was separable mechanically from the alkalinized solution.

The salt residues from these evaporations were finely ground and extracted with 1 liter of boiling 70% alcohol per mole of sulfite consumed. The solution was filtered from the inorganic insolubles and the filtrate taken to dryness as before. The organic residue was then treated with 10 cc. of 90% alcohol per gram, the mixture boiled, cooled to room temperature, and filtered. The residue from this step consists of nearly pure hydroxyphenethyl sodium sulfonate, which may be efficiently recrystallized from 70% alcohol as pearly white platelets. From the filtrate may be obtained, by evaporation to dryness, a mixture of phenethyl and phenethylene sodium sulfonates. These may be recrystallized from 85–90% alcohol or from saturated aqueous salt solutions, but the former solvent often leads to difficultly filterable pastes and the latter to products contaminated with inorganic salts. A much more satisfactory procedure is to convert the sodium to the barium salts by metathesis with barium bromide and recrystallize from water. The sodium salts of both these compounds are obtained as small, shiny white plates from alcohol or as coarse, thin, transparent plates from brine. The barium salts crystallize from water as tiny, white scales, containing one molecule of water of crystallization. Either of the materials may be obtained in a pure state by any of the above methods from a mixture with the other in which it preponderates. The saturated sulfonate also may be freed from any proportion of the unsaturated by destroying the latter with potassium permanganate. No scheme has yet been devised for the separation of both components of an approximately equimolar mixture, or for the isolation of small amounts of unsaturated sulfonate from a mixture rich in the saturated.

Preparation of Sulfonamides.—Sulfonamides were prepared from both the saturated and unsaturated salts in the manner described by Kharasch, May and Mayo.[1] That obtained from the former melted at 124° and from the latter at 143° as they reported. In neither case did a mixed melting point with an authentic specimen show any depression.

Anal. (3) Sodium 2-hydroxy-2-phenylethanesulfonate. Calcd. for $C_8H_9SO_4Na$: C, 42.85; H, 4.05; Na, 10.26. Found: C, 42.69; H, 4.05; Na, 10.24.

Establishment of Structure of Sodium 2-Hydroxy-2-phenylethane Sulfonate.—The analytical data reproduced above for this salt correspond to those calculated for sodium 2-phenethylenesulfonate containing one molecule of water per mole. We have never been able to prepare such a hydrate, however (it is only the barium salt which forms a stable hydrate). Furthermore, a sample of the material was observed to have lost no weight after standing for a week over phosphorus pentoxide *in vacuo*. The stability of the compound to cold permanganate shows the material to be saturated, and the fact that when it is oxidized under more vigorous conditions only benzoic acid (identified by its mixed melting point of 123° with a known sample) can be isolated in high yield, indicates that all substituents are in the side-chain. Treatment with phosphorus pentachloride in the cold resulted in a vigorous exothermic reaction, accompanied by the evolution of much hydrogen chloride and yielding a sulfonyl chloride which was transformed by the action of ammonia into the unsaturated amide of melting point 143°. The over-all conversion of the salt into amide was about 70%. This reaction, together with the stability of the salt to both acid and base (no inorganic sulfur was liberated even on long boiling), demonstrated the absence of sulfate ester and the position of the sulfonic group as beta to the phenyl. The hydroxyl cannot also be beta to the phenyl group, since compounds having a hydroxyl on the same carbon atom as a sulfonic acid group are known to be easily decomposed by either acid or base into sulfur dioxide and an aldehyde. The configuration thus arrived at has been shown to be correct by synthesis from styrene bromohydrin (see below).

The hydroxyl group here present exhibits none of the reactions characteristic of its class. All attempts to esterify it uniformly failed. No treatment with reagents designed to replace it with halogen was successful: either the salt was recovered unchanged or only the unsaturated derivative was obtained.

Styrene bromohydrin was prepared according to Read and Reid,[6] although it was not found possible to reproduce the high (95–98%) yield reported. Under the best circumstances only 80 to 85% of the bromine employed added as hypobromous acid, the remainder forming styrene dibromide, while as little as 60% of the theoretical quantity of bromohydrin was isolated from larger runs. The two products were efficiently separated by thoroughly cooling the crude oil in the icebox and filtering the still-liquid bromohydrin from the crystallized dibromide.

Styrene iodohydrin was prepared by the method of Brunel.[7]

Styrene dibromide was obtained both as a by-product in the manufacture of the bromohydrin and in the manner of Evans and Morgan.[8]

Sodium 2-hydroxy-2-phenylethanesulfonate resulted from treatment of styrene bromo- or iodohydrin with aqueous sodium sulfite according to the procedure of Houlton and Tartar[9] for alkyl halides in general. It was found to be identical in all its properties, physical and chemical, with that fraction of the reaction products analytically identified as such.

Phenylhydrazinium 2-hydroxy-2-phenylethanesulfonate

(6) Read and Reid, *J. Chem. Soc.*, 1487 (1928).
(7) Brunel, *Ann. chim.*, (viii) **6**, 219 (1905).
(8) Evans and Morgan, THIS JOURNAL, **35**, 56 (1913).
(9) Houlton and Tartar, *ibid.*, **50**, 544 (1938).

was prepared by the method of Latimer and Bost[10] from samples of hydroxysulfonate resulting from both addition to styrene and metathesis of the bromohydrin. It crystallized from alcohol as small yellowish plates, very soluble in water and melting sharply at 180–181° with decomposition. Mixtures from the several sources showed no depression of the melting point.

Sodium 2-phenethylenesulfonate was produced in high yield from the hydroxysulfonate by grinding with excess phosphorus pentachloride, drowning in water and refluxing the resulting water-insoluble sulfone chloride with excess saturated aqueous sodium carbonate solution to complete disappearance of the oily layer. On cooling the unsaturated salt separated as a loose mass of large, thin, transparent plates.

Sodium Benzoylmethanesulfonate.—This salt was prepared also according to Houlton and Tartar,[9] and crystallized from 85% alcohol as soft, asbestos-like fibers. No amide could be obtained from this material, nor was any fraction even remotely resembling it in any of its properties ever isolated from our various reaction products.

Addition of Sodium Bisulfite to Substitution Product.—Ten grams (0.05 mole) of sodium 2-phenethylenesulfonate, from either direct substitution or the hydroxysulfonate as above, was dissolved in a solution of 10.5 g. (0.1 mole) of sodium bisulfite and 25 g. (0.2 mole) of sodium in 250 cc. of water and shaken with oxygen in the same apparatus used for styrene additions until absorption of the gas ceased. The solution was evaporated to dryness on the steam-bath and the residue finely ground. It was then exhaustively extracted with boiling 70% alcohol and the soluble salts isolated by evaporation of the filtrates. The product separated from smaller volumes of dilute alcohol as a pulpy mass of soft, silky needles grouped in rosets. This material no longer gave a positive permanganate test for unsaturation, but was still oxidizable by more powerful reagents to benzoic acid, showing that the additional molecule of bisulfite indicated by the analysis had added to the double bond to form a side-chain disulfonate. Treatment with phosphorus pentachloride eliminates a sulfonic group and causes extensive decomposition. The only amide isolable, and that in extremely small yield, proved to be the β-phenethylene sulfonamide of melting point 143°.

Anal. Disodium 2-phenylethane-1,1-disulfonate dihydrate. Calcd. for $C_8H_8S_2O_6Na_2 \cdot 2H_2O$: Na, 13.28; H_2O, 9.54. Found: Na, 13.12; H_2O, 9.22.

Disodium 2-phenylethane-1,2-disulfonate was prepared from styrene dibromide by Houlton and Tartar's[9] procedure. It crystallized from 70% alcohol as small, elongated prisms totally unlike the needles described immediately above. The action of phosphorus pentachloride and ammonia, however, on this disulfonate was practically identical with that on the addition compound, only a very small quantity of the same unsaturated amide resulting.

Phenylhydrazinium 2-phenylethane-1,2-disulfonate, synthesized according to the instructions of Latimer and Bost,[10] melted sharply at 187–188° with decomposition. It crystallizes from alcohol as microscopic yellowish scales, very soluble in water.

Phenylhydrazinium 2-phenylethane-1,1-disulfonate was prepared in the same manner as the above from the addition product disulfonate. This salt possesses the lowest water solubility of any organic phenylhydrazinium derivative thus far studied by us. It may be recrystallized from water as tiny yellowish scales, and melts at no definite temperature. In a slowly heated bath it darkens at 173° and sinters at 180–185° with decomposition to brownish-black products which thereafter are infusible. When introduced into a pre-heated bath at 195–200°, it visibly melts with evolution of gas and transformation into the same dark residue.

We have been unable to prepare by unambiguous synthesis the β,β-disulfonate we assume the above addition product to be. However, we have shown (1) that both groups are in the chain, (2) that one at least must be terminal, and (3) that the compound is not identical with the α,β-disulfonate of known structure. By elimination, then, the configuration must be that represented by formula (IV), 2-phenylethane-1,1-disulfonic acid.

Summary

1. Previous findings on the production of 2-phenylethanesulfonic acid and 2-phenethylenesulfonic acid by the oxygen- or nitrite-promoted reaction of styrene with bisulfite have been qualitatively confirmed.

2. The interaction of styrene with bisulfite yields mainly 2-hydroxy-2-phenylethanesulfonic acid.

3. A mechanism involving oxygen has been proposed to explain the substitution of bisulfite in styrene, and one independent of the nature of the oxidant to account for the formation of the hydroxy derivative.

4. Four new sulfonic acids, namely, 2-hydroxy-2-phenylethanesulfonic acid, 2-phenylethane-1,2-disulfonic acid, 2-phenylethane-1,1-disulfonic acid, and benzoylmethanesulfonic acid have been prepared, together with derivatives of each of the first three named.

Isolation of 2,2-Dimethylbutane from Natural Gas and Determination of its Physical Properties[1]

BY MILDRED M. HICKS-BRUUN, JOHANNES H. BRUUN AND W. B. MASON FAULCONER

1. Introduction.—In previous publications,[2,3] the authors have reported the isolation of pure samples of four isomeric hexanes: *n*-hexane b. p. 68.7°, 3-methylpentane b. p. 63.2°, 2-methylpentane b. p. 60.19° and 2,3-dimethylbutane b. p. 57.93°. While the fifth of the isomeric hexanes, 2,2-dimethylbutane b. p. 49.7° has been prepared synthetically,[4–8] it seems that no one has ever isolated this compound in a pure condition from any naturally occurring product such as petroleum or natural gas. In our recent investigation[3] of the 55–66° cut from Clendenin Gas Field in West Virginia, we found that approximately 7.4% of this cut, when fractionated in our 100-plate bubble cap stills,[9,10] distilled between 38 and 58°. A subsequent refractionation of this low boiling cut resulted in a definite flat break between 49 and 50° of the distillation curve. The refractive index of the material distilling within this range, however, was too high to correspond to 2,2-dimethylbutane alone and it was concluded that it was mixed with cyclopentane, b. p. 49.2°. Because of the relatively small amounts of this fraction available in the 55–66° cut we were unable at that time to isolate the missing isomer of hexane in a pure condition. The distillation served to indicate, however, that a complete separation might be possible provided the investigation was started with larger amounts of the material boiling as near 49–50° as possible. Inasmuch as the isolation of the 2,2-dimethylbutane would supply complete data on the natural occurrence of the isomeric hexanes in petroleum, it was thought advisable to complete this work.

2. Raw Material Used.—From the Viking Distributing Company, 20 gallons (76 liters) of the 38–55° cut from the natural gas originating in the Clendenin Field in West Virginia has been obtained. This cut was reported to be present to the extent of 18 gallons (68 liters) of liquid per 1000 cubic feet (28,317 liters) of the natural gas measured at a pressure of 14 pounds per square inch (1 atm.).

3. Isolation of the 2,2-Dimethylbutane.—About 37 liters of the raw material was extensively fractionated in two semi-automatic all-glass stills having bubble cap columns of 100 plates each and still pots of 3 and 5 liters capacity. The reader is referred to previous publications for a complete description of these stills.[9,10]

The first distillation consisted of 11 separate runs with charges of either 2500 or 4500 ml. each. The stills were operated at a reflux ratio of about 20:1 and the distillates were collected at a rate of about 0.8 ml. per minute between 26 and 40° and of about 0.1 ml. per minute in the range between 40 and 50°. The temperature–volume relationships of these runs were exactly identical and are given in Fig. 1. As shown in this figure, over 50% of the raw material consisted of *n*-pentane (boiling point 36°) while the 2,2-dimethylbutane fractions (refractive index, $n^{20}D$ averaged 1.380) represented about 10% of the original 38–55° cut. It is noted that the true boiling range of the 38–55° commercial cut varied from about 26 to above 60°.

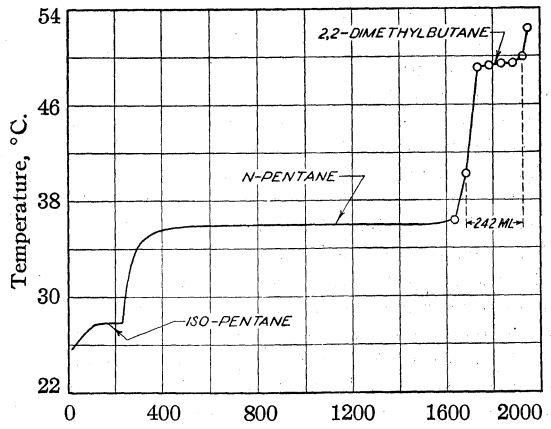

Fig. 1.—First distillation of the raw material.

For the second distillation all of the cuts from the first distillation having boiling ranges of 40–50° were combined and recharged into one of the 100-plate stills which in this case was operated at about 75:1 reflux ratio while the distillate was being collected at a rate of 0.1 ml. per minute. During this run about 80% of the charge distilled between 49.2 and 49.8°.

The third distillation consisted in mixing all fractions from the second distillation boiling at about 49.7° and having refractive indices corresponding to that of the 2,2-dimethylbutane and then subjecting them to a final fractionation in the 100-plate still. The final charge consisted

[a] Present investigation. [b] *Bull. soc. chim. Belg.*, **31**, 65 (1922). [c] THIS JOURNAL, **58**, 373 (1936). [d] *Bull. soc. chim. Belg.*, **31**, 389 (1922). [e] THIS JOURNAL, **60**, 17 (1938). [f] U. O. P. Bull. 219, 1938, p. 21. [g] *In vacuo.*

of only 760 ml. of material and the total boiling spread of this charge was found to be 0.1°. The two best samples of about 40 ml. each obtained from the upper end of this distillation had a boiling spread of 0.01° in the 100-plate column.

4. Determination of the Physical Constants of 2,2-Dimethylbutane.—The freezing point, boiling point, the refractive index and the specific gravity of the isolated 2,2-dimethylbutane were determined by using the same apparatus and technique as that employed for the other isomeric hexanes.[3]

The boiling point was determined by means of a Cottrell boiler and the conventional corrections have been applied to the value given in Table I. A Valentine Abbe type refractometer which reads to the fifth decimal place was used to determine the refractive index. Its calibration was checked with pure distilled water and pure *n*-hexane.

The freezing point was determined under vacuum. The 25-ml. sample was placed in a small unsilvered Pyrex vacuum flask, of which the vacuum chamber was equipped with a manometer and stopcock. This arrangement enabled the operator to vary the rate of cooling by changing the vacuum around the sample. A stirrer and a 5-junction copper–constantan thermocouple were provided in order to stir and to read the temperature of the sample. The thermocouple was calibrated by the National Bureau of Standards. The vacuum sample tube was surrounded by a bath of liquid nitrogen which was contained in an unsilvered Pyrex thermos flask.

The specific gravity was determined in a 5-ml. pycnometer specially designed and loaned by S. S. Kurtz, Jr., of the Development Division of this Company. The values were corrected for buoyancy effect and are believed to be accurate to the fourth decimal place.

All of the final corrected values are listed in Table I, together with the best available data on the synthetic hydrocarbon.

5. Discussion of the Results.—From the close agreement of the physical constants, as well as the freezing behavior, it has been concluded that a very pure sample of 2,2-dimethylbutane can be obtained from petroleum by efficient distillation alone.

In Table I, the physical constants are given for the best fraction of 2,2-dimethylbutane which has been obtained in this Laboratory. For direct comparison, the best values from the literature of the physical constants of the pure synthetic hydrocarbon are also included. It can be seen that they are in close agreement with the best of the values except for the freezing point. The freezing behavior proved to be very interesting. The best values found in the literature were those of Timmermans[4] and of van Risseghem,[5] which were both −98.2°, while Smittenberg, Hoog and Henkes[6] found −100.5° and a transition point of −146°. The latter authors were unable to obtain a flat horizontal portion of the curve during the time that freezing took place. They concluded that the substance was pure but the crystallization was inadequate to maintain the temperature at a constant point over the period of freezing.

In the present investigation, in which 25 ml. of 2,2-dimethylbutane was frozen *in vacuo* in concentric transparent vacuum flasks, certain unusual freezing characteristics could be observed. In a normal freezing process supercooling occurs, followed by the formation of white crystals and a horizontal plateau on the time–temperature cooling curve. From the curve in Fig. 2, it can be seen that the first white crystals appeared and a flat portion was obtained about one degree below the point at which the material began to solidify. Thus at −98.7 ± 0.2°, the liquid, without the change in viscosity, which usually occurs if it becomes a glass, began to solidify but remained

transparent. By the time the temperature had dropped one degree, the 2,2-dimethylbutane was almost solid, but still clear. At this point small groups of white crystals began to form and spread rapidly throughout the mass, while the temperature became stationary. This behavior could be duplicated, although it sometimes happened that the white crystals began to form directly at about −99°. In such cases, the temperature did not remain stationary but fell gradually. This behavior gave a time–temperature curve such as that described by Smittenberg, Hoog and Henkes.[6] Whether the first solidification to a transparent mass, with the subsequent change to a white crystalline mass, is evidence of a definite transition point or merely that the first crystals are exceedingly small has not been established. As the main purpose of this investigation has been only to isolate the 2,2-dimethylbutane in a pure condition, no further work has been done on this point. However, due to the rapid change in temperature when the material began to freeze, it is somewhat difficult to establish conclusively the exact temperature of the initial freezing point. The heat of fusion of 2,2-dimethylbutane is 111 cal.$_{15°}$ per mole,[11] which is very low. Calculated from this value, if the freezing point of −98.2° found by Timmermans[4] and van Risseghem[5] is correct and the one for the present sample is 0.5° lower, the purity of the latter is still 99.91%.

A transition point of about −146° has been reported.[6,11] Stull measured the heat of transition at this temperature and found it to be 1095 cal.$_{15°}$ per mole[11] or about ten times the heat of fusion. In the present sample, considerable supercooling (about 20°) occurred before the transition took place. However, the transition point of −146° has been confirmed in this Laboratory.

6. Percentage of the Various Isomeric Hexanes in the Natural Gas.—In Table II, the authors have listed the approximate relative quantities in which the isomeric hexanes are present in the natural gas.

(11) D. R Stull, THIS JOURNAL, **59**, 2726–2733 (1937).

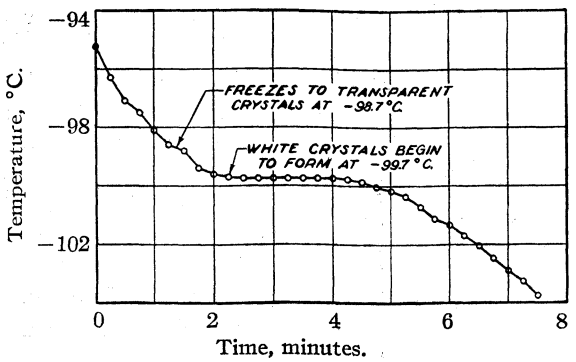

Fig. 2.—Time–temperature cooling curve of 2,2-dimethylbutane.

TABLE II

CALCULATED AMOUNTS OF ISOMERIC HEXANES IN NATURAL GAS

Compound	Boiling point, °C.	Minimum amount present, ml. of liquid per cu. m. natural gas
2,2-Dimethylbutane	49.72	168
2,3-Dimethylbutane	57.93	74[3]
2-Methylpentane	60.19	420[3]
3-Methylpentane	63.2	196[3]

Summary

2,2-Dimethylbutane, the only isomeric hexane that has never been separated from natural sources, has been isolated in a pure condition from natural gas. A careful study of the freezing behavior of 2,2-dimethylbutane has revealed that the compound froze to transparent solid crystals at −98.7° without resulting in a flat portion in its time–temperature cooling curve. One degree lower at −99.7° white crystals began to form and a horizontal plateau appeared on the freezing curve. No attempt has been made to establish whether this behavior is due to the initial formation of very fine crystals or to a definite transition point between two crystal modifications.

The isolated compound is present in natural gas to the extent of 168 ml. per cu. m., and is thus next to 2,3-dimethylbutane, the least predominant isomer of hexane.

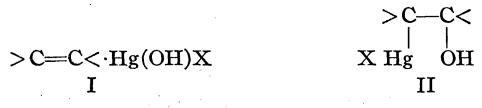
The Coördination Complexes of Mercuric Ion with Cyclohexene

BY H. J. LUCAS, F. R. HEPNER AND S. WINSTEIN

The formation of compounds from olefins and mercuric salts has been studied very extensively since 1900. Hofmann, Sand and co-workers[1] showed that ethylenic compounds combined with mercuric salts in aqueous solution to yield compounds designated by the formula types I or II.



I II

Manchot[2] mainly because of the ease of regenerating the olefin from its addition compound claimed that such products are merely molecular compounds and are best represented by formulas of type I. Considerable discussion has appeared in the literature as to the relative validity of the formula types I and II and later investigators[3] on the basis of various sorts of evidence have established the idea that such compounds are formed by real addition to the double bond and are to be represented by formulas of type II.

There have been indications, however, that there may exist coördination compounds of olefins and mercuric salts (type I) in addition to products of type II. Thus, Sand and Breest,[1d] studying the rate of establishment of equilibrium between ethylene, mercuric chloride and ethanol mercuric chloride and not being able to fit the data very well, thought it possible that an equilibrium existed between compounds of the types I and II. Also, Wright[3d] found a serious downward drift in the bimolecular rate constants for the mercuration of several ethylenic compounds. Wright also found that in testing for completeness of the reaction of mercuration of an ethylenic compound, thiocyanate ion would indicate considerable unused mercuric salt when hydroxide ion failed to indicate any. Further, it was found[4] in this Laboratory that isobutene hydrated incompletely in the presence of mercuric nitrate, the residual isobutene being analyzable by bromination and equivalent to the mercuric nitrate.

Recently it was shown by the distribution method that coördination with silver ion[5] is a general property of ethylenic compounds and we have felt that mercuric ion should act analogously to silver ion. We have now investigated by the distribution method possible complex formation between cyclohexene and mercuric ion in aqueous solution and have found that mercuric ion does indeed complex strongly with cyclohexene. In this paper are presented the results of this investigation and some comments on their significance.

Notation.—For the sake of convenience the symbols to be employed together with their definitions are here listed together. The notation used here is as much as possible nearly identical with the notation previously used in connection with the coördination of silver ion with ethylenic compounds.[5b]

B = unsaturated substance, in this case cyclohexene

(Bt) = total concentration of B in the aqueous phase, moles/liter

(B) = concentration of uncomplexed B in the aqueous phase, moles/liter

$(B)_c$ = concentration of B in carbon tetrachloride, moles/liter

(Hg^{++}) = concentration of uncomplexed mercuric ion in the aqueous phase, moles/liter

(Hgt) = total concentration of Hg in aqueous phase, moles/liter

(BHg^{++}) = concentration of the species, BHg^{++} in the aqueous phase, moles/liter

$(BHgOH^{+})$ = concentration of the species, $BHgOH^{+}$ in the aqueous phase, moles/liter

(HNO_3) = concentration of added nitric acid, moles/liter

(H^{+}) = concentration of total acid in the aqueous phase, moles/liter

μ = ionic strength = normality

$K_D = (B)_c/(B)$ = distribution ratio of cyclohexene between carbon tetrachloride and 1 N potassium nitrate = 4305[5b]

$$K_E = \frac{(Bt) - (B)}{(B)_c[(Hgt) - (Bt) + (B)]} = \text{evaluated constant} = \frac{(Bt)}{(B)_c[(Hgt) - (Bt)]}$$ with negligible error

$K_N = \frac{(B \cdot Hg^{++})}{(B)\ (Hg^{++})}$ = coördination constant of mercuric ion for the formation of the complex BHg^{++} (neutral from the acid base standpoint)

$K_B = \frac{(BHgOH^+)(H^+)}{(B)\ (Hg^{++})}$ = coördination constant of mercuric ion for the formation of the basic complex $BHgOH^+$

$K_0 = K_N/K_D$

$K_0' = K_B/K_D$

Procedure and Analysis.—The procedure followed was essentially that described previously in the silver work,[5] with some modifications. Of these, the most important was in the method of preparing the solutions and of taking the samples, so as to eliminate the presence of oxygen. This was a more serious complication than in the silver case, mainly because the presence of oxygen accelerated the separation of some sort of solid organo-mercuric compound. The cyclohexene was distilled from sodium in an atmosphere of nitrogen, weighed into a volumetric flask filled with nitrogen and made up to the mark with carbon tetrachloride. This solution or one diluted with carbon tetrachloride was used for the distributions.

The apparatus for the distribution measurements as shown in Fig. 1 was kept in a thermostat at 25.0 ± 0.03°. The flask, 200 ml., was filled with nitrogen; the materials were pipetted into the flask through the 10-mm. vertical glass tube which usually was kept closed with rubber tubing. A stream of nitrogen, flowing through the stopcock into the atmosphere, was directed into the flask whenever material was introduced into or taken from the flask. The sampling was done with a pipet having a sealed on 3-way stopcock.[4]

There were three stock solutions, *viz.*, (a) 0.286 *M* in mercuric nitrate and 0.142 *N* in added nitric acid, (b) 1 *N* potassium nitrate and (c) 1 *N* nitric acid. Since all three of these have ionic strength $\mu = 1$, solutions of different concentrations, but of same ionic strength, could be obtained easily by mixing.

The mercuric nitrate stock solution was standardized by titration with potassium thiocyanate. The acid concentration (HNO_3) in this solution was found to be 0.147 *N* and not 0.142 *N* as was intended because of nitric acid in the solid mercuric nitrate. The acid concentration was obtained by precipitating the mercury as mercuric sulfide with hydrogen sulfide, and titrating the acid in the filtrate after removal of excess hydrogen sulfide by boiling.

The length of time allowed for the separation of the two phases was much shorter than that allowed in the silver work,[5b] because in this work the concentrations of cyclohexene in the two phases were of the same order of magnitude.

In connection with possible side reactions it was necessary to know how the hydration product of cyclohexene behaved during the bromination procedure. Cyclohexanol, m. p. 22°, purified and distilled, did not react with bromine according to the analytical procedure, in the presence or absence of carbon tetrachloride.

The analytical method has been described previously.[6]

(6) Lucas and Pressman, *Ind. Eng. Chem., Anal. Ed.*, **10**, 140 (1938).

In the presence of mercuric ion, the bromate–bromide method of analysis gave satisfactory results with attention to some precautions. It was desirable to allow sufficient time, five minutes, for the initial liberation of bromine and at least five minutes between the addition of sodium chloride and potassium iodide solutions. This time interval could be increased to eleven minutes, without causing differences greater than 0.1%. The excess of bromate–bromide solution could be varied from 15 to 65% without introducing an error greater than ±0.5%. When analyzing the carbon tetrachloride phase, the mercuric ion concentration was made comparable to that in the aqueous phase by the addition of 5 ml. of 0.286 *M* mercuric nitrate.

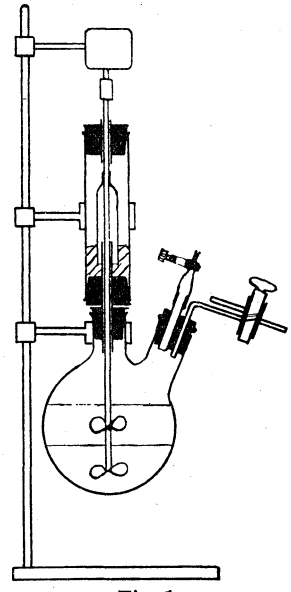

Fig. 1.

The extent to which mercury compounds dissolve in the carbon tetrachloride while cyclohexene is being distributed between carbon tetrachloride and aqueous mercuric nitrate was shown to be less than 0.01 mmol. per liter. This was done by evaporating 50 ml. of the organic phase, after the system had stood for twenty-four hours, taking up the residue (none was visible) in 6 *N* nitric acid, diluting with an equal volume of water, adding saturated hydrogen sulfide solution, and comparing the color with that from known amounts of mercury.

Nature of the Reactions of Cyclohexene in Mercuric Nitrate Solution.—When cyclohexene was distributed between carbon tetrachloride and mercuric nitrate solution containing nitric acid, K_E was much higher than in the case of the silver work[5b] but it varied with time when the acid concentration was low. For about twenty minutes, which seemed to be the time necessary with the present apparatus for establishment of equilibrium between the phases, K_E increased and then it gradually decreased. Thus, when (Hgt) = 0.1907 and (HNO_3) = 0.0980, K_E is 76 at zero time (extrapolated), about 70 after two hours and finally 54 in about twenty hours. At higher acid concentrations this drift seems to be eliminated, K_E varying only as much as would be expected from experimental errors. K_E varies markedly with the acid concentration.

Cyclohexene dissolves readily in aqueous mercuric nitrate. When it does so acid is produced. Under conditions where K_E drifts, there is also a slow further production of acid. These facts are

TABLE I

CHANGE IN pH[a] OF MERCURIC NITRATE BY CYCLOHEXENE

Initial (Hgt)	Initial pH	pH with cyclohexene added: Initial	After 3 hrs.
0.0954	1.55	1.16	1.04
.1907	1.30	1.07	0.77
.1907	1.19	0.92	0.77[b]

[a] Determined by use of Beckmann pH meter. [b] After two hours.

illustrated in Table I. Under conditions where K_E drifts, the apparent mercury concentration as given by thiocyanate titration decreases with time. Thus, when two ml. of cyclohexene is dissolved in 100 ml. of the 0.286 M mercuric nitrate stock solution, the thiocyanate consumption at the beginning is the theoretical value for all the mercury but it drops a few per cent. per hour at the start and some 27% in thirteen hours. The apparent amount of unsaturation as given by bromination is within experimental error of the theoretical for about one and one-half hours under these conditions and then increases at an accelerating rate so that it is some 3% high after three hours and some 40% high after seventeen hours. In time a solid product separates. When cyclohexene dissolves in mercuric nitrate solution, the odor of cyclohexene is not apparent but it becomes so as thiocyanate is added.

The ready solubility of cyclohexene in aqueous mercuric nitrate with loss of cyclohexene odor, the initial production of acid, the initial theoretical consumption of thiocyanate ion, and the variation of K_E with acid concentration in the distribution measurements indicate the rapid coördination of cyclohexene with mercuric ion to give some sort of compound of the formula type I mentioned previously, accompanied by the production of acid. The secondary effects observed at the lower acid concentrations such as the decrease in apparent mercury concentration, the drift of K_E with time, the further production of acid, the increase in the apparent unsaturation after a time, and the separation of a solid indicate that secondary reactions, not as yet completely understood, are taking place. One of the secondary reactions would seem to be the production of a compound of the formula type II. This would produce acid and decrease the consumption of thiocyanate since compounds of type II consume only half as much thiocyanate as mercuric ion does.[3d] These secondary reactions were not investigated further because our chief interest at this time was the study of the coördination type of reaction involving mercuric ion.

At higher acid concentrations, K_E is evaluated easily because the coördination process proceeds with essentially no side reactions. At the lower concentrations a simple extrapolation is sufficient to give K_E quite accurately since the secondary reactions are relatively slow.

Equilibria and Equilibrium Constants.—Distributions were made under conditions in which the concentrations of cyclohexene, mercuric nitrate and nitric acid were changed. The data are summarized in Table II. In each case three independent distributions were made, in duplicate, and the stirring times were 0.5, 1.0 and 1.5 hours, respectively. The evaluated constant K_E for each condition was obtained by averaging the three values of K_E or by extrapolating to zero time when there was a systematic decrease of K_E with time.

TABLE II

VALUES OF K_E OBTAINED BY DISTRIBUTION AT 25° OF CYCLOHEXENE BETWEEN CCl_4 AND $Hg(NO_3)_2 + HNO_3 + KNO_3$ AQ. AT $\mu = 1$

(Hgt)	Extrapolated $(B)_c$	(Bt)	(HNO_3)	K_E: 0.5 hr.	1 hr.	1.5 hr.	Extrap.
0.0477	0.0320	0.0271	0.2731	41.4	41.6	40.6	41.2
.0954	.0135	.0558	.0490	108.5	105.8	103.2	111.2
.0954	.0153	.0529	.0963	83.6	81.2	79.5	85.6
.0954	.0209	.0449	.2740	42.4	42.2	42.5	42.4
.0954	.00805	.0256	.2740	45.6	44.5	46.5	45.5
.0954	.00364	.0137	.2740	45.0	46.3	46.5	45.9
.0954	.0252	.0376	.5490	24.9	25.8	26.3	25.7
.1907	.0158	.1040	.0980	74.4	72.5	71.0	76.0
.1907	.01001	.0606	.2756	45.5	47.7	47.4	46.8

K_E is relatively insensitive to changes in (Hgt) and $(B)_c$ indicating the formation of a complex ion from one molecule of cyclohexene and one mercuric ion. The large variation of K_E with (HNO_3) speaks against the description of the coördination process by equation 1, which one would write

$$C_6H_{10} + Hg^{++} \overset{K_N}{=\!=} C_6H_{10}Hg^{++} \quad (1)$$

$$C_6H_{10} + Hg^{++} + HOH \overset{K_B}{=\!=} C_6H_{10}HgOH^+ + H^+ \quad (2)$$

on the basis of strict analogy between mercuric and silver[5] ions. If reaction 1 were the only one to be considered, K_E would equal K_0 and no variation with (HNO_3) would be observed. Reaction 2 suggests itself as being very important.

If we assume that the reaction of cyclohexene with mercuric ion proceeds entirely in the sense of equation 2, the total acid concentration (H^+) is given, with negligible error, by equation 3 as the sum of the acid present in

$$(H^+) = (HNO_3) + (Bt) \quad (3)$$

the mercuric nitrate solution and that produced by reaction 2. Also, according to equation 4,

K_0' the product of (H^+) and K_E, should be a constant. The values of K_0' which are obtained in

$$K' = K_B/K_D = (H^+)\,K_E = \frac{(BHgOH^+)(H^+)}{(B)_c(Hg^{++})} \quad (4)$$

this way are given in the last column of Table III. K_0' is seen to be reasonably constant, varying only between 11.7 and 15.7, with 13.7 ± 1.2 as the mean value. The conclusion can be drawn, therefore, that the reaction between cyclohexene and mercuric ion proceeds predominantly in the sense of equation 2 to produce a complex ion $C_6H_{10}\cdot HgOH^+$.

TABLE III

VALUES OF K_0' USING EQUATIONS 3 AND 4

(Hgt)	$(B)_c$	(Bt)	K_E	(HNO_3)	$(H^+) = (Bt) + (HNO_3)$	$K_0' = (H^+)K_E$
0.0477	0.0320	0.0271	41.2	0.2731	0.3002	12.4
.0954	.0135	.0558	111.2	.0490	.1048	11.7
.0954	.0153	.0529	85.6	.0963	.1492	12.8
.0954	.0209	.0449	42.4	.2740	.3189	13.5
.0954	.00805	.0256	45.5	.2740	.2996	13.5
.0954	.00304	.0137	45.9	.2740	.2877	13.0
.0954	.0252	.0376	25.7	.5490	.5866	15.1
.1907	.0158	.1040	76.0	.0980	.2020	15.4
.1907	.01001	.0606	46.8	.2756	.3362	15.7
					Mean	13.7
					Mean deviation	±1.2

On the assumption that reaction proceeds according to both equations 1 and 2 the data can be correlated somewhat better than on the basis of only the one reaction. From equation 5

$$K_E = \frac{(BHg^{++}) + (BHgOH^+)}{(B)_c(Hg^{++})} \quad (5)$$

and the definitions of K_0 and K_0', the relation between K_E, K_0, K_0' and (H^+) is given by equation 6.

$$K_E = K_0 + K_0'/(H^+) \quad (6)$$

A first approximation to K_0 can be obtained from the series of runs in which (Hgt) = 0.0954 by plotting K_E against $1/(H^+)$, using (H^+) from Table III. The first approximation was five. Then this value of K_0 was used to obtain a better approximation to the total acid concentration with the relation shown in equation 7

$$(H^+) = (HNO_3) + (Bt)(K_E - K_0)/K_E \quad (7)$$

where $(K_E - K_0)/K_E$ represents the fraction of (Bt) in the form of $(BHgOH^+)$. When K_E was plotted against the corrected (H^+) as shown in Fig. 2, the value of K_0 by this second approximation was five also.

On recalculating K_0' by means of equation 6 using the corrected (H^+) values and the value of $K_0 = 5$, K_0' varies only from 10.9 to 11.9 (Table IV) with 11.6 ± 0.3 as the mean value. The agreement is even better, if the result at the very lowest acid concentration is neglected.

TABLE IV

CORRECTED K_0' VALUES, WITH (Hgt) = 0.0954, $K_0 = 5$ USING EQUATION 6

$(B)_c$	(Bt)	K_E	(HNO_3)	(H^+) equation 7	$K_0' = (K_E-5)(H^+)$
0.0135	0.0558	111.2	0.0490	0.1023	10.9
.0153	.0529	85.6	.0963	.1461	11.8
.0209	.0449	42.4	.2740	.3136	11.7
.00805	.0256	45.5	.2740	.2968	11.9
.00304	.0137	45.9	.2740	.2862	11.7
.0252	.0376	25.7	.5490	.5793	11.8
				Mean	11.6
				Mean deviation	±0.3

From the data of Table IV it can be concluded that when mercuric ion coördinates with cyclohexene, there are two one-to-one complexes formed, *viz.*, $C_6H_{10}Hg^{++}$ and $C_6H_{10}HgOH^+$. The respective equilibrium constants, $K_N = K_0K_D$ and $K_B = K_0'K_D$ are 2.2×10^4 and 5.0×10^4, respectively, when (Hgt) is approximately 0.1 *M*.

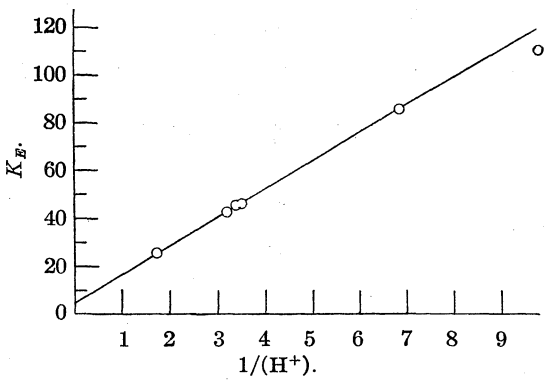

Fig. 2.—Change of K_E with $1/(H^+)$ at (Hgt) = 0.0954 *M*. (H^+) is obtained from equation 7.

There would appear to be a drift in K_0' as (Hgt) is varied. If the assumption is made that K_0 does not change, then K_0' as calculated from equations 6 and 7 varies with (Hgt) as shown in Table V. K_0 may and probably does change somewhat with (Hgt) but since it is so small compared to $(K_E - K_D)$, such a variation can hardly affect very much the trend in K_0' in Table V.

TABLE V

EFFECT OF CHANGE IN (Hgt) ON K_0', WHEN $K_0 = 5$

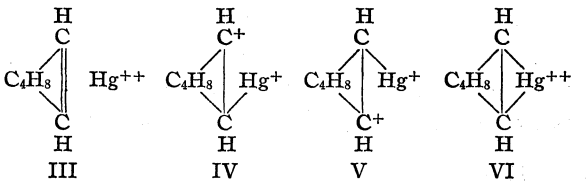
(Hgt)	$K_0' = (H^+)(K_E-5)$
0.0477	10.6
.0954	11.6[a]
.1907	13.7[b]

[a] Average K_0' value, Table IV. [b] Average of two values, 13.8 and 13.6.

A similar but somewhat smaller trend in the constant with the proportion of the various salts making up the total ionic strength of unity was

observed previously in the olefin–silver work.[5] These trends must be due to the fact that even though in the silver work the ionic strength was kept at unity and in the present work it was kept at unity except for changes due to reaction 2, the activity coefficients of the various ionic species change as silver or mercuric nitrate is substituted for potassium nitrate or nitric acid.

Structures.—The coördination complexes of mercuric ion with cyclohexene can be formulated much like the silver–olefin[5] or the positive bromo-olefin complexes.[7] The resonating forms of the cyclohexenemercurinium ion[8] can be represented as III, IV, V and VI and the cyclohexenemercurinium hydroxide ion $C_6H_{10}\cdot HgOH^+$ can be represented similarly with the difference that the mercury atom holds one hydroxyl radical.



The values of K_B and K_N which have been obtained indicate the very extensive hydrolysis of the species $C_6H_{10}Hg^{++}$. In fact, the value for the ionization constant of the base $C_6H_{10}\cdot HgOH^+$ which is given by K_B and K_N is approximately 5×10^{-15}. One would rather expect a low value for the ionization constant of this base, especially if structure VI is at all important, for this form involves an increase in the effective charge on the mercury atom and a consequent decrease in the strength of the corresponding base.

Significance of Mercurinium Complexes.—From a theoretical point of view these coördination complexes of mercury are of great importance. They may be regarded as typical examples of the rather large group of poorly defined substances which are recognized as intermediates in chemical changes, but which usually cannot be isolated.

The process of mercuration of an olefin with production of stable reaction products would appear to be analogous to the *trans* addition of bromine or of bromine derivatives to the double bond. Negative ions or various solvent molecules can attack the substituted ethylenebromonium ions to give dibromides, bromohydrins, etc.[7] Just so are the substituted ethylenemercurinium ions thought to give compounds of the formula type II. One difference is that the mercury complex is so much less reactive that it can be studied directly. In reactivity the mercury complexes would appear to be intermediate between the silver ion and positive bromine analogs. Because of the analogy between bromination and mercuration, we would expect *trans* addition in mercuration also. Actually the mode of addition is uncertain but there is plenty of evidence that mercuration does not proceed by two concurrent reactions, *i. e.*, *cis* addition and *trans* addition[3] to the double bond.

Solid mercury–olefin coördination complexes, comparable to the known solid silver–olefin coördination complexes,[5b] would be expected to exist. It may be that some of the products which have been obtained by workers in the past were actually of the coördination type.

With the finding of coördination complexes of an olefin and mercuric ion the state of the reaction of mercuration has been somewhat complicated. It is known that the mercuration reaction proceeds in some cases to a measurable equilibrium.[1d,3d] Now it would appear that equilibria between the olefin, mercuric salt, compound of type I and compound of type II are involved. In many reactions of mercurated olefins it remains to be seen to what extent these equilibria play a role.

Summary

Coördination complexes of mercuric ion with cyclohexene have been studied chiefly by the distribution of cyclohexene between carbon tetrachloride and aqueous solutions containing mercuric nitrate, nitric acid and potassium nitrate at ionic strength of $\mu = 1$.

The data indicate that two rapid reactions take place: $C_6H_{10} + Hg^{++} \rightleftarrows C_6H_{10}Hg^{++}$ and $C_6H_{10} + Hg^{++} + H_2O \rightleftarrows C_6H_{10}HgOH^+ + H^+$. The equilibrium constant K_N for the first reaction is 2.2×10^4 and K_B, for the second reaction, is 5.0×10^4.

Secondary slower reactions proceed concurrently with the other two.

The significance of mercury–olefin complexes for mercuration phenomena is discussed briefly.

A Study of Organic Parachors. IV. Constitutive Variations of the Parachors of a Series of Tertiary Chlorides[1]

BY OSBORNE R. QUAYLE, KATHERINE OWEN AND ELLINGTON M. BEAVERS[2]

The concept of the highly constitutive nature of parachor has grown out of the fact that it has been shown that many irregularities between observed and calculated values are due, not to experimental error as first believed, but to differences in molecular volume arising from the variations within the molecule. Isomeric compounds show that the additive nature of this constant is modified by constitutive effects. The branching of the chain in hydrocarbons[3,4] causes a lowering of the parachor from that of the value for the straight chain.

Any explanation of the difference in chemical behavior of two carbon atoms in the same general type of structure ultimately must be resolved to a postulation of differences in the extent of consumption of the valence forces of the two, caused by the influences of spatial arrangement and minor differences in adjacent groups. Since the effective volume of an atom is dependent upon its electrical forces, an accurate atomic and molecular volume property should vary slightly from compound to compound because of constitutive influences. On the assumption that the parachor is such a property, most observed deviations are explainable. The validity of this assumption has been tested by comparing the parachors of regular series of compounds.

Beck, Macbeth and Pennycuick[5] measured the parachors of a series of malonic esters, noting the effect of lengthening the ester chain and that of alkyl substitution in the malonic residue. The differences between the observed and calculated parachors showed a regular, depressive constitutive effect, the depression increasing with the length of the alkyl ester chain and apparently reaching a limiting value with the butyl group.

In a study of a series of alkylbenzenes, Buehler, Gardner and Clemens[6] found that the CH_2 parachor value decreased in a very regular manner through the butyl substitution, the amyl rising to the normal value.

In a previous paper,[7] the authors pointed out the influence of varying the length of normal straight chains attached to a tertiary carbon atom jointed to an hydroxyl group. Using trimethylcarbinol as a standard, the effect of substitution in the alcohol was most constitutive with the first CH_2 units added and approached the CH_2 constant of Mumford and Phillips[8] as the length of the chains approached five. These values gave a closer agreement between calculated and observed parachors than those of previous determinations.

This paper is concerned with the measurement of the parachors of the corresponding tertiary chlorides[9] and the resulting extension of the knowledge of the constitutive constants of the compounds containing branching of the tertiary type. As with the alcohols, the chain branching of the chlorides used is limited to the tertiary carbon atom. The values obtained from these compounds afford a second series of position values in tertiary branching. Since chlorides are generally non-associated these values also would indicate any large effect of association that had distorted the values previously recorded for the alcohols.

For the lower molecular weight chlorides densities (Table I) were determined at 15, 25, 50 and 65° with the exception of trimethylchloromethane which boils at 51°. The densities of the higher molecular weight chlorides were determined at 25, 50 and 75°. Extrapolation from the curves shown in Fig. 1 was used to obtain all values at 0°. The surface tensions (Table II) were measured at 0, 25 and 50° for the lower molecular weight compounds and at 25, 50 and 75° for those of higher weight. The estimated experimental precision of the surface tension determinations by

The parachors of the chlorides (Table III) decrease with the exception of ethylpropylpropylchloromethane, in a linear manner with temperature (Fig. 3). The rate of this decrease is less than 0.2% per 10° rise in temperature. The experimental precision of measurement was approximately 0.1%. The parachors were calculated from the mathematical expression[10] $P = \gamma^{1/4} M/D$ where M is the molecular weight, γ is the surface tension, and D is the density of the liquid.

Since the parachor values for the series vary in an essentially regular manner with temperature, comparisons would be essentially the same at any temperature within the range studied. The com-

(10) The more exact expression $P = \gamma^{1/4} M/(D - d)$ includes the value of d the density of the vapor at same temperature. The omission of d introduces an error of less than 0.05% and the shorter expression has been used throughout.

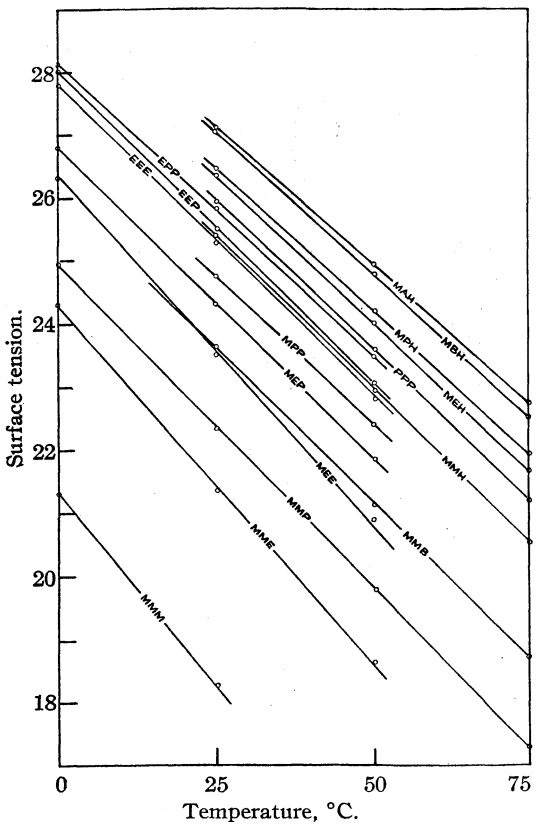

Fig. 2.—Variation of surface tension with temperature for sixteen tertiary chlorides.

parisons recorded are for convenience made at 25°. Trimethylchloromethane was taken as an observed base for the purpose of making comparisons. The value of the $\rangle$C–Cl group was obtained by subtracting the value of the three methyl groups from the total value. By assuming this basic value, the effect of uniformly lengthening the chains on the value of the $\rangle$C–Cl group may be observed (Table IV).

The effect is of the same order of magnitude as that obtained for the tertiary carbinols. The first several additions to the chains cause the greatest crowding and adsorption of any residual forces on the tertiary carbon.

The effect of substitution at different distances from the tertiary carbon atom has been calculated for the CH_2 values (Table V), and is quite comparable to those obtained in a similar manner for the tertiary carbon in the carbinol series.[8]

The curves of Fig. 4 showing the results of the study of the chlorides, while in no sense identical with those obtained with the corresponding carbinols, are unmistakably of the same general shape.

While by the very nature of the postulate of the extreme constitutive nature of the parachor, the values for the various CH_2 units would not be expected to be identical in the two series, the main structural feature of both series is the same, the varying tertiary carbon atom, and it is of interest to substitute in the chloride series the average

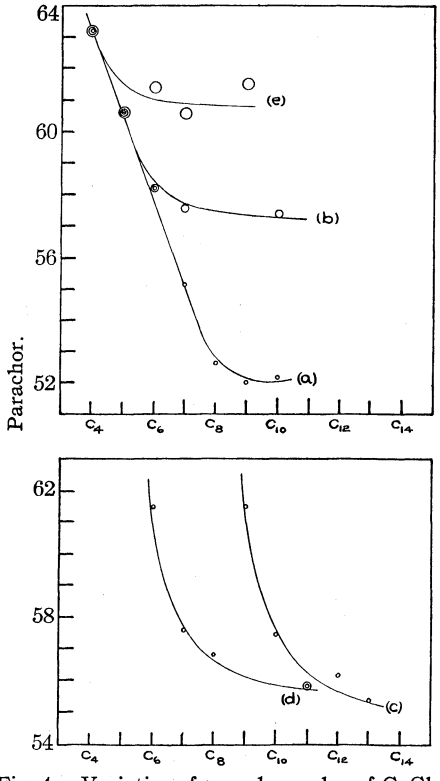

Fig. 4.—Variation of parachor value of C–Cl groups in series.

CH_2 values as obtained from the two series (Table VI).

		Average % diff.	1.8		0.2		0.3

The average error using the previous most satisfactory values is approximately three times the maximum error of that using these newer values. Still more exact values for the various CH_2 positions of this series as indicated in Table V may be calculated from the chloride values here reported

and when applied show an average error of 0.2%. If averages be found between these two sets of values, the new set would describe both the alcohols and the chlorides with an average error of 0.3% when applied to the chlorides.

The constitutive effect is strikingly brought out by comparing homologs. The maximum CH_2 value from methylethylhexylchloromethane to ethylpropylpropylchloromethane would be 14.8 units or 45% higher than the minimum value in comparing propylpropylpropylchloromethane and methylmethylhexylchloromethane.

Summary

1. The densities, surface tensions and parachors of sixteen tertiary chlorides have been determined.

2. The parachors show a decrease with temperature of approximately 0.2% per 10° rise in temperature.

3. The effect of substitution in trimethylchloromethane has been found to be of the same order as that with trimethylcarbinol.

4. Values for the individual CH_2 groups in the tertiary chlorides have been determined and found to be of approximately the same value as those obtained for the corresponding CH_2 groups in the tertiary carbinols.

5. The similarity of the values obtained for the chlorides and alcohols indicates that association is not an important factor in the parachor values of the alcohol series.

6. The values for the tertiary branching give closer agreement between the calculated and observed values than the values previously used.

The Second Ionization Constant of Oxalic Acid from 0 to 50°

BY HERBERT S. HARNED AND LESLIE D. FALLON

From the electromotive forces of the cells

$$H_2 \mid NaHC_2O_4(xm_1), Na_2C_2O_4(xm_2), NaCl(xm_3) \mid AgCl\text{–}Ag$$

the ionization constant of $HC_2O_4^-$ has been determined at 5° intervals from 0 to 50°.

The observed electromotive forces are given in Table I. The concentrations of the most concentrated solution, m_1, m_2 and m_3, are given. The concentrations of all other solutions are given by xm_1, xm_2 and xm_3 where x is less than unity. The concentrations were known with an accuracy greater than 0.1%. The reproducibility of the measurements was of the order of ±0.05 mv.

The Determination of the Ionization Constant.—By applying the method of Harned and Ehlers[1] in the manner used by Nims[2] for the second ionization constant of phosphoric acid, the electromotive force of the cell may be expressed by

$$\frac{(E - E_0)F}{RT} + \log \frac{m_{Cl}\, m_{HC_2O_4}}{m_{C_2O_4}} + \frac{2u\sqrt{\mu}}{1 + A\sqrt{2\mu}} = -\log K_2 + f(\mu) = -\log K_2' \quad (1)$$

where the symbols have their usual significance. This differs from the equation of Nims by including the Debye and Hückel factor containing A which allows for the effect of the mean distance of approach of the ions. In order to determine the ionization constant, K_2, it is necessary to evaluate

the left side of this equation and extrapolate to zero ionic strength. The ionization constant is of the order of 5×10^{-5} and this is great enough to require a small correction to the ratio of $m_{HC_2O_4}$ to $m_{C_2O_4}$ in the term containing these quantities. This correction was made by arithmetical approximation using the expression for the thermodynamic ionization constant and the Debye and Hückel equation for the activity coefficient. At the lowest concentration the correction amounts to 0.007 in $-\log K_2$ and at the higher concentrations it is negligible. In Fig. 1, various extrapolations are shown. The upper plots represent the

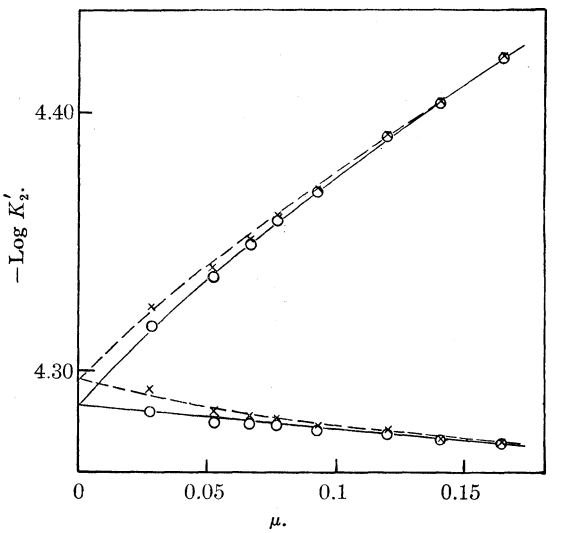

Fig. 1.—Extrapolation at 25°: crosses, uncorrected extrapolation function; circles, extrapolation function corrected for hydrogen ion concentration; upper plots, limiting law; lower plots, limiting equation with term for "mean distance of approach of ions"; diameter of circles equals 0.2 mv.

extrapolation when the Debye and Hückel term, $2u\sqrt{\mu}$, is employed. The lower plots represent the extrapolation when the complete Debye and Hückel expression is used. A was taken to be unity. From the character of these graphs, it is apparent that the latter function yields the better extrapolation. The crosses are the values of the left side of equation (1) uncorrected for hydrogen ion concentration, while the circles represent the values of this quantity when the ratio of $m_{HC_2O_4}$ to $m_{C_2O_4}$ has been corrected. The uncorrected function (dashed lines) leads to a higher value of $-\log K_2$. The corrected function (lowest plot) is a straight line and is easy to extrapolate. The uncertainty in the evaluation of $-\log K_2$ is about 0.002.

Parton and Gibbons[3] and Parton and Nicholson[4] have used a similar cell in which the hydrogen electrode was replaced by the quinhydrone electrode for the determination of K_2. The plots of their results lie very close to ours. At 25°, they obtained 4.300 for $-\log K_2$ at 25° but they did not make the hydrogen ion correction. The present results lead to a value of 4.297 under these circumstances which is excellent evidence of the experimental accuracy of both series of results. Our corrected value is 4.286 at 25°. The same remarks also apply to their results at 30 and 35°.

Heat Content and Heat Capacity of the Ionization Reaction.—Results have been obtained at a sufficient number of temperatures to permit the evaluation of the thermal data from the values of $(-\log K_2)$ given in Table II. The equation of

Constants of equation (2): $\log K_m = \bar{5}.774$; $\Theta = -6.8°$; $p = 6 \times 10^{-5}$.

Harned and Embree[5]

$$\log K_2 = [\log K_m - p\Theta^2] + 2p\Theta t - pt^2 \quad (2)$$

was found to fit the data very accurately if p has the value of 6×10^{-5}. In this equation, K_m is the value of K_2 at its maximum, and Θ is the temperature at which K_2 is a maximum. In most cases of uni-univalent electrolytes, a value of 5×10^{-5} for p is suitable. In the present case, the higher value is somewhat better. K_m was found to be 5.94×10^{-5} at $-6.8°$. Substitution of these values in equation (2) leads to the convenient numerical equation

$$\log K_2' = \bar{5}.771 - 0.000816t - 6 \times 10^{-5} t^2 \quad (3)$$

The agreement between the observed results and those calculated by this equation is shown in the

second and third columns of Table II. The maximum deviation is 0.003 at 50° and the average deviation is only 0.001.

The changes in heat content and heat capacity accompanying the ionization reaction are given by the equations

$$\Delta H = -5.69 \times 10^{-4}\, T^2(t - \Theta) \quad (4)$$

$$\Delta C_p = -5.49 \times 10^{-4}\, T(T + 2(t - \Theta)) \quad (5)$$

which are derived by differentiation of equation (1). Values of these quantities are contained in the last two columns of Table II.

Summary

1. By means of suitable cells without liquid junction, the second ionization constant of oxalic acid, K_2, has been determined at 5° intervals from 0 to 50°.

2. The equation $\log K_2 = \bar{5}.771 - 0.000816t - 6 \times 10^{-5}\, t^2$ expresses the observed values of $\log K_2$ with an average accuracy of ± 0.001.

3. Values of the heat content and heat capacity of the ionization reaction have been tabulated.

Properties of Electrolytes in Mixtures of Water and Organic Solvents. IV. Transference Numbers of Hydrochloric Acid in Water and Dioxane–Water Mixtures from 0 to 50°

BY HERBERT S. HARNED AND EDWIN C. DREBY[1]

In conjunction with the extensive study of the thermodynamic properties of hydrochloric acid in water and in media covering a wide range of the dielectric constant by measurements of the electromotive force of cells of the type

$$\mathrm{Pt/H_2/HCl}(m), \text{ dioxane}(X), \mathrm{H_2O}(Y)/\mathrm{AgCl\text{–}Ag} \quad (1)$$

it was considered appropriate to investigate the phenomenon of transference for this acid in the same media by means of the cells with transference of the type

$$\mathrm{Ag\text{–}AgCl/HCl}(m), \text{ dioxane}(X), \mathrm{H_2O}(Y)/\mathrm{HCl}(r), \text{ dioxane}(X), \mathrm{H_2O}(Y)/\mathrm{AgCl\text{–}Ag} \quad (2)$$

Very extensive measurements were made which covered the acid concentration range from 0.005 to 3 M, a temperature range from 0 to 50° in solvents consisting of 0, 20, 45 and 70% dioxane–water mixtures. Results of less accuracy were also obtained in 82% dioxane–water mixtures ($D \sim 10$).

The transference number which has been calculated is that defined by the well-known thermodynamic relation

$$T^+ = \mathrm{d}E_t/\mathrm{d}E \quad (3)$$

where the transference number, T^+, at any particular concentration is the slope at the corresponding point on the plot of E_t, the electromotive force of the cell with transference, versus E the electromotive force of the cell without transference.

This is by far the most extensive study of the transference number of an electrolyte as a function of its concentration, the temperature and solvent composition. It is well known that this method is not so accurate as the moving boundary method, but it is reliable, rapid and therefore suitable for an extensive survey of the subject.

Experimental Procedure

A diagram of the cell used is shown in Fig. 1. It consisted of two half-cells connected by means of a stopcock at

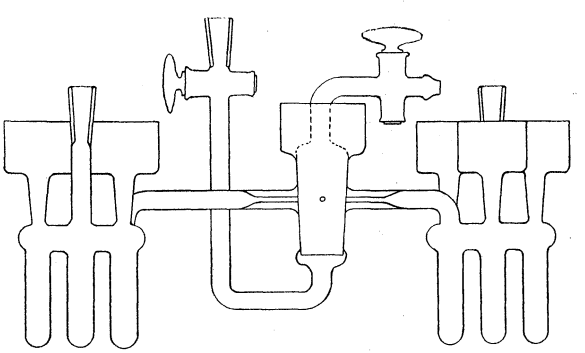

Fig. 1.—Transference cell.

which the liquid junction was formed. Each half-cell contained three legs into which the silver–silver chloride electrodes were inserted. Interchangeable ground glass joints were used between cell and electrode to give air-tight

joints which would not contaminate the dioxane mixtures with grease or rubber. The side arm on each half-cell was used for filling purposes. The junction stopcock consisted of a three-way hollow core with one-inch (2.5-cm.) capillaries leading to the half-cells. The three way stopcock was essential in filling the cells and between measurements the stopcock was set at an intermediate position to prevent diffusion between the two half-cells.

The vacuum technique used in electromotive force work in this Laboratory was not applicable in this case. The procedure was to insert the electrodes and the filling vessels in their respective holes and evacuate the apparatus through the junction stopcock. It was then filled with hydrogen and reëvacuated. This process was carried out three times, finally leaving the whole apparatus under a slight pressure of hydrogen. The solution was then allowed to run in, forcing out the atmosphere of hydrogen. The solutions had previously been saturated with hydrogen and were air free.

The preparation of the solutions and electrodes and the method of measurement was identical with that described by Harned and Morrison.[4] The arrangement of having three electrodes in each half-cell permitted the checking of the electrodes against each other, thus facilitating the detection of faulty electrodes.

Electromotive Forces

In order to obtain reproducible and consistent results, it was found advisable to keep the acid activity ratio in the transference cells less than ten to one. This made it impossible to use the same reference concentration in every cell measured. Instead, a series of cells, interrelated, was measured over the concentration range, and the results were combined in such a manner as to give values of the electromotive force over the entire acid concentration range all referred to one reference concentration

The procedure was to least square the original experimentally determined values of the electromotive force to fit the equation

$$E = E_{25} + a(t - 25) + b(t - 25)^2 \qquad (4)$$

These equations were then combined so as to give the electromotive forces in terms of the reference concentration. The resultant constants were then smoothed concentration-wise. Table I gives values of the constants E_{25}, a and b at the measured concentrations for water, 20, 45 and 70% dioxane–water mixtures.

The average deviations listed in the last column of Table I are the differences in millivolts between the values calculated by equation (4) and the original experimental values, averaged over the temperature range for each cell. The values with the asterisk obviously are associated with poor experimental results and these were not included in

computing the over-all $\Delta_{av.}$ listed at the bottom of the column. The experimental results were the average of at least four readings. The spread in these readings was, in the majority of cases, less than 0.1 mv. Only in the higher dioxane mixtures was it impossible to keep within this limit, and here the average was taken from a greater number of readings. The values obtained are believed to be correct within ± 0.05 mv. The $\Delta_{av.}$ listed in Table I would indicate that the quadratic formula is adequate for expressing the data.

Interpolated values of the measurements of these cells at 25° in aqueous solutions by Shedlovsky and MacInnes agree to within 0.1 mv. or less with our results.[8]

Computation of the Transference Number

From equation (3), it is seen that it is necessary to construct a graph of E_t, the electromotive force of the cell with liquid junction, against E, the electromotive force of the cell without liquid junction. The range of values of E_t and E, however, is so large that graphing them directly would cause the loss of significant figures necessary for the accurate determination of the slope. A method was devised whereby values of E at equally spaced intervals of E_t were determined without the loss of significant figures. Furthermore, the results in this form made it possible to determine the slope analytically and hence improve the accuracy.

Deviation functions, defined by the relations

$$X = E + 2k \log m/m_r;\ X_t = E_t + 2k \log m/m_r$$

gave values of X_t and X corresponding to the values of E_t and E where k is defined by $2.303\ RT/F$. These values of X_t and X covered a very small range, so they could be plotted very accurately and with no loss of significant figures. Values of X_t were interpolated graphically to the round concentrations for which values of X existed. These data were used to make a plot of $X - X_t$ *versus* X. It is to be noted that $X - X_t$ is simply $E - E_t$. From this graph, values of $X - X_t$ were read off for values of X_t corresponding to values of E_t spaced at equal intervals of 0.01 v., the latter being obtained from a plot of E_t against X_t. Adding together the appropriate values of $X - X_t$ and E_t gave the desired results, namely, values of E for values of E_t spaced at intervals of 0.01 v. The data were then in a form for the analytical determination of the slope, which is the transference number.

A derivative function derived by Rutledge[9] was employed for the determination of the transference number. It is of the form

$$\frac{dE}{dE_t}(E) = \frac{1}{12h}(C_{-2}E_{-2} + C_{-1}E_{-1} + C_0E_0 + C_1E_1 + C_2E_2)$$

where $(dE/dE_t)(E)$ is the slope at a value, E, of the dependent variable; h is the magnitude of the chosen interval in the independent variable; E_{-2}, E_{-1}, etc., are consecutive values of the dependent variable; and C_{-2}, C_{-1}, etc., are constants. There are three sets of constants, the choice of any one being dependent on whether the slope is to be determined at E_{-1}, E_0 or E_1. Except at the extremes, the values of the slope were determined by taking the average of the results obtained by placing the Rutledge formula in the three possible positions.

This method, as well as any other method used for the determination of slopes, has decreased accuracy at the extremes of the curve. Beside this difficulty, there is also the added fact that data in the more dilute regions are less accurate because of greater experimental difficulties. Thus, in subsequent handling of the data, less stress is laid on the values of the transference number below 0.03 M than on the values at the higher concentrations.

The values of the transference number obtained by application of the Rutledge formula to the data were smoothed by plotting them against values of E_t and reading back values of T^+ for values of E corresponding to round concentrations. Typical of such plots is that shown in Fig. 2 for water at 25°. This is, of course, a concentration-wise smoothing. Subsequently a temperature-wise smoothing was also performed but not until the limiting value of the transference number had been evaluated.

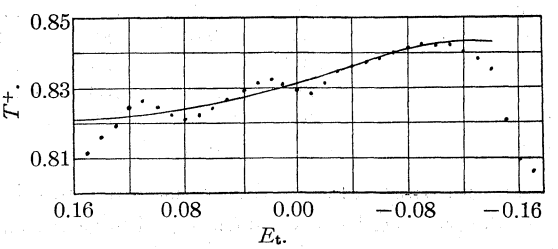

Fig. 2.—Smoothing of transference numbers. Solvent is water.

The limiting value of the transference number was determined by the method of Longsworth.[10] This consisted in plotting the function

$$T_0^{+\prime} = \frac{T^+\Lambda' + \beta\sqrt{c}}{\Lambda' + 2\beta\sqrt{c}}$$

where

$$\Lambda' = \Lambda^0 - (\alpha\Lambda^0 + 2\beta)\sqrt{c}$$

against the concentration c and extrapolating to $c = 0$ to give the value of the limiting transference number, T_0^+. In this equation, T^+ is the transference number at concentration c in moles per

(10) Longsworth, THIS JOURNAL, 54, 2741 (1932).

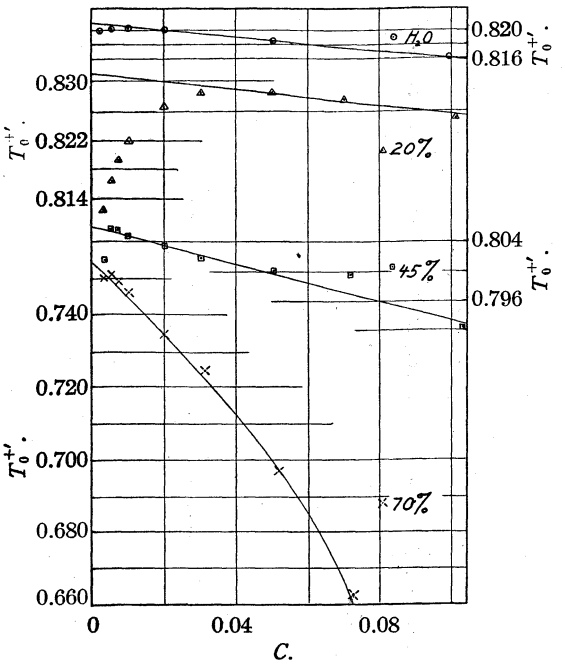

Fig. 3.—Extrapolations for limiting transference numbers.

liter, Λ^0 is the equivalent conductance at infinite dilution and α and β are the constants of the Onsager conductance theory. This function worked very well for water, 20% and 45% dioxane–water mixtures, giving practically straight lines. It began to fail in the 70% mixture, but the curvature was not great enough to seriously affect the extrapolation. Figure 3 shows the nature of these extrapolations in water, 20, 45 and 70% dioxane–water mixtures at 25°. We note that at concentrations below 0.03 *M*, particularly with the 20% dioxane mixtures, the points do not fall on the line used for the extrapolation. We attribute this behavior to the previously mentioned difficulty of obtaining slopes of a curve at the extreme end of the curve, and to a somewhat greater uncertainty in the measurements in the 20% dioxane mixtures.

With the values of the transference number at infinite dilution and the computed values of the transference number smoothed over the concentration range, plots were now made of the transference number *versus* the square root of the concentration and the values for the whole temperature range were plotted on the same sheet of paper. In drawing any one curve the points on either side corresponding to the next higher and lower temperature interval, respectively, were considered. This resulted in a temperature-wise smoothing. In every case but one, the deviations of the drawn curve from the plotted points were well within the expected limit of error. Values of the transference number at round concentrations and at 5° intervals for water, 20, 45 and 70% dioxane–water mixtures are listed in Table II.

Discussion of Errors

From a consideration of the Rutledge derivative function, it can be shown that an error of 0.00001 in E produces an error of 0.001 in T^+. The mean deviations in Table I give, in all probability, a close approximation to the expected error in E from which the error in T^+ can be determined. Also, the average of the deviations of the plotted points from the smooth curve in Fig. 2 will give the order of magnitude of the expected error in the transference number. The results obtained by the first method lead to expected errors of 3, 7, 4 and 8 and the second method of 2, 5, 4 and 8 units in the third place of the transference number for water, 20, 45 and 70% dioxane–water mixtures, respectively. The consistency

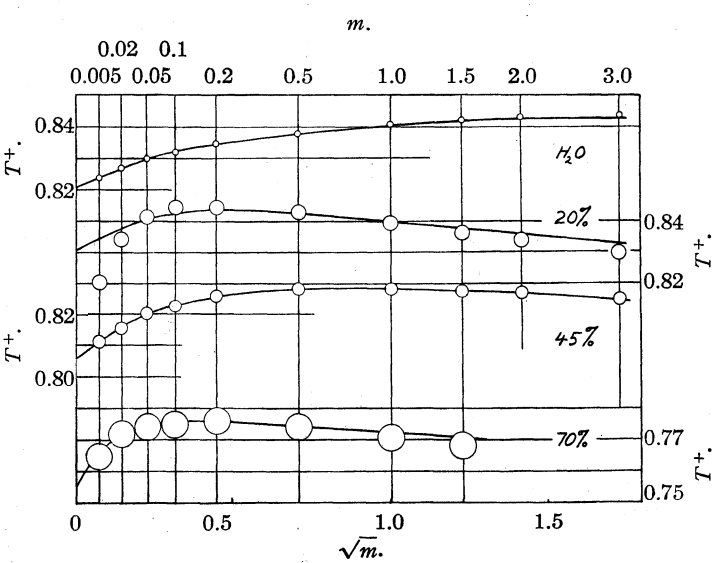

Fig. 4.—Smoothed transference numbers and degree of error.

in the plotted points from which Table II was formed would lead one to believe the error is well within these limits.

A comparison of the transference numbers at 25° for the various solvents with the limit of error

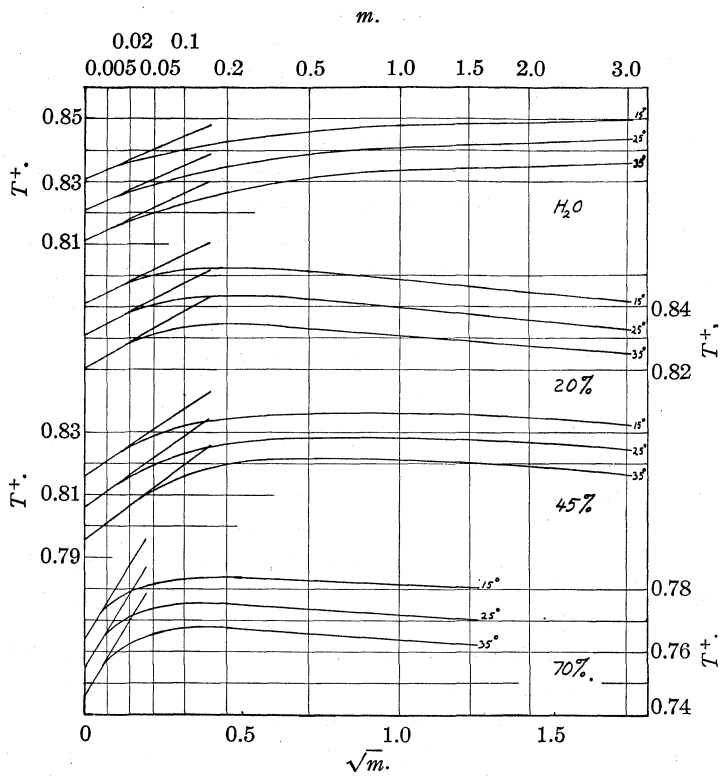

Fig. 5.—Transference numbers and theoretical limiting slopes.

as determined by the second method listed above is shown in Fig. 4. The diameters of the circles represent the size of the error. The circles are drawn about the points determined by the smoothing process of Fig. 2. The lines are drawn through the points listed in Table II.

Limiting Slopes for the Transference Numbers.—The Onsager conductance theory leads to an expression for the limiting slope

$$\text{slope} = \frac{(2T_0^+ - 1)\beta}{\Lambda^0}\sqrt{d_0}$$

where T_0^+ is the limiting value of the transference number, Λ^0 is the limiting equivalent conductance, β is the constant from the Onsager conductance theory and d_0 is the density of the pure solvent. This is the slope for T^+ versus the $\sqrt{m}$. Table III gives the values of the slope in water, 20, 45 and 70% dioxane–water mixtures.

Figure 5 shows plots of the transference numbers at 15, 25 and 35° with the limiting slopes drawn in for water, 20, 45 and 70% dioxane–water mixtures. It is to be noted that, even where the slope is steep as is the case for the higher dioxane mixtures, there is a tendency for the curve to fall rapidly into the limiting slope from 0.02 *M* on down.

Comparison with Other Methods.—Extensive work has not been carried out previously on the determination of the transference numbers of hydrochloric acid over wide concentration and temperature ranges by any one method. Table IV gives values for the transference number of hydrochloric acid in water determined by the three principal methods: electromotive force, Hittorf,

and moving boundary, as listed in the "International Critical Tables." The values found in this investigation are listed within parentheses for comparison. On the whole, the agreement is satisfactory.

The most accurate method for the determination of transference numbers is the moving boundary method, particularly in its refined form as developed at the Rockefeller Institute. Longsworth[10] has determined the transference number of hydrochloric acid in water with great precision at 25°. The values determined in this investigation are compared with his in the last two rows of Table IV. The excellent agreement obtained is good confirmation that the method used in computing the transference number from the electromotive forces is a sound one.

Transference Numbers in 82% Dioxane.—The difficulties in obtaining the electromotive forces of the cells with liquid junction for the 82% dioxane–water mixture were not easy to overcome. There was a much greater tendency for diffusion of the electrolyte at the junction and the low conductivity of the solutions made it difficult to make measurements of the electromotive force. A cell was used similar to that in Fig. 1 but without the capillary tubing. It was necessary to have reservoirs of the solutions in the side arms to flush out the junction tubes whenever the junction stopcock had been opened for any length of time. Furthermore, the electrodes took considerable time to come to equilibrium and they did not remain constant over long periods of time.

The electromotive forces of the cells with transference are listed in Table V. The large deviations, particularly in the lower concentrations, indicate that the transference numbers cannot be determined with great precision for the dilute acid solutions. Figure 6 shows the final smoothed values of the transference number at 15, 25 and 35°, represented by the heavy curved lines.

The Longsworth method was not very satisfactory in determining the limiting value of the transference number but the accuracy of the data did not warrant the search for another method. With full knowledge that these values are probably incorrect but that they do give the order of magnitude, the theoretical limiting slopes were calculated. These are shown in Fig. 6 by the heavy straight lines drawn into the origin.

The dashed lines in Fig. 6 show what is believed to be nearer the correct values for the transference number in the dilute region, since they approach the theoretical limiting slopes in a logical manner. It is not unreasonable to assume this when it is considered that, in this region of concentration, the error must be of the order of 10 or 15 units in the third place of the transference number. Despite the possible justification for these assumptions, the transference numbers for the 82% dioxane–water mixtures are listed in Table VI from 0.05 to 0.5 M only, the region in which reliable

values for the electromotive force were obtainable. The extrapolated values of the transference number used in the calculation of the limiting slope are listed in the first row of the table.

Summary

1. Electromotive forces of the cells Ag–AgCl/HCl (m), dioxane (X), $H_2O(Y)$/HCl(r), dioxane (X), $H_2O(Y)$/AgCl–Ag have been obtained for 0, 20, 45, 70 and 82% dioxane solutions at 5° intervals from 0 to 50° and from 0.005 to 3.0 M acid concentration.

2. The cation transference number has been calculated over these ranges of temperature and concentration from these results and previous measurements of the cells without liquid junction.

3. The limiting transference number has been determined by extrapolation for all the solutions over the entire temperature range.

4. Agreement with the limiting law of the Onsager conductance theory was observed in the water, 20, 45 and 70% dioxane–water mixtures.

5. Results obtained with the mixtures containing 82% dioxane were less accurate. They have a value, however, since no transference number data in media of as low a dielectric constant ($D_{25} = 9.57$) are available.

Phosphoryl Bromofluorides

BY HAROLD SIMMONS BOOTH AND CHARLES GEORGE SEEGMILLER[1]

It has been found in this Laboratory that phosphoryl trichloride can be fluorinated stepwise to yield phosphoryl chlorofluorides[2a] by means of antimony trifluoride with antimony pentachloride as catalyst, and that phosphorus tribromide likewise can be fluorinated stepwise by means of antimony trifluoride but with bromine as the catalyst.[2b]

While the phosphoryl chlorofluorides were quite stable, the compounds $PBrF_2$ and PBr_2F decomposed on standing to PF_3 and PBr_3. Hence it was of interest to learn whether phosphoryl bromide could be similarly fluorinated stepwise and whether the fluorobromides so produced were stable.

Experimental

Phosphoryl tribromide[3] was prepared by the reaction between phosphorus pentabromide and phosphorus pentoxide: $P_2O_5 + 3PBr_5 = 5POBr_3$. The phosphoryl tribromide was fluorinated at a pressure of 25 to 50 mm. by the slow addition of sublimed antimony trifluoride[4] in the generator as described by Booth and Bozarth.[5] During the early stages, the reaction was vigorous at 60°, but in its later stages it became quite slow, so that it was found advantageous to raise the temperature gradually to 100°. It was unnecessary to add a catalyst, perhaps due to traces of bromine left in the phosphoryl tribromide.

The product consisted of about 60% phosphoryl trifluoride, 10% phosphoryl monobromodifluoride, and 30% phosphoryl dibromomonofluoride. The products were separated and purified and their physical constants established, as described by Booth and Bozarth.[6] It was found in the case of the $POFBr_2$ and POF_2Br that an ice–salt mixture made a satisfactory refrigerant for the acetone which was circulated by an automatically actuated centrifugal pump through the fractionating column head.

Analysis.—The phosphoryl trifluoride was established by approximate boiling points obtained from a thermocouple in the fractionating column head, by molecular weight determinations by a gas density balance,[6] and by chemical analysis for phosphorus.

Samples of the phosphoryl bromofluorides were condensed in glass bulbs connected to the apparatus by conical joints as previously described[2a] and absorbed in an excess of potassium hydroxide. They reacted energetically with the solution on warming and were completely dissolved. The solution was then heated on a steam-bath for fifty hours to ensure completion of the reaction. Bromine was determined gravimetrically as silver bromide, and phosphorus

by precipitation as the phosphomolybdate and direct weighing as such. One set of samples was reprecipitated as magnesium ammonium phosphate and ignited to the pyrophosphate, and was found to be in good agreement with the above method.

Physical Properties.—The determination of the vapor pressure of phosphoryl monobromodifluoride was made by direct observation of the vapor pressure of the liquid held in a small glass bulb immersed in a thermostat, in the manner described by Booth and Bozarth.[6] Two separate samples, A and B, were run; as an extra check, a small portion was distilled out of each sample after a set of readings had been taken, at a pressure different from the pressure of the original distillation of the substance, and a few more points then determined. The temperature was observed with a Leeds and Northrup resistance thermometer calibrated by the United States Bureau of Standards.

The vapor pressure data for phosphoryl dibromomonofluoride, which is a liquid at room temperature, were determined in an isoteniscope,[7] as was that small portion of the curve for phosphoryl monobromodifluoride which was run above room temperatures (Sample C). Here again, for the phosphoryl dibromomonofluoride, two separate samples A and B were run, and small portions were pumped off and more points run as a further check of purity.

The freezing points of phosphoryl dibromomonofluoride and phosphoryl monobromodifluoride were observed in the glass melting point apparatus which is standard in this Laboratory. The rate of cooling was observed on the Micromax recording potentiometer actuated by a three-junction thermocouple which had been calibrated against a platinum resistance thermometer standardized by the United States Bureau of Standards. The freezing points obtained were sharp and easily reproducible. Both compounds showed supercooling under favorable experimental conditions, sometimes as much as 15°.

The liquid density of the phosphoryl bromofluorides at 0° was determined using a pycnometer as described by Booth and Herrmann.[8]

Discussion

Phosphoryl tribromide was found to yield the expected intermediate fluorination products as well as phosphoryl trifluoride. No catalyst was found to be necessary, possibly due to traces of bromine in the phosphoryl tribromide, although Schumb and Gamble[9] found a catalyst was unnecessary in the fluorination of $SiBr_4$ by SbF_3. No tendency toward decomposition of the intermediate compounds to the completely brominated and completely fluorinated end-products was observed at any temperature used, in which the phosphoryl bromofluorides resemble the phosphoryl chlorofluorides and not the fluorobromophosphines.

[a] Indicates check run after part was distilled out. [b] Observed pressures have been corrected to 0° and standard gravity according to the "International Critical Tables." [c] Calculated values were determined by the use of the above equations.

The properties of the phosphoryl bromofluorides lie between those of the tribromide and the trifluoride. When pure, both phosphoryl bromofluorides are colorless in all states. They hydrolyze and fume in moist air, and react violently with water. They attack nichrome wire only slightly or not at all. In order to investigate the possibility of determining critical constants,

samples of the two intermediates were sealed up with mercury in glass capillary tubes and heated to their approximate critical temperatures as estimated by the "three-halves" rule. The mercury was badly attacked in both cases, so that the critical constants could not be determined.

Summary

The fluorination of phosphoryl tribromide with antimony trifluoride yields three products, a gas, phosphoryl trifluoride, first described by Moissan, and two new, stable, volatile liquids, phosphoryl monobromodifluoride and phosphoryl dibromomonofluoride. All three have been isolated and purified. The boiling points, vapor pressure data, gaseous and liquid densities of the two phosphoryl bromofluorides have been determined and recorded along with some of their chemical properties.

[CONTRIBUTION FROM THE CHEMICAL LABORATORIES OF BROWN UNIVERSITY AND OF THE UNIVERSITY OF ILLINOIS]

(I) The Reaction of Gallium with Perchloric Acid and (II) the Preparation and Properties of Gallium Perchlorate Hydrates

BY LAURENCE S. FOSTER

I. Reaction of Gallium with Perchloric Acid

Metallic gallium dissolves very slowly in the common mineral acids. Sebba and Pugh[1] reported recently that concentrated nitric acid was the most rapid reagent but, when it was kept near the boiling point, even it dissolved only 5 g. of the metal in ten hours. The rate was somewhat increased by alternately heating and cooling the mixture. They found, in addition, that because of the pronounced passivity of gallium, it was possible to free it from many metallic impurities with little loss of gallium by allowing it to remain in contact with concentrated nitric acid.

Perchloric acid and mixtures of perchloric acid with other acids have been used to dissolve many ordinarily very resistant alloys, particularly "stainless steels."[2] These same reagents have now been shown to dissolve gallium more rapidly than any used hitherto.

Experimental

Reaction of Gallium with Perchloric Acid.—A small piece of gallium (0.5 g.) was heated with 20 ml. of perchloric acid (72%) in an Erlenmeyer flask (250 ml.) equipped with a Smith refluxing head.[2] A vigorous reaction took place and the metal was dissolved completely within fifteen minutes. In another experiment 5 g. of gallium was dissolved in 60 ml. of the acid within an hour. The gallium perchlorate formed is moderately soluble in the hot concentrated acid, but as soon as the mixture is cooled slightly, hexa-aquo gallium perchlorate separates in the form of coarse, white crystals. The remaining acid, recovered by filtration through a sintered-glass funnel, contains almost no gallium.

Reaction of Gallium with Mixed Perchloric–Sulfuric Acids.—The reaction of gallium with a mixture containing two-thirds sulfuric acid (98%) and one-third perchloric acid (72%) was found to be more rapid than that with perchloric acid alone. Gas evolution started as soon as the cold acid mixture came in contact with the metal and proceeded very rapidly when it was warmed. Five grams of gallium was dissolved in 60 ml. of the mixture in about one-half hour. The reaction product was not so soluble in the mixed acids as in perchloric acid alone, however, and separated immediately as a finely divided, white precipitate. Its presence did not interfere with the progress of the reaction, and after the metal had disappeared the excess perchloric acid was removed by distillation with no "bumping" until sulfur trioxide fumes began to escape. At this point, "bumping" became severe. By dissolving the cooled mixture in water, a clear solution of gallium sulfate, containing excess sulfuric acid, was prepared. The entire process was accomplished in less than an hour.

Reaction of Gallium (III) Oxide with Perchloric Acid.—The soluble form of gallium oxide was found to dissolve readily in perchloric acid, but the insoluble form did not

react. The latter dissolves fairly rapidly in hot hydrochloric acid, however, and after the mixture has become clear, the excess hydrogen chloride may be removed by heating with perchloric acid. Hexa-aquo gallium perchlorate separates when the solution is cooled.

II. Preparation of Gallium Perchlorate Hydrates

Aluminum perchlorate forms crystalline compounds containing 15, 12, 9 and 6 moles of water. It has been reported that a basic aluminum perchlorate, $2Al(ClO_4)_3 \cdot Al_2O_3$, is formed when the nonahydrate is heated rapidly.[3] With indium, the only perchlorate which has been prepared has the formula $In(ClO_4)_3 \cdot 8H_2O$.[4] It has now been found that gallium perchlorate is stable only when extensively hydrated. The following hydrates have been identified: $Ga(ClO_4)_3 \cdot 6H_2O$ and $Ga(ClO_4)_3 \cdot 9^1/_2H_2O$. Basic gallium perchlorates of indeterminate composition are formed when the hydrated crystals are heated.

Experimental

Preparation of Hexa-aquo Gallium Perchlorate.—Ten grams of pure gallium, or an equivalent amount of the soluble form of gallium sesquioxide, is allowed to react with excess perchloric acid (72%) as described in a previous section. If the volume of acid used is larger than 150 ml., the product is entirely soluble at the boiling point of the mixture (200°) and the observation of the disappearance of the last small globules of the metal is facilitated. If less acid is used, the gallium perchlorate formed separates as a coarsely crystalline precipitate, but it does not interfere with the course of the reaction. Heating is continued after the metal has all reacted to remove water and the perchloric acid reduction products (Cl_2, etc.). The characteristic fumes of constant boiling perchloric acid soon appear, and heating is discontinued. When the mixture has cooled, the product may be collected by suction filtration on a sintered glass Büchner funnel and pressed dry with a glass or porcelain spatula. (The small amount of gallium in the filtrate is recovered separately.) The entire process does not require much more than an hour.

NOTE.—The moist crystals must not be allowed to come in contact with any organic material such as filter paper or a horn spatula. Because of the removal of water, due to the formation of hydrated crystals, the perchloric acid adhering to the product is more highly concentrated than 72%.

The remaining excess acid may be removed from the crystals by heating them *in vacuo* at 125° for about an hour in a glass tube, sealed at one end and large enough to hold the porcelain boat containing the product, and exhausted through a glass connection held in a rubber stopper. The tube may be heated conveniently in a thermostated electric drying oven. It should be long enough (2 ft., 61 cm.) to afford an opportunity for the perchloric acid which is volatilized to condense and cool before it reaches the rubber stopper, and it is desirable to expand a section of the tube to provide a bulb into which the condensate may run. If a mechanical pump is used, it should be protected from the acid fumes by a trap containing solid sodium hydroxide.

The hexa-aquo gallium perchlorate thus prepared is a dry, free running powder. Large crystals of hexa-aquo gallium perchlorate may be prepared by slow evaporation, over concentrated sulfuric acid in a vacuum desiccator, of an aqueous solution of gallium perchlorate which contains excess perchloric acid.

Analysis.—Since the hydrates of gallium perchlorate were found to be very soluble in alcohol, it was possible to carry out analyses on a single sample for both the perchlorate ion and the gallium, and by difference to compute the percentage of water. Potassium perchlorate, precipitated by the addition of an excess of an alcohol solution of potassium thiocyanate, was weighed in a sintered glass filtering crucible, after having been dried for an hour at 120°. Water was added to the filtrate and after the alcohol had been removed by distillation, the gallium was precipitated by means of tannin.[5]

Anal. Calcd. for $Ga(ClO_4)_3 \cdot 6H_2O$: Ga, 14.64; ClO_4, 62.65. Found: (A. Crystals heated *in vacuo* for six hours at 120°), Ga, 14.8 (av.); ClO_4, 62.5 (av.). (B. Large crystals from perchloric acid solution, dried quickly on filter paper), Ga, 14.24; ClO_4, 61.8, 61.7.

Properties of Hexa-aquo Gallium Perchlorate.—After it has been freed of excess perchloric acid, the hexa-aquo complex is a dry crystalline meal. It is very deliquescent, extremely soluble in water, forming a clear solution, and very soluble in alcohol and glacial acetic acid. The crystals which are deposited by slow evaporation from a perchloric acid solution are large, regular octahedra. In polarized light they are seen to be isotropic and may be classified as *cubic*. At atmospheric pressure, the hexa-aquo complex decomposes at 175° and *in vacuo* at 155°, yielding gaseous products and basic gallium perchlorate residues of indefinite composition. At still higher temperatures, it is finally converted to the insoluble form of gallium oxide.

Since hexa-aquo gallium perchlorate is readily prepared from either the metal or the oxide and readily freed from the excess acid, it serves admirably as the starting material for the synthesis of other gallium compounds. Conversely, Willard and Fogg[6] electrolyzed a solution of gallium perchlorate for the preparation of the pure metal.

Preparation and Properties of Gallium Perchlorate. $9^1/_2$ Hydrate.—A concentrated aqueous solution of hexa-aquo gallium perchlorate, containing only a slight contamination of free perchloric acid, was allowed to evaporate in a vacuum desiccator over concentrated sulfuric acid. The very large crystals, 3 cm. × 5 mm. × 2 mm., which formed were shown to contain 9.5 moles of water by the analytical method previously described.

Anal. Calcd. for $Ga(ClO_4)_3 \cdot 9^1/_2H_2O$: Ga, 12.93; ClO_4, 55.33. Found: Ga, 12.92 (av.); ClO_4, 55.63 (av.).

A known weight of the $9^1/_2$-hydrate, in the form of a single, large, clear crystal still slightly moist with mother liquor and contained in an uncovered wide-form weighing bottle, was heated at 120° at atmospheric pressure. After thirty-six hours, the loss in weight corresponded to the loss of about one mole of water, and although the crystal had become translucent and somewhat deformed, it had not lost completely its original contours. The sample continued to lose water only very slowly. After a few days, the weighing bottle was transferred to a vacuum desiccator and at the end of six weeks the loss in weight indicated a conversion of the original material to the hexa-aquo derivative. The composition of the product was confirmed by analysis.

Anal. Calcd. for $Ga(ClO_4)_3 \cdot 6H_2O$: Ga, 14.64; ClO_4, 62.65. Found: Ga, 14.80; ClO_4, 62.32.

The behavior of crystal fragments when heated in small melting point tubes was quite different. Under these circumstances the $9^1/_2$-hydrate underwent a transition, at about 80°, to a mixture of the hexa-aquo complex in equilibrium with a small amount of saturated solution. Evidently, when it is heated in an open vessel, water evaporates rapidly enough to coat the surface with an adherent film sufficiently strong to permit the entire mass to retain substantially its original shape.

The $9^1/_2$-hydrate usually crystallized in large, colorless, transparent, pseudo-hexagonal prisms terminated in clinodomes, but occasionally it appears as a mass of fine needles. Both forms are monoclinic and exhibit parallel extinction in the prismatic region, and seem to be identical except for size. The substance is very soluble in water, alcohol and glacial acetic acid and is very deliquescent.

Thermal Decomposition of Hexa-aquo Gallium Perchlorate.—When hexa-aquo gallium perchlorate is heated in an evacuated Pyrex tube in an electric furnace, it begins to undergo decomposition at about 155°. Above that temperature it crumbles and some particles are swept out of the container in the stream of evolved gases, giving the appearance of sublimation. This product, however, is not volatile and upon analysis is seen to be a basic gallium perchlorate. Analyses of the residues in the container show the composition to be variable and dependent upon the duration of heating and the temperature attained. Some of the products corresponded fairly closely to the formulas $2Ga(ClO_4)_3 \cdot 3Ga_2O_3$, and $3Ga_2O_3 \cdot Ga(ClO_4)_3$. Others showed intermediate compositions. Only once, when the heating was not prolonged, did the analysis of the residual material correspond at all closely to that of anhydrous gallium perchlorate, $Ga(ClO_4)_3$.

Due to the insolubility of the basic perchlorates in alcohol, the method of analysis used with the hydrated perchlorates could not be followed. Attempts were made to determine the amount of perchlorate ion by precipitating methylene blue perchlorate[7] from a solution of the basic salt in dilute acids, but the results were unreliable. The precipitate was hard to filter and analyses of aliquot parts of a solution differed by as much as 50% due to incomplete precipitation. It was found practicable, however, to prepare an alcoholic solution of the sample by moistening it with glacial acetic acid and allowing it to stand for two hours or more to convert it to a soluble acetate. When alcohol was then added, a clear solution usually resulted. Potassium perchlorate was precipitated and weighed, and the gallium was determined as gallium oxide after precipitation by means of tannin as before.

A sample of a basic perchlorate, the formula of which corresponded fairly closely to $3Ga_2O_3 \cdot Ga(ClO_4)_3$, was heated in a covered porcelain crucible over a Meker burner. The product was the insoluble form of gallium oxide.

Anal. Calcd. for $2[3Ga_2O_3 \cdot Ga(ClO_4)_3] \rightarrow 7Ga_2O_3$: loss, 29.5%. Found: 32.7%.

Acknowledgment.—The author wishes to acknowledge his indebtedness to the University of Illinois for the use of laboratory facilities and materials and to the members of the Chemistry Staff, particularly Professors G. F. Smith and J. C. Bailar, Jr., for their advice and coöperation.

Summary

1. Gallium has been found to dissolve rapidly in hot concentrated perchloric acid and in perchloric–sulfuric acid mixtures.

2. Two hydrates of gallium perchlorate, containing 6 and 9.5 molecules of water of crystallization, have been prepared and characterized.

3. The conditions of stability of the hydrates have been investigated and their conversion at elevated temperatures to basic perchlorates of indefinite composition and finally to the insoluble form of gallium oxide has been established.

The Effect of Hydrochloric Acid Concentration on the Reduction of Molybdate in the Silver Reductor

BY C. F. HISKEY,[1] V. F. SPRINGER AND V. W. MELOCHE

In the course of a series of studies associated with an investigation of the thiocyanate complex of molybdenum, it was necessary to prepare relatively pure solutions of quinquevalent molybdenum. Among the various methods for preparing this substance there are three common quantitative procedures available. In all cases, a molybdate is reduced with moderately strong reducing agents in solutions approximately 2 normal with hydrochloric acid. Lang and Gottlieb[2a] used stannous chloride solution, Birnbaum and Walden[2b] used the silver reductor, and Furman and Murray[3] used metallic mercury. Because of certain requirements in our experiments, we selected the silver reductor for our investigations. In earlier studies, Walden, Hammett and Edmonds[4] obtained erratic results when they used silver for the reduction of molybdate. However, Birnbaum and Walden showed later that by regulating the normality of the acid, the rate of flow through the reductor tube and the temperature, molybdate was reduced completely to the quinquevalent state.

It will be recalled that high acid concentrations exert a pronounced effect upon quinquevalent molybdenum solutions as well as upon the reduction of molybdate.[5,6] A solution of five-valent molybdenum in 2 normal hydrochloric acid is amber in color while one in 8 normal hydrochloric acid is green. However, if molybdate is reduced with such vigorous agents as the Jones reductor (Zn) in 2 normal sulfuric acid solutions, the molybdenum is trivalent and the solution is green.[7] When molybdate is reduced electrolytically in 8 normal hydrochloric acid solutions, trivalent molybdenum is formed but the solution is pink instead of green.[8] The work of these authors has been summarized in Latimer's "Oxidation Potentials"[9] in the following scheme

$$Mo^{3+}\ (green) \xrightarrow{+0.25v.} Mo^{5+} \xrightarrow{-0.53v.} Mo^{6+}$$
$$Mo^{3+}\ (red) \xrightarrow{-0.11v.} \uparrow$$

Relative stability of solutions of quinquevalent and trivalent molybdenum is another important consideration. It will be remembered that when molybdenum is reduced in the Jones reductor, the reduced solution of trivalent molybdenum is usually caught in ferric alum, or else the solution is protected from the air by an atmosphere of carbon dioxide. Solutions of quinquevalent molybdenum are much more stable. Furman and Murray have indicated that a solution of quinquevalent molybdenum can be titrated with ceric sulfate without any special precautions. In fact, the quantitative procedure for the estimation of molybdenum by means of the silver reductor depends on the fact that if some trivalent molybdenum is formed in the course of the reduction enough air will be dissolved in the solution to oxidize the molybdenum back to the quinquevalent state.

Reductor Technique.—Since we were interested in the true extent of the reduction, it was necessary to prevent oxidation by air. To this end, a one-liter flask was provided with a three-holed stopper and this was arranged in such a manner that it could be attached to the reductor and the air could be displaced in the attached flask by a stream of carbon dioxide before and during the reduction. In a regular procedure, the reductor was heated by passing through it about 200 ml. of boiling hot hydrochloric acid of the same concentration as that of the molybdate sample which was to be reduced. Following the warming process, a one-liter receiving flask was attached and the air displaced by a rapid stream of carbon dioxide. About 40 ml. of 0.02482 molar molybdate which was 8 normal to hydrochloric acid was diluted with the appropriate amount of boiled distilled water to bring the acid concentration to the desired value. This hot solution was passed through the reductor at a rate of about 60 drops per minute. The reductor was then washed with 100 ml. of hot hydrochloric acid which had the same concentration as that of the sample. The reduced solution was received in a molybdate solution which contained about four times as much molybdate as did the original sample. After suitable dilution to

bring the whole solution to such a volume that the hydrochloric acid concentration was 2 normal, it was titrated with 0.07217 *N* ceric sulfate. Orthophenanthroline-ferrous complex was used as an internal indicator.

Results.—Table I shows the data for a series of samples which represent different acid concentrations. The extent of the reductions is indicated by the calculation of equivalent valence changes. A better picture of the trend of these reductions is shown in the graph in which acid concentration of the various samples is plotted against valence change.

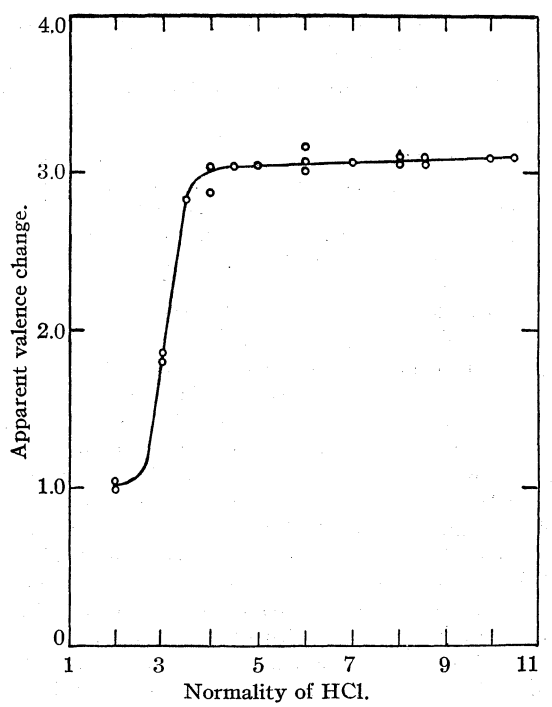

Fig. 1.

Examination of the results indicates that under the conditions of these experiments, a trace of molybdenum is reduced below the five-valent state even in 2 normal hydrochloric acid. Above 4 normal, the molybdate appears to be reduced quantitatively to the trivalent state and the possibility exists that part of the molybdenum is being reduced to an even lower valence state.

In order to see whether such values as those obtained with the 2 normal acid were really due to a reduction of traces of quinquevalent molybdenum to the trivalent state, several samples were treated according to the Birnbaum–Walden procedure without using boiled water or the protective atmosphere of carbon dioxide. The reduced solutions were not caught in molybdate solution. Under such conditions the results obtained showed a valence change of one unit. Typical results for the apparent valence changes were 1.000, 0.9995 and 1.001.

Concerning the fact that in higher acid concentrations the reduction apparently produces a valence change of as much as 3.1, a possible interpretation is that some divalent molybdenum is being formed. The irregularity cannot be due to the titration since all of the titrations were performed in solutions 2 normal to hydrochloric acid. It seemed desirable to compare this behavior with that of Jones reductor under similar conditions. To this end, samples were reduced in the Jones reductor, care being used to avoid all possible oxidation by the air. Titrations were performed in the same manner as those in conjunction with the silver reductor. Some of the data obtained, when this type of reduction was used, are shown in Table II.

TABLE II

Normality HCl	Ml. of MoO_4 0.02482 *M*	Ml. of Ce^{++++} 0.07217 *N*	Apparent valence change
3	39.99	41.30	3.006
	40.00	41.30	3.005
4	40.00	41.30	3.005
	40.03	41.34	3.006
6	40.05	41.41	3.013
	40.06	41.30	3.002

Although extremely high acid concentrations were not used, it is evident that the hydrochloric acid concentration does not affect the degree of reduction in the Jones reductor, at least up to 6 normal. One would want more substantial evidence before concluding that the effect in the silver reductor was due to reduction to a valence state lower than 3.

Acknowledgments.—The authors would like to express their appreciation to the Works Progress Administration for the grant which made this work possible.

Summary

1. It has been shown that when the reduction of molybdate is performed according to the method of Birnbaum and Walden in 2 normal hydrochloric acid, using a silver reductor, their conclusions are substantiated. Although traces of trivalent molybdenum may be formed in the process, exposure to the air oxidizes it to the quinquevalent state before the sample is titrated with ceric sulfate. Therefore their procedure produces quantitative reduction of the molybdate to the quinquevalent state.

2. When reduction of molybdate in 2 normal hydrochloric acid is performed in the silver reductor, using special precautions to avoid air oxidation, the reduction corresponds to slightly more than 1 equivalent in valence change of the molybdenum. If the acid concentration is greater than 4 normal, molybdenum in the molybdate is reduced mainly to the trivalent state. In high acid concentrations such as 10 normal, the reduction shows an apparent valence change as high as 3.1.

3. When reduction of molybdate is performed in a Jones reductor using precautions to prevent air oxidation, the apparent change of valence for molybdenum is not greater than three even though the acid concentration is as high as 6 normal.

Internal Rotation in 1,1,2-Trichloroethane[1]

BY ANTHONY TURKEVICH AND J. Y. BEACH

The problem of the freedom of rotation around the carbon–carbon single bond in halogen substituted ethanes recently has been attacked by the electron diffraction method. Studies have been made of ethylene chloride,[2] ethylene chlorobromide,[3] and ethylene bromide.[3] In all three cases it was found that the *trans* configuration was the stable configuration and that the potential barrier to internal rotation was 5 kcal./mole or greater. In this paper we shall report an electron diffraction investigation of the freedom of internal rotation in 1,1,2-trichloroethane.

The compound used was an Eastman Kodak Co. product, purified by fractional distillation in a 30-inch (76-cm.) column on which the reflux ratio could be controlled. The electron diffraction apparatus was similar to the one described by Brockway.[4] The electron wave length was 0.0590 Å. and the distance from the photographic plate to the nozzle was 12.19 cm. The photographs, taken with the compound warmed to about 65°, show seven irregularly spaced maxima. The fourth maximum is weaker than the third or fifth. The observed values of $s(=(4\pi \sin \theta/2)/\lambda)$ and the visually estimated intensities, I, of the maxima and minima are tabulated in Table I.

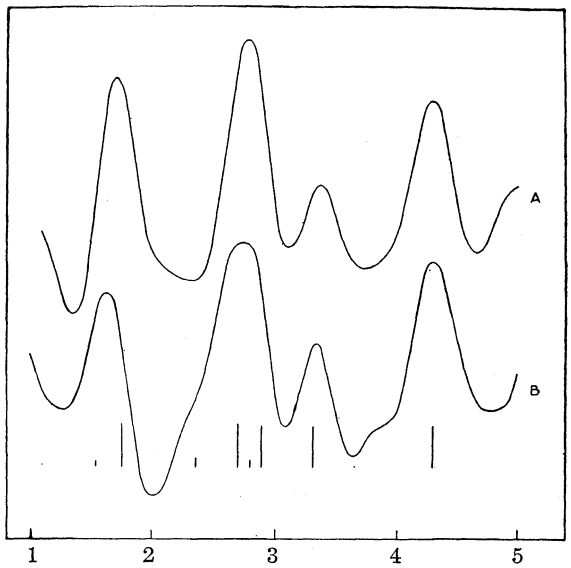

Fig. 1.—Radial distribution functions for 1,1,2-trichloroethane. In curve A the coefficients of the (sin ls)/ls terms are $s^2e^{-as^2}$ times the visually estimated intensities of the maxima. The minima are not used. a is determined by setting e^{-as^2} equal to 0.1 for the largest ring. Curve B is calculated according to the method of Schomaker. Both maxima and minima are used. The C's in Table I are the coefficients of the (sin ls)/ls terms.

and has been called the modified radial distribution method in several previous publications.[7] Curve B was calculated by a procedure suggested by Schomaker[8] in which both maxima and minima are used in a slightly different way. The first peak at about 1.70 Å. represents the carbon–chlorine bond distance together with the carbon–carbon distance. The broad peak at 2.77 Å. represents the short chlorine–chlorine distance and the long carbon–chlorine distance. The two peaks at 3.36 and 4.30 Å. must represent distances between chlorine atoms bonded to different carbon atoms, and the interpretation of these two peaks leads to the most important result of the investigation—the most stable configuration of the molecule. In designating the internal configuration we shall use the relative azimuthal angle of the two ends of the molecule, ϕ. ϕ is 0° when the molecule is *cis* and 180° when it is *trans*. The *cis* and *trans* configurations are the only ones which possess a plane of symmetry. If, as might have been expected at first, the *trans* configuration were the most stable, the radial distribution function should possess a single maximum at 3.95 Å. in place of the two at 3.36, 4.30 Å. In the *trans* configuration the atoms involved in the long chlorine–chlorine distances are at an angle of 120° with respect to each other. The peaks at 3.36 and 4.30 Å. correspond to distances between chlorine atoms separated by angles of about 70 and 180°, respectively. These immediately are seen to be the angles involved in a model for which ϕ is about 130°. The radial distribution function shows, therefore, that the most stable configura-

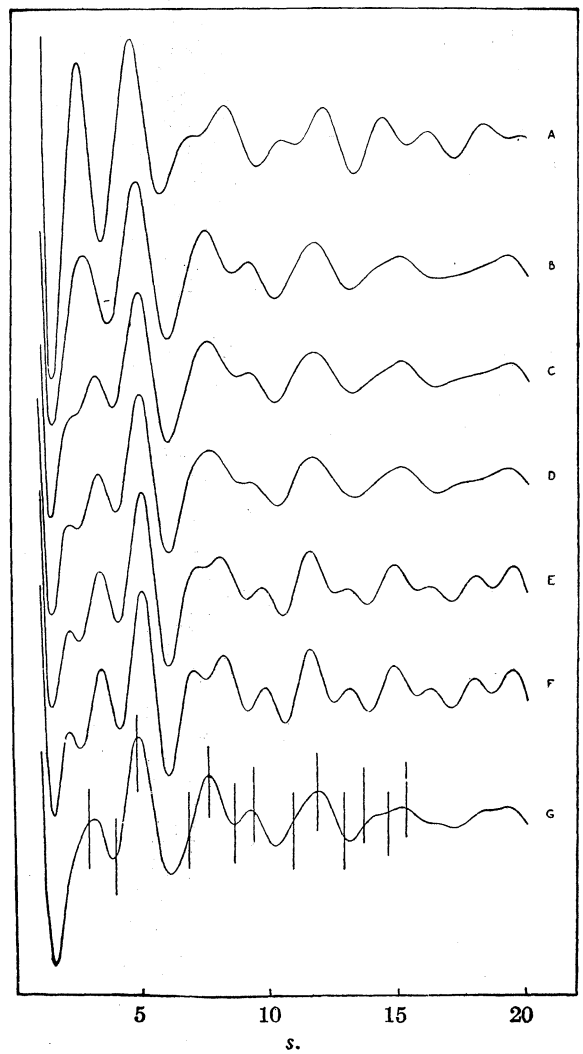

Fig. 2.—Theoretical intensity curves for 1,1,2-trichloroethane. Curve A, *cis* model. Curve B, freely rotating model. Curve C, model having a sinusoidal potential barrier of 5 kcal./mole, the *trans* configuration being the most stable. Curve D, same as for C except that the barrier is 10 kcal./mole. Curve E, same as for C except that the barrier is 20 kcal./mole. Curve F, *trans* model. Curve G, calculated for a model in which the potential barrier is taken to be the sum of the electrostatic interactions and the exchange repulsions.

(7) L. O. Brockway and J. Y. Beach, THIS JOURNAL, **60**, 1836 (1938); J. Y. Beach and Anthony Turkevich, *ibid.*, **61**, 299 (1939).

(8) V. F. H. Schomaker, paper presented to the American Chemical Society at Baltimore, Md., April, 1939.

tion of the molecule is not the *trans* but is *rotated about 50°* from the *trans* configuration. In making this argument it was assumed that the interatomic distances in the molecule are those given by the table of covalent radii,[9,10] and that the bond angles on the carbon atoms are tetrahedral.

In interpreting the photographs by the usual visual method, theoretical intensity curves were first calculated for a rigid *cis* and a rigid *trans* model. These curves are shown in Fig. 2, curves A and F, respectively. In calculating these curves and curves for the other models considered, the interatomic distances in the molecule were taken to be those given by the table of covalent radii.[9] All the bond angles were assumed to be tetrahedral except the Cl–C–Cl angle which was taken to be 111°, the value found in chloroform.[11] Other values for this angle were tried but gave unsatisfactory results. The *cis* curve shows the fourth maximum to be higher than the third or fifth, while the photographs show it to be weaker than the third or fifth. The *cis* model is, therefore, ruled out. The *trans* curve does not resemble the photographs in that it shows extra maxima that are not observed on the photographs. This is easily seen by examining the positions of the observed maxima and minima and curve F in Fig. 2.

If the interaction of the chlorine atoms on the two ends of the molecule is assumed to produce a sinusoidal potential barrier, then the two such interactions in 1,1,2-trichloroethane, when added together, will give again a sinusoidal potential barrier, the stable configuration being the *trans*. Although this result has been shown to be not valid by the radial distribution function, we shall consider it in calculating theoretical intensity curves. Theoretical curves were calculated for sinusoidal potentials having heights of zero, 5, 10 and 20 kcal./mole. These curves are shown in Fig. 2. The curve for zero barrier corresponds to completely free rotation. This curve is unsatisfactory because it shows only one maximum instead of the sixth and seventh. The 5 and 10 kcal./mole curves are unsatisfactory for the same reason. The 20 kcal./mole curve resembles the *trans* curve in showing too many maxima and therefore is not acceptable. We have thus reached the same conclusion as was reached by examination of the radial distribution function—the most stable configuration is not the *trans* configuration.

In calculating these curves the same procedure was followed as in the case of the disubstituted ethanes.[2,3] For the disubstituted ethanes curves were calculated for molecules having all possible configurations differing by 30°. These curves were then added together using the Boltzmann factor as a weighting factor. For 1,1,2-trichloroethane it was found necessary to include molecules having values of ϕ differing by 10° instead of by 30°, except for the steeper barriers.

A potential barrier to internal rotation can be calculated in the following manner. The nine electrostatic interactions can be evaluated by the use of the individual bond moments. These moments have been tabulated by Smyth.[12] In making this calculation it was assumed that the bond moments were due to charges at the centers of the atoms involved in the bond. The sums of these interactions are tabulated in Table II as a function of the angle ϕ. The exchange repulsions also must be considered. We have evaluated the nine exchange repulsions by the method of Eyring.[13] The Morse curve was assumed to be 20% coulombic in each case. These totals are tabulated in Table II as a function of ϕ. The sums of the electrostatic and exchange interactions are tabulated in Table II and shown in Fig. 3, curve A. It is seen that the stable configuration of the molecule is about 60° removed from the *trans* configuration. This is in agreement with the result deduced from the radial distribution function.

TABLE II

ELECTROSTATIC AND EXCHANGE INTERACTIONS AS A FUNCTION OF THE INTERNAL CONFIGURATION, KCAL./MOLE

Interactions	0°	30°	60°	90°	120°	150°	180°
Electrostatic	2.64	2.60	2.43	1.83	1.15	0.55	0.34
Exchange	13.31	14.28	15.56	14.83	14.25	15.36	16.11
"Corrected" exchange	16.09	17.42	19.19	17.53	15.78	16.16	16.70
Electrostatic plus exchange, $E(\phi) - E(\text{min.})$	0.55	1.48	2.59	1.26	0	0.51	1.05
Electrostatic plus "Corrected" exchange, $E(\phi) - E(\text{min.})$	2.02	3.31	4.91	2.65	0.22	0	0.3

In treating the disubstituted ethanes,[2,3] it was found necessary to apply a correction to the halogen–halogen exchange repulsions to obtain agreement with the photographs.[2] When this method is used to get the chlorine–chlorine exchange re-

(9) L. Pauling and M. L. Huggins, *Z. Krist.*, **87A**, 205 (1934).

(13) H. Eyring, THIS JOURNAL, **54**, 3191 (1932).

pulsions in 1,1,2-trichloroethane, we obtain the "corrected" exchange repulsions collected in Table II. The sums of the "corrected" exchange repulsions and the electrostatic interactions are given in Table II and shown in Fig. 3, curve B.

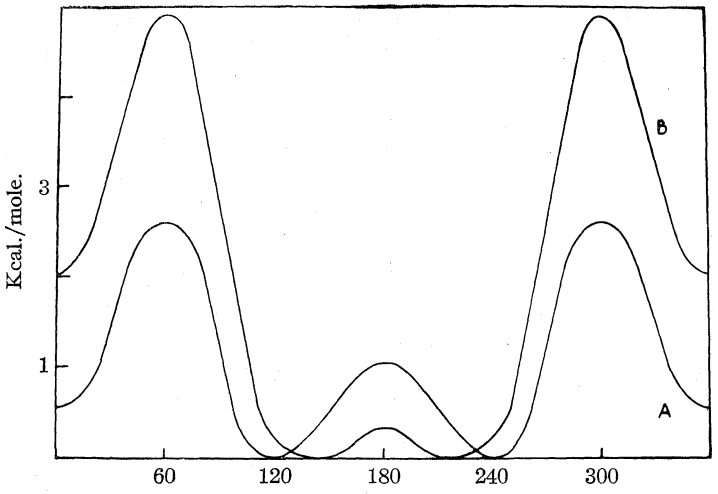

Fig. 3.—The potential barrier to internal rotation. Curve A, the electrostatic interactions plus the exchange interactions, assuming the Morse curve to be 20% coulombic. Curve B, the electrostatic interactions plus the "corrected" exchange interactions.

The shape of the potential curve is changed somewhat but the most stable configuration is essentially the same.

Theoretical intensity curves were calculated for the potential functions shown in Fig. 3. These two curves are practically indistinguishable to the eye so only one of them (curve G) has been included in Fig. 2.

Both curves are quantitatively compared with the photographs in Table I. Curve G resembles the photographs more closely than any other curve calculated. The vertical lines represent the positions of the observed maxima and minima. The incomplete resolution of the sixth and seventh maxima would probably be remedied if the temperature factor had been included and the Z approximation had not been made.

The vertical lines in Fig. 1 indicate the position and importance in the scattering function of the finally determined interatomic distances. The values shown for the long chlorine–chlorine distances are those for a model in the most stable configuration—when ϕ is 130°. The oscillation about this position will, of course, smear these points to some extent.

The radial distribution function and the qualitative and quantitative comparison of the photographs with the calculated intensity curves lead to the final results.

Summary

From an electron diffraction investigation it has been shown that 1,1,2-trichloroethane is not a rigid molecule in the *cis* or the *trans* configuration, nor does it have a sinusoidal potential barrier to internal rotation with the *trans* configuration the most stable. The most stable configuration is rotated about 50° from the *trans* position. A potential barrier calculated from electrostatic (dipole) and exchange interactions is in agreement with the experiments. The C–Cl distance is 1.75 ± 0.03 Å. The Cl–C–Cl angle is 111° 30 ± 2°. The C–C and C–H distances were assumed to be 1.54 and 1.09 Å., respectively.

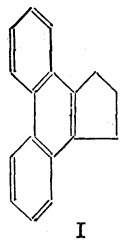
Synthesis of Phenanthrene Derivatives. IV.[1] 9,10-Cyclopenteno- and 9,10-Cyclohexenophenanthrene

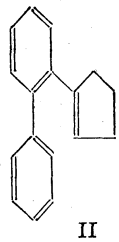
BY CHARLES K. BRADSHER

The first synthesis of 9,10-cyclopentenophenanthrene (I) was that by Bachmann and Kloetzel[2] who obtained this hydrocarbon, together with the isomeric 5,6-benzo-2,3-dihydrobenzonaphthene, upon reduction of the mixture of ketones formed by the cyclization of β-(9-phenanthryl)-propionic acid.

A more convenient route, and one which suggested itself to the aforementioned authors, is that through the cyclization of 1-(2-biphenyl)-cyclopentene-1 (II). They found, however, that the cyclopentene (II), upon treatment with



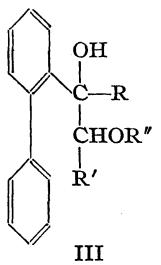
I



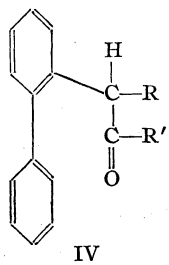
II

aluminum chloride, gave not the desired 9, 0-cyclopentano-9,10-dihydrophenanthrene, but the corresponding spiran.

In the preceding papers of this series, we have described a general method for the synthesis of 9- and 9,10-substituted phenanthrene hydrocarbons. This method involves the cyclization of carbinols of type III by hydrobromic acid.



III

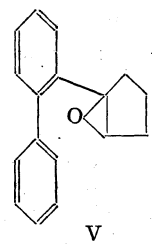


IV

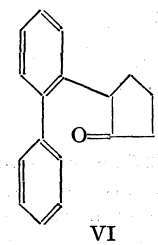
(R′ = alkyl, aryl, or H)

Although the evidence does not as yet amount to a demonstration, it has appeared increasingly probable that a carbonyl compound of type IV, or its enol form, is an intermediate in this cyclization. It should then follow that any carbonyl compound of type IV, or any substance capable of being converted by acids to such a carbonyl compound, would undergo cyclization to give a phenanthrene derivative.

For our purposes, the most satisfactory compound fulfilling the latter requirement seemed to be the cyclopentene oxide (V).



V



VI

Such a compound could be formed readily by the action of monoperphthalic acid on the cyclopentene and would be expected to isomerize under the influence of acids to give 2-(2-biphenyl)-cyclopentanone-1 (VI). Whether or not this was the mechanism of the reaction, when 1-(2-biphenyl)-cyclopentene-1 (II) was oxidized with monoperphthalic acid, and the crude oxide (V) thus afforded refluxed with a mixture of acetic and hydrobromic acids, 9,10-cyclopentenophenanthrene was obtained.

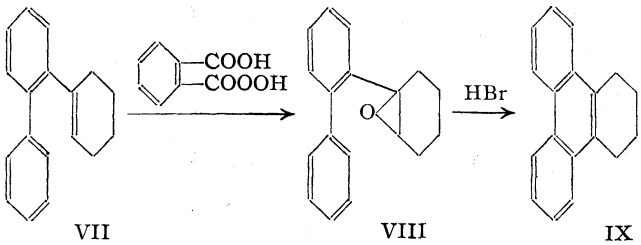
The synthesis of 9,10-cyclohexenophenanthrene (1,2,3,4-tetrahydrotriphenylene (IX)) has been accomplished previously by Bergmann and Blum-Bergmann[3] both by partial dehydrogenation of dodecahydrotriphenylene and by the reduction of the ketone obtained when γ-(9-phenanthryl)-butryic acid was cyclized.

The hydrocarbon (IX) was synthesized by us in a manner analogous to that employed in the case of 9,10-cyclopentenophenanthrene. The Grignard reagent from 2-iodobiphenyl was treated with the cyclohexanone and the crude carbinol dehydrated with potassium bisulfate to give 1-(2-biphenyl)-cyclohexene-1 (VII). The cyclohexene (VII) was treated with monoperphthalic acid to give the corresponding oxide (VIII) and the crude oxide cyclized to 1,2,3,4-tetrahydrotriphenylene by the action of hydrobromic acid.

(1) For the preceding paper of this series see THIS JOURNAL, **61**, 2184 (1939).

(2) Bachmann and Kloetzel, *ibid.*, **59**, 2207 (1937). Weizmann, Bergmann, and Berlin likewise prepared this hydrocarbon by a similar method, *ibid.*, **60**, 1331 (1938).

(3) Bergmann and Blum-Bergmann, *ibid.*, **59**, 1441 (1937).



VII VIII IX

The yield of the hydrocarbon from the cyclohexene was 30%.

The importance of this method is that it is applicable to the synthesis of alkyl tetrahydrotriphenylenes which would be expected to give alkyltriphenylenes upon dehydrogenation.

The author is indebted to Dr. W. E. Bachmann for the gift of a sample of 9,10-cyclopentenophenanthrene.

Experimental

1-(2-Biphenyl)-cyclopentene-1 (II).—A Grignard reagent was prepared from 30.8 g. of 2-iodobiphenyl and 3.74 g. of magnesium. To this was added 8.4 g. of cyclopentanone in ethereal solution. The mixture was refluxed for a half hour and then decomposed by the addition of a 20% solution of ammonium chloride. The ether layer was dried, the ether distilled off and the residue heated for one hour at 160° with 30 g. of powdered potassium bisulfate. At the end of this period, water and benzene were added. The benzene layer was separated, concentrated to a small volume and the residue distilled under reduced pressure. After a large fore-run, consisting chiefly of biphenyl, the desired cyclopentene (II) came over as a colorless oil, b. p. 150–159° (5 mm.); yield 4.0 g.

Monoperphthalic acid was prepared by the action of an alkaline solution of hydrogen peroxide on phthalic anhydride by a method essentially that of Böhme.[4] We found, however, that satisfactory yields of the acid could be obtained only when the alkaline solution of hydrogen peroxide was stirred vigorously with a mechanical stirrer and when the solution was cooled by the addition of crushed ice. In every case the yields of monoperphthalic acid obtained were verified by iodimetric titration.

9,10-Cyclopentenophenanthrene (I).—The cyclopentene (II) (2 g.) was dissolved in ether, cooled in an ice-bath and poured into an ice-cold ether solution containing 0.019 mole of monoperphthalic acid. The mixture was allowed to stand for twelve hours at room temperature, after which the acids were extracted from the solution with sodium bicarbonate solution. The ether was evaporated off and the crude cyclopentene oxide (V) was dissolved in 25 cc. of acetic acid. To this was added 25 cc. of 34% hydrobromic acid and the mixture refluxed for twenty-four hours. Upon cooling, the hydrocarbon solidified, but contained some resinous material which made crystallization impossible. The hydrocarbon was, therefore, purified by vacuum sublimation. The sublimation product, once recrystallized from acetic acid, was obtained pure as long slender needles, m. p. 150–151°; yield, 0.31 g. It showed no depression of melting point when mixed with an authentic sample of 9,10-cyclopentenophenanthrene.

Anal. Calcd. for $C_{17}H_{14}$: C, 93.5; H, 6.5. Found: C, 93.5; H, 6.4.

The picrate prepared in alcohol was obtained as red needles, m. p. 164–165° (Bachmann,[2] 161.5–162°).

1-(2-Biphenyl)-cyclohexene-1 (VII).—A Grignard reagent was prepared from 14 g. of 2-iodobiphenyl and 4.9 g. of cyclohexanone added. The mixture was decomposed with ammonium chloride solution and the crude carbinol dehydrated as in the preparation of the corresponding cyclopentene (II). Upon distillation, 3.4 g. (29%) of a yellowish oil was obtained, b. p. 183–193° (23 mm.).

9,10-Cyclohexenophenanthrene (IX).—The cyclohexene (VII) (3.4 g.) obtained above was dissolved in ether and oxidized with an ether solution containing 0.024 mole of monoperphthalic acid. After sixteen hours, the acids were extracted with bicarbonate solution, the ether evaporated and the crude oxide (VIII) cyclized by refluxing for twenty-four hours in a mixture of hydrobromic and acetic acids. Upon cooling, the hydrocarbon crystallized from the solution. Twice recrystallized from acetic acid, it was obtained as pure, colorless needles, m. p. 122–123° (Bergmann,[3] 120–121°); yield, 1.0 g. (30%).

Anal. Calcd. for $C_{18}H_{16}$: C, 93.1; H, 6.9. Found: C, 92.9; H, 6.9.

Summary

By the use of a new modification of the ring closure, 9,10-cyclopenteno- and cyclohexeno-phenanthrene have been synthesized.

Secondary Alpha Furfuryl Amines

BY J. E. ZANETTI AND J. T. BASHOUR

Little has been published on secondary furfuryl amines. The methyl and ethyl furfuryl amines were first prepared by Schwabbauer,[1] by the reduction of the condensation products of methyl and ethyl amine with furfural. This work was repeated by Litterschied.[2] No further work was done on these compounds until 1921 when von Braun and Braunsdorf[3] stated that they had prepared the furfurylethylamine by the action of furfuryl bromide on ethylamine but did not describe their procedure. The Goodyear Tire and Rubber Company[4] took a patent in 1934 for a method of preparing secondary furfuryl amines by reducing the corresponding condensation products of amines and furfural with hydrogen under pressure but although their claims extend to a large number of amines, the only product described was the di-α-furfurylamine which had been prepared by Zanetti and Beckmann[5] by the action of furfuryl bromide on ammonia.

In connection with a study of furfuryl bromide already published in part it seemed of interest to study its reactions on amines which had been but briefly touched upon by von Braun and Braunsdorf. In this study we employed the ether solution of α-furfuryl bromide since as we have demonstrated the pure product is so unstable as to be unmanageable.[6]

The action of the bromide on a primary amine in ether solution is rapid. In a few minutes a crystalline precipitate appears which we thought at first was the hydrobromide of the secondary amine but proved to be the hydrobromide of the primary amine, the action proceeding according to the equation

$$2RNH_2 + BrCH_2C_4H_3O \longrightarrow RNHCH_2C_4H_3O + RNH_2HBr$$

The secondary amine being a much weaker base than the primary amine is released from its hydrobromide formed by the addition of the furfuryl bromide, by the primary compound. In order, therefore, to make the addition complete mole with mole we carried the reaction in the presence of potassium hydroxide, which proved to be a satisfactory method. The yields were only fair, varying from 50 to 65% assuming the yield of the bromide to be 70% of theoretical. In all cases varying amounts of what appears to be the tertiary amines were formed but these condensation products have not yet been investigated.

The secondary amines are colorless liquids turning yellowish in a few days as do most furan compounds, except α-furfurylphenylamine, which is yellow even when repeatedly distilled. They are soluble in ethanol, ether, acetone, carbon tetrachloride, but only slightly soluble in boiling petroleum ether. The specific gravities and the indices of refraction of these compounds, none of which has been previously reported, are given in Table I.

TABLE I

Amine	B. p. °C.	Mm.	Sp. gr., 25/25	n^{20}	M. p. of hydrochloride, °C
α-Furfurylmethyl	149–149.5	761	0.992	1.4729	144–146
α-Furfurylethyl	165–167	761	.963	1.4688	127–128
α-Furfuryl-*n*-butyl	198–200	768	.935	1.4669	189–191
α-Furfuryl-*n*-amyl	214–216	756	.927	1.4668	185–188
α-Furfurylphenyl	109–110	0.5	1.110	1.5834	150–151, dec.

The amines decompose slightly when boiled under ordinary atmospheric pressure but distil readily under reduced pressure. The boiling point of the phenylamine derivative could not be determined as at atmospheric pressure decomposition is too great.

These amines readily form hydrochlorides and the aliphatic ones also form picrates. The furfurylphenylamine, however, did not form a picrate.

Experimental

General Procedure.—The ethereal furfuryl bromide solution was added at once to the ethereal solution of the amine standing over crushed potassium hydroxide. The mixture was stirred continuously from one to two hours and then allowed to stand overnight. After filtration and washing of the potassium hydroxide and bromide with ether, the ether was distilled off and products separated by fractional distillation *in vacuo*.

Furfurylmethylamine, $C_4H_3OCH_2NHCH_3$.—Methylamine was generated from the hydrochloride (81 g.) by the addition of 50% potassium hydroxide solution. The

(6) Zanetti and Bashour, *ibid.*, **61**, 2249 (1939).

vapors were driven through an upright water-cooled condenser, a long drying tube containing potassium hydroxide pellets into a receiver containing crushed potassium hydroxide (80 g.) covered with dry ether, the receiver being immersed in a dry-ice–ethylene trichloride bath. Heating was continued until the bulk of the amine had distilled over. Furfuryl bromide solution (prepared according to the method of Zanetti[7] from 38 g. of furfuryl alcohol) was cooled to minus 10° and siphoned into the solution of the amine. The mixture was rocked for several minutes, then removed from the bath and shaken frequently for two hours. It was then allowed to stand overnight. After filtration, the ether was removed by distillation and the product was fractionally distilled *in vacuo*. The fraction boiling 50–57° at 16.5–18 mm. was redistilled; yield, 15 g. (50% of theoretical, assuming 70% yield of bromide). As this amine had been prepared before no analysis was made.

Furfurylethylamine, $C_4H_3OCH_2NHC_2H_5$.—Ethylamine was generated from the hydrochloride (50 g.) in an apparatus consisting of the following train: an ordinary distilling flask equipped with a dropping funnel, a long slightly inclined drying tube containing potassium hydroxide pellets, a water-cooled condenser, and the same receiver as in the preparation of the methylamine. The ethereal furfuryl bromide solution prepared from 25 g. of furfuryl alcohol and precooled to minus 10° was introduced by siphon as before, and the product separated as in the preceding case. The fraction boiling at 63–65° at 17–18 mm. was redistilled; yield, 13 g. (58% on basis of 70% yield of the bromide). This amine having been prepared previously no analysis was made.

Furfurylbutylamine, $C_4H_3OCH_2NHC_4H_9$.—Twenty-five grams of normal butylamine, previously dried over potassium hydroxide and distilled, was added at once to a 20-g. batch of the ethereal furfuryl bromide solution over 50 g. of crushed potassium hydroxide. The whole was stirred for one hour and then allowed to stand overnight. After filtration and removal of the ether, the fraction boiling at 92–95° at 16–18 mm. was redistilled; yield, 13 g. (60% on basis of 70% yield of furfuryl bromide).

Anal. Calcd. for $C_9H_{14}ON$: C, 70.58; H, 9.80; N, 9.15. Found: C, 70.40; H, 9.96; N, 9.29.

Furfurylamylamine, $C_3H_3OCH_2NHC_5H_{11}$.—The procedure was similar to the preceding: 8 g. of amylamine and a 4-g. batch of the furfuryl bromide solution were used. The fraction boiling at 108–111° at 16–18 mm. was redistilled; yield, 3.0 g. (65% on basis of 70% yield of bromide).

Anal. Calcd. for $C_{10}H_{17}ON$: N, 8.48. Found: N, 8.66.

Furfurylphenylamine, $C_4H_3OCH_2NHC_6H_5$.—Forty-five grams of aniline and a 20-g. batch of furfuryl bromide were used in this case. On distillation, the main fraction came over at 113–120° at approximately 1 mm. On redistillation this fraction boiled at 109–110° under 0.5 mm.

Anal. Calcd. for $C_{11}H_{11}ON$: C, 76.30; H, 6.36; N, 8.09. Found: C, 76.51; H, 6.47; N, 8.26.

Summary

1. The action of α-furfuryl bromide in ether solution on primary amines has been studied and found to form secondary amines.

2. The methyl, ethyl, butyl, amyl and phenyl α-furfuryl amines have been prepared by the above method and their properties reported.

Derivatives of Aminomethanethiol

BY ARTHUR BINZ AND LELAND H. PENCE

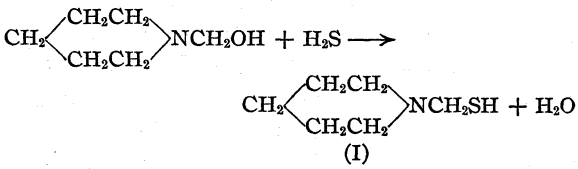
Hydroxymethanethiol, $HOCH_2SH$, was assumed by Baumann[1] to be formed as an unstable intermediate on treating formaldehyde with hydrogen sulfide, and he showed that the reaction proceeds to insoluble trithioformaldehyde, $HCHO + H_2S \longrightarrow HOCH_2SH \longrightarrow (CH_2S)_3$. Since trithioformaldehyde because of its low solubility and reactivity is of no particular interest for biochemical research, it was considered advantageous to investigate hydroxymethanethiol, either as such or in the form of easily soluble and reactive products obtained from it. For these reasons Binz, Räth, and Walter[2] attempted to isolate hydroxymethanethiol by reducing formaldehyde-sulfoxylate with hypophosphorous acid, $HOCH_2SO_2H \longrightarrow HOCH_2SH$, and obtained a product which appeared to be the desired thiol, but the yield was very small.

In taking up this work again we endeavored to obtain a derivative of the corresponding aminomethanethiol which would be stable, by first condensing formaldehyde-sulfoxylate with piperidine and then reducing the product with hypophosphorous acid in the presence of hydriodic acid according to the reaction $C_5H_{10}NCH_2SO_2H \longrightarrow C_5H_{10}NCH_2SH$. Hydrogen sulfide was also used as a reducing agent, but in both cases the yields of a compound showing the reactions of a thiol were very small.

(1) Baumann, *Ber.*, **23**, 1869 (1890).

(2) Binz, Räth and Walter, *ibid.*, **57**, 1398 (1924).

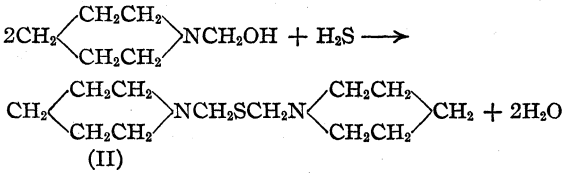
Another method, however, was successful. When piperidine was added to formaldehyde and the 1-piperidinemethanol thus obtained treated with hydrogen sulfide, a vigorous reaction with strong evolution of heat set in and 1-piperidinemethanethiol (I) was obtained in good yield



(I)

It is a clear oil at room temperature, crystallizing in the icebox.

When the reaction was conducted with cooling, 1,3-di-(1′-piperidine)-2-thiapropane (II)[3] was formed:

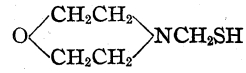


(II)

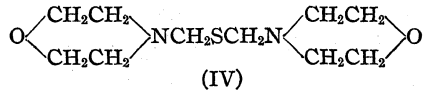
It is probable that the latter reaction is the primary one and that the thiol (I) is produced from the splitting of the sulfide (II) by excess hydrogen sulfide at a higher temperature.

Compound (II) has been obtained by LeFèvre and LeFèvre[4] by saturating an aqueous solution of piperidine with hydrogen sulfide and then adding formaldehyde. These authors had to keep the piperidine at 0° in order to dissolve the necessary amount of hydrogen sulfide and for this reason obtained only the monosulfide (II), not the thiol (I). Furthermore, experiments carried out in this Laboratory by Dr. F. E. Reinhart have shown that our method, even in the case of monosulfides, is more generally applicable than the LeFèvre method, since an excess of hydrogen sulfide must be used in some cases. This is possible only if a stream of the gas is applied to the previously formed aminomethanol.

The application of our procedure to morpholine gave results which closely correspond to those obtained with piperidine. Treatment of morpholine with formaldehyde and hydrogen sulfide yielded 4-morpholinemethanethiol (III); when the reaction was carried out with cooling 1,3-di-(4′-morpholine)-2-thiapropane (IV) was formed.

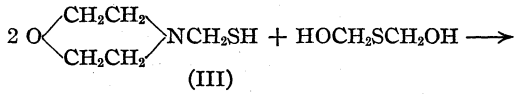


(III)

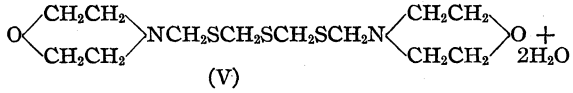


(IV)

One difference in comparison with piperidine was that the formation of compound (III) required the presence of hydrochloric acid. This was unexpected because the addition compounds of amines and aldehydes are sensitive to acids. A greater difference, however, was that compounds (III) and (IV) did not appear as the only reaction products. Simultaneously with (III) was formed 1,7-di-(4′-morpholine)-2,4,6-trithiaheptane (V); apparently di-(hydroxymethyl) sulfide was formed during the reaction and condensed with some of the (III)

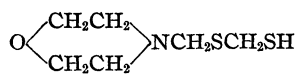


(III)



(V)

Compound (V) was formed as the chief product, if, instead of equivalent amounts of morpholine and formaldehyde, an excess of the latter was added before the introduction of hydrogen sulfide. Simultaneously with compound (IV), 3-(4′-morpholine)-2-thiapropanethiol (VI) was formed as a by-product.



(VI)

Compounds (V) and (VI) are white flocculent precipitates which show no sharp melting points, and cannot be purified by crystallization. The fact that these compounds are quite soluble in the usual organic solvents precludes the possibility that they are mere mixtures of the amine and trithioformaldehyde.

This tendency to form polymerized thioformaldehyde derivatives was still more pronounced when diethanolamine was treated with formaldehyde and then with hydrogen sulfide. A white flocculent mass (VII) was obtained which according to analysis contained 7 molecules of thioformaldehyde bound to 1 molecule of diethanolamine, although the reaction mixture contained no excess of formaldehyde. This means that some primary compound, perhaps the mono-

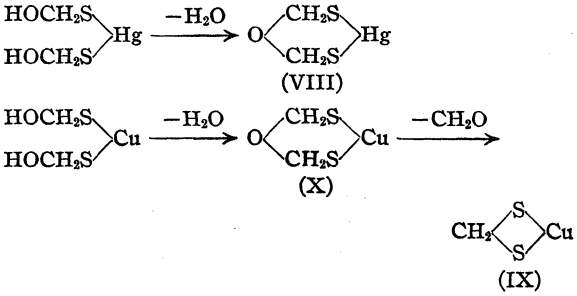
(3) This nomenclature is in conformity with that published in *C. A.* **31**, 9486 (1937), and specifically with Rule 16, THIS JOURNAL, **55**, 3912 (1933).

(4) LeFèvre and LeFèvre, *J. Chem. Soc.*, 1142 (1932).

sulfide $[(HOCH_2CH_2)_2NCH_2]_2S$, has undergone further changes during the reaction. In fact, an oily compound corresponding to this formula was obtained by conducting the reaction between methanoldiethanolamine and hydrogen sulfide at zero degrees. This oil decomposes with water to a white solid mass.

The result of analysis of compound (VII) suggests the formula, $(HOCH_2CH_2)_2N(CH_2S)_7H$. Although this formula might indicate the presence of $2(CH_2S)_3$, trithioformaldehyde could not be extracted with any solvent, nor could it be obtained by sublimation when the compound was heated *in vacuo*.

Most of the compounds give precipitates with the salts of heavy metals. Some of these precipitates have been investigated, and it was found that both 1-piperidinemethanethiol (I) and 4-morpholinemethanethiol (III) with mercuric chloride in alcoholic solution yield the same precipitate, which, according to analysis, appears to be mercuric di-(mercaptomethyl) ether (VIII), $Hg(SCH_2)_2O$. Under the same conditions copper acetate reacts with either (I) or (III) to give a precipitate, the analysis of which indicates it to be cupric methylene dimercaptide (IX), CuS_2CH_2. Perhaps the primary reaction is: $2R_2NCH_2SH + HgCl_2 \longrightarrow (R_2NCH_2S)_2Hg + 2HCl$, a corresponding one occurring with copper acetate. Then the piperidine and morpholine are split off and further changes ensue



We do not consider these conclusions final, as the compounds could not be redissolved and purified. For that reason the possible existence of an equimolecular mixture of the usual cuprous salt of a thiol, in this case $CuSCH_2SCu$, and CH_2S_2 cannot be excluded entirely; this assumption, however, does not appear justified since it would require the two components to have the same high degree of insolubility in order to account for the analytical results obtained (1Cu: 2S).

Many of the compounds are lethal. From an investigation carried out under the direction of Dr. J. O. Ely, of our Cytological Department, we submit the following data. 1-Piperidinemethanethiol (I) and 1,3-di-(1′-piperidine)-2-thiapropane (II) in 0.04% water solution killed paramecia immediately, and daphnia in twenty minutes. Lethal doses of 4-morpholinemethanethiol (III), 1,3-di-(4′-morpholine)-2-thiapropane (IV), compound (VII), 1-piperidinemethanethiolhydrochloride (XI), and 1,3-di-(1′-piperidine)-2-thiapropane dihydrochloride (XII), are, respectively, 0.025, 0.021, 0.165, 0.05, and 0.083 mg. per g. of body weight when injected intravenously into mice. The lethal doses of piperidine, 1-methylpiperidine, 1-ethylpiperidine, and coniine, injected subcutaneously into rabbits, have been reported[5] to be 0.5, 0.4, 0.3, and 0.09 mg. per g. body weight, respectively. Thus most of these sulfur compounds are even more poisonous than coniine, without possessing the latter's characteristic side chain. Thioacetic acid, which was tested in comparison, has a lethal dose of 0.125 mg. per g. body weight when injected intravenously in mice, and is tolerated better than our compounds.

It was difficult to obtain several of the compounds analytically pure, as many of them were either insoluble, amorphous, or unstable.

Experimental

1-Piperidinemethanethiol (I).—Piperidine (10 g.) was poured gradually and with cooling into 37% aqueous formaldehyde (20 cc.), and shaken with anhydrous potassium carbonate (10 g.). The 1-piperidinemethanol, $C_5H_{10}N-CH_2OH$, thus formed[6] was separated from the aqueous layer, placed in a large test-tube, weighed, and gassed with hydrogen sulfide. The temperature rose spontaneously to 68°. After fifteen minutes an oily turbidity appeared, and at the end of two and one-half hours the hydrogen sulfide uptake was 3.3 g. The mixture was shaken with 10% sodium hydroxide (25 cc.) to remove unreacted hydrogen sulfide, and the oil was extracted with ether (75 cc.). After separating, drying with sodium sulfate, and evaporating the ether *in vacuo* at room temperature (to prevent decomposition), there remained 13.6 g. (yield, 88%) of 1-piperidinemethanethiol. The oil solidified in the icebox to colorless crystals; m. p. 12.5–15°. It is soluble in the ordinary organic solvents and dilute acid, but insoluble in alkaline solutions.

Anal. Calcd. for $C_6H_{13}NS$: N, 10.68; S, 24.44. Found: N, 9.55; S, 22.65; $n^{21}D$ 1.5552.

Although the analytical results showed a ratio of nitrogen to sulfur of 1:1.03, the values were too low because of the difficulty in removing the last traces of ether from the

(5) Wolffenstein and Wolffenstein, *Ber.*, **34**, 2403 (1901).
(6) L. Henry, *Bull. soc. chim.*, [3] **14**, 157 (1895).

oil at room temperature. A sample of the oily base was therefore converted into the solid hydrochloride for analysis.

1-Piperidinemethanethiol Hydrochloride (XI).—After dissolving 1-piperidinemethanethiol (2.3 g.) in toluene (15 cc.), hydrogen chloride gas was introduced through an inverted funnel with stirring and cooling. The white, solid hydrochloride, which precipitated immediately, was filtered and washed with ether: yield 2.5 g.; m. p. 195–205°.

Anal. Calcd. for $C_6H_{14}NSCl \cdot {}^1/_2H_2O$: N, 7.93; S, 18.15; Cl, 20.07. Found: N, 7.35; S, 18.18; Cl, 20.25.

After dissolving the hydrochloride in water and adding 10% sodium carbonate solution, the oily 1-piperidinemethanethiol was reprecipitated.

It was not possible to purify the 1-piperidinemethanethiol by distillation. On heating 1-piperidinemethanethiol (10 g.) at 4 mm. pressure and 150–170° bath temperature, the main fraction distilled at 75–81° and proved to be di-(1-piperidyl)-methane, $C_5H_{10}NCH_2NC_5H_{10}$, contaminated with a small amount of a sulfur compound.

Anal. Calcd. for $C_{11}H_{22}N_2$: N, 15.4. Found: N, 15.9; S, 0.24; $n^{15}D$ 1.4891.

Putochin[7] found $n^{15}D$ 1.4883 for di-(1-piperidyl)-methane. Piperidine has $n^{15}D$ 1.4538. The residue in the distillation flask consisted of 2.4 g. of a brittle brownish mass; m. p. 228–231°; S found, 58.4%.

1-Piperidinemethanethiol (10 g.) refluxed with dilute hydrochloric acid (25 cc.) at 90° for two hours gradually deposited needles of trithioformaldehyde. The total yield after repeating several times with the filtrate was 3 g.; theoretical, 3.5 g.; m. p. 216–218°. An analogous decomposition had been observed by LeFèvre and LeFèvre[4] with compounds obtained from reactions between dimethyl- and diethylamines, hydrogen sulfide and formaldehyde.

To 1-piperidinemethanethiol (1.3613 g.) dissolved in ethyl alcohol (10 cc.) there was added mercuric chloride (1.409 g.) dissolved in ethyl alcohol (39.2 cc.). A flocculent dark yellow precipitate of mercuric di-(mercaptomethyl) ether (VIII) appeared, which was filtered and washed with absolute ethanol: yield 97%; decomposition at 95–105°. The compound is very insoluble. When hydrogen sulfide gas was passed through an aqueous suspension of this mercury derivative, mercuric sulfide was precipitated immediately, this reaction being characteristic of mercuric mercaptans.

Anal. Calcd. for $HgS_2C_2H_4O$: Hg, 64.97; S, 20.77; C, 7.77; H, 1.31. Found: Hg, 64.51; S, 20.10; C, 6.34, 6.34; H, 1.19, 1.22.

To 1-piperidinemethanethiol (1.8201 g.) dissolved in ethyl alcohol (125 cc.) there was added a saturated alcoholic solution of cupric acetate until a permanent blue color was established. The resulting yellow-tan flocculent precipitate was centrifuged and washed five times with absolute ethanol (150 cc. each), and dried at room temperature *in vacuo;* yield 0.8964 g., (91% based on cupric methylene dimercaptide (IX)); decomposes at 105–110°. Sodium sulfide solution produced a coating of black copper sulfide on the surface of the compound, which hydrogen sulfide would not accomplish. The high insolubility of the compound prevented any further purification.

Anal. Calcd. for CuS_2CH_2: Cu, 44.86; S, 45.24. Found: Cu, 43.74, 43.90; S, 44.09 (Ratio, 1.000 N; 1.995 S).

1,3-Di-(1′-piperidine)-2-thiapropane (II).—1-Piperidinemethanol, prepared from piperidine (10 g.), was treated with hydrogen sulfide at 0° for one and one-half hours, 2.6 g. of the gas being absorbed. The reaction product was extracted with ether (100 cc.), shaken with 10% sodium hydroxide (50 cc.), separated, and dried with calcium chloride. On evaporation of the ether an oil was obtained which crystallized on cooling: yield, 3.2 g.; m. p. 48.5–50.5°. The compound is soluble in the ordinary organic solvents and dilute acid, but insoluble in alkaline solutions.

Anal. Calcd. for $C_{12}H_{24}N_2S$: N, 12.27; S, 14.04. Found: N, 12.38, 12.45; S, 14.56.

1,3-Di-(1′-piperidine)-2-thiapropane Dihydrochloride (XII).—1-Piperidinemethanol, prepared as before from piperidine (10 g.), was dissolved in concd. hydrochloric acid (10 cc.), cooled, and treated with hydrogen sulfide for one hour. The colorless, crystalline mass of 1,3-di-(1′-piperidine)-2-thiapropane dihydrochloride was filtered and washed with acetone; yield, 4.2 g.; m. p. 171–175°, with decomposition.

Anal. Calcd. for $C_{12}H_{26}N_2SCl_2 \cdot H_2O$: N, 8.77; S, 10.04; Cl, 22.21. Found: N, 8.70, 8.60; S, 10.24, 10.33; Cl, 22.01.

An aqueous solution of the hydrochloride, treated with 10% sodium carbonate, yielded a precipitate of the free base (II); m. p. 50–53°.

4-Morpholinemethanethiol (III).—To morpholine (17.5 cc.) there was added slowly with cooling 37% aqueous formaldehyde (18 cc.), followed by concd. hydrochloric acid (17 cc.); *p*H 3.5. On treatment with hydrogen sulfide at 55° for two hours, the solution absorbed 5.1 g. of the gas (calcd., 6.8 g.). The reaction mixture was treated with 10% sodium hydroxide (100 cc.), and extracted with ether (200 cc.). The extract, which was dried with calcium chloride, and concentrated, deposited crystals of 4-morpholinemethanethiol; yield 8 g. Recrystallization from methanol (15 cc.) gave 5.3 g. of fine prisms; m. p. 86–88°. Cooling below room temperature during the recrystallization was avoided to prevent the precipitation of the by-product (V) of the reaction.

Anal. Calcd. for $C_5H_{11}NSO$: N, 10.52; S, 24.07. Found: N, 10.46, 10.50; S, 24.14, 24.08.

When the thiol (1.85 g.) was refluxed for one hour with concd. hydrochloric acid (25 cc.), trithioformaldehyde (0.6 g. or 94%) was obtained; m. p. 219°. S, calcd. 69.6; found, 69.0.

To 4-morpholinemethanethiol (1.3309 g.) dissolved in ethyl alcohol (30 cc.) there was added mercuric chloride (1.3575 g.) dissolved in ethyl alcohol (37.7 cc.). A flocculent canary-yellow precipitate of mercuric (di-mercaptomethyl) ether (VIII) appeared immediately. After purification by washing with absolute ethanol and centrifuging several times, the precipitate was dried: yield 94%; decomposition at 110–115°. When an aqueous suspension of the compound was treated with hydrogen sulfide, mercuric sulfide was precipitated.

(7) Putochin, *Ber.*, **55**, 2749 (1922).

Anal. Calcd. for $HgS_2C_2H_4O$: Hg, 64.97; S, 20.77; C, 7.77; H, 1.31. Found: Hg, 65.08, 65.10; S, 20.70; C, 5.26, 5.27; H, 1.03, 1.04.

To 4-morpholinemethanethiol (0.6655 g.) dissolved in ethyl alcohol (15 cc.) there was added a saturated alcoholic solution of cupric acetate until a permanent blue color was imparted to the solution. The flocculent yellow precipitate was purified as much as possible by washing several times with absolute ethanol, centrifuged, and dried at room temperature: yield, 94% based on cupric methylene dimercaptide (IX); decomposition at 100–110°. When suspended in sodium sulfide solution the compound immediately acquired a black coating of copper sulfide; hydrogen sulfide had no effect.

Anal. Calcd. for CuS_2CH_2: Cu, 44.86; S, 45.24; C 8.47; H, 1.43. Found: Cu, 45.79; S, 43.71; C, 5.98, 6.08; H, 1.78, 1.60.

In these cases also the mercury and copper derivatives were too insoluble for further purification, and the values found for carbon are too low, presumably because of the difficulty of obtaining complete combustion.

The ether filtrate obtained after removal of the 8 g. of crude 4-morpholinemethanethiol (III) was cooled to 0°, yielding 5 g. of an amorphous white compound. The latter was purified by dissolving in hot ethanol and cooling, followed by two similar treatments from acetone, and gave a precipitate which melted at 72–80°. This is apparently the same compound which is formed when the reaction between morpholine, formaldehyde, and hydrogen sulfide is carried out without hydrochloric acid, but with twice as much formaldehyde as was previously used. Morpholine (8.75 g.) was added gradually with cooling to 37% formaldehyde (18 cc.), followed by benzene (40 cc.). Hydrogen sulfide was then passed in, with moderate cooling, until 5 g. was absorbed. After the reaction mixture was shaken with 10% sodium hydroxide (25 cc.), the benzene layer was separated, washed with water, concentrated, and cooled to 0°. A colorless, amorphous solid (7.6 g.) was obtained; m. p. 67–78°. Successive purifications with hot methanol, and acetone, raised the melting point to 77–84°.

Anal. Calcd. for $C_{12}H_{24}N_2S_8O_2$: N, 8.64; S, 29.60. Found: N, 8.88, 8.78; S, 30.21.

According to this analysis the compound is probably 1,7-di-(4′-morpholine)-2,4,6-trithiaheptane (V).

1,3-Di-(4′-morpholine)-2-thiapropane (IV).—Morpholine (35 cc.) was added gradually with cooling to 37% formaldehyde (36 cc.). The reaction mixture was shaken with anhydrous potassium carbonate (20 g.), to give an upper layer of 4-morpholinemethanethiol which was separated and treated with hydrogen sulfide at 0°. The crystalline precipitate of 1,3-di-(4′-morpholine)-2-thiapropane formed almost at once. After fifteen minutes the yield of filtered crystals was 12.8 g. The filtrate on treatment with hydrogen sulfide gave a second crop of 11.6 g. and a third crop of 2.6 g. After recrystallizing the product twice from acetone and once from ether the 1,3-di-(4′-morpholine)-2-thiapropane separated as colorless, cube-like crystals, melting at 107–108°.

Anal. Calcd. for $C_{10}H_{20}N_2SO_2$: N, 12.06; S, 13.80. Found: N, 12.16; S, 13.85.

In preparing 1,3-di-(4′-morpholine)-2-thiapropane, a certain amount remains dissolved in the aqueous filtrate after the crystals have been removed. This filtrate on standing deposits a white flocculent precipitate which appears to be identical with a compound obtained from 1,3-di-(4′-morpholine)-2-thiapropane directly by dissolving 3.7 g. in 75 cc. of water at room temperature. After twenty-four hours 0.15 g. of a white precipitate had formed, m. p. 72–82°. The filtrate after warming on the water-bath gave an additional 1.6 g.

Anal. Calcd. for $C_6H_{13}NS_2O \cdot {}^1/_2H_2O$: N, 7.44; S, 34.06. Found: N, 7.41; S, 33.58, 33.51.

According to this analysis the compound is probably 3-(4′-morpholine)-2-thiapropanethiol (VI), $OC_4H_8NCH_2SCH_2SH$.

The Reaction between Diethanolamine, Formaldehyde, and Hydrogen Sulfide.—According to German Patent 564,787 (1931) (I. G. Farbenindustrie), diethanolamine and formaldehyde, when warmed for one-half hour at 50°, form hydroxyethyloxazolidine. We have added diethanolamine to formaldehyde[8] in the cold, thus avoiding the formation of the oxazolidine ring, and have treated the resulting methanoldiethanolamine with hydrogen sulfide.

Gradually and with cooling diethanolamine (5.2 g.) was poured into 37% aqueous formaldehyde (4.5 cc.). Hydrogen sulfide was passed into the solution and within one-half hour a white mass filled the test-tube. The entire reaction mixture was digested with boiling ethanol, in which it did not dissolve, and was then filtered and washed with alcohol and ether: yield, 3.3 g. of compound (VII); m. p. 224–226°.

Anal. Calcd. for $(HOCH_2CH_2)_2N(CH_2S)_7H$: N, 3.28; S, 52.47. Found: N, 3.03; S, 52.39.

Compound (VII) can be dissolved in 20 parts of boiling diethanolamine and remains in solution on addition of water. Since the melting point is near that of trithioformaldehyde (216°) the question arises, whether trithioformaldehyde (S calcd. 69.7) has formed during the reaction and become part of the compound. This is doubtful, as trithioformaldehyde when dissolved in 20 parts of boiling diethanolamine is precipitated by adding water.

Another preparation made from diethanolamine (21 g.) and aqueous formaldehyde (18 cc.) was treated with hydrogen sulfide for one hour. The absorbed gas amounted to 6.8 g. when the tube began to fill with the white semi-solid mass. This was boiled in acetone (600 cc.), in which most of it dissolved. The filtrate on cooling gave 6.7 g. of (VII) as a white precipitate, m. p. 218–221°. When the compound was placed in a bath at 170° it melted immediately to a clear liquid, then solidified, and remelted at 218–228°.

Anal. Calcd. for $(HOCH_2CH_2)_2N(CH_2S)_7H$: N, 3.28; S, 52.47. Found: N, 3.46, 3.43, 3.37; S, 52.00.

We tried to ascertain whether it was possible to obtain the same compound by using the components in the ratio suggested by the above formula. Into 37% formaldehyde (18 cc.) was poured diethanolamine (3 g.). In order to

(8) The reaction between diethanolamine and formaldehyde has been studied by Lyubomudrov, *Ukrain. Khem. Zhur.*, **11**, Wiss. Tl. 119 (1936); *C. A.*, **30**, 5957 (1936).

keep the resulting compound more dispersed, water was added (175 cc.), and the hydrogen sulfide was passed into the suspension at 65°. Within one hour 7.4 g. of the gas had been absorbed. The resulting suspension of white precipitate was made alkaline with 10% sodium hydroxide (20 cc.) and then washed with water by centrifuging. After drying *in vacuo* a yield of 7 g. was obtained; m. p. 220–224°. When placed in the bath at 180°, the compound did not melt until 230–233° Found: N, 1.56; S, 51.08.

This compound (XIII) has a ratio N:S = 1:14.4, which shows that this preparation is different from the one mentioned above.

However, as in the case of (VII), it is not likely that this compound (XIII) is a molecular combination of diethanolamine with trithioformaldehyde. Both are much less soluble in acetone, ether, absolute alcohol, and benzene, and far more soluble in hot diethanolamine than the trithioformaldehyde. Furthermore, the three substances show a marked difference when submitted to sublimation, as is shown in the table.

	100°	230°
$(CH_2S)_3$	Started to sublime	Completely sublimed
(VII)	Slight sublimation with subsequent melting of sublimate	Residue melted with decomposition
(XIII)	Nothing sublimed	Residue unchanged

The analyses were done by Dr. H. K. Alber of our Microchemical Department.

Summary

Piperidine, morpholine, and diethanolamine were treated with aqueous formaldehyde to form the corresponding aminomethanols.

The 1-piperidinemethanol, 4-morpholinemethanol, and methanoldiethanolamine were treated with hydrogen sulfide under varying conditions, yielding 1-piperidinemethanethiol, 1,3-di-(1-piperidine)-2-thiapropane, 4-morpholinemethanethiol, 1,3-di-(4′-morpholine)-2-thiapropane, and polymerized thioformaldehyde derivatives of methanoldiethanolamine, respectively.

The lethal doses of the sulfur derivatives of piperidine, morpholine, and diethanolamine were determined by intravenous injections in mice.

The Alkylation of α-Sulfonylamides[1]

BY AUSTIN POMERANTZ[2] AND RALPH CONNOR

A number of α-sulfonyl-α-alkylacetamides recently were prepared[3] by the alkylation of α-sulfonylacetamides. While this method was adequate for the compounds previously investigated, continuation of the earlier work disclosed that in certain cases the yields were low and the products difficult to purify. Since the alkylation products were of some interest as hypnotics,[4] a more complete study of this reaction was undertaken. The discussion will be limited to the ethylation of α-*n*-butylsulfonylacetamide (I) but examples of other alkylations will be given in the experimental part.

In several ethylations of α-*n*-butylsulfonylacetamide under the conditions previously used (sodium ethoxide and an alkyl halide in alcohol solution), a considerable amount of unchanged I was always present and consequently the purification of the product (α-*n*-butylsulfonyl-*n*-butyramide, II) was very difficult. The recovered starting material was not present in the reaction mixture as unreacted sodium derivative, for the solution was refluxed until it became neutral. It therefore seemed likely that the methylene group of I was not sufficiently activated to compete successfully for the sodium with the large excess of alcohol that was present[5] and that the true situation might be represented according to the equations[6]

(1) This communication is constructed from a thesis submitted by Austin Pomerantz in partial fulfilment of the requirements for the degree of Doctor of Philosophy at the University of Pennsylvania in June, 1939.

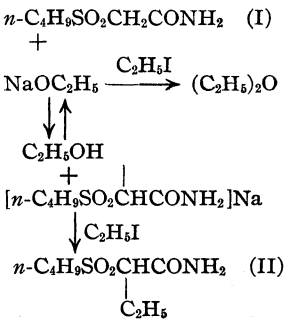
(3) d'Ouville and Connor, THIS JOURNAL, **60**, 33 (1938).

(4) A pharmacological examination of the compounds reported in this paper is being made under the direction of Dr. Robert S. Shelton of the Wm. S. Merrell Company and will be reported elsewhere.

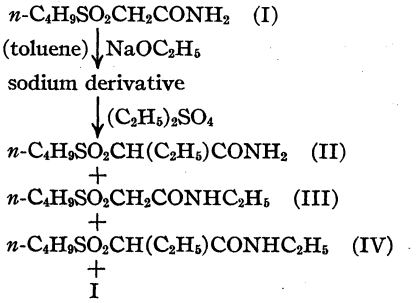
(5) Tröger and Lux [*Arch. Pharm.*, **247**, 618 (1909)] reported that α-phenylsulfonylacetamide ($C_6H_5SO_2CH_2CONH_2$) formed no sodium derivative with alcoholic sodium ethoxide. However, the alkylations of α-*p*-tolylsulfonylacetamide previously reported[3] were carried out in alcoholic solution and appeared to be more satisfactory than the alkylation of I.

(6) The weak acidity of the methylene group of I is not surprising in view of the fact that both the sulfone and carbonamide groups are generally considered to be relatively weak labilizing groups.[5,7] It is interesting to note, however, that when a methylene group

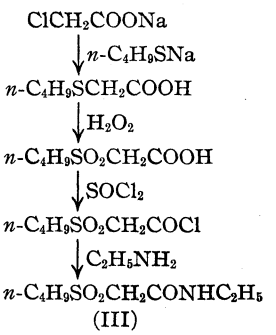


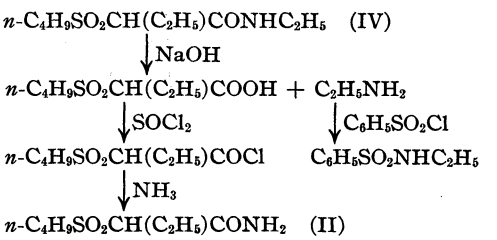
In order to avoid the effect of a high concentration of alcohol upon the above equilibrium the alkylation was next carried out in dry benzene and in dry toluene containing sodium ethoxide prepared by the reaction of sodium with the theoretical amount of alcohol. The equivalent of alcohol liberated by the reaction of I with sodium ethoxide was insufficient to interfere with the alkylation reaction since similar results were obtained whether or not this alcohol was removed before alkylation. Under these conditions the sodium derivative of I was formed quantitatively and precipitated from the hot solution as a yellow-orange oil which dried to a yellow powder. By acidification of the sodium derivative unchanged I was recovered in an amount which showed that no side reaction had occurred as a result of the sodium ethoxide treatment. The sodium derivative reacted very slowly with alkyl halides and a bromide analysis after refluxing for twenty-five hours in toluene with five equivalents of *n*-butyl bromide showed that 56% of the theoretical amount of sodium bromide had been formed. Treatment of the sodium derivative in boiling benzene with six equivalents of ethyl iodide gave a reaction mixture which was alkaline after refluxing for fifty-five hours. With ethyl sulfate the reaction was much more rapid and the alkylation mixture was neutral after refluxing for three hours. Analysis showed that the theoretical amount of sodium ethyl sulfate had been formed.

The reaction of the sodium derivative of I with ethyl sulfate in toluene gave, in addition to unchanged I, the expected *α*-*n*-butylsulfonyl-*n*-butyramide (II) and also *α*-*n*-butylsulfonyl-N-ethylacetamide (III) and *α*-*n*-butylsulfonyl-N-ethyl-*n*-butyramide (IV). The pure products were isolated in yields of 30, 7 and 0.04%, respectively. Separation was difficult, however,



and these figures do not show the relative amounts of the three compounds actually formed. It was estimated that the ratio of II to III was near to 2:1. The structure of III was established by comparison with a sample prepared by a conventional synthetic method and the identity of IV was shown by the isolation and identification of its hydrolysis products.





The results of these alkylations may be rationalized by recalling that amides undergo many reactions analogous to those generally considered typical of active methylene compounds. It may therefore be considered that in I there are two activated groups, —CH_2— and —NH_2. The data indicate that while the methylene group is somewhat the more active, their relative activity is such that both groups undergo alkylation. This possibly involves two different types of sodium derivatives, V and VI,[10] which could be interconverted by a prototropic change and which

is activated by two sulfone groups[8] or by two carbonamide groups,[9] alkylation in alcoholic solution is apparently more successful than in the case of I.

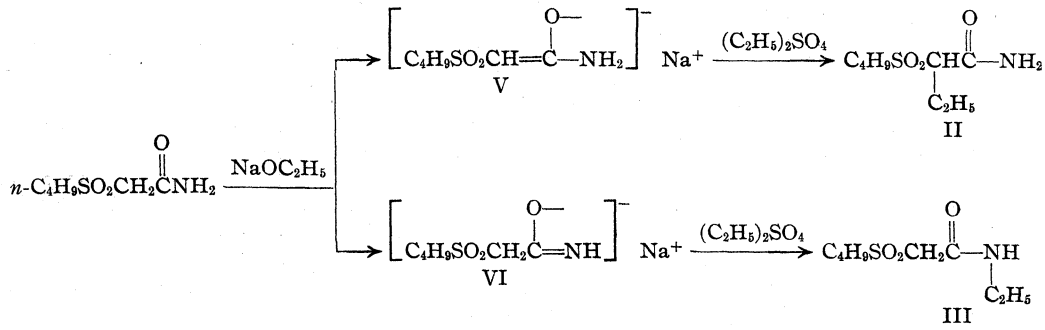
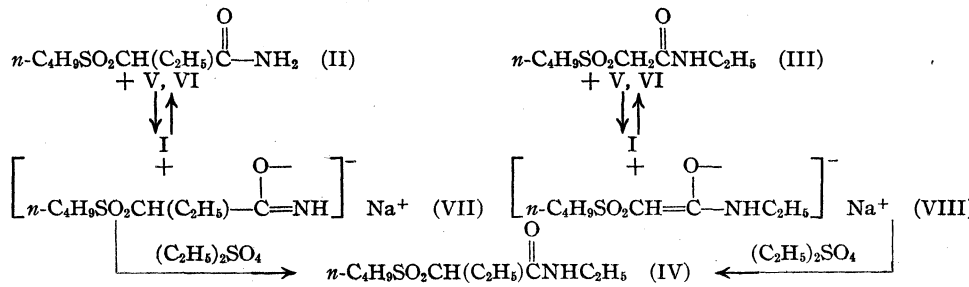
(9) Meyer, *Monatsh.*, **28** 1 (1907); Conrad and Schulze, *Ber.*, **42**, 729 (1909).

(10) Various other structures might be written for these sodium derivatives. Since a consideration of such possibilities adds nothing to the present discussion, V and VI have been arbitrarily selected to show that in one case the methylene group is involved and in the other case the —NH_2.



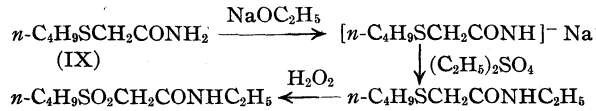
might be in dynamic equilibrium. It is also possible that the equilibrium is modified by the insolubility of the sodium derivatives; the slow rate of reaction with ethyl iodide might be construed as an indication that VI is present and not readily converted to V.[11]

The formation of a dialkylation product, IV, obviously occurred by the reaction of the monoalkylation products (II and III) with V and VI to give I and the sodium derivatives (VII and VIII) of II and III.



In the above equations the formation of only one sodium derivative from each monoalkylation product has been shown. The basis for this is the fact that the alkylation both of pure II and of pure III gave IV.[12] Furthermore, this is in accord with the view that in the system $-CH_2-\overset{O}{\overset{\|}{C}}-NH_2$ the $-CH_2-$ and $-NH_2$ are activated to approximately the same extent. Substitution of an ethyl group would change the relationship by decreasing the activity of the group to which it was attached, not only because of steric factors but also due to the fact that an alkyl group has an effect opposite to that of the common labilizing groups.[13] Therefore in II the H of $-NH_2$ is more active than that of $-CH(C_2H_5)-$ while in III the H of $-CH_2-$ is more active than that of $-NHC_2H_5$ and the formation of sodium derivatives and their alkylation should proceed as shown above.

To compare the influence of the RS— and RSO_2— groups, the alkylation of α-(*n*-butylthio)-acetamide (IX) was investigated. The reaction of IX with sodium ethoxide in dry toluene gave a gelatinous sodium derivative. In this case an unknown side reaction apparently occurred, since only 70% of the starting material was recovered after acidification. With ethyl sulfate the sodium derivative gave an oil which was oxidized to III. It seems fairly certain that



no alkylation occurred on carbon and hence that the sodium derivative was an amide salt. Therefore, the RS— group, as would be expected, is not a labilizing group so far as this reaction is concerned. The yield of III was too low to make this a promising synthetic method.

(11) While it is well known that the sodium derivatives of amides may be converted to N-alkyl amides by the action of alkylating agents, Titherly [*J. Chem. Soc.*, **79**, 391 (1903)] observed that alkyl halides were unreactive in such syntheses while potassium alkyl sulfates reacted satisfactorily.

(12) Theoretically, II might give α-*n*-butylsulfonyl-α,α-diethylacetamide and III might give α-*n*-butylsulfonyl-N,N-diethylacetamide. Possibly these are formed in small amounts. No evidence was obtained for the former reaction. However, the crude material remaining in the mother liquors from the recrystallizations of the product from the alkylation of III was hydrolyzed and the detection of traces of diethylamine showed that alkylation of the $-NHC_2H_5$ group had occurred to a slight extent.

Experimental Part

All melting points are uncorrected unless otherwise specified. The absolute alcohol used was the commercial material which had been further dried over lime and then treated with sodium and ethyl phthalate. Benzene and toluene were dried over sodium ribbon. The ligroin used was the fraction boiling at 70–90°.

I. Alkylation in Alcohol Solution

α-*n*-Butylsulfonyl-*n*-butyramide (II).—The reaction of α-*n*-butylsulfonylacetamide[3] (I) with ethyl bromide and sodium ethoxide was carried out using 0.05 molar quantities and the conditions previously[3] described. The diluted reaction mixture was concentrated under reduced pressure and chilled. The impure product weighed 7.1 g. and after repeated recrystallization from water gave 1.17 (11%) of the alkylation product (II), m. p. 124–125°. Repeated recrystallization of the residues obtained by evaporation of the aqueous mother liquors gave 1.78 g. (20%) of slightly impure starting material (I), m. p. 114–117°.

α-*n*-Butylsulfonyl-*n*-caproamide.—Using 0.03 molar quantities of the reagents and 125 ml. of alcohol as a solvent, the reaction of (I) with *n*-butyl bromide and sodium ethoxide was carried out as in the ethylation reaction. The reaction mixture was not neutral after refluxing for eight hours. Dilution with water gave no precipitate and the solution was concentrated, first under reduced pressure and then at atmospheric pressure. Several fractions of impure solid were obtained and when combined weighed 2.78 g., m. p. 104–115°. Recrystallization from water gave 1.06 g. (15%) of alkylation product, m. p. 104–105°, which was not purified further. The preparation of the pure compound is described below.

II. Alkylations with Alkyl Halides in Inert Solvents

Sodium ethoxide was prepared by the method of Cox and McElvain[14] with four modifications: (1) benzene or toluene were used instead of ether, (2) approximately 2–5% excess of absolute alcohol was used, (3) the reaction was carried out at room temperature and the completion of the reaction assured by allowing the mixture to stand overnight before use and (4) the air in the apparatus was displaced by dry nitrogen to avoid discoloration of the sodium ethoxide and a slow stream of dry nitrogen passed through the apparatus during the course of the reaction. The theoretical quantity of α-sulfonylamide was then added and the reaction mixture refluxed in an oil-bath until the formation of the insoluble sodium derivative was complete (one-half to two hours). In some cases the hot solvent was then decanted from the oily sodium derivative and replaced by fresh solvent in order to remove any unreacted starting material as well as the alcohol liberated in the reaction. However, the results did not differ in comparable runs in which decantation was omitted, so that this was not adopted as a general procedure. Evaporation of the decanted solvent in several experiments showed that the unreacted starting material was negligible and hence that the formation of the sodium derivative was complete.

An excess of the alkyl halide was then added and the reaction mixture refluxed in an oil-bath with stirring for periods up to fifty-five hours. In no case did the solution become neutral to moist litmus. The mixture was filtered through a fluted filter while hot to remove sodium halide and unreacted sodium derivative. The filtrate was concentrated and chilled to obtain the α-sulfonylamides. Further concentration of the mother liquors gave in all cases a small amount of an oil which was not successfully crystallized, although in some cases there appeared to be solid present. Since the oil was apparently a mixture of compounds similar to those described later in the discussion of the reaction of ethyl sulfate, no further attempts at characterization were made.

α-*n*-Butylsulfonyl-*n*-butyramide (II).—The sodium derivative from 6.46 g. (0.036 mole) of α-*n*-butylsulfonylacetamide (I) in 150 ml. of benzene was refluxed with 34.0 g. (0.22 mole) of ethyl iodide for fifty-five hours and the reaction product isolated as described above. From the benzene filtrate was obtained 1.8 g. (24%) of impure II, m. p. 117–120°. Recrystallization from water gave 1.4 g. (19%) of the pure material, m. p. 124–124.5°.

The alkaline, benzene-insoluble residue obtained by filtration of the reaction mixture was suspended in acetone, neutralized with glacial acetic acid and the solvent removed on the steam-bath. The residue was extracted repeatedly with small amounts of benzene and the extracts chilled. The first extracts appeared to consist mainly of II and the last of I. They were therefore divided into two portions; recrystallization of the less soluble portion from benzene gave a small amount of I. Recrystallization of the other fraction from water gave 1.1 g. (15%) of II, bringing the total yield of alkylation product to 2.5 g. (33% of the theoretical).

α-*n*-Butylsulfonyl-*n*-caproamide.—The sodium derivative from 4.48 g. (0.025 mole) of *n*-butylsulfonylacetamide (I) in 100 ml. of toluene was refluxed for twenty-five hours with stirring with 17.1 g. (0.125 mole) of *n*-butyl bromide. Isolation of the product by the general method described above gave 2.3 g. of impure solid, m. p. 85–95°. Recrystallization from water gave 1.1 g. (19%) of impure α-*n*-butylsulfonyl-*n*-caproamide, m. p. 107–108°. The product was very difficult to purify further but repeated recrystallizations from dilute alcohol gave analytically pure material, m. p. 110.5–111° (corr.).

Anal. Calcd. for $C_{10}H_{21}O_3NS$: N, 5.95; S, 13.62. Found: N, 5.90, 5.91; S, 13.74, 13.35.

The toluene-insoluble solid isolated by filtration of the reaction mixture was dissolved in dilute nitric acid and a solution of silver nitrate added. The silver bromide formed weighed 2.6 g., indicating 56% reaction.

α-*p*-Tolylsulfonyl-*n*-caproamide.—The sodium derivative from 9.45 g. (0.044 mole) of α-*p*-tolylsulfonylacetamide[3] in 150 ml. of dry toluene was refluxed with stirring for nineteen hours with 24.3 g. (0.18 mole) of *n*-butyl bromide. The product was 5.05 g. of impure material, m. p. 128–138°. Several recrystallizations from dilute alcohol gave 3 g. (25%) of the pure alkylation product, m. p. 165.5–166° (corr.).

Anal. Calcd. for $C_{13}H_{19}O_3NS$: N, 5.20; S, 11.90. Found: N, 5.18, 5.15; S, 11.93, 11.60.

α-Benzyl-α-*p*-tolylsulfonylacetamide.—The sodium derivative from 14.62 g. (0.07 mole) of a α-*p*-tolylsulfonylacetamide in 200 ml. of dry toluene was refluxed with

(14) Fieser, "Organic Syntheses," John Wiley and Sons, Inc., New York, N. Y., 1937, Vol. XVII, p. 54.

stirring for eighteen hours with 15.4 g. (0.12 mole) of benzyl chloride. The impure product weighed 4.3 g. but was separated by repeated recrystallization from dilute methanol into the starting material, α-*p*-tolylsulfonylacetamide, and 1.6 g. of the alkylation product.

The toluene-insoluble material was washed with dilute hydrochloric acid, dried and recrystallized from dilute alcohol. The weight of α-benzyl-α-*p*-tolylsulfonylacetamide from this source was 7.6 g., making the total yield of the product 9.2 g. (44%), m. p. 203–204° (corr.).

Anal. Calcd. for $C_{16}H_{17}O_3NS$: N, 4.62; S, 10.57. Found: N, 4.61, 4.58; S, 10.47.

III. Alkylations with Ethyl Sulfate in Toluene

Ethylation of α-*n*-Butylsulfonylacetamide (I).—The sodium derivative prepared from 76.7 g. (0.43 mole) of I in 700 ml. of dry toluene by the procedure mentioned above was refluxed with stirring with 72.6 g. (0.47 mole) of freshly distilled ethyl sulfate. The reaction mixture became neutral after three and one-half hours but heating was continued until the total reaction time was seven hours. At the end of this time the solution was no longer alkaline to moist litmus and the sodium ethyl sulfate obtained by filtering the hot solution weighed 62.0 g. (98% of the theoretical). The filtrate was concentrated and chilled, giving 43.9 g. of impure material, m. p. 100–108°. Repeated recrystallization from water gave 27.0 g. (30%) of pure α-*n*-butylsulfonyl-*n*-butyramide (II). The water was evaporated from the combined filtrates from these recrystallizations and the residue recrystallized repeatedly from a mixture of benzene and alcohol. While the separation of I from mixtures with II was very difficult, this procedure gave a considerable amount of unchanged I.

Further concentration of the toluene filtrate of the original reaction mixture gave a thick oil which could not be crystallized. The solvent was removed completely and the residue distilled under reduced pressure in a modified Claisen flask. The fraction (29 g.) boiling at 168–177° (2 mm.) was a viscous liquid which partly solidified in the receiver but which could not be crystallized by ordinary methods. However, using methanol as a solvent and a cooling bath of dry-ice–acetone, 9.3 g. of impure solid was isolated. Recrystallization of this product from a mixture of benzene and ligroin gave 6.2 g. (7%) of α-*n*-butylsulfonyl-N-ethylacetamide (II), m. p. 73–73.5° (corr.), which was identical with the synthetic material described later. The methanol solution obtained by filtration after the dry-ice–acetone treatment stood for some time at room temperature and a crystal growth of α-*n*-butylsulfonyl-N-ethyl-*n*-butyramide (IV), 0.4 g. (0.04%), m. p. 63–64°, was formed. This was identical with the definitely characterized material described later. Attempts to crystallize the remainder of the material were unsuccessful but it appeared to be a mixture of III and IV. In other experiments repeated attempts to separate III and IV satisfactorily were unsuccessful; small amounts were separated by crystallization and none at all by distillation.

Ethylation of α-*n*-Butylsulfonyl-N-ethylacetamide (III).—Thirty-one grams (0.15 mole) of III (prepared as described later in this paper) was refluxed with stirring for two and one-half hours in 400 ml. of dry toluene containing one equivalent of sodium ethoxide. The sodium derivative precipitated as a white granular solid. There was then added 28.2 g. (0.18 mole) of freshly distilled ethyl sulfate and the mixture refluxed in an oil-bath with stirring for two and one-half hours. This alkylation was relatively rapid; the reaction mixture had become neutral to litmus within one hour. The hot solution was filtered to remove the sodium ethyl sulfate which, when dry, weighed 20.0 g. (91% of the theoretical). The filtrate was concentrated and chilled but there was no crystallization. Removal of all of the solvent gave a thick oil which was distilled in a modified Claisen flask. The fraction (31.0 g.) boiling at 174–178° (3 mm.) was a viscous liquid boiling almost entirely at 174° (3 mm.). This distillate remained an oil for two weeks but solidified when seeded with α-*n*-butylsulfonyl-N-ethyl-*n*-butyramide (IV) isolated from the above ethylation. Recrystallization was very difficult but was accomplished by using methanol as a solvent and dry-ice in acetone as a cooling bath. The pure product weighed 16.4 g. (47%), m. p. 64–65°. Evaporation of the methanol gave an oil from which no additional pure solid was obtained. The hydrolysis of 4.9 g. of this impure material was carried out by refluxing with 60 ml. of 17% sulfuric acid for fifty hours. The solution was made alkaline, steam-distilled, and the distillate collected in dilute hydrochloric acid. A Hinsberg separation was carried out on the distillate, using *p*-toluenesulfonyl chloride.[15] There were isolated 1.5 g. of N-ethyl-*p*-toluenesulfonamide, m. p. 59–60°, and 0.15 g. of N,N-diethyl-*p*-toluenesulfonamide, m. p. 56–58°. These products did not depress the melting points of authentic samples of the proper amides.

The structure of the pure IV was established by refluxing 1.8 g. of the product for twenty-two hours with 35 ml. of 10% sodium hydroxide solution. The ethylamine evolved was absorbed in dilute hydrochloric acid and converted to N-ethylbenzenesulfonamide,[15] m. p. 56–57°. The saponification mixture was acidified with dilute hydrochloric acid, extracted with ether, and the extracts dried over sodium sulfate. The ether was removed by evaporation and the crude acid converted to the acid chloride and then the amide,[16] m. p. 124–124.5°. The identities of both derivatives were confirmed by mixed melting points with synthetic samples.

Ethylation of *n*-Butylsulfonyl-*n*-butyramide (II).—Forty-five grams (0.22 mole) of II[17] was refluxed with stirring for two hours in 400 ml. of dry toluene containing one equivalent of sodium ethoxide. The sodium derivative was soluble in hot and cold toluene. There was then added 36.9 g. (0.24 mole) of freshly distilled ethyl sulfate and the mixture refluxed in an oil-bath with stirring for eight and one-half hours. The reaction mixture was neutral; it was filtered while hot to remove the sodium ethyl sulfate which, when dry, weighed 30.0 g. (93% of the theoretical). The filtrate was concentrated and cooled and 4.67 g. (10%) of unchanged II, m. p. 117–119°, obtained. The solvent was removed completely and the thick oily residue distilled in a modified Claisen flask. In addition to

(16) Shriner and Fuson, "Identification of Organic Compounds," John Wiley and Sons, Inc., New York, N. Y., 1935, p. 144.

(17) The material used in this reaction was identical with that obtained by alkylation but was prepared by a method to be described in a later paper.

the customary fore-run of ethyl sulfate, there was obtained 40.8 g., b. p. 172–178° (3–4 mm.), which solidified when seeded with α-*n*-butylsulfonyl-N-ethyl-*n*-butyramide (IV). Recrystallization from a mixture of benzene and ligroin gave 30.5 g. (60%) of impure IV, m. p. 58–61°. Several recrystallizations gave 24 g. (47%) of the pure material, m. p. 64.5–65° (corr.), which did not depress the melting points of the material obtained by the ethylation of III or that obtained as one of the products from the ethylation of I.

Anal. Calcd. for $C_{10}H_{21}O_3NS$: N, 5.95; S, 13.62. Found: N, 5.91, 5.90; S, 13.72, 13.68.

Ethylation of α-(*n*-Butylthio)-acetamide.—The sodium derivative was prepared by refluxing with stirring 74.7 g. (0.51 mole) of α-(*n*-butylthio)-acetamide[3] for two and one-half hours in 800 ml. of dry toluene containing an equivalent amount of sodium ethoxide. The sodium derivative was soluble in hot toluene but precipitated as a gelatinous mass on cooling. The sodium derivative was refluxed with stirring for eight and one-half hours with 82.5 g. (0.54 mole) of freshly distilled ethyl sulfate. At the end of this period the reaction mixture was neutral to moist litmus. The sodium ethyl sulfate obtained by filtration of the hot solution weighed 70 g. (93% of the theoretical). The filtrate was concentrated and the oily residue distilled in a modified Claisen flask. Fraction 1, 12.7 g., distilled at 73–81° (4–6 mm.). Ethyl sulfate was shown to be present in this mixture by the formation of barium sulfate. Another component of the fraction was probably ethyl α-(*n*-butylthio)-acetate[18] which is reported[19] to boil at 89–90° (10 mm.). Fraction 2, 47.5 g., distilled at 122–125° (4 mm.). Considerable decomposition occurred during distillation and the residue was large. The entire fraction was dissolved in 270 ml. of 1:1 acetic acid–acetic anhydride mixture and treated with 70 ml. of 30% hydrogen peroxide according to the method already described.[3] At the end of the oxidation period the excess peroxide was decomposed by manganese dioxide and the solvent removed under reduced pressure. The residue was an oil which dissolved in hot benzene and was precipitated as a solid by the addition of ligroin. The product thus obtained weighed 41.11 g., corresponding to approximately 75% of the theoretical for the oxidation step. Crystallization from benzene gave 5 g. of I, m. p. 117–118°, and the addition of ligroin to the filtrate gave 24.1 g. of impure III, m. p. 65–67° (23% of the theoretical, based on α-(*n*-butylthio)-acetamide). Since the separation of I and III in other experiments was fairly easy, it seems safe to say that the product of the oxidation was III contaminated with relatively small amounts of I. Several recrystallizations of the impure III raised its melting point to 72°.

IV. Reactions of Amides with Sodium Ethoxide

The general procedure was to prepare sodium ethoxide in benzene by the method already described, add an equivalent amount of the amide and reflux in an oil-bath for the periods of time stated below. Glacial acetic acid was then added in 10% excess of the theoretical amount and heating continued until the mixture was neutral to moist litmus.

α-*n*-Butylsulfonylacetamide (I).—To 150 ml. of benzene containing sodium ethoxide was added 4.05 g. (0.023 mole) of I and the mixture refluxed for two and one-half hours. After treatment with glacial acetic acid as described above, the hot solution was filtered, concentrated and chilled. The amount of I recovered was 3.40 g. (84%), m. p. 116–117°. Considering the mechanical losses that might be expected, it seems safe to say that no appreciable side reactions arise from the action of sodium ethoxide on I. Evidence for the complete conversion of I to the sodium derivative has been mentioned earlier in the experimental part.

α-(*n*-Butylthio)-acetamide (IX).—To 100 ml. of benzene containing sodium ethoxide was added 6.01 g. (0.041 mole) of the amide and the mixture refluxed for five hours. After treatment with glacial acetic acid as described above, the hot solution was filtered, concentrated, and the amide precipitated by the addition of ligroin. The recovery was 4.16 g. (69%), m. p. 55–56°. The poor recovery and the large residue after distillation of the alkylation product as mentioned above both suggest that the reaction of sodium ethoxide with α-(*n*-butylthio)-acetamide gives other products in addition to the sodium derivative.

V. Preparation of α-*n*-Butylsulfonyl-N-ethylacetamide

α-(*n*-Butylthio)-acetic Acid.[20]—This compound was prepared from sodium chloroacetate and sodium *n*-butylmercaptide.[21] An aqueous solution of sodium chloroacetate was prepared by mixing a concentrated aqueous solution containing 66.2 g. (0.7 mole) of chloroacetic acid with a concentrated aqueous solution containing 28 g. (0.7 mole) of sodium hydroxide and diluting with water to a total volume of 150 ml. The solution was placed in a 1-liter, three-necked, round-bottomed flask equipped with a mechanical stirrer and a dropping funnel and immersed in an ice–salt bath. A solution of 75.5 ml. (63.1 g., 0.7 mole) of *n*-butyl mercaptan and 28.0 g. (0.7 mole) of sodium hydroxide in 110 ml. of water was added, with stirring, over a period of one and one-half hours. The reaction mixture was allowed to come to room temperature as the freezing bath melted and after standing overnight was heated on the steam-bath for three hours. The solution was transferred to a separatory funnel, an excess of concentrated sulfuric acid added and the oily upper layer separated. The aqueous layer was extracted with two 100-ml. portions of ether, the extracts added to the original acid layer and the solution dried over calcium chloride. The ether was removed on the steam-bath and the residue distilled in a modified Claisen flask. The product weighed 93.4 g. (90%), b. p. 125–130° (5–6 mm.).

α-*n*-Butylsulfonylacetic Acid.[20]—A solution of 93.4 g. (0.63 mole) of α-(*n*-butylthio)-acetic acid in 630 ml. of 1:1 acetic acid–acetic anhydride mixture was chilled in an ice–salt bath and a one-third excess (172 ml.) of 30% hydrogen

(18) In the alkylation of the α-sulfonylamides, as well as in this case, it often was noted that a fraction corresponding to the ethyl ester was present unless freshly dried alcohol was used. Apparently the slightest traces of moisture cause saponification and the salt formed is converted to the ester by the ethyl sulfate: $RSO_2CH_2CONH_2 \xrightarrow{NaOH} RSO_2CH_2COONa \xrightarrow{(C_2H_5)_2SO_4} RSO_2CH_2COOC_2H_5$.

(19) Uyeda and Reid, THIS JOURNAL, **42**, 2385 (1920).

(20) The conditions for these reactions were worked out in this Laboratory by Mr. Gordon Urquhart.

(21) This reaction had been described previously by Uyeda and Reid.[19] Since certain modifications were made in their directions and higher yields obtained, our method has been described in detail.

peroxide solution added slowly to the cold mixture. The solution was allowed to come to room temperature as the ice-bath melted and stand at room temperature overnight.[22] Manganese dioxide[23] was added, the solution transferred to a Claisen flask and the solvent removed under reduced pressure. The solid residue was dissolved in a mixture of ether and acetone, dried over sodium sulfate and the solvent removed on the water-bath. The yield of crude product was 88 g. (77%), m. p. 59–62°. Recrystallization from toluene gave the pure acid, m. p. 67.5–68.5° (corr.).

Anal. Calcd. for $C_6H_{12}O_4S$: S, 17.79. Found: S, 17.76, 17.91.

α-*n*-Butylsulfonyl-N-ethylacetamide (III).—Crude α-*n*-butylsulfonylacetic acid (40.5 g., 0.225 mole) was placed in an Erlenmeyer flask which was connected by a wide rubber tube to the neck of a three-necked, round-bottomed flask. The acid chloride was prepared by adding the solid acid slowly to thionyl chloride and treating according to the method described for *n*-butyryl chloride.[24] Ethylamine, generated from the hydrochloride by the addition of concentrated alkali and heating, was passed through a tube of soda-lime and bubbled into 250 ml. of dry ether in a 1-liter, three-necked, round-bottomed flask surrounded by an ice–salt bath. When the increase in weight of the ethereal solution was 26 g. (0.58 mole of ethylamine) the flask was fitted with a reflux condenser, a mercury-sealed stirrer and a dropping funnel, kept in the cooling bath, and the acid chloride added dropwise. The reaction mixture stood overnight and the ether then distilled on the steam-bath and replaced by dry benzene during the distillation. The resulting benzene solution was filtered while hot through a fluted filter, concentrated, and the product precipitated by the addition of ligroin and chilling. The product weighed 37.6 g. (81%), m. p. 60–65°, but was contaminated with *n*-butylsulfonylacetic acid. It was dissolved in cold benzene, washed with a saturated solution of sodium bicarbonate, dried over sodium sulfate and recrystallized from a benzene–ligroin mixture. The pure product so obtained weighed 17.4 g., m. p. 73–73.5° (corr.). Concentration of the mother liquor gave an additional 7.4 g., m. p. 70–71°, making the total yield of product 24.8 g. (53%).

Anal. Calcd. for $C_8H_{17}O_3NS$: N, 6.76; S, 15.47. Found: N, 6.69, 6.71; S, 15.36, 15.55.

(22) A longer oxidation period would probably give better results.

(23) Manganese dioxide was used in small amounts, since it formed a manganese salt of the product. Nevertheless, it appeared to assist in the decomposition of the excess peroxide and was always used.

(24) Gilman, "Organic Syntheses," John Wiley and Sons, New York, N. Y., 1932, Coll. Vol. I, p. 142.

Summary

The alkylationi n alcohol of α-alkylsulfonylamides ($RSO_2CH_2CONH_2$) was complicated by the fact that the compounds were not acidic enough to form sodium derivatives satisfactorily in the presence of a considerable amount of alcohol. In inert solvents alkyl halides were not very reactive but ethyl sulfate reacted readily with the sodium derivative of α-*n*-butylsulfonylacetamide (I). The products of this reaction were, in addition to unchanged starting material, α-*n*-butylsulfonyl-*n*-butyramide (II), α-*n*-butylsulfonyl-N-ethylacetamide (III) and α-*n*-butylsulfonyl-N-ethyl-*n*-butyramide (IV). Under similar conditions both II and III gave IV. The results may be interpreted as evidence that in the system —CH_2—CO—NH_2 of this series, two types of sodium derivatives are formed and that the —CH_2— and —NH_2 are activated to about the same extent. Introduction of an alkyl substituent on either —CH_2— or —NH_2 decreases the relative reactivity of the group to which the alkyl substituent is attached and subsequent alkylation occurs on the other active group.

The Reductive Alkylation of Aromatic Primary Amines. II[1]

BY WILLIAM S. EMERSON AND W. D. ROBB

In view of earlier success with the reductive alkylation of aniline[1] it seemed advisable to test the generality of this reaction with other aromatic primary amines. For this purpose we selected *p*-toluidine, *p*-anisidine and α- and β-naphthylamines.

Using the procedure previously described[1] ethyl-α-naphthylamine was prepared in 88% yield, ethyl-, *n*-butyl- and benzyl-β-naphthylamine, and ethyl- and *n*-butyl-*p*-toluidine in 50 to 64% yields. These amines were identified by the formation of known salt or amide derivatives.

The new substances, N-*n*-butyl-α-naphthylamine and N-ethyl- and N-*n*-butyl-*p*-anisidine, were also prepared by this method. Their properties, as well as those of the new benzamide of benzyl-α-naphthylamine, are given in Table I.

N,N-Dialkylarylamines.—In the alkylation of *p*-toluidine and *p*-anisidine with *n*-butyraldehyde, a high boiling fraction was obtained. Three grams of this material was boiled with 20 cc. of acetic

(1) For paper I, see Emerson and Walters, THIS JOURNAL, 60, 2023 (1938).

anhydride for one-half hour and then diluted with water. After neutralization with sodium carbonate the mixture was boiled until all the tertiary amine had distilled. Upon extraction of the oil from the filtrate with ether and evaporation of the ether the alkylations were found to have produced a 19% yield of N,N-di-*n*-butyl-*p*-toluidine and a 25% yield of N,N-di-*n*-butyl-*p*-anisidine.

Summary

The method for preparing N-alkylanilines by reducing an alcoholic solution of aniline and an aldehyde with hydrogen in the presence of Raney nickel and sodium acetate has been extended to four other aromatic primary amines from which ten N-alkylarylamines have been obtained in 24 to 88% yield.

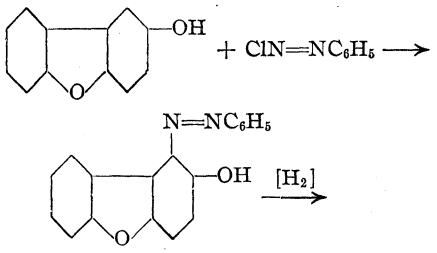
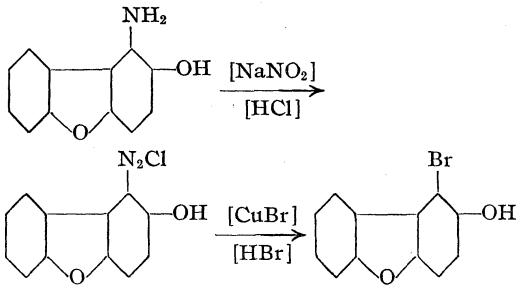
Dibenzofuran. XIV. Diazo Coupling of 2-, 3-, and 4-Hydroxy Compounds[1]

BY HENRY GILMAN AND MARIAN WESTON VAN ESS

Introduction

The recent availability of authentic specimens of some bromohydroxydibenzofurans[2] has made possible the determination of structure of the benzeneazo-hydroxydibenzofurans formed by diazo coupling with the 2-, 3-, and 4-hydroxydibenzofurans. The following transformations illustrate the general procedure used for proof of structure of the coupling products.





The 3-hydroxydibenzofuran also coupled in an ortho position to give 2-benzeneazo-3-hydroxydibenzofuran; but the 4-hydroxydibenzofuran coupled in a para position to give 1-benzeneazo-4-hydroxydibenzofuran. These general directions of coupling are consistent with early observations on phenols.[3] However, there are two available ortho positions for diazo coupling of the 2- and the 3-hydroxydibenzofurans. On general grounds, it might have been predicted that 3-hy-

(1) Paper XIII, Gilman, Parker, Bailie and Brown, THIS JOURNAL, **61**, 2836 (1939).

(3) Chattaway and Hill, *J. Chem. Soc.*, **121**, 2756 (1922).

droxydibenzofuran would couple predominantly in the 2-position rather than in the 4-position, because (other than by metalation) the 4- and the 6-positions are generally not susceptible to the introduction of substituents.[1]

The problem of selective ortho diazo coupling is not without some interest in connection with the relative fixation of possible bond structures in dibenzofuran. It is quite likely that diazo coupling and bromination of both phenols and aliphatic enols are intimately associated, and that each involves an enolic double bond.[4] From the experimental evidence presented at this time, it appears that there is no preferential stabilization of one of the bond structures for the isomeric hydroxydibenzofurans. If there were marked rigidity, a condition that would be unusual in the simple monosubstituted types, then the observed coupling in the 1-position of 2-hydroxydibenzofuran would indicate double bonds between the 1- and 2- and between the 3- and 4-positions. However, a fixed double bond between the 3- and 4-positions would lead one to expect that 3-hydroxydibenzofuran would couple in the 4-position, and not in the 2-position as was the case.

The solubilities of the coupling products in alkali conform with related types in the naphthalene series. The azo dyes derived from the 2- and 3-hydroxydibenzofurans were found to be insoluble in dilute alkali, even when heated, whereas the dye derived from 4-hydroxydibenzofuran was easily soluble in cold alkaline solution. 1-Hydroxy-2-benzeneazonaphthalene[5] and 1-benzeneazo-2-hydroxynaphthalene[6] are insoluble in alkali, and 1-hydroxy-4-benzeneazonaphthalene[6] is readily soluble.

Experimental Part

1-Benzeneazo-2-hydroxydibenzofuran.—The general procedure for the coupling reaction was adapted from that used by Werner and Frey[7] in preparing the benzeneazo derivative of 10-hydroxyphenanthrene. The 2-hydroxydibenzofuran, 3.68 g. (0.02 mole), was dissolved in 15 cc. of 15% potassium hydroxide solution, and subsequently diluted with 60 cc. of water, then cooled to 0° in a 200-cc. three-necked flask equipped with a stirrer, dropping funnel, and thermometer. The diazonium solution was prepared by adding 5 cc. of concd. hydrochloric acid to a mixture of 1.86 g. (0.02 mole) of aniline and 15 g. of finely cracked ice, then adding dropwise a solution of 1.46 g. (0.021 mole) of sodium nitrite in a few cc. of water, until a slight but permanent test for nitrite ion was indicated by a test with starch–potassium iodide paper. The diazonium solution was added dropwise to the cold solution of 2-hydroxydibenzofuran through the chilled dropping funnel. The temperature was maintained at 0° by means of an ice-bath. A red precipitate formed at once. To ensure complete reaction the mixture was stirred for thirty minutes after addition was completed. The product was then removed by filtration and washed well with water. Acidification is not necessary since the desired product is insoluble in alkali. The yield was almost quantitative. The crude product melted at 161–164°, and two recrystallizations from alcohol gave red needles melting at 165.5–166°.

Anal. Calcd. for $C_{18}H_{12}O_2N_2$: N, 9.72. Found: N, 9.84 and 9.98.

2 - Benzeneazo - 3 - hydroxydibenzofuran.—The 3-hydroxydibenzofuran was coupled with benzenediazonium chloride in exactly the manner described above for 2-hydroxydibenzofuran. It was found to be advantageous, however, to run the reaction at a slightly lower temperature (−5°). The mixture was filtered at the close of the reaction without previous acidification. The yield from 3.68 g. (0.02 mole) of 3-hydroxydibenzofuran was 4 g. or 73% of the theoretical. The product after twice crystallizing from alcohol, and once from ethyl acetate, and once from a mixture of ethyl acetate and alcohol melted at 177–178°. It crystallized in minute lustrous golden-brown plates.

Anal. Calcd. for $C_{18}H_{12}O_2N_2$: N, 9.72. Found: N, 9.70 and 9.83.

1 - Benzeneazo - 4 - hydroxydibenzofuran.—The 4-hydroxydibenzofuran was coupled with benzenediazonium chloride by the procedure described for 2-hydroxydibenzofuran. In this case the resulting azo compound formed a salt which separated in very fine orange crystals. Direct acidification of the reaction mixture gave purplish material which turned green upon drying and was difficult to purify. In order to obtain a pure sample it was necessary either to filter out the potassium salt from the reaction mixture and then acidify, or to crystallize the purplish material obtained by acidification of the reaction mixture at once from dilute alcohol without allowing it to stand. The purified product which separated in yellow-orange needles from dilute alcohol melted at 174–175°.

Anal. Calcd. for $C_{18}H_{12}O_2N_2$: N, 9.72. Found: N, 9.77 and 9.99.

Conversion of 1-Benzeneazo-2-hydroxydibenzofuran to 1-Bromo-2-hydroxydibenzofuran.—The method described by Pschorr[8] for the reduction of 9-hydroxy-10-benzeneazophenanthrene was used as a basis for the reduction of the hydroxyazodibenzofurans. One gram (0.0045 mole) of 1-benzeneazo-2-hydroxydibenzofuran was dissolved in 40 cc. of boiling glacial acetic acid, and a solution of 2.0 g. of stannous chloride hydrate in 15 cc. of concd. hydrochloric acid added gradually. The color of the solution quickly faded to yellow. The solution was then cooled, whereupon fine white needles separated out. These crystals

(6) Liebermann, *ibid.*, **16**, 2860 (1883).

(7) Werner and Frey, *Ann.*, **321**, 303 (1902).

(8) Pschorr, *Ber.*, **35**, 2734 (1902).

proved to be the hydrochloride of 1-amino-2-hydroxydibenzofuran. A quantitative yield was obtained. The compound had a tendency to oxidize in air, hence it was used at once to prepare the corresponding bromohydroxy compound.

The diazotization of all of the hydroxyaminodibenzofurans proved rather difficult owing to their marked sensitivity to oxidation. The procedure finally used was based on a patented process for the diazotization of *o*-aminonaphthols.[9] The hydrochloride of 1-amino-2-hydroxydibenzofuran was suspended in ether and treated with an equivalent amount of sodium carbonate solution. The ether layer was washed with water, dried over sodium sulfate and the amine hydrobromide precipitated by passing in dry hydrogen bromide.[10] The hydrobromide, 0.45 g. (0.0025 mole), was suspended in 30 cc. of water at 0° and poured gradually into a similarly cooled solution of 0.12 g. (0.0017 mole) of sodium nitrite and 0.08 g. of copper sulfate hydrate in 10 cc. of water. A light brown precipitate formed. Fifteen minutes was allowed for the completion of the diazotization, whereupon the mixture was poured into a suspension of 0.81 g. (0.0021 mole) of cuprous bromide in 20 cc. of water, and 13 cc. of 40% hydrobromic acid was added gradually. As soon as the evolution of gas ceased, the mixture was boiled for a few minutes. Some very dark precipitate was filtered from the hot solution. The filtrate on cooling deposited grayish needles, 0.015 g., melting at 115–116°. When decolorized with charcoal and crystallized from dilute alcohol, the melting point was 121.5–122° and was not depressed by mixture with an authentic sample of 1-bromo-2-hydroxydibenzofuran.

Conversion of 2-Benzeneazo-3-hydroxydibenzofuran to 2-Bromo-3-hydroxydibenzofuran.—The 2-benzeneazo-3-hydroxydibenzofuran was reduced according to the procedure described for the 1-benzeneazo-2-hydroxydibenzofuran. In the case of the 3-hydroxy derivative, the hydroxy-amine formed a complex with the tin salt and hence did not precipitate out directly as the hydrochloride upon cooling the reaction mixture. In order to break up the complex, the solution obtained after reduction was complete was cooled in an ice-bath and treated with small portions of 30% sodium hydroxide solution until the precipitated tin hydroxide had redissolved, then made barely acid with hydrochloric acid, and finally slightly basic with ammonium hydroxide. The solution was then extracted with ether, the ether layer dried over sodium sulfate, and the amine hydrobromide precipitated with dry hydrogen bromide.

The conversion of the hydrobromide to 2-bromo-3-hydroxydibenzofuran was accomplished by the method employed for the hydrobromide of 1-amino-2-hydroxydibenzofuran. From 0.45 g. (0.0025 mole) of the hydrobromide the yield was 0.04 g. of crude product, which after decolorizing and crystallizing from dilute alcohol melted at 111–112°. A mixed melting point determination with authentic 2-bromo-3-hydroxydibenzofuran showed no depression.

Conversion of 1-Benzeneazo-4-hydroxydibenzofuran to 1-Bromo-4-hydroxydibenzofuran.—The 1-benzeneazo-4-hydroxydibenzofuran was reduced in the same manner as described for 1-benzeneazo-2-hydroxydibenzofuran. The amine hydrochloride did not form a complex with the tin salt, but separated out at once in greenish-gray crystals. The hydrochloride was converted to the hydrobromide, diazotized, and the diazonium group replaced by bromine as previously outlined for 1-amino-2-hydroxydibenzofuran. From 0.45 g. (0.0025 mole) of the hydrobromide, a crude yield of 0.015 g. of bromohydroxydibenzofuran melting at 145–146° was obtained. By decolorizing and crystallizing from dilute alcohol, white needles were produced melting at 150°. Identification of the compound as 1-bromo-4-hydroxydibenzofuran was completed by a mixed melting point determination.

Miscellany.—In some orienting experiments we have so far not succeeded in coupling dibenzofuran with benzenediazonium chloride in alcohol solution in the presence of potassium acetate, nor with the more active 2,4-dinitrobenzenediazonium chloride[11] in acetic acid. 2-Amino- or 2-acetaminodibenzofuran also failed to couple with benzenediazonium chloride under conditions which give quantitative yields with β-naphthylamine.[12] The principal present difficulty in this case appears to be the greater insolubility of the amine or the acetamino compound in the alcoholic reaction medium even when the reaction is run at a somewhat higher temperature.

Summary

Coupling of 2-, 3-, and 4-hydroxydibenzofurans with benzenediazonium chloride gives, respectively, 1-benzeneazo-2-hydroxydibenzofuran, 2-benzeneazo-3-hydroxydibenzofuran, and 1-benzeneazo-4-hydroxydibenzofuran. The non-isolation of any 4-benzeneazo-3-hydroxydibenzofuran from the coupling with 3-hydroxydibenzofuran indicates absence of fixed bond structures in these simple types.

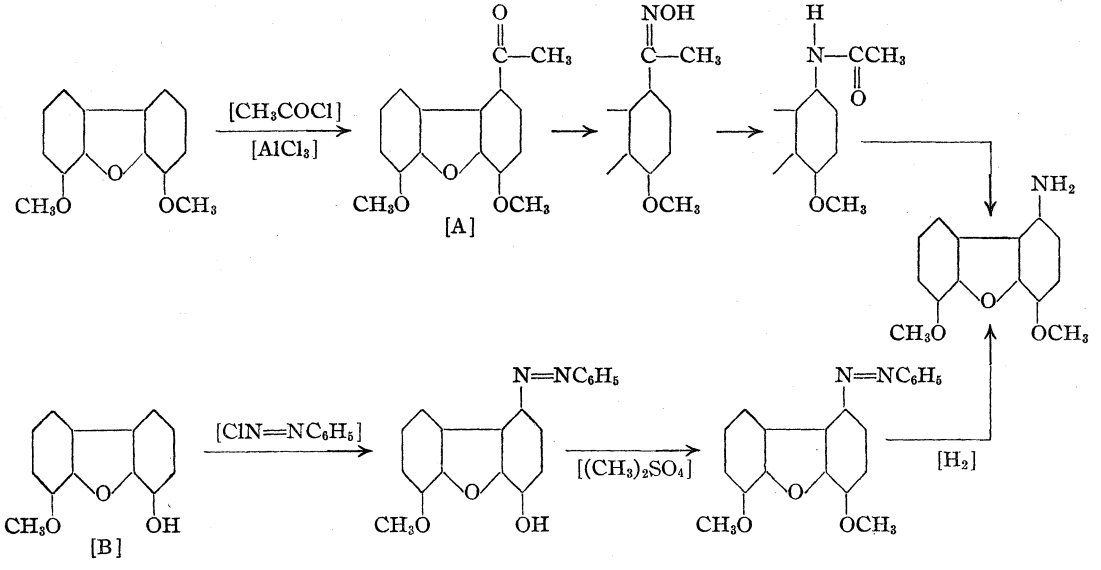
Dibenzofuran. XV. 1,4- and 1,4,6-Derivatives[1]

BY HENRY GILMAN AND LEE C. CHENEY

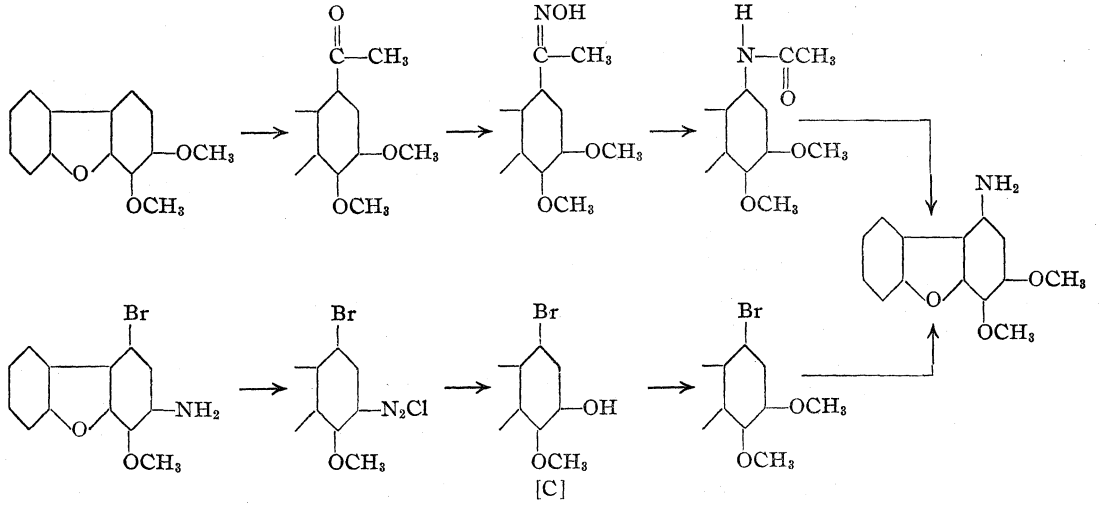
Introduction

Bridging of the 1,9-positions in dibenzofuran undoubtedly will be facilitated by the presence in the 4- and 6-positions of strong ortho-para directing groups. The recent availability of procedures for the introduction of such substituents, as well as some authentic reference compounds having a substituent in the 1-position,[2] now permits the synthesis of desirable 1,4- and 1,4,6-derivatives.

Friedel–Crafts Acylations.—Acetylation of 4,6-dimethoxydibenzofuran gave 1-acetyl-4,6-dimethoxydibenzofuran, the structure of which was established by the following sequence of reactions



The diazo coupling reaction with 4-hydroxy-6-methoxydibenzofuran [B] undoubtedly involved the nucleus containing the phenolic hydroxyl group. It was shown recently[1] that diazo coupling with 4-hydroxydibenzofuran goes para to the hydroxyl to yield 1-benzene-azo-4-hydroxydibenzofuran.

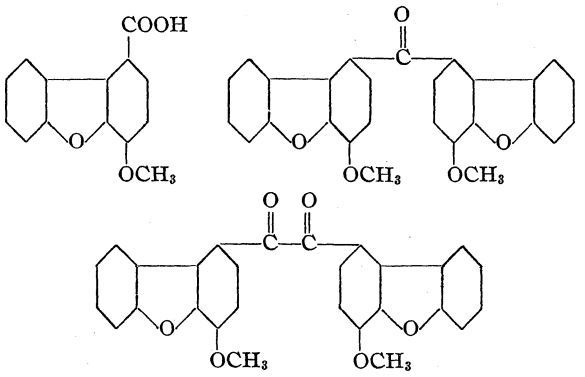


(1) Paper XIV is Gilman and M. W. Van Ess, THIS JOURNAL, **61**, 3146 (1939).

(2) Gilman and P. R. Van Ess, *ibid.*, **61**, 1365 (1939).

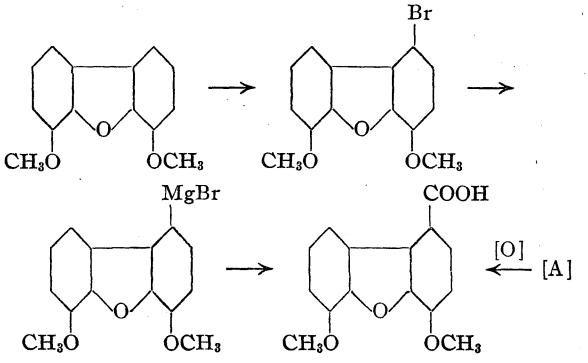
The recent proof of structure of 1-bromo-3-amino-4-methoxydibenzofuran[3] provided the essential compound for establishing the constitution of the acetylation product of 3,4-dimethoxydibenzofuran by the transformations shown.

Oxalyl chloride, aluminum chloride and 4-methoxydibenzofuran gave the following three products: 4-methoxy-1-dibenzofurancarboxylic acid, di-(4-methoxy-1-dibenzofuryl) ketone, and bi-(4-methoxy-1-dibenzofuroyl), all of which owe their formation to initial acylation in the 1-position.



The same three types (acid, ketone and benzil analog) resulted from interaction of 4,6-dimethoxydibenzofuran with oxalyl chloride.

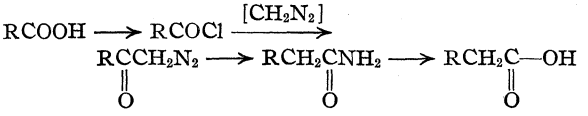
Bromination.—The structure of the monobromination product of 4,6-dimethoxydibenzofuran was established as follows



Dibromination of 4,6-dimethoxydibenzofuran gave 1,9-dibromo-4,6-dimethoxydibenzofuran. The same dibromo compound resulted on dibromination of 4,6-dihydroxydibenzofuran with subsequent methylation. However, dibromination of 4-hydroxy-6-methoxydibenzofuran followed by methylation produced a dibromo-4,6-dimethoxydibenzofuran which, unexpectedly, proved to be unlike the compound obtained by dibromination of 4,6-dimethoxydibenzofuran. This isomer is probably 1,3-dibromo-4-hydroxy-6-methoxydibenzofuran. It would be interesting to establish the course of dibromination of 1-hydroxy-8-methoxy-naphthalene.

Bromination of 3,4-dimethoxydibenzofuran yielded 1-bromo-3,4-dimethoxydibenzofuran. The proof of structure of this product was established by first preparing 1-bromo-3-hydroxy-4-methoxydibenzofuran [C] from the authentic 1-bromo-3-amino-4-methoxydibenzofuran by means of the diazo reaction. Then the 3-hydroxy-4-methoxydibenzofuran was brominated to give the same 1-bromo-3-hydroxy-4-methoxydibenzofuran, and this on methylation yielded 1-bromo-3,4-dimethoxydibenzofuran, identical with the product of bromination of 3,4-dimethoxydibenzofuran.

4,6-Dimethoxy-1-dibenzofurylacetic Acid.—In the synthesis of this compound, 4,6-dimethoxy-1-dibenzofurancarboxylic acid (used as the starting material) was prepared by two procedures: oxidation of 1-acetyl-4,6-dimethoxydibenzofuran, and carbonation of the Grignard reagent prepared from 1-bromo-4,6-dimethoxydibenzofuran. The transformations of the acid were as follows, where R = 4,6-dimethoxy-1-dibenzofuryl.



1,2,3,4-Tetrahydro-6-aminodibenzofuran.—Reduction of 4-aminodibenzofuran by sodium and alcohol was shown to involve the nonsubstituted nucleus, for the resulting tetrahydro-6-aminodibenzofuran formed no carbonate, but did undergo diazotization and subsequent coupling with β-naphthol.

Experimental Part

4,6-Dihydroxydibenzofuran.—Refluxing a solution of 8.56 g. (0.04 mole) of 4-hydroxy-6-methoxydibenzofuran with 20 ml. of hydrobromic acid (sp. gr. 1.49) in 50 ml. of acetic acid gave a 91.6% yield of 4,6-dihydroxydibenzofuran. The compound crystallized in needle form from dilute methanol, and melted at 200–202°. This melting point is higher than that reported for the dihydroxy compound obtained by two other procedures.[4]

4,6-Dimethoxydibenzofuran.—Methylation was effected by an adaptation of the procedure of Stevens and Tucker.[5] From 24.5 g. (0.115 mole) of 4-hydroxy-6-methoxydibenzofuran, 0.345 mole of dimethyl sulfate, 39 ml. of 60%

(5) Stevens and Tucker, *J. Chem. Soc.*, **123**, 2140 (1923).

potassium hydroxide, and acetone as a solvent, the yield of 4,6-dimethoxydibenzofuran was practically quantitative. The compound crystallized from petroleum ether (b. p. 60–68°) as pearly plates melting at 128–129°.

Anal. Calcd. for $C_{14}H_{12}O_3$: methoxyl, 27.2. Found: methoxyl, 26.4.

The picrate of 4,6-dimethoxydibenzofuran was obtained as deep yellow needles, melting at 161–162° after crystallization from alcohol. Under corresponding conditions of preparation, the isomeric 3,4-dimethoxy compound did not form a picrate.

Anal. Calcd. for $C_{14}H_{12}O_3 \cdot C_6H_3O_7N_3$: N, 9.19. Found: N, 9.11.

1-Acetyl-4,6-dimethoxydibenzofuran.—Admixture of reagents was effected in the cold between 17.35 g. (0.0761 mole) of 4,6-dimethoxydibenzofuran, 5.97 g. (0.0761 mole) of acetyl chloride, and 10.18 g. (0.0761 mole) of aluminum chloride in 100 ml. of nitrobenzene. When addition of aluminum chloride was complete, the contents of the flask were allowed to come slowly to room temperature, and stirring was continued for twenty hours. Subsequent to hydrolysis, and removal of the nitrobenzene by steam distillation, there was isolated 12.35 g. (a 60% yield) of 1-acetyl-4,6-dimethoxydibenzofuran which melted at 178.5–179.5° after crystallization from alcohol or dilute acetone.

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22. Found: C, 71.18 and 71.30; H, 4.93 and 5.08.

Oxime of 1-Acetyl-4,6-dimethoxydibenzofuran and its Beckmann Rearrangement Product.—By using the procedure for the preparation of the oxime of 1-acetyl-4-methoxydibenzofuran,[3] there was obtained an 88% yield of the oxime of 1-acetyl-4,6-dimethoxydibenzofuran which crystallized from alcohol as plates melting at 203–204°.

Anal. Calcd. for $C_{16}H_{15}O_4N$: N, 4.91. Found: N, 5.02.

Rearrangement of a benzene suspension of the oxime by phosphorus pentachloride gave a 76.4% yield of **1-acetamino-4,6-dimethoxydibenzofuran,** which crystallized from benzene as fine needles melting at 244–245°.

Anal. Calcd. for $C_{16}H_{15}O_4N$: N, 4.92. Found: N, 4.93.

Hydrolysis of the acetamino compound by heating an alcohol–concd. hydrochloric acid solution gave a 94.5% yield of 1-amino-4,6-dimethoxydibenzofuran hydrochloride, obtained as needles melting at 286–287°. The hydrochloride and ammonium hydroxide gave 1-amino-4,6-dimethoxydibenzofuran melting at 162–162.5° after crystallization from methanol, and identical (mixed m. p.) with the amine obtained by reduction of 1-benzeneazo-4,6-dimethoxydibenzofuran.

1 - Benzeneazo - 4 - hydroxy - 6 - methoxydibenzofuran.—The extreme insolubility of the potassium salt of 4-hydroxy-6-methoxydibenzofuran necessitated a modification of the procedure used for the coupling of 4-hydroxydibenzofuran.[1]

The alkaline solution of the phenol prepared from 4.28 g. (0.02 mole) of 4-hydroxy-6-methoxydibenzofuran, 15 ml. of 15% potassium hydroxide solution, and 385 ml. of water, was placed in a one-liter three-necked flask equipped with stirrer, low-temperature thermometer and dropping funnel. The diazonium salt solution was prepared from 2.58 g. (0.02 mole) of aniline hydrochloride in 15 ml. of water, 15–25 g. of cracked ice, 3.4 ml. of concd. hydrochloric acid, and 1.46 g. (0.021 mole) of sodium nitrite in 15 ml. of water. This ice-cold benzenediazonium chloride solution was added to the cold, stirred, alkaline solution of the phenol at such a rate that the temperature did not rise above 3°. A beautiful orange precipitate formed at once. After addition was complete, the reaction mixture was stirred for forty-five minutes, and the coupling product filtered off and dried. Two crystallizations from alcohol yielded rust-colored needles of 1-benzeneazo-4-hydroxy-6-methoxydibenzofuran, m. p. 175°. The yield was 3.6 g. or 56.6%.

Anal. Calcd. for $C_{19}H_{14}O_3N_2$: N, 8.84. Found: N, 8.89.

1-Benzeneazo-4,6-dimethoxydibenzofuran and its Reduction to 1-Amino-4,6-dimethoxydibenzofuran.—Methylation of 1.59 g. (0.005 mole) of 1-benzeneazo-4-hydroxy-6-methoxydibenzofuran by dimethyl sulfate and potassium hydroxide in acetone gave an 88% yield of deep orange prisms, melting at 170° when crystallized from benzene.

Anal. Calcd. for $C_{20}H_{16}O_3N_2$: N, 8.44. Found: N, 8.51.

The 1-benzeneazo-4,6-dimethoxydibenzofuran (1 g.) was reduced in essential accordance with the procedure described for the reduction of 1-benzeneazo-4-hydroxydibenzofuran.[1] The yield of 1-amino-4,6-dimethoxydibenzofuran was 0.24 g. (32.8%).

Anal. Calcd. for $C_{14}H_{13}O_3N$: N, 5.77. Found: N, 5.88.

Friedel–Crafts Reaction with 4-Methoxydibenzofuran and Oxalyl Chloride.—Into a solution of 9.90 g. (0.05 mole) of 4-methoxydibenzofuran and 7.0 g. (10% excess over 0.05 mole) of oxalyl chloride in 75 ml. of nitrobenzene contained in a three-necked flask equipped with stirrer and condenser topped with a calcium chloride tube, was gradually added 14.7 g. (10% excess) of anhydrous aluminum chloride. Throughout the addition an ice-bath cooled the reaction mixture, which was then allowed to come slowly to room temperature. After twenty-eight hours, the red-brown mixture was hydrolyzed with ice and hydrochloric acid, the nitrobenzene was removed with steam, and the amorphous solid boiled with 5% sodium hydroxide solution and filtered. The dried acidification product from the filtrate (0.7 g.), after crystallization from acetic acid, melted at 276–277° and was shown to be **4-methoxy-1-dibenzofurancarboxylic acid** by mixed melting point.

The dried, amorphous, alkali-insoluble solid was extracted with 100 ml. of acetic acid. From the cold filtrate was obtained 1.9 g. (18%) of **di-(4-methoxy-1-dibenzofuryl) ketone** in the form of colorless needles, m. p. 234°.

Anal. Calcd. for $C_{27}H_{18}O_5$: C, 76.8; H, 4.29. Found: C, 76.1; H, 4.37.

The acetic acid insoluble residue, which proved to be **bi-(4-methoxy-1-dibenzofuroyl)**, crystallized from nitrobenzene in the form of pale yellow needles, m. p. 329°. The yield was 3.9 g. or 34.6%.

Anal. Calcd. for $C_{29}H_{22}O_7$: C, 72.2; H, 4.62. Found: C, 72.3; H, 4.68.

Friedel–Crafts Reactions of 4-Methoxydibenzofuran with Chloroacetyl Chloride and Ethyl Chloroglyoxalate.—From 12.5 g. (0.063 mole) of 4-methoxydibenzofuran, 7.9 g. (0.07 mole) of chloroacetyl chloride, 8.5 g. (0.0635 mole) of aluminum chloride and 60 ml. of nitrobenzene there was obtained 6.3 g. or a 53.2% yield of **1-chloroacetyl-4-methoxydibenzofuran** which crystallized from alcohol as needles melting at 165–166°.

Anal. Calcd. for $C_{15}H_{11}O_3Cl$: Cl, 12.92. Found: Cl, 13.12 and 13.05.

From a corresponding reaction between 9.9 g. (0.05 mole) of 4-methoxydibenzofuran, 7.5 g. (10% excess) of ethyl chloroglyoxalate, 8.0 g. (20% excess) of aluminum chloride and 60 ml. of nitrobenzene there resulted 6.4 g. (43%) of **1-ethoxalyl-4-methoxydibenzofuran** which melted at 113° after crystallization from alcohol.

Anal. Calcd. for $C_{17}H_{14}O_5$: C, 68.4; H, 4.73. Found: C, 68.0; H, 4.82.

Hydrolysis of 1 g. of 1-ethoxalyl-4-methoxydibenzofuran by refluxing with 15% sodium hydroxide gave (subsequent to acidification) 0.43 g. of **4-methoxy-1-dibenzofuryl-α-oxoacetic acid** which crystallized from alcohol as pale yellow needles melting at 187°.

Anal. Calcd. for $C_{15}H_{10}O_5$: C, 66.64; H, 3.73. Found: C, 66.39; H, 3.75.

Concentrated sulfuric acid colored the keto acid deep red. Oxidation of the keto acid by alkaline permanganate gave 4-methoxy-1-dibenzofurancarboxylic acid (mixed m. p.). The **semicarbazone of 4-methoxy-1-dibenzofuryl-α-oxoacetic acid** melted at 211.5–212° with decomposition after crystallization from alcohol.

Anal. Calcd. for $C_{16}H_{13}O_5N_3$: N, 12.84. Found: N, 12.83.

Friedel–Crafts Reaction with 4,6-Dimethoxydibenzofuran and Oxalyl Chloride.—The procedure described for the reaction of 4-methoxydibenzofuran and oxalyl chloride was used. Into an ice-cold solution of 4.56 g. (0.02 mole) of 4,6-dimethoxydibenzofuran and 2.8 g. (10% excess over 0.02 mole) of oxalyl chloride in 50 ml. of nitrobenzene, was slowly added 6.42 g. (20% excess over 0.04 mole) of powdered, anhydrous aluminum chloride. Addition required one and three-fourths hours, after which the reaction mixture was allowed to come to room temperature, stirring being continued for twenty hours. Hydrolysis was effected with ice and hydrochloric acid, after which the nitrobenzene was removed with steam. The remaining gray solid was extracted with 200 ml. of 10% sodium hydroxide solution to remove any acids. Acidification of the filtrate furnished 0.37 g. of **4,6-dimethoxy-1-dibenzofurancarboxylic acid,** m. p. 297–298°.

The gray solid residue was extracted (Soxhlet apparatus) with 100 ml. of acetic acid to yield 0.5 g. (10.4%) of **di-(4,6-dimethoxy-1-dibenzofuryl) ketone,** m. p. 254–255°.

Anal. Calcd. for $C_{29}H_{22}O_7$: C, 72.17; H, 4.62. Found: C, 72.31 and 71.54; H, 4.93 and 4.68.

The pale yellow, extremely insoluble residue from the acetic acid extraction crystallized from nitrobenzene in the form of very small needles, m. p. above 300°. Analysis showed the compound to be **bi-(4,6-dimethoxy-1-dibenzofuroyl)**. The yield was 3.1 g. (60.7% of the theoretical).

Anal. Calcd. for $C_{30}H_{22}O_8$: C, 70.65; H, 4.35. Found: C, 70.94 and 70.63; H, 4.60 and 4.69.

3,4-Dihydroxydibenzofuran and 3,4-Diacetoxydibenzofuran.—An 88% yield of 3,4-dihydroxydibenzofuran was obtained by refluxing an acetic acid solution of 8.56 g. (0.04 mole) of 3-hydroxy-4-methoxydibenzofuran with hydrobromic acid (sp. gr. 1.49). Recrystallization from hot water gave needles melting at 164–164.5°.

Anal. Calcd. for $C_{12}H_8O_3$: C, 71.98; H, 4.03. Found: C, 71.56; H, 4.21.

From 3,4-dihydroxydibenzofuran (1.95 g.), acetic anhydride and a drop of concd. sulfuric acid was obtained a 74.1% yield of 3,4-diacetoxydibenzofuran which melted at 104–105° after crystallization from methanol.

Anal. Calcd. for $C_{16}H_{12}O_5$: C, 67.5; H, 4.28. Found: C, 67.6; H, 4.21.

3,4-Dimethoxydibenzofuran.—Methylation of 49.2 g. (0.39 mole) of 3-hydroxy-4-methoxydibenzofuran by dimethyl sulfate and 10% sodium hydroxide gave an 81% yield of 3,4-dimethoxydibenzofuran, which crystallized from petroleum ether (b. p. 28–38°) as needles melting at 60–61°.

Anal. Calcd. for $C_{14}H_{12}O_3$: methoxyl, 27.2. Found: methoxyl, 26.8.

1-Acetyl-3,4-dimethoxydibenzofuran.—Acetylation of 13.7 g. (0.06 mole) of 3,4-dimethoxydibenzofuran by the procedure used with the 4,6-dimethoxy compound gave a 55.5% yield of 1-acetyl-3,4-dimethoxydibenzofuran which crystallized from alcohol as needles melting at 90.5–91°.

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22. Found: C, 71.11 and 70.54; H, 5.41 and 5.42.

Some demethylated phenol also was isolated.

Oxime of 1-Acetyl-3,4-dimethoxydibenzofuran and its Rearrangement to 1-Acetamino-3,4-dimethoxydibenzofuran.—The oxime of 1-acetyl-3,4-dimethoxydibenzofuran (84% yield) was crystallized from alcohol as needles melting at 156–157°.

Anal. Calcd. for $C_{16}H_{15}O_4N$: N, 4.91. Found: N, 5.11.

A Beckmann rearrangement of a benzene solution of the oxime by phosphorus pentachloride gave a 94% yield of 1-acetamino-3,4-dimethoxydibenzofuran which crystallized from alcohol (to which several drops of acetic anhydride were added) as needles melting at 196–196.5°.

Anal. Calcd. for $C_{16}H_{15}O_4N$: N, 4.92. Found: N, 5.02.

Hydrolysis of 1 g. of 1-acetamino-3,4-dimethoxydibenzofuran by alcoholic potash gave a 48% yield of 1-amino-3,4-dimethoxydibenzofuran (m. p., 162.5–163°) which showed no depression in a mixed m. p. determination with the compound obtained by amination of 1-bromo-3,4-dimethoxydibenzofuran.

1-Amino-3,4-dimethoxydibenzofuran.—A mixture of 7.5 g. (0.0244 mole) of 1-bromo-3,4-dimethoxydibenzofuran, 15 g. of powdered cuprous bromide, and 130 ml. of concd. ammonium hydroxide was heated in a bomb for fourteen and one-half hours at 220–230°. After working up in a customary manner there was obtained a 10% yield of 1-amino-3,4-dimethoxydibenzofuran which crystal-

lized from dilute methanol as needles melting at 162.5–163°.

Anal. Calcd. for $C_{14}H_{13}O_3N$: N, 5.76. Found: N, 5.94.

Bromination of 4,6-Derivatives.—Bromination of 22.8 g. (0.1 mole) of 4,6-dimethoxydibenzofuran in 600 ml. of acetic acid by the dropwise addition of 100 ml. of a molar solution of bromine in acetic acid gave a 73% yield of 1-bromo-4,6-dimethoxydibenzofuran which crystallized from a large volume of alcohol as plates melting at 152°. In addition, 3.7 g. (12%) of product melting at 144–147° was isolated.

Anal. Calcd. for $C_{14}H_{11}O_3Br$: Br, 26.01. Found: Br, 26.23.

From 3.0 g. (0.0132 mole) of 4,6-dimethoxydibenzofuran in 120 ml. of acetic acid and 52.7 ml. of a 0.5 molar solution of bromine in acetic acid was obtained a 74% yield of **1,9-dibromo-4,6-dimethoxydibenzofuran** which crystallized from acetic acid as needles melting at 167–168°.

Anal. Calcd. for $C_{14}H_{10}O_3Br_2$: Br, 41.42. Found: Br, 41.60.

Instantaneous decolorization was noted when 40 ml. of a 0.5 molar solution of bromine in acetic acid was added to a solution of 2.0 g. (0.01 mole) of 4,6-dihydroxydibenzofuran in 20 ml. of acetic acid. The yield of **1,9-dibromo-4,6-dihydroxydibenzofuran** was essentially quantitative. The melting point after crystallization from xylene was 239–240° (with decomposition).

Anal. Calcd. for $C_{12}H_6O_3Br_2$: Br, 44.66. Found: Br, 44.77.

Methylation by dimethyl sulfate converted the dibromodihydroxy compound quantitatively to 1,9-dibromo-4,6-dimethoxydibenzofuran, identical with the dibromination product of 4,6-dimethoxydibenzofuran.

Decolorization was less rapid when 40 ml. of a 0.5 molar solution of bromine in acetic acid was added to 2.14 g. (0.01 mole) of 4-hydroxy-6-methoxydibenzofuran in 20 ml. of acetic acid. The dibromo compound, probably **1,3-dibromo-4-hydroxy-6-methoxydibenzofuran,** crystallized from acetic acid as needles melting at 177–178°; yield, 2.17 g. (58.6 %).

Anal. Calcd. for $C_{13}H_8O_3Br_2$: Br, 42.98. Found: Br, 43.10.

The dibromo-4-hydroxy-6-methoxydibenzofuran was methylated in the usual manner (using acetone as part of the medium) to give a quantitative yield of what is probably **1,3-dibromo-4,6-dimethoxydibenzofuran.** This compound crystallized from acetic acid as needles melting at 173.5–174°.

Anal. Calcd. for $C_{14}H_{10}O_3Br_2$: Br, 41.42. Found: Br, 41.68.

Bromination of 3,4-Derivatives.—Decolorization proceeded rapidly when 13.4 ml. of a 0.5 molar solution of bromine in acetic acid was added slowly and with shaking to 1.5 g. (0.0066 mole) of 3,4-dimethoxydibenzofuran in 15 ml. of acetic acid. Crystallization from alcohol gave an 88.5% yield of **1-bromo-3,4-dimethoxydibenzofuran** in the form of fine needles which melted at 108°.

Anal. Calcd. for $C_{14}H_{11}O_3Br$: Br, 26.03. Found: Br, 26.11.

To a stirred solution of 4.28 g. (0.02 mole) of 3-hydroxy-4-methoxydibenzofuran in 50 ml. of acetic acid was slowly introduced 40 ml. of a 0.5 molar solution of bromine in acetic acid. The decolorization was almost instantaneous. Dilution of the reaction mixture, followed by filtration, furnished 5.65 g. of substance which melted at 130–149°, indicating that isomers were probably present. After one crystallization from 30% alcohol and three recrystallizations from benzene, white fluffy needles of **1-bromo-3-hydroxy-4-methoxydibenzofuran,** m. p. 161–162°, were obtained. The yield was 3.1 g. or 54.6% of the theoretical. No attempt was made to isolate the more soluble isomer.

Anal. Calcd. for $C_{13}H_9O_3Br$: Br, 27.28. Found: Br, 27.32.

An intimate mixture of this compound and authentic 1-bromo-3-hydroxy-4-methoxydibenzofuran prepared from the known 1-bromo-3-amino-4-methoxydibenzofuran showed no melting point depression.

1-Bromo-3,4-dimethoxydibenzofuran, m. p. 108°, was prepared by methylating 0.5 g. of 1-bromo-3-hydroxy-4-methoxydibenzofuran at room temperature with 3 ml. of dimethyl sulfate and 5 ml. of 10% sodium hydroxide solution. The compound obtained by direct bromination of 3,4-dimethoxydibenzofuran was proved identical with this by a mixed melting point determination.

Conversion of 1-Bromo-3-amino-4-methoxydibenzofuran to 1-Bromo-3-hydroxy-4-methoxydibenzofuran.—An iced diazonium solution prepared from 0.95 g. (0.00325 mole) of 1-bromo-3-amino-4-methoxydibenzofuran, sodium nitrite and sulfuric acid was added dropwise to a boiling solution of 75 g. of copper sulfate in 250 ml. of water contained in a distilling flask fitted with a condenser. The white solid which steam-distilled was dissolved in 5% sodium hydroxide solution, treated with Norite, filtered, and acidified. The white needles of authentic 1-bromo-3-hydroxy-4-methoxydibenzofuran thus obtained, m. p. 161–162°, weighed 0.2 g. (21% yield). No depression in melting point was observed when this compound was mixed with the bromination product of 3-hydroxy-4-methoxydibenzofuran.

4-Bromo-6-hydroxydibenzofuran.—A suspension of 0.5 g. of 4-bromo-6-methoxydibenzofuran in 5 ml. of hydriodic acid (sp. gr. 1.67) was heated to give a 19% yield of 4-bromo-6-hydroxydibenzofuran which crystallized from water as needles melting at 138–139°. An alcoholic solution of this phenol gave a green color with ferric chloride solution.

Anal. Calcd. for $C_{12}H_7O_2Br$: Br, 30.39. Found: Br, 30.47.

4-Amino-6-methoxydibenzofuran and 4-Amino-6-hydroxydibenzofuran.—An intimate mixture of 5 g. (0.018 mole) of 4-bromo-6-methoxydibenzofuran and 6 g. of freshly prepared cuprous bromide was placed in a large test-tube, covered with 150 ml. of concd. ammonium hydroxide, and electrically heated in a steel bomb at 100° for ten hours. The temperature was then raised to 215° and held constant for eight hours. The **hydrochloride** of **4-amino-6-methoxydibenzofuran,** isolated in a 51% yield by customary procedures, crystallized from water as fine needles melting at 235–236° with discoloration. The **4-amino-6-methoxydibenzofuran,** m. p. 109°, was obtained

in the form of needles by adding ammonium hydroxide to a hot solution of the hydrochloride.

Anal. Calcd. for $C_{13}H_{11}O_2N$: N, 6.57. Found: N, 6.53.

To 2.35 g. (0.0094 mole) of 4-amino-6-methoxydibenzofuran, dissolved in 25 ml. of glacial acetic acid, was added 25 ml. of hydrobromic acid (sp. gr. 1.49), and the mixture was refluxed for nine hours. The hydrobromide, which precipitated on cooling, was dissolved in hot water and the hydrochloride, in the form of small plates melting at 265–266° dec., was precipitated from this solution by passing in dry hydrogen chloride. The free 4-amino-6-hydroxydibenzofuran, crystallizing as needles which melted at 191.5–192.5°, was not discolored by atmospheric oxygen.

Anal. Calcd. for $C_{12}H_9O_2N$: N, 7.03. Found: N, 7.15.

4,6-Diaminodibenzofuran and 4,6-Diacetoxydibenzofuran.—In each of four Carius tubes, a mixture of 1.0 g. (0.005 mole) of 4,6-dihydroxydibenzofuran, 7.5 g. of sodium bisulfite dissolved in 15 ml. of water, and 15 ml. of concd. ammonium hydroxide was sealed. The tubes were then heated at 185–195° in an electric furnace for twenty hours. The cooled mixtures were combined and extracted thrice with a total volume of 400 ml. of ether. The ether solution was washed thoroughly with 10% sodium hydroxide solution and then with water. The **4,6-diaminodibenzofuran dihydrochloride,** m. p. 297–298° with decomposition, was precipitated from the dried ether solution by the introduction of dry gaseous hydrogen chloride. The yield was 4.4 g. or 81% of the theoretical. The hydrochloride was dissolved in about 25 ml. of hot water, digested with Norite, filtered and precipitated again with gaseous hydrogen chloride to give needles which melted at 298° with decomposition.

Anal. Calcd. for $C_{12}H_{12}ON_2Cl_2$: N, 10.33. Found: N, 10.52.

The free **4,6-diaminodibenzofuran,** liberated by the addition of ammonium hydroxide to a solution of the hydrochloride, crystallized from the methanol in the form of colorless prisms, m. p. 152°. This compound has been obtained recently by the reduction of 4,6-dinitrodibenzofuran, which in turn was prepared by a biphenyl ring closure.[6a]

The **picrate of 4,6-diaminodibenzofuran** crystallized from alcohol as shiny, red-brown plates which melted at 213° with pronounced decomposition.

Anal. Calcd. for $C_{12}H_{10}ON_2 \cdot C_6H_3O_7N_3$: N, 16.40. Found: N, 16.28.

The **4,6-diacetaminodibenzofuran,** prepared in quantitative yield from the 4,6-diamino compound and acetic anhydride, crystallized from acetic acid as needles melting at 297–298°.

Anal. Calcd. for $C_{16}H_{14}O_3N_2$: N, 9.93. Found: N, 9.92.

Yamasiro[6a] has reported a melting point of 322.5–323.5° for this compound. In the same paper are reported 4-aminodibenzofuran, m. p. 118–119°, and 4-acetaminodibenzofuran, m. p. 235–236°. The melting points observed in this Laboratory for these two compounds were 84.5–85.5° and 172.5°, respectively.[6b]

4,6-Diacetoxydibenzofuran (prepared in 53% yield from 4,6-dihydroxydibenzofuran, acetic anhydride and a drop of concd. sulfuric acid) crystallized from methanol as small, shiny plates melting at 177°.

Anal. Calcd. for $C_{16}H_{12}O_5$: C, 67.5; H, 4.28. Found: C, 67.4; H, 4.31.

Coupling of Benzenediazonium Chloride with 4,6-Dihydroxydibenzofuran.—A cold benzenediazonium chloride solution prepared from 7.75 g. (0.06 mole) of aniline hydrochloride was added to a cold solution of 6.0 g. (0.03 mole) of 4,6-dihydroxydibenzofuran in aqueous potassium hydroxide to give 5.1 g. of a very dark brown microcrystalline product which melted at about 224° with decomposition. Recrystallization from acetic acid raised the melting point to 228° with decomposition. The product dissolved in acetone with a brilliant red color and, because the nitrogen analyses were nearly one per cent. low for 1,3,9-tribenzeneazo-4,6-dihydroxydibenzofuran, the impurity may be a dibenzeneazo derivative. Methylation imparted stability to the molecule, and a pure compound was isolated by methylating in acetone to give a 77% yield of what is probably **1,3,9-tribenzeneazo-4,6-dimethoxydibenzofuran.** Crystallization from acetic acid gave a red-orange product melting at 191–193°. The structure assigned the compound is based largely on our present knowledge of diazo coupling of hydroxydibenzofurans.

Anal. Calcd. for $C_{32}H_{24}O_3N_6$: N, 15.56. Found: N, 15.52.

4,6-Dimethoxy-1-dibenzofurancarboxylic Acid. A.—Oxidation of 1 g. of 1-acetyl-4,6-dimethoxydibenzofuran by the procedure of Fuson and Tullock[7] (iodine–potassium iodide, sodium hydroxide and dioxane) gave a 55.2% yield of 4,6-dimethoxy-1-dibenzofurancarboxylic acid which melted at 297–298° after crystallization from acetic acid.

Anal. Calcd. for $C_{12}H_{12}O_5$: C, 66.45; H, 4.45. Found: C, 66.21; H, 4.53.

B.—The filtered Grignard reagent prepared from 22.5 g. (0.073 mole) of 1-bromo-4,6-dimethoxydibenzofuran in a 1:1 ether-benzene solution, was carbonated by solid carbon dioxide to give the same 4,6-dimethoxy-1-dibenzofurancarboxylic acid (m. p. 297–298°). Mixed melting point determinations were made not only with the two acids from (A) and (B), but also with the methyl esters from each of these acids.

The **methyl 4,6-dimethoxy-1-dibenzofurancarboxylate,** prepared in a quantitative yield from the acid and diazomethane, melted at 163°.

Anal. Calcd. for $C_{16}H_{14}O_5$: C, 67.11; H, 4.93. Found: C, 67.2; H, 5.11.

Diazomethyl 4,6-Dimethoxy-1-dibenzofuryl Ketone.—The directions used were those of Arndt and Eistert,[8] adapted to dibenzofurans. The required acid chloride was prepared by refluxing 11.5 g. (0.042 mole) of 4,6-dimethoxy-1-dibenzofurancarboxylic acid with 80.0 g.

(0.672 mole) of thionyl chloride for two and one-half hours, during which time the solid acid slowly dissolved to produce a clear red solution. The excess thionyl chloride was distilled off at diminished pressure at a temperature of 100° (water-bath). The crude pink acid chloride, after crystallization from dry benzene, melted over a wide, indefinite range which indicated incomplete conversion. Purification was effected by boiling the substance with petroleum ether (b. p. 77–115°). The acid chloride dissolved and 5.2 g. of impure, unconverted acid was removed by filtration. The colorless product which separated from the cooled solution melted at 147–150°. The yield was 6.2 g. or 50.5% of the theoretical.

To a stirred solution of diazomethane prepared from 20 ml. of ethyl N-nitroso-N-methylcarbamate was introduced, in several portions, 6.2 g. (0.0213 mole) of 4,6-dimethoxy-1-dibenzofurancarboxylic acid chloride. After five minutes of stirring, 100 ml. of anhydrous dioxane was added to effect solution. The ice-bath was removed and the clear yellow reaction mixture was allowed to stand overnight. The pale yellow crystals of diazomethyl 4,6-dimethoxy-1-dibenzofuryl ketone, melting at 151° with gas evolution, were filtered from solution. The yield was 1.34 g. or 21.2% of the theoretical.

Anal.[9] Calcd. for $C_{16}H_{12}O_4N_2$: N, 9.46. Found: N, 9.51.

4,6-Dimethoxy-1-dibenzofurylacetamide.—A solution of 1.25 g. (0.0042 mole) of diazomethyl 4,6-dimethoxy-1-dibenzofuryl ketone in 75 ml. of dioxane was placed in a 250-ml. flask fitted with reflux condenser and mechanical stirrer. With efficient stirring, 15 ml. of concd. ammonium hydroxide was added followed by 5 ml. of 10% silver nitrate solution. Heating on the steam-bath and stirring were continued for forty-five minutes. Then 5 ml. more of concd. ammonium hydroxide was added, and the stirred solution was heated for thirty minutes longer.

The hot solution was filtered and diluted to a volume of 300 ml. with water. Cooling in the refrigerator precipitated 0.82 g. (66% yield) of the gray amide, m. p. 206–207°. Pure 4,6-dimethoxy-1-dibenzofurylacetamide crystallized from alcohol, after digestion with Norite, in the form of needles, m. p. 210–211°. The yield of pure compound was 0.62 g. or 51.6%.

Anal. Calcd. for $C_{16}H_{15}O_4N$: N, 4.91. Found: N, 4.86.

4,6-Dimethoxy-1-dibenzofurylacetic Acid.—A mixture of 0.5 g. (0.00175 mole) of 4,6-dimethoxy-1-dibenzofurylacetamide, 25 ml. of 15% sodium hydroxide solution and 5 ml. of alcohol was refluxed for thirteen hours before a clear solution was realized. The reaction mixture was diluted with 50 ml. of water, gently boiled with a pinch of Norite, and filtered. Acidification of the solution precipitated the crude acid in nearly quantitative yield, m. p. 204–205°. Two crystallizations from alcohol gave colorless needles of 4,6-dimethoxy-1-dibenzofurylacetic acid, m. p. 205.5–206.5°. The yield was 0.36 g. or 71.7%.

Anal. Calcd. for $C_{16}H_{14}O_5$: C, 67.11; H, 4.93. Found: C, 67.0; H, 4.98.

(9) The authors are grateful to Messrs. L. D. Apperson and T. H. Cook for help with some of the nitrogen analyses.

3-Hydrazinodibenzofuran.—In essential accordance with the directions of Fischer,[10] 9.2 g. (0.05 mole) of 3-aminodibenzofuran was diazotized, and the suspension of diazonium chloride was reduced by stannous chloride.

The white **3-hydrazinodibenzofuran hydrochloride** was filtered off and crystallized from a large volume of water. It melted with decomposition at 242–243°. The yield was 10.3 g. or 87.3%.

Anal. Calcd. for $C_{12}H_{11}ON_2Cl$: N, 11.94. Found: N, 11.98.

The free 3-hydrazinodibenzofuran was obtained by decomposing a hot solution of the hydrochloride with sodium acetate. The base readily dissolved in hot alcohol, crystallizing from this solvent in the form of small pale yellow needles, m. p. 174–175°, which turned orange in color in contact with the atmosphere.

Anal. Calcd. for $C_{12}H_{10}ON_2$: N, 14.14. Found: N, 14.09.

A melting point of 225° for the hydrochloride, and 152° for the free base, have been reported.[11]

1,2,3,4-Tetrahydro-6-aminodibenzofuran.—Two and five-tenths grams (0.0136 mole) of 4-aminodibenzofuran was dissolved in 100 ml. of absolute alcohol contained in a three-necked flask equipped with stirrer and reflux condenser. A nitrogen atmosphere was used throughout the reduction. While the solution was stirred vigorously, the sodium (8.0 g.) was added in small pieces through the top of the condenser. After the addition, which required twenty-five minutes, the solution was boiled gently to dissolve the remaining sodium. A noticeable amount of ammonia was evolved during the reduction.

The hot reaction mixture was poured promptly into ice and hydrochloric acid in sufficient quantity to render the resulting solution acid to litmus. After removal of the alcohol by steam distillation, the mixture was immersed in a freezing mixture, made alkaline with 10% sodium hydroxide, and extracted thrice with a total volume of 400 ml. of ether. This red solution was dried over anhydrous sodium sulfate, and, following filtration, gaseous hydrogen chloride was introduced. The solid was filtered off and repeatedly washed with sodium-dried ether to remove a red resinous impurity adhering to the shiny pink plates of the hydrochloride. The yield was 1.9 g. or 62%. The salt was dissolved in water, digested with Norite, and filtered. Gaseous hydrogen chloride precipitated small pink plates which commenced to darken at 214° and melted at 228° with decomposition. Attempts to prepare a solid free base were unsuccessful, the product remained as an oil at 0°. The low hydrogen values indicated that some unreduced amine may have been present as an impurity.

Anal. Calcd. for $C_{12}H_{14}ONCl$: C, 64.4; H, 6.31. Found: C, 64.4 and 64.4; H, 6.06 and 5.99.

In experiments to determine which ring had been reduced, the observation was made that a dry ether solution of the tetrahydro-6-aminodibenzofuran would not form a carbonate, although carbon dioxide was bubbled into the solution for an hour.

The following coupling reaction definitely established the aromatic nature of the reduced amine. Five milli-

(10) Fischer, *Ann.*, **232**, 237 (1885).

(11) Borsche and Bothe, *Ber.*, **41**, 1940 (1908).

liters of dilute (6 *N*) hydrochloric acid was added to a solution of 0.1 g. (0.00045 mole) of the tetrahydro-6-aminodibenzofuran hydrochloride in 15 ml. of water. Diazotization was effected by cautiously adding a 5% solution of sodium nitrite to the ice-cold, well-stirred solution until cadmium iodide–starch paper immediately turned blue when moistened with the stirring rod. After the clear yellow diazonium solution had stood for thirty minutes, it was slowly added to a cold solution of 0.1 g. of β-naphthol in 25 ml. of 10% sodium hydroxide. A brilliant carmine red dye, m. p. 199–201°, immediately precipitated in quantitative yield (0.15 g.).

Summary

Incidental to studies concerned with the bridging of the 1- and 9-positions in dibenzofuran types, series of 1,4- and 1,4,6-derivatives have been synthesized. In these compounds the 4- and the 4,6-substituents are strong ortho–para directors. Among other compounds described are 4,6-dimethoxy-1-dibenzofurylacetic acid and 1,2,3,4-tetrahydro-6-aminodibenzofuran.

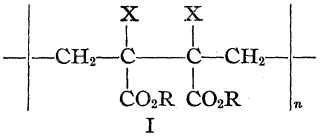
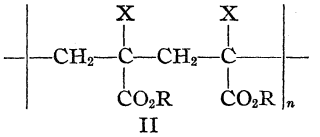
The Structure of Vinyl Polymers. IV.[1] The Polymers of the Methyl α-Haloacrylates

BY C. S. MARVEL AND JOHN CHARLES COWAN[2]

The polymers of the α-haloacrylates are especially suitable for a study of the arrangement of the structural units in the polymeric chain, since the reactions of the simple 1,2- and 1,3-dihalogen esters which correspond to the two most probable arrangements (I and II) of the structural units in these polymers are well known.

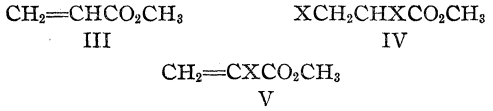


I



II

The polymer of methyl α-chloroacrylate has been described[3] but the corresponding bromo compound apparently has not been prepared previously. In the present work the α,β-dihalopropionates (IV) were treated with quinoline to give the α-haloacrylates (V).



III IV V

The monomeric esters polymerized readily on standing or more rapidly on warming in the presence of peroxides. The polymers could be obtained either as clear, pale amber glassy solids or as white powders. They were readily soluble in dioxane and acetone. Viscosity measurements on 0.606% (0.0368 molar, based on monomeric unit) solutions indicated a molecular weight of about 11,500. One sample of methyl α-chloroacrylate which polymerized slowly at room temperature over a period of nine months gave a polymer insoluble in acetone, benzene and dioxane; this insolubility indicates a very high molecular weight.

When either the chloro or bromo polymer was treated with potassium iodide in peroxide-free acetone or dioxane, iodine was liberated. This reaction is characteristic for 1,2-dihalogen compounds[4] and indicates that the methyl α-haloacrylate polymers have structure I above and thus do not have the usual 1,3-distribution of the functional groups which has been accepted as the structural feature of most vinyl polymers. A comparison of the amount of iodine liberated from potassium iodide by ethyl α,α′-dibromosuccinate (VI), ethyl α,α′-dibromoglutarate (VII),

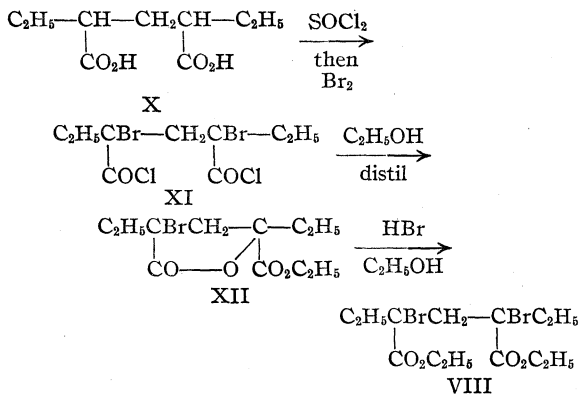
ethyl α,α′-dibromo-α,α′-diethylglutarate (VIII) and the polymer of methyl α-bromoacrylate (IX) is given in Table I.

TABLE I

LIBERATION OF IODINE FROM POTASSIUM IODIDE BY VARIOUS DIBROMO ESTERS

Ester used	% iodine liberated: Acetone soln. 24 hr. 25°	Boiling acetone soln. 24 hr.	Dioxane 24 hr. 25°	Boiling dioxane 72 hr.
Polymer of methyl α-bromoacrylate	30	49	24	92
Ethyl α,α′-dibromosuccinate	33	53	26	96
Ethyl α,α′-dibromoglutarate	4	6	4	21
Ethyl α,α′-dibromo-α,α′-diethylglutarate	2	5	..	..

The comparison with ethyl α,α′-dibromo-α,α′-diethylglutarate seemed to be desirable in order to be sure that a substituted bromoglutarate of this type did not react with potassium iodide. This ester was prepared by the reactions indicated. The starting acid (X) was prepared by methods described in earlier literature.[5]



Evidence to support the "head to head, tail to tail" formulation of these α-haloacrylate polymers (I) was obtained by the use of zinc. This reagent readily removed 97% of the bromine from the bromo polymer, an amount far above that which could be removed from a 1,3-dibromopolymer as shown by the calculation of Flory.[6]

Additional evidence supporting the 1,2-dihalogen structure was found in a comparison of the effect of heat on the polymer of methyl α-bromoacrylate, ethyl α,α′-dibromosuccinate (VI), and ethyl α,α′-dibromo-α,α′-diethylglutarate (VIII). The polymer and the succinate (VI)[7] lost hydrogen bromide at a much lower temperature than did the glutarate (VIII). During the preparation of the glutarate (VIII), it was noticed that the ester on distillation under reduced pressure lost ethyl bromide. During the pyrolysis of the polymer of methyl α-bromoacrylate, methyl bromide was formed but only after the appearance of hydrogen bromide. Heating the polymer of methyl α-bromoacrylate with quinoline removed half of the bromine as hydrogen bromide.

Further evidence supporting the 1,2-dihalogen structure (I) for the polymers was obtained by a comparison of the ultraviolet absorption spectra of the polymers of methyl α-bromoacrylate, ethyl α,α′-dibromosuccinate and ethyl α,α′-dibromoglutarate. Figure 1 shows the absorption curves for these compounds.

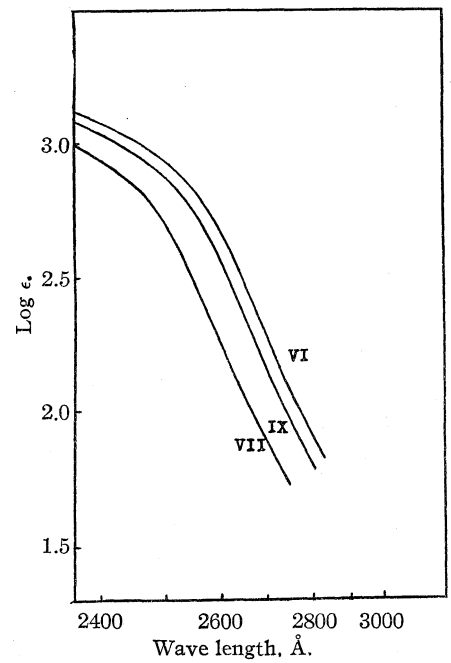


Fig. 1.—Absorption spectra.

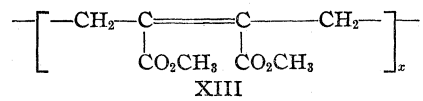
The unsaturated polymeric ester (XIII) which undoubtedly results from the action with potassium iodide apparently undergoes some further polymerization to give a cross-linked product, as the debrominated compound is insoluble.



XIII

However, it does decolorize aqueous potassium permanganate solution slowly, thus indicating

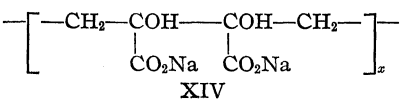
unsaturation. All attempts to isolate definite products from the oxidation have been unsuccessful.

When zinc reacts with the bromo polymer there is apparently some cross-linking. This would account for the fact that not quite all of the halogen is eliminated from the polymer. For each halogen which is used up in the cross-linking reaction, an isolated halogen will remain in the polymer after the reaction is complete. The debrominated product is again an insoluble product as would be expected if cross-linking had occurred.

The polymers on alkaline hydrolysis yielded the salt of a 1,2-dihydroxy dibasic acid (XIV). The



XIV

product (XIV) reduces periodic acid to iodic acid in approximately forty-eight hours. This oxidation is characteristic of 1,2-glycols.[8] Reduction of the iodic acid also occurs; this observation has also been noted by Jackson and Hudson[9] in a study of the oxidation of cellulose. The amount and rate of oxidation varied with different samples of the polymers, but in every test some oxidation occurred.

Experimental

Methyl α-Bromoacrylate.—In a 250-cc. modified Claisen flask was placed 73 g. (0.3 mole) of methyl α,β-dibromopropionate (prepared by addition of bromine to methyl acrylate)[10] and 39 g. (0.3 mole) of freshly distilled quinoline.[11] The methyl α-bromoacrylate was distilled out of this mixture at once. The yield was 40 g. (82% of the theoretical amount) of a colorless liquid which boiled at 72.5–74° (78 mm.); d^{20}_{20} 1.61; $n^{20}D$ 1.4840.

Anal. Calcd. for $C_4H_5O_2Br$: Br, 48.48. Found: Br, 47.90.

Methyl α-Chloroacrylate.—The same method was used for the preparation of methyl α-bromoacrylate.[10,11] The yield from 47 g. (0.3 mole) of methyl α,β-dichloropropionate was 33 g. (73% of the theoretical amount). The ester boiled at 57–59° (55 mm.); d^{20}_4 1.189; $n^{20}D$ 1.4400.

Anal. Calcd. for $C_4H_5O_2Cl$: Cl, 29.43. Found: Cl, 29.02.

Synthesis of Ethyl α,α′-Dibromo-α,α′-diethylglutarate.—Ethyl propane-1,1,3,3-tetracarboxylate[12] was treated with sodium ethoxide and ethyl iodide[5] to form ethyl heptane-3,3,5,5-tetracarboxylate. The latter was hydrolyzed with potassium hydroxide in diethylene glycol[5] and decarboxylated by refluxing in dilute hydrochloric acid.[5]

The crude diethylglutaric acid (33 g.) was warmed (60–80°) with thionyl chloride for twenty-four hours, and the excess thionyl chloride was removed by distillation. Dried bromine (21 cc.) was added to the residual acid chloride and the mixture was heated at 70° for five hours. The bromine treatment was repeated with 15 cc. of dried bromine. The bromination mixture was allowed to stand for two days, and the bromo acid chloride was poured into absolute ethyl alcohol. This solution was distilled and after the removal of all the low-boiling material a fraction boiling at 134–138° (3 mm.) was obtained as the main product: d^{20}_{20} 1.358; $n^{20}D$ 1.4775. The yield was 25 g. (48% of the theoretical amount). The analysis showed that this product was the bromo-lactone (XII).

Anal. Calcd. for $C_{11}H_{17}O_4Br$: C, 45.05; H, 5.71. Found: C, 45.14; H, 5.98.

The bromo-lactone (25 g.) was dissolved in absolute ethyl alcohol and saturated with dry hydrogen bromide.[13] The reaction mixture was allowed to stand for twenty-four hours. All low-boiling material was removed from the reaction mixture under diminished pressure. Analysis showed the residue was mainly the ethyl α,α′-dibromo-α,α′-diethylglutarate.

Anal. Calcd. for $C_{13}H_{22}O_4Br_2$: Br, 39.81. Found: Br, 38.70.

Polymerization of the Methyl α-Haloacrylates.—The monomers were polymerized either without solvent or in dioxane or toluene solution. Forty grams of methyl α-bromoacrylate was allowed to stand in a glass container at room temperature for three weeks; the liquid gradually became viscous and finally turned to a clear, pale amber, brittle solid.

Anal. Calcd. for $(C_4H_5O_2Br)_n$: C, 29.09; H, 3.03; Br, 48.48. Found: C, 29.20; H, 3.20; Br, 47.88.

Twenty grams of methyl α-bromoacrylate was dissolved in 100 cc. of dry dioxane and 0.48 g. of benzoyl peroxide was added. The solution was warmed at 35° for forty-eight hours and the addition of benzoyl peroxide repeated. After an additional forty-eight hours at 35°, the reaction mixture was diluted with approximately 500 cc. of ether and the polymer was precipitated as a white powder. It was collected on a filter, washed with ether, and dried; the yield was 15 g. When toluene was used as a solvent for polymerization, the yields were lower than when dioxane was used.

The methyl α-chloroacrylate gave a clear, pale amber, brittle solid when the monomer was allowed to stand in a glass container for one month. The methyl α-chloroacrylate also polymerized in dioxane or toluene solution. Ten grams of the methyl α-chloroacrylate was dissolved in 100 cc. of toluene, and 0.5 g. of benzoyl peroxide was added. The solution was warmed at 35° for twenty-four hours and the polymer precipitated as a white powder by the addition of approximately 500 cc. of ether. The yield was 3 g.

Anal. Calcd. for $(C_4H_5O_2Cl)_n$: C, 39.85; H, 4.19; Cl, 29.43. Found: C, 39.51; H, 4.48; Cl, 27.26.

Both the bromo and chloro polymers were soluble in acetone and dioxane when freshly prepared. Both polymers were insoluble in ether, ethyl alcohol, and carbon tetrachloride. One sample of methyl α-chloroacrylate which stood for ten months gave a polymer that did not dissolve when shaken with dioxane for forty-eight hours. This insolubility indicates that the polymer had a very high molecular weight.

The molecular weight of one sample of methyl α-bromoacrylate was determined by viscosity measurement. The sample which was used was prepared in dioxane with benzoyl peroxide at 35°. The relative viscosity of a 0.0368 molar dioxane solution (molarity based on the monomeric unit) was found to be 1.11. Using 2.6×10^{-4} for the value of K_m[14] in the equation $N_{sp}/C = K_m M$, the molecular weight was found to be approximately 11,500.

Study of the Reaction of Potassium Iodide with the Polymers of α-Haloacrylates and with the Esters of Dibromosuccinic and Dibromoglutaric Acids.—Standard solutions of the polymers and the esters were prepared in peroxide-free dioxane or acetone and to each of these solutions was added a measured amount of an aqueous solution of potassium iodide. Each of the reaction mixtures was placed in an all-glass apparatus and subjected to conditions as shown in Table II.

The iodine liberated was determined with standard thiosulfate. In some of the determinations, the procedure was modified further by using an acetone solution of potassium iodide instead of an aqueous solution. The results are summarized in Table II.

TABLE II

LIBERATION OF IODINE FROM POTASSIUM IODIDE BY HALOGENATED ESTERS

Compound	Molality in dioxane	Treatment Time, hr.	Treatment Temp., °C.	Molality of iodine liberated	Conversion, %

[a] Based on the polymeric unit I.

A 0.0084 molal acetone solution of the polymer of methyl α-chloroacrylate was heated to 90° for five days in a sealed tube with aqueous potassium iodide and approximately 58% of the calculated amount of iodine was liberated. The amount of iodine liberated in this experiment was determined colorimetrically.

Debrominated Polymers from the Polymer of Methyl α-Bromoacrylate.—The debrominated polymers were obtained by the action of potassium iodide and by the action of zinc dust on the polymer of methyl α-bromoacrylate.

To a solution of 3 g. of the polymer in 100 cc. of peroxide-free dioxane was added 10 cc. of 30% aqueous potassium iodide. The mixture was warmed at 80–85° for three days. The solution became deeply colored by the liberation of iodine, and a polymeric precipitate formed in the reaction flask. It was isolated, washed with water and alcohol and dried. Analysis showed that 93% of the bromine had been removed.

Anal. Calcd. for $(C_8H_{10}O_4)_n$: C, 56.47; H, 5.88. Found: C, 52.10; H, 4.36; Br, 3.77.

This debrominated polymer decolorized an aqueous solution of potassium permanganate in a period of about forty-eight hours. A 5-g. sample of the polymer of methyl α-bromoacrylate was dissolved in 100 cc. of dioxane and 4 g. of purified zinc dust was added. The mixture was refluxed gently for forty-eight hours. After the solution cooled, the unreacted zinc and the precipitated organic material were separated from the dioxane by filtration.

The filtrate gave a positive test for halogen ion, indicating that the zinc had reacted. The residue was suspended in dilute hydrochloric acid for forty-eight hours in order to dissolve the zinc. The residue was collected on a filter and washed thoroughly with water. It burned with a smoky flame, decolorized aqueous permanganate at room temperature within forty-eight hours, and gave a slight test for halogen. The yield was 2 g.

Anal. Calcd. for $(C_8H_{10}O_4)_n$ (XIII): C, 56.47; H, 5.88. Found: C, 50.61; H, 5.24; Br, 3.20. A portion of the polymer which had precipitated on the sides of the flask and which was not contaminated with zinc was analyzed. Found: C, 53.52; H, 5.62; Br, 1.42.

Effect of Heat on the Polymers of Methyl α-Bromoacrylate, Methyl α-Chloroacrylate, and on the Esters of Halogenated Succinic and Glutaric Acids.—The materials were heated in 50-cc. Erlenmeyer flasks and the vapors passed into water and then through a trap immersed in a dry-ice–acetone bath. The liberation of hydrogen bromide was noted by an indicator (congo red) which was placed in the water, and the dry-ice–acetone trap was used to catch any low-boiling substances which were liberated. The polymer of methyl α-bromoacrylate began to lose hydrogen bromide when heated to 110°, and the reaction was rapid between 120 and 150°. The hydrogen bromide appeared before any loss of methyl bromide was noticed. Finally, the polymer was heated to 220° to give a shiny, dark brown residue.

Anal. Calcd. for $(C_7H_6O_4)_n$: C, 54.50; H, 3.90. Found: C, 55.18; H, 4.00.

The ethyl α,α′-dibromosuccinate (VI) lost hydrogen bromide at 130–170°, which is in agreement with observations recorded in the literature.[7] The ethyl α,α′-dibromo-α,α′-diethylglutarate (VIII) began to lose hydrogen bromide at approximately 175°, the major portion of the decomposition occurring at 190–200°.

The polymer of methyl α-chloroacrylate was heated to 330° under pressure of 3 mm. for one hour. The residue was a shiny dark brown material which was very brittle. It burned with a smoky flame, contained no chlorine, and was insoluble in organic solvents.

Anal. Calcd. for $(C_4H_4O_2)_n$: C, 57.10; H, 4.76. Found: C, 59.37; H, 4.65.

(14) Staudinger and Schwalbach, *Ann.*, **488**, 8 (1931).

Reaction of the Polymer of Methyl α-Bromoacrylate with Quinoline.—One and one-half grams of methyl α-bromoacrylate was dissolved in 100 cc. of dried dioxane and 3 g. of quinoline was added. The reaction mixture was warmed at 60° for eight hours. It was diluted with 300 cc. of ether and a polymeric material was precipitated. The precipitate was washed alternately with water and alcohol to remove impurities. Analysis of the polymer showed that a molecule of hydrogen bromide had been removed for each unit (see formula IX).

Anal. Calcd. for $(C_8H_9O_4Br)_n$: C, 38.50; H, 3.61; Br, 32.10. Found: C, 39.10; H, 3.94; Br, 30.40.

Absorption Spectra.—The spectra were taken on a Bausch and Lomb ultraviolet spectrograph. A hydrogen discharge tube operating on 15,000 volts was used as the source of ultraviolet light and the hydrogen lines were used to calibrate the wave length scale. The absorption coefficients were determined by comparing the absorption of the compounds with the absorption of a 10^{-4} molal naphthalene solution. Dioxane, which had been carefully purified, was used as the solvent.[15] The results are shown in Fig. 1.

Hydrolysis and Subsequent Oxidation of the Polymer of Methyl α-Bromoacrylate.—A 14-g. sample of the polymer of methyl α-bromoacrylate was warmed with 150 cc. of aqueous sodium hydroxide (8 g. of sodium hydroxide) for twenty hours. The polymer dissolved slowly to give a dark brown solution. This was cooled and the alkali neutralized with hydrochloric acid. The solution was inclosed in parchment paper and dialyzed for seventy hours, when the solution gave a negative test for halogen ion. The solution was evaporated to dryness on a steam-bath to give a brown residue. This residue burned with a luminous flame and gave a white residue on ignition. The white residue when dissolved in water gave an alkaline reaction. Analysis of the material indicated that it was the sodium salt of a polymeric hydroxy acid (XIV).

Anal. Calcd. for $(C_3H_3O_2Na)_n$: C, 32.80; H, 2.73; Na_2O, 28.20; Na_2O_2, 35.45. Found: C, 35.20; H, 3.31; ash, 34.50.

A 0.5375-g. sample of the brown residue was dissolved in 50 cc. of water and the solution was cooled to 17°. To this solution was added 50 cc. of periodic acid solution containing 5 cc. of dilute hydrochloric acid, and the mixture was immersed in a water-bath at 17°. A 25-cc. sample was removed immediately and titrated with standard sodium thiosulfate. This value was used to determine the normality of the periodic acid (0.75 *N*) in the reaction mixture. After thirty minutes, another 25-cc. sample was titrated. The difference in titrations was 3.00 (35.50–32.50) cc. of 0.528 *N* sodium thiosulfate. This difference amounts to 33.8% reduction of the periodic acid to iodic acid.

A 7.095-g. sample of the polymer of methyl α-bromoacrylate was treated with hot dilute alkali for twenty-four hours. The solution was acidified with an excess of dilute hydrochloric acid and the volume diluted to 250 cc. After cooling the solution to 16°, 100 cc. of periodic solution (cooled to 16°) was added. Throughout the oxidation the mixture was kept at 16°. A 25-cc. sample was immediately titrated. Table III gives the change in titration in cubic centimeters of 0.269 *N* sodium thiosulfate with time.

TABLE III

Time	Cc. of 0.269 *N* $Na_2S_2O_3$ per 25 cc. sample	% reduction of HIO_4
0	41.20	0
15 min.	40.98	3.1
47 min.	40.05	11.9
107 min.	39.85	14.0
6.5 hours	37.95	33.8
46.5 hours	31.30	103
52.5 hours	30.45	..
53.5 hours	30.30	..
71.5 hours	28.25	..

At the end of approximately forty-six hours all of the periodic acid had been reduced to iodic acid but the titration value in terms of thiosulfate slowly decreased, indicating that the iodic acid was being reduced further.

Summary

The structures of the polymers of methyl α-chloroacrylate and methyl α-bromoacrylate have been determined. The structural unit present in these polymers has been shown to be

Hydrogen Bonding by S–H. VII.[1] Aryl Mercaptans

BY M. J. COPLEY, C. S. MARVEL AND EMANUEL GINSBERG

It has been commonly held that hydrogen bonding is restricted to hydrogen atoms attached to fluorine, oxygen, or nitrogen. Recently, however, large masses of data involving diverse types of physical measurements (polarization measurements,[2] solubility,[3,4] heat of mixing,[1,5] infrared absorption,[6,7] and viscosity[8]) have shown definitely that a hydrogen attached to a highly negatively substituted carbon atom, for example, $CHCl_3$, $CHCl_2F$, CH_2Cl_2, or $C_6H_5C{\equiv}CH$, will bond to an unshared pair of electrons on an oxygen or a nitrogen atom in an organic molecule. Infrared absorption measurements by Buswell, Rodebush and Roy[6] and by others[9] have also shown that the ether–hydrogen chloride complex is another case of hydrogen bonding.

These results have suggested to the authors that hydrogen bonding is more common than hitherto believed, and that whenever a hydrogen is attached to another atom by a sufficiently ionic link, it will further bond to an unshared pair of electrons on a donor atom. To test this hypothesis, the heats of mixing of an alkyl mercaptan and of an aryl mercaptan with some donor solvents have been measured. The method followed in making the measurements has been described in a previous publication.[5] In Table I are tabulated the heat effects on mixing equimolar quantities of *n*-heptyl or phenyl mercaptan with four organic solvents. For comparison, corresponding heats of mixing of chloroform and phenylacetylene[1] are included where available. Where the statement "No heat" is made, either a slight cooling or inappreciable heating was observed. In Fig. 1 the complete heat of mixing curves are shown for phenyl mercaptan with the three donor solvents, N,N-dimethylacetamide, ethyl ether, and acetone.

TABLE I

HEATS OF MIXING IN CALORIES PER MOLE OF SOLUTION AT 3° FOR EQUIMOLAR MIXTURES

	n-Heptyl mercaptan	Phenyl mercaptan	Phenyl-acetylene	Chloro-form
N,N-dimethyl-acetamide	No heat	572	644	920[a]
Ethyl ether	No heat	173	272	700[b]
Acetone	No heat	150	200	. . .
Benzene	No heat	No heat	No heat	No heat

[a] Unpublished data obtained in this Laboratory. [b] McLeod and Wilson, *Trans. Faraday Soc.*, **31**, 596 (1935).

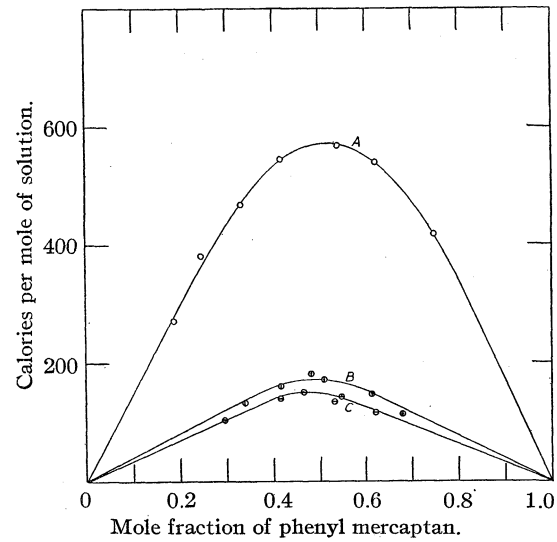

Fig. 1.—The heat evolved per mole of solution at 3° *versus* the mole fraction of phenylmercaptan: A, N,-N-dimethylacetamide, B, ethyl ether, and C, acetone.

The data show that whereas *n*-heptyl mercaptan gives no evidence of hydrogen bonding, the more acidic phenyl mercaptan bonds to the donor atoms, oxygen or nitrogen. The location of the maxima at 0.5 mole fraction suggests the formation of an equimolar complex in each case. From the magnitude of the heats of mixing alone, it appears that the S–H←O or N bonds are considerably weaker than the C–H←O or N bonds formed by chloroform, and slightly weaker than the C–H←O or N bonds formed by phenylacetylene; however, it must be remembered that if weak S–H←S bonds are present in phenyl mercaptan they would lead to lower heats of mixing.

In Table II the boiling points of methyl mercaptan, methyl sulfide, phenyl mercaptan, and phenylmethyl sulfide along with their oxygen analogs are listed. Methyl mercaptan has a lower

boiling point than methyl sulfide; similarly phenyl mercaptan has a lower boiling point than phenylmethyl sulfide; on the other hand, the reverse is true for the oxygen analogs. This indicates that phenyl mercaptan as well as alkyl mercaptans is unassociated or at most forms very weak S–H←S bonds. This is in agreement with previous work[3] which showed that a sulfur atom is an extremely poor donor atom for the bonding of a hydrogen on a carbon.

Summary

The heats of mixing of *n*-heptyl and phenyl mercaptans with N,N-dimethylacetamide, ethyl ether, acetone, and benzene have been measured. The results afford evidence of hydrogen bonding to donor oxygen and nitrogen atoms by phenyl mercaptan, but not by *n*-heptyl mercaptan. The failure of aryl mercaptans to show association is a result of the weak donor ability of the sulfur atom for hydrogen bonding and not from any lack of acceptor ability on the part of the hydrogen of the S–H link. It is pointed out that whenever a hydrogen is attached to another atom by a sufficiently ionic link, hydrogen bonding is possible.

Electrical Characteristics of Molecular Films

BY FRANCIS J. NORTON

1. Introduction

It has been shown by Blodgett and Langmuir[1,2] that single layers of molecules on water surfaces can be transferred to polished metal slides by dipping the slide through the water surface. When one molecular layer goes on the slide as it is dipped downward, but none as the slide is withdrawn, this transferred layer is called an X film. When one layer is transferred on the down dip and one on the up dip, they are called Y films.

Porter and Wyman[3,4] found that X films of calcium and barium stearates, deposited from baths of *p*H above 9, possess a potential which increases with the number of molecular layers. The Y films of calcium and barium stearates, on the other hand, do not show this growth of potential with successive dips.

The experimental results of Porter and Wyman have been repeated and confirmed, using both the vibrating plate method and also a polonium–air electrode to measure surface potential. The interpretation of certain of our experiments indicates, according to the theory given by Langmuir,[5] that the principal portion of the charge on calcium and barium stearate X films may be due, not to molecular orientation within the films, but to a surface electrification.

(4) Porter and Wyman, *ibid.*, **60**, 1083 (1938).
(5) Langmuir, *ibid.*, **60**, 1190 (1938).

2. Apparatus

The vibrating plate method is that described by Zisman[6] and Porter.[7] A beat frequency oscillator (RCA type TMV 134–A) was used to produce the audio frequency which was amplified and fed to a loud speaker element in a sturdy support. This element vibrated an insulated polished nickel disk just above the film. When a potential exists between the disk and film, this vibration plate condenser feeds an alternating current into an audio-frequency amplifier. An opposing potentiometer and voltmeter was used to balance out the surface potential to a minimum of sound in earphones.

The polonium–air electrode affords an independent method of measuring surface potentials. The use of radioactive material for measuring contact potentials was described by Lord Kelvin shortly after the discovery of radioactivity. The polonium method has been used by Guyot, Frumkin, Rideal and others. Old radon tubes were crushed and soaked in 4 *N* hydrochloric acid. A buffed disk of nickel 0.5 cm. in diameter, 0.025 cm. (10 mils) thick was welded to a nickel wire. When this is rotated for a few minutes in hydrochloric acid extract from radon tubes, polonium is deposited on the nickel disk. The disk was then washed in distilled water and dried.

(6) Zisman, *Rev. Sci. Instruments*, **3**, 367 (1932).
(7) Porter, THIS JOURNAL, **59**, 1883 (1937).

The polonium ionizes the air in the neighborhood, and this polonium–air electrode can be used to explore the potentials existing between the disk and the metal slide, or the surface of thin insulating films on the slide.

One essential feature of the method was a guard sleeve around the disk, so the ionized air was confined to the immediate region of the film being measured, and stray currents did not flow to other parts of the apparatus. The slide was held on a small adjustable table. It was brought 2 mm. from the polonium disk and 1 mm. from the protecting sleeve. The whole was enclosed in a grounded metal box, as was the amplifier and lead to the grid of the tube.

By a d-c. amplifier using an FP-54 tube[8] the small ionization currents were amplified and put into a photoelectric recording micro-ammeter.[9] This had a coil resistance in the primary galvanometer element of 1200 ohms, and a damping resistance of 20,000 ohms across the meter terminals. By putting various known values of grid resistances, from $R_g = 10^8$ to $R_g = 10^{11}$ ohms, into the amplifier circuit, currents down to 10^{-13} ampere could be continuously recorded. The resistors were made by the S. S. White Dental Mfg. Company. Care was taken not to touch the resistor element with the fingers, and the air in the amplifier box containing resistor and tube was kept at low humidity by phosphorus pentoxide. The usual grid resistor used was 10^9 ohms, which was near the value of resistance of the ionized air constituting the polonium–air electrode. Where these two resistances are of the same order, best sensitivity is obtained. The usual range of current was 10^{-8} to 10^{-11} ampere. As shown in Fig. 1, a potentiometer and voltmeter enabled various potentials to be applied so as to bring the current to zero on the recording microammeter, and the surface or contact potentials existing between the film surface and the nickel–polonium disk could thus be determined. The calibration of the recording galvanometer to give actual currents was made by putting a known high resistance externally in place of the polonium–air electrode. Then various voltages were applied by the external potentiometer, and for each applied voltage a reading was obtained on the galvanometer. A circulating current is obtained in the circuit: external resistance, voltmeter, ground, grid resistor. The galvanometer reading represents the amplification of this current. Knowing the values of voltage and of the two resistors in the circuit, the value of the current for each galvanometer reading can be calculated from Ohm's law.

The procedure for obtaining the resistance of the polonium–air contact was as follows. The nickel slide was buffed so as to offer the same type of surface as the small polonium coated disk. After a time, the value of surface potential between disk and slide became nearly zero as measured on the external potentiometer circuit. Then various values of voltage were applied by the potentiometer to give various readings on the galvanometer. These were translated into current readings by the calibration described in the preceding paragraph, and the value of total resistance obtained in the circuit: polonium–air electrode, voltmeter, ground, grid resistor. Knowing the value of the grid resistor, and using various resistors as a check, the resistance of the polonium–air electrode was calculated. It was found to be ohmic in the range of voltages used.

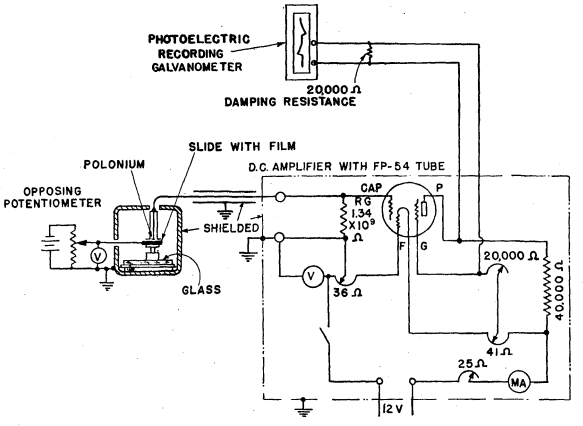

Fig. 1.

The two methods, vibrating plate and polonium–air electrode, gave substantial agreement in values of surface potential. The obvious difference is that a film left in the ionized air loses its charge, as the surface is continually short-circuited. This behavior is discussed later.

The principal baths used were:

Solution 1: for Ca stearate Y films *p*H 7, 10^{-4} *m* $CaCl_2$, 3×10^{-4} *m* $KHCO_3$

Solution 2: for Ca stearate X films *p*H 10, 10^{-4} *m* $CaCl_2$, 10^{-3} *m* $KHCO_3$, raise *p*H by adding NH_4OH

Solution 3: Ba baths like Ca

Solution 4: for Cu stearate Y *p*H 5.0, 10^{-4} *m* Cu acetate, 3×10^{-5} *m* HCl

Solution 5: for Pb stearate X *p*H 5.7, 10^{-4} *m* $PbCl_2$, 2×10^{-6} *m* HCl

Solution 6: for Pb stearate Y *p*H 5.7, 10^{-4} *m* $PbCl_2$, 2×10^{-6} *m* HCl, 10^{-5} *m* $SnCl_2 \cdot 2H_2O$

The *p*H values were measured by a glass electrode *p*H meter.

Effect of *p*H of Bath.—The surface potential of calcium stearate films put on by 20 round-trip dips was found to vary with the bath *p*H in the manner shown in Fig. 2. At *p*H 9, the layers are definitely of the X type; at *p*H 7, definitely Y. The transition region may give a mixture.

It is interesting to note that the region where charged X films are formed on dipping is one of change in sign of electrical potential of stearic acid films on the bath surface. When stearic acid is spread on a water of *p*H 6, the surface becomes more positive by +250 mv.[10] At *p*H 7 this change is about +160 mv., but near *p*H 9, spreading stearic acid on water causes no change in its surface potential. Above 9 the surface becomes negative with respect to the clean water surface, and it is in this region that the greatest surface charges on the transferred films are found.

(9) LaPierre and Carson, *Gen. Elec. Rev.*, **36**, 271 (1938).

(10) Porter, THIS JOURNAL, **59**, 1883 (1937).

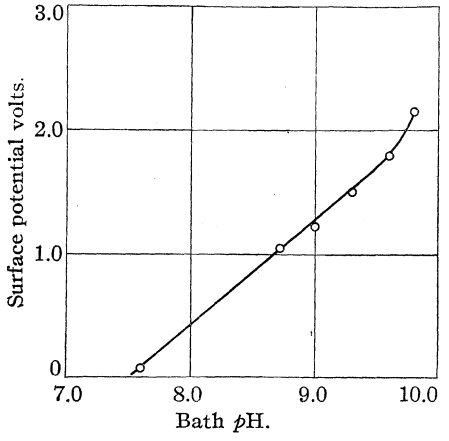

Fig. 2.

Age of Film on Bath Surface.—Another factor influencing the voltage acquired by calcium stearate X films on dipping is the age of the stearic film spread on water. If the film is transferred immediately after spreading, a higher charge per dip results than if an interval of ten or twenty minutes elapses between the time of spreading and the time of dipping. This is illustrated in Fig. 3 and was observed many times. The data of this figure also confirm the result of Porter and Wyman—that one Y dip will take away the charges resulting from X dips.

Various Types of Films.—Dr. Blodgett has found that stearic acid ($C_{17}H_{35}COOH$) spread on a bath 10^{-4} molal in lead chloride, *p*H 5.5, will yield an X type film when transferred to metal. If arachidic acid ($C_{19}H_{39}COOH$) is used on this same bath a Y type of film results. This affords an excellent opportunity to find out if the surface potential depends on the film type.

Surface type	Potential volts	ΔE
Bare Cr	+0.25	
55 mol. layers Pb arachidate Y films	+ .38	+0.13
Bare Cr	+ .43	
40 mol. layers Pb stearate X films	+ .55	+ .12

This would indicate that X films of lead stearate do not possess the high surface charge which calcium and barium X films show, or else lose the charge much more quickly.

Another test involving X and Y films deposited from a bath at the same *p*H is afforded by Dr. Blodgett's discovery that adding a small amount of stannous chloride (10^{-5} molal in bath) to a lead bath of *p*H 5.5, causes Y films to be deposited, whereas without the tin, X films are deposited.

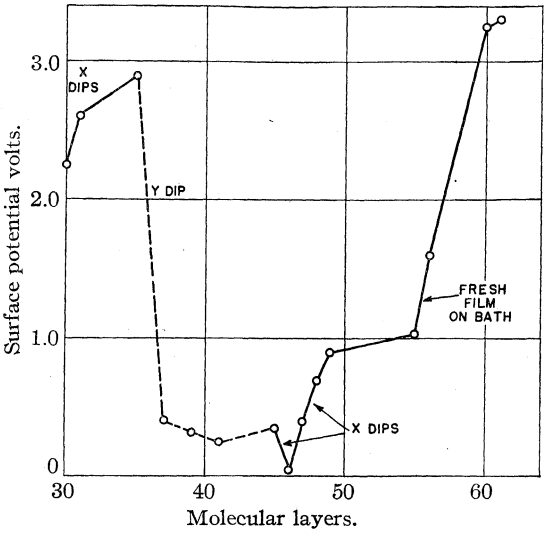

Fig. 3.

When this was tried, the measurements being made within a minute of completing the film transfer, the results indicated two things: first, lead stearate X films can build up an initial potential at about a tenth of the rate for calcium stearate X films; second, these lead X films have this potential even though they are made from a bath of *p*H 5.5, whereas Y films do not have the charge. The stannous chloride enabled both X and Y films to be made from a bath of the same *p*H.

Experiments to be presented in detail in a subsequent publication indicate that lead stearate films have lower electrical resistance than calcium stearate films and hence do not hold their surface charges so well.

Dipping into Various Solutions

The effect of dipping various films into clean water at different *p*H values indicated the composition of the bath and especially *p*H governed the magnitude of the charge developed on the surface.

A calcium stearate X film, 30 round-trip dips in bath *p*H 8.8, with stearic acid spread on it, gave 31 molecular layers (counting the initial layer on the rubbed slide) and a surface potential $E = +2.20$ volts, measured by the vibrating plate method. This was then dipped into baths which had no stearic film on. The successive changes in surface potential upon successive dips are:

Bath	*p*H	Δ*E*
		+2.20 as made
Clean Ca bath	9.4	+2.40
Clean Ca bath	8.25	+2.30
Distilled water	6.7	+1.70
Distilled water	6.1	+0.50
Clean Ca bath	9.4	+1.30

Successive dips into a bath of *p*H 9.4 will, as Porter and Wyman report, make the X films more negative after the first dip. On the other hand, Y films became consistently more negative on dipping into an alkaline bath, as shown below.

Δ*E*	Dips	
+0.27		Bare Ni surface
+ .08		37 Ca stearate Y layers, bath *p*H 7.5
+ .046	1	Clean Ca bath *p*H 9.5
+ .022	2	Clean Ca bath
− .15	7	Clean Ca bath
		Left in Po to discharge
0	..	Start
− .20	1	Clean Ca bath *p*H 9.5
− .22	2	Clean Ca bath
− .54	7	Clean Ca bath

These films all came out dry. If they are dipped into solutions containing aluminum or thorium ions, the surfaces are made hydrophilic, they emerge wet and the surface charge is near zero.

Solutions were made from sodium chloride, barium chloride, aluminum sulfate, thorium nitrate and hydrochloric acid with the *p*H values given below; 21 calcium stearate X layers were then dipped and held for thirty seconds in each with the results shown in Table I.

TABLE I

21 CA STEARATE X LAYERS ON NICKEL

Bath 0.001 *N*	*p*H	Δ*E* Initial	Δ*E* 1st dip	Δ*E* 2nd dip	Surface emerged
Na	6.1	+1.2	+1.0	..	Dry
Ba	5.95	+1.7	+1.15	+0.85	Dry
Al	4.5	+1.45	0	0	Wet
Th	3.4	+1.15	+0.13	− .15	Wet
HCl	3.45	+1.0	+1.15	+ .78	Dry

This illustrates the importance of the composition of the solution on changes of surface potential on dipping. In every case it has been found that when the film surface comes out wet, the surface charge has been lost. Sometimes the drying takes place very quickly as the film is being raised out of the water.

Surface Potential of Films on Glass.—To find out whether the metal surface on which Y films were deposited was essential to their possessing a surface potential, the following experiment was devised. A glass electrode was made from very thin special glass of high conductivity such as is used in *p*H electrodes. A portion was made flat, and on this X films of Ca stearate were deposited. The interior of the glass electrode was filled with 0.1 *N* hydrochloric acid and contact made to this by a platinum wire. This flat thin glass with calcium stearate film on the top surface and hydrochloric acid beneath was then made the lower plate, and the surface potential measured by the vibrating plate method.

It was found at the start that the clean glass had a potential relative to the vibrating nickel plate of near zero, ±0.005 v. This was raised to +0.80 v. by 25 X dips of calcium stearate on glass and with more layers finally a potential of +1.5 v. was attained. This value was checked by the ionized air method.

Through ionized air, 10 v. was applied, so the surface potential of these calcium stearate X films was raised to +6.2 v. The surface was then taken out of the ionized air and the next day was +3.3 v. Upon dipping the glass with the film into a solution of citrate–phosphate buffer of *p*H 7, the film was displaced from the glass and floated on the solution as iridescent fragments.

Application and Decay of Surface Potential in Ionized Air.—As described, the air–polonium electrode was so arranged that voltage could be applied with a potentiometer arrangement, and the small current resulting recorded continuously. Upon applying and maintaining a voltage, a relatively high initial current flows. This then decays exponentially, as the charges accumulate on the insulating surface film. These charges create an opposing potential, the magnitude of which is given by Equation 2, in Langmuir's paper[5]

$$V = 4\pi\sigma et/D$$

where σ = surface intensity of electrification
e = elementary charge = 4.77×10^{-10} e. s. u.
t = thickness of film = 24×10^{-8} cm. per layer
D = dielectric constant = 2.56

If the film is a good insulator, the initial charging current drops to zero, if a poor insulator, to a constant value of current, the conduction current of the insulator. The automatic record is shown in Fig. 4. At "*a*," 5.0 v. were applied to 41 calcium stearate X layers. The initial current was "*b*" which decayed to "*c*." At "*c*" the external voltage was taken off and the current "*d*" resulted from the surface charge. This then decayed along "*de*."

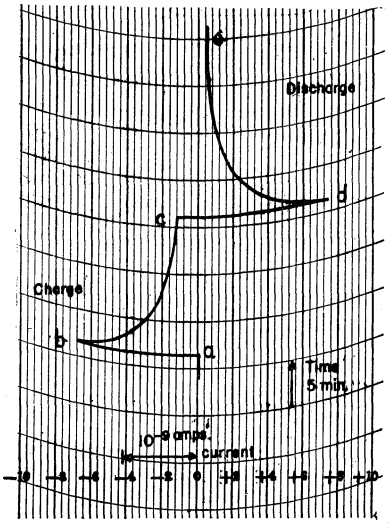

Fig. 4.

Thus when a charged film is put into ionized air, with no voltage applied, but the nickel slide and polonium electrode grounded, the ionized air short circuits the charges on the film surface, and the voltage decays exponentially to zero.

The magnitude of surface intensity of electrification is interesting, especially when considered as number of charges relative to the number of surface molecules.

On 41 calcium stearate Y layers a surface potential was built up by putting it into the ionized air beneath the polonium–air electrode and applying 0.5 v. for sixteen minutes. On taking off the voltage, a surface potential of 0.48 v. was found. This, left in the ionized air, decayed to $1/e^{\text{th}}$ of its value in one hundred and eighty seconds.

First can be calculated σ from the equation given above, remembering to convert the ordinary volts to e. s. u. and putting in the proper film thickness. The surface intensity comes out 7×10^{10} elementary charges per square centimeter. The cross sectional area of the stearate molecule is 20 square Ångströms, or 20×10^{-16} sq. cm., a total of 5×10^{14} molecules per sq. cm. Hence to produce the surface potential of 0.48 v., there need be only one elementary charge per 7000 surface molecules, and if distributed in a square array, two charges would be separated by some 84 molecules.

The 7×10^{10} elementary charges per sq. cm. amount to 1.11×10^{-8} ampere-second, or coulomb, per sq. cm. Since the area of the polonium–air electrode is 3.14 sq. cm., the total amount of electricity in that area is 3.5×10^{-8} coulomb. The recording meter gives amperes $\times$ seconds, so by graphically integrating the area under the decay curve, the total amount of electricity discharged is found. This integration gave 5.3×10^{-8} coulomb, compared to the 3.5×10^{-8} calculated from the voltage equation. This discrepancy undoubtedly is due to a difference between the actual effective area of the polonium–air electrode and that calculated from its dimensions.

The capacitance of this 3.14 sq. cm. of charged film is $C = AD/4\pi t$ (where A is the area) $= 6.5 \times 10^4$ cm. or 7.2×10^{-8} farad. The time constant of a condenser discharge in seconds is $\tau = CR$. The resistance in this circuit is the polonium–air gap, of 0.9×10^9 ohms, and that of the grid resistor, 1.34×10^9 ohms. Hence

$$\tau = 7.2 \times 10^{-8} \times 2.24 \times 10^9 = 161 \text{ sec.}$$

This is to be compared to the observed value of 180 sec.

From these calculations three results emerge which seem to indicate that the surface potential on molecular films can be regarded as a surface electrification.

(1) The value of σ, the surface intensity of electrification, is reasonable, and when thought of in relation to the total number of molecules on the surface, it is surprising what a low density of charge population will account for the observed surface potentials.

(2) The total amount of electricity as observed in the charge decay curve is approximately the same as that calculated from the voltage equation of Langmuir's paper.

(3) The time constant of decay observed is near that calculated, regarding the charged film simply as a charged condenser.

By the corona discharge from a spark coil leak tester, a surface potential of 4.0 v. was put on 5 molecular layers of calcium stearate X films. This is a gradient through the film of 3,300,000 v./cm., and the surface intensity of electrification can be calculated as 4.7×10^{12} elementary charges per sq. cm. There is thus one charge for a hundred molecules on the surface, and this represents some type of saturation value for this particular film.

Application of Surface Potential by Corona Discharge.—The sharp point of a portable spark coil leak tester was held 7 cm. above a film on a grounded nickel slide, so a corona discharge but not actual sparks occurred in the air just above the film. It became charged to a value

which depended on the number of molecular layers in the film, and on the time in the corona atmosphere, up to saturation. This is shown in Table II.

TABLE II

EFFECT OF CORONA

Mol. layers Ca stearate X	After ½	1	1½	2
	Minutes in corona, surface potential is volts			
2	+0.685	1.1	1.2	1.25
3	1.5	2.0	2.3	2.3
5			3.85	4.0
10				9.3

The gradient in these films of various thicknesses is high, and of the same order of magnitude, as Table III shows.

TABLE III

CA STEARATE X, CHARGE PUT ON BY CORONA

Mol. layers	Surface potential, v.	Volts per layer	Gradient volts/cm.
2	1.25	0.63	2,600,000
3	2.3	.77	3,200,000
5	4.0	.80	3,300,000
10	9.3	.93	3,700,000
50	23.5	.47	2,000,000

Corona was also produced by high voltage d. c., and it was found that the film collected a positive charge on its surface when the underlying nickel slide was made negative relative to the sharp point from which the corona was proceeding. With the nickel slide positive, a negative charge accumulated on the surface of the insulating film, presumably the negative ions attracted to the positively charged slide.

As discussed in a communication by Norton and Langmuir[11] corona from high voltage a. c., as near an unlighted Coolidge X-ray tube, caused a negative charge to accumulate on the surface film of a grounded slide, as though there were a preponderance of negative ions in the neighborhood or a higher mobility of the negative ions. The film becomes negative, even though there are no X-rays. Experiments involving X-rays will be presented in a subsequent paper. The results are, briefly, that when air is rendered conducting by X-rays, surface charges of either sign can be put on the film by applying the appropriate field.

Loss of Charge in Air.—As Porter and Wyman have indicated, calcium stearate X films can maintain their surface potentials for a surprisingly long time. I have found that the charges put on by ionized air, as well as the potentials on the film by dipping, persist after a rapid initial drop.

The fact that the charge stays on for weeks must mean that the calcium stearate films are extremely good insulators. How then is the loss of charge to be explained? An examination of the rate is of interest.

One film of 71 molecular layers had a surface potential of 1.22 v. at twelve days, and 0.97 v. at forty-eight days, a loss of 0.25 v. in thirty-six days when kept out in the air, away from radioactive material. From the voltage equation, it can be calculated that this represents a loss of 6750 elementary charges per second from each square centimeter, or a current of

$$6750 \times \frac{4.77 \times 10^{-10}}{3 \times 10^{9}} = 1.07 \times 10^{-15} \text{ ampere per sq. cm.}$$

In an article on "Ionization of the Atmosphere" Koller[12] states that for the gradient existing in the earth's atmosphere of some 100 v./m., the air conductivity leads to a current of 2×10^{-16} amp./sq. cm. constantly flowing toward the earth. It will be observed that this is near the order of magnitude of the leakage of charge from the molecular films, where a similar gradient exists to the bare metal near-by.

Similarly, Porter and Wyman[4] find on a 245-layer film a potential 6.02 v. at four days and 5.19 v. at nine days, a leakage of 0.16 v./day. This represents a loss from each sq. cm. of 3.9×10^{4} elementary charges per second or 6.2×10^{-15} amp./sq. cm. Since the voltage gradient is about six times greater on Porter and Wyman's slide, their results reduce to the same value as mine, 1×10^{-15} amp./sq. cm., and the loss of charge can be explained as being due to normal air conductivity.

The following three examples illustrate the loss of charge in the air, away from radioactive material. These surface potentials were all measured by the vibrating plate method.

(1) On 20 Ca stearate Y layers were put 51 Ca stearate X layers, a total of 71 molecular layers on a nickel slide

Time, days	0	4	12	15	18	22	23	48
Potential	+3.20	+1.90	+1.22	+1.40	+1.15	+1.08	+1.07	+0.97

(2) 21 Ca stearate X layers. Slide made positive and 90 volts applied through air ionized by Po for half an hour, then slide taken out

Time	0	30 min.	5 days	8	11	15 days
Potential	−6.88	−4.3	−2.42	−2.25	−2.25	−2.17

(3) 21 Ca stearate X. Slide made negative and 90 volts applied through air ionized by Po, 15 min. then slide taken out

(11) Norton and Langmuir, THIS JOURNAL, **60**, 1513 (1938).

(12) Lewis R. Koller, *Jour. Franklin Inst.*, **214**, 543 (1932).

Time, min.	0	2	5	14	24
Potential	+6.9	+6.5	+6.2	+5.5	+5.0
Time, hr.	1½	4	5		
Potential	+4.0	3.3	3.0		
Time, days	5	8	11	15	
Potential	+1.74	+1.65	+1.51	+1.45	

It is apparent that the usual potentials acquired by dipping, or potentials of either sign put on by ionized air, all behave in a similar manner.

Summary

Surface potentials can be put on X or Y stearate multi-films by applying a voltage while the films are in a conducting medium as air ionized by polonium. With voltage off, the films lose their charge exponentially. The coulombs represented by the area under the automatically registered discharge curve agree with Langmuir's equation which calculates potential resulting from surface charges.

The slow leakage of charge from X films left in ordinary air can be explained by the natural electrical conductivity of air.

Surface potentials were found to exist on calcium stearate X films deposited on glass.

Magnetic Measurements on Hexaphenyldigermane

BY P. W. SELWOOD[1]

The molecular weight of hexaphenyldigermane has been reported by Morgan and Drew[2] as 560 to 566 determined ebullioscopically in benzene. They interpret this as evidence for "no recognizable dissociation" although the value obtained is slightly lower than the molecular weight (606.8) computed for the compound.

A sample of this compound was obtained through the courtesy of Professor Warren C. Johnson of the University of Chicago.

Experimental Part

Magnetic Measurements.—The magnetic susceptibilities were measured by means of the Gouy balance previously described.[3] The only modifications were (1) the use of a magnetically damped microbalance, and (2) a modified temperature control. In previous work the temperature of the sample had been maintained through careful injections of liquid air into a lead block surrounding the sample. In the present work oxygen was liquefied by passing it through a condenser surrounded by liquid nitrogen. The oxygen was then allowed to fall, drop by drop, into the lead block. Through control of the rate of flow of oxygen into the condenser, a high degree of temperature control was possible.

All measurements were referred to freshly boiled distilled water, the specific susceptibility of which was assumed to be -0.7200×10^{-6} at 20°.

Preparation of Materials.—Measurements were made on powdered hexaphenyldigermane and on a solution of the digermane in benzene. Some rather interesting experiences were encountered in preliminary tests on the powder, and are described.

The substance gave evidence of having a magnetic susceptibility markedly dependent on field strength. The apparent susceptibility varied from $+1.45 \times 10^{-6}$ at 1000 oersteds to -0.10×10^{-6} at 11,000 oersteds. This behavior strongly suggested the presence of a ferromagnetic impurity. The digermane was therefore recrystallized from benzene, after which the susceptibility became normal, that is, constant, from about 1000 to 17,000 oersteds. A small insoluble residue was found to contain a very few almost microscopic specks of some highly magnetic substance, presumably magnetic oxide of iron. These results are illustrated in Fig. 1 in which Δw, the apparent change in weight on application of the field, is plotted against i, the current through the magnet. While these results have no bearing on the main problem, yet they do show the extraordinary sensitivity of the magnetic method for detecting ferromagnetic impurities and the necessity for excluding iron-bearing laboratory dust from samples under investigation.

The benzene solution used in this work was prepared by shaking the powdered digermane with redistilled thiophene-free benzene. No effort was made to exclude air. The solution was analyzed by evaporating to dryness at 125° and weighing the residue. The density was determined pycnometrically.

Results

The susceptibility of the powdered hexaphenyldigermane at several temperatures is given in Table I.

These results follow the relationship $\chi = A + (C/T + \Delta)$ where χ is the susceptibility, A is the constant diamagnetic part of the susceptibility, C is the Curie constant of the paramagnetic part, T is the absolute temperature, and Δ is the "molecular field constant." In the above relationship $A = -0.47 \times 10^{-6}$ and this is believed

TABLE I

SUSCEPTIBILITY AT FIELD STRENGTH 13,100 OERSTEDS

Temp., °C.	Susceptibility per gram, $\chi \times 10^6$
20	−0.436
0	− .431
−20	− .423
−40	− .410
−60	− .390
−80	− .357

to be the magnetic susceptibility of undissociated hexaphenyldigermane. The Curie constant is 5.0×10^{-3} and $\Delta = -150°$.

The temperature dependence of the measured susceptibility may be interpreted as evidence for slight dissociation or for the presence of a paramagnetic impurity in very small amount. If triphenylgermanium exists, it may be expected to have a molar paramagnetic susceptibility of about 1270×10^{-6}, corresponding to a single unpaired electron spin.[4] About 1% of dissociation would then account for the results. However, this is considered improbable because the molecular field constant, Δ, would not be expected to approach $-150°$ for such a compound having, as is likely, no orbital contribution to the susceptibility. On the other hand, molecular field constants of $-150°$ are not unusual for such highly paramagnetic oxides as might be present as impurities to the extent of a few thousandths of a per cent.

Further, if dissociation actually takes place it may be expected to increase sharply with rise in temperature. The data do not indicate such an effect.

The measurements on the powder therefore set an upper limit of 1% as to the extent of dissociation in the solid. The weight of evidence is that no dissociation takes place.

Hexaphenyldigermane is not very soluble in benzene at room temperature. Measurements had therefore to be made as accurately as possible.

TABLE II

Field strength, oersteds	Pure benzene $\chi \times 10^6$	0.00387 M soln. $\chi \times 10^6$
11,450	−0.7024	−0.7017
16,080	− .7027	− .7033
17,100	− .7019	− .7018
Averages	− .7023	− .7023

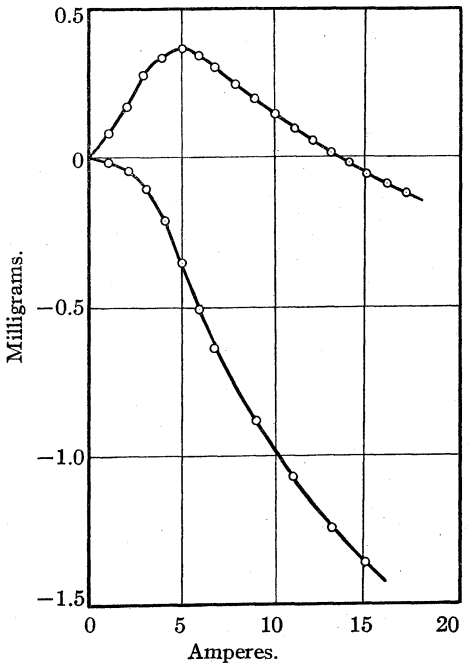

Fig. 1.—Apparent change in weight, Δw, plotted against current through magnet: upper curve, original sample; lower, recrystallized sample.

A single solution 0.00387 M in digermane was investigated at 25°. Measurements were made at several field strengths. The results are given in Table II.

The susceptibility of the solution, assuming no dissociation, may be calculated to be -0.7022×10^{-6}, using Wiedemann's law and the observed susceptibility of the solid. On the other hand, the susceptibility of the solution, assuming complete dissociation, may be calculated to be -0.7012×10^{-6}. It is therefore evident that nothing approaching complete dissociation takes place. It is probable that as little as 20% dissociation would have been detected.

Summary

Magnetic measurements on hexaphenyldigermane set upper limits of dissociation at 1% in the solid and 20% in a nearly saturated benzene solution at 25°. It is considered improbable that any dissociation takes place under these conditions.

A Thermodynamic Study of the Zinc–Antimony System. The Thermodynamic Properties of the Intermetallic Compounds: ZnSb, Zn_3Sb_2 and Zn_4Sb_3

BY BERNARD DEWITT AND HARRY SELTZ

In a previous paper[1] the authors have reported the results of an electromotive force study of liquid cadmium–antimony solutions and have calculated the thermodynamic properties of the intermetallic compounds CdSb and Cd_3Sb_2. By similar methods, zinc–antimony solutions have now been investigated and the thermodynamic properties of the three intermetallic compounds, ZnSb, Zn_3Sb_2 and Zn_4Sb_3, which appear as stable, solid phases, have been determined. The equilibrium diagram (Fig. 1a) for this system has been established accurately by the exhaustive studies of Takei,[2] and his solubility curves have been used in this work.

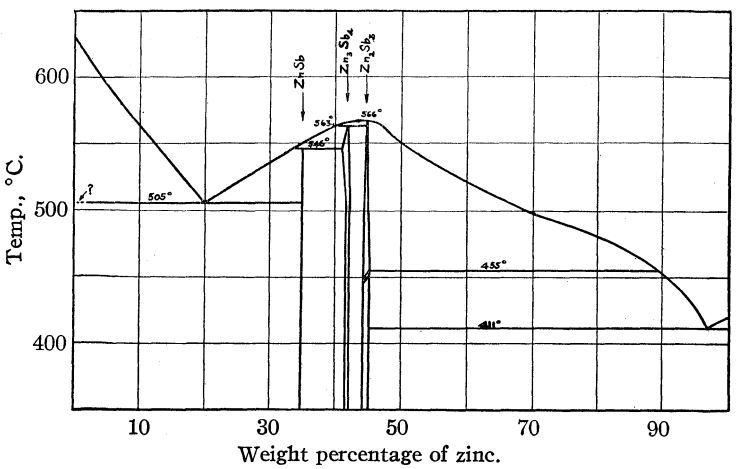

Fig. 1a.—Equilibrium diagram for the zinc–antimony system.

Experimental Results

The electromotive force measurements were made on evacuated cells of the type

$Zn(l)/ZnCl_2$ in LiCl + KCl(l)/Zn (in Zn–Sb liquid solutions)

and the results are given in Table I along with the calculated activities of zinc, a_1, and relative heat contents, $\bar{L}_1$.

From these a_1 and $\bar{L}_1$ values for zinc the corresponding a_2 and $\bar{L}_2$ values for antimony have been calculated along with the ΔH of formation of a mole of the liquid melts from the pure liquid metals. These results are given at round number mole fractions in Table II, and the activities are plotted in Fig. 1 and the $\bar{L}$ and ΔH values in Fig. 2.

The activity curves show deviations from Raoult's law similar to those encountered in the cadmium–antimony system, except that here they are even more pronounced. The a_1 values at higher mole fractions of zinc exhibit definite positive deviations and at lower mole fractions very marked negative deviations. As stated elsewhere,[3] in the binary systems of which antimony is a component there seem to be opposing influences at work, one tending to produce positive and the other negative deviations. A theoretical explanation of this behavior is not as yet forthcoming. The abnormal forms of the $\bar{L}$ and ΔH curves also are worthy of note.

TABLE I

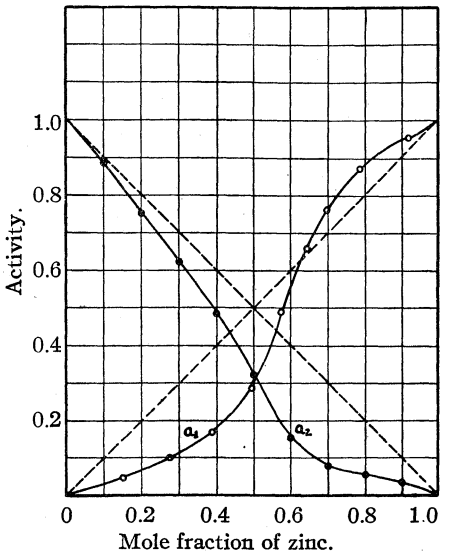

Fig. 1.—Activity curves at 823.1°K.: ○, experimental; ●, calculated.

Calculations

In the calculations which follow, the heats and free energies of fusion of antimony and zinc at various temperatures are required. Equations for these quantities have been set up from the fusion and heat capacity data recommended by Kelley[4] and are given below

$$\text{Sb(s)} = \text{Sb(l)}$$

$$\Delta H = 4015 + 1.64T - 0.89 \times 10^{-3}T^2 \quad (1)$$

$$\Delta F^\circ = 4015 - 1.64T \ln T + 0.89 \times 10^{-3}T^2 + 5.914T \quad (2)$$

$$\text{Zn(s)} = \text{Zn(l)}$$

$$\Delta H = 555 + 2.34T - 1.075 \times 10^{-3}T^2 \quad (3)$$

$$\Delta F^\circ = 555 - 2.34T \ln T + 1.075 \times 10^{-3}T^2 + 13.49T \quad (4)$$

The Solid Solubility of Zinc in Antimony.—From equation 2 the activity of pure solid antimony, a_2(s), relative to pure liquid as standard state, can be calculated at any temperature by the relation, $\Delta F^\circ = -RT \ln a_2$(s). From the solubility or freezing point curve[2] the activity of antimony in the equilibrium liquid at a given temperature is calculated from the experimental a_2 and $\bar{L}_2$ values corresponding to this composition. The $\bar{L}_2$ values are considered constant over the temperature range. If the a_2(s) and a_2 values thus determined are equal, the equilibrium solid phase is pure antimony. If, however, the value of a_2 is less than a_2(s), the equilibrium solid must be a solid solution of zinc in antimony. For small solubilities the solid solution can be considered ideal, as shown for the Pb–Bi system,[5] and the mole fraction composition, N_2(s), is given by the relation $N_2(s) = a_2/a_2(s)$. In Table III the data and solubilities are given at temperatures between the melting point and the eutectic.

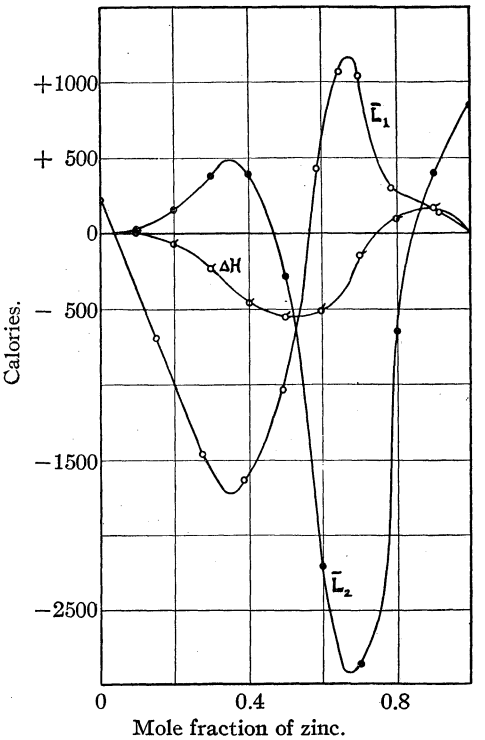

Fig. 2.—Relative heat content and heat of formation.

TABLE III

Temp., °K.	N_2 Equil. liq.	a_2(s)	a_2	N_2(s) Equil. solid soln.
865.1	0.900	0.890	0.883	0.992
823.4	.800	.773	.751	.972
784.6	.800	.670	.627	.936
778.1 (eutectic)	.682	.653	.609	.933

Thermodynamic Properties of ZnSb, Zn_3Sb_2 and Zn_4Sb_3.—At any temperature where a liquid phase is in equilibrium with a solid intermetallic compound such as ZnSb, we can write for the equilibrium constant

$$K_{ZnSb} = \frac{1}{a_1 \times a_2}$$

where a_1 and a_2 are the activities of zinc and antimony in the equilibrium liquid and where the activity of the solid is unity. Hence, for the formation of the compound from the two pure liquids, we write

$$\text{Zn(l)} + \text{Sb(l)} = \text{ZnSb(s)}; \quad \Delta F^\circ = -RT \ln \frac{1}{a_1 \times a_2}$$

(4) Kelley, Bureau of Mines Bulletins 383 (1935) and 393 (1936).

(5) Strickler and Seltz, THIS JOURNAL, 58, 2084 (1936).

Similarly for the Zn_3Sb_2 and Zn_4Sb_3

$$3Zn(l) + 2Sb(l) = Zn_3Sb_2(s);\ \Delta F^\circ = -RT \ln \frac{1}{a_1^3 \times a_2^2}$$

$$4Zn(l) + 3Sb(l) = Zn_4Sb_3(s);\ \Delta F^\circ = -RT \ln \frac{1}{a_1^4 \times a_2^3}$$

Using the solubility curves of Takei and the experimental activities and relative heat contents from this investigation, the values of ΔF° of formation of the compounds at different temperatures are given in Table IV. For Zn_3Sb_2 and Zn_4Sb_3 the

TABLE IV

Temp., °K.	Solubility N_1	a_1	a_2	ΔF°
	Zn(l) + Sb(l) = ZnSb(s)			
778.1	0.318	0.117	0.609	− 4,085
791.4	.375	.153	.528	− 3,957

810.3	.450	.225	.410	− 3,838
816.7	.475	.259	.369	− 3,815
	3Zn(l) + 2Sb(l) = Zn_3Sb_2(s)			
837.1	0.610	0.551	0.152	− 9,243
823.1	.655	.682	.103	− 9,314
806.0	.700	.780	.076	− 9,449
774.2	.800	.892	.052	− 9,625
760.1	.850	.938	.045	− 9,762
	4Zn(l) + 3Sb(l) = Zn_4Sb_3(s)			
819.1	0.485	0.272	0.350	−13,604
823.1	.502	.300	.317	−13,515
826.1	.513	.320	.298	−13,445
829.4	.525	.341	.283	−13,335
832.3	.538	.362	.266	−13,294
836.1	.558	.410	.233	−13,183

slight solid solubilities are negligible; their activities are taken as unity at each temperature.

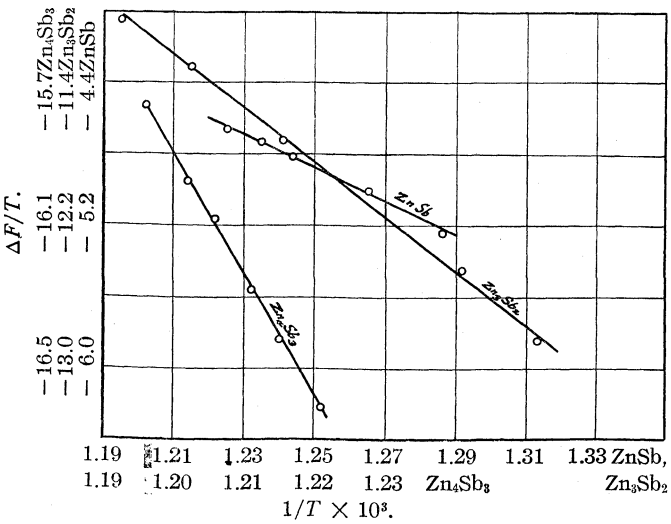

Fig. 3.—Plots of $\Delta F^\circ/T$ against $1/T$.

Plots of $\Delta F^\circ/T$ against $1/T$ for the three compounds are shown in Fig. 3, where it is seen that the points lie satisfactorily on straight lines, the slopes of which give directly the ΔH values of the reactions. Taking the mid-temperature for each compound the following relations obtain

$Zn(l) + Sb(l) = ZnSb(s);\ \Delta F^\circ_{804.1} = -3881;$
$\Delta H_{804.1} = -9570$ cal.

$3Zn(l) + 2Sb(l) = Zn_3Sb_2(s);\ \Delta F^\circ_{806} = -9449;$
$\Delta H_{806} = -14{,}800$ cal.

$4Zn(l) + 3Sb(l) = Zn_4Sb_3(s);\ \Delta F^\circ_{826.1} = -13{,}445;$
$\Delta H_{826.1} = -34{,}400$ cal.

Combining these values with those calculated from equations (1), (2), (3) and (4) at the corresponding temperatures, and calculating to 298.1°K. by the usual thermodynamic methods, with the assumption that ΔC_p is zero, we obtain

$Zn(s) + Sb(s) = ZnSb(s);\ \Delta F^\circ_{298.1} = -3361;$
$\Delta H_{298.1} = -3069;\ \Delta S_{298.1} = 0.98$ e. u.

$3Zn(s) + 2Sb(s) = Zn_3Sb_2(s);\ \Delta F^\circ_{298.1} = -3700;$
$\Delta H_{298.1} = -51;\ \Delta S_{298.1} = 12.25$ e. u.

$4Zn(s) + 3Sb(s) = Zn_4Sb_3(s);\ \Delta F^\circ_{298.1} = -13{,}581;$
$\Delta H_{298.1} = -13{,}095;\ \Delta S_{298.1} = 1.63$ e. u.

These values of $\Delta S_{298.1}$ with the entropies of Sb(s) and Zn(s)[6] lead to the following entropies for the compounds

ZnSb(s), $S_{298.1} = 21.43$ e. u.; Zn_3Sb_2(s); $S_{298.1} = 63.65$; Zn_4Sb_3(s); $S_{298.1} = 73.48$ e. u.

It should be noted that these thermodynamic quantities refer to the forms of the solid Zn_3Sb_2 and Zn_4Sb_3 as they exist at temperatures of the liquid–solid equilibria and do not consider any transformations which have been reported at lower temperatures. There is still some uncertainty as to the nature of these changes and no thermal data are available for them.

Of the three compounds, Zn_3Sb_2 is the only one which melts congruently and the heat of fusion can be evaluated from the $\bar{L}$ values and the heat of formation. For the change

$3Zn(l) + 2Sb(l) = Zn_3Sb_2$(liq. soln. $N_1 = 0.6$)

$\Delta H = 3\bar{L}_1(N_1 = 0.6) + 2\bar{L}_2(N_1 = 0.6) = 3 \times 600 + 2(-2205) = -2610$ cal.

Combining this value with the ΔH of formation of the compound from the pure liquid metals, we obtain the heat of fusion

$Zn_3Sb_2(s) = Zn_3Sb_2(l);\ \Delta H = 12{,}190$ cal.

Summary

1. The activities and partial molal relative heat contents of zinc and antimony in their liquid melts have been determined over the entire concentration range.

(6) K. K. Kelley, Bureau of Mines Bulletin 394.

2. The solid solubility of zinc in antimony has been calculated.

3. The free energies and heats of formation and the entropies of ZnSb, Zn_3Sb_2 and Zn_4Sb_3 have been evaluated.

4. The heat of fusion of Zn_3Sb_2 has been calculated.

The Electron Diffraction Investigation of the Molecular Structures of the *meso* and Racemic 2,3-Dibromobutanes[1]

BY D. P. STEVENSON[2] AND VERNER SCHOMAKER

The recent electron diffraction investigations of the structures of some ethylene halides by Beach[3] and co-workers have provided considerable information regarding the magnitude of the repulsive forces acting between halogen atoms attached to adjacent carbon atoms. In order to extend the work of Beach to the study of the interactions of the methyl group with other methyl groups and with bromine atoms attached to adjacent carbon atoms, *meso* and racemic 2,3-dibromobutane were selected for electron diffraction investigation. It was hoped that the quite different chemical properties of this pair of molecules[4] might result from an appreciable difference in the relative orientations of the "isopropyl bromide" groups about the 2,3 carbon–carbon single bond, inasmuch as these molecules would be expected to show structural differences in only this respect.

Experimental.—The *meso* and racemic 2,3-bromobutanes used in this research were portions of samples prepared for another investigation.[5] It was estimated by Dr. Winstein that neither compound contained more than 2% of the other and that both were otherwise very pure. Inasmuch as the racemic and *meso* compounds are structurally very similar, such a quantity of one in the other would have no effect on the electron diffraction photographs.

The electron diffraction apparatus used in this investigation has been described by Brockway.[6] The wave length of the electrons, determined in the usual way from transmission photographs of gold foil, was 0.0611 Å. Photographs were taken with two camera distances, 10.86 and 20.21 cm.

As the compounds are not very volatile (b. p. *ca.* 150°), it was necessary to use the high temperature nozzle[7] in order to obtain sufficient gas pressure. Photographs were taken with the liquid in the boiler at 100 to 130°.

Interpretation.—The photographs of each molecule showed 13 rings, and were practically identical qualitatively. Only small quantitative differences of doubtful reality were found. Curve C of Fig. 2, to be discussed below, gives a good representation of the appearance of the photographs. The observed values of $s\left(s_0 = \frac{4\pi}{\lambda}\sin\frac{\vartheta}{2}\right)$ for the maxima and minima as well as the visually estimated intensities, I, are given in Table I.

Radial distribution functions[8] were calculated using the formulas

$$D(l) = \sum_n C_n \frac{\sin s_n l}{s_n l} \qquad (1)$$

$$C_n = f(I_n, s_n) \qquad (2)$$

The values of C_n were chosen in accordance with the recommendations of Schomaker[9] and are given in column 4 of Table I.

The curves of Fig. 1 are plots of the radial distribution functions calculated from the measurements of the maxima and the minima for the *meso* and the racemic compounds. The two curves for each compound are in satisfactory agreement with respect to the two peaks at ~2.8 and ~4.6 Å., the precise location being for the *meso*-maxima curve, 2.83 and 4.61 Å., the *meso*-minima 2.85 and 4.62, the racemic-maxima 2.82 and 4.58 Å., and the racemic-minima 2.87 and

[a] Calculated with C–Br = 1.91 Å., C–C = 1.54 Å., ∠C–C–C = 110.5°, ∠C–C–Br = 108.5° and "*trans*" configuration (Curve C).

4.60 Å. The pronounced peaks at lesser values of l are unreliable as is indicated by the disagreement between the two distribution curves calculated for each compound. For a model with tetrahedral angles, C–C and C–Br bond distances of 1.54 and 1.91 Å. (the covalent values),[10] respectively, and a "*trans*" configuration with respect to the bromines, the shorter non-bonded carbon–bromine distance is 2.82 Å., and the bromine–bromine distance is 4.57 Å. An increase of less than 1° in the carbon–carbon–bromine angle brings the calculated distances into agreement with those indicated by the radial distribution curves.

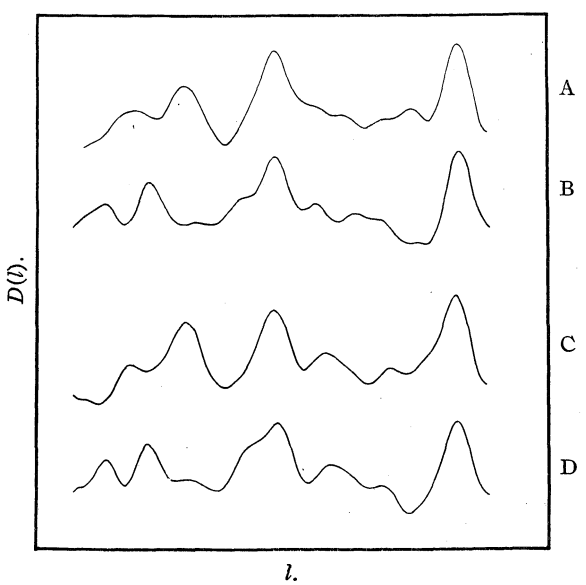

Fig. 1.—Radial distribution function $D(l)$ against l: Curve A, *meso*, maxima; Curve B, *meso*, minima; Curve C, racemic, maxima; Curve D, racemic, minima.

Three theoretical intensity curves were calculated using equation (3). The Z's are the atomic

$$I(s) = \sum\sum \frac{(Z_i - f_i)(Z_j - f_j)}{(Z_C - f_C)^2} \frac{\sin l_{ij}\, s}{l_{ij}\, s} \qquad (3)$$

numbers, the f's the atomic scattering factors,[11] and the l_{ij}'s the interatomic distances involving the i^{th} and j^{th} atoms. It was assumed that the ends of the molecule are like isopropyl bromide[12]

(10) L. Pauling and L. O. Brockway, THIS JOURNAL, **59**, 1234 (1937); H. A. Levy and L. O. Brockway, *ibid.*, **59**, 1662 (1937).

(11) L. Pauling and J. Sherman, *Z. Krist.*, **81**, 1 (1932).

(12) J. Y. Beach and D. P. Stevenson, THIS JOURNAL, **61**, 2463 (1939).

with respect to angles and distances, and that the bromines are "*trans*" to each other, as is indicated by the radial distribution functions. Only one group of curves was calculated, since for the "*trans*" configuration there are, in $I(s)$, only unimportant terms which are different for the *meso* and racemic compounds. These terms, involving the methyl–methyl distances, have such small coefficients that they may be discarded without appreciably affecting $I(s)$. Furthermore, the terms involving hydrogen atoms, which are dependent on the orientation of the methyl groups with respect to their carbon–carbon bonds, were omitted because of their small coefficients and their undoubtedly severe temperature factors.

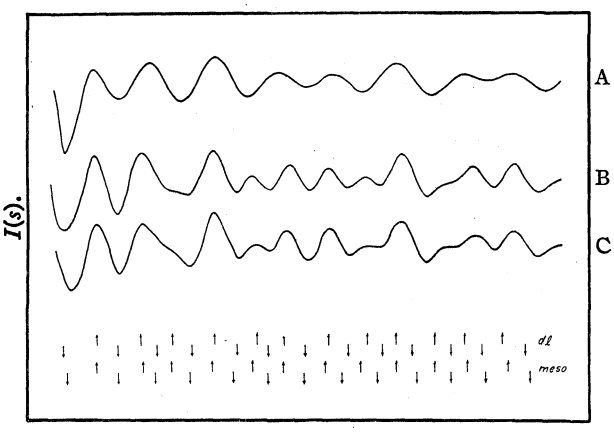

Fig. 2.—Theoretical intensity curves: Curve A, C–Br = 1.91 Å., C–C = 1.54 Å., C–C–C = 110.5°, C–C–Br = 108.7°. Terms dependent on rotational orientation omitted. Curve B, Curve A plus terms dependent on orientation, *trans* configuration. Curve C, Curve A plus bromine–bromine term, *trans* configuration.

In the calculation of curve A, Fig. 2, all of the terms which depend on the orientation about the 2,3-bond were omitted. Curve B includes these terms, with the exceptions indicated in the preceding paragraph. Curve C, which is in best agreement with the photographs, includes all the terms of B except that involving the bromine to methyl–carbon distance. The better agreement obtained when the methyl–carbon to bromine term is omitted indicates that the amplitude of libration is sufficiently large to make the temperature factor in the coefficient of this term severe, but that it is not large enough to cause an effective temperature factor in the coefficient of the bromine–bromine term. An average displacement of about 20 to 30° from the "*trans*" configuration is consistent with these observations.

Dielectric constant measurements[13] on liquid *meso* and racemic 2,3-dibromobutane show these molecules to have considerable dipole moments. This is possible only if the amplitude of libration is considerable, in agreement with the results of our investigation.

The quantitative comparison of the photographs with curve C is given in Table I. The agreement between the curve and the photographs of the racemic and *meso* compounds is quite satisfactory, indicating that the assumption of isopropyl bromide angles and distances is justified. Our final results are Br–Br = 4.60 ± 0.03 Å., C–Br = 2.83 ± 0.02 Å., ∠ C–C–Br = 109.5 ± 2°, C–Br = 1.91 Å. (assumed), C–C = 1.54 Å. (assumed), ∠ C–C–C = 110.5° (assumed).

Discussion.—The results of the studies of the deviations of the bond angles from the tetrahedral value in substituted methanes[10b,12,14] may be summarized by the following set of inequalities, $R_{CH_3-CH_3} > R_{CH_3-X}$, $R_{X-X} > R_{X-H}$, R_{CH_3-H}, where R is the repulsion between the groups indicated by the subscripts and X represents a chlorine or bromine atom.

The data available at present are insufficient to set up a similar set of inequalities for substituted ethanes. On the basis of several fairly reasonable assumptions, however, it is possible to draw some conclusions regarding the interaction of nonbonded groups in substituted ethanes. We are interested in only that part of the total potential energy of an ethane-like molecule which depends on the internal rotation. This potential we regard as the sum of the interaction potentials of pairs of groups and a symmetrical three-fold potential similar to that of ethane. The three-fold potential drops out in any consideration of the relative energies of orientations differing by 120°. We designate the interaction potentials of the groups i and j in an ethane-like molecule for the two orientations of Fig. 3 by V_A and V_B and their differences $V_A - V_B$, by X_{ij}.

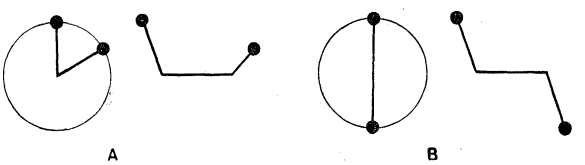

Fig. 3.

(14) R. E. Sutton and L. O. Brockway, THIS JOURNAL, **57**, 413 (1935); J. Y. Beach and D. P. Stevenson, *ibid.*, **60**, 475 (1938).

The heat contents of *meso* and racemic 2,3-dibromobutane are practically the same[15] and both molecules have the "*trans*" configuration; hence it follows that

$$X_{CH_3-CH_3} + X_{H-H} - 2X_{CH_3-H} = 0 \quad (a)$$

and from the results of Beach and Turkevich[3b] we have

$$X_{Br-Br} + X_{H-H} - 2X_{Br-H} > 2.5 \text{ kcal./mole}) \quad (b)$$

while from the "*trans*" configuration of racemic 2,3-dibromobutane

$$X_{Br-Br} + X_{CH_3-CH_3} - 2X_{Br-CH_3} > 0 \quad (c)$$

It is interesting to note that while additivity obtains for the X's involving methyl groups and hydrogen atoms, (a), it does not hold for the X's involving bromine atoms in substituted ethanes.

From equation (a) it follows that the three staggered configurations of *n*-butane have approximately the same energy, in agreement with the assumption of Pitzer.[16]

The authors would like to express their thanks to Dr. Saul Winstein of the Institute for the samples of the compounds used in this research, as well as for information regarding the properties and purity of the compounds.

Summary

From electron diffraction photographs it has been found that both racemic and *meso* 2,3-dibromobutane have "*trans*" configurations with respect to the bromine atoms, the bromine–bromine distance being 4.60 ± 0.03 Å. It has been shown further that a model for the structure of this pair of compounds, based on the known structure of isopropyl bromide, gives a theoretical scattering curve which is compatible with the photographs. Evidence for considerable torsional oscillation about the equilibrium "*trans*" configuration is presented.

The Homogeneous Decomposition of Ethyl Chlorocarbonate

BY A. R. CHOPPIN, H. A. FREDIANI AND G. F. KIRBY, JR.

Though a number of homogeneous decomposition reactions in the gas phase are reported in current literature, the number of such reactions which are not complicated as to order or mechanism is comparatively small. From a series of compounds which have been investigated in this Laboratory, ethyl chlorocarbonate was chosen for more complete study since it appeared to have the characteristics of a member of this somewhat select group. Ethyl chlorocarbonate was found to undergo homogeneous, unimolecular decomposition to ethyl chloride and carbon dioxide between 150 and 200°.

Experimental

The ethyl chlorocarbonate used in this series of experiments was obtained from the Eastman Kodak Company. The commercial product was purified as follows: 250 ml. of the substance was placed in a round-bottomed flask, fitted with a 90-cm. fractionating column and distilled. The first and last 100 ml. were discarded, the intermediate 50 ml. retained. This intermediate portion was refractionated. The first 20 ml. was discarded and the next 10 ml., having a boiling range of 0.01°, was used for study.

The thermostat employed had a capacity of five gallons (20 liters), was insulated with filter-cell set in a plaster of paris mold, and employed as a bath medium hydrogenated cottonseed oil circulated by means of a turbine stirrer. After a short period of use the oil darkened in color, cracking became less pronounced, and the bath was serviceable at temperatures as high as 250°.

Three specially wound resistance coils capable of a total heat input of 1200 watts constituted the permanent heater. In addition to this heating unit, two 250-watt hairpin type heaters were connected to the line through a 460-ohm rheostat to give a partial regulation of the heat input. These two sets of heaters were so adjusted as to maintain the bath within one degree of the desired temperature.

Exact temperature regulation was obtained by means of a 200-watt light bulb operated by the thermoregulator, which consisted of a Leeds and Northrup reflecting galvanometer connected to a platinum resistance thermometer through a Wheatstone bridge. The circuit was so arranged that light reflected from the galvanometer turned on the light heater at zero scale reading through a photoelectric cell. An unbalanced circuit through a resistance change in the platinum resistance thermometer caused the light to swing away from the cell a distance of 10 cm. for a change of less than 0.01°. The temperature of the bath was constant to 0.01°.

The reaction was followed by a static method in an all-glass system. Reaction vessels were constructed of

Pyrex glass, and the pressure was balanced through a diaphragm actuating platinum contacts, as described by Daniels.[1] Small bulbs containing the reactant were introduced through a side-arm and broken at the proper time by a glass enclosed, solenoid-operated hammer. A mercury relay was actuated by the completion of the diaphragm circuit. This relay was in turn connected to a power relay, the arm of which was placed opposite the tip of an automatic valve sealed into the outside system. Completion of the relay circuit by an unbalanced condition of the diaphragm resulting from a pressure increase inside the reaction vessel caused the arm of the power relay to tap the valve at a rate of about 300 times per minute, admitting air into the outside system. In this way automatic pressure regulation was secured by practically continuous balancing of the outside pressure with the pressure inside the reaction vessel. The changes in pressure were followed by means of a mercury manometer which fell smoothly during the course of a reaction. For experiments in which the initial pressure was 100 mm. or greater, a vertical mercury manometer reading to 0.5 mm. was used. In those experiments in which the initial pressure was below this value, a Fisher vacuum gage and a calibrated inclined mercury manometer were sealed into the line. Each of these gave pressure readings directly to an accuracy of 0.05 mm. of mercury.

The diaphragms employed in the system were flexed to a constant zero point before use. This required about half an hour of automatic flexing with a slightly reduced pressure inside the reaction vessel and the vacuum pump working only on the outside system.

Before use cells were boiled with cleaning solution, rinsed with fuming nitric acid and finally with distilled water. There was no opportunity for contact with stopcock grease, mercury or other foreign materials and no dead space correction was necessary.

To test the homogeneity of the reaction runs were made at the same temperature and approximately the same pressure with the unpacked vessel and with a vessel having an increased surface. The increase in surface was obtained by packing the vessel with ground glass, quartz or with glass wool.

A bulb of ethyl chlorocarbonate was chosen to give approximately the desired pressure and sealed into the side arm of the reaction cell. The vessel was evacuated to a pressure of 0.001 mm. of mercury, rinsed with nitrogen, and this process repeated several times. Pressures on each side of the diaphragm were equalized by drawing gas from the cell through a small side tube which was sealed off immediately preceding a run. After the final evacuation and sealing of the cell, the bulb of reactant was broken by the solenoid operated hammer and the bath quickly raised by means of a hydraulic jack to immerse the vessel. The initial pressure was taken as one-half the final constant pressure eventually reached and this value was checked against the value calculated from the weight of the sample and the volume of the cell, which was determined with distilled water.

The final products were analyzed for ethyl chloride gravimetrically and for carbon dioxide by means of a Fisher apparatus. In order to obtain large amounts of material for analysis, a special type of vessel was used. A sealed bulb containing from 0.1 to 0.5 g. of ethyl chlorocarbonate was introduced into the vessel, after which the vessel was rinsed with nitrogen and sealed. The bulb was broken by shaking and the vessel submerged in the thermostat. At the end of the time required for complete decomposition it was removed from the thermostat, packed in dry ice–acetone, and the ethyl chloride collected as a liquid. Silver nitrate was used to precipitate the chloride and the carbon dioxide was absorbed in 40% potassium hydroxide. The analysis of carbon dioxide was accurate within 2% and the more accurate gravimetric determination of chloride checked the theoretical within 0.5%.

No chemical evidence of products other than ethyl chloride and carbon dioxide has been obtained. No test for chlorine could be obtained upon allowing the decomposition products to come in contact with a potassium iodide–starch solution. Spectroscopic work being done on the compound at present should give a more positive answer as to the possibility of the presence of small amounts of substances other than those determined chemically. Typical examples of the data taken from chemical analyses of the products are shown in Table I.

Experimental Results

Since the only products of the reaction found by the analytical methods employed thus far are carbon dioxide and ethyl chloride, the equation for the reaction is

$$C_2H_5OCOCl = CO_2 + C_2H_5Cl$$

Since the decomposition of one mole of reactant results in an increase of one mole in the total number of moles of gases present, the pressure increase upon decomposition may be taken as directly proportional to the change in concentration of the reactant. Thus the concentration of undecomposed ethyl chlorocarbonate is given by the equation

$$p = 2P_1 - P_t$$

where P_1 is the initial pressure, P_t the pressure at any time t and p the partial pressure of undecomposed ethyl chlorocarbonate. The apparent simplicity of the reaction does not seem to be general for the chlorocarbonates.[2]

The curves obtained by plotting pressure against time are the typical log curves of a first order reaction. The number of these curves which have been plotted over the normal pres-

multiplied by 2.303 according to the conventional first order rate equation

$$-\log c = kt/2.303 + C$$

The values of the specific rate constant k determined by this method have been reported in Table II. The value of k_0 in this table was taken as the average value of the velocity constants of the high pressure runs.

The increase in the high pressure decomposition rate with temperature is shown in Fig. 4. The

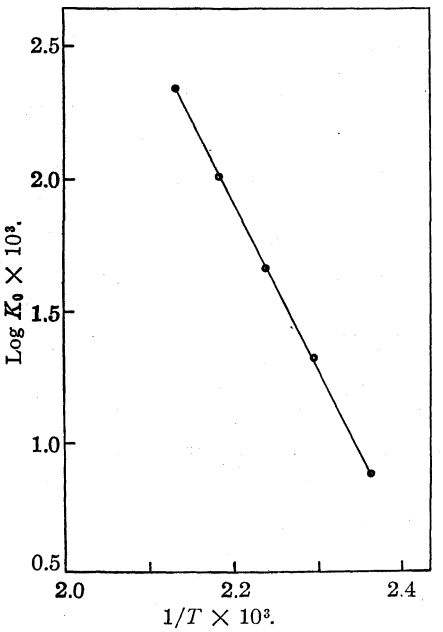

Fig. 4.

energy of activation calculated from the simple Arrhenius equation using this straight line is 29,410 cal. per mole. From this value are calculated the values of the frequency factor s in the expression $k = se^{-E/RT}$ as recorded in Table III.

TABLE III

T, °K.	423	448	468	478
$s \times 10^{-10}$	5.943	5.254	5.225	5.403

The rate of reaction, then, may be obtained from the equation

$$k = 5.5 \times 10^{10} e^{-29,410/RT}$$

The magnitude of s, while smaller than similar values obtained in most unimolecular reactions,[3] has been calculated over the active temperature range and an average value taken as suggested by Rice and Gershinowitz.[4]

that in experiments with t-butyl chloride much more reproducible results were obtained with coated walls. A similar effect has been reported by Daniels[6] in the decomposition of ethyl bromide. In view of the negligible influence of packing on the decomposition of ethyl chlorocarbonate, no appreciable surface catalysis was expected. However, pressure measurements of decomposition in clean vessels were observed to fluctuate slightly, with this effect disappearing and the pressure increasing smoothly after about two runs with the same vessel.

The exact effect of pressure[7] on the specific rate constant of unimolecular reactions is still

controversial. Recent statements by Pease[8] and Daniels[9] have shown that some investigators are far from satisfied with the present theories of quasi-unimolecular mechanisms. Reactions which throw light on this situation are still of great value, and the present series of experiments seems to have definite possibilities in this connection. The effect of pressure on rate has been studied at several temperatures, and more closely at 175°. The observed effects are shown graphically in Fig. 5 in which k is plotted against P_1. The fall off in rate has been found to begin appreciably above the expected value of about 40 mm.

The low pressure approach to a second order rate is demonstrated in Fig. 6. The reciprocal of reactant pressure has been plotted against time for several runs having initial pressures lower than 100 mm.

(8) Pease, *J. Chem. Phys.*, **7**, 749 (1939).
(9) Ref. 1, pp. 71, 72; ref. 5, p. 100.

The effect of foreign materials has been investigated quite thoroughly. An account of this effect will be published in the next paper of the present series.

Summary

1. Ethyl chlorocarbonate has been found to decompose homogeneously and by a unimolecular mechanism between 150 and 195° and over a pressure range from 10 to 700 mm. of mercury.

2. The specific reaction rate may be obtained from the equation

$$k = 5.5 \times 10^{-10} e^{-29,410/RT}$$

3. A slight effect has been observed in the comparison of runs in coated and uncoated vessels.

4. It has been found that at low pressures the rate constant falls appreciably and that the reaction approaches a second order rate.

Molecular Weight and Association of the Enzyme Urease

BY DAVID B. HAND

Introduction

The osmotic pressure of crystalline urease solutions corresponds to an average particle weight of 700,000[1] but the diffusion rate, when measured by activity, establishes the presence of active particles of 17,000 or less. Although much is known about the particle weights of proteins in general, there is yet no knowledge of the size of the smallest units which can exist with unaltered specific properties. In the case of the protein urease, it is possible to prove that smaller particles than those predominating in the solution possess enzyme activity.

Osmotic Pressure Measurements

An apparatus has been designed for measuring the osmotic pressure in a 1.0 ml. sample of solution. Even with these small volumes the expense and difficulty of obtaining the urease were considerable. The apparatus, which has proved convenient, is shown in Fig. 1. The collodion sack is mounted on the outer portion of a universal glass joint, thus making the filling of the sack very simple. Mineral oil is used as a manometer fluid and can be added through the side arm after the apparatus is set up. Equilibrium is reached rapidly since only 0.5 ml. of outer solution are needed. The details of the method are essentially those described by other workers.[2,3,4] Figure 2 gives the measurements of osmotic pressure which were made at pH 7.0 in 0.01 M citrate buffer and at pH 6.3 in 0.001 M phosphate. It is impossible to work nearer the isoelectric point of 5.0[5] or to increase the buffer concentration because of the lower solubility of urease under these conditions.[6] It was found that osmotic pressures were high in 0.001 M buffer due to unequal distribution of ions, but that this effect was repressed in 0.01 M buffer (see Fig. 3).

Mineral oil above both the inner and the outer solutions was allowed to rise in capillary tubes so that a value for osmotic pressure was obtained directly from the difference in the height of the oil in the two capillary tubes. The capillary tube for the outer solution is not illustrated in Fig. 1. The density of the oil was 0.842. In a typical experiment 32 lots of jack bean meal of 100 g. each were extracted with a total volume of 16 liters of 31.6% acetone by the method of Sumner and the urease allowed to crystallize. After centrifuging, washing and recrystallizing, the urease was dissolved in 4.0 ml. of water at 0°.

(5) Sumner and Hand, THIS JOURNAL, **51**, 1255 (1929).
(6) When the concentration of citrate is increased, the urease crystallizes in octahedra which are better defined and larger than those obtained with 32% acetone.

The clear solution contained 77.3 mg. of urease per cc. To 1.0 ml. of the urease solution was added 0.1 ml. of 0.1 *M* citrate buffer, *p*H 7.0. The osmotic pressure of this solution at 3° was found to be 4.1 cm. of oil.

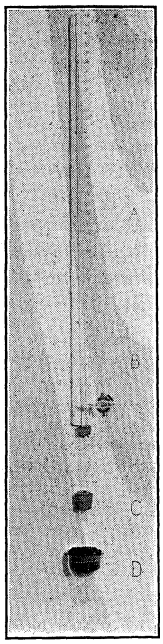

Fig. 1.—Osmometer for measuring osmotic pressure of protein solutions: A, scale and manometer tube; B, side tube for adding mineral oil; C, collodion sack mounted on interchangeable joint; D, outer vessel.

The curve for the variation of osmotic pressure with concentration of urease is not a straight line, so the calculation of particle weight has to be made by extrapolation. Particle weights are calculated from the osmotic pressure at the various concentrations and these values are extrapolated to zero concentration. When this is done the particle weight is found to be 700,000. This is a minimum value for the average particle weight depending on how completely the unequal distribution of ions was suppressed. The apparatus and method have been checked with hemoglobin which is known to be homogeneous with particle weight of 68,000.

Diffusion Measurements

The rate of diffusion of urease through a porous glass membrane was determined by the method of Northrop and Anson[7] as simplified by Dawson.[8] The urease was crystallized once and dissolved in 0.1 molar glycine, *p*H 6.0, to protect against destruction in the outer solution due to extreme dilution. The concentrations in the inner and outer solutions were determined by allowing aliquot portions to act on urea in phosphate buffer and then aerating off the ammonia into standard acid.[9] The rates of diffusion of oxyhemoglobin and hydrochloric acid were also determined with the same cell, for comparison with the urease and calculation of the cell constant. The diffusion of hemoglobin was measured colorimetrically by comparison of the outer solution with the original inner solution. Tables I, II, and III give the experimental data together with the calculated values of diffusion rate. For convenient calculation of diffusion coefficient the rate of diffusion was expressed in cubic centimeters of inner solution diffusing per hour.[7] The diffusion rate of the proteins decreased during the first two or three days, but then remained constant. The final value found for hemoglobin is in agreement with those of other workers using cells either with sintered glass membranes[7,10] or without membranes.[11,12]

No error is introduced by the fact that the diffusion rates of urease and hemoglobin decrease during the first few days in the diffusion cell since calculation of particle weight is made by comparison of the two proteins. Both

proteins behaved in the same way and the same value is obtained when either the initial or final rates of diffusion are compared. The decrease in diffusion rate was found not to be due to denaturing of the proteins because there was no measurable loss of native protein in the inner cell except that accounted for by diffusion. The decrease in diffusion rate was also shown not to be due to a progressive clogging of the pores during the experiment. No clogging of the pores occurred during the diffusion experiments. An independent measure of the clogging of the pores can be obtained from the rate of flow of solution through the membrane under a given hydrostatic pressure. During the flow of protein solution, but not during the diffusion, the pores become clogged so that the rate of flow for a given pressure becomes progressively slower. Even after the pores have been so completely clogged that the flow of liquid is practically prevented, the rate of diffusion through the cell is unchanged. Zeile[10] has reported a decrease in the rate of diffusion of hemoglobin during the course of the experiment and he has attributed this to a change in concentration gradient.

Calculations of diffusion coefficients are based on a value of 1.655×10^{-5} cm.^{2} per sec. for the diffusion coefficient of molar hydrochloric acid at 0°.[10,13,14,15] The diffusion coefficient of urease, when measured by activity, is 5.83×10^{-7} cm.^{2} per sec. and that of hemoglobin is 3.67×10^{-7} cm.^{2} per sec.

The diffusion rate of urease activity is thus 59% faster than that of hemoglobin under the same conditions. Particle weights of proteins calculated from diffusion by the Einstein equation[16] are larger than the true weights if the particles are hydrated or non-spherical. Polson has proposed a method for obtaining the shape of protein particles from viscosity data and has found, for all the proteins investigated, that the diffusion coefficients are about 0.7 as great as they would be for spherical particles and also that the hydration factor is approximately the same for all the proteins.[17] This relationship might reasonably be expected to hold for crystalline proteins which yield solutions of similar and comparatively low viscosity.[18] Insofar as these relationships hold, a very satisfactory value for the particle weight of a given protein can be obtained by comparison of the diffusion rate with that of some known protein such as hemoglobin. Particle weights are inversely proportional to the third power of the diffusion coefficients. The particle weight so obtained is equal to the weight of the diffusing particle only if the solution is homogeneous with respect to particle size. Otherwise the calculated value is somewhat larger than the smallest, most rapidly diffusing particle. Thus by comparison with hemoglobin it can be calculated that a maximum value for the weight of the diffusing particle of urease is 17,000.

The experiments described in this paper to determine the particle weight of urease[1] are not in disagreement with the later measurements of sedimentation and diffusion velocity[19] by Sumner, Gralén and Eriksson-Quensel in Svedberg's laboratory. It was shown by these workers that urease solutions (twice crystallized) could be prepared which consisted of two to five components. In all the solutions the component with particle weight 483,000 predominated. In the most homogeneous solutions all but 15% of the protein consisted of this component. For the urease solution containing five components of different particle weights, the relative amounts of the components and the activity of this preparation were not reported. No experiments were made to determine whether the enzyme activity was restricted to a single particle size.

Diffusion experiments with other enzymes have not indicated any dissociation or association of the particles. The diffusion rate for the activity is the same as the diffusion rate for protein material with pepsin[20] and chymotrypsin.[21] The results reported for catalase are uncertain. Stern's experiments[22] on the diffusion of catalase by activity measurements indicate a particle weight somewhere between 8500 and 500,000 with an average of 68,900, while Zeile finds a destruction of the catalase during diffusion.[10] By physical measurements the catalase particle is found to have a weight of 250,000.[23,24,26] In the case of horse antibody, Kabat[25] has reported that many lots could be prepared which were inhomogeneous in

amounts up to 65% of the total protein present. He found that the "degraded components" possessed antibody activity. Frampton and Saum have found that the particle weight of tobacco mosaic virus protein as determined from diffusion and viscosity is decreased in 6 molar urea solution to 100,000 without any decrease in biological activity.[27]

Discussion

Although it has been shown by the diffusion rate of urease that particles of a weight as low as 17,000 can carry the activity, it has not been proved that urease exists in this dissociated form at the time that it exerts its catalytic action. The particles may associate again under the conditions in which the activity is measured. Similarly the associated fractions, as separated in the ultracentrifuge, might dissociate in the test solution. There is no evidence to show that dissociation or association has any effect on the activity of urease. Incidentally, urease activity is determined in a solution which is very dilute with respect to protein and which contains 1.5% urea. Both of these conditions are known to be favorable to the dissociation of proteins.

However, in the case of enzymes other than urease, the conditions for measurement of activity might not be so favorable to complete dissociation. It is conceivable that the state of aggregation might have a considerable influence on the activity per gram. This may account for the enzyme preparations which have been reported to be more active than the same enzymes in crystalline preparations. Furthermore, a slow dissociation and association might well give rise to one or more forms of the same enzyme similar to the lyo- and desmo-enzymes of Willstätter.

The weight of the smallest particle of active enzyme is perhaps of more interest than the weight of the associated particles. Theoretically the aggregate dissociates by breaking very weak bonds under such influences as the presence of urea or a shift in *p*H. However, a final unit is reached which cannot be further dissociated except by breaking strong bonds, as for example by peptic or acid hydrolysis. Any further breakdown of this basic unit is accompanied by loss of enzyme activity. Although the term molecular weight has been justifiably applied to the aggregate, it probably would be less confusing to chemists if molecular weight referred only to the smallest particle still possessing enzyme activity, and the term associated molecular weight were used for the aggregates. For example, the molecular weight of acetic acid is 60, although it is known to associate. In this sense the molecular weight of urease is no greater than 17,000, and the average associated molecular weight is 700,000.

Acknowledgment.—The author is indebted to Professor J. B. Sumner for valuable criticism and advice during the course of the work; to Dr. J. S. Kirk for the synthesis of the glycine; and to Dr. S. F. Howell for the purification of the buffer solutions.

Summary

1. From the osmotic pressure the average particle weight of crystalline urease solutions is found to be 700,000.

2. From the rate of diffusion, particles with a weight as low as 17,000 are shown to possess urease activity.

3. There is no evidence to show in which form urease exists at the time that it exerts its catalytic action.

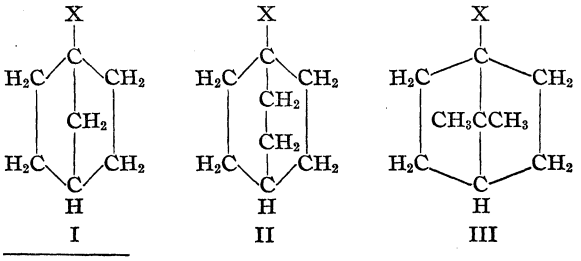
Bicyclic Structures Prohibiting the Walden Inversion. Replacement Reactions in 1-Substituted 1-Apocamphanes[1]

BY PAUL D. BARTLETT AND LAWRENCE H. KNOX

Many replacement reactions at a saturated carbon atom are known to proceed with Walden inversion, many with racemization, and a few with retention of configuration. Recent research has resulted in great emphasis on the first of these groups. Indeed, some workers in this field[2] have proposed that one negative substituent cannot replace another at a saturated carbon atom without a Walden inversion, and that retention of configuration in such a reaction necessarily means that two successive steps each involving inversion have occurred. The present work was undertaken to test this hypothesis of the universality of the Walden inversion with respect to the replacement of the amino group by hydroxyl and by halogen, and to the interchange of hydroxyl groups and halogen atoms in a saturated compound.

A derivative of bicyclo-[2,2,1]-heptane (I) or bicyclo-[2,2,2]-octane (II) with a substituent on the bridge-head is incapable of reacting by the currently favored mechanism of negative substitution with Walden inversion. In the first place, no negative ion or other nucleophilic reagent can approach carbon atom 1 from the side opposite to the substituent and get within bond-forming distance, because carbon atoms 3, 4, 5, and 7 or 8 form a cage around it. In the second place, the three carbon atoms directly bound to the bridge-head (carbons 2, 6, and 7) are not free to alter their positions as required for an inversion of configuration. Both these restrictions apply whether there is optical activity present in the system or not. Hence we may work with an optically inactive series of compounds and still be sure that the mechanism of reaction which, in optically active compounds, underlies the Walden inversion, is excluded.



I II III

Compounds of this type containing the readily replaceable amino or hydroxyl group or halogen on the bridge-head are exceedingly rare. As the most available starting material we have chosen 1-apocamphanecarboxylic acid (III, X = COOH), which can be prepared by the reduction of ketopinic acid by the Wolff–Kishner or, better, by the Clemmensen method as modified by Martin.[3] The yields by these two methods are 62 and 50%, respectively, of purified acid melting at 217–218°. The greater convenience of the Clemmensen procedure for large quantities offsets its slightly lower yield.

In conformity with the experience of Houben and Pfankuch[4] with dihydrocamphene-4-carboxylic acid, we found that the amide of 1-apocamphanecarboxylic acid, treated with methyl alcoholic alkaline solution of bromine, readily gave the Hofmann reaction to methyl 1-apocamphylcarbamate, obtained in 60% yield. This urethan melted, after recrystallization from petroleum ether, at 93–94°. Though quite resistant to hydrolysis, it could be converted in 82% yield into 1-apocamphylamine, m. p. 175°, by refluxing for forty-three hours with concentrated potassium hydroxide in methanol–water solution. The amine yielded an acetyl derivative, m. p. 132°, which could not be hydrolyzed by twenty-four hours of boiling with 8 *N* potassium hydroxide in 80% ethyl alcohol. Since N-*t*-butylacetamide proved similarly resistant, this property is not to be attributed to the special character of the apocamphane ring system.

Treatment of 1-apocamphylamine with four equivalents of sulfuric acid and two equivalents of sodium nitrite in concentrated aqueous solution resulted in a quantitative evolution of nitrogen and a 66% yield of an alcohol melting at 161–162° which we believe to be apocamphanol-1 on the basis of the following evidence. The analysis

for carbon and hydrogen is that of an apocamphanol. After standing for twenty-four hours at 25–30° with chromic anhydride in glacial acetic acid, it had produced no color change and the alcohol was recovered in 51% yield. The loss seems likely to have been manipulative, since a sample of only 0.115 g. was used in this experiment. This resistance to oxidation indicates a tertiary alcohol. In agreement with this, its esterification was very slow, the *p*-toluenesulfonate (m. p. 93°) being obtained in only 34% yield from the reaction of the alcohol with the acid chloride in anhydrous pyridine for twenty hours on the steam-bath.

In spite of being a tertiary alcohol, this compound dissolves reversibly and with no evidence of polymerization in concentrated sulfuric acid. A pale yellow color, which turns to red on standing, is produced in the solution but is discharged by the addition of water, which precipitates the original alcohol. This suggests that dehydration, and molecular rearrangements leading to it, are prohibited in this compound. This is what we should expect from Bredt's rule[5] and the considerations concerning rearrangements discussed later in this paper, if our alcohol is in fact apocamphanol-1 (III, X = OH). We have not succeeded in establishing this structure in any more direct way.

We attempted to replace the hydroxyl group of this tertiary alcohol with halogen by a number of standard methods, all with negative results. As was expected, 1-apocamphyl *p*-toluenesulfonate was recovered (in 91% yield) from refluxing with a saturated acetone solution of lithium iodide for twenty-three hours. This type of replacement reaction, when it occurs, always involves Walden inversion, and we tried this experiment merely for the sake of completeness. More surprising is the failure of thionyl chloride, which has been credited by Hughes, Ingold, and their co-workers[6] with the ability to replace certain hydroxyl groups by chlorine without the occurrence of any configurative inversion. On the addition of apocamphanol-1 to excess thionyl chloride, a vigorous reaction occurred, after which the mixture was refluxed on the steam-bath for fifteen hours. From the product, after pouring on ice, a white solid could be obtained, melting at 95–98°, which contained no halogen and which was slowly hydrolyzed to apocamphanol by dilute sodium hydroxide in 50% ethyl alcohol in the cold. This product was clearly a sulfite.

From the reaction of apocamphanol-1 with phosphorus pentachloride a white solid was obtained having the properties and composition of a loose molecular compound between two molecules of the alcohol and one of hydrogen chloride. Its melting point was not reproducible, ranging between 157 and 168°. It depressed the melting point of apocamphanol-1 slightly, but did not depress the melting point of camphor in an attempted molecular weight determination. This is consistent with the structure of an oxonium salt, insoluble in camphor. The proposed composition recalls the "dipinacol hydrobromide" of Ayers.[7]

The passage of gaseous hydrogen bromide into a petroleum ether solution of apocamphanol-1 deposited an oil which crystallized and yielded a product of melting point 83–84° which appeared to be the bromine counterpart of the hydrochloride just described. Water decomposed it immediately into hydrogen bromide and apocamphanol-1, as did mere standing in a desiccator over calcium chloride for several weeks. Its bromine content corresponded approximately to a diapocamphanol hydrobromide.

The treatment of N-apocamphylbenzamide with phosphorus pentachloride, a method successfully used by von Braun[8] for the conversion of an amine into a chloride, yielded only starting material and tars.

These experiments with apocamphanol-1 indicate clearly that this tertiary alcohol lacks a necessary structural feature for the direct replacement of its hydroxyl group by halogen. The obvious method remaining to be tried for the preparation of the chloride was the reaction between 1-apocamphylamine and nitrosyl chloride. The addition, in ether at −10°, of pure nitrosyl chloride to the amine resulted in a smooth evolution of nitrogen and a solid product which proved to be a mixture of the desired chloride with the alcohol, apocamphanol-1. This mixture could be separated completely by extraction of the petroleum ether solution with 95% sulfuric acid, which removed the alcohol. The resulting chloride was a white, very volatile, solid melting at 154–156°. Allowance being made for recovered amine, the yield of the chloride was 45%.

All attempts to replace the chlorine of 1-chloroapocamphane failed. After refluxing for twenty-one hours with 30% potassium hydroxide in 80% ethanol, 70% of the chloride was recovered unchanged and no apocamphanol could be obtained by a sulfuric acid extraction. The attack of the alkali upon the glass made the detection of small amounts of chloride ion impracticable. To escape this limitation an experiment was tried in which the chloride was refluxed with silver nitrate in aqueous ethanol solution for forty-eight hours. At the end of this time the solution was perfectly clear, with no opalescence, and 60% of the original 0.1-g. sample of chloride was recovered unchanged. All recovered products were identified by mixed melting points in these experiments. Taking the solubility product of silver chloride in this alcoholic medium to be the same as in water, a concentration of silver chloride as small as 2.4×10^{-10} should have been detectable by opalescence. If the concentration was less than this, then the bimolecular velocity constant (time in hours) for the reaction of silver nitrate with 1-chloroapocamphane is less than 1.7×10^{-10} at about 85°.

We were unable, by the use of ordinary dry ether and the usual methods and precautions, to prepare 1-apocamphylmagnesium chloride, but we are not ready to make this the basis of any theoretical conclusions.

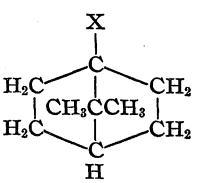
We then considered the possibility that some structural feature of the apocamphane derivatives other than location of the functional group on the bridgehead of a caged ring system might be responsible for the remarkable inertness of these compounds toward replacement reactions. One obvious suggestion is that the substituent X in Formula III, though on a tertiary carbon atom, has "neopentyl" character, that is, it is situated on a carbon atom which is adjacent to a quaternary carbon atom. Neopentyl alcohol is inert to ordinary methods of replacing the hydroxyl group, and the possibility is not to be ignored that apocamphanol-1 might owe some of its inertness to the same cause as neopentyl alcohol, whatever that cause may be. Accordingly we prepared *t*-butyldiethylcarbinol and its chloride (IV, X = OH and Cl) identical with III except for the replacement of two ring-closures remote from the functional group by four hydrogen atoms. This carbinol is converted into the chloride instantly by gaseous hydrogen chloride, and the resulting chloride reacts in ethyl alcohol–water much faster than *t*-butyl chloride. In 80% ethanol at 25° in eight hours, 98% of the possible hydrogen chloride has been liberated. We tried to estimate the amount of olefin formed in this reaction as was done by Hughes and his co-workers.[9] Unfortunately, in the present case variations in the time of the bromine titration produced continuous changes in the apparent fraction of olefin, up to well over 100% of the calculated. Evidently this nonene cannot be reliably titrated with bromine. There is, of course, a possibility that all the appearance of hydrogen chloride was due to elimination and none to direct replacement of halogen. However, this seems unlikely in view of the figures in Table I, where it appears that the actual rate of replacement is much greater in *t*-amyl than in *t*-butyl chloride despite the greater molecular size of the former. The experimental figures on these two chlorides are those of Hughes and his co-workers.

TABLE I

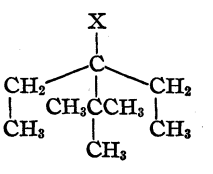
UNIMOLECULAR VELOCITY CONSTANTS AT 25° IN 80% ALCOHOL FOR THE FORMATION OF HYDROCHLORIC ACID (k_{HCl}) AND FOR SOLVOLYSIS (k_s) BY TERTIARY ALKYL CHLORIDES

Chloride	k_{HCl}	% Olefin in product	k_s
t-Butyl	0.0329	15	0.028
t-Amyl	.324	42	.19
α,α-Diethylneopentyl	.42	..	...

Another possibility to be reckoned with is that a rearrangement may have occurred in the reaction of nitrosyl chloride with 1-apocamphylamine. Past experience, and current theories, would not lead us to expect such rearrangements, and the behavior of our apocamphanol toward oxidizing and dehydrating agents seems to exclude them in its case. Nevertheless, it seemed well to make a comparison of the behavior of our chloroapocamphane with that of a similarly constituted and rather inert secondary chloride, bornyl chloride (V), which incidentally also contains a neopentyl system.

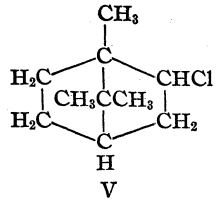


III



IV

(9) Hughes, Ingold and Shapiro, *J. Chem. Soc.*, 225 (1936).



V

At room temperature, in 75% (by volume) ethanol–water solution, neither bornyl chloride nor chloroapocamphane gave any hydrochloric acid. However, with silver nitrate, under the identical conditions of the negative experiment with chloroapocamphane, bornyl chloride lost 22% of its chlorine in five minutes and 84% in an hour. The latter figure corresponds to a bimolecular velocity constant (time in hours) for the reaction between silver nitrate and bornyl chloride of 11.25, thus certainly at least ten powers of ten greater than the corresponding constant for 1-chloroapocamphane. From all these experiments it appears that apocamphanol-1 and 1-chloroapocamphane are unique among known alcohols and saturated chlorides in their resistance to replacement of their functional groups, and that this uniqueness can be associated only with the location of these groups on the bridge-head of a bicyclic ring system.

Interpretation of Results

The reasoning out of which this work arose—that the Walden inversion is prohibited in replacement reactions among compounds of the type III—allows only positive results to be interpreted with certainty. We can now say quite definitely that no inversion, or series of inversions, need be involved in the Hofmann rearrangement of an amide or in the reaction of an amine with nitrous acid or nitrosyl chloride. All three of these reactions proceed as smoothly and rapidly when the Walden inversion is prohibited as when it is possible. It is still a question whether these reactions proceed by concerted intramolecular processes or through the intermediate formation of a practically free ion with its charge on carbon. In the case of the Hofmann rearrangement, such an ion, if formed, would carry a negative charge,[10] while the intermediate ions, if any, in the reaction of amines with nitrous acid and nitrosyl chloride would be positively charged. There are difficulties in both types of mechanism which are not resolved by the present work. In view of the considerations brought forward below, the purely intramolecular mechanism now seems the more probable for those cases of this reaction which proceed without inversion. This does not exclude the existence of a competing negative replacement reaction with inversion in compounds capable of inversion.

In the case of the reactions which fail to occur—reciprocal replacement of the hydroxyl group and halogen atom—the interpretation runs into complications. To be sure, the lack of any dehydration or elimination of hydrogen chloride is readily explained if we consider the large amount of strain which the formation of the resulting cycloolefin would necessarily entail. The impossibility of a double bond at the bridge-head of a bicyclo-[2,2,1]-heptane often has been discussed theoretically and supported experimentally.[11] Likewise, the failure of the system to rearrange into one capable of olefin formation can be correlated with the observation that the rearrangement of certain cyclic alcohols and chlorides is attended by inversion at the carbon atom originally holding the functional group.[12] The back side of carbon atom 1 in 1-apocamphanol can no more be attacked by a migrating radical or hydrogen atom than it can by an extraneous reagent, and hence the Wagner–Meerwein rearrangement is among the processes of which this compound is incapable.

With regard to the failure of replacement reactions in this alcohol and halide, the first explanation to present itself is that these reactions cannot proceed without Walden inversion, and that any racemization observed in them is ordinarily due to mobile inversions in the solvated cation (conjugate acid of the alcohol) reacting with the solvent. This may indeed be the correct explanation, but if it is it means the discarding of some very satisfactory features of the theory of the dual mechanism of solvolytic reactions of halides. Hughes and his co-workers have shown[13] that halides can be broadly divided into those in which the rate of replacement of the halogen atom by hydroxyl or alkoxyl is influenced by the concentration of the hydroxyl or alkoxyl ion, and which therefore react by a bimolecular mechanism, and those in which this rate of replacement is independent of the hydroxyl or alkoxyl ion concentra-

tion, and which therefore may be said to react by a unimolecular or pseudo-unimolecular mechanism. Both these mechanisms are presumably possible in all halides, and in certain cases the presence of both has been demonstrated. Now, any theory which makes the attack of a nucleophilic reagent on the back side of the halogenated carbon atom necessary to the occurrence of replacement thereby postulates that the bimolecular and pseudo-unimolecular mechanisms are exactly alike except that in the former case a strongly basic ion, and in the latter case a weakly basic solvent molecule, does the attacking. It seems out of all reason that the hydroxyl ion should be the most powerful reagent for a primary chloride, but the water molecule the most powerful reagent for a tertiary chloride, as is actually observed, if the fundamental mechanism is exactly the same in both cases. The insertion of other solvent molecules in the activated complex, some of which may have an acceptor, rather than a donor, function, does nothing to resolve this difficulty since it would seem that with any halide an activated complex involving a powerful donor in the position where a donor is needed should have a lower activation energy for reaction than an otherwise identical one involving a weaker donor in the donor position.

This difficulty is avoided completely if we may assume, with Hughes and Ingold, that in the unimolecular mechanism there is no donor molecule contributing at all to the energy of the transition state, but that the rate-determining step is entirely a "pull" which removes the halogen leaving a carbonium ion.[14] Such an assumption is consistent, though not uniquely so, with observations of the catalytic effect of acceptor ions and molecules on the solvolysis of halides.[15] To make this assumption compatible with the facts about 1-chloroapocamphane, what we need is some reason why the 1-apocamphyl positive ion cannot be formed while the *t*-butyldiethylcarbonium ion can be. In this direction we have one suggestion to make.

Evidence has long been accumulating that carbonium ions either have a permanently planar arrangement of the three bonds attached to the unsaturated carbon atom, or oscillate rapidly between what may be called the *d*- and *l*-tetrahedral configurations. Recent evidence from electron diffraction[16] has shown that in the molecule of trimethylborane the boron and carbon atoms all lie in the same plane. The boron atom in this compound is the nearest analog in a stable compound to the carbon atom with an open sextet, and the situation here suggests that a permanently planar arrangement is the only possible one for any carbonium ion. If this is so, then it is to be expected that the formation of the 1-apocamphyl positive ion will be attended by considerable strain. In order to bring carbon atoms 2, 6, and 7 of the bicyclo-[2,2,2]-octane ring system into the same plane with carbon atom 1 a total strain of at least 58°24′ would be distributed among three valence angles, and for the apocamphane ring system the strain would be considerably greater. A strain of 19°28′ per CH_2 group is present in cyclobutane, and a comparison of the heat of combustion of cyclobutane with that of cyclohexane gives 7.5 kcal. per methylene group as the approximate translation of this strain into heat units. This suggests that the energy of activation for the unimolecular solvolysis of 1-chlorobicyclo-[2,2,2]-octane (assuming the ionization mechanism) should be higher than that of an acyclic analog by at least $3 \times 7.5 = 22.5$ kcal. This corresponds to a factor of more than 10^{14} in the rates of reaction at 350°K. and hence is an important enough effect to take account of the experimental observations. Incidentally, this 22.5 kcal. is the same approximate amount by which such a bicyclic compound with a double bond at the bridge-head would be more strained than an isomer with the double bond in the 2-position. Bredt's rule is thus seen to embody a high degree of probability in thermodynamic terms.

There exists, therefore, an hypothesis which would reconcile our present results with the general theory of solvolytic reactions which postulates ionization of the tertiary halide as a rate-controlling step. The evidence for this hypothesis is obviously far from complete, but we feel that the absolute rates of solvolysis of the tertiary halides in alcohol–water mixtures are not without significance in this connection. When a model of *t*-butyldiethylcarbinyl chloride is constructed out of atomic calotte models according

(14) The semiquantitative arguments recently presented by Ogg (ref. 2) against this mechanism apply only to methyl and, less strongly, to ethyl halides. These and other primary halides, of course, are the very ones which *do not* hydrolyze by the unimolecular or pseudo-unimolecular mechanism in the presence of basic ions.

(15) For example, the work of Roberts and Hammett, THIS JOURNAL, 59, 1063 (1937).

(16) Levy and Brockway, *ibid.*, 59, 2085 (1937).

to H. A. Stuart,[17] even the most favorable orientation of the atoms seems to offer little opportunity for a solvent molecule to approach within bond-forming distance of the central carbon atom on the side opposite to the halogen. If this kind of participation of the solvent is necessary to solvolysis, we should expect this compound to occupy a position intermediate between *t*-butyl chloride and 1-chloroapocamphane with respect to its ease of solvolysis. Instead, it gives no indication that mere hindrance to the back side of the central carbon atom, unattended by restriction of the bond angles, is of the slightest inhibitory influence in the solvolytic reaction. Another case in point is that of dimesitylchloromethane.[18] It is impossible to make a Stuart model of a transition state in which both the chlorine atom of this compound and the oxygen of an alcohol molecule are within bond-forming distance, and on opposite sides, of the central carbon atom, assigning to the atoms their commonly accepted interference radii. Nevertheless, the chlorine of dimesitylchloromethane is replaced by alkoxyl as readily as would be expected in a substituted benzhydryl chloride. This case is free from the possibility of an olefinic intermediate. Thus the balance of the present evidence seems to us in favor of the ionization mechanism for the solvolysis of tertiary chlorides and its reverse reaction, with the carbonium ion having a planar arrangement of its central carbon atom with the three atoms attached to it.

Experimental

dl-**Ketopinic acid** was prepared by the direct oxidation of *dl*-camphor-10 sulfochloride. This eliminates a step in the procedure of Wedekind and Weindand[19] without loss in yield. The use of racemic camphor as the starting material is advantageous, as the racemic forms of compounds in this series have better crystallizing properties than the optically active forms. The camphorsulfochloride (100 g.) was added in three portions with stirring to 1000 g. of a 10% solution of sodium carbonate, heated on the steam-bath, together with the three corresponding portions of a hot solution of 100 g. of potassium permanganate in 600 cc. of water. Heating was continued for an hour, after which the excess permanganate and manganese dioxide were destroyed with bisulfite. Long needles of ketopinic acid separated when the clear solution was cooled. The remainder of the acid was obtained by ether extraction of the cold solution. Recrystallization from water yielded 28–32 g. of the pure acid (38.4–42.7% of the theoretical) melting at 233–234°.

Anal. Calcd. for $C_{10}H_{14}O_3$: C, 65.89; H, 7.75. Found: C, 65.95, 66.20; H, 8.21, 8.03.

The reduction of ketopinic acid to apocamphane-1-carboxylic acid was carried out by both the Wolff–Kishner method[20] and the method of Clemmensen as modified by Martin.[3] The latter method is preferable for working in quantity. From 50 g. of ketopinic acid the product, after four recrystallizations from water, amounted to 28 g. (60.4%) and melted at 217–218°.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.58. Found: C, 71.00; H, 9.53.

A mixed melting point with the acid obtained by the Wolff–Kishner method showed no depression.

Amide of Apocamphane-1-carboxylic Acid.—The acid (28 g.) was refluxed with thionyl chloride (80 g.) for one hour. After removal of the excess thionyl chloride under diminished pressure the acid chloride was taken up in dry ether and ammonia gas passed in. The yield of amide, after crystallization from ligroin, was 25.5 g. (92.1%). The melting point was 185°.

Anal. Calcd. for $C_{10}H_{17}NO$: C, 71.81; H, 10.23. Found: C, 71.67; H, 10.12.

Methyl 1-Apocamphylcarbamate.—To a solution of 7 g. of sodium in 385 cc. of methyl alcohol was added 25 g. of the amide. To the ice-cold solution 24 g. of bromine was added dropwise with stirring. The mixture was refluxed on the steam-bath for fifteen minutes, cooled, and diluted with a liter of water. A white solid precipitated which was separated by three extractions with 100-cc. portions of petroleum ether. After drying with anhydrous sodium sulfate and removal of the solvent, the urethan was obtained as an oil which crystallized on cooling. The yield was 8.3 g. (60.2%). Recrystallization from petroleum ether gave a product melting at 93–94°.

Anal. Calcd. for $C_{11}H_{19}O_2N$: C, 66.95; H, 9.71. Found: C, 66.97; H, 9.39.

1-Aminoapocamphane was obtained in 82.7% yield (8.5 g.) by refluxing the urethan (14.5 g.) with a solution of 50 g. of potassium hydroxide in 117 cc. of methyl alcohol and 33 cc. of water for forty-three hours. The product was isolated by diluting with water, extracting with petroleum ether, and purifying through the hydrochloride. The amine is very volatile and melts at 175° in a sealed tube.

Anal. Calcd. for $C_9H_{17}N$: C, 77.64; H, 12.28. Found: C, 77.69; H, 12.79.

The hydrochloride began to discolor at 235–240°, but did not melt below 320°.

N-Acetyl-1-apocamphylamine crystallizes from ligroin in long, slender needles melting at 132°.

Anal.[20a] Calcd. for $C_{11}H_{19}ON$: C, 72.88; H, 10.56. Found: C, 73.09; H, 10.79.

After refluxing 0.7 g. of this amide with 15 g. of potassium hydroxide in 25 cc. of 80% aqueous ethyl alcohol for twenty-four hours, we recovered 0.6 g. (85.7%) of the amide. There was an odor of the amine, but none could be isolated.

(20a) Starred analyses (*) were performed by H. S. Wight.

N-Benzoyl-1-apocamphylamine melts at 112° after crystallization from ligroin.

Trimethylacetamide, m. p. 154–156°, was prepared in 73.5% yield by the procedure of Whitmore and Langlois.[21]

***t*-Butylamine,** b. p. 46.4°, was prepared in 64% yield (as the hydrochloride) by the action of aqueous sodium hypobromite on the amide at 0°.

N-*t*-Butylacetamide, prepared from the amine and acetic anhydride, melted at 97°, was volatile with steam and very hygroscopic. A mixture of 25 cc. of a 25% aqueous solution of potassium hydroxide and 2.32 g. of the amide was heated to reflux in an apparatus with a trap for collecting vapors of the amine which might escape. After twenty and one-half hours 1.7 g. of the amide was recovered and 0.11 g. of *t*-butylamine hydrochloride was isolated from the trap.

Reaction of 1-Aminoapocamphane with Nitrous Acid.—In dilute solution no reaction of 1-aminoapocamphane with nitrous acid could be detected even on long standing at room temperature. In an experiment carried out at 80°, in which the nitrogen evolved could be estimated quantitatively, 0.0039 mole of amine hydrochloride was used, 0.0021 mole was recovered, and 0.0018 mole of nitrogen was evolved (calcd., 40.30 cc.; found, 40.00 cc., at S. T. P.). The apocamphanol-1 isolated from this experiment amounted to 0.0011 mole.

Apocamphanol-1.—To a solution of 5 g. of 1-apocamphylamine in 70 cc. of 10% sulfuric acid (five times the calculated amount) 5 g. of sodium nitrite (twice the calculated amount) in concentrated aqueous solution was added. When the vigorous reaction had abated, the reaction flask was warmed for ten to fifteen minutes on the steam-bath. After cooling, the product was isolated by ether extraction and recrystallization from petroleum ether. The yield was 1.58 g. (66.6% of the unrecovered material) of silky white needles melting at 161–162° in a sealed tube and subliming readily.

*Anal.** Calcd. for $C_9H_{16}O$: C, 77.03; H, 11.50. Found: C, 76.80; H, 11.44.

By making the mother liquor from the diazotization alkaline and extracting with ether, 2.63 g. of the free amine was recovered.

1-Apocamphyl *p*-toluenesulfonate, crystallized from 50% ethanol, melts at 93°.

*Anal.** Calcd. for $C_{16}H_{22}O_3S$: C, 65.27; H, 7.53. Found: C, 65.36; H, 7.52.

Behavior of Apocamphanol-1 toward Hydrogen Bromide.—Dry hydrogen bromide was passed into a solution of 1 g. of the alcohol in 75 cc. of dry ether, cooled in an ice-bath. Evaporation after half an hour yielded a yellow oil from which crystals slowly deposited. Both the oil and the crystals were insoluble in petroleum ether, but in contact with water a white solid was formed immediately which proved identical with the alcohol and amounted to 0.7 g.

In another experiment, hydrogen bromide was passed into a petroleum ether solution of the alcohol for two hours. After several hours of standing the oil which was at first deposited solidified. By decantation of the mother liquor the solid residue of brittle crystals was isolated. These fumed strongly in air and melted at 83–84°. A further crop was deposited slowly from the mother liquor.

Anal. Calcd. for $C_{18}H_{33}O_2Br$: Br, 22.14. Found: Br, 24.46.

The sample was stored in a desiccator over anhydrous calcium chloride. The melting point rose from day to day, and after several weeks it had reached 157–160° and this melting point was not lowered by mixture with apocamphanol-1. In contact with water, this alcohol was immediately produced, as shown by a mixed melting point.

Behavior of Apocamphanol-1 toward Phosphorus Pentachloride.—A solution of 1 g. of the alcohol in 40 cc. of petroleum ether (b. p. 20–40°) was treated with 2 g. of phosphorus pentachloride. The mixture was allowed to stand overnight in a glass-stoppered Erlenmeyer flask and was then washed carefully with ice water and the petroleum ether solution was dried and evaporated. Since we expected to get the chloride, the solid residue was next sublimed. The sublimed material melted unreliably between 157 and 168°.

*Anal.** Calcd. for $C_{18}H_{33}O_2Cl$: C, 68.21; H, 10.49; Cl, 11.19. Found: C, 67.79; H, 10.49; Cl, 11.04.

An attempt to determine the molecular weight of this substance by the Rast method was unsuccessful, since no depression of the melting point of camphor was obtained.

Nitrosyl Chloride.—Dry sulfur dioxide was passed for several hours into 150 cc. of fuming nitric acid cooled in ice. The resulting crystalline mass was freed of adhering liquid by suction filtration and stored in a desiccator over sulfuric acid. Equivalent amounts of this nitrosylsulfuric acid and sodium chloride were warmed gently and the nitrosyl chloride condensed in a U-tube surrounded by dry-ice. A stream of dry nitrogen was passed through this liquid to remove as much dissolved hydrogen chloride as possible. The nitrosyl chloride was stored in the dark.

1-Chloroapocamphane.—A solution of 5 g. of 1-aminoapocamphane in 100 cc. of dry ether was cooled below −10° in a 250-cc. three-necked flask fitted with a mercury-sealed stirrer, dropping funnel, and gas exit tube for collecting the gaseous products of the reaction over water. An ethereal solution of nitrosyl chloride was added dropwise until the orange-yellow color of the reagent persisted and nitrogen ceased to be evolved. The volume of nitrogen collected was roughly estimated at between 450 and 500 cc. When the reaction mixture had come to room temperature a little cold water was added to dissolve the amine hydrochloride precipitated by the hydrogen chloride remaining in the reagent. The ether layer was removed, dried, and concentrated. The yellow, semi-solid residue was taken up in 25 cc. of low-boiling petroleum ether and extracted with three 5-cc. portions of 95% sulfuric acid. The petroleum ether solution was then washed with cold water, dried with sodium sulfate, and concentrated. White crystals (1.7 g.) were obtained melting at 154–156°. Mixture with apocamphanol-1 depressed the melting point to 145–148°.

Anal. Calcd. for $C_9H_{15}Cl$: C, 68.13; H, 9.53; Cl, 22.35. Found: C, 67.71; H, 9.72; Cl, 21.95.

1-Aminoapocamphane (1.8 g.) was recovered from the aqueous extract from the original reaction by the addition of sodium hydroxide and extraction with ether. The yield

(21) Whitmore and Langlois, THIS JOURNAL, **54**, 3438 (1932).

of 1-chloroapocamphane, based upon the amount of amine consumed, was 45% of the theoretical. Its great volatility may have been responsible for some loss in isolation.

Attempted Hydrolysis of 1-Chloroapocamphane.—A solution of 0.096 g. of the chloride and 1.5 g. of potassium hydroxide in 5 cc. of 80% ethyl alcohol by volume was refluxed for twenty-one hours. The solution became discolored. It was diluted with water and extracted with several portions of petroleum ether. The aqueous extract was acidified with pure nitric acid and an excess of 10% silver nitrate solution added. A brownish opalescence was produced. After standing for thirty-six hours the mixture was filtered, yielding 0.0256 g. of solid having the appearance of discolored glass. This was digested with concentrated aqueous ammonia and again filtered. A colorless glassy precipitate remained, weighing 0.0221 g., which was evidently not silver chloride. These residues were dried at 120°. Acidification of the ammoniacal solution gave a precipitate weighing 0.0020 g. Extraction of the petroleum ether solution with concentrated sulfuric acid removed no organic matter which could be precipitated by dilution; hence no detectable amounts of alcohol or ether were produced. From the petroleum ether extract 0.067 g. of unchanged chloride was recovered, which depressed the melting point of the alcohol and not that of the chloride.

Behavior of 1-Chloroapocamphane toward Silver Nitrate.—A solution of 0.1 g. of the chloride and 0.54 g. of silver nitrate in 2 cc. of water and 7 cc. of absolute ethyl alcohol was refluxed for forty-eight hours. At the end of this time the solution was still perfectly clear, and remained free of opalescence on cooling to room temperature. By the usual procedure 60% of the chloride was recovered and its identity checked by mixed melting points with both pure 1-chloroapocamphane and apocamphanol-1.

Behavior of Bornyl Chloride toward Silver Nitrate.—A solution of 0.10 g. of bornyl chloride and 0.54 g. of silver nitrate in 2 cc. of water and 7 cc. of absolute ethyl alcohol was refluxed for a measured length of time and the precipitate of silver chloride collected on a sintered glass funnel and weighed. Three such samples were run for different lengths of time, with the following results.

Weight of bornyl chloride	Time of reflux, min.	Weight of AgCl	% reaction
0.10	5	0.0182	22
.1013	10	.0256	30
.1021	60	.0711	84

An approximate calculation of the bimolecular velocity constant k, neglecting any heterogeneous reaction or autocatalysis, on the basis of the sixty minute point, gives

$$k = \frac{2.3}{0.3542} \log_{10} \frac{0.3648 \times 0.0658}{0.0106 \times 0.420} = 11.25$$

time being expressed in hours.

2,2-Dimethyl-3-ethylpentanol-3 (*t*-butyldiethylcarbinol) was prepared from ethylmagnesium bromide and trimethylacetyl chloride, as described by Whitmore and coworkers.[22] The yield was supplemented by oxidizing the *t*-butylethylcarbinol produced in the reaction and treating the ketone again with the ethyl Grignard reagent. In the preparation of trimethylacetyl chloride use was made of the excellent method described by Brown.[23] The *t*-butyldiethylcarbinol, obtained in 22.9% yield from the direct reaction of Grignard reagent and acid chloride, boiled at 118–119.6° under 160 mm. pressure.

2,2-Dimethyl-3-ethyl-3-chloropentane.—Dry hydrogen chloride was passed into 20 g. of the carbinol at 0° until no further increase in the water layer was apparent. The water layer was then removed and the organic layer again saturated with hydrogen chloride. After washing and drying of the chloride it was distilled, giving 12.5 g. of colorless liquid boiling at 53–54° under 6 mm. pressure.

Anal. Calcd. for $C_9H_{19}Cl$: Cl, 21.97. Found: Cl, 21.54.

In an earlier preparation the distillation of the product under 150 mm. pressure yielded a considerable amount of olefin, boiling at 80.6–81° (150 mm.).

*Anal.** Calcd. for C_9H_{18}: C, 85.64; H, 14.36. Found: C, 85.09; H, 14.46.

Hydrolysis of the Acyclic Chloride.—A kinetic study of the hydrolysis at 25° in 80% ethyl alcohol by volume was carried out in order to have results comparable with those in the literature on other tertiary chlorides. The chloride (0.6220 g.) was weighed into a glass-stoppered Erlenmeyer flask and diluted to 50 cc. with the solvent, which had already been brought to temperature in a thermostat bath. Five-cc. portions were removed at suitable intervals, swirled with carbon tetrachloride, and the acid in the aqueous layer titrated with sodium hydroxide solution. The logarithms of the molar concentrations of the remaining chloride were plotted against time, yielding a fairly good straight line. From the slope of this line the unimolecular velocity constant was found to be 0.4206 (time in hours).

Summary

Apocamphane-1-carboxylic acid amide has been converted by the Hofmann reaction into 1-aminoapocamphane. Although the amino group is so situated that it cannot possibly be replaced in any reaction involving a Walden inversion, this compound readily reacts with nitrous acid to yield apocamphanol-1 and with nitrosyl chloride to yield 1-chloroapocamphane. This alcohol and chloride cannot be interconverted. The alcohol forms loose molecular compounds with hydrogen chloride and hydrogen bromide, while the 1-chloroapocamphane withstands forty-eight hours of boiling with silver nitrate in water–alcohol solution without producing any opalescence.

It is concluded from the reactions of the amide and amine that the Walden inversion, in which one negative substituent replaces another on the opposite side of the same carbon atom, is not a universal necessity for the occurrence of a "negative substitution" reaction.

(22) Whitmore, Meyer, Pedlow and Popkin, THIS JOURNAL, **60**, 2788 (1938).

(23) H. Brown, *ibid.*, **60**, 1325 (1938).

The inertness of the bridge-head hydroxyl group and chlorine atom may be interpreted as indicating either (1) that a Walden inversion is absolutely necessary in the replacement of these groups, or (2) that in a carbonium ion the central carbon atom and the three atoms forming bonds with it must be coplanar. Certain drawbacks to the former of these interpretations are pointed out.

Synthesis of α-2-Methoxyphenyl-β,β,β-triphenylethane

BY H. A. IDDLES, K. S. FRENCH AND E. F. MELLON

In 1932 Parsons and Porter[1] reported a synthesis of the methyl ether of α-2-hydroxyphenyl-β,β,β-triphenylethane (m. p. 172°) and used the product in establishing the probable structure for the methylation product (m. p. 172°) which they had prepared from Schorigin's[2] so-called "kryptophenol." Schorigin had obtained this rearrangement product as a by-product during the synthesis of triphenylmethyl *o*-tolyl ether and by a direct rearrangement of the ether when it was heated with metallic sodium. He postulated a structure, α-2-hydroxyphenyl-β,β,β-triphenylethane, from a somewhat analogous case in which benzyl *o*-tolyl ether was rearranged to give *o*-hydroxydibenzyl[2] by heating with metallic sodium. Van Alphen[3] also reported results on the preparation and rearrangement of this triphenylmethyl *o*-tolyl ether but gave no proof of structure of the product obtained.

However, the work of Boyd and Hardy[4] has questioned the unusual and special interpretation of Schorigin[2,5,6] which postulates the migration of the triphenylmethyl group to the side chain of *o*-cresol. They distilled the triphenylmethyl rearrangement products from the three cresols and phenol with soda lime, obtaining triphenylmethane in each case, and warmed each product with sulfuric acid, producing triphenylcarbinol. Consequently they conclude there is no evidence for postulating a different constitution for the ortho derivative.

To aid in clarifying these opposing points of view, further syntheses of "kryptophenol" as its methyl ether have been carried out. This seemed particularly desirable since the one direct synthesis of Parsons and Porter[1] has one unusual step in which the hydrolysis of the Grignard addition compound gave a hydrocarbon instead of the expected secondary alcohol.

For use in two separate syntheses, *o*-methoxybenzyl chloride was prepared by methylation of salicylic acid, electrolytic reduction to methoxybenzyl alcohol and treatment of the alcohol with thionyl chloride. In the first method the methoxybenzyl chloride was treated with triphenylmethylsodium in an atmosphere of nitrogen according to the procedure of Schlenk and Marcus,[7] who similarly produced unsymmetrical tetraphenylethane from triphenylmethylsodium and benzyl chloride. The product melted at 142–143°. In a second sequence a Grignard reagent was prepared from the *o*-methoxybenzyl chloride and this was coupled with triphenylchloromethane following an analogous reaction of Gomberg and Cone,[8] who reported an almost quantitative yield of unsymmetrical tetraphenylethane from benzylmagnesium bromide and triphenylchloromethane. The product in this case melted at 140–142° and there was no depression in a mixed melting point of the two synthetic products. However, neither agreed with the m. p. of 172° recorded by Parsons and Porter[1] for their synthetic product and a depression in melting point occurred when each of these synthetic samples was mixed with the methylated rearranged product of m. p. 162–163°.

The non-agreement between these synthetic samples and the methylated rearranged compound supports the interpretation of mechanism of Boyd and Hardy[4] which maintains that the original rearrangement of the triphenylmethyl group involves a ring position instead of the side

chain of *o*-cresol as first postulated by Schorigin.[2] Further work is in progress to determine the actual course of this rearrangement.

Experimental

Preparation of Rearranged Compound from *o*-Cresol.—Approximately the condensation method of Baeyer and Villiger[9] was followed in which 15 g. of triphenylcarbinol, 50 g. of *o*-cresol and 360 g. of glacial acetic acid were mixed and 75 g. of concentrated sulfuric acid was gradually added. After standing for two days or longer, an orange precipitate appeared whereupon the reaction mixture was poured into water. The crystals and oily layer were extracted with ether and this extract repeatedly washed with 10% sodium hydroxide solution. After drying and evaporation of the ether, the residue was taken up in ligroin (b. p. 70–90°) and this solution was extracted with Claisen's solution (equal parts of 50% aqueous potassium hydroxide and methyl alcohol). Upon acidification of the alkaline extract, the product precipitated and was purified by recrystallization from ethyl alcohol. The yields of colorless product (m. p. 182–183°) averaged 70%.

Preparation of Methyl Ether of Rearranged Compound.—Ten grams of the phenolic rearranged compound was suspended in a solution of 250 ml. of 2 *N* sodium hydroxide and 37.5 g. of dimethyl sulfate was added with constant stirring. After stirring for three or four hours, 10 g. of sodium hydroxide was added and the mixture was refluxed for one hour to hydrolyze excess dimethyl sulfate. The reaction mixture was then cooled, neutralized with hydrochloric acid, and the insoluble material filtered from the aqueous solution and dried. The dried solid was dissolved in a mixture of 10% ether and 90% ligroin (70–90°) and the solution extracted with Claisen's solution to remove unchanged phenolic compound. The residue from evaporation of the dried ether layer was recrystallized from alcohol, yielding 3.6 g. of product of m. p. 162–163°. Since 5.2 g. of unchanged phenol was recovered, this was a yield of 73%.

Anal. Calcd. for $C_{27}H_{24}O$: C, 88.97; H, 6.64. Found: C, 88.93; H, 6.66.

This product agrees satisfactorily with the product obtained by Boyd and Hardy[4] by two independent syntheses and to which they assign the m. p. 165°. However, there is considerable discrepancy between these two closely agreeing melting point values and that of 172° reported by Parsons and Porter,[1] who methylated by means of methyl iodide and silver oxide.

Preparation of *o*-Methoxybenzoic Acid.—One hundred grams of salicylic acid was methylated according to the directions of Graebe,[10] producing 98.6 g. or a 89.5% yield of methoxybenzoic acid, m. p. 96–98°.

Electrolytic Reduction of *o*-Methoxybenzoic Acid to *o*-Methoxybenzyl Alcohol.—The *o*-methoxybenzoic acid was electrolytically reduced according to the directions of Tafel[11] and Mettler.[12] *o*-Methoxybenzyl alcohol, 49.2 g., was recovered, boiling from 120–122° at 12 mm. pressure, a yield of 54.7%.

(9) Baeyer and Villiger, *Ber.*, **35**, 3013 (1902).
(10) Graebe, *Ann.*, **139**, 137 (1866).
(11) Tafel, *Ber.*, **33**, 2209 (1900).
(12) Mettler, *ibid.*, **39**, 2933 (1906).

Preparation of *o*-Methoxybenzyl Chloride.—*o*-Methoxybenzyl alcohol, 34 g., in 50 ml. of ether was dropped into 50 g. of concentrated hydrochloric acid in 50 ml. of ether according to Quelet and Allard.[13] From the reaction 27.5 g. of product was obtained, boiling at 111–113° at 14 mm. pressure.

Preparation of α-2-Methoxyphenyl-β,β,β-triphenylethane.—A Grignard reagent was prepared by adding 10.7 g. of freshly distilled *o*-methoxybenzyl chloride, dissolved in 300 ml. of anhydrous ether, to 1.58 g. of magnesium turnings. After refluxing and stirring for four hours, the solution was decanted from a trace of unreacted magnesium and a solution of 6 g. of triphenylchloromethane in 50 ml. of dry benzene was added. This mixture was refluxed for two hours, causing the formation of a yellow precipitate.

To prevent subsequent formation of triphenylcarbinol from the hydrolysis of any unreacted triphenylchloromethane with the resulting contamination of the product, 5 g. of zinc dust was added to the reaction mixture to form free triphenylmethyl. After filtering the solution from the zinc, oxygen was passed through the mixture, but no triphenylmethyl peroxide precipitated, indicating complete reaction of the triphenylchloromethane with the Grignard reagent.

The ether–benzene solution was then evaporated to dryness on the steam-bath, leaving a dark oil which was recrystallized from alcohol. Three grams of pure crystals was obtained, m. p. 140–142°. This material was not identical with the methyl ether prepared from the rearranged triphenylmethyl ether of *o*-cresol, m. p. 162–163°.

Anal. Calcd. for $C_{27}H_{24}O$: C, 88.97; H, 6.64. Found: C, 88.79; H, 6.68.

Reaction between Triphenylmethylsodium and *o*-Methoxybenzyl Chloride.—The triphenylmethylsodium was prepared by the method of Schlenk and Ochs[14] from 200 g. of 2% sodium amalgam and 10 g. of triphenylchloromethane suspended in ether and protected by an atmosphere of nitrogen. When the triphenylmethylsodium had formed, as evidenced by the deep red color, 5.6 g. of *o*-methoxybenzyl chloride, dissolved in ether, was added. The mixture was allowed to stand until the red color disappeared. It was aerated for several hours with dry air to convert any free triphenylmethyl to the peroxide, then filtered and the ether evaporated. A heavy viscous brown oil remained which, after recrystallization from alcohol, gave 4 g. Several recrystallizations gave 2.2 g. of colorless crystals, m. p. 142–143°. A mixed melting point proved this product was identical with that prepared by the Grignard reaction. It was not identical with the methylated rearranged compound.

Anal. Calcd. for $C_{27}H_{24}O$: C, 88.97; H, 6.64. Found: C, 88.48; H, 6.87.

Summary

1. α-2-Methoxyphenyl-β,β,β-triphenylethane, m. p. 142–143°, has been prepared by two direct syntheses. This compound is not identical with the methylated rearranged compound obtained

(13) Quelet and Allard, *Bull. soc. chim.*, [v] **4**, 1468 (1937).
(14) Schlenk and Ochs, *Ber.*, **49**, 608 (1916).

from rearrangement of the triphenylmethyl ether of *o*-cresol, m. p. 162–163°.

2. This study supports the evidence of Boyd and Hardy,[4] who conclude the migrating radical has not entered the side chain when triphenylmethyl *o*-tolyl ether undergoes rearrangement.

The Utilization of Aliphatic Nitro Compounds. (I) The Production of Amines and (II) The Production of Oximes[1]

BY KENNETH JOHNSON WITH ED. F. DEGERING

The nitroparaffins were studied by a number of investigators following their first production by Victor Meyer[2] in 1872. The preparation of these compounds, however, was such that not very large amounts were available for experimentation and in many cases the investigators were not very thorough. With the work of Hass, Hodge and Vanderbilt,[3] begun in 1930, a process was perfected whereby the paraffin hydrocarbons were nitrated directly, making the nitroparaffins available at a lower cost and in greater abundance. The possibility of industrial development of this process brought about renewed interest in the study of nitroparaffins and their derivatives and a broad investigation was begun. The work reported here is a part of that much larger work.

I. Reduction of Nitroparaffins to Amines

A number of investigators[3,4] have reported the reduction of nitroparaffins with different reagents and under different experimental conditions, but in every case the yields of isolatable products have been small.

(a) **Reduction with Iron and Hydrochloric Acid.**—After several preliminary experiments the following apparatus and procedure were adopted: a three-necked flask is equipped with a mercury-seal stirrer (motor driven) and a reflux condenser. A trap containing standard hydrochloric acid is arranged to absorb any amines which might pass through the condenser. To 35 g. of 40-mesh iron filings are added 75 ml. of water and 10 ml. of concd. hydrochloric acid. After the evolution of hydrogen has stopped, one-sixth of a mole of the nitroparaffin is added and, with rapid stirring, the mass is heated at 100° for thirteen to fifteen hours. The solution is then made alkaline and the amine distilled out into standard hydrochloric acid. The conversion is calculated from the amount of hydrochloric acid required for neutralization. In another series of experiments, 1 g. of ferric chloride was added to the reaction mixtures.

The reaction mixture was evaporated to dryness, and the hydrochlorides of the amines extracted with butanol. No ammonium chloride remained as a residue. The amine hydrochlorides were further identified by titration with silver nitrate, from which data the molecular weight was calculated, and by a Van Slyke determination of amino nitrogen.

(b) **Catalytic Hydrogenation.**—These nitroparaffins were also reduced with hydrogen to give yields of 92–98% of the theoretical, by dissolving 0.25–0.33 mole of nitroparaffin in 175 ml. of methyl or ethyl alcohol and treating with hydrogen in a Parr bomb under 6–110 atmospheres over 7.5 g. of Raney nickel[5] for two to five hours, at 40–50°, with rocking. The non-formation of ammonia and the identity and yields of the amines were established as in the reductions with iron and hydrochloric acid.

Other catalysts were studied, but the results were unsatisfactory.[6]

The following nitro compounds were reduced in this way: nitromethane, nitroethane, 1- and 2-nitropropane, 1- and 2-nitrobutane, and 1- and 2-nitro-2-methylpropane. Percentage conversions of 82–94% were obtained in the absence of, and 93–97% in the presence of, ferric chloride. The titration gave the calculated molecular weight with an average deviation of only 1% and with an extreme deviation of 2.3%, while the amino nitrogen was found in every case to be either the exact amount required by the formula or within 1% thereof.

II. Reduction of Nitroparaffins to Oximes

The partial reduction of primary and secondary nitroparaffins produces oximes.[7,8] A number of reducing agents were tried, but the procedure adopted is: to 100 ml. of glacial acetic acid and 15 ml. of 1-nitropropane, add 35 g. of zinc dust, stir, and reflux for six hours. Hydrolyze the oxime by adding 25 ml. of water, then 5 ml. of concd. sulfuric acid, and heating. Distil the aldehyde and

(8) Ponzio, *ibid.*, **82**, 334 (1902).

identify by its reaction with $H_2NOH \cdot HCl$. The conversion to aldehyde is 43%.[9]

Summary

All the nitroparaffins available from the nitration of propane, butane, and isobutane have been reduced to the corresponding amines by the use of iron and hydrochloric acid and catalytic hydrogenation. These processes produce good yields of easily purified products and require only simple technique. The results indicate that primary, secondary, and tertiary nitroparaffins can be reduced to give almost quantitative yields of the corresponding amines.

The conversion of nitroparaffins to oximes gives, in general, rather low yields because of the simultaneous formation of the amines.

Preparation and Cyclization of Monoacylethylenediamines. II

BY SAMUEL R. ASPINALL

It has been shown[1] that the best method of preparing 2-substituted-4,5-dihydroimidazoles is by dehydrating monoacylated ethylenediamines.

$$RCOOEt + NH_2CH_2CH_2NH_2 \longrightarrow RCONHCH_2CH_2NH_2 \xrightarrow{-H_2O} RC\begin{matrix}N{-}CH_2\\ \diagup\quad\ \diagdown\\ NHCH_2\end{matrix}$$

The investigation herein reported was undertaken to determine the extent of the applicability of this method. As a result of this and previous work[1] it is shown that an ester may be converted to the corresponding 4,5-dihydroimidazole in an over-all yield of about 75% when R is any one of such divergent groups as: CH_3—, C_2H_5—, *n*-C_5H_{11}—, $(C_2H_5)_2CH$—, (iso-C_5H_{11})$_2$CH—, C_6H_5—, *p*-$CH_3C_6H_4$—, or $C_6H_5CH_2$—. The yield of 2-diphenylmethyl-4,5-dihydroimidazole from ethyl diphenylacetate was considerably lower. Because reaction conditions for this series of experiments were more or less arbitrarily fixed in order to give comparable data, the yield reported for any given experiment is not necessarily the best obtainable.

Two slight changes in the procedure heretofore employed[1] have resulted in simplification and generally higher yields. (a) The reaction of ethylenediamine and esters of six or more carbon atoms which are branched in the alpha position requires higher temperatures than heretofore used. This effect is presumably due to the condition usually described as steric hindrance. (b) If the mixture of monoamide and diamide resulting from the reaction of ethylenediamine and an ester is treated in the usual way with lime, the yields are somewhat higher than those obtained by dehydrating the isolated monoamide with lime. This fact is in accord with earlier observations[2] that ethylenediamides yield some 4,5-dihydroimidazole when heated at a high temperature with acid binding materials.

A typical experiment is now carried out as follows: **2-diethylmethyl-4,5-dihydroimidazole.** Forty-eight grams (1/3 mole) of ethyl diethylacetate and 60 g. (1 mole) of ethylenediamine are heated at 215° for twenty-four hours, and the low boiling material consisting of ethyl alcohol and excess ethylenediamine removed at diminished pressure. The remaining 39 g. of monoamide and diamide is heated with 94 g. (5/3 mole) of calcium oxide at 225° for fifteen hours in an atmosphere of nitrogen. The organic products are extracted from the lime with alcohol, the solvent removed, and the product distilled at low pressure. 2-Diethylmethyl-4,5-dihydroimidazole, which distils as a pure white oil, solidifies immediately on cooling and is obtained as glistening white needles from petroleum ether.

It was earlier[1] pointed out that although the lower aliphatic monoacylethylenediamines are distillable under ordinary laboratory vacuum conditions, the corresponding aromatic derivatives are not, because the latter dehydrate to the 4,5-dihydroimidazole configuration at a temperature below that required for their distillation. It has now been found the behavior of the higher and phenylated aliphatic derivatives upon distillation is somewhat variable and depends upon structural features. (a) A higher aliphatic monoacylethylenediamine containing an alkyl group branched in the alpha position may be smoothly distilled at constant temperature to yield a distillate whose purity and homogeneity were demonstrated by quantitative conversion to simple derivatives. Presumably the steric factors which inhibit the initial reaction between the ester and

[a] Reported analytical results are the average of two determinations whose maximum absolute deviation from theoretical is less than 0.15%. [b] Picrates are made in the usual way in water, alcohol or dilute alcohol and recrystallized from alcohol or dilute alcohol. [c] All hydrochlorides are made by passing dry hydrogen chloride into an absolute alcohol–absolute ether solution of the base, and are recrystallized from absolute alcohol or absolute alcohol–absolute ether mixtures. All hydrochlorides are extremely soluble in water, warm alcohol and acetone. Insoluble in absolute ether. [d] Usually made in benzene and recrystallized from alcohol or acetone. [e] Reaction temperature, 100°. Isolated by solvent extraction. See Hill and Aspinall, THIS JOURNAL, **61**, 822 (1939). [f] Crude product. [g] Literature 38.8°, *ibid.*, **57**, 2424 (1935). [h] Literature 128°, *ibid.*, **57**, 2424 (1935). [i] The spaces so marked indicate that the hydrochloride is unsuitable for characterization because it is liquid or excessively hygroscopic. In these cases the hydrochlorides may be converted to well-defined chloroplatinates which may be accurately analyzed for platinum by ignition, provided extreme care is exercised to prevent spattering. The derivatives have no sharp melting points but char and melt with decomposition at a temperature dependent upon the rate of heating. A typical analysis: Calcd. for (iso-$C_5H_{11})_2CHC$  $\cdot{}^1/_2H_2PtCl_6$: Pt, 22.78; found 22.75. [j] Made in and recrystallized from petroleum ether. [k] This derivative apparently exists in dimorphic forms. When a sample is slowly heated there is a definite slight shrinking at 150° (corr.) after which no further change occurs until the sample melts sharply at 179° (corr.). If, however, a sample is introduced into a melting point bath at any temperature between 150 and 179° there is an immediate and complete fusion followed in a few seconds by an equally rapid and complete solidification, after which no change is evident until the sample permanently remelts at 179°. A sample once melted always remelts at 179°. [l] Undistillable. After extraction with alcohol 2-diphenylmethyl-4,5-dihydroimidazole was isolated as follows: the alcohol was removed the solid residue dissolved in dilute hydrochloric acid, boiled with charcoal, filtered, and reprecipitated with sodium carbonate. The white product so obtained was recrystallized from acetone.

ethylenediamine likewise prevent cyclization to the 4,5-dihydroimidazole configuration. (b) On the other hand, a monoacylethylenediamine derived from an ester containing five or more carbon atoms and not branched in the alpha position does undergo a slow dehydration at the temperature required to distil it at ordinary laboratory vacuum or if too high reaction temperature is used. When monocaproylethylenediamine is distilled, the temperature is originally at 135° (7 mm.), but slowly falls during the course of the distillation to 108° (7 mm.). The lower temperature is the boiling point of 2-*n*-amyl-4,5-dihydroimidazole and the higher temperature is probably the boiling point of monocaproylethylenediamine.[3] That dehydration proceeds during distillation was definitely proved by the fact that derivatives of both the cyclic and acyclic bases were isolated from the distillate.

The higher and phenylated aliphatic 4,5-dihydroimidazoles are well-defined white solids which may be recrystallized from petroleum ether, ethyl acetate or benzene. They react readily with picric acid, hydrogen chloride and phenyl isocyanate, although the derivatives formed are not suitable for characterization in all cases. The author is indebted to Miss Bettina Meyerhof for preparing some of the esters used in this work. Further investigations dealing with monoacylated aliphatic polyamines are in progress.

(3) The boiling point of any 2-alkyl-4,5-dihydroimidazole has been found to be invariably lower than the boiling point of the corresponding monoacylethylenediamine from which it is derived.

Summary

1. The preparation of 2-substituted-4,5-dihydroimidazoles from monoacylethylenediamines has been shown to proceed in excellent yields for many types of hydrocarbon substituents.

2. Refinements in previous experimental procedure have been introduced.

3. A study of the ease of dehydration of monoacylethylenediamines has been made.

4. The cyclic and acyclic bases prepared in this study have been fully characterized as picrates, hydrochlorides, chloroplatinates and phenyl ureas.

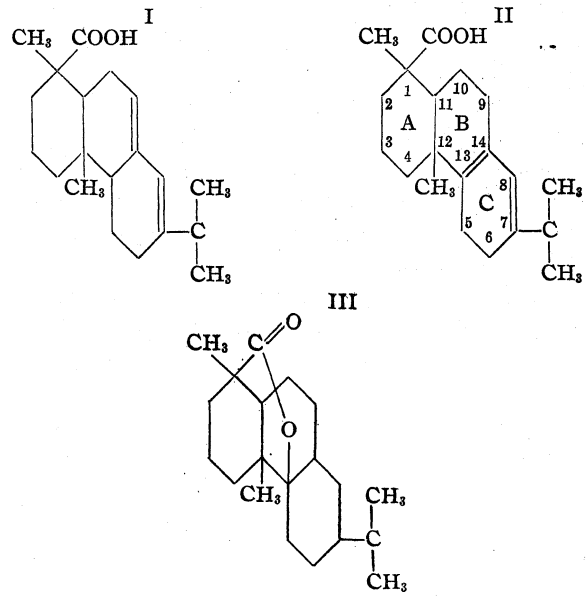
Lactonization of Dihydro-*l*-abietic and Dihydro-*l*-pimaric Acids

BY ELMER E. FLECK AND S. PALKIN

As is well known in the pine resin acid series, isolation of the individual isomers, because of pronounced isomorphism, is attended with considerable difficulty. Similar difficulties are encountered in isolating the individual isomers from dihydro mixtures obtained on hydrogenating *l*-abietic or *l*-pimaric acid. Thus there are reported in the literature dihydroabietic acids ranging from $[\alpha]_D$ −23 to +108°, and melting points of 141 to 218°, and dihydro-*l*-pimaric acids from $[\alpha]_D$ +24 to +35°, and melting points of 135 to 144°.

Ruzicka and co-workers[1] first showed that dihydroabietic acid, $[\alpha]_D$ −12°, m. p. 167–168°, may be converted with strong mineral acids into a completely saturated lactone, $C_{20}H_{32}O_2$. It has now been found possible to prepare this same lactone from the high-rotating dihydro-*l*-abietic acid, $[\alpha]_D$ +108°,[2] and from dihydro-*l*-pimaric acid, $[\alpha]^{20}_D$ +35°. This raises the question as to the identity of the dihydro acid shown to exist in pine oleoresin and in rosin,[3] since the dihydro acid was isolated as the lactone and therefore may be any one or a mixture of the three dihydro compounds shown to give this lactone.

Up to the present time there has been little evidence as to the point of lactonization in lactonized dihydroabietic acid. The C-10 position has been suggested[4] and seemed possible on the basis that the positions of the double bonds in *l*-abietic acid I are such that, on hydrogenation to the dihydro compound, lactonization could occur on the residual double bond in ring B, with the postulation of a shift to the 9,10-position, thus forming a five-membered lactone. There are, however, other possibilities for this lactone that appear more plausible.



l-Pimaric acid II[5] is now represented as containing a system of conjugated double bonds confined to ring C. *l*-Abietic acid I[5] is represented as having a conjugated system of double bonds distributed in rings B and C. An inspection of the structure of *l*-pimaric acid and *l*-abietic acid indicates the $\Delta^{13,14}$ for dihydro-*l*-pimaric acid, and $\Delta^{9,14}$ for dihydro-*l*-abietic acid, assuming hydrogenation to take place at the $\Delta^{7,8}$ position in both cases, that is, under the simplest possible conditions. A 1:4 addition to the conjugated system of either *l*-pimaric or *l*-abietic acid would produce a $\Delta^{14,8}$ dihydro derivative.

On saturation of one of the double bonds of either acid, formation of a series of isomeric dihydro-*l*-pimaric and dihydro-*l*-abietic acids which have the residual double bond in any one of the positions, 14,13, 14,9, 14,8 and 7,8 would seem quite possible.

It may be shown how the three possible positions of the double bond in dihydro derivatives

(14,13, 14,9, 14,8) might conceivably give rise to the same lactone at C-14, but this would necessitate an assumption of a 7-membered lactone. A more probable view would be lactonization at C-13, with formation of a six-membered lactone, such as shown in formula III. This is possible by assuming a shift of the double bond from the 9,14 or 8,14 to the bridge-head position, 13,14, a reasonable assumption, when these acids are under the influence of strong mineral acids. Lactonization on C-10, as previously suggested,[4] would, on the other hand, necessitate a much greater shift of double bonds, and hence becomes less probable.

An effort was made to obtain additional information on the point of lactonization by the preparation of typical derivatives and by oxidation experiments with tetrahydrohydroxyabietic acid obtained by hydrolysis of the lactone. Of the three possible points of lactonization two, C-9 and C-10, should yield secondary hydroxyl groups when the lactone is opened. Either of these should yield a ketone on oxidation. The third possibility, C-13, would give rise to a tertiary hydroxyl group and should be stable against oxidation. Actually, the oxidation experiments led to no ketone and, while such evidence would tend to support the assumption of a tertiary hydroxyl and consequently the C-13 position for lactonization, the weakness of such negative evidence is recognized. Moreover, the strong tendency of tetrahydrohydroxyabietic acid and even its methyl ester to lactonize further complicated the oxidation experiments and the attempts to prepare derivatives.

The tetrahydrohydroxyabietic acid was prepared by an improved procedure involving fusion of lactonized dihydroabietic acid III with potassium hydroxide and subsequent acidification of the reaction mass. This acid was methylated with diazomethane to obtain a crystalline tetrahydrohydroxyabietic methyl ester, m. p. 50–51°, $[\alpha]^{20}D$ + 21°. The methyl ester could be distilled unchanged and showed the usual stability against alkaline hydrolysis. In warm acetic acid, however, the methyl ester was rapidly converted into the lactone. All attempts to acetylate the methyl ester with acetic anhydride and sodium acetate, acetyl chloride and acetic anhydride gave only the lactone. No benzoate was obtained by the pyridine and benzoyl chloride method. Attempts to oxidize the methyl ester with chromic anhydride in acetic acid at room temperature and above yielded only the lactonized dihydroabietic acid. The hydroxy methyl ester was completely stable against potassium permanganate in acetone solution. Similarly alkaline potassium permanganate at room temperature for twenty hours did not materially affect tetrahydrohydroxyabietic acid.

Experimental Part

Lactonization of Dihydro-*l*-pimaric Acid.—One gram of dihydro-*l*-pimaric acid, m p. 144–146°, $[\alpha]^{20}D$ +35°,[6] was added to 10 cc. of concentrated sulfuric acid cooled to −5 to −10°. Stirring and cooling was continued for forty-five minutes. The light yellow-colored solution was poured on ice and the resulting mixture was extracted with ether. The ether solution was washed with water, then 0.25 *N* sodium hydroxide and finally with water until neutral to phenolphthalein. When the ether was distilled and the residue dried in vacuum at 80°, 1 g. of crystalline material was obtained that melted at 127–129°. The product when recrystallized from alcohol melted at 131–132°, $[\alpha]^{20}D$ −4°. *Anal.* Calcd. for $C_{20}H_{32}O_2$: C, 78.88; H, 10.60. Found: C, 78.91; H, 10.87. No depression of melting point was observed when this compound was mixed with lactonized dihydroabietic acid.[3]

Tetrahydrohydroxyabietic Acid from Lactonized Dihydroabietic Acid.—A solution of 0.3 g. of the lactone from dihydro-*l*-pimaric acid, in 10 cc. of 10% *n*-butyl alcoholic potassium hydroxide, was hydrolyzed as previously outlined.[2] The resulting acid melted at 164–165° with effervescence. When the melt was cooled and allowed to crystallize, it remelted at 130–131°. *Anal.* Calcd. for acid, $C_{20}H_{34}O_3$: C, 74.47; H, 10.63. Found: C, 74.48; H, 10.79. There was no lowering of the melting point when the acid was mixed with tetrahydrohydroxyabietic acid.

Lactonization of High-Rotating Dihydroabietic Acid Isomer.—Two cc. of concentrated sulfuric acid was cooled to −5 to −10° and 50 mg. of dihydroabietic acid, $[\alpha]D$ +108°,[2] was added. Stirring and cooling were continued for forty-five minutes. The reaction mass was poured on ice and worked up as described for dihydro-*l*-pimaric acid. Twenty-five mg. of neutral residue was obtained. Stout prisms were obtained from methyl alcohol that melted at 130–131°. No lowering of melting point was observed when mixed with authentic lactonized dihydroabietic acid. Owing to the small amount of material available and the difficulty involved in preparing more of the dihydro-isomer, no further characterization of the product was feasible.

Tetrahydrohydroxyabietic Methyl Ester.—Six grams of lactonized dihydroabietic acid was hydrolyzed with *n*-butyl alcoholic 10% potassium hydroxide.[2] The resulting tetrahydrohydroxyabietic acid was esterified with diazomethane in the usual manner. The methyl ester was crystallized as needles from methyl alcohol by slow addition of water. When dried in vacuum at room temperature the methyl ester melted at 50–51°, $[\alpha]^{20}D$ +21°.[6] *Anal.* Calcd. for $C_{21}H_{36}O_3$: C, 74.94; H, 10.79; OCH_3, 9.22. Found: C,

(6) The specific rotations recorded in this publication were all taken on 2% absolute alcoholic solutions.

74.92; H, 10.94; OCH_3, 9.20. The Zerewitinoff test showed 5.38% OH; calcd. for $C_{21}H_{36}O_3$, 5.06.

Saponification with 0.1 *N* sodium hydroxide in alcoholic solution for four hours at reflux temperature: Calcd.: 4.34 cc. of 0.1 *N* sodium hydroxide; found, 0.23 cc.

One gram of the methyl ester distilled at 175–180° at 2 mm. Found: C, 75.06; H, 10.92; OCH_3, 9.16.

Fusion of Lactonized Dihydroabietic Acid with Potassium Hydroxide.—Four grams of 88% potassium hydroxide was melted and heated to 200° in a nickel crucible. To this one gram of lactonized dihydroabietic acid was added. The mixture was stirred and the heating was continued for fifteen minutes. As the reaction proceeded the insoluble potassium salt separated as a white powder that floated on the surface of the caustic. The fusion mass was cooled and dissolved in 200 cc. of water and shaken with ether to remove any unchanged lactone. The alkaline solution was made acid to litmus with 10% acetic acid. The tetrahydrohydroxyabietic acid that separated as pearly plates was filtered and washed with water. When dried in vacuum the acid melted at 164–165° with effervescence and showed no depression with tetrahydrohydroxyabietic acid prepared by the *n*-butyl alcoholic hydrolysis. When the melted acid was allowed to cool and crystallize, it remelted at 130–131°.

Summary

Dihydro-*l*-pimaric acid and dihydro-*l*-abietic acid, $[\alpha]_D$ +108°, have been lactonized to form lactones identical with lactonized dihydroabietic acid.

Formulations for these dihydro compounds have been advanced to show how they may all yield the same lactone.

Oxidation and acylation experiments have been shown to indicate the C-13 position as a more probable point of lactonization than C-10.

A rapid method for hydrolysis of lactonized dihydroabietic acid by caustic fusion has been developed.

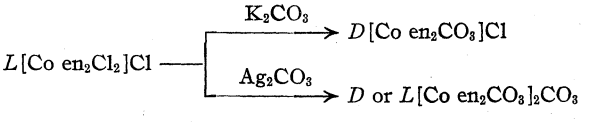
The Stereochemistry of Complex Inorganic Compounds. V. The Reaction of Carbonates with Dichloro-dipropylenediamine Cobaltic Chloride. A New Method of Determining Relative Configurations

BY JOHN C. BAILAR, JR., AND J. P. MCREYNOLDS[1]

The reaction of dichloro-diethylenediamine cobaltic chloride with potassium and silver carbonates yielded the first example of the Walden inversion in the field of optically active inorganic complex compounds.[2] Bailar, Jonelis and Huffman[3] found that either enantiomorph of the resulting carbonato compound could be produced by the action of silver carbonate, depending upon the conditions under which the reaction took place.



Mathieu[4] checked the Walden inversion reaction of Bailar and Auten[2] and from circular dichroism measurements came to the conclusion that the carbonato diethylenediamine cobaltic salt resulting from the use of potassium carbonate was the non-inverted form.

It was thought that the use of rotatory dispersion curves for closely related compounds might lead to valuable information in respect to this reaction. Lowry, Pickard and Kenyon[5] found that the rotatory dispersion curves for a series of secondary alcohols showed similarities as to dispersion ratios. The rotatory dispersion curves for a large number of diethylenediamine cobaltic complexes are given by Mathieu.[6] A comparison of these curves with those of analogous members of the di-levo-propylenediamine (*l*-pn) cobaltic series was undertaken as a method of attacking the Walden inversion problem.

Evidence has been presented to show that cobaltic complexes containing optically active diamines do not exist in all of the possible stereochemical forms, but only in certain preferred configurations. Hürlimann,[7] working with dinitrodipropylenediamine cobaltic compounds, could isolate only half of the calculated number of *cis* forms. Jaeger,[8] using active cyclopentylenediamine, observed the same result. He assigned

the structures $[Co_D(l\text{-cptd})_2X_2]^+$ and $[Co_L(d\text{-cptd})_2X_2]^+$ to the two isomers stable enough to be isolated. It was supposed from this that $[Co(l\text{-pn})_2Cl_2]^+$ and $[Co(l\text{-pn})_2CO_3]^+$ would each exist in only one form, so that the conversion of the former into the latter could not produce a Walden inversion. It has been found, however, that the carbonato salt can exist in both possible configurations. One of these is much more stable than the other, however, so the principle involved evidently can be used to determine configurations.

Upon comparison of the rotatory dispersion curves of *cis*-dichloro-diethylenediamine cobaltic chloride[6] and *cis*-dichloro-di-*l*-propylenediamine cobaltic chloride it was found that the general shape of the curves, the maxima, the minima and the points of zero rotation were essentially the same (Fig. 1). The absorption curves for the two

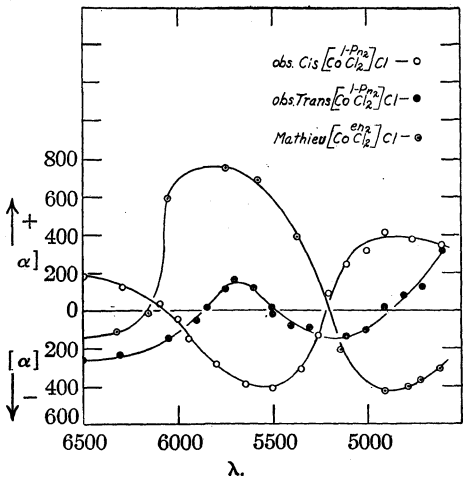

Fig. 1.

compounds (not shown here) were also found to be almost identical. Comparison of the rotatory dispersion curve for carbonato diethylenediamine cobaltic chloride[6] with those for the two diastereoisomeric forms of carbonato di-*l*-propylenediamine cobaltic carbonate shows one of these forms to give a curve very similar to that of the diethylenediamine compound while the other form shows a curve of markedly different characteristics (Fig. 2). The form of the carbonato di-*l*-propylenediamine complex which showed the marked dissimilarity as to dispersion characteristics was easily converted to the other diastereoisomeric form by heating in solution. Using Jaeger's convention[8] for the stable form, the starting material is assigned the structure $[Co_D(l\text{-pn})_2Cl_2]^+$, the more stable product $[Co_D(l\text{-pn})_2CO_3]^+$ and the less stable form $[Co_L(l\text{-pn})_2CO_3]^+$.

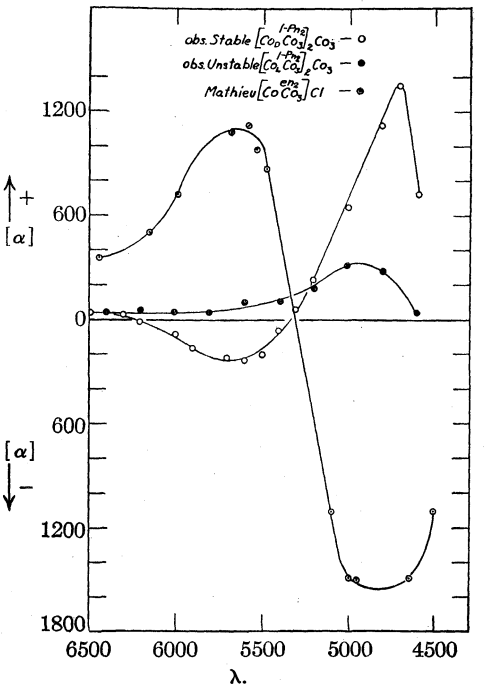

Fig. 2.

In the di-*l*-propylenediamine series the inversion can be brought about by either silver carbonate alone or potassium carbonate alone by varying the conditions under which the reaction is carried out. Under the conditions similar to those by which Bailar, Jonelis and Huffman[3] produced the inversion with silver carbonate alone, analogous results are obtained. With potassium carbonate alone they were unable to produce an inversion in the diethylenediamine series. In the di-*l*-propylenediamine series such an inversion is produced easily. The stable diastereoisomeric form is produced by either reagent when conditions are favorable for a slow reaction. The assignment of inverted and non-inverted forms in the diethylenediamine series as made by analogy with the di-*l*-propylenediamine series agrees with that of Mathieu.[4]

In the course of the preparation of the diastereoisomeric carbonato di-*l*-propylenediamine complexes an explanation of the apparent effect of large excesses of insoluble silver carbonate was found. In every case in which the unstable diastereoisomer was produced, it was observed that the change from the purple dichloro starting material to the red carbonato compound was ex-

tremely rapid, while in the cases in which the stable diastereoisomer resulted the change was rather slow. The *cis*-dichloro-di-*l*-propylenediamine cobaltic chloride undergoes aquation when allowed to stand in solution. This reaction proceeds at a fairly rapid rate, so that it seemed probable that the stable or non-inverted form resulted from a series of reactions. That this postulate was true was shown by allowing a solution of the dichloro-di-*l*-propylenediamine compound to stand until aquation was complete and then treating with silver carbonate. This procedure led to the production of the stable carbonato compound. The inverted form evidently is produced when conditions are such that the substitution of the carbonato group for the chloride ions in the complex proceeds directly, while the non-inverted form is produced by the stepwise displacement of chloride ions by water molecules and the subsequent displacement of the water molecules by the carbonato group.

Since this mechanism rests entirely upon the relative speeds of the aquation and the substitution reactions, the possibility of producing an inversion in the diethylenediamine series by the use of potassium carbonate alone was investigated further. It was found that the aquation rate in this series is more rapid than in the di-*l*-propylenediamine series and was markedly catalyzed by the addition of an alkaline reagent. To avoid the effect of an alkaline solution solid dichloro-diethylenediamine cobaltic chloride was ground with a large excess of dry potassium carbonate. After intimate grinding, water was added. The change to the carbonato compound was almost instantaneous and the product showed a rotation of opposite sign to that obtained by reaction with potassium carbonate in solution. This seems to substantiate the mechanism set up for the Walden inversion reactions discussed.

Experimental

Preparation of Compounds.—*l*-Propylenediamine was prepared by resolving commercial propylenediamine with tartaric acid by the method of Baumann[9] as modified by Bailar, Stiegman, Balthis and Huffman.[10] The dichloro-di-*l*-propylenediamine cobaltic chloride was prepared according to the directions of Bailar, Stiegman, Balthis and Huffman.[10]

The stable diastereoisomeric form of carbonato di-*l*-propylenediamine cobaltic carbonate was prepared by adding a 20% excess of silver carbonate to a solution of *cis*-dichloro-di-*l*-propylenediamine cobaltic chloride and allowing the reaction to progress slowly until no purple color remained and no more silver chloride was formed. The solution was then filtered and evaporated until a red waxy mass remained. This mass was dried by extraction with a mixture of equal parts of absolute alcohol and absolute ether. The resultant product was crystalline but was too soluble in water to be purified by recrystallization. The same product was also obtained by allowing a solution of dichloro-di-*l*-propylenediamine cobaltic chloride to stand for twenty-four hours (to allow aquation to proceed to completion) and then adding an excess of silver carbonate. After silver chloride ceased to be precipitated, the product was isolated as before. The stable diastereoisomer could be obtained with potassium carbonate only when the amount of potassium carbonate added was much below the theoretical amount needed to produce the carbonato carbonate. Best results were obtained when an amount just in excess of the theoretical amount to produce carbonato chloride was added to the solution. This product was not isolated from solution due to the fact that its great solubility prevented a successful separation from the potassium salts. The solutions resulting from all three methods gave specific rotations of $-170°$ when read in a 0.1% solution at the sodium D line.

The unstable diastereoisomeric form of the carbonato complex was prepared by adding the dry dichloro complex to a paste of silver carbonate with grinding. Best results were obtained by using an excess of at least five times the amount of silver carbonate necessary to produce the carbonato-carbonate and adding the dichloro compound in very small quantities over a period of an hour or more, with constant grinding. To isolate the compound it was necessary to filter out the silver chloride and evaporate the solution to a waxy mass at room temperature, since heating converts the product rapidly to the more stable form. The unstable form was prepared but not isolated by the action of an excess of potassium carbonate upon a solution of the dichloro complex.

Analyses for total carbon dioxide content were made upon the stable diastereoisomer obtained by the action of silver carbonate upon the fresh solution (no. 1), upon the stable diastereoisomer obtained by the action of silver carbonate upon the completely aquated solution (no. 2) and upon the stable diastereoisomer obtained by heating a solution of the unstable diastereoisomer (no. 3). These were carried out by displacing the carbonate radicals with hot sulfuric acid and absorbing the evolved carbon dioxide upon ascarite. Since the compounds could not be purified by recrystallization and the samples used were quite small, the checks obtained were not very satisfactory. For this reason the theoretical percentages for the other products which might reasonably be expected from such a reaction are included for comparison.

Anal. Found: CO_2, no. 1, 21.4; no. 2, 19.8; no. 3, 19.9. Calculated: $[Co(l\text{-pn})_2CO_3]_2CO_3$, 22.2; $[Co(l\text{-pn})_2(OH)H_2O]CO_3$, 14.5; $[Co(l\text{-pn})_2(OH)_2]_2CO_3$, 8.2; $[Co(l\text{-pn})_2(H_2O)_2]_2(CO)_3$, 19.7.

It seems quite improbable that the diaquo salt could be formed under the conditions used, for it is definitely acid. To establish this point definitely, however, samples

(9) Baumann, *Ber.*, **28**, 1179 (1895).

(10) Bailar, Stiegman, Balthis and Huffman, THIS JOURNAL, **61**, 2402 (1939).

of the stable isomer (prepared from the aquated dichloro salt and silver carbonate) and the unstable isomer, were analyzed for the ratio of ionic to non-ionic carbonate. Samples of about 0.5 g. were treated with calcium nitrite in excess. After standing for an hour the precipitated calcium carbonate was filtered out. The filtrate was heated on the steam-bath for several hours to effect the reaction

$$[Co(l\text{-pn})_2CO_3]^+ + 2NO_2^- \longrightarrow [Co(l\text{-pn})_2(NO_2)_2]^+ + CO_3^=$$

(which requires several weeks at room temperature), and the calcium carbonate was again filtered out. Making allowance for the slight amount of silver carbonate which goes into solution (determined by a blank) the ratios of ionic to non-ionic carbonate were found to be: stable isomer, 0.51; unstable isomer, 0.47; calculated, 0.50.

Rotatory Dispersion Curves.—The polarimeter readings for the rotatory dispersion curves were made with a Schmidt–Haensch polarimeter using an ordinary 1000-watt tungsten filament projection bulb as a light source. The wave lengths reported are not strictly monochromatic but represent an intensity average for a band of approximately 100 Å. obtained with a monochromator. All data represent an average of at least four readings and for the most part six or more readings were made. The polarimeter was scaled to read to 0.001° but the accuracy obtainable in this work was of the order of ±0.01° in the regions of high transparency and much less in the regions of high absorption.

TABLE I

cis-DICHLORO-DI-*l*-PROPYLENEDIAMINE COBALTIC CHLORIDE (FIG. 1)

The solution used contained 0.05 g. of complex in 100 cc. of water.

Wave length, Å.	Observed rotation, °	Specific rotation, °
6500	+0.09	+180
6300	+ .06	+120
6100	+ .02	+ 40
6000	− .02	− 40
5800	− .12	−240
5650	− .19	−380
5500	− .20	−400
5350	− .15	−300
5250	− .06	−120
5200	+ .05	+100
5100	+ .13	+260
5000	+ .16	+320
4900	+ .21	+420
4750	+ .19	+380
4600	+ .18	+360

Due to the rapid aquation of these compounds, it was found necessary to prepare a fresh solution for every four wave lengths, or at time intervals of about every thirty minutes. The readings above represent data taken upon at least two different solutions at each wave length.

In this series aquation did not affect the stability of the solution so that the same solution could be used for all the readings.

Extension of the Mechanism to Inversion of the Diethylenediamine Complex by Potassium Carbonate.—Forty grams of potassium carbonate was ground with 0.2830 g. of dry *l*-*cis*-dichlorodiethylenediamine cobaltic chloride for one and one-half hours. Sufficient water was then added to give a solution containing 0.1% of the carbonato complex. An immediate reaction took place giving a product which showed a rotation of −0.03°. Normally the potassium carbonate reaction leads to a dextro product if allowed to proceed through the aquation intermediate. The levo rotation indicated that the inverted form was produced in excess. To check the effect of the presence of such large excesses of potassium carbonate upon the rotation of the carbonato complex, a 0.1% solution of carbonato diethylenediamine cobaltic carbonate was prepared having a rotation of −0.24°. To 20 cc. of this solution sufficient potassium carbonate was added to give the same concentration as was used above. The resultant solution had a volume of 22 cc. and a rotation of −0.21°. The effect of the large excess of potassium carbonate is evidently very slight.

TABLE II

STABLE CARBONATO DI-*l*-PROPYLENEDIAMINE COBALTIC CARBONATE (FIG. 2)

Wave length, Å.	Observed rotation, °	Specific rotation, °
6500[a]	+0.04	+ 40
6300[a]	+ .02	+ 20

5400	− .04	− 80
5300	+ .03	+ 60
5200	+ .10	+ 200
5000	+ .32	+ 640
4800	+ .56	+1120
4700	+ .66	+1320
4600	+ .36	+ 720

[a] These wave lengths were read upon a solution containing 0.1 g. of complex in 100 cc. of water, the remainder upon a solution containing 0.05 g. of complex in 100 cc. of water.

TABLE III

UNSTABLE CARBONATO DI-*l*-PROPYLENEDIAMINE COBALTIC CARBONATE (FIG. 2)

Wave length, Å.	Observed rotation, °	Specific rotation, °
6400[a]	+0.04	+ 40
6200[a]	+ .06	+ 60
6000[a]	+ .04	+ 40
5800[a]	+ .04	+ 40
5600[a]	+ .10	+100
5400[a]	+ .10	+100
5200	+ .09	+180
5000	+ .16	+320
4800	+ .14	+280
4600	+ .02	+ 40

[a] These wave lengths were read upon a solution containing 0.1 g. of complex in 100 cc. of water. The other readings were made upon a solution containing 0.05 g. of complex in 100 cc. of water.

Summary

1. Two diastereoisomeric forms of carbonato di-*l*-propylenediamine cobaltic carbonate have been prepared by a Walden inversion method. The inverted form is unstable in hot water, being converted to the more stable non-inverted form.

2. Rotatory dispersion curves have been made for *cis*-dichloro-di-*l*-propylenediamine cobaltic chloride and for the two diastereoisomeric forms of carbonato di-*l*-propylenediamine cobaltic carbonate. By comparison of these curves with those for analogous compounds in the diethylenediamine series, it has been possible to determine which of the two carbonato forms is obtained by an inversion about the central cobalt atom in the latter case.

3. A mechanism for the production of the two forms of the carbonato complex has been advanced. The non-inverted form is produced through the preliminary displacement of the chloride ions in the *cis*-dichloro-di-*l*-propylenediamine cobaltic chloride by water molecules, followed by the displacement of the water molecules by carbonato groups. The inverted form is produced by direct substitution of the carbonato group for the chloride ions within the complex. It was found possible by varying the reaction conditions on the basis of this mechanism to produce either form with either silver carbonate alone or potassium carbonate alone. Further it was found possible to produce the inverted form of carbonato diethylenediamine cobaltic carbonate with potassium carbonate for the first time.

Kinetics of the Thermal Decomposition of Ethyl Formate

BY R. F. MAKENS[1] AND W. G. EVERSOLE

The vapor phase decomposition of ethyl formate in the absence of catalysts, other than the glass used as containers, has not been investigated extensively. Sabatier and Mailhe[2] found no appreciable decomposition when ethyl formate was passed through a glass tube at 400°. At 300° in a sealed flask the decomposition of this ester was reported by Engler and Grimm.[3] Hurd[4] states, "The esters with the general formula $RCOOCH_2CH_2R$ should decompose into free acid and olefin." If this explanation is correct, ethyl formate should yield formic acid or its decomposition products and ethylene. The gases found by Engler and Grimm[3] were in accord with this theory; however, the amounts of the various constituents which they found varied greatly from those required by the reaction. Sabatier and Mailhe,[2] Pearce and Wing[5] and others have shown that this reaction does not predominate in the presence of any one of several different catalysts. Sabatier and Mailhe[2] found that the vapors of formic esters may decompose in two ways

$$2HCOOC_nH_{2n+1} \longrightarrow HCHO + CO_2 + (C_nH_{2n+1})_2O \quad (1)$$

$$HCOOC_nH_{2n+1} \longrightarrow CO + C_nH_{2n+1}OH \quad (2)$$

This paper reports quantitative data on the thermal decomposition of ethyl formate. The data permit the calculation of the order of the principal primary reaction and its energy of activation. Evidence of the other associated reactions including those given above also is presented.

Experimental

Materials.—Ethyl formate (Eastman Kodak Co.) was dried and distilled in a packed column, and the resultant product was redistilled. It was found that the middle portion, which was the part used in the investigation, boiled at 54.20–54.26° (corr.). The density was d^{25}_4 0.9055 and the refractive index $n^{25}D$ 1.3582.

Apparatus and Procedure.—The apparatus, a modification of that used by Thompson and Frewing,[6] was of the static type. The reaction vessel consisted of a 220-cc. Pyrex flask. For the rapid removal of gaseous decomposition products a large Toepler pump was provided. Liquid products were condensed by passing through a carbon dioxide–acetone trap and subsequently allowing the temperature to reach −10°. The resulting vapor was added to the main gas sample, while the remainder of the liquid was analyzed by micro-methods. A mercury vapor pump backed by a Hyvac oil pump comprised the evacuation equipment. Pressures in the system were reduced

to 0.2 micron or less before each run. During a run the pressures were read on an ordinary manometer connected through a heated capillary manometer to the reaction flask.

The furnace was controlled to ±0.3° by a circuit described by Zabel and Hancox.[7] A modified Orsat apparatus equipped with a flushing manifold was used for the gas analysis.

Cleaning of the reaction flask was effected by hot concentrated nitric acid and water followed by drying and evacuation at 450°.

Results

The decomposition of ethyl formate was very slow at 300°. Two runs were made; one at an initial pressure of 39.05 cm. and one at 39.86 cm. In the first run the pressure increase in thirty hours was 2.83 cm. and the volume of gaseous products was 5.85 ml.; in the second run the pressure increase was 2.92 cm., and the volume of gaseous products was 5.70 ml. The same gaseous decomposition products were present at all temperatures. The liquid product gave a very weak aldehyde test with Schiff reagent. Fractional distillation of the liquid product according to Emich and Schneider[8] permitted the identification of ethyl formate and water.

At 375° the decomposition rate was satisfactory, but at 350° it was much too slow. Table I shows the data for two duplicate series of decompositions made without disturbing the reaction flask.

TABLE I

GASEOUS PRODUCTS FROM ETHYL FORMATE DECOMPOSITIONS AT 375°

$(a - x)$[b]	22.7	13.4	8.5	5.3	3.4	0.0

[a] Corrected for an average initial pressure of 38.3 cm. [b] Maximum volume of ethylene formed minus the volume formed in the time interval given.

The polymerization of ethylene to butylene, noted by Storch,[9] no doubt accounts for the presence of the higher unsaturates. Thus the total ethylene originally formed would equal the volume found plus twice the volume of higher unsaturates.

The production of ethylene conforms to a first order reaction as shown by plotting the logarithms of the values of $(a - x)$ in Table I against time. The liquid products contained ethyl formate, water, formic acid, and a small amount of some aldehyde. After distilling off and discarding the more volatile portion, the formic acid was identified in the residue by forming the cerous derivative and observing these crystals under crossed nicols.[10] The presence of an aldehyde was established by the use of Schiff reagent, which produced a weak reaction.

In like manner, without disturbing the reaction flask, two duplicate series of runs were made at 425°. The data reported in Table II are the average of these duplicate runs.

The production of ethylene at 425° conforms to a first order reaction as was shown in the previous instance. At 425° and at 375° the liquid decomposition products were also qualitatively identical. The specific velocity constants calculated from the data in Tables I and II are $K_{375°} = 0.824 \times 10^{-4}$ and $K_{425°} = 7.61 \times 10^{-4}$. The energy of activation calculated by substitution of these constants in the Arrhenius equation is 40,010 cal. The value of K from four duplicate runs made at 400° is 2.441×10^{-4}. Log K plotted against the reciprocal of the absolute temperature produces a straight line.

Preliminary work proved that the method of cleaning the reaction flask had a very decided effect on the rate of formation of carbon monoxide, carbon dioxide and hydrogen, but had no effect on the rate of formation of ethylene. This observation is in agreement with Hinshelwood, Hartley and Topley[11] who noted that the decomposition of formic acid varied with the nature of the glass surface. To avoid the difficulty the data were all obtained without disturbing the reaction flask.

Discussion

The principal primary reaction in the decomposition of ethyl formate produces ethylene by a reaction which is represented by the first order

equation. The greater part of the carbon monoxide and carbon dioxide must be produced by secondary reactions, as can be seen by an inspection of Fig. 1. (A similar curve is obtained by plotting the corresponding data from Table II.) Since the curves do not pass through the zero point, as shown by plotting according to the method of least squares, and since the final ratio of carbon monoxide and carbon dioxide to ethylene is greater than one, one or more minor primary reactions simultaneous with the principal primary reaction are present. The fact that the ratio of carbon dioxide to carbon monoxide was greater at the earlier stages of the decomposition suggests that at least one of these minor reactions produces carbon dioxide.

The reaction suggested by Hurd[4] in which the ethyl formate decomposes to form ethylene and formic acid is confirmed. Formic acid was identified in the liquid products; the production of carbon monoxide, carbon dioxide and hydrogen paralleled the decomposition of formic acid as observed by Hinshelwood, Hartley and Topley,[11] and by Nelson and Engelder.[12]

The minor primary reactions are probably those designated (1), (2) in this paper. Sabatier and Mailhe,[2] Senderens[13] and Pearce and Wing[5] have shown that these products are formed when ethyl formate is passed over various heated catalysts. These reactions and their secondary decomposition products account for the excess of carbon monoxide plus carbon dioxide over ethylene in the final runs, for part of the pressure change, for the small amounts of methane formed, and for the higher ratio of carbon dioxide to carbon monoxide in the shorter than in the longer runs.

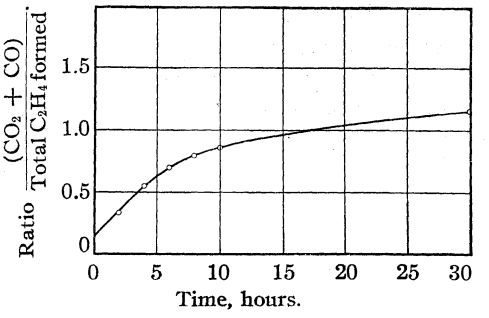

Fig. 1.—The ratio of carbon monoxide plus carbon dioxide to the total ethylene formed at 375°.

If the principal reactions continued to completion and if no other reactions were present, the pressure theoretically would be tripled and the ratio of carbon monoxide plus carbon dioxide to ethylene formed would be one. Several factors contributed to a pressure ratio lower than would be predicted by these assumptions. The dead space in the apparatus used was about 2.3%. This would alter the theoretical pressure ratio from 3.0 to less than 2.9 when calculated on the basis of the equation developed by Allen.[14] The minor primary reactions postulated would produce less than three moles of product per mole of ethyl formate. Figure 1 indicates that the decomposition of the formic acid may not have been complete; the acid reaction of the final liquid decomposition products supports this assumption.

Summary

1. The decomposition of ethyl formate has been shown to be very slow at 300°. At 375,

(12) Nelson and Engelder, *J. Phys. Chem.*, **30**, 470 (1926).

(13) Senderens, *Compt. rend.*, **196**, 979 (1933).

(14) Allen, THIS JOURNAL, **56**, 2053 (1934).

400, and at 425° the reaction rates were determined for the principal primary reaction. Evidence is presented concerning the other reactions involved.

2. The principal primary reaction is shown to be

$$HCOOC_2H_5 \longrightarrow C_2H_4 + HCOOH$$

This is followed by the decomposition of formic acid

$$HCOOH \longrightarrow CO + H_2O$$
$$HCOOH \longrightarrow CO_2 + H_2$$
$$2HCOOH \longrightarrow CO_2 + HCHO + H_2O$$

3. Evidence is presented that minor primary reactions occur, and the nature of these reactions is suggested.

4. Calculated from the present data, the energy of activation of the reaction producing ethylene is 40,010 cal.

Vapor–Liquid Equilibrium. IV. Carbon Tetrachloride–Cyclohexane Mixtures[1]

BY GEORGE SCATCHARD, S. E. WOOD AND J. M. MOCHEL

In the third paper of this series,[2] we showed that benzene–cyclohexane mixtures have an entropy increase on mixing which is larger than that of an ideal solution even at constant total volume, and which we attributed tentatively to some lack of randomness in at least one of the pure liquids. Since earlier calculations[3] had given no indication of such an effect for benzene–carbon tetrachloride mixtures, and since cyclohexane has an unusually small entropy of fusion, we have next studied carbon tetrachloride–cyclohexane mixtures. Although there is a slight excess entropy of mixing at constant total volume, it is less than a tenth of that for benzene–cyclohexane mixtures. Mixtures of cyclohexane with carbon tetrachloride agree with simple theory in every respect more closely than do those with benzene.

The cyclohexane was purified as in III. Merck C. P. carbon tetrachloride was refluxed for eleven hours with an aqueous solution 10% in potassium permanganate and 10% in sodium hydroxide. The carbon tetrachloride was distilled off, dried with calcium chloride and rectified in the column described in Paper III. The boiling points of the products and of the rejected portions were measured in a small Cottrell apparatus with a five-junction thermocouple. The normal boiling points, which should be used for relative values only, are:

	CCl_4	Product		76.69
Tops	75.93	76.54	76.67	76.69
Bottoms	76.72	76.69	76.68	
	C_6H_{12}	Product		80.73
Tops	79.29	80.41	80.69	80.68
Bottoms	82.64	80.99	80.74

The gas heater for the equilibrium still was replaced by an electrical heater with a Variac control which greatly increased the accuracy of the regulation of the boiling. To prevent direct radiation to the thermometer, the bottom of the glass still is painted with black stovepipe enamel which is renewed when necessary. A hood of aluminum foil is placed over the top of the still, and for temperatures of 60° or higher a shield of aluminum foil is placed around the still. This protection prevents the increase of material in the inner boiler during the runs at high temperatures, but does not affect the decrease during the low temperature runs.

The thermocouple was recalibrated from 60 to 100° as before by measuring the vapor pressure of water and determining the temperature from this pressure by the equation of Smith, Keyes and Gerry,[4] and the low temperature calibration was checked by a determination of the transition point of sodium sulfate decahydrate. Measurements of the vapor pressure of cyclohexane agreed with those with the gas heated still except at 30 and 35°. Apparently there had been radiation from the flame to the thermometer which cancelled out at those temperatures at which the calibration had also been carried out in the still. So the measurements for benzene at 30, 35 and 40° were repeated, and new equations were derived for cyclohexane and benzene. The equations are

$$CCl_4: \quad \log p_1 = 6.68148 - 1045.022/T - 99{,}577/T^2$$
$$C_6H_{12}: \quad \log p_2 = 6.65859 - 1040.641/T - 104{,}865/T^2$$
$$C_6H_6: \quad \log p_3 = 6.66457 - 1007.742/T - 116{,}197/T^2$$

($T = t + 273.16$.) The standard (root mean square) deviations are 0.5, 1.3 and 1.5 × 10^{-4}, respectively. The normal boiling point of carbon tetrachloride is 76.68₇°. Timmermans and Martin[5] give 76.75. The new boiling points of cyclohexane and benzene are 80.73₉ and 80.10₅°, which are 0.004 lower and 0.005° higher than our former values. The values of the vapor pressures of these three substances at rounded temperatures are given in Table II.

(4) L. B. Smith, F. G. Keyes and H. T. Gerry, *Proc. Am. Acad. Arts and Sci.*, **69**, 137 (1934).

(5) J. Timmermans and F. Martin, *J. chim. phys.*, **23**, 747 (1926).

The compositions were determined from the densities at 25°, which are given by the equation

$$d = (0.77383 + 0.81031\, z_1)/(1 + z_1 z_2/150) \quad (1)$$
$$z_1 = 1 - z_2 = 1/(1 + w_2 d_1/w_1 d_2) \quad (2)$$

in which w_1 is the weight of carbon tetrachloride, d_1 its density, and z_1 its volume fraction, and w_2, d_2 and z_2 are the corresponding quantities for cyclohexane. In Table I are given the weight fractions and mole fractions of carbon tetrachloride, the measured densities, the difference of these densities from those calculated by equation 1, and the measured values of $100V^M/V^0$. V is the volume of the mixture, V^0 that of the unmixed components, and $V^M = V - V^0$. From equation 1, it follows that

$$V^M/V^0 = z_1 z_2/150 \quad (3)$$

TABLE I

DENSITIES OF CYCLOHEXANE–CARBON TETRACHLORIDE MIXTURES AT 25°

Weight fraction CCl_4	Mole fraction CCl_4	Density	Deviation from eq. 1	$100V^M/V^0$

1.0000	1.0000	1.58414	.....	...

There is a systematic error in these results which corresponds to a loss of 2–4 mg. of the component first weighed out, and which we confirmed later as the approximate loss by evaporation between the two weighings. Since this corresponds to only 0.01–0.02% in the composition, it was not considered worth while to repeat these measurements with a different technique, but we have used equation 1 to determine the equilibrium compositions.

Vapor–liquid equilibrium measurements were made at intervals of approximately one-eighth in the mole fraction at 40 and 70° and for a single mixture, about 50 mole per cent., at 30, 50 and 60°. For mixtures containing more than 40% carbon tetrachloride, nitrogen replaced helium as the confining gas. The measurements at 40° are shown in Fig. 1, in which the curves are determined from equations 6, 7, 14 and 15 and the circles are the individual experimental points. The top curve gives the equilibrium pressure as ordinate and the liquid composition as abscissa. The curve just below it and the flagged circles have the vapor composition as abscissa, and the two lower curves are the derived partial pressures with the liquid composition as abscissa. The broken lines are the Raoult's law lines for the total and partial pressures *vs.* liquid composition.

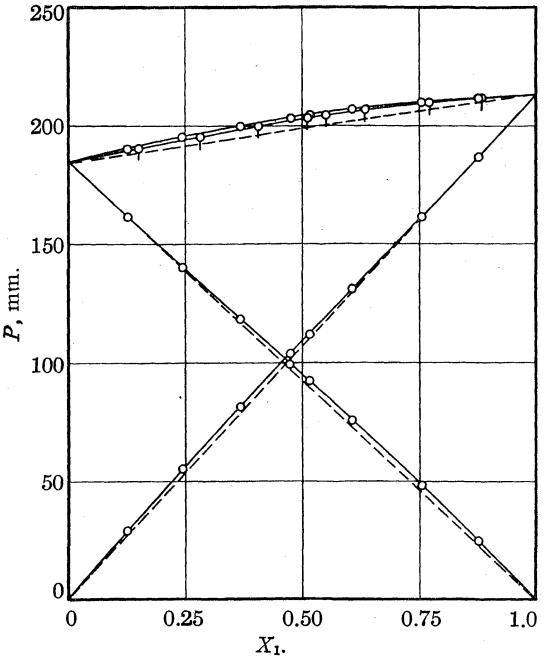

Fig. 1.—Vapor pressure *vs.* mole fraction for carbon tetrachloride–cyclohexane at 40°.

TABLE II

VAPOR PRESSURES OF PURE SUBSTANCES

Temp., °C.	Carbon tetrachloride, mm.	Cyclohexane, mm.	Benzene, mm.
30	141.55	121.60	119.16
40	213.34	184.61	182.70
50	312.04	271.80	271.34
60	444.28	389.29	391.66
70	617.43	543.95	551.03
80	....	743.27	757.56

The measurements are reported in detail in Table III as mole fraction of carbon tetrachloride in the liquid and in the vapor, equilibrium pressure, and the derived excess free energy of mixing. After each of the last three is given the deviation of the corresponding quantity from that calculated by equations 6, 7, 14 and 15.

After the measurements with mixtures there was a distinct odor of phosgene which was stronger from the condensate than from the liquid and which increased after each measurement. Therefore three approximately equimolal mixtures

were studied at 40 and at 70°. The first was the last of a series which included all those preceding it, the third was the last of a series which included all those following it run in the order opposite to that of the table, and the second was made up fresh from the components. The first and third check extremely well, and the deviations of the third are in opposite directions at the two temperatures. A test with *p*-dimethylaminobenzaldehyde[6] indicated less than 0.005% phosgene. This confirms the evidence from the equilibrium measurements that the effect of the phosgene is negligible.

In II it was shown[2] that, if the liquid and vapor volumes are given, respectively, by

$$V/(N_1 + N_2) = V_1x_1 + V_2x_2 \quad (4)$$

$$V'/(N_1 + N_2) = RT/P + \beta_1y_1 + \beta_2y_2 \quad (5)$$

the excess chemical potentials and other excess thermodynamic functions are given by

$$\mu_1^E = RT \ln Py_1/P_1x_1 + (\beta_1 - V_1)(P - P_1) \quad (6)$$

$$\mu_2^E = RT \ln Py_2/P_2x_2 + (\beta_2 - V_2)(P - P_2) \quad (7)$$

$$F_x^E = F^E/(N_1 + N_2) = x_1\mu_1^E + x_2\mu_2^E \quad (8)$$

$$S_x^E = -(\partial F_x^E/\partial T)_{p,N} \quad (9)$$

$$H_x^E = H_x^M = F_x^E + TS_x^E \quad (10)$$

in which N_1 and N_2 are the numbers of moles of the two components, x_1 and x_2 are the mole fractions in the liquid, y_1 and y_2 the mole fractions in the vapor, P is the vapor pressure of the solution, P_1 and P_2 are the vapor pressures of the components, V_1 and V_2 are the molal volumes of the liquid components, and β_1 and β_2 are functions of the temperature, each characteristic of one of the components. The effect on the subsequent equations of the deviations from equation 4 is entirely negligible, and the effect of deviations from equation 5 may probably be neglected.

For β_1 and β_2 we have used 0.9 the value calculated by the theory of corresponding states from the equation of Keyes, Smith and Gerry[7] for water vapor. The values for carbon tetrachloride are one-sixth to one-third larger than those measured by Eucken and Mayer,[8] but their measurements with carbon tetrachloride do not seem consistent with those on other gases.

These results may be expressed by the equations

$$F_x^E = (1.3335 - 0.0022916T)V_x^0z_1z_2 \quad (11)$$

in which $V_x^0 = x_1V_1 + x_2V_2 = V^0/(N_1 + N_2)$

$$H_x^M = 1.3335\ V_x^0z_1z_2 \quad (12)$$

$$S_x^E = 0.0022916\ V_x^0z_1z_2 \quad (13)$$

$$\mu_1^E = (1.3335 - 0.0022916T)V_1z_2^2 \quad (14)$$

$$\mu_2^E = (1.3335 - 0.0022916T)V_2z_1^2 \quad (15)$$

The calculated results from which the deviations in Table III are calculated are from equation 11 for F_x^E, and from the combination of equations 6, 7, 14 and 15 for P and y_1.

The constants are chosen to give the average of F_x^E at 40 and 70° and a linear variation of F_x^E with the temperature. The average deviation is 0.07% in y_1 and about 0.01% in P. Although the equation is simpler than that of III, the agreement is considerably better than in that paper. There is no indication that a more complicated function of the composition or of the temperature would be preferable. The solutions are far from regular. The ratio of the temperature coefficient of equation 11 to the constant term is 0.0017. The corresponding coefficient for benzene–cyclohexane mixtures is 0.0019.

For theoretical purposes we are interested in the mixing process at constant total volume.[3] We will designate the functions calculated for this process with a subscript $_v$, and the values measured at constant pressure with a subscript $_p$. We apply the equations as in III, using for the coefficients of thermal expansion and of compressibility and their ratio at 25°

$$\alpha_0 = 1.228(1 - 0.018z_2) \times 10^{-3}$$

$$\beta_0 = 1.10(1 + 0.009z_2) \times 10^{-4}$$

$$(\alpha_0/\beta_0) = 11.16(1 - 0.027z_2)$$

$(\mathrm{d} \ln \beta)/\mathrm{d}T = 0.0076$, which is its value for carbon tetrachloride as well as for benzene.

$$V_x^0 = 97.111/(1 - 0.10706z_2) \text{ cc./mole}$$

(6) L. Rosenthaler, *Pharm. Acta. Helv.*, **12**, 6 (1937).

(7) F. G. Keyes, L. B. Smith and H. T. Gerry, *Proc. Am. Acad. Arts and Sci.*, **70**, 319 (1936).

(8) A. Eucken and L. Mayer, *Z. physik. Chem.*, **B5**, 452 (1929).

Then at 25°

$$F^E = (V^0/2\beta)(V^M/V^0)^2$$

$$(A^E_v - F^E_p)_x = 0.004891 \times 97.111\, z_1^2 z_2^2/(1 + 0.009 z_2)(1 - 0.10706 z_2) \text{ cal./mole} \quad (16)$$

$$S^E_v - S^E_p = -V^M \alpha_0/\beta_0 + (V^0/2\beta)(V^M/V^0)^2\, \mathrm{d} \ln \beta/\mathrm{d}T$$

$$(S^E_v - S^E_p)_x = -0.001802 \times 97.111(1 - 0.027 z_2) z_1 z_2/(1 - 0.10706 z_2) + 0.0076(A^E_v - F^E_p) \text{ cal./mole °C.} \quad (17)$$

$$(E^M_v - H^M_p)_x = T(S^E_v - S^E_p)_x + (A^E_v - F^E_p)_x \quad (18)$$

In Fig. 2 are shown F^E_{px} at 25° and at 70° from equation 11, H^M_{px} from equation 12, and E^M_{vx} at 25°, calculated from H^M_{px} and equation 18. The difference between A^E_{vx} and F^E_{px} at 25° is less than half the width of the line, so the same curve may serve for both. TS^E_{px} is the difference between the top curve and the third, and TS^E_{vx} is the difference between the second curve and the third. This second difference is less than a quarter of the first, so three-quarters of the deviation from regularity is accounted for by the change in volume on mixing.

These mixtures are so nearly ideal that we should expect the deviations from random distribution to have a very small effect. Using, as in III, Kirkwood's equation[9] for this effect for a mixture of spheres of equal radii, each with eight nearest neighbors, and with the same value of E^M_{vx} for an equimolal mixture as for carbon tetrachloride–cyclohexane, 20.7 cal./mole, we obtain

$$E^M_{vx} = B_{12} x_1 x_2 - (B_{12}^2/4RT) x_1^2 x_2^2 \quad (19)$$

$$20.7 = B_{12}/4 - B_{12}^2/64RT$$

$$B_{12} = 84$$

$$E^M_{vx} - A^E_{vx} = (-84^2/8RT) x_1^2 x_2^2 = -0.09 \text{ cal./mole, when } x_1 = 0.5 \quad (20)$$

This effect is very small compared to the measured difference of +4.0 cal./mole.

The difference of 4 cal./mole is so small that it is well to consider the corresponding difference in the more familiar quantities which are directly measured. The effect on y_1 is very small and may be neglected. In an equimolal mixture the measured pressure is 2.63% greater than that calculated by Raoult's law at 40°, and 2.17% greater at 70°. This decrease of 0.46% would be only 0.18% if the solutions were regular. Of the remaining 0.28%, 0.22% is accounted for by the volume change on mixing, and there is only 0.06% left unexplained. However, our measurements are so precise that we believe that the uncertainty of this figure is less than 0.02% or less than one-third its value.

(9) J. G. Kirkwood, *J. Phys. Chem.*, **43**, 97 (1939).

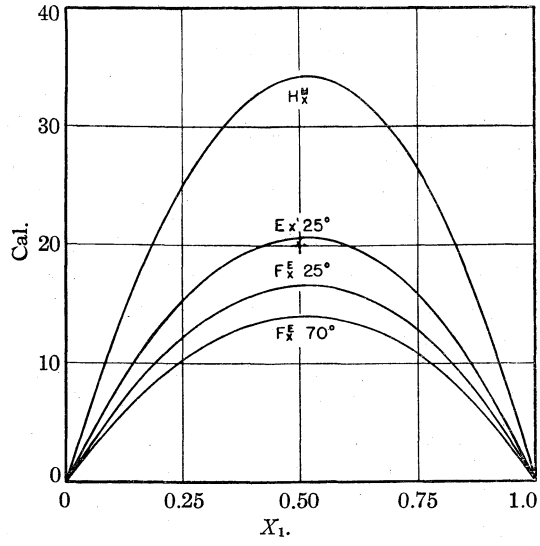

Fig. 2.—Various thermodynamic functions for carbon tetrachloride–cyclohexane.

We are particularly interested in the comparison with benzene–cyclohexane mixtures, for which the unexplained difference is 50 cal. per mole, or thirteen times as great as for carbon tetrachloride–cyclohexane. If the explanation is to be sought in incomplete randomness in one of the component liquids, not more than one-thirteenth is contributed by the cyclohexane unless there are compensating effects in the mixtures of cyclohexane with carbon tetrachloride. However, earlier measurements indicate that benzene–carbon tetrachloride mixtures are almost regular.[3] We are at present making further measurements on this system.

With the assumptions that the cohesive energy density, $a = (E - E_0)/V$, is equal to $-(\partial E/\partial V)_T$ and that S^E_v is zero, E^M_v may be computed from V^M and β by the equation

$$E^M_v = V^M/\beta \quad (21)$$

This leads to a value of 41 cal. per mole for an equimolal mixture, which is approximately twice as great as the directly determined value of 21 cal. per mole and is even larger than the heat of mixing at constant pressure, which is 34 cal. per mole. The absolute difference is not, however, so very great.

From the equations for the vapor pressures of the components, the equations for the deviations from the perfect gas laws, and the densities of the components at 25°, the cohesive energy densities of the components are calculated as $a_{11} = -72.96$ and $a_{22} = -66.54$. The assumption

that the mutual energy per unit volumes, a_{12}, is equal to $\sqrt{a_{11}a_{22}}$ leads to the result

$$E^M_{vx} = -(\sqrt{a_{11}} - \sqrt{a_{22}})^2 V^0_x z_1 z_2 \qquad (22)$$

For an equimolal mixture this yields $E^M_{vx} = 3.8$ cal. per mole instead of the measured 20.7. However, if we calculate $-a_{12}$ from the relation

$$E^M_{vx} = (2a_{12} - a_{11} - a_{22}) V^0 z_1 z_2 \qquad (23)$$

and the measured 20.7 for equimolal mixtures, we obtain $-a_{12} = 69.34$, which is only 0.5% less than $\sqrt{72.96 \times 66.54} = 69.67$. So, quadratic combination gives a very good approximation for a_{12}, and the small error is in the direction predicted by the quantum theory. The treatment of solutions makes too drastic demands for a simple theory in requiring a small difference between large numbers. On the other hand, measurements on solutions afford a correspondingly accurate measure of one of these quantities if the others are known.

Summary

The vapor–liquid equilibrium pressure compositions of carbon tetrachloride–cyclohexane mixtures have been measured at 40 and 70° over the whole composition range, and at 30, 50, and 60° for approximately equimolal mixtures. The densities have been determined at 25°.

These measurements have been expressed analytically, and corresponding equations derived for the thermodynamic functions, including the energy and entropy of mixing at constant total volume.

The dependence upon composition agrees with the predictions of the simple theory. The deviation from regularity is relatively large but most of it is explained by the volume change on mixing.

The unexplained entropy increase on mixing is only one-thirteenth as large as for benzene–cyclohexane mixtures.

Solutions of the Paraffin-Chain Sulfonic Acids as Colloidal Electrolytes

BY EVELYN LAING MCBAIN, WALTER B. DYE AND STEWART A. JOHNSTON

Colloidal electrolytes since their first recognition by McBain in 1913 have received steadily increasing attention, because of their interesting departures from the behavior of ordinary electrolytes and because they embrace such large groups of substances. The soaps originally studied do not lend themselves to precise examination in very dilute solution on account of the prominent effects of hydrolysis. It remained therefore for Lottermoser and Püschel[1] to show that in great dilution many non-hydrolyzable salts of alkyl sulfuric acids conform to the behavior of the Debye–Hückel theory, rather suddenly departing from it at a very low concentration designated, by Bury and collaborators, the critical concentration for micelles. This has been confirmed by many subsequent investigators, and necessitated a modification of the original formulation to conform more closely to later conceptions of interionic attraction. Different authors, however, differ in their formulations. It is desirable to have exact measurements of many different properties of a non-hydrolyzable pure material of simple chemical composition sufficiently soluble that it may be studied over a wide range of concentrations.

The present communication comprises measurements of lowering of freezing point, conductivity, viscosity and density of straight chain sulfonic acids with special emphasis upon dodecyl sulfonic acid. The results for diffusion have been published[2] and a provisional discussion is being given elsewhere,[3] although it is not until our measurements of transport number are completed that a sufficient number of equations will be available for a definitive solution of the problem, except in its principal outlines which are already generally known.

Experimental

An especially pure preparation of laurylsulfonic acid was made by M. E. Synerholm by the method of Noller and Gordon[4]; its equivalent weight by titration was 100.05% of the theoretical, the excess probably being water. The other sulfonic

acids from C_2 to C_{14} were prepared by F. M. McMillan. The potassium methyl, ethyl and propyl sulfonates were purchased from Kahlbaum, their solutions being filtered before use. The acids were made up by weight on the basis of their titrated value with conductivity water, from a Barnstead still, of specific conductance 0.3 to 0.4×10^{-6} mho.

The conductivity measurements were made with complete Leeds and Northrup Jones–Dike equipment, with an oil thermostat at 25°. Potassium chloride solutions were made up by the Jones and Bradshaw method. The cells were H-shaped with electrode leads from opposite ends, one[5] for use with stronger solutions and another shortened one for the most dilute solutions.

The Conductivity Data

To save space the density and conductivity results obtained by one of us (W. B. D.) for the lower members of the homologous series are given graphically in Figs. 1 and 2, which also include for comparison the "I. C. T." values for hydrochloric acid. Figure 2 also includes the data for the higher homologs and for the potassium salts. It will be noted that the first clear indication of departure from the behavior of ordinary strong electrolytes occurs with C_7 and that in concentration above about 0.4 *N*. There is a slight effect in solutions of C_6 approaching 1 *N*, and it is possible that in still greater concentrations the lower homologs of the free acids would give similar indications.

The conductivity data for the higher homologs are given in Tables I to IV for the sulfonic acids C_9, C_{11}, C_{12}, and C_{14}. The necessary density data by one of us (E. L. M.) were included in a previous publication,[6] except those for nonylsulfonic acid where very little material was available and where the density is so nearly that of water (d^{25}_4 0.9994 for 0.098 *m*) that other concentrations are based upon a linear graph.

The most interesting portions of the data for the present purpose are those for extreme dilution which are plotted in Fig. 3; the measurements of the most dilute solutions of C_{11} and C_{14} (by W. B. D.) may possibly be affected by some systematic error. Indeed, it was found to be the case in the corresponding measurements of C_{12} (by W. B. D.). However, it does not show in the measurements with C_2 in the same dilutions.

Figure 3 also includes the straight line representing the Onsager slope $\mu_e = \mu_\infty - [0.2274\ \mu_\infty + 59.78]\ \sqrt{N_V}$ for complete dissociation. The limiting equivalent conductances are, for the acids, 385 for C_2, 374 for C_9, 372 for C_{12} and 361 for C_{14}; and for the potassium salts 109, leaving 35.5 for the C_2 anion. From this the limiting mobilities of the anions are, for C_2 35, for C_9 24, and for C_{12} 22. For sodium dodecyl sulfate, Ward[7] obtained $\mu_\infty = 65.46$ at 20°, from which we deduce for the anion 22 to 23 depending upon whether one uses the data for Na^+ from "I. C. T.," Ward or MacInnes, Shedlovsky and Longsworth.[8] Howell and Robinson for the same sulfate had $\mu_\infty = 85.1$ at 25°, but with a systematic error still to be corrected, meanwhile leaving 35.1 mhos for the C_{12} ion. Reed and Tartar had $\mu_\infty = 86$ for the sodium dodecyl sulfonate or 36 mhos for the anion, but their more recent paper[9] contains conductivities for this particular substance that differ by as much as 6 to 20% from their previous paper.

(7) Ward, *J. Chem. Soc.*, 522 (1939).

(8) MacInnes, Shedlovsky and Longsworth, THIS JOURNAL, **54**, 2762 (1932).

(9) Wright, Abbot, Sieverts and Tartar, *ibid.*, **61**, 550 (1939).

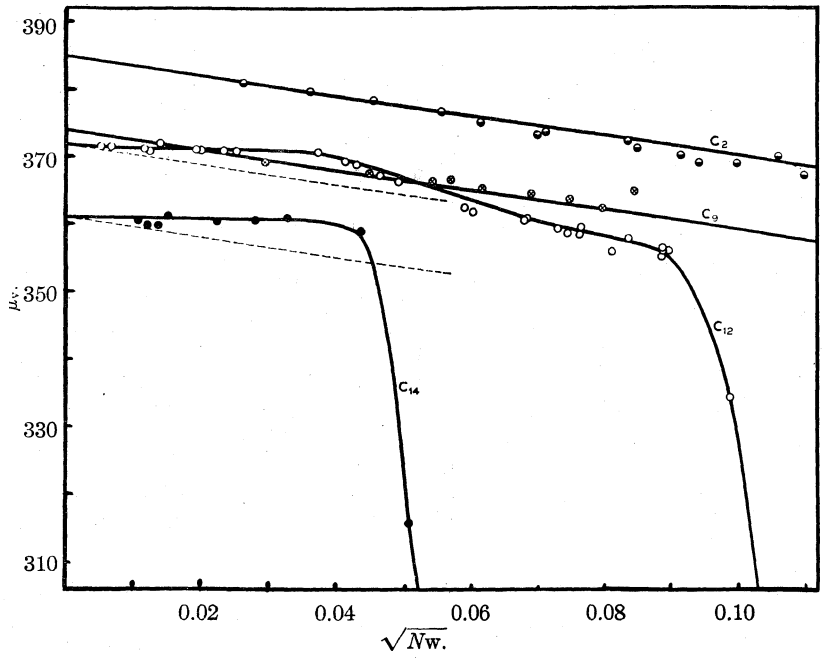

Fig. 3.

Their value for C_{14} at 40° was 2 mhos less. Lottermoser and Püschel obtained $\mu_\infty = 75$ for sodium dodecyl sulfate at 25° (but extrapolating linearly against $\sqrt[3]{N}$) giving 24.5 mhos for this anion, and a value for C_{12} 4 mhos less than C_{14} at 40°. We shall take our own value of 22 mhos as being the most likely for C_{12} anion with 35 mhos for the C_2 anion, which may be compared with the "I. C. T." value of 36.7 mhos for acetate and the MacInnes, Shedlovsky and Longsworth value of 40.87 mhos for the acetate ion.

The slope of the conductivity curve at extreme dilution in Fig. 3 is exactly the Onsager value for C_2 but with the higher members the conductivity of the colloidal electrolyte in this range decreases less than expected with concentration. Tartar's collaborators likewise noted the same effect. For example, for sodium dodecyl sulfonate at 40, 60 and 80°, they obtained slopes of 80, 109 and 140; whereas Onsager's equation would demand 106, 115 and 203, respectively. A noticeable increase of conductivity above that derived by the Onsager equation at infinite dilution could in these great dilutions only be accounted for on the basis of small amounts of highly conducting ionic micelle. Indeed, the fact that in dilutions such as 0.0004 N the conductivity of methylene blue is very greatly above the value for infinite dilution (of the order of 25–30% excess) was explained similarly by Moillet, Collie, Robinson and Hartley. They noted that even when with *m*-benzopurpurin the conductivity slope appeared normal, transport measurements conclusively proved the presence of micelles conducting better than the ions from which they were formed.

The mass law requires that for small micelles or complexes their formation must be gradual and extend over the whole range of concentration. A sharp break in the slope, at the "critical concentration to form micelles," is incompatible with the mass law even for the largest micelles. Writers since Lottermoser and Püschel have tended to overstress the sharpness of this break. Our critical concentrations are C_9 0.04, C_{11} 0.015, C_{12} 0.08 and C_{14} 0.0026 N, as read from the graph of equivalent conductivity, Fig. 3, with slightly different and likewise arbitrary values if read from the graph of specific conductivity, Fig. 4. The value for C_{12} is less than would be expected from those of the sodium salts,[9] whereas that for C_{14} is slightly greater.

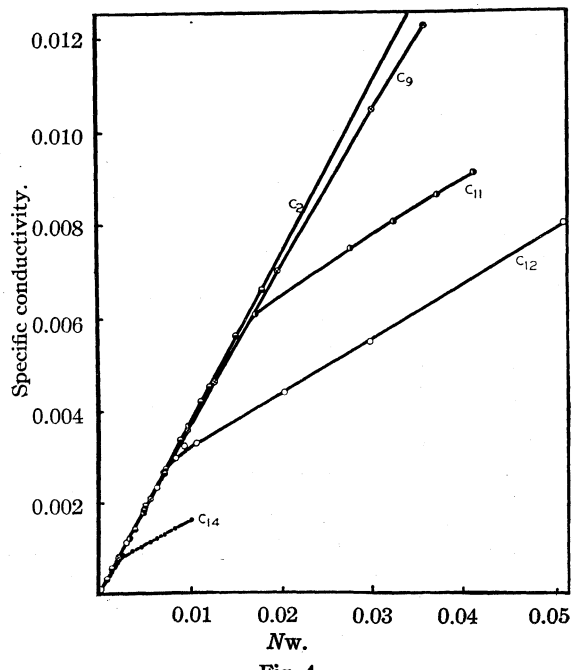

Fig. 4.

Those for the acids of uneven carbon atoms lie likewise at lower concentrations than those predicted for the sodium salts, being more nearly equal to the next highest homolog of even carbon number. The curve is very smoothly rounded for C_9 with increasing abruptness for the higher homologs.

Refractive Index

Refractive index, being essentially a measurement of atomic volumes, is but little affected by change from crystalloid to colloid. Lifshitz and Brandt[10] found that the molar refraction for the soaps as observed in soap solutions agreed with that calculated for ordinary organic chemicals. For this reason refractive index is frequently a valuable method of analysis of soap solutions since with the dipping refractometer and auxiliary prism only 0.03 cc. is required for measurement and the readings at 25° are linear when plotted against % or against equivalent weights in 1000 g. of total solution, as shown in Fig. 5. The slopes for the first four homologs are as shown in the figure 0.0293, 0.0247, 0.0210, and 0.0186, respectively.

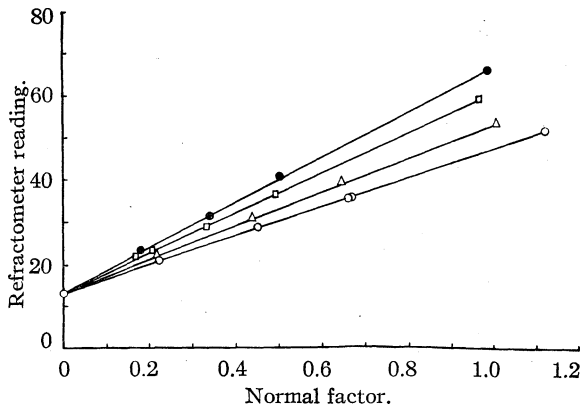

Fig. 5.—The refractometer reading at 25° of the sulfonic acids C_2 to C_5 plotted against the normal factor (equiv./1000 g. of solution): O, $C_2H_5SO_3H$; △, $C_3H_7SO_3H$; □, $C_4H_9SO_3H$; ●, $C_5H_{11}SO_3H$.

Viscosity Data

The following results were obtained (by E. L. M.) for the viscosity of dodecyl sulfonic acid solutions at 25°, taking the value for water as unity, and employing an Ostwald viscometer.

N_W	0.020	0.035	0.050	0.060	0.090	0.105	0.302	0.36
r	1.14	1.19	1.21	1.22	1.26	1.30	1.82	2.01
N_W	0.455	0.565	0.77	0.805	0.95	1.026	1.052	
r	2.28	3.01	4.64	5.04	7.54	10.93	13.4	

The viscosity results are graphed in Fig. 6. The rapid rise in the more concentrated solutions

(10) Lifshitz and Brandt, *Kolloid Z.*, **22**, 142 (1918).

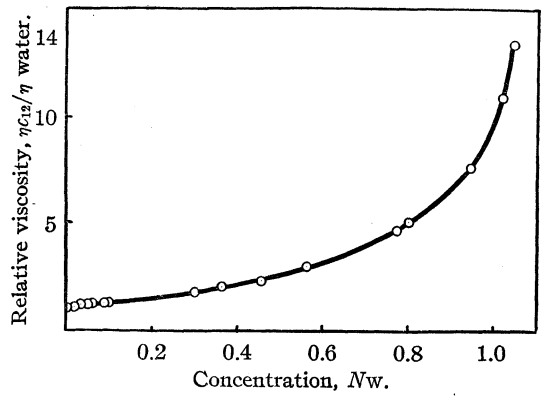

Fig. 6.

corresponds to structural viscosity. Thus the equivalent conductivity throughout the most concentrated range is rising in spite of an increase in viscosity amounting to many fold. Were it not for this, the increase of conductivity with increase of concentration evidently would be still greater. In the most concentrated solutions diffusion and conductivity show definite signs of reduction.

Freezing Point Data (by S. A. J.)

The freezing equipment was modelled after that of Scatchard.[11] The e. m. f. across the twenty-four junction thermocouple is measured by a relatively inexpensive null method designed by Dr. Stuart W. Grinnell, Fig. 8, and sensitive to 5×10^{-5} degree or 5×10^{-8} volt. The voltage divider AB (ratio 1:1627.3), like the galvanometer circuit, is of copper; P is a simple potentiometer to give a fine adjustment.

The thermocouple is calibrated directly by measuring the thermal e. m. f. produced by the freezing point lowering of approximately 0.15 *N* potassium chloride solutions, and calculating the freezing point depression using *g* values obtained by Scatchard.

The freezing point results for dodecylsulfonic acid are assembled in Table V and are shown

(11) Scatchard, Jones and Prentiss, THIS JOURNAL, **54**, 2676 (1932).

graphically in Fig. 7. The concentrations are in moles per 1000 g. of water, θ is the number of degrees lowering of freezing point, and g is the Bjerrum osmotic coefficient, $g = \theta/2\ \lambda\ m$, where $\lambda = 1.858°$ and g = van't Hoff's $i/2$ and Lewis and Randall's $l - j$.

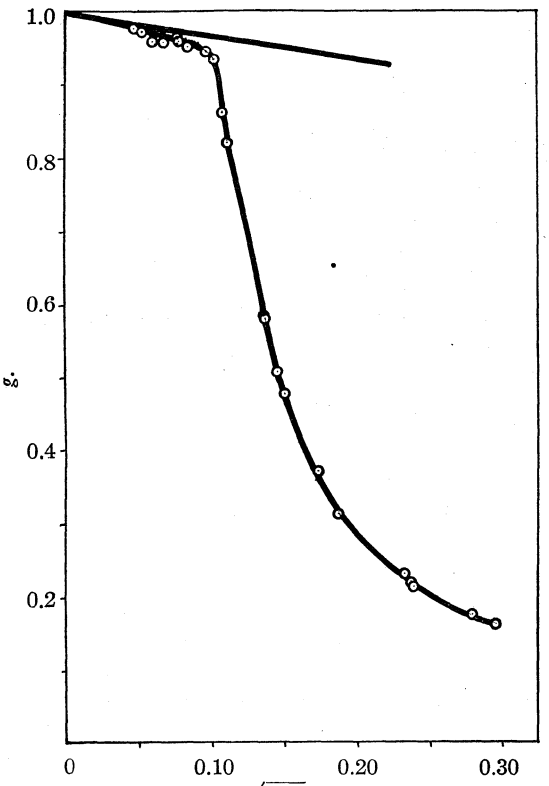

Fig. 7.

Attention may be called to the extremely steep drop in the values of g in the neighborhood of 0.02–0.03 N where the actual freezing point, $-\theta°$, is only just progressively lowered by increase in concentration. In other words, these dilute solutions are almost on the verge of separating into a heterogeneous mixture of two solutions both dilute and within this range. The requirement that θ should increase continuously with concentration to prevent such separation is paralleled by the requirement that $g/N + dg/dN$ must be positive where N is the mole fraction of the solute.

Discussion

The salient features of the data are, first, the regularity within the homologous series showing a gradual transition from typical fully dissociated electrolytes in the lowest members to well characterized colloidal electrolytes in the higher members. In the latter there is the region in extreme dilution corresponding approximately to the Debye–Hückel–Onsager behavior followed by the region of concentration in which conductivity and lowering of freezing point fall to a fraction of their former values, and then after a minimum the third characteristic region where equivalent conductivity and molar lowering definitely increase with increasing concentration.

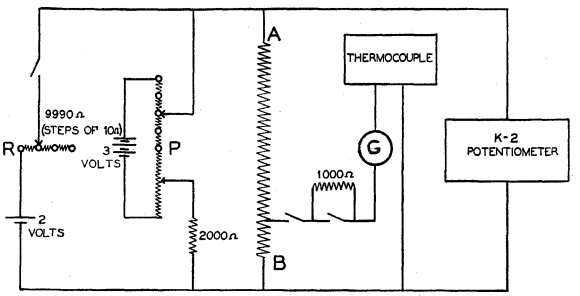

Fig. 8.

The transition from the first to the second region occurs over a very appreciable range of moderately concentrated solutions for heptyl- and nonylsulfonic acids, the transition being very gradual. This transition zone is commonly called the critical concentration for micelles. We believe, as is indeed evident from a comparison with freezing point lowering, that even in the solutions of greater dilution there is at least some ionic micelle that enhances the conductivity. After the transition zone or critical concentration, the much larger micelles of low conductivity like ordinary colloidal particles, which McBain called "neutral colloid," are formed so rapidly that they destroy much of the conductivity and freezing point lowering, in spite of any relatively small increase of highly conducting or ionic micelles. However, after the minimum, the effects due to the latter gain the upper hand by their steady increase, and the conductivity rises again.

Summary

1. Conductivity measurements are presented for the homologous series of straight chain sulfonic acids from two to fourteen carbon atoms, together with data for density and refractive index. The data show the gradual transition from the behavior of fully dissociated electrolytes for the lowest homologs through the intermediate members in higher concentration to the typical behavior of colloidal electrolytes for the higher homologs. The latter approximate to complete

dissociation in extreme dilution, then rather suddenly lose much of their conductivity through association of ion-pairs and ions to form colloidal particles of low conductivity, but after a well-defined minimum in moderately dilute solution, regain some of their conductivity through increasing formation of better conducting or ionic micelles.

2. This interpretation is in agreement with exact freezing point and diffusion data for dodecylsulfonic acid.

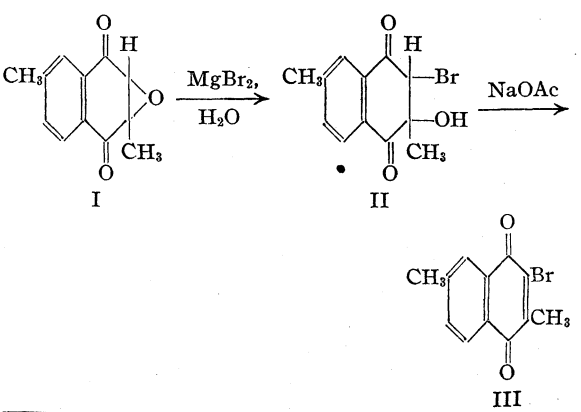
Naphthoquinones of the Vitamin K_1 Type of Structure[1]

BY LOUIS F. FIESER, WILLIAM P. CAMPBELL, EDWARD M. FRY[2] AND MARSHALL D. GATES, JR.

The synthesis of various allyl derivatives of α-naphthoquinone[3,4] by utilization of the Claisen rearrangement reaction was undertaken to provide model substances of the structural types postulated for vitamins K_1 and K_2. It was recognized that methods involving use of this reaction probably would not be applicable to the synthesis of the vitamins themselves, and the present paper reports attempts to develop methods suitable for accomplishing this second objective.

One scheme tried without success consisted in the attempted addition of a Grignard reagent to a naphthoquinone oxide. The reaction between allylmagnesium bromide and 2,6-dimethyl-1,4-naphthoquinone oxide (I) was studied because addition in the desired direction would lead to 2,6-dimethyl-3-allyl-1,4-naphthoquinone,[3] which was already characterized. The chief product isolated, however, proved to be the bromohydrin II, the structure following from the analysis of the colorless product and from its conversion to a yellow bromodimethylnaphthoquinone of the composition of III. That cleavage of the oxide ring is due, as in comparable cases,[5] to interaction of the oxide with magnesium bromide present in the Grignard solution was established by the observation that the bromohydrin can be obtained in 73% yield from the oxide and magnesium bromide in ether. On attempted coupling of the MgBr derivative of II with allylmagnesium bromide there was isolated a small amount of the oxide, indicating that the cleavage reaction is reversible. When 2-methyl-1,4-naphthoquinone oxide was treated with methylmagnesium chloride and the oily product refluxed with alcoholic hydrochloric acid, a colorless substance resulted which appears to be formed by the addition of the elements of methane and of hydrogen chloride. The investigation was not pursued beyond these unpromising observations. A useful outcome of the brief study is the development of a method of preparing 1,4-naphthoquinone oxides which is much more convenient than Zincke's[6] hypochlorite procedure.



I II III

A few trials were made of the method of introducing a β-unsaturated group by direct C-alkylation of a phenolic salt, and it was observed that a small amount of 2-methyl-3-benzyl-1,4-naphthoquinone can be isolated from the very dark mixture produced by refluxing of 2-methyl-1,4-naphthohydroquinone with benzyl bromide and potassium carbonate in acetone. When the reaction was conducted at room temperature with two equivalents of benzyl bromide the mixture remained light in color and the sole crystalline product was methylnaphthohydroquinone dibenzyl ether (73% yield). With one equivalent

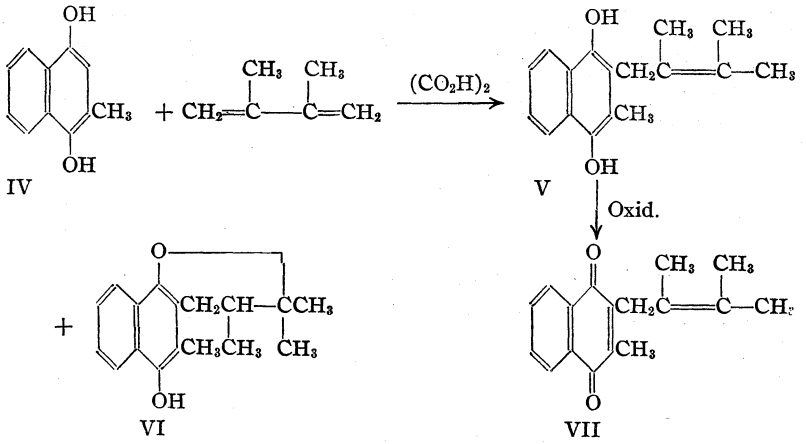
of the halide at room temperature a part of the starting material remained unchanged and both the mono and dibenzyl ethers were formed, but there was no indication of C-benzylation.



On the basis of the postulated[3] origin of vitamin K_1 in nature it seemed likely that this substance might be obtainable by the direct condensation of phytol with a 2-alkyl-1,4-naphthoquinone in either the oxidized or the reduced form. Trials with 2-methyl-1,4-naphthoquinone were invariably unpromising and attention was directed to use of the hydroquinone. From the investigations of Karrer, L. I. Smith, Todd, and others it is known that alkylated benzohydroquinones having a free nuclear position condense readily with β-unsaturated alcohols or with dienes in the presence of a mineral acid or a zinc halide, or under conditions where a mineral acid is liberated in the course of the initial condensation. The reported condensations invariably are attended by cyclization to compounds of the tocopherol type.[7] For the most direct approach to a substance of the desired vitamin K_1 type, it would appear necessary to avoid the natural disposition for the formation of a structure characteristic of vitamin E. The naphthalene derivatives, moreover, show a high sensitivity to mineral acids not encountered in the benzene series. It seemed desirable to seek a milder and less destructive condensing agent less prone to promote cyclization and other side reactions. Anhydrous oxalic acid fulfils the requirements, and dioxane is a suitable solvent. In isolated experiments successful use was made of trichloroacetic acid as the catalyst and ethylene glycol monomethyl ether as solvent.

On refluxing methylnaphthohydroquinone (IV) with excess 2,3-dimethylbutadiene in dioxane solution in the presence of anhydrous oxalic acid, the starting material was completely consumed in twenty-four hours, and in this time there was no appreciable discoloration or decomposition. The reaction mixture contained both the substituted hydroquinone V and an isomeric substance which probably is a naphthotocopherol of the structure VI, although this product has not been studied in detail. The hydroquinone V can be separated from the mixture by virtue of its sparing solubility in petroleum ether, or it can be extracted with a liberal amount of strong alkali containing sodium hydrosulfite. The naphthotocopherol is considerably more soluble in the hydrocarbon solvent and shows even feebler acidic properties than the hydroquinone. The latter substance, which forms a diacetate, was oxidized in good yield to 2-methyl-3-(β,γ,γ-trimethylallyl)-1,4-naphthoquinone (VII). The spectrum of this crystalline yellow compound in absolute alcohol, kindly determined by Mr. D. M. Bowen, is very similar to that of vitamin K_1 as reported by Dam, Karrer, *et al.*,[8] and shows the following maxima (log E values in parenthesis): 243 mμ (4.23), 249, 264, 270.5 mμ (4.27), 329 mμ (3.43).

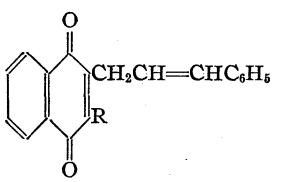
Reductive acetylation of the quinone VII under mild conditions gave the above diacetate, but when the temperature was not suitably controlled a part of the material was converted into a substance of the composition of the naphthotocopherol acetate. A new procedure for the reductive acetylation of quinones which avoids secondary reactions consists in the use of zinc dust, acetic anhydride, and a small amount of pyridine as catalyst. The reaction proceeds rapidly at 0°. In trials with 2-methyl- and 2-ethyl-1,4-naphthoquinone, it was found that reductive benzoylation can be accomplished readily by treating the quinone with zinc dust, pyridine and benzoyl chloride; this constitutes a useful method of preparing crystalline derivatives of low melting quinones.

Under the conditions indicated, the substituted hydroquinone V was obtained in 29% yield and

(7) Professor Lee I. Smith has kindly informed us that the isolation of hydroquinones is reported in papers from his Laboratory which are now in press.

(8) Dam, Geiger, Glavind, P. Karrer, W. Karrer, Rothschild and Solomon, *Helv. Chim. Acta*, **22**, 310 (1939).

the naphthotocopherol VI in 15% yield. Using isoprene as the second component, no condensation was observed at the reflux temperature, but a small amount of product was formed at 180°. Piperylene likewise reacted less readily than 2,3-dimethylbutadiene, but there were indications of condensation at a temperature of 120°. Cinnamyl alcohol reacted rather readily at the reflux temperature with methylnaphthohydroquinone (22% yield), and somewhat less readily with ethylnaphthohydroquinone (9.4% yield). In each case some starting material was recovered by extraction with 1–2% alkali containing hydrosulfite, and the substituted hydroquinone was then separated most conveniently by repeated extraction with 10% alkali-hydrosulfite. The reaction products were readily converted into crystalline quinones of the type VIII. Benzyl



VIII (R = CH_3, C_2H_5)

alcohol combined with methylnaphthohydroquinone only to a minor extent at the boiling point, giving after oxidation 2-methyl-3-benzyl-1,4-naphthoquinone. With allyl alcohol no reaction occurred at 180°. It appears, therefore, that in the presence of anhydrous oxalic acid in dioxane solution certain highly reactive dienes, β-unsaturated alcohols, and aryl carbinols condense to a greater or less extent with alkylnaphthohydroquinones, but that the reaction has distinct limitations. It is significant, however, that with a compound of suitable reactivity, condensation to a hydroquinone with a β-unsaturated side chain can be accomplished without undue cyclization of the primary product.

In the Dam–Karrer[8] test with alcoholic alkali 2-methyl and 2-ethyl-3-cinnamyl-1,4-naphthoquinone give intense blue colors which persist somewhat longer than observed with corresponding allyl compounds.[3] The 3-benzyl compound gives a light purple color, but no purple or blue phase was observed with 2-methyl-3-trimethylallyl-1,4-naphthoquinone (VII). The presence of a substituent on the β-unsaturated carbon atom apparently interferes with the color reaction.

In bio-assays kindly conducted by Dr. W. L. Sampson, 2-methyl-3-benzyl-1,4-naphthoquinone was inactive at a dosage level of 100 γ and the corresponding 3-trimethylallyl compound was inactive at a level of 200 γ. From carefully repeated assays of the compounds described in the early reports from our Laboratory[3,4,9] it is concluded that the only substance in the group previously considered which has appreciable antihemorrhagic activity is 2,3-dimethyl-1,4-naphthoquinone.[3] In addition, 2-methyl-3-cinnamyl-1,4-naphthoquinone has been found active at a dosage of 100 γ but not at 10 γ.

Experimental Part[10]

Preparation of Starting Materials

2-Methylnaphthoquinone (M. D. G.).—Satisfactory results were obtained by a procedure considerably shorter than that of Anderson and Newman.[11] (The yield was much lower when the oxidation was conducted at the reflux temperature as in the preparation of certain dimethylnaphthoquinones.[12]) A solution of 200 g. of β-methylnaphthalene in 2 liters of glacial acetic acid was added in the course of two hours to a well-stirred solution of 800 g. of chromic anhydride in 1.5 liters of 80% acetic acid, cooling the mixture in an ice-bath and keeping the temperature from rising above 20°. At the end of the addition the temperature was allowed to rise slowly; after a few hours cooling was again required to moderate the reaction and keep the temperature from rising above 50–60°. After a total period of thirty-six hours, the solution was poured into water and the precipitated quinone collected and washed and obtained as a good yellow solid (100 g.). This was crystallized directly from methanol (Norite), giving in all 70 g. (29%) of yellow prismatic needles, m. p. 105–106°.

2-Ethyl-1,4-naphthoquinone.—In the preparation of β-ethylnaphthalene the best results were obtained (W. P. C.) using 50 g. of β-acetonaphthalene, 150 cc. of benzene, 300 cc. of methanol, 200 cc. of concentrated hydrochloric acid, and 155 g. of zinc amalgamated with 10 g. of mercuric chloride. The mixture was refluxed vigorously for twenty-four hours with the addition of three 20-cc. portions of fresh acid. About 1.5 liters of water was then added and a little ether was used to facilitate separation of the benzene layer. The latter, combined with an ether extract of the aqueous layer, was dried and the product distilled, giving 29 g. (63%) of colorless β-ethylnaphthalene, b. p. 127–129° at 14 mm. When the reflux period was extended to forty-seven hours the yield was 57%. The yield by the Martin procedure (M. D. G., 57%) was essentially the same as previously reported.[13]

The following oxidation procedure (W. P. C.) is regarded as more convenient than that described for the lower homolog or that of the literature.[14] A solution of

TABLE I

ALKYL-1,4-NAPHTHOQUINONE OXIDES

Alkyl substituents	Properties M. p., °C.	Cryst. form	Analyses, % Carbon Found	Carbon Calcd.	Hydrogen Found	Hydrogen Calcd.
None	134.5–135.5	Prism. needles	...	...	..	..
2-Methyl	95.5– 96.5	Long needles	70.38	70.20	4.36	4.29
2,6-Dimethyl	97– 98	Prisms	71.23	71.27	5.07	4.99
2,7-Dimethyl	91– 92	Slender needles	71.29	71.27	5.09	4.99

70 g. of chromic anhydride in 30 cc. of water, diluted with 150 cc. of acetic acid, was added in one hour to a stirred solution of 29 g. of β-ethylnaphthalene in 200 cc. of acetic acid while maintaining the temperature at 45–50° by suitable cooling. The exothermic reaction was soon over, and after standing for fifteen hours the mixture was stirred at 60° for one hour and poured into 2 liters of water. The quinone separated as a light yellow solid and crystallization from methanol gave 12.6 g. (39%) of satisfactory material, m. p. 86–87°, in two crops.

2-Methyl-1,4-naphthohydroquinone (L. F. F., M. D. G.) (a) with Stannous Chloride.—A solution of 10 g. of 2-methyl-1,4-naphthoquinone in 100 cc. of hot alcohol was cooled rapidly to room temperature and the resulting paste treated with 40 g. of stannous chloride in 40 cc. of concentrated hydrochloric acid. The quinone dissolved at once giving a transient deep brown color (quinhydrone) rapidly fading to light yellow, and the solution became hot. Water (165 cc.) was added and the hydroquinone which precipitated was brought into solution at the boiling point. The solution was clarified with norite, filtered, diluted with an equal volume of water at the boiling point and set aside to crystallize. The hydroquinone separated as colorless needles and after thorough washing with cold water was dried at 50–60° either in the air or at 20 mm.; yield 9.2–9.5 g. When obtained by this procedure in an initially colorless condition, the material keeps for several days without deterioration.

(b) With Sodium Hydrosulfite.—A solution of 10 g. of the quinone in 50 cc. of hot alcohol was treated with a solution of hydrosulfite (about 30 g.) in water until the color (yellow, then brown) was discharged and the cooled mixture was diluted and the product extracted with ether. The dried, nearly colorless ethereal solution was evaporated nearly to dryness and the residual solid was triturated with petroleum ether and collected. The hydroquinone was obtained as a white powder (9.7 g.). This method is rapid and the product entirely suitable for immediate use, but the material darkens more rapidly on storage than the crystalline product of (a).

The **diacetate**[11] of 2-methyl-1,4-naphthohydroquinone, prepared by reductive acetylation of the quinone using either sodium acetate or pyridine, formed colorless prisms from ether–petroleum ether or ether, m. p. 112.5–113°. The dibenzoate was prepared by adding 1 cc. of benzoyl chloride by drops to a mixture of 0.5 g. of methylnaphthoquinone, 0.5 g. of zinc dust, and 3 cc. of pyridine, while cooling with ice. Reaction occurred at once and after standing at room temperature for ten minutes the pale yellow mixture was heated to boiling, cooled, and the product extracted with ether–alcohol. After washing with dilute acid and with soda solution and concentrating the dried solution to a small volume, the dibenzoate separated as colorless needles (0.6 g.), m. p. 178.5–179.5°. Two crystallizations from alcohol (35 cc.) raised the m. p. to 180–180.5°.

Anal. Calcd. for $C_{25}H_{18}O_4$: C, 78.53; H, 4.75. Found: C, 78.71; H, 4.80.

2-Ethyl-1,4-naphthohydroquinone was prepared by the second procedure described above (b) with similar results; the material softened at 140° and melted at 144–145°, dec. The **diacetate** was obtained by adding 2 drops of pyridine to a suspension of 0.2 g. each of ethylnaphthoquinone and zinc dust in 2 cc. of acetic anhydride. Heat was evolved and the mixture became colorless; acetic acid was added and the mixture filtered at the boiling point, using more acetic acid and water in subsequent extractions of the residue. (A yellow color not connected with the acetylative reduction becomes quite pronounced if the reaction mixture is allowed to stand for some time but the color is easily eliminated in the purification process.) After suitable dilution at the boiling point the product separated in a good condition, m. p. 104–105° (0.20 g.). It forms prism clusters of the same m. p. from ether–petroleum ether or ligroin. The **dibenzoate**, prepared by reductive benzoylation as above, formed short needles from alcohol, m. p. 164–165°.

Alkylnaphthoquinone Oxides (L. F. F.)

In a typical experiment 5 g. of 2-methyl-1,4-naphthoquinone was dissolved in 15 cc. of alcohol and the solution was cooled to 45° and treated with 10 cc. of 30% hydrogen peroxide followed by a solution of 2.5 g. of sodium carbonate in 10 cc. of water. Heat was evolved, the yellow color was discharged, and inorganic salts separated. After five minutes the mixture was diluted well with water, whereupon 2-methyl-1,4-naphthoquinone oxide separated in the form of long colorless needles. One crystallization from dilute alcohol gave 3.6 g. of satisfactory product, m. p. 94.5–95.5°. The properties and analyses of purified samples of this and other oxides are recorded in Table I. The preparations were conducted as described, using sufficient alcohol to keep the quinone in solution at about 45°, and the yields were as reported in the example. The parent substance corresponds to the description of Zincke[6] (m. p. 136°); the 2-methyl derivative had the properties noted by Madinaveitia[15] except that the m. p. is considerably lower (M., 102°). The oxides crystallize well from alcohol, dilute alcohol, or ligroin.

Grignard Reactions with Alkylnaphthoquinone Oxides (E. M. F.)

2,6-Dimethyl-1,4-naphthoquinone Bromohydrin (II), (a) Grignard Reaction of Oxide.—The Grignard reagent obtained from 1.5 cc. of allyl bromide, added in 80 cc. of

(15) Madinaveitia, *Rev. acad. cienc. Madrid*, **31**, 617 (1934).

ether during one and one-half hours to a stirred suspension of 1.4 g. of magnesium in 20 cc. of ether, was added slowly to a solution of 3.16 g. of 2,6-dimethyl-1,4-naphthoquinone oxide in 50 cc. of ether. A white complex separated at once and on displacing most of the ether with benzene and refluxing for one-half hour it turned somewhat red. Decomposition was effected with dilute acetic acid (yellow color), and extraction of an ethereal solution of the reaction product with sodium carbonate (red solution) gave 0.1 g. of 2,6-dimethyl-3-hydroxy-1,4-naphthoquinone,[16] m. p. 192–194.5°, mixed m. p. 193–194.5°. The residual oil when treated with dilute alcohol afforded 0.38 g. of a crystalline product identified as the unchanged oxide and 1.25 g. of 2,6-dimethyl-1,4-naphthoquinone bromohydrin. This crystallized from dilute alcohol in colorless, rectangular plates, m. p. 146–148°.

Anal. Calcd. for $C_{12}H_{11}O_3Br$: C, 50.90; H, 3.92; Br, 28.23. Found: C, 51.05, 51.05; H, 4.24, 4.18; Br, 28.33.

(b) **With Magnesium Bromide.**—A solution prepared from 5.32 g. of bromine and 150 cc. of dry ether was added slowly to a stirred suspension of 0.81 g. of magnesium in ether. A vigorous reaction took place with the separation of a yellow oil turning dark purple at the end. After stirring for twenty minutes, 3 g. of 2,6-dimethyl-1,4-naphthoquinone oxide was added slowly in ether solution. A complex soon formed and eventually separated as a white solid mixed with a little of the dark oil. After stirring for fifteen minutes water was added and the yellowish ether layer was washed, dried, and evaporated. The crystalline residue, washed free of oil with a little ether, amounted to 3.07 g. (73%) and consisted of nearly pure bromohydrin. Recrystallized from dilute alcohol the substance melted at 147–148.5° and showed the properties of the sample obtained in (a).

In a further experiment 3 g. of the bromohydrin was treated in ether with two equivalents of allylmagnesium bromide (2 cc. of the halide). A complex formed at once with evolution of heat; after refluxing for seventeen hours and decomposing with dilute acetic acid, a small amount of acidic material was removed by extraction with 1 *N* alkali and the residual oil afforded 0.4 g. of 2,6-dimethyl-1,4-naphthoquinone oxide (m. p. 96.5–97.5°; no depression on mixing). No other pure product was isolated.

3-Bromo-2,6-dimethyl-1,4-naphthoquinone.—A solution of 0.1 g. of the bromohydrin II and 0.1 g. of sodium acetate in 2 cc. of acetic acid was refluxed for one-half hour, when it had become red, and diluted with water. The precipitated material on crystallization from alcohol gave 0.03 g. of yellow needles, m. p. 114–114.5°. The substance gives a positive Beilstein test and is not soluble in alkali.

Anal. Calcd. for $C_{12}H_9O_2Br$: C, 54.36; H, 3.42. Found: C, 54.64; H, 3.61.

Action of Methylmagnesium Chloride on Methylnaphthoquinone Oxide.—The reagent from 0.51 g. of magnesium was added to a solution of 3.35 g. of 2-methyl-1,4-naphthoquinone oxide in 75 cc. of ether. A complex separated at once and did not appear to undergo change on refluxing for two hours and allowing the mixture to stand overnight. After decomposition with acetic acid and washing the ethereal solution with soda, 0.38 g. of starting material was collected on crystallization from dilute alcohol. The residual oil yielded a solid product only on being refluxed for a few minutes with two volumes of alcohol and 0.5 cc. of concentrated hydrochloric acid. The dark red solution was evaporated in vacuum, and the oil then crystallized from ether–petroleum ether. A total of 1 g. of crude brown product was collected, and crystallization from ether using Norite afforded 0.7 g. of colorless material in the form of parallelograms. The substance decomposes when heated slowly; when immersed in a bath just below the m. p. it melts at 141.5–142° to a colorless liquid which rapidly darkens with gas evolution.

Anal. Calcd. for $C_{12}H_{13}O_2Cl$: C, 59.88; H, 5.45; Cl, 14.73. Found: C, 60.05, 60.16; H, 5.75, 5.67; Cl, 14.99.

Benzylation of Methylnaphthohydroquinone (L. F. F.)

In the most successful preparation of **2-methyl-1,4-naphthohydroquinone dibenzyl ether** a mixture of 2 g. of the hydroquinone, 4 g. of benzyl bromide and 20 cc. of acetone was flushed out with nitrogen, 4 g. of finely powdered potassium carbonate was added, and the vessel was stoppered and shaken at room temperature for twenty-five hours. The solution was orange-red at the start but became light yellow. The mixture was poured into water, extracted with ether, and the extract washed twice with 10% potassium hydroxide, which removed only a trace of phenolic material. Evaporation of the dried ether solution left a yellow oil which went solid on rubbing. Crystallization from 35 cc. of alcohol gave 2.91 g. (72%) of slightly yellow product, m. p. 72–3°. On further purification by crystallization from ligroin (b. p. 60–90°) the ether formed colorless needles, m. p. 74.5–75°.

Anal. Calcd. for $C_{25}H_{22}O_2$: C, 84.71; H, 6.26. Found: C, 84.93; H, 6.33.

The **monobenzyl ether** was isolated along with the diether in an experiment conducted as above but using only one equivalent of benzyl bromide (1 g. of hydroquinone, 1 g. of bromide, 1.5 g. of potassium carbonate, 10 cc. of acetone). The mixture was poured into aqueous sodium hydrosulfite solution, extracted with ether, and the light yellow ethereal solution extracted three times with 2% potassium hydroxide containing hydrosulfite, which removed about 0.2 g. of impure starting material (yellow alkaline liquor). Eight extractions with 10% alkali containing hydrosulfite (total, 200 cc.) then extracted the monobenzyl ether; after acidification this was taken into ether and the solution dried and evaporated. The oily residue yielded a solid on treatment with ether–petroleum ether, and after two recrystallizations from ligroin the substance formed small, colorless plates, m. p. 159–160°, with some previous darkening; yield 3 mg.

Anal. Calcd. for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10. Found: C, 81.81; H, 6.25.

From the neutral fraction there was obtained 0.34 g. of the dibenzyl ether in a crystalline condition. In a qualitative trial the reaction seemed to proceed about the same in boiling ethylene glycol dimethyl ether as in cold acetone.

2-Methyl-3-benzyl-1,4-naphthoquinone was isolated in an exploratory experiment in which 2 g. of the hydroqui-

(16) Fieser and Seligman, THIS JOURNAL, 56, 2690 (1934).

none was refluxed for fifteen and one-half hours with 4 g. of benzyl bromide, 4 g. of potassium carbonate, and 20 cc. of acetone. The very dark reaction mixture was diluted with water and extracted with ether and the extract shaken with dilute alkali-hydrosulfite. The ethereal solution remained very dark brown throughout this and other washings and the residue on evaporation was a dark resin. On distillation in vacuum the bulk of the material came over without decomposition and a part of the distillate solidified. Using this seed and employing ether–petroleum ether as solvent, a crystalline crust was obtained yielding on one crystallization from alcohol 0.3 g. of yellow crystals of the quinone, m. p. 107–108°. After two more crystallizations the substance formed ball-like clusters of bright yellow needles, m. p. 107.5–108°.

Anal. Calcd. for $C_{18}H_{14}O_2$: C, 82.41; H, 5.38. Found: C, 82.50; H, 5.42.

The substance gives a large depression when mixed with methylnaphthoquinone. It yields a colorless hydroquinone on reduction with aqueous hydrosulfite in alcoholic solution, and with 5% alcoholic potassium hydroxide in the cold it gives a light purple color changing through brown to greenish-yellow.

Condensation of Methylnaphthohydroquinone with 2,3-Dimethylbutadiene (L. F. F.)

A solution of 3 g. of 2-methyl-1,4-naphthohydroquinone, 3 g. of anhydrous oxalic acid (prepared by heating the hydrate at 140°), and 10 cc. of 2,3-dimethylbutadiene in 30 cc. of dioxane (purified with sodium) was refluxed for twenty-four hours and the pale orange solution was poured into water and extracted with ether. After washing with water the solution was extracted three times with 1% alkali containing hydrosulfite, each extract being weakly yellow. The alkaline liquor was washed with ether, acidified, and the precipitated solid dissolved in alcohol and treated with ferric chloride solution. This afforded 0.11 g. (m. p. 94–95°) of the quinone VII described below, showing that the starting material had been completely consumed. The ethereal solution was washed, dried, and evaporated to a small volume, and on displacing the ether with petroleum ether and cooling there was obtained 1.18 g. of a nearly colorless crystal powder which proved to be the hydroquinone of VII in an essentially pure condition (total yield, 29%).

On allowing the petroleum ether mother liquor to stand overnight, a few large prisms of the naphthotocopherol VI separated on the walls (0.08 g., m. p. 71.5–72°). To isolate the bulk of this the dark mother liquor was extracted with 4% alkali until this was colorless (five times) to remove traces of the substituted hydroquinone and the light yellow organic layer was dried and evaporated. A rather mobile yellow oil resulted, and when seeded with the above prisms gave a crystalline paste. After rubbing with methanol and cooling well there was collected 0.59 g. of colorless naphthotocopherol, m. p. 71.5–72°; total yield 15%.

When the refluxing time in the preparation was decreased to sixteen hours a significant amount of starting material was unconsumed (removed in one extraction with 1% alkali). In one experiment ethylene glycol monomethyl ether was used as solvent and the reaction was conducted at 70°. Three extractions from ether with 1% alkali-hydrosulfite removed 38% of recovered starting material, identified by conversion to methylnaphthoquinone (m. p. 103–104°), and the yield of substituted hydroquinone based on material not recovered was 15%; some naphthotocopherol was also formed.

2 - Methyl - 3 - (β,γ,γ - trimethylallyl) - 1,4 - naphthoquinone (VII).—On adding a solution of 0.49 g. of ferric chloride crystals in dilute hydrochloric acid to a solution of 0.23 g. of the crude hydroquinone in 2 cc. of alcohol and gradually adding water, the quinone separated in yellow blades, m. p. 94–95° (0.22 g.). Lead tetraacetate gave nearly as good results (0.18 g., m. p. 93–94.5°). A sample for analysis was sublimed at 130–150° (2 mm.) and crystallized twice from methanol, forming bright yellow blades, m. p. 95–95.5°.

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.28; H, 7.14. Found: C, 80.33; H, 7.25.

On treating a cold alcoholic solution of the quinone with an equal volume of 10% alcoholic potassium hydroxide, the original yellow color gives place to a faint pinkish coloration changing to dull red when heated. No blue or purple phase has been observed.

2 - Methyl - 3 - (β,γ,γ - trimethylallyl) - 1,4 - naphthohydroquinone Diacetate.—The crude hydroquinone separated from the reaction mixture as described above underwent oxidation on attempted crystallization from ligroin or dilute alcohol and was not obtained pure; the best material was pale rose colored and turned yellow on standing. For characterization the substance was therefore acetylated by warming with acetic anhydride–sodium acetate for a few minutes. The crude product was an oil, but after washing in ether with soda solution, drying, and replacing the solvent with petroleum ether, it was obtained as a white powder. The diacetate then crystallized from ligroin (b. p. 60–90°) in colorless cubes, m. p. (constant) 119–120°.

Anal. Calcd. for $C_{21}H_{24}O_4$: C, 74.09; H, 7.11. Found: C, 74.04; H, 7.23.

A product of the same m. p. and mixed m. p. was obtained by reductive acetylation of the quinone by the pyridine method without application of heat. In an earlier experiment the reaction was conducted with zinc dust, acetic anhydride, and sodium acetate and the mixture was boiled for a few minutes. In this case, after extraction with ether and crystallization from petroleum ether and then twice from ligroin there was obtained, in very poor yield, a substance having the composition of the acetate of the naphthotocopherol VI. The substance forms large, colorless, transparent prisms, m. p. 128.5–129°.

Anal. Calcd. for $C_{19}H_{22}O_3$: C, 76.48; H, 7.43. Found: C, 76.36; H, 7.54.

Naphthotocopherol of Probable Structure VI.—The material separated with methanol as described crystallized most satisfactorily from petroleum ether, in which it is quite soluble, but less so than in methanol. The substance forms large, transparent prisms, m. p. 73–73.5°.

Anal. Calcd. for $C_{19}H_{20}O_2$: C, 79.65; H, 7.87. Found: C, 79.95; H, 7.63.

The substance forms no picrate or trinitrobenzene derivative from alcohol. It is not extracted from ether by 10%

alkali but dissolves in alcoholic alkali with a deep yellow color and precipitates on dilution. No reaction was observed on treating the substance with silver nitrate in methanol, with ferric chloride in alcohol, or with lead tetraacetate in acetic acid.

Other Condensations of Methyl and Ethylnaphthohydroquinone (W. P. C.)

2-Methyl-3-cinnamyl-1,4-naphthoquinone.—A solution of 3 g. of methylnaphthohydroquinone, 1.54 g. of cinnamyl alcohol, and 2 g. of anhydrous oxalic acid in 20 cc. of dioxane was refluxed for twenty-two hours, poured into water and extracted with ether. Starting material was extracted with a total of 150 cc. of 1% sodium hydroxide-hydrosulfite and collected in the form of the quinone, m. p. 100–103° (1.0 g.). The ethereal solution was dried and evaporated and the oily product digested with three 80-cc. portions of petroleum ether. The solution each time was decanted and eventually left 1.55 g. of solid consisting largely of methylcinnamylnaphthohydroquinone. This was dissolved in ether, shaken with 5 g. of silver oxide and anhydrous sodium sulfate (twenty minutes) and the material left on filtering and evaporating the yellow solution was crystallized from ether–petroleum ether and gave 0.8 g. of the quinone, m. p. 124–126° (yield, allowing for recovered material, 22%). Purified by further crystallizations from alcohol the substance formed bright yellow blades, m. p. 127–127.5°. In the test with alcoholic alkali in the cold it gives an intense indigo blue which persists for about fifteen minutes and fades to brown.

Anal. Calcd. for $C_{20}H_{16}O_2$: C, 83.31; H, 5.59. Found: C, 83.63; H, 5.71.

In other runs the methylcinnamylnaphthohydroquinone was separated from the ethereal solution by repeated extraction with 10% alkali containing hydrosulfite, and this seemed more convenient than the above procedure. The extraction method was employed in an experiment paralleling that above but employing trichloroacetic acid (2 g.) in place of oxalic acid as the condensing agent (3 g. of the hydroquinone, twenty-three hours). There was obtained 0.7 g. of quinone, m. p. 126.5–127°, and 0.15 g., m. p. 125–126°; the yield is thus the same as in the above preparation.

The **hydroquinone diacetate** was obtained both from the crude hydroquinone with acetic anhydride and pyridine in the cold and from the quinone, zinc dust, acetic anhydride and pyridine. It crystallized from ether–petroleum ether in fine, silky needles, m. p. 167.5–168°.

Anal. Calcd. for $C_{24}H_{22}O_4$: C, 76.98; H, 5.92. Found: C, 77.17; H, 6.09.

2-Ethyl-3-cinnamyl-1,4-naphthoquinone.—2-Ethyl-1,4-naphthohydroquinone (3 g.) was condensed with cinnamyl alcohol (1.54) exactly as described for the lower homolog (twenty-two hours) and unchanged starting material (1.68 g.) was extracted with three portions of 2% alkali-hydrosulfite. The substituted hydroquinone was then extracted with 10% alkali (five portions) and the yellow liquor washed with ether and acidified. The product was taken into ether and oxidized with silver oxide and the crude quinone (0.38 g.) crystallized three times from alcohol; yield, 0.2 g. (9.4%, based on material consumed). The quinone forms flat needles, m. p. 118–118.5°; the behavior in the test with alcoholic alkali is like that of the methyl compound.

Anal. Calcd. for $C_{21}H_{18}O_2$: C, 83.41; H, 6.00. Found: C, 83.29; H, 6.10.

The **hydroquinone diacetate,** prepared as above by the pyridine method, was obtained from ether–petroleum ether as elongated prisms, m. p. 123.5–124.5°. Recrystallization from methanol did not change the m. p.

Anal. Calcd. for $C_{25}H_{24}O_4$: C, 77.30; H, 6.23. Found: C, 77.23; H, 6.34.

Condensation with Isoprene.—A solution of 2 g. each of methylnaphthohydroquinone, isoprene, and anhydrous oxalic acid in 20 cc. of dioxane was heated in a sealed tube at 180° for fifteen hours. Unchanged hydroquinone was extracted with 1% alkali-hydrosulfite (75 cc.) and yielded 0.6 g. of pure methylnaphthoquinone. Extraction with 100 cc. of 10% alkali-hydrosulfite in four portions and acidification with acetic acid gave 0.3 g. of white solid. This was oxidized with ferric chloride giving the quinone as a yellow oil which failed to crystallize and which was therefore converted by reductive acetylation (sodium acetate) to **2-methyl-3-(γ,γ-dimethylallyl)-1,4-naphthohydroquinone diacetate.** On purification this crystallized from ether–hexane as colorless prisms, m. p. 104.5–105.5°.

Anal. Calcd. for $C_{20}H_{22}O_4$: C, 73.60; H, 6.80. Found: C, 73.52; H, 6.79.

Condensation with Benzyl Alcohol.—The reaction was conducted with methylnaphthohydroquinone (2 g.), benzyl alcohol (1.24 g.), oxalic acid (2 g.), and dioxane (20 cc.) at the reflux temperature (twenty-five hours) and worked up as in the reaction with isoprene. The recovered starting material isolated as the quinone (m. p. 105–106°) amounted to 1.5 g., and oxidation of the product extracted with 10% alkali (75 cc.) afforded a few milligrams of **2-methyl-3-benzyl-1,4-naphthoquinone.** After two crystallizations from ether–petroleum ether this melted at 105–107.5°; a mixture with the sample described above melted at 107–108°, and the m. p. of methylnaphthoquinone was depressed to 73°.

Other Trials.—The starting material was largely recovered (1.4 g., as quinone) on attempted condensation of allyl alcohol (0.8 g.) with methylnaphthohydroquinone (2 g.) at 180° for twenty-four hours under the above conditions. Piperylene did not react readily, but there were indications of partial condensation at 120°. No reaction occurred on refluxing either the diacetate (thirty-six hours) or the dibenzyl ether (twenty-eight hours) of methylnaphthohydroquinone with dimethylbutadiene and oxalic acid in dioxane, the starting materials being recovered unchanged.

Summary

By using a mild condensing agent such as anhydrous oxalic acid in dioxane solution, 2-alkyl-1,4-naphthohydroquinones can be condensed with sufficiently reactive β-unsaturated alcohols, dienes or aryl carbinols, and under these conditions the substituted hydroquinones first formed are only partially cyclized and can be isolated and con-

verted into quinones of the structural type of vitamin K_1.

Another observation of this work is that a typical 2-alkyl-1,4-naphthoquinone oxide is converted into a bromohydrin by the action of magnesium bromide in ether. New methods are described for the preparation of such oxides and for carrying out the reductive acetylation of quinones.

Quantum Yields and Kinetics of a Photosensitized Production of Reducing Sugars from Sucrose in Aqueous Solutions of Uranyl Sulfate by Visible and Ultraviolet Light

BY LAWRENCE J. HEIDT

Aqueous solutions of sucrose are about as transparent as water in the visible and near ultraviolet to 200 mμ, so light in this region has not been found to produce any measurable effect upon the stability of sucrose dissolved in water. When uranyl ions are added to these solutions, they absorb visible and ultraviolet light; but their extinction coefficients between 470 and 208 mμ are the same as if no sucrose was present. Neither does the uranyl sulfate greatly affect the specific rotation of sucrose, which remains within 0.2% of 66.5° for the D lines of sodium.

Illumination of these sucrose–uranyl solutions with light absorbed by the uranyl ion causes a decrease in their optical activity and the formation of products which reduce the alkaline cupric solutions of Shaffer, Hartmann and Somogyi.[1]

Materials.—The sucrose was U. S. Bureau of Standards sample 17, lot 3650, and the fructose and glucose were recrystallized specimens with the correct rotations.[2] They were stored in vacuum over "Anhydrone" and were kept in the dark as much as possible.

The uranyl salts, oxalic acid, and permanganate were recrystallized and centrifuged specimens like those used previously.[3]

The sodium oxalate used to standardize the permanganate solutions was U. S. Bureau of Standards sample 40c.

All the other chemicals were reagent quality.

Apparatus and Procedure.—Monochromatic light was obtained by means of a prism monochromator using crystal quartz lenses. The 60° cornu prism was 6.5 cm. high and had faces 8 cm. long. It was purchased with a grant from the Warren Fund of the American Academy of Arts and Sciences. The monochromator transmitted in air the 185 mμ line of aluminum and separated the 578 and 546 mμ lines of mercury. In combination with a zinc spark, the energies at 208, 254 and 280 mμ transmitted by the exit slit were about the same as those obtained elsewhere with similar apparatus.[4]

Two reaction cells were used with the monochromator ensemble. One was rectangular, 20 mm. wide and 40 mm. high and held 5 cc. of solution in a 5-mm. layer. The other cell was trapezoidal and held 12 cc. of solution in a 30-mm. layer between the parallel windows. The front window was 10 mm. wide and 20 mm. high and the back window, 20 mm. wide and 40 mm. high. The transparency of the windows of both cells agreed within 2% at 208 mμ.

The source of light at 366 and 436 mμ was an inverted "U" type mercury vapor arc lamp.[5] Its intensity at these wave lengths was increased by reducing to 5 mm. the internal diameter of the quartz tubing containing the arc. This made available behind the exit slit (1 mm. wide × 10 mm. high) 7×10^{17} photons per minute at 366 mμ and 4×10^{17} at 436 mμ, varying less than 1% in twenty hours when the lamp was properly operated.

The amount of monochromatic light at 254 mμ was increased over 200-fold, to 5×10^{19} photons per minute, as described elsewhere.[6] Duplicate cells and stirrers used with this apparatus were made from the same pieces of transparent quartz. Quantum yields were the same whether obtained with this set-up or with the monochromator (see Table I, Expts. 12 and 13). The effectiveness of the light-proof aluminum tube that acted as a shutter was demonstrated in Expt. 9d, Table I, where the values in parentheses are directly proportional to the light flux which would have been incident on the sugar solution had the shutter been removed.

Analytical.—The light flux entering the actinic systems was measured with the uranyl oxalate solutions recommended for use as actinometers.[3,7] The oxalate content of the solutions was determined by electrometric titration with permanganate after proof that the method gave the same values of ϕ as titration to a color end-point. The

end-point by the electrometric method can be reproduced to 0.04 cc. of 0.0002 molar permanganate (4×10^{-8} equivalent) when the volume of the titrated solution is less than 10 cc. Titrations were made with solutions weighed to 1 mg.

The amount of reducing sugars formed was determined with the Shaffer–Hartmann–Somogyi (S.–H.–S.) reagent, whose composition is given in reference 1. The procedure was modified when the solutions containing reducing sugars were buffered. In the first place, accurately measured aliquots of the buffered sugar solutions were made up to 5 cc. by adding more buffer if necessary. Then they were neutralized with caustic soda solution, before adding 5 cc. of the S.–H.–S. reagent. Second, instead of 5, 10 cc. of 1 *N* sulfuric acid was added to liberate the iodine before titration with approximately 0.002 *M* sodium thiosulfate, hereafter called "hypo." This avoided a fading end-point which occurred when the *p*H of the titrated solution was not low enough.

The calibration plots of mg. reducing sugar *vs.* cc. hypo (equivalent to the cuprous oxide formed) showed that the acetate buffer, the uranyl sulfate, the concentrations of the reducing sugars and sucrose, the dark reaction, and the reoxidation of the cuprous oxide during the heating and at room temperature—all affected the S.–H.–S. titrations. These effects, however, altered less than 10% the estimations of the reducing sugars formed in photolysis, as calculated from the observed difference between the titrations on the samples photolyzed and on those kept in the dark under otherwise similar conditions. The acetate buffer and uranyl sulfate increased slightly the weight of reducing sugar equivalent to a cc. of hypo, and corrections made for these effects were less than 7%. A yellow precipitate formed sometimes when the uranyl sulfate solutions were neutralized, but this did not seem to interfere with the reproducibility of the titrations. The calibration plots of the S.–H.–S. reagents used agreed within 3%.

Both "dark" and illuminated solutions were analyzed at the same time and under the same conditions. In most cases, the dark reaction was less than 2% of the total, but at the highest concentrations of sucrose, the dark reaction and the presence of the sucrose caused a reduction of the S.–H.–S. reagent, equivalent to 0.6 cc. of hypo per cc. of sugar solution.

The range of *p*H was confined between 3 and 6. At lower values, the hydrolysis of sucrose in the dark becomes appreciable.[1] At higher values, the stability of fructose and glucose decreases—the former being most stable at *p*H 3.3.[8] In addition, it was observed that as the *p*H was increased from 6 to 11, a 0.01 *M* solution of uranyl sulfate changed from green to yellow and finally produced a yellow precipitate.

The *p*H values were measured to 0.05 on a vacuum tube *p*H meter which used a glass electrode against a calomel half-cell saturated with potassium chloride.

Stock solutions of sugar always were made up less than an hour before withdrawing a sample and were not used a second day except in experiments covering more than a day. These solutions were made from tared samples of dry sucrose, 0.04 *M* uranyl sulfate, and enough water or 1 or 0.1 molar acetate buffer to complete the solution. Other organic compounds used as buffers between *p*H 3 and 6 absorb light strongly at 254 mμ. Even acetate absorbs 208 mμ and was omitted when working at this wave length. It was omitted also at 366 and 436 mμ because extinction coefficients of the acetate solutions were not available to evaluate the light transmitted. Phosphate buffers precipitated the uranyl ion and left solutions which transmitted through 3 cm. both 254 and 208 mμ, accompanied by a green fluorescence.

Results

Extinction coefficients, k, were measured from 45,000 to 21,000 cm.$^{-1}$ for aqueous solutions of uranyl sulfate at 0.04 and 0.0004 molar and for 0.0365 and 0.000365 *M* uranyl sulfate containing sucrose at 4.02 and 0.0402 *M*, respectively. The null photographic method was used. The presence of the sucrose had no effect upon k and Beer's law was obeyed. These facts strongly suggest that in this part of the spectrum the absorbing species in solutions of uranyl sulfate were not changed when 100 times as much sucrose was added or when concentrations were varied 100-fold.

The observed values of k agreed with the best values in the literature,[9] but the dip in absorption at 366 mμ has a broader minimum on the long wave length side than the values previously obtained by extrapolation between 365 and 405 mμ. The smoothed values of $\log_{10} k$ are 0.6 at 450, 380 and 364 mμ; 0.7 at 445, 385 and 352 mμ; 0.8 at 443, 390 and 351 mμ; 0.9 at 440, 395 and 350 mμ; and 1.0 at 430, 405 and 349 mμ. $k = [\log_{10} (I_0/I)]/cd$ where c is in moles per liter and the depth d of the absorbing layer is in centimeters.

Pringsheim's photographs[10] of the absorption spectrum of 0.05 *M* uranyl sulfate also show a broad minimum about 366 mμ.

No measurements of k were made on solutions containing acetate buffer because absorption of 254 mμ was complete whenever acetate buffer was used. It was observed, however, that the presence of acetate in uranyl sulfate solutions gave rise at 313 mμ and longer wave lengths to a green fluorescence which even defined the variations of the light intensity in the beam. At 254 mμ, the green fluorescence changed to blue. The oxalic acid–uranyl sulfate solutions gave only a very faint, visible fluorescence. An analysis of the visible and near ultraviolet absorption and fluores-

cent spectra of uranyl salts has been published.[11]

Table I summarizes all the data obtained when reactions were followed with the copper reduction technique. This eliminated any corrections for the mutarotation of the liberated reducing sugars, and was many times more sensitive than following the accompanying change in the optical activity. Even in a 4-dm. tube, a change of 0.01° was equivalent per cc. of solution to nearly 0.5 cc. of hypo, which was reproduced within 0.1 cc.

Column II gives the average of two or more determinations of the reducing sugars formed by light in 1 cc. of the solutions photolyzed. These entries refer to the sensitivity of the S.-H.-S. reagent when reduced one-fourth by a solution containing invert sugar in the presence of 1 M acetate buffer and 0.008 M uranyl sulfate. Under these conditions 1 cc. of hypo was equivalent to 5.8×10^{-5} g. of invert sugar which represented the average of 5.74×10^{-5} g. for glucose alone, and 5.85×10^{-5} g. for fructose alone. This amount of invert sugar could be formed from $5.8 \times 6.06 \times 10^{18}/360 = 9.76 \times 10^{16}$ molecules of sucrose.

Column III gives the average of four or more determinations of the cc. of 0.00179 molar potassium permanganate equivalent to the oxalate particles which disappeared in 1 cc. of the actinometer solution each minute it was photolyzed. One-twentieth to one-fifth of the oxalate was decomposed. At the lowest intensities, the actinometer solutions were photolyzed immediately before and after illuminating the sugar solution; otherwise, the light intensities were determined at the beginning, middle, and end of a day. These values always agreed within 5% and showed no trend, so their average was taken for all experiments that day.

The actinometer was 0.001 M in uranyl sulfate and 0.0067 M in oxalic acid at 208 and 254 mμ, and 0.01 M in uranyl sulfate and 0.067 M in oxalic acid at 366 and 436 mμ. The fraction of an oxalate particle which disappeared per photon absorbed by these solutions at 25° was taken[3,9] as 0.49 at 208 mμ, 0.63 at 254 mμ, 0.49 at 366 mμ and 0.58 at 436 mμ with a ten degree temperature coefficient of 1.03 at all these wave lengths.

The volumes of the actinometer and sugar solutions photolyzed were 11 cc. except when the change in optical activity of the sugar solution was followed; then they were 12 cc. However, when the monochromator was used, the photolyzed samples were only large enough to intercept the diverging beam from the exit slit.

Quantum yields, ϕ, in Table I are equal to a constant, A, multiplied by column II divided by the product of columns I and III.

Light at 208 and 254 mμ was completely absorbed by the sugar and actinometer solutions, so at 25° for 208 mμ, A equals 9.76×10^{16} divided by $(2.72 \times 10^{18}/0.49)$ to give 0.0176; and for 254 mμ, A equals 0.0212 at 10° and 0.0288 at 35°.

Light at 366 and 436 mμ was not completely absorbed by the 30-mm. depths of either the (1) actinometer or (2) sugar solutions. Solution (1) absorbed 72% of the light incident at λ 366 mμ and 60% at λ 436 mμ. Solution (2) absorbed 52% at 366 mμ and 82% at 436 mμ. These percentages include the amount absorbed after reflection from the back window of the cell and were calculated from the data in reference 9a. Therefore, for 366 mμ, $A = 0.0248$; and for 436 mμ, $A = 0.0155$.

The reproducibility of the quantum yields for the sugar solutions was 3% as shown in Table I by Expts. 3 and 4 made six weeks apart, and by 19 and 20 made five weeks apart.

The products of the reaction which reduced the S.-H.-S. reagent were assumed to be equal weights of glucose and fructose commonly called invert sugar. This is, no doubt, too simple an hypothesis during the latter stages of the photolysis when much sucrose has been decomposed. Many attempts were made to test this hypothesis by following the decrease in the optical activity of the solution which accompanied the formation of the reducing sugars. It was impossible, however, to decompose by photolysis enough sucrose to decrease the observed rotations more than a fraction of a degree before the solutions became discolored or a precipitate appeared. Moreover, solutions could not be made alkaline to eliminate corrections for the mutarotation of the liberated reducing sugars because sucrose mutarotates in alkaline solutions containing uranyl salts.[12] Specific rotations, $\alpha^{21.5°}D$, therefore, were obtained for glucose (52.0°), fructose (−91.0°), and sucrose (66.4°) at concentrations covering the range used in the photolysis. The fraction of d-glucose (starting at $\alpha > 100$) that underwent mutarotation each minute at 21.5° varied from 0.026 at pH 3.0 to 0.031 at pH 3.5 in these solutions. The

TABLE I

Data giving the photochemical efficiency, ϕ, of the production by light of reducing sugars in aqueous solutions of sucrose and uranyl sulfate. $\phi = A$ multiplied by column (II)/(I)(III). The appropriate values of A are given in the text. The temperature was 10 ± 1° except as noted in column I. A starred ϕ indicates that the light was isolated by a prism monochromator and accompanying entries in columns II and III, marked "*t*," represent the amount photolyzed (per min. for III) in the total volume illuminated. In the *p*H column, the unmarked values represent solutions buffered with 1 *M* acetate, and values with one star those buffered with 0.1 *M* acetate. The barred w values are for unbuffered solutions and represent the average of the initial and final *p*H, which differed less than 0.1 except in Expt. 15 where the difference was 0.15. Solutions were placed only in glass vessels sterilized at 110° and then cooled to 25° just before being used.

mutarotation of fructose was completed in less than ten minutes. Thus, the small decreases in the optical activities, when no discoloration was evident, were known only within 5% although the rotations were read to 0.02° in a 4-dm. tube. Despite this uncertainty combined with those in the S.–H.–S. method, the experiments showed that the reducing sugars—assuming them to have the same reducing power as invert sugar—produced by the photochemical decomposition of the sucrose had a combined *negative* rotation whose absolute value was not greater than that of invert sugar.

The decreases in the optical activities of the samples kept in the *dark* agreed in every case to ±0.02°, with the S.–H.–S. estimates of invert sugar, and no discoloration or precipitate occurred even when 13% of the sucrose had been inverted in a solution containing 4% sucrose in 0.016 *M* uranyl sulfate buffered with 1 *M* acetate at *p*H 3.0. The invert sugar derived from a gram of sucrose was taken to have an α of 360 (52.0 − 91.0)/2 × 342 = −20.5°.

The dark rates for the inversion of sucrose at 21.5° and *p*H 3.0 to 3.5 were not changed in solutions partially inverted by photolysis.

Subsequent reactions in the early stages of the photolysis affected little the amount of reducing sugar formed. Quantum yields did not change more than corresponded to the depletion of the sucrose when 15% of the sucrose was decomposed in Expt. 2a, Table I, and the molar ratio of sucrose decomposed to uranyl sulfate initially present was less than one as in Expt. 21. Nevertheless, the decrease of 0.05 to 0.15 in the *p*H of the unbuffered solutions can be attributed to a minute amount of direct[13] and also photosensitized decomposition of the reducing sugars initially formed.

Side reactions due to the deactivating effect of the acetate halved the efficiency of the measured reaction as shown by Expts. 12 and 14, Table I. Decreasing the acetate buffer from 1 *M* in Expt. 6 to 0.1 *M* in Expt. 7, however, had no effect, but in both experiments the concentration of the acetate was many times greater than the sucrose or uranyl sulfate. The deactivating effect of acetate, therefore, had reached a limit at 254 mμ before its concentration was ten times greater than the uranyl sulfate.

When sucrose was omitted from an acetate buffered uranyl sulfate solution as in Expt. 1, no substances were produced which reduced the S.–H.–S. reagent[14] nor were they produced when 0.008 *M* uranyl sulfate alone in water absorbed per cc. of solution 3×10^{19} photons of λ 254 mμ. The depletion of uranyl particles[15] also did not change the *p*H of this solution, which remained at 3.5.

In a preliminary experiment, a solution containing 0.14 g. of sucrose in 50 cc. of 0.0008 *M* uranyl sulfate without buffer was photolyzed under its own vapor pressure, and the results showed that the production of the reducing sugars was affected less than 20% by dissolved oxygen from the air which enters the photosensitized oxidation of iodide by uranyl sulfate.[16]

Kinetics of the Photosensitized Reaction.—The primary act is the capture of a photon by a uranyl particle. Part of the activated uranyl particles are sufficiently close to sucrose and the other reactants and properly oriented to initiate the hydrolysis. The fraction of the activated particles so disposed is proportional to ϕ, whereupon

$$\phi = B[UO_2SO_4]^n[\text{sucrose}]^m[H_3O^+]^l \cdots/[UO_2SO_4] \quad (1)$$

where B is the proportionality constant and the sum of the exponents in the numerator equals the number of reactant particles entering the photochemically active cluster. When ϕ cannot exceed a finite value a

$$\phi = a[1 - \exp(-gx)] \quad (2)$$

where x is directly proportional to the right side of (1) and g includes B. At small values of gx equation (2) becomes

$$\phi = agx \quad (3)$$

In this range of values, each exponent except that of the photosensitizer, uranyl sulfate, equals the slope of the plot of log ϕ against the logarithm of the concentration of the corresponding reactant when other variables are fixed. For the photosensitizer, however, n equals one plus the slope. The independence of ϕ upon the concentration of uranyl sulfate between 0.008 and 0.0008 *M* in Expts. 4 and 5, and in 19, 20 and 21, therefore, shows that only one uranyl particle enters the reactive complex. These results also confirm the observed independence of ϕ upon the light intensity, I, in Expts. 6 and 8, and 9 and 10, where I was changed over 200-fold, yet ϕ was not affected. They also show that the stirring adequately prevented the local depletion of reactants in the zones absorbing most of the actinic light, and that the transparent quartz stirrers did not alter the amount of light absorbed by the solutions even when there impinged on the stirrers possibly one-tenth of the light incident on the most dilute solutions of uranyl sulfate.

The points on a plot of log ϕ at 254 mμ. in the buffered solutions against log (sucrose) fell on a curved line that approached unit slope, within experimental error,[17] only when ϕ was less than 0.1. Therefore, the largest observed values of ϕ are too near the maximum value for equation (3) to hold. The approach of the plot to unit slope when ϕ is small, however, shows that $m = 1$. Thus, one molecule of sucrose enters the reaction with each uranyl particle.

In Fig. 1, the equation for the curve is

$$\phi = 0.3\ [1 - \exp\ (-\ g[\text{sucrose}])\ ] \quad (4)$$

$g = 1$ when, as plotted [sucrose] equals grams in 50 cc. of solution, but for [sucrose] in moles per liter of solution, $g = 0.585$.

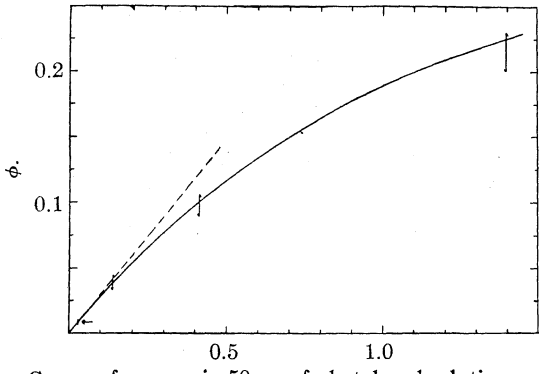
(17) A straight line through all the points had a slope of 0.77 calculated by the method of least squares.

The choice of 0.3 for a and of 1 for m was confirmed by a plot of log log $[(a - \phi)a]$ against log [sucrose] in which the points, within the limits of error, fell on a line with unit slope.



Grams of sucrose in 50 cc. of photolyzed solution.

Fig. 1 illustrates, for the initial reaction, the increase of quantum yields, ϕ, at 254 mμ. with [sucrose] in acetate buffered solutions of uranyl sulfate. No other variables needed to be fixed because ϕ was independent of them. Vertical lines represent the spread of all the observed values at pH 3.5 to 6.0 and at 10 to 35°. The curve was calculated from theory. The dotted line gives the linear dependence of ϕ upon [sucrose] as both terms approach zero. The slope of this line equals ag where a is the maximum value of ϕ and g is also a constant.

The factor a equals the maximum value of ϕ at this wave length in these buffered solutions. It is a function of the transfer and utilization of energy within the complex.

The factor g includes the equilibrium constant K for the reaction defined in equation (1). As the stability of the cluster increases, g will increase. When more clusters are formed with increasing temperature, ϕ will approach a, and the temperature coefficient of ϕ will approach zero. The temperature coefficient will also be small for ϕ much less than a when $\mathrm{d}(\ln K)/\mathrm{d}T = -\Delta H/RT^2$ is small. In Expts. 6 and 10, ϕ remained unchanged while the temperature was increased from 10 to 35°, which shows that ΔH is small since these values of ϕ were not near $\phi = a$.

The independence of ϕ upon the pH in Expts. 4 and 6, and 21 and 22, shows that the catalytic effect of the hydrogen ions is replaced by the activated uranyl salts.

In Fig. 2, the plots of wave length against log ϕ for the sugar and actinometer solutions have a dip in the ultraviolet at which ϕ is, roughly, 25% of ϕ at 436 mμ. The values of ϕ for sucrose at 366 and 436 mμ may be slightly high because absorption of light was incomplete and small increases in the concentration of the uranyl sulfate from the values given would increase ϕ measurably, but would hardly be detected in the measurements of the extinction coefficients by the null photographic method. The dip in ϕ at 208 mμ for the actinometer is due to absorption of this wave length by the oxalic acid.[9b]

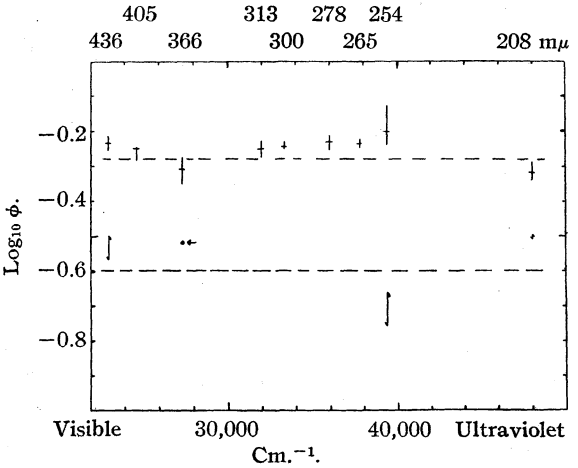


Fig. 2 illustrates the variations in quantum yields with wave length. The dotted lines only serve to emphasize these variations. Vertical lines of equal length give the same percentage spread of the separate, observed values of ϕ included in the average values tabulated. Lines with arrows represent the data for the photolysis of sucrose in the unbuffered solutions of uranyl sulfate given in Table I. Expt. 11 is not included. Lines without arrows represent the maximum values of ϕ at 25° for the oxalic acid–uranyl sulfate actinometer. The points where these lines are crossed give the logarithm of the weighted average values.[9]

It is also seen from Fig. 2 and Table I that blue light, at 436 mμ, is just as efficient as the ultraviolet in the photosensitized production of reducing sugars from sucrose. This suggests that a part of the polysaccharides in plants is converted into simpler sugars by sunlight acting through naturally occurring photosensitizers.

Summary

Reducing sugars have been produced from sucrose by visible and ultraviolet light acting through uranyl salts as photosensitizers.

The decrease in the optical activity which accompanied the formation of the reducing sugars was approximately equivalent to the Shaffer–Hartmann–Somogyi estimations of reducing sugars calculated as invert sugar.

Quantum yields, ϕ, were calculated as molecules

of sucrose decomposed per photon absorbed by the system. The variation in ϕ with the concentration of sucrose was given by $\phi = a[1-\exp(-g[\text{sucrose}])]$. At 254 m$\mu$, $a = 0.3$ and $g = 0.6$ when [sucrose] was expressed in moles per liter and solutions were buffered with acetate. ϕ increased when the solutions were not buffered, but the *p*H then decreased slightly due to subsequent reactions. ϕ was independent of (1) the light intensity over a 200-fold range, (2) the temperature between 10 and 35°, (3) the *p*H between 3 and 6, and (4) the concentration of uranyl sulfate between 0.0008 and 0.008 molar.

The kinetics of the reaction have been discussed.

Extinction coefficients of uranyl sulfate solutions were obtained at intervals of 0.1 in the logarithm and are given for the dip in absorption about 366 mμ. Beer's law was obeyed and sucrose concentrations up to 100 times those of uranyl sulfate did not affect the measurements.

The Aquation of Carbonato Pentammine Cobaltic Bromide

BY ARTHUR B. LAMB AND ROGER G. STEVENS

Carbonate tetrammine cobaltic salts undergo little or no aquation in pure aqueous solution at ordinary temperatures. In other words, the carbonate group is not readily displaced from the complex ion by molecules of water. This is explained by its firm attachment, presumably by two covalent links.

In carbonato pentammine salts the carbonato group appears to be held by one polar and one covalent link. While the former would permit dissociation, the latter holds the carbonato group firmly, so that it cannot function as a separate ion. In agreement with this, their freshly prepared solutions, like those of the corresponding carbonato tetrammine salts, do not give the characteristic tests for the carbonate ion and exhibit the conductance to be expected of uni-univalent electrolytes.

One might expect, however, that carbonato pentammine salts with but a single covalent link holding the carbonato group, would undergo aquation more readily than the carbonato tetrammine salts. Yet, Werner and Gosling,[1] to whom we owe most of our knowledge of the carbonato pentammines, appear never to have observed any aquation of these substances, and Schwartz and Tede[2] state that dilute solutions of the nitrate are stable both in the dark and when exposed to ultraviolet light, as shown by the constancy of their electrical conductance. Duff,[3] to be sure, found that while dilute solutions of the nitrate showed no change in conductance at 25° by themselves, an increase in conductance took place when the solutions were left in contact with platinum electrodes. Solely on the basis of this evidence he inferred that carbonato pentammine nitrate does not aquate spontaneously, but does so under the catalytic influence of the platinum. The latter part of this inference was and is quite unjustified, because no such catalytic effect on aquation has ever been observed by others, while it has long been recognized that the decomposition of cobalt ammines is markedly accelerated by contact with platinum electrodes.[4]

In this situation it appeared of interest to examine solutions of these carbonato pentammines more particularly for possible aquation, and this we have now done by means of measurements of the conductance of dilute solutions of the bromide at 25 and 0°.

The carbonato pentammine cobaltic bromide was prepared through the nitrate following the methods of Werner and Gosling.[1] The conductances were measured using "dip" electrodes following the procedure previously described in another connection.[5] Duplicate readings were taken over an interval of more than an hour with and without the removal of the electrodes from the solution. Identical changes in conductance took place in each instance indicating that the platinum electrodes exerted no perceptible effect under the circumstances.

It can be seen that the conductance increases slowly, indicating a slow aquation. A stationary state is reached after about an hour at 25° and after perhaps ten hours at 0°.

It was possible, to be sure, that the observed increase in conductance was caused by a decomposition of the ammine. If this occurred, free ammonia should be present. A current of air was therefore bubbled through a solution of the ammine and thence into Nessler reagent, blank tests having shown that minute amounts of ammonia in a solution can be detected in this way. With the ammine solution at 0° no trace of ammonia was indicated until after an hour's bubbling. At 25° a trace was indicated in thirty minutes and a marked test was obtained in seventy minutes. Since the change in conductance is nearly complete before any decomposition is detectable, the observed change in conductance cannot be ascribed to decomposition.

Tests were also made to confirm the presence of the bicarbonate ions produced by the aquation. For this purpose a weakly ammoniacal solution of barium chloride was added to freshly prepared solutions of the bicarbonato ammine bromide at 0°. At first no indication of carbonate or bicarbonate was obtained, but after the solution had stood for an hour at this temperature a small precipitate was formed. A similar solution kept at 25° for seventy minutes and then cooled to 0° gave an immediate and copious precipitate when the barium hydroxide was added. These results confirm the inference drawn from the conductance measurements that aquation of the carbonato pentammine does indeed take place.

From the data in Table I values of k in the formula for a unimolecular reaction have been computed taking a, the concentration of the reacting substance, as equal to the total change in conductance and $a - x$ as equal to the change in conductance at the time t. Since the final state reached is, on the basis of all our previous studies of aquation, an equilibrium, the constants thus obtained represent the sum of the individual constants for the direct and the reverse reaction, *i. e.*, $k_1 + k_2$. They are given in the last column of Table I and show a reasonable constancy at each temperature.

The Mechanism of the Aquation

Aquation is usually looked upon as a direct replacement of a complexly held anion by a molecule of water. An alternative mechanism would be the primary addition of hydrogen ion to the complexly held anion with the formation of the undissociated acid which is then replaced by a molecule of water. It is, however, unlikely that this latter is the sole mechanism of aquation, because then the anions of weak acids should aquate more rapidly and completely than those of strong acids, and this does not appear to be the case.

This mechanism is, however, presumably operative in the case of the carbonato pentammines. They react rapidly with acids to give carbonic acid and aquo pentammine salts. Direct replacement of the complexly attached carbonato group by water certainly could not account for so rapid a reaction. There can, therefore, be little doubt that the hydrogen ion here combines directly with carbonato group to form the bicarbonato group. The resulting ion, for electrostatic reasons, would aquate much more rapidly than the carbonato ion itself. Indeed, it might aquate with sufficient rapidity to account entirely for the observed aquation of the carbonato ammine.

Aquation and Anation of the Bicarbonato Pentammines.—To ascertain how rapidly and completely the aquation of the bicarbonato pentammine takes place, we have measured the conductance of dilute solutions of its nitrate at 0° and at successive intervals of time. The data are given in the second column of Table II.

It can be seen that a relatively rapid rise in conductance takes place, indicating rapid aquation, a stationary state being reached in about

eighteen minutes. The extrapolated initial molecular conductance, 124.2 1/ohm, is what would be expected from the previously observed[6] conductance of hydroxo pentammine chloride, 132 1/ohm.

To ascertain whether this final stationary state represents an equilibrium, we have also carried out the reverse process, *i. e.*, the anation[7] of the aquo pentammine. For this purpose we added an equivalent weight of aquo pentammine bromide to a solution of sodium bicarbonate and followed the change of the conductance with the time. The resulting data are collected in Table III.

The observed specific conductances are given in the second column of the table. They exhibit a rapid *decrease*, indicating the formation of the bicarbonato pentammine ion, *i. e.*, anation. To compare these data with those obtained in the previous aquation experiment it was necessary to eliminate the conductance of the sodium bromide present here as shown by the equation

$$(Co(NH_3)_5H_2O)Br_3 + NaHCO_3 \longrightarrow (Co(NH_3)_5HCO_3)Br_2 + NaBr + H_2O$$

and not present in the aquation experiment. This was accomplished by multiplying the observed specific conductance of the sodium bicarbonate solution before the addition of the ammine (0.0001334 1/ohm) by the ratio of the molecular conductances of sodium bromide and sodium bicarbonate at the prevailing concentration, and subtracting the product from the observed specific conductances. The resulting corrected specific conductances were then converted to molecular conductances and were corrected for the diminished conductances, both of the ammine and of the sodium bicarbonate, in the mixture. These corrected molecular conductances are given in the third column of Table III and are shown graphically as the upper curve in Fig. 1. The

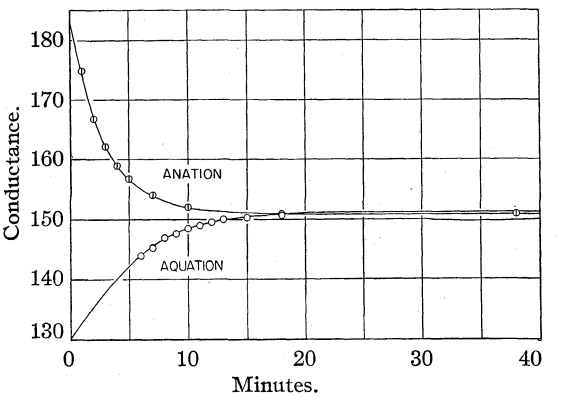

Fig. 1.—Change in conductance (corrected) of a solution of bicarbonatopentammine cobaltic bromide (aquation) and of a solution of aquopentammine cobaltic bromide and sodium bicarbonate (anation) at 0°.

corresponding molecular conductances observed with the bicarbonato pentammine nitrate, corrected to bromide by addition of 5.8 1/ohm for the difference in mobility between two bromide and two nitrate ions, are given in the third column of Table II and are also shown as the lower curve in Fig. 1. It can be seen that these two curves approach each other and after about eighteen minutes become nearly coincident. This indicates that the stationary condition reached both by aquation and anation is indeed an equilibrium.

(6) Lamb and Stevens, ref. 5, p. 2649.

(7) A. B. Lamb, THIS JOURNAL, **61**, 699 (1939).

The composition of the solution of aquo pentammine bromide and sodium bicarbonate at the start, before any bicarbonato pentammine has been formed by anation, can be computed from the known dissociation constants of aquo pentammine ion and carbonic acid. The reactions involved in this equilibrium can be represented as follows

$$(Co(NH_3)_5HCO_3)^{++} \underset{}{\overset{\text{(slow)}}{\rightleftharpoons}} (Co(NH_3)_5H_2O)^{+++} + HCO_3^-$$
$$\downarrow\uparrow\text{(fast)} \qquad\qquad \downarrow\uparrow\text{(fast)}$$
$$(Co(NH_3)_5CO_3)^{+++} \qquad (Co(NH_3)_5OH)^{++} + H_2CO_3$$

Calling Aq^{+++} and Hy^{++} the concentrations of aquo and hydroxo pentammine ions, respectively, and considering solely the above equilibria on the right

$$Hy^{++}/Aq^{+++} = \sqrt{\frac{K_{Aq}}{K_{H_2CO_3}}} = \sqrt{\frac{1 \times 10^{-7}}{4 \times 10^{-7}}} = 1/2$$

That is, $Aq^{+++} = 2Hy^{++}$ at the start.[8] Taking the molecular conductances of the aquo and hydroxo pentammine bromide, sodium carbonate and sodium bromide at 0°, and at the prevailing concentration, as 222, 130, 47.5 and 62.6 1/ohm, respectively, the initial conductances of the system on the right, before any bicarbonato had formed, would be 222 + 47.5 − 62.6, or 206.9 1/ohm, if the pentammine were exclusively aquo, and 130 1/ohm, if exclusively hydroxo. Since, however, $Aq^{+++} = 2Hy^{++}$, the initial conductance should be 206.9 − 1/3(206.9 − 130) = 181.3 1/ohm. This value corresponds closely with the extrapolated value shown in Fig. 1.

The concentrations of the various ions in these solutions at any time during the aquation or anation could likewise be calculated from the observed conductances and the known dissociation constants of aquo pentammine ion and carbonic acid if the dissociation constant for the bicarbonato pentammine ion were also known. From these concentrations velocity constants for aquation and anation could then be directly evaluated with a good deal of certainty. Lacking this information as to the bicarbonato ammine, we have simply assumed, as usual, that the extent of the reaction is proportional to the change in conductance, and since an equilibrium is attained we have taken the total concentration of reacting substance as equal to the amount transformed at equilibrium. The resulting apparent velocity constants for a unimolecular reaction of this sort, $k_1 + k_2$, the sum of the unimolecular velocity constants of the simple aquation and anation reactions, respectively, are given in the final columns of Tables II and III.[7]

It can be seen that the individual values for $k_1 + k_2$ are in each series reasonably constant. The average of the values obtained in the anation measurements is, however, considerably larger than the average obtained in the aquation measurements. This may well be due to a lack of rigor in our assumption of direct proportionality between the change in conductance and the concentrations of the ions undergoing either aquation or anation, or to the failure of the approximate unimolecular formula to represent adequately the bimolecular anation reaction when corrected for the kinetic salt effect.[7]

Aquation in Mixtures of Carbonato and Bicarbonato Pentammine.—We have also made measurements of the change in conductance of solutions of carbonato pentammine bromide to which aliquot amounts of hydrochloric acid have been added. This has afforded a convenient means of obtaining mixtures of the carbonato and bicarbonato ammines. The observed conductances of the ammine immediately upon the addition of the acid and at intervals thereafter are given in Table IV. Velocity constants computed in the same way as for the pure compounds are also given.

It can be seen that the solution to which an equivalent amount of acid was added showed substantially the same initial conductance and the same rate of aquation as a solution of pure bicarbonato pentammine. Solutions containing lesser amounts of acid showed progressively smaller velocities of aquation. Indeed, the velocity constants for the aquation of the several solutions followed closely the formula

$$k_1 + k_2 = 0.214 \frac{(Co(NH_3)_5HCO_3)^{++}}{0.00286}$$

the calculated values for $k_1 + k_2$ when $1/10$ and $1/4$ equivalents of hydrochloric acid were added, being 0.0214 and 0.0535, respectively, whereas 0.0233 and 0.0515 were actually observed.

The application of this formula to the 0.00286 M solution of pure carbonato pentammine bromide where the velocity constant of aquation is 0.0092 1/min. would indicate a concentration of bicarbonato pentammine = 0.0092 × 0.00286/0.214, or 0.00012 M, provided aquation takes

place exclusively via the bicarbonato ammine, that is, with no direct aquation of the carbonato. This concentration of bicarbonato in equilibrium with the carbonato in pure water would correspond to a dissociation constant of about 4×10^{-10}. A direct determination of this constant would show the actual concentration of bicarbonato in equilibrium with the carbonato and thus permit a decision as to what part of the aquation of the carbonato takes place directly and what part via the bicarbonato pentammine.

Summary

1. It has been found from conductance measurements that carbonato pentammine bromide undergoes a slow aquation to give an equilibrium mixture of bicarbonato, aquo and hydroxo pentammines. Bicarbonato pentammine salts undergo a much more rapid aquation, reaching an equilibrium with the opposing anation reaction by which aquo pentammine is converted into bicarbonato pentammine. The velocities of these aquation and anation reactions have been measured and velocity constants have been computed.

2. Evidence is presented to show that in the equation of the carbonato pentammine salts a rapid, reversible addition of hydrogen ion to the complexly held carbonato group takes place, followed by a relatively slow, but reversible, aquation of the bicarbonato group.

3. It has been pointed out that these measurements, coupled with measurements of the dissociation constant of the bicarbonato pentammine ion would permit an estimate of how much of the aquation of the carbonato pentammine takes place directly and how much through the intermediate formation of the bicarbonato pentammine.

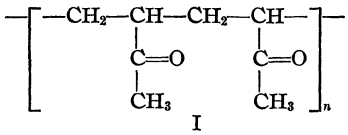
CAMBRIDGE, MASSACHUSETTS RECEIVED JUNE 27, 1939

NOTES

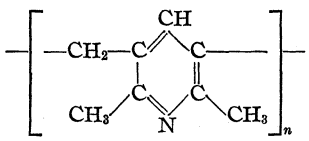
Structure of Vinyl Polymers. V.[1] Some Reactions of the Polymer of Methyl Vinyl Ketone

By C. S. Marvel and Charles L. Levesque[2]

Work from this Laboratory has shown[3] that the polymer of methyl vinyl ketone has a "head to tail" structure (I), and hence contains 1,5-diketone units. However, when this polyketone was treated with hydroxylamine, the corresponding polyketoxime rather than the expected polypyridine (II)[4] was obtained. It has now been found possible to prepare the polypyridine (II) by heating the polyketoxime with alcoholic hydrogen chloride.[5] Flory has shown[6] that no more than 86.47% of the ketoxime groups can participate in this reaction. Analytical results support the conclusion that under the conditions employed in our experiment, the remaining 13.53% of the ketoxime groups were hydrolyzed.

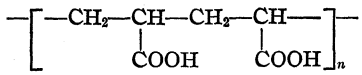


I



II

By treating a dioxane solution of the polymer of methyl vinyl ketone with aqueous sodium hypochlorite,[7] a polyacrylic acid (III) has been obtained. Attempts to compare this polyacid with that obtained by the polymerization of acrylic acid are now in progress.



III

Experimental

Preparation of the Polypyridine.[5]—A solution of 3.2 g. of the oxime of the polymer of methyl vinyl ketone[3] in 50 cc. of concentrated hydrochloric acid was placed in a 1-liter flask and a solution of 135 g. of hydrogen chloride in 500 cc. of alcohol was added. A reflux condenser was attached, and the milky solution was heated to boiling. Enough water to effect complete solution (40 cc.) was added and the mixture was refluxed for nineteen hours. The clear red reaction mixture was concentrated to 15 cc. and neutralized with ammonium hydroxide. The solid which precipitated was collected on a filter and dried under reduced pressure over solid potassium hydroxide. The product was 2.0 g. of light brown powder, readily soluble in acids, but insoluble in aqueous sodium hydroxide.

Anal. Calcd. for 0.4323 mole of C_8H_9N + 0.1353 mole of C_4H_6O: N, 9.94. Found: N, 9.53.

This product may be identical with the basic polymer which Balthis has obtained by the action of ammonia on the polymer of methyl vinyl ketone.[8]

Preparation of the Polyacid.[7]—A solution of sodium hypochlorite was prepared by bubbling chlorine into 160 g. of cold 10% sodium hydroxide until the gain in weight was 12 g. This solution was cooled by an ice-bath and stirred while a solution of 2.8 g. of the polymer of methyl vinyl ketone in 450 cc. of dioxane was added slowly. After the addition was complete, the mixture was stirred at room temperature for six hours. The lower aqueous layer was separated and concentrated under reduced pressure to 35 cc. The concentrate was filtered and the filtrate was acidified with concentrated hydrochloric acid. A white precipitate formed. The mixture of solution and precipitate was placed in a parchment paper sack and dialyzed until freed from chloride ion. The yellow solution remaining in the sack was filtered and the filtrate was evaporated to dryness. The residue was 1.15 g. of brittle, brown solid.

Anal. Calcd. for $(C_3H_4O_2)_n$: C, 50.0; H, 5.55. Found: C, 53.19; H, 5.92. The analysis indicates that about 90% of the methyl ketone groups have been oxidized.

The Rotatory Power of Zinc Lactate[1]

By W. Dayton Maclay, Raymond M. Hann and C. S. Hudson

In a recent article[2] we published measurements of the specific rotation of pure zinc D-lactate dihydrate in water for the concentrations 3.2 and 5.2%, which indicated that the change in rotation with concentration is a small one. Professor

(1) Publication authorized by the Surgeon General, U. S. Public Health Service.

(2) Maclay, Hann and Hudson, This Journal, **61**, 1666 (1939).

Karl P. Link has kindly informed us that he and Mr. R. J. Dimler have measured the rotation of zinc L-lactate in the course of a research on some derivatives of lactic acid, soon to be published, and have found considerable variation in rotation with concentration. We have repeated and confirmed their measurements and, at their suggestion, now record the two sets of values over the wider range of concentrations from 1.5 to 7.0%. In this range the $[\alpha]_D$ values may be expressed approximately as $[\alpha]^{20}D = -9.2° + 0.4(c)$, in aqueous solution, for zinc L-lactate dihydrate. (The configuration of L-lactic acid is $CH_3-\underset{H}{\overset{OH}{C}}-COOH$.)

TABLE I

VARIATION OF ROTATION WITH CONCENTRATION, AQUEOUS SOLUTIONS OF ZINC L-LACTATE DIHYDRATE (ACCURACY ±0.1°)

5.0	−7.2	−7.1
7.0	−6.7	−6.6

In our article we expressed the opinion that the rotations $[\alpha]^{15}D$ +6.84° (*c*, 5.6) for zinc D-lactate dihydrate and $[\alpha]^{20}D$ −6.83° (*c*, 7.1) for zinc L-lactate dihydrate, found by Irvine,[3] indicated some racemization of the lactic acids. It is now seen, however, that these values fit the new measurements very well, from which it may be concluded that the procedure which Irvine used in preparing the zinc lactates does not cause racemization and is therefore preferable to the more laborious procedure which we employed in order to exclude the possibility of racemization.

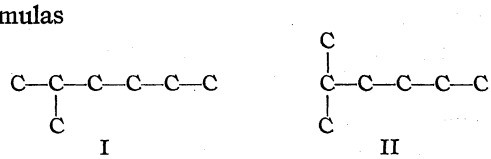
Molecular Structure of Aliphatic Compounds and their Boiling Points

BY E. NEYMAN-PILAT

On the basis of Walker's formula C. R. Kinney recently[1] has developed a new system correlating molecular structure of organic compounds with their boiling points. In a paper dealing specially with aliphatic compounds, the boiling point numbers (b. p. n.) for carbon and hydrogen as well as for some radicals and characteristic groups have been presented. From these data and the given formula the boiling points at atmospheric pressure of aliphatic compounds may be calculated easily and with fair accuracy.

C. R. Kinney has stated that due to the lack of adequate boiling point determinations recorded in the literature for the branched hydrocarbons, the b. p. n.'s for only the methyl, ethyl, propyl and butyl radicals were calculated and that even those may undergo some alteration when more boiling points will be recorded. This point of view would seem to be open to question, as some of the paraffin hydrocarbons listed in Table I of the quoted paper may be considered as being derivatives of different radicals. For example the 2-methylhexane may be treated as a methyl (I) as well as a butyl derivative (II) according to the structural formulas



I II

In the same way the 3-methyloctane may be regarded as 2-pentylbutane and the 3-methylnonane as 2-hexylbutane, etc.

The calculated B. P. N. obviously must be independent of the way in which the structural formulas are expressed.

Taking as a basis the values of 0.8, 1.0 and 3.05 for C, H and CH_3 as given by Kinney, and calculating the B. P. N. for both formulas of each hydrocarbon, the characteristic values for the alkyl radicals have been established. The values as presented in Table I differ by 2.8 for all the neighboring members of the series, this being in accordance with the value calculated from Kinney's data for the CH_2 group. The calculated b. p. n.'s as seen from Table I are somewhat higher

TABLE I

Alkyl radical	B. p. n. calcd. by Kinney	B. p. n. calcd. by the author
CH_3	3.05	3.05
C_2H_5	5.5	5.85
C_3H_7	7.0	8.65
C_4H_9	9.7	11.45
C_5H_{11}		14.25
C_6H_{13}		17.05
C_7H_{15}		19.85
$C_{10}H_{21}$		28.25
$C_{15}H_{31}$		42.25

than those of Kinney but seem to be more accurate as may be seen from the following examples.

(1) C. R. Kinney, THIS JOURNAL, **60**, 3032 (1938).

(1) The 2-methylhexane with a b. p. of 90° has the calcd. B. P. N. of 20.85. If expressed as 2-butylpropane its B. P. N. calcd. with the new value for the butyl radical 11.45 amounts to 20.85 and with the Kinney value 9.7 to 19.1. The b. p. calcd. from the last value amounts to 72.2° while from the first to 90.4°.

(2) For the 2-methylpentane b. p. 60° with the B. P. N. equal to 18.05, the corresponding values for the second formula 2-propylpropane are 18.05 when based on b. p. n. 8.65, and 16.4 when based on b. p. n. equal to 7.0 for the propyl radical. The corresponding calcd. b. p.'s are 60.7 and 41.7°.

(3) The 3,3-diethylpentane has the obsd. B. P. N. of 26.04, the calcd. by Kinney of 25.00 and the calcd. with the new increment for the ethyl radical (5.85) amounting to 25.70.

(4) The 2-methylheptadecane with a b. p. of 311°[2] has the B. P. N. equal to 51.65 (13.6 + 35 + 3.05 or regarded as 2-pentadecylpropane: 2.4 + 7 + 42.25) and the calcd. b. p. of 314.1°.

Using for alkyl radicals the proposed values of b. p. n. the calculated boiling points are in better agreement with observed b. p. for all the ethyl derivatives quoted by Kinney. However, in the case of propyl derivatives as well as of 5-butylnonane, the Kinney values agree much better than those now proposed. It seems to be very plausible that these discrepancies are due either to inaccurate b. p. determinations or to some other unadditive factors bearing on the boiling phenomena.

Instead of calculating the b. p. n. for all the possible radicals, it seems to be much more advisable to calculate the B. P. N. of a compound as a sum of the atomic b. p. n. and take into account the number and kind of the branching present. The increment for a singular branching in the hydrocarbon series amounts in this system evidently to 0.75 (3.8 − 3.05) and must be subtracted from the total B. P. N. In such a way the B. P. N. for *e. g.*, the 2-ethylpentane (C_5H_{16}) will amount to: $(7 \times 0.8) + (16 \times 1) - 0.75 = 20.85$.

It is possible that the value of 0.75 which is true for a single branching, does not hold good in case of two radicals being attached to one carbon atom in the paraffinic chain, and that this is responsible for the discrepancies found in strongly packed molecules.

In addition to the above, mention should be made that Kinney in his calculations does not take into account the influence of the position of the radicals in relation to the whole molecule, although this considerably affects the boiling points of organic compounds.

The Calculation of the Boiling Point Numbers of Aliphatic Compounds

BY CORLISS R. KINNEY

In Dr. Neyman-Pilat's note, "Molecular Structure of Aliphatic Compounds and their Boiling Points," the view was taken that, "The calculated B. P. N. obviously must be independent of the way in which the structural formulas are expressed." If this means that the B. P. N. (molecular boiling point number) of a compound may be calculated without regard for the relationships between the structural components in the molecule, the statement is misleading and the results obtained are variable and consequently of no value. This is true because the relationships between the atoms and groups in molecules do have an effect upon the boiling point of the substance.

By way of example, Dr. Neyman-Pilat suggested that the B. P. N. of 2-methylhexane may be calculated, considering it as 2-butylpropane, by adding the b. p. n. of the side chain butyl group to the b. p. n.'s for the propane chain. Since this gave erroneous results, a new set of b. p. n.'s for the alkyl radicals were proposed (Table I). However, these values were found by Dr. Neyman-Pilat to give unsatisfactory results for those derivatives in which the higher radicals were attached to a longer chain, which, of course, is of no advantage. Furthermore, these values must be used in a particular way, just as the original b. p. n.'s[1] must. This may be demonstrated as follows. Dr. Neyman-Pilat considered 2-methylhexane as 2-butylpropane and, by assigning a new b. p. n. to the butyl radical, obtained a satisfactory B. P. N. However, 2-methylhexane may also be considered as butyldimethylmethane and, if Dr. Neyman-Pilat's new value of 11.45 be used in calculating the B. P. N. of butyldimethylmethane, the result is 19.35 which is much too low. Therefore, by using Dr. Neyman-Pilat's values in a way in which they were

(1) Kinney, THIS JOURNAL, 60, 3032 (1938).

not designed to be used, just as erroneous results may be obtained as when the original b. p. n.'s are used in an erroneous fashion. Since these calculations also show that it is not possible to obtain universal b. p. n.'s for the alkyl groups as Dr. Neyman-Pilat has attempted, it seems advisable to retain the original values which were obtained on the basis that the alkyl radicals were derivatives of the normal paraffin hydrocarbons and not of the 2-methylparaffins. It is essential that the longest chain in the molecule be considered as the base to which the smallest possible radicals are attached. Following this procedure always gives uniform results. The underlying reason is well known to organic chemists in the fact that the boiling point of a substance is not only dependent upon the kind and number of atoms in the molecule, but is also dependent upon the arrangement of those atoms and especially upon the length of the chain.

Dr. Neyman-Pilat has suggested that a higher b. p. n. for the ethyl group than that given in the original paper would give better results. However, it should be pointed out that this is true particularly for the paraffin hydrocarbons and that the value was adopted because it gave more uniform results with all types of organic compounds.

Parachor of Aluminum Bromide in Benzene

BY ISIDORE POPPICK AND ALEXANDER LEHRMAN

The work described here was carried out with the object of determining if the molecular formula of aluminum bromide when dissolved in benzene is the same as that determined for molten aluminum bromide.[1] The method used was to determine the mean parachor of solutions of aluminum bromide in benzene, and to see whether an extrapolation (assuming that the parachor obeys the straight line mixture law) to 100% solute using the formula of Hammick and Andrew[2] would lead to a value of the parachor of pure aluminum bromide that agrees with the value determined by Sugden.[1]

In this method

$$P_m = M_m\gamma^{1/4}/d$$
$$M_m = M_2(X) + M_1(1 - X)$$

(1) Sugden, *J. Chem. Soc.*, 320 (1929).
(2) Hammick and Andrew, *ibid.*, 754 (1929).

Before many measurements had been made, however, it was noticed that the solutions of aluminum bromide in benzene gradually separated into two layers: one, a dense light red oil which turned dark brown-purple on standing, and a less dense colorless layer. All our measurements were made before the separation into the second phase occurred. B. Menschutkin[3] found that the presence of moisture or the introduction of hydrogen bromide into solutions of aluminum bromide in benzene caused the separation into two layers. In our work no hydrogen bromide had been introduced, so it is probable that some water vapor had reacted with the aluminum bromide in the benzene, liberating hydrogen bromide, which in turn caused the formation of the heavy oil. Norris and Rubinstein[4] investigating the formation of complexes of aluminum bromide with toluene in the presence of hydrogen bromide, found by analysis that the complex was $Al_2Br_6 \cdot 6C_6H_5CH_3$. The oil in the case of benzene is probably $Al_2Br_6 \cdot 6C_6H_6$.

Because of the formation of this oil we were unable to carry on work in more concentrated solutions.

Experimental.—The benzene was allowed to stand for one week over mercury, fractionated three times, and dried over phosphorus pentoxide.

Bromine was purified by the method of P. C. Terwogt.[5]

Aluminum bromide was prepared by the method of Kaveler and Monroe.[6] Samples were distilled directly into weighing vials in an atmosphere of dry carbon dioxide.

Densities were determined with a pycnometer with ground glass caps.

Surface tensions were determined using a slightly modified form of Sugden's apparatus.[7] Successive readings were consistent to within 0.4%.

All measurements were made at 34.90 ± 0.03°.

Table I lists the results obtained when the formula Al_2Br_6 is assumed.

TABLE I

Density of solution, d	Mole fraction Al_2Br_6, X	Mean mol. wt., M_m	Surface tension, γ dyne/cm.	Mean parachor P_m
0.9454	0.01737	84.21	26.55	206.6

(7) Sugden, *J. Chem. Soc.*, **125**, 27 (1924).

from a straight line over the region investigated by 1% (the total change in the parachor in this range being 11%).

Sugden[1] had obtained 457.6 as the parachor of molten aluminum bromide, assuming the same formula Al_2Br_6. The value obtained here deviates by 3% from Sugden's value. If Sugden had used the formulas $AlBr_3$ or Al_3Br_9, he would have obtained parachors of 228.8 and 686.4, respectively; in this work the same formulas give values of 232.9 and 703.2 after extrapolation, which represent deviations of a little less than 3%.

Our extrapolation is over a large range, so that any errors made at low concentrations will magnify greatly the error in the final value of the parachor. For this reason, it is somewhat surprising that the extrapolated values for the solution fall so near the values for the molten salt.

Owing to the above uncertainty, we can say only that the results obtained here tend to indicate that the formula of aluminum bromide dissolved in benzene is the same as that for the molten compound.

Preparation of Di-*o*-tolylchloromethane

BY EUGENE B. REID

Incidental to a program of measurement of physical properties, di-*o*-tolylchloromethane was prepared. It has not been described previously in the literature.

o,o'-Dimethylbenzohydrol was prepared by reducing *o,o'*-dimethylbenzophenone with 2% sodium amalgam; m. p. 120.5–121.5°. Boyd and Hatt[1] found 119–119.5°. A benzene solution of the carbinol was kept in contact with a concentrated aqueous hydrochloric acid solution for two days; the two layers were separated, and the benzene solvent evaporated. The di-*o*-tolylchloromethane crystallized from petroleum ether as long prisms; m. p. 70–71°; yield 90%.

Anal. Calcd. for $C_{15}H_{15}Cl$: Cl, 15.37. Found: Cl, 15.44.

The Dipole Moment of the Amino Benzoic Acids in Dioxane

BY LLOYD VAN BLARICOM AND E. C. GILBERT

The dipole moments of *o*-, *m*- and *p*-aminobenzoic acid have been determined in water solution[1] in which solvent they occur partially in the zwitter-ion form. In non-polar solvents they should exist in ordinary molecular form but their low solubility has precluded measurements of their moment in such solvents. However, their solubility in dioxane proved upon examination to be sufficiently high to allow satisfactory measurements, which are reported in this paper. Dioxane has an additional advantage in that it does not cause association, in general, and it has therefore been used in the determination of the moments of many acids which associate in the ordinary non-polar solvents.[2]

Apparatus and Method.—The apparatus has been described previously.[3] It is based upon the heterodyne beat method and has been demonstrated to give correct results on substances of known dielectric constant. Refractive index was measured with a Bausch and Lomb dipping refractometer. Densities were determined with a pycnometer designed to avoid evaporation losses.[4] All weights were reduced to vacuum.

Materials.—Eastman Kodak Co. dioxane was refluxed with sodium hydroxide for ten hours and fractionated, discarding the first and last portions. It was then refluxed over sodium metal for another ten hours, and again distilled. That used for the measurements had the following constants: m. p. 11.7°; $n^{25}D$ 1.41990; ϵ^{25} 2.2266; d^{25}_4 1.02681.

The amino acids were Eastman best grade, further recrystallized three times. They were boiled with charcoal when necessary to improve the color and fractionally crystallized. They had the melting points: ortho, 144.5–145°; meta, 173–174°; para, 187–188° (all corrected for emergent stem).

Results

The results are shown in Table I, and summarized in Table II. It is frequently assumed that the dipole moments of acids will be similar to those of their methyl esters. Estermann has determined the moments of the three methyl esters of these acids and they are included in the tables for comparison.[5] In each case the moment of the free acid is greater than that of the ester by a considerable percentage.

Dielectric studies of these acids in aqueous solu-

Para	301.5	40.6	44.7	3.51	3.40	3.30

In the non-polar solvent dioxane, on the other hand, it assumes the expected intermediary position between the para- and ortho-. This may be shown by a rough calculation of the moment by the method of Williams involving vector addition,[7] the results of which are shown in Table II, column 4. In making them a value of -1.9 is assigned to the carboxyl group and $+1.5$ to the amino group. Such simple assumptions cannot be applied quantitatively to structures as complicated as these molecules since they neglect the effects of valency angles, rotation, resonance, etc. Qualitatively, however, they are useful in illustrating the effect of polarity of the solvent upon the behavior of the meta acid.

NEW BOOKS

Organic Syntheses. An Annual Publication of Satisfactory Methods for the Preparation of Organic Chemicals. Vol. XIX. By JOHN R. JOHNSON, *Editor-in-Chief*, HOMER ADKINS, C. F. H. ALLEN, W. E. BACHMANN, N. L. DRAKE, R. L. SHRINER, LEE IRVIN SMITH and A. H. BLATT, *Secretary*. John Wiley and Sons, Inc., 440 Fourth Ave., New York, N. Y., 1939. vi + 105 pp. 15.5 × 23.5 cm. Price, $1.75.

The present volume, like the preceding one, is in harmony with the contemporary interest in biochemistry. As a reviewer of this volume (G. Bryant Bachman) recorded in a recent number of our News Edition, "it is interesting to note that 17 of the 30 preparations described are of nitrogen compounds." The methods of preparation have all been carefully tested. In a few instances—as in preparations IX, XXII, XXV, and XXX—a brief statement is given concerning the specific usefulness of the compound. Some of us, I am sure, would be glad to see an extension of this desirable feature.

The list of the new preparations is as follows: α-acetaminocinnamic acid, acetylglycine, acridone, 2-amino-4-methylthiazole, benzimidazole, benzohydroxamic acid, ε-benzoylamino-α-bromocaproic acid, ε-benzoylaminocaproic acid, ω-bromoacetophenone, *n*-butyl sulfate, *n*-butyl sulfite, copper chromite catalyst, cyclohexylbenzene, dichloroacetic acid, *p*-dinitrobenzene, ethyl benzoyldimethylacetate, ethyl hydrogen sebacate, hexamethylene glycol, 5-iodoanthranilic acid, iodobenzene, *m*-iodobenzoic acid, *dl*-lysine hydrochlorides, methyl nitrate, *dl*-β-phenylalanine, *o*-phenylenediamine, phenylnitromethane, phenylpyruvic acid, *p*-thiocyanodimethylaniline, 1,2,3-triiodo-5-nitrobenzene, triphenylmethylsodium.

M. GOMBERG

Chemie der Zucker und Polysaccharide. (Chemistry of Sugars and Polysaccharides.) By FRITZ MICHEEL, Professor of Organic Chemistry at the University of Münster (Westfalen). Akademische Verlagsgesellschaft m. b. H., Sternwartenstrasse 8, Leipzig C 1, Germany, 1939. xvi + 399 pp. 16 × 23.5 cm. Price, RM. 26.80; bound, RM. 28.40.

The author, whose important carbohydrate researches are well known, has now published one of the best treatises dealing with this field. The chemistry of the sugars, with

main emphasis on the structural and stereochemical side, is presented thoroughly, logically and concisely, with a wealth of literature references. In addition, there are short chapters concerning starch, cellulose and other polysaccharides, biochemical aspects of carbohydrates, and industrial utilizations. A scholarly selection of those topics in which knowledge is now certain, a thorough but concise and objective presentation of matters which still admit of doubt, combined with a precise yet lucid style of writing, have enabled the author to condense the essentials of the subject into such compass that the book can well be recommended as a text for a one-year course in carbohydrate chemistry. It is also valuable as a reference book because of its clear critical judgments and its literature references.

C. S. HUDSON

Qualitative Organic Chemistry. By NEIL CAMPBELL, Lecturer in Organic Chemistry, University of Edinburgh. D. Van Nostrand Company, Inc., 250 Fourth Avenue, New York, N. Y., 1939. ix + 231 pp. Illustrated. 14 × 20.5 cm. Price, $2.60.

The book is divided into two approximately equal parts. Part A comprises six brief chapters dealing with: (1) Isolation and criteria of purity of pure compounds, (2) Preliminary tests and general procedure for identification of organic compounds, (3) Supplementary and color tests, (4) Choice of derivatives, (5) Preparation of derivatives, (6) Examination of mixtures. It is both interesting and significant that of 57 references cited in the chapter on derivatives 68% are to journals of American origin, while only 3 (*i. e.*, 4%) are to German publications.

Part B consists mainly of 94 pages of tables of compounds. These are arranged by liquids and solids under each of the following headings (numbers indicate the numbers of individual compounds discussed).

Paraffins and cycloparaffins (8), unsaturated hydrocarbons (9), aromatic hydrocarbons (30), halogen derivatives of the hydrocarbons (58), nitro compounds (25), halogen-nitro compounds (18), alcohols (31), phenols (19), halogeno- and nitro-phenols (17), ethers (23), cyclic ethers (3), aldehydes and ketones (52), halogeno- and nitro-carbonyl compounds (12), quinones (8), carbohydrates (14), glycosides (4), carboxylic acids (58), halogeno- and nitro-carboxylic acids (19), acid anhydrides (9), esters (46), esters of inorganic acids (9), acid chlorides (10), amides, imides and ureas (32), nitriles (14), amines (primary and secondary) (39), amines (tertiary) (9), halogen substituted amines (13), nitro amines (14), hydroxy- and alkoxyamines (9), anilides and toluidides (50), amino acids (14), phenylhydrazines (10), nitroso-, azoxy-, hydrazo- and azo-compounds (13), heterocyclic compounds (23), aromatic sulfonic acids (7), substituted sulfonic acids (15), sulfonyl chlorides (6), sulfonamides (6), thioamides (3), and finally isothiocyanates (8).

Part B also includes the usual explanatory material, a general index, author index (136 entries) and an alphabetical index of compounds given in the tables. A count of this last index indicates that 755 compounds have been included. Within each of the solid and liquid sections the compounds are arranged in increasing order of m. p. or b. p., respectively, their values being rounded off to even degrees in each case. For most of the compounds one or two derivatives are suggested (not three for each as stated by the publisher in an extravagantly worded current advertisement); occasionally a very brief remark calls attention to a specific property. For many of the liquids (but by no means all) values of density are given to three figures.

The book is intended primarily for students taking a course in organic qualitative analysis. It will prove useful and stimulating for short elementary courses in this field.

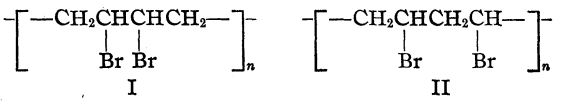
The Structure of Vinyl Polymers. VI.[1] Polyvinyl Halides

BY C. S. MARVEL, J. H. SAMPLE AND MAX F. ROY

The earliest work on the structure of the polyvinyl halides was that of Ostromysslenski[2] who showed that zinc removes bromine from polyvinyl bromide in chlorobenzene solution. He stated that this reaction showed that polyvinyl bromide had the same structural unit which occurred in the perbromide of polybutadiene (I).



I

II

The properties of the two bromine-containing products were compared and it was stated that they were identical. Somewhat later a patent[3] was granted on the preparation of a caoutchouc-like product by the action of zinc on polyvinyl halides.

Harries[4] made a vigorous attack on the authenticity of Ostromysslenski's work. He pointed out that the perbromide of polybutadiene never can be obtained with the theoretical bromine content of 74.7% corresponding to that of polyvinyl bromide. Actually bromination of polybutadiene gave a product with a bromine content of 62.4 to 71.8%. The difficulties of proving the identity of two polymeric products were pointed out by Harries.

Later Staudinger, Brunner and Feisst[5] studied the reactions of polyvinyl bromide and concluded that it was a 1,3-dihalide (II). They confirmed the observation of Ostromysslenski that zinc removes the halogen from a polyvinyl halide and accounted for this by ring formation. They also noted that zinc alkyls removed bromine from polyvinyl bromide and that reduction produced paraffin-like products.

In the present study of the structure of the polyvinyl halides most of the work has been done with polyvinyl chloride. When a saturated solution in dioxane of this polymer was heated with zinc, an insoluble product still containing most of the halogen was formed. When a very dilute solution of polyvinyl chloride in dioxane was heated with zinc the cross-linking reaction which produced the insoluble material was avoided and a smooth dehalogenation reaction occurred. It was never possible to remove all of the chlorine under the conditions used, but the amount removed under the most favorable conditions varied from 84 to 87%. Similarly, zinc removed 85.9% of the bromine from polyvinyl bromide. These facts are particularly significant, since Flory[6] has shown that random removal of pairs of halogens in a polymeric 1,3-dihalide should take out 86.47% of the halogen and leave 13.53% of the halogen isolated from reactive neighbors and non-removable except by cross-linking of the carbon chains. The polymeric material left after the reaction of polyvinyl chloride with zinc was still soluble in dioxane. It did not decolorize an alkaline solu-

tion of potassium permanganate if care was taken to avoid contamination with peroxides from the dioxane. Treatment of the dehalogenated polymer with ozone and subsequent hydrolysis in the presence of an oxidizing agent did not give definite products, whereas under the same conditions polybutadiene gave succinic acid.[7] Nitric acid did not attack the dehalogenated polymer readily. Chlorine would attack the dehalogenated polymer and both addition and substitution of chlorine occurred. All of these reactions indicate that the dehalogenated polymer consists of cyclopropane units with occasional isolated —CH_2CHCl— units (III).

$$-CH_2CHCH_2CHCH_2CHCH_2CHCH_2CH-$$

III

Another fact which supports the 1,3-dihalide structure for the polyvinyl halides is that neither the chloride nor the bromide liberates iodine from a peroxide-free dioxane solution of potassium iodide, a reaction which is characteristic of 1,2-dihalides.[8]

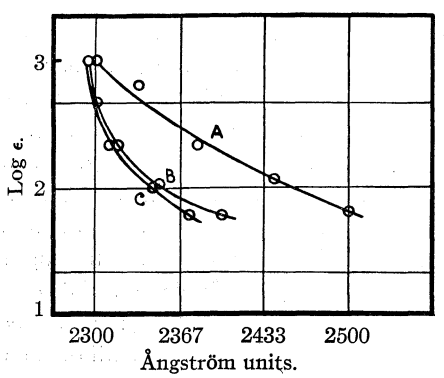

Fig. 1.—Ultraviolet absorption spectra, ϵ = extinction coefficient: A, 2,3-dichloropentane; B, 2,4-dichloropentane; C, polyvinyl chloride.

Further evidence for the 1,3-dihalide structure is obtained by a comparison of the ultraviolet absorption spectra of 2,3-dichloropentane (IV), 2,4-dichloropentane (V) and polyvinyl chloride (VI). The absorption curves are given in Fig. 1.

(Cl, Cl)

VI

It is interesting to note that treatment of a "Cellosolve" solution of polyvinyl chloride with potassium hydroxide removes halogen acid and leads to the formation of an insoluble shiny reddish-brown polymer which corresponds to the polymer $(CH)_x$ reported by Ostromysslenski.[3] This product is probably a very long chain polyene (VII). We have not investigated this polymer in any detail.

$$-[-CH=CH-CH=CH-]_n-$$

VII

All of the reactions and properties of the polyvinyl halides are thus best accounted for on the basis of the 1,3-dihalide structure which was first proposed by Staudinger, Brunner and Feisst.[5]

Experimental

The polyvinyl chloride used in this investigation was furnished by the Carbide and Carbon Chemicals Corporation.[9] It had been prepared by the polymerization of vinyl chloride in the presence of peroxides. Its chlorine content was 56.7%. The polymer was stable to boiling water. It was insoluble in most solvents but did dissolve slowly in dioxane.

Reaction of Polyvinyl Chloride with Zinc.—Ordinary zinc dust was purified by treating it with dilute hydrochloric acid to remove oxide and sulfide, then by washing with water to remove acid and with acetone to remove water. The zinc was dried in a desiccator and used without long exposure to air. In the air the zinc became unreactive in about two months.

When a saturated solution of polyvinyl chloride in dioxane was boiled with zinc, a rubbery gray mass separated out. This material contained halogen and a great deal of occluded zinc. It was not soluble in organic solvents and no satisfactory procedure could be devised to separate the organic and inorganic constituents.

When a very dilute solution of polyvinyl chloride in peroxide-free dioxane was boiled with zinc, halogen was

(9) The authors desire to express their thanks to Mr. H. B. McClure of Carbide and Carbon Chemicals Corporation for his aid in this connection.

removed and the organic residue remained soluble. The dehalogenation reaction proceeded rather slowly and seemed to stop after about one hundred fifty to one hundred sixty hours. The excess zinc could be removed by filtration and the addition of water to the filtrate precipitated a rubbery polymer. Analysis of this polymer and of the remaining solution showed that the zinc treatment had removed about 85% of the chlorine from the polyvinyl chloride. Some typical experiments are listed in the table.

Properties of the Dehalogenated Polymer.—The dehalogenated polymer was precipitated from the dioxane solution as a rubbery mass by the addition of water. This polymer dissolved slowly in carbon tetrachloride. Its dioxane solution did not give a test for unsaturation when shaken with 2% alkaline potassium permanganate solution.

A carbon tetrachloride solution of the rubbery polymer was treated with ozone and then hydrolyzed but no evidence of ozonolysis was obtained. Treatment with nitric acid caused some oxidation but did not yield crystalline products. When the dioxane solution from the zinc treatment was mixed with a solution of chlorine in carbon tetrachloride, it was found that chlorine added again to the polymer but also chlorination occurred as more chlorine was taken up for the solution than had been removed from the polyvinyl chloride by the zinc.

Polyvinyl Bromide and Zinc.—Vinyl bromide was prepared by the method of Kharasch[10] and polymerized by warming it with benzoyl peroxide. The white amorphous powder thus obtained was washed with ether, dilute hydrochloric acid, distilled water, and finally with ethyl alcohol and ether. The bromine content of the polymer was 74.45%.

A solution of 0.0667 g. of polyvinyl bromide in 50 cc. of peroxide-free dioxane was refluxed with a slight excess of active zinc for one hundred and forty-six hours. The solution was filtered and the bromide ion was determined by titration. This treatment removed 85.9% of the bromine from the sample of polyvinyl bromide.

Treatment of Polyvinyl Halides with Potassium Iodide.—Heating a solution of 1.2109 g. of polyvinyl chloride and 9.0227 g. of potassium iodide in 500 cc. of peroxide-free dioxane to boiling under a reflux condenser for two hundred and twenty-three hours did not liberate enough iodine to give a test with starch paste. Similarly heating a solution of 0.2 g. of polyvinyl bromide and excess potassium iodide in 100 cc. of peroxide-free dioxane to boiling under reflux for eighty-two hours liberated only a trace of free iodine.

Action of Potassium Hydroxide on Polyvinyl Chloride.—A solution of potassium hydroxide in "Cellosolve" was added to a solution of polyvinyl chloride in the same solvent and the resulting clear colorless solution was boiled under reflux. Almost immediately it turned a light yellow which quickly changed to dark yellow, to orange, and finally to a reddish-brown with the formation of a brown gelatinous precipitate. On further heating, the color of the solution became darker and the gelatinous precipitate coagulated to a black stringy mass.

After several hours, heating was stopped, the solution was cooled and the black precipitate removed by filtration and discarded. Acidification of the dark reddish-brown filtrate with concentrated nitric acid discharged most of the color, and addition of silver nitrate to the acidified solution gave a copious precipitate of silver chloride.

A mixture of 3.000 g. of polyvinyl chloride in 100 cc. of 5% solution of potassium hydroxide in "Cellosolve" was refluxed for thirty hours. (The solubility of polyvinyl chloride in "Cellosolve" is considerably less than 3 g. in 100 cc. so that most of the polyvinyl chloride was present at the start of the reaction as undissolved polyvinyl chloride.)

As refluxing was started, the color of the solution and of the undissolved solid quickly became a dark reddish-brown and remained so throughout the period of refluxing.

The solution was cooled and the dark red-brown solid was collected on a sintered-glass filter, washed with "Cellosolve" and with water, and dried in a vacuum desiccator over concentrated sulfuric acid for forty-eight hours. During this period the color of the material changed from deep red-brown to deep orange. The weight of the dried material was 1.746 g., indicating a loss in weight of 1.254 g. from the original weight of polyvinyl chloride.

This orange material burned with a smoky flame without any visible melting and, unlike the original polyvinyl chloride, was insoluble in hot dioxane. On further standing the color became lighter and lighter and after two weeks was a faint yellow. Some of the material was heated with concentrated nitric acid on a steam-bath. All of the solid slowly dissolved with the evolution of gas. Evaporation to dryness left no appreciable residue.

The filtrate and washings from the above were combined and the resulting solution was acidified with nitric acid. Silver nitrate solution was then added until no further precipitation of silver chloride occurred. The silver chloride was collected on a sintered-glass filter, dried in a vacuum desiccator over concentrated sulfuric acid, and weighed. The weight of silver chloride was 6.744 g., equivalent to 1.668 g. of chlorine. The original 3.000 g. of polyvinyl chloride (56.73% chlorine) contained 1.702 g. of chlorine which was removed to the extent of 98% by the action of the potassium hydroxide in "Cellosolve" solution.

Ultraviolet Absorption Spectra Studies.—The spectra were taken with a Bausch and Lomb ultraviolet spectrograph. A hydrogen discharge tube operating on 15,000 volts gave a continuous ultraviolet source and the Hα, Hβ, and Hγ lines served to calibrate the wave length scale of the instrument. Eastman Kodak Company D-O-(double coated) Ortho plates were used and the pictures were taken with a slit opening of $10\mu \times 4$ mm. and a 1-cm. quartz cell. Each exposure was for one and one-quarter minutes. The absorption coefficient was determined by comparison with the blackness of a trace in a 10^{-4} molar solution of naphthalene. A concentration of 0.02 M for the dichloropentanes was used. The concentration of the polymer was 0.02 M on the basis of a dimer unit.

Summary

Zinc removes 84–87% of the halogen from polyvinyl halides in dilute solution to yield a rubbery

(10) Kharasch, THIS JOURNAL, **55**, 2521 (1933).

polymer which does not decolorize aqueous potassium permanganate solution. Polyvinyl halides do not liberate iodine from potassium iodide. The ultraviolet absorption spectrum of polyvinyl chloride is very similar to that of 2,4-dichloropentane and somewhat different from that of 2,3-dichloropentane. All of these facts support the view that polyvinyl chloride has the 1,3-dihalide structure.

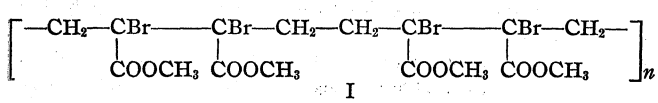
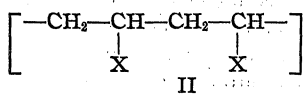
The Structure of Vinyl Polymers. VII. Polyacrylyl Chloride[1]

BY C. S. MARVEL AND CHARLES L. LEVESQUE[2]

Recent work from this Laboratory[3] has shown that the polymers of alkyl α-haloacrylates have a "head to head, tail to tail" structure (I), in contrast to many other vinyl polymers which have a "head to tail" structure (II, X = halogen, OH, $COCH_3$).[4]



I

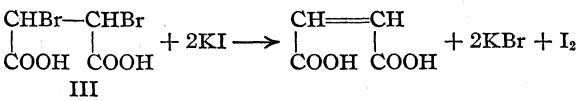


II

Since the vinyl halides are known to form "head to tail" polymers,[4a] this anomalous behavior of the haloacrylates must be due either to the presence of two activating groups attached to the vinyl group, or it must be peculiar to acrylic acid derivatives. The results reported in this paper support the latter explanation.

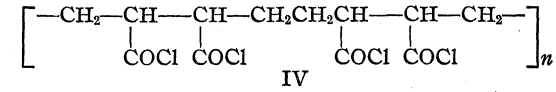
Acrylyl chloride prepared from sodium acrylate and phosphorus oxychloride[5] may be polymerized either by peroxides or ultraviolet light. When thionyl chloride is substituted for the phosphorus oxychloride in the preparation of the acrylyl chloride, the product obtained is polymerizable only by ultraviolet light. It is probable that this acrylyl chloride was contaminated with a little thionyl chloride, which inactivated the peroxide catalyst. The polymers obtained are all brittle, pale yellow solids, soluble in phosphorus oxychloride and dioxane, but insoluble in other common solvents.

By treating a phosphorus oxychloride solution of photopolymerized acrylyl chloride with bromine, it was possible to introduce into the polymer bromine equivalent to one atom for every 3.4 acrylyl chloride units. When this brominated polymer was transformed into the corresponding methyl ester and heated with potassium iodide in acetone solution, free iodine was released. The amount of iodine was equivalent to 46% of the bromine in the polymer. This reaction is characteristic of 1,2-dibromo compounds, especially those in which the bromine atoms are adjacent to a negative group, as in dibromosuccinic acid (III).[6]



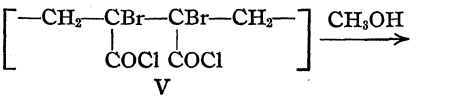
III

The production of 1,2-dibromo units by the bromination of polyacrylyl chloride is most logically explained by assuming a "head to head, tail to tail" structure for this polymer (IV).

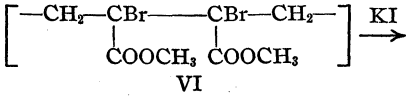


IV

Since bromine readily substitutes in the α-position of an acid chloride, bromination of IV would give rise to 1,2-dibromo units (V). The corresponding methyl ester (VI) would release iodine from potassium iodide, forming an unsaturated ester (VII).



V



VI

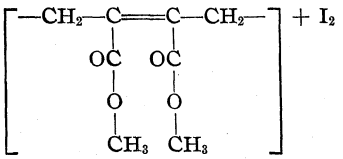
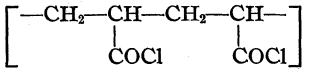
(6) Davis and Heggie, *J. Org. Chem.*, **2**, 470 (1937); see also ref. 3.



VII

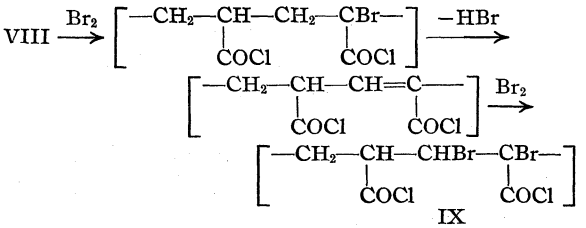
Since only a third of the hydrogen atoms in the α-positions of the polymer were replaced by bromine, the possibility of the presence of some "head to tail" units (VIII) is not excluded. The



VIII

presence of any appreciable fraction of these units, however, would make it quite improbable that the substitution of bromine in only one-third of the α-positions of the polymer would place nearly half of the bromine atoms on adjacent carbon atoms.

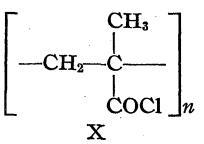
A polyacrylyl chloride having only the "head to tail" structure (VIII) might give rise to 1,2-dibromo units (IX) by the following series of reactions. However, the fact that even in the



IX

presence of bases, ethyl α-bromoglutarate is transformed into glutaconic acid in only very small yields argues against this mechanism.

Although the direct substitution of bromine in other than the α-position of polyacrylyl chloride seemed unlikely, this possibility was investigated. Polymethacrylyl chloride (X) was treated with bromine under conditions identical with those



X

prevailing during the bromination of polyacrylyl chloride. The α-positions of this polymer are not available for substitution and, as expected, no bromination occurred.

From these facts it is evident that at least a part of the units of polyacrylyl chloride are arranged in a "head to head, tail to tail" structure (IV).

Experimental

Preparation of Acrylyl Chloride.—Acrylyl chloride was prepared from phosphorus oxychloride and sodium acrylate.[5] The first crude product was purified by careful fractionation. The yield of acrylyl chloride boiling from 72–73° was 22%. When thionyl chloride was substituted for the phosphorus oxychloride, the yield dropped to 19%.

Polymerization of Acrylyl Chloride by Benzoyl Peroxide.—In a round-bottomed flask connected by a ground joint to a reflux condenser carrying a calcium chloride tube was placed 3 cc. of acrylyl chloride prepared from phosphorus oxychloride, 50 cc. of dry carbon tetrachloride and a few crystals of benzoyl peroxide. The mixture was boiled for four hours. The polyacrylyl chloride separated as a pale yellow solid which adhered to the sides of the flask. The solvent was decanted and the polymer was scraped into a tared evaporating dish. After drying under reduced pressure, it weighed 1.1 g. (45%). The polymer was soluble in phosphorus oxychloride.

Acrylyl chloride prepared from thionyl chloride did not polymerize under similar conditions.

Polymerization of Acrylyl Chloride by Ultraviolet Light.—A solution of 15 g. of acrylyl chloride in an equal volume of dry carbon tetrachloride was placed in a tightly stoppered quartz test-tube and irradiated with light from a mercury vapor arc for thirty hours. The polyacrylyl chloride separated as a brittle, light yellow solid. It was isolated by removing the solvent under reduced pressure in a stream of dried air. It weighed 7.2 g. (48%).

Bromination of Polyacrylyl Chloride.—A solution of 7.2 g. of photopolymerized acrylyl chloride in 90 cc. of phosphorus oxychloride was placed in a 200-cc. round-bottomed flask and 6.3 cc. of bromine was added. A reflux condenser carrying a calcium chloride tube was attached to the flask by a ground joint, and the mixture was irradiated for seven days with light from a 100-watt lamp. Most of the phosphorus oxychloride was removed by distillation under reduced pressure and a mixture of 50 cc. of toluene and 50 cc. of methanol was added to the viscous residue. The mixture was refluxed for one hour. The excess methanol was removed by distillation and the residual toluene solution was filtered through a sintered glass funnel. The brown gel remaining on the funnel was treated with 150 cc. of acetone and most of it dissolved. The acetone solution was filtered and the filtrate was added to the toluene filtrate. The combined filtrates were diluted with four volumes of alcohol and the tacky, brown solid which separated was isolated by decantation. The solid was redissolved in 50 cc. of acetone and reprecipitated with alcohol. The precipitate was collected on a filter. After drying under reduced pressure over sulfuric acid, the product was 5.8 g. of a fibrous, light brown solid.

Anal. Calcd. for $C_4H_5O_2Br$: Br, 48.5. Found: Br, 21.26.

The analysis shows the presence of one bromine atom for every 3.4 methyl acrylate units.

Reaction of the Brominated Polymer with Potassium Iodide.[6]—A solution of 4.000 g. of the brominated polymer in acetone was made up to exactly 100 cc. This solution was placed in a flask containing 2.0 g. of powdered

potassium iodide and a reflux condenser was attached by a ground joint. The mixture was boiled gently on a steam cone. At intervals 25 cc. of the reaction mixture was removed with a pipet, diluted with 250 cc. of water and titrated with 0.03620 *N* sodium thiosulfate, using starch solution as an indicator. At seventeen, twenty-three and twenty-nine hours, 41.7, 46.3 and 46.0% of bromine, respectively, were removed from the polymer.

A solution of 1.677 g. of the brominated polymer in acetone was made up to exactly 50 cc. The solution was placed in a glass-stoppered Erlenmeyer flask containing 1.0 g. of powdered potassium iodide. The flask, which was allowed to stand at room temperature, was shaken occasionally. At intervals 10-cc. samples were removed, diluted with 125 cc. of water and titrated with 0.03620 *N* sodium thiosulfate.

Under these conditions the percentages of bromine removed from the polymer were 25.9, 26.8, 32.2 and 32.1 after twenty-one, twenty-four, forty-five and seventy-nine hours, respectively.

Attempted Bromination of Polymethacrylyl Chloride.—A sample of polymethacrylyl chloride was obtained through the courtesy of Dr. B. C. Pratt of the du Pont Experimental Station. Four grams of this polymer was dissolved in 50 cc. of phosphorus oxychloride contained in a 100-cc. flask and 3.2 cc. of bromine was added. A reflux condenser protected by a calcium chloride tube was attached to the flask by a ground joint, and the mixture was irradiated for eight days with light from a 100-watt lamp. The product, isolated by the methods employed for the brominated polyacrylyl chloride, was 2.2 g. of brittle, brown solid.

Anal. Found: Br, 0.23.

Summary

Polyacrylyl chloride has been brominated and then esterified to give a polymeric bromoacrylic ester which liberated iodine from potassium iodide solution. This indicates that polyacrylyl chloride has some of its units arranged in a "head to head, tail to tail" fashion.

URBANA, ILLINOIS RECEIVED AUGUST 4, 1939

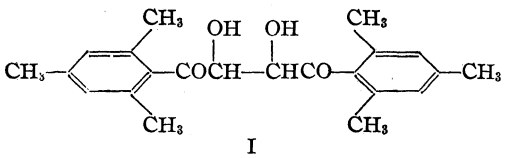
1,2-Diacylethylene Glycols

BY REYNOLD C. FUSON, C. H. MCBURNEY AND W. E. HOLLAND

Mesitylglyoxal reacts with the binary mixture, Mg + MgI_2,[1] in a very remarkable fashion; the reduction is entirely bimolecular, yielding 1,2-dimesitoylethylene glycol (I).[2] In the present work *t*-butylglyoxal, phenylglyoxal, 3,5-dibromomesitylglyoxal, 2,4,6-triethylphenylglyoxal and isodurylglyoxal have been found to behave in this same manner. In each case the product is the corresponding 1,2-diacylethylene glycol



I

$$2RCOCHO \longrightarrow RCO\underset{|}{\overset{OH}{CH}}—\underset{|}{\overset{OH}{CH}}COR$$

The hindered glyoxals gave only one glycol while phenylglyoxal yielded two—presumably diastereoisomers

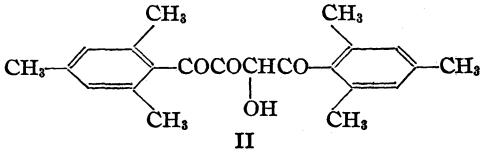
$$C_6H_5CO\underset{|}{\overset{OH}{CH}}—\underset{|}{\overset{OH}{CH}}COC_6H_5$$

Thus it would seem that while steric hindrance is not responsible for the success of the reaction it may influence its course.

Two of the glyoxals, isodurylglyoxal and 3,5-dibromomesitylglyoxal, have not been reported before. They were made from acetoisodurene and 3,5-dibromoacetomesitylene, respectively, by treatment with selenium dioxide. The semicarbazones and the phenylhydrazones of the two glyoxals were prepared. The glyoxals were found to undergo rearrangement to the corresponding glycolic acids when treated with 10% potassium hydroxide solution.

The yield of glycol was found to depend on the time of reaction and on the ether–benzene ratio of the solvent. For example, in one experiment with phenylglyoxal, using an ether–benzene ratio of 1:2, the yield of glycol was only 2% of the theoretical; in another experiment in which an ether–benzene ratio of 2:3 was used the yield was 55%. If too long a reaction time is employed, side reactions occur. When mesitylglyoxal was treated with the binary mixture, Mg + MgI_2, for one hour the resulting glycol was contaminated with 1,2-dimesitoylformoin (II). In view of this fact a standard reaction time of fifteen minutes was used in all of the experiments.

(1) Gomberg and Bachmann, THIS JOURNAL, **49**, 236 (1927).
(2) Gray and Fuson, *ibid.*, **56**, 739 (1934).

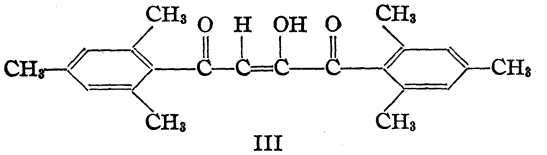


II

To see whether similar glycols might be produced from diketones, mesityl phenyl diketone was subjected to the reduction. The product was 2,4,6-trimethylbenzoin

$$C_9H_{11}COCH(OH)C_6H_5$$

The bimolecular reduction product (I) of mesitylglyoxal underwent dehydration when treated with either oxalic acid or sulfuric acid, producing in both cases the same compound, 1,4-dimesityl-1,3,4-butanetrione enol (III). Likewise, the glycol gave an acetone compound when treated with acetone, magnesium sulfate and sulfuric acid.[3] Oxidation with lead tetraacetate gave mesitylglyoxal.



III

The glycol (I) also underwent oxidation with copper sulfate in pyridine, producing dimesityl diketone; oxidation with selenium dioxide gave dimesityl triketone. Dimesityl tetraketone was probably an intermediate in these reactions, carbon monoxide being lost to give first the triketone and then the diketone

$$C_9H_{11}\underset{\displaystyle OH}{\underset{|}{C}}H-\underset{\displaystyle OH}{\underset{|}{C}}HCOC_9H_{11} \longrightarrow C_9H_{11}COCOCOCOC_9H_{11} \xrightarrow{-CO} C_9H_{11}COCOCOC_9H_{11} \xrightarrow{-CO} C_9H_{11}COCOC_9H_{11}$$

An attempt was made to effect the transposition of a carbonyl group with an α-hydroxyl group by treatment with sodium ethoxide—a procedure which has been used with success by Henze[4] for similar compounds. Instead of the expected rearrangement product there was obtained 1,4-dimesityl-1,3,4-butanetrione enol (III).

The inability of the glycol to pass readily into the enol form was shown by the failure of attempts to prepare a tetraester. Treatment with four moles of ethylmagnesium bromide followed by four moles of acetyl chloride gave the formoin (II) instead of a tetraacetate; heating under reflux with benzoyl chloride according to the method of Lees[5] gave the benzoate of the enol (III) instead of a tetrabenzoate; treatment with sodium acetate and acetic anhydride gave an intractable oil.

Experimental

A. Glyoxals

3,5-Dibromomesitylglyoxal.—After 5.1 g. of selenium dioxide had been dissolved by warming in 100 cc. of wet dioxane, 14.5 g. of 3,5-dibromoacetomesitylene was added and the mixture refluxed for four hours. After most of the dioxane had been distilled, 250 cc. of toluene was added and the distillation continued until the distillate was no longer cloudy. The residual toluene was removed under reduced pressure. The glyoxal distilled at 157° (4 mm.); the yield was 41.5% of the theoretical. The **hydrate** melts at 100–102°.

Anal. Calcd. for $C_{11}H_{10}Br_2O_2$: Br, 47.90. Found: Br, 47.89.

The **semicarbazone** after several recrystallizations from alcohol and water melted at 238–241°.

Anal. Calcd. for $C_{12}H_{13}Br_2H_3O_2$: C, 36.83; H, 3.35. Found: C, 37.11; H, 3.71.

The **phenylhydrazone** crystallized from alcohol; m. p. 183–184.5°.

Anal. Calcd. for $C_{17}H_{16}Br_2N_2O$: C, 48.11; H, 3.77. Found: C, 48.44; H, 3.79.

3,5-Dibromomesitylglycolic acid was prepared by heating a suspension of the glyoxal hydrate with 10% sodium hydroxide solution. Acidification produced the white, crystalline acid which, after recrystallization from water, melted at 184–185°.

Anal. Calcd. for $C_{11}H_{12}Br_2O_3$: C, 37.53; H, 3.44. Found: C, 37.64; H, 3.39.

Isodurylglyoxal.—This glyoxal was prepared from acetoisodurene in 72% yield by the method just described; b. p. 123–127° (8 mm.). The hydrate melts at 86–87°.

Anal. Calcd. for $C_{12}H_{14}O_2$: C, 75.79; H, 7.36. Found: C, 75.90; H, 7.42.

The **semicarbazone** after recrystallization from alcohol melted at 207–208°.

Anal. Calcd. for $C_{13}H_{17}N_3O_2$: C, 63.16; H, 6.88. Found: C, 63.19; H, 7.19.

The **phenylhydrazone** crystallized from alcohol; m. p. 118–119°.

Anal. Calcd. for $C_{18}H_{20}N_2O$: C, 77.14; H, 7.14. Found: C, 76.92; H, 7.65.

Isodurylglycolic acid was prepared by heating the glyoxal hydrate with a solution of 10% potassium hydroxide. Acidification produced the white crystalline acid which, after recrystallization from water, melted at 171.5–172°.

Anal. Calcd. for $C_{12}H_{10}O_3$: C, 69.22; H, 7.69. Found: C, 69.48; H, 7.69.

The melting point of this acid is given by Claus and Foecking[6] as 156°. They obtained their product by the

(5) Lees, *J. Chem. Soc.*, **83**, 145 (1903).
(6) Claus and Foecking, *Ber.*, **20**, 3097 (1887).

reduction of isodurylglyoxylic acid. The acetoisodurene from which their glyoxylic acid was prepared may have been contaminated with acetoprehnitene and acetodurene, the isodurene used having been prepared by the action of methyl iodide and aluminum chloride on mesitylene. The isodurene used in the present experiments was made by the action of methyl sulfate upon mesitylmagnesium bromide.[7]

B. Glycols

1,2-Di-(2,4,6-triethylbenzoyl)-ethylene Glycol.—Seven grams of iodine was added in small portions to a warm mixture of 25 cc. of dry benzene, 17 cc. of dry ether and 2.5 g. of magnesium turnings; the additions were made through the condenser at such a rate as to keep the mixture just boiling. After the iodine had all been added and the initial vigorous reaction had subsided, the mixture was refluxed until the iodine color had disappeared. To this mixture, after cooling, was added 8.8 g. of 2,4,6-triethylphenylglyoxal. The flask was stoppered and shaken vigorously, with frequent cooling, for fifteen minutes, then the solution was decanted into 100 cc. of water, shaken and the magnesium hydroxide dissolved with dilute acetic acid. The organic layer was removed, washed with water and sodium thiosulfate solution, and the glycol was isolated by evaporation of the ether and benzene. After recrystallization from ethanol the glycol melted at 104–105° (corr.); yield, 3.7 g., which was 42% of the theoretical.

Anal. Calcd. for $C_{28}H_{38}O_4$: C, 76.66; H, 8.74. Found: C, 76.95; H, 8.81.

1,2-Di-3,5-dibromomesitoylethylene Glycol.—This glycol was obtained by the foregoing procedure in a 27% yield; m. p. 229–232°.

Anal. Calcd. for $C_{22}H_{22}O_4Br_4$: C, 39.42; H, 3.31. Found: C, 39.14; H, 3.64.

1,2-Di-(2,3,4,6-tetramethylbenzoyl)-ethylene Glycol.—Isodurylglyoxal gave a 37% yield of glycol; m. p. 160–161°.

Anal. Calcd. for $C_{24}H_{30}O_4$: C, 75.34; H, 7.92. Found: C, 75.65; H, 7.84.

1,2-Dipivalylethylene Glycol.[8]—*t*-Butylglyoxal was reduced in an atmosphere of nitrogen; otherwise the procedure was the same as that used for the three preceding glycols.

1,2-Dibenzoylethylene Glycol.—Reduction of phenylglyoxal gave two forms of 1,2-dibenzoylethylene glycol. These were separated by digesting the reduction mixture with small portions of ether until the residue had a constant melting point. In this way there was obtained from 19 g. of reaction mixture 3 g. of glycol melting at 125–127°. Although somewhat unstable this high-melting isomer could be recrystallized from ethanol by warming gently and stirring the mixture until solution was accomplished and then chilling the solution, m. p. 126–127.5° (corr.).

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.09; H, 5.23. Found: C, 71.03; H, 5.46.

The **diacetate** of this glycol was prepared by refluxing with acetyl chloride for thirty minutes, pouring the reaction mixture into ice water and recrystallizing the solid from ethanol, m. p. 168–169° (corr.).

Anal. Calcd. for $C_{20}H_{18}O_6$: C, 67.75; H, 5.13. Found: C, 68.01; H, 5.21.

When the combined ether filtrates from the digestions were evaporated to one-half their volume and placed in the ice box, a mixture of crystals formed from which several crystals of the known isomer were separated by hand. The rest of the mixture was redissolved in ether and, after seeding with the hand-picked crystals, the solution allowed to evaporate to dryness. In this way 2 g. of the low-melting form of 1,2-dibenzoylethylene glycol was obtained which after recrystallization from ethanol melted at 118–119° (corr.).

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.09; H, 5.23. Found: C, 71.28; H, 5.39.

This glycol was also prepared according to the general method of Milas and Sussman[9] using hydrogen peroxide and also by permanganate oxidation by a procedure based on that of Straus and Rohrbacher[10] for Δ'-dihydronaphthalene. Melting points of mixtures showed the products from the three sources to be identical.

2,4,6-Trimethylbenzoin.—The reduction of 5.04 g. of mesityl phenyl diketone with the binary mixture gave 1.5 g. of 2,4,6-trimethylbenzoin.[11]

C. Reactions of 1,2-Dimesitoylethylene Glycol (I)

Dehydration.—(a) Five-tenths gram of the glycol was dissolved in 5 cc. of concentrated sulfuric acid at 0° and allowed to stand at this temperature for thirty minutes. When the deep red solution was poured on ice, the solid enol separated and was isolated by filtration; it was purified by fractional crystallization from benzene, m. p. 112–113° (corr.). A mixture with an authentic sample of 1,4-dimesityl-1,3,4-butanetrione enol (III), prepared according to the method of Lutz,[12] showed no depression of the melting point.

(b) Four grams of the glycol was mixed thoroughly with 20 g. of hydrated oxalic acid and the mixture heated at 160° for four hours. At the end of this time the mixture was cooled and digested with hot water to remove the excess oxalic acid. The yellow enol (III), when recrystallized from ethanol, melted at 112–113° (corr.); yield, 3 g.

(c) A suspension of 3.5 g. of the glycol in 30 cc. of absolute ethanol was cooled to 0° and a solution of 0.23 g. of sodium in 10 cc. of absolute ethanol was added. The flask was closed with a cork and allowed to stand three hours at room temperature, with occasional shaking to prevent the suspension from settling out. The oil obtained by distilling the solvent at 30–40° *in vacuo* was dissolved in 50 cc. of ether and the solution washed with cold, dilute sulfuric acid and then with water. The residual oil obtained by driving off the ether was dissolved in the minimum amount of low-boiling petroleum ether and the solvent allowed to evaporate spontaneously. The residue consisted of yellow crystals covered with a yellow oil, which was removed by pressing the mass on a porous plate. The yellow enol after recrystallization from ethanol melted at 112.5–113° (corr.); yield, 1 g.

(12) Lutz, *ibid.*, **60**, 705 (1938).

The Acetone Compound.—The glycol when treated with acetone, concentrated sulfuric acid and anhydrous magnesium sulfate according to the method of Derx[3] gave the expected acetone compound, m. p. 117–118° (corr.).

Anal. Calcd. for $C_{25}H_{30}O_4$: C, 76.09; H, 7.67. Found: C, 76.03; H, 7.56.

Oxidation

(a) **Lead Tetraacetate.**—After 3.5 g. of the glycol had been dissolved in 100 cc. of dry chloroform 4.4 g. of lead tetraacetate was added in small portions to the well-stirred solution. At the end of two hours of stirring the insoluble lead acetate was removed by filtration, the solvent distilled and the residual mesitylglyoxal converted to the hydrate. The air-dried hydrate weighed 3.2 g.; yield, 91% of the theoretical. The glyoxal was identified as the phenylhydrazone, m. p. 136.5–137.5° (corr.).[13]

(b) Treatment of the glycol with copper sulfate and pyridine according to the method of Clark and Dreger[14] gave dimesityl diketone, m. p. 120–121°.

(c) After 10 g. of selenium dioxide had been dissolved by warming in 100 cc. of wet dioxane, 10 g. of the glycol was added and the mixture was refluxed for ten hours. One-half the dioxane was removed by distillation and the residue poured into 200 cc. of water. The solid product was dissolved in the minimum amount of low-boiling petroleum ether and the solution allowed to evaporate to dryness. After being freed from unchanged glycol by hand separation, the red dimesityl triketone melted at 110.5–111°; yield, 4.5 g. It was identified by a mixed melting point with an authentic sample.

Reaction with Phenylhydrazine.—After a solution of 2 g. of the glycol, 3 cc. of phenylhydrazine and 40 cc. of ethanol had been heated for forty-eight hours in a sealed tube on the steam cone, it was concentrated to one-half its volume and placed in the ice box overnight. The precipitate amounted to 1 g. of pale yellow crystals which, after three recrystallizations from ethanol, melted at 128–129° (corr.). The compound was not identified.

Anal. Calcd. for $C_{28}H_{28}O_2N_2$: N, 6.59. Found: N, 6.79.

(13) This melting point was erroneously reported as 145–146° by Fuson and Gray, *loc. cit.*

(14) Clark and Dreger, "Organic Syntheses," Coll. Vol. I, 1932, p. 80.

Reaction with Benzoyl Chloride.—After refluxing 2 g. of the glycol with 10 cc. of benzoyl chloride for six hours the solution was cooled to 0° and poured into 10 cc. of cold methanol. The reaction mixture, after standing overnight in the ice box, was freed of the dibenzoate by filtration; the methanol and methyl benzoate were removed by distillation under reduced pressure. After the residue was dissolved in low-boiling petroleum ether and allowed to evaporate spontaneously, the yellow enol benzoate was separated by hand from the white dibenzoate of the glycol. The enol benzoate, after recrystallization from ethanol, melted at 141–142° (corr.) and was identified by a mixed melting point with an authentic sample of the benzoate of 1,4-dimesityl-1,3,4-butanetrione enol.

Anal. Calcd. for $C_{29}H_{28}O_4$: C, 79.05; H, 6.41. Found: C, 79.17; H, 6.73.

Treatment of the Glycol with Ethylmagnesium Bromide and Acetyl Chloride.—To a solution of 1.75 g. of the glycol in 40 cc. of benzene under nitrogen was added slowly with stirring an ether solution of ethylmagnesium bromide (4 moles). After refluxing the mixture for fifteen minutes, 5 cc. of acetyl chloride was added and the refluxing continued for thirty minutes. Removal of the solvents under reduced pressure left a few milligrams of the formoin (II) and an intractable oil. The formoin, after recrystallization from ethanol, melted at 187–188°; the melting point of a mixture with an authentic sample showed no depression.

Treatment of the Glycol with Sodium Acetate and Acetic Anhydride.—Two grams of the glycol was refluxed with 1 g. of anhydrous sodium acetate and 20 cc. of acetic anhydride for six hours. When the reaction mixture was decomposed with water an oil was obtained which could not be distilled or crystallized.

Summary

Five glyoxals have been reduced to the corresponding 1,2-diacylethylene glycols by the action of the binary mixture, Mg + MgI_2.

The properties of the glycol from mesitylglyoxal, 1,2-dimesitoylethylene glycol, have been described in detail.

Organic Syntheses with Sulfuryl Chloride[1]

BY W. W. BINKLEY WITH ED. F. DEGERING

The present investigation is a study of sulfuryl chloride in condensation reactions with the lower aliphatic alcohols and the lower dialkylamines.

Esters of Chlorosulfonic Acid.—Since there is some disagreement in the values of the physical constants of the esters of chlorosulfonic acid, we have prepared these substances again and have purified them by careful rectification.[2]

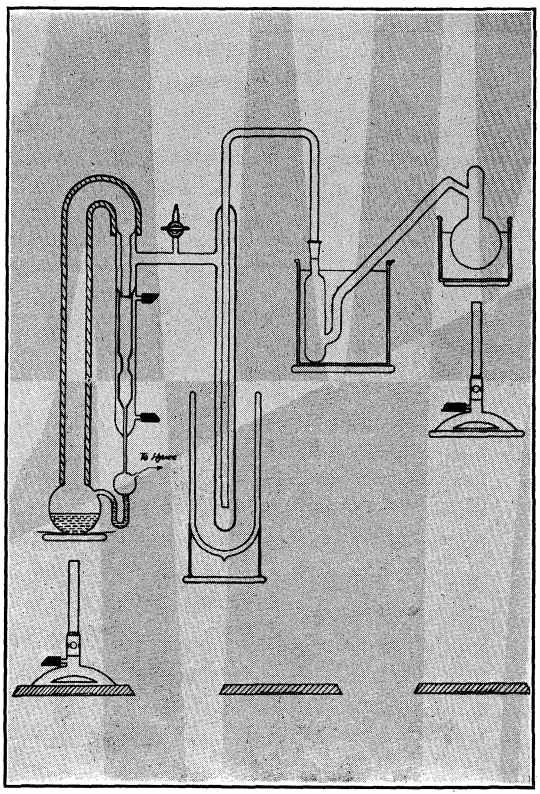

Fig. 1.

Dialkylaminesulfuryl Chlorides.—The lower dialkylaminesulfuryl chlorides may be prepared by the action of sulfuryl chloride on the amine hydrochlorides. However, these chlorides may be obtained in better yields by the careful addition of the amine to a large excess of sulfuryl chloride, followed by gentle refluxing for twenty-four hours.

(1) Abstracted from a portion of a thesis submitted by W. W. Binkley in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry, June, 1939.

(2) Binkley and Degering, THIS JOURNAL, **60**, 2810 (1938).

Experimental

Sulfuryl chloride (one-third mole) was placed in a three-necked distilling flask equipped with a mechanical stirrer, a reflux condenser, and a small dropping funnel. The flask was surrounded with an ice-bath, and the amine (one-third mole) was added very slowly to the sulfuryl chloride during vigorous agitation. The reaction mixture was warmed and poured into a flask which was connected to a reflux condenser by means of a ground-glass joint. Gentle refluxing was held for twenty-four hours. The dialkylaminesulfuryl chlorides were extracted from the reaction mixture by means of anhydrous ethyl ether and the dimethyl and diethyl compounds purified by rectification under diminished pressure. However, the di-*n*-propyl and di-*n*-butylaminesulfuryl chlorides will not withstand long heating and are better purified by repeated distillations under diminished pressure in the apparatus shown in Fig. 1. The characteristic physical constants and analyses are collected in Table I.

TABLE I

-Aminesulfuryl chloride	d^{25}_4	Ref. index 20°	B. p., °C.	Chlorine, % Calcd.	Found
Dimethyl	1.337	1.4526	66.0/10	24.74	24.7
Diethyl	1.221	1.4564	69.0/5	20.70	20.8
Di-*n*-propyl	1.195	1.4615	83.5/4	17.79	17.9
Di-*n*-butyl	1.142	1.4648	95–6/3	15.60	15.5

All the lower dialkylaminesulfuryl chlorides have an irritating effect on the skin, and the dimethylaminesulfuryl chloride is also a lachrymator. They are colorless liquids insoluble in water but dissolve in the common organic solvents. They react slowly with aqueous solutions of acids and are not attacked readily by aqueous alkali.

Esters of N,N-Dialkylamidosulfonic Acids.—These esters were obtained from the metathesis of diethylaminesulfuryl chloride and the proper sodium alkoxide, and in small yields by the action of the appropriate ester of chlorosulfonic acid on diethylamine.

Experimental

Sodium (0.1 mole), dissolved in 50 ml. of the proper alcohol, was placed in a flask equipped with a mechanical stirrer and a dropping funnel. The dialkylaminesulfuryl chloride (0.1 mole), dissolved in an equal volume of anhydrous ethyl ether, was added dropwise into the sodium alkoxide–alcohol solution during vigorous agitation. After twelve hours of stirring, the insoluble solids were separated with a centrifuge, and the esters purified by rectification under diminished pressure. The average yield was about 6 g. The characteristic physical constants and sulfur contents of only the ethyl, *n*-propyl and *n*-butyl esters are listed in Table II since the methyl ester was not obtained by this procedure.

TABLE II

Diethylamidosulfonate	d^{25}_4	Ref. index 20°	B. p., °C.	Mm.	Sulfur, % Calcd.	Found
Ethyl	1.076	1.4307	86	5	17.68	17.8
n-Propyl	1.068	1.4331	80.5	3	16.41	16.3
n-Butyl	1.046	1.4352	73.5	2.25	15.31	15.3

The alkyl N,N-diethylamidosulfonates are pleasant smelling liquids, only slightly soluble in water but quite soluble in the common organic solvents.

The methyl esters of the N,N-dialkylamidosulfonic acids were prepared by the action of methyl chlorosulfonate on the dialkylamine hydrochlorides and by the alcoholysis of the dialkylaminesulfuryl chlorides with methyl alcohol.

The dialkylamine hydrochloride (0.1 mole) was added in small quantities to methyl chlorosulfonate (0.2 mole) in a small flask. After heating this mixture for one hour on a steam cone, the excess methyl chlorosulfonate was removed with a water pump, and the heating continued for twenty-four hours. The product was purified with methyl alcohol. Yields were 4–6 g.

The dialkylaminesulfuryl chloride (0.1 mole) and 50 ml. of anhydrous methyl alcohol were allowed to reflux for forty-eight hours. The solid ester was crystallized from the reaction mixture and purified further with methyl alcohol. Yields were 2–4 g.

Analytical data and melting points of the methyl N,N-dialkylamidosulfonates are recorded in Table III.

TABLE III

Methyl ester of	M. p., °C.	Sulfur, % Calcd.	Found
N,N-Diethylamidosulfonic acid	80	19.16	19.3
N,N-Di-*n*-propylamidosulfonic acid	135	16.46	16.4
N,N-Di-*n*-butylamidosulfonic acid	117	14.25	14.2

Summary

Sulfuryl chloride has been condensed with lower aliphatic alcohols and/or lower dialkylamines to yield (1) esters of chlorosulfonic acid, (2) dialkylaminesulfuryl chlorides, and (3) N,N-dialkylamidosulfonic acids. Some of the properties of these compounds have been studied and reported.

The Identification of Organic Acids by the Use of *p*-Chlorobenzyl Pseudothiuronium Chloride

BY BARTLETT T. DEWEY AND ROBERT B. SPERRY

Donleavy,[1] Chambers and Scherer,[2] and Veibel and Lillelund[3] have suggested the use of S-benzylthiuronium chloride as a reagent for the identification of organic acids. The method has the advantages of cheapness and ease of preparation of the reagent, rapidity of the reaction, ease of recovery of the salts, and well-defined crystalline structure of the products. Some of the salts, however, are readily hydrolyzed with subsequent decomposition of the free base into products which have very unpleasant odors, and the salts do not show a satisfactory distribution of melting points.

Thirty-one salts of *p*-chlorobenzyl pseudothiourea have been prepared and their melting points determined in an attempt to find a reagent which retains the desirable features of the above method with a diminution of the undesirable ones.

Experimental.—The reagent was prepared by refluxing a mixture of 161 g. of *p*-chlorobenzyl chloride and 76 g. of thiourea in 200 cc. of ethanol for thirty minutes. The reaction mixture was cooled and the ethanol removed on a suction filter. The *p*-chlorobenzyl pseudothiuronium chloride was recrystallized from a mixture of equal parts of concentrated hydrochloric acid and water. The melting point was 197°. No evidence of polymorphism was observed similar to that recorded by Donleavy[1] and by Veibel and Lillelund[3] for S-benzylthiuronium chloride. Analysis showed 11.68% N; calculated 11.84%.

In the preparation of the salts of organic acids, the acid was carefully neutralized to phenolphthalein with sodium or potassium hydroxide. Care must be exercised that no excess of base is present, for basic solutions cause the formation of the unstable *p*-chlorobenzyl pseudothiuronium hydroxide. To the aqueous solution of the sodium or potassium salt of the acid an equivalent quantity of a cold 10% alcoholic solution of *p*-chlorobenzyl pseudothiuronium chloride was added. If the salt did not precipitate immediately, some of the solvent was removed under diminished pressure and the remaining solution was cooled in ice water. The precipitated salt was removed by filtration.

The precipitated salt was obtained in the pure state in most cases. Ethanol, ether, benzene, ligroin, carbon tetrachloride, and dioxane were tried as solvents when recrystallization was necessary. Some decomposition took place in hot alcoholic solutions. The solubility of the salts in ether, benzene, ligroin, and carbon tetrachloride was too small to make these practicable solvents. The solubility of the salts in dioxane was satisfactory. No decomposition was apparent when the solution was boiled for one hour.

(1) J. J. Donleavy, THIS JOURNAL, **58**, 1004 (1936).

(2) R. F. Chambers and P. C. Scherer, *Ind. Eng. Chem.*, **16**, 1272 (1924).

(3) S. Veibel and H. Lillelund, *Bull. soc. chim.*, (5) **5**, 1153 (1938).

By observing the following precautions, hydrolytic decompositions have been prevented: avoid excess base; keep solutions cool during mixing; avoid long contact of salt with mother liquor; recrystallize from dioxane.

The melting points of twenty-two of the salts prepared lie between 140 and 170°. There is not sufficient diversity to make these salts satisfactory derivatives of general application. Mixtures of salts with identical or nearly identical melting points produce depressions of 5 to 9°. They do offer advantages over S-benzylthiuronium salts in making certain distinctions; formate from butyrate, for example.

Analyses of the salts by the Kjeldahl method show good agreement with the calculated values.

Infrared Absorption Studies. IX. Bonding of Hydrogen in Nitrogen Compounds

BY A. M. BUSWELL, J. R. DOWNING AND W. H. RODEBUSH

The behavior of hydroxyl hydrogen has been treated at length in previous publications by ourselves and by other authors. In organic molecules the hydrogen of hydroxyl is usually sufficiently active to show bonding (association, chelation or perturbation) with oxygen, hydroxyl or other basic groups. The hydroxyl group is active in the infrared, showing a strong absorption usually in the neighborhood of 2.75 μ. When association or chelation takes place, this absorption is increased markedly and shifted to the neighborhood of 3.0 μ, the extent of the shift and the breadth of the resulting band depending to a considerable extent upon the particular molecules involved. Enolization, for example, is nearly always the result, rather than the cause, of such bonding. With a few exceptions, therefore, the behavior of hydroxyl hydrogen is easily followed by the infrared absorption and definite statements can be made as to whether the hydrogen is bonded or not.

As a matter of fact, little doubt need usually be felt as to the exceptions mentioned above. Certain alcohols show a somewhat lower hydroxyl frequency (longer wave length) than is customary. Examples are given in Figs. 1 and 2. The hydroxyl in benzoin shows an absorption at 2.87 μ under circumstances where there seems to be no question of association or chelation. This displacement must be due to the phenyl group but other factors may be involved.

One peculiar case has been discussed elsewhere. Wulf[1] and his collaborators investigated the *cis* monoxime of benzil and found the second harmonic present contrary to the predictions from the assigned structure. So far as the infrared is concerned the two compounds might be identical and both molecules show evidence of association with increasing concentration. As might have been expected, we have verified the results of Wulf that no chelation occurs.

In a previous publication[2] we have presented results of our investigation of association in the acid amides and oximes. Those compounds in which the hydrogen attached to nitrogen is acidic,

(2) A. M. Buswell, W. H. Rodebush and M. F. Roy, *ibid.*, **60**, 2444 (1938).

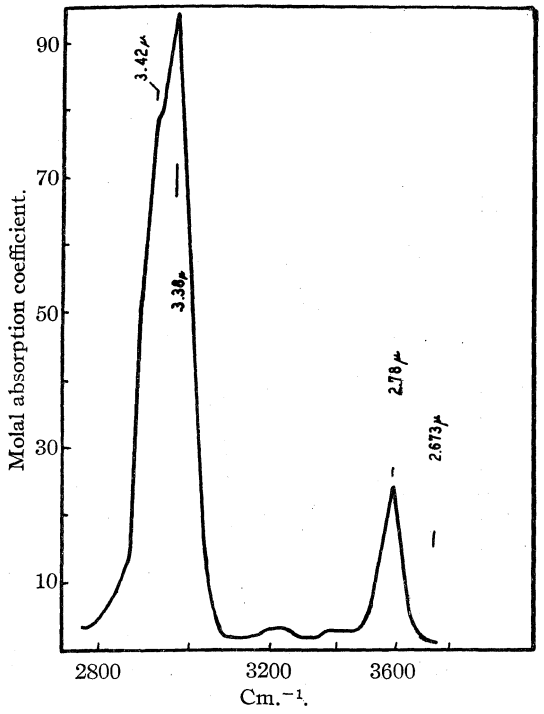

Fig. 1.—Pivaloin in carbon tetrachloride: 0.016 *M* in 1.262-cm. cell.

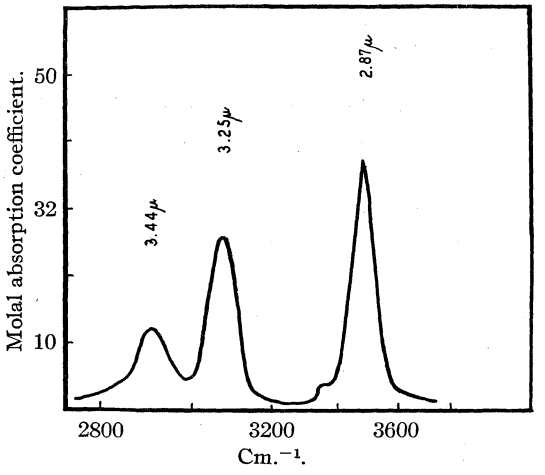

Fig. 2.—Benzoin in CCl_4: 0.016 *M* in 1.262-cm. cell.

as for example the acid amides, show a very strong tendency toward association, greater perhaps even than the alcohols. It was not possible to deduce with certainty in the case of these substances whether the intermolecular association was the result of N–H⟶N or N–H⟶O bonding and in some cases at least there was strong reason to believe that the hydrogen might have shifted to the oxygen in the process of association.

In order to settle the questions suggested above,

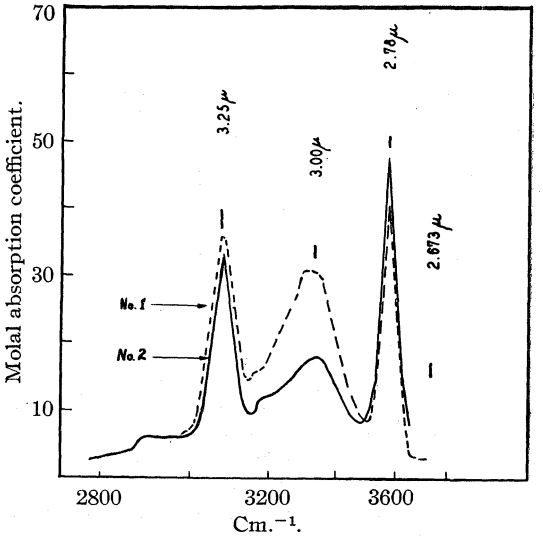

Fig. 3.—*trans* Benzil monoxime in CCl_4: (1) 0.008 *M* in 2.532-cm. cell; (2) 0.002 *M* in 10.180-cm. cell. Identical curves are obtained for the *cis* isomer.

it would be desirable to study nitrogen compounds which do not contain oxygen. Naturally the amines would be the first to be considered. These compounds, however, have proved to be very disappointing as material for infrared study. In the first place the more basic amines show very little absorption due to hydrogen. This low absorption coefficient appears to characterize the N–H bond in the more basic nitrogen compounds. One may assume therefore that the dipole moment of the N–H bond in these molecules is small. The small dipole moment may be taken as an indication that the linkage of hydrogen to nitrogen is largely covalent rather than ionic in character. Since we have assumed elsewhere[3] that the formation of a hydrogen bond involves a transformation of the bond character toward the ionic type, we may therefore anticipate little tendency toward hydrogen bond formation in the more basic types of nitrogen compounds. Even aniline shows no evidence of bonding in the pure liquid (Fig. 4). The absorption at 3.09 μ is apparently present at all concentrations. Liquid aniline has a dielectric constant about the same as liquid acetic acid. The latter substances exist largely in the form of dimers of zero dipole moment but there is no reason to suppose that aniline can form a closed dimer. There is some evidence from other sources[4] of a slight association in aniline but there

(3) W. H. Rodebush and A. M. Buswell, *J. Phys. Chem.*, **43**, 219 (1939).

(4) M. J. Copley, G. T. Zellhoefer and C. S. Marvel, THIS JOURNAL, **60**, 2666 (1938).

is certainly no strong tendency as exists for example in the alcohols.

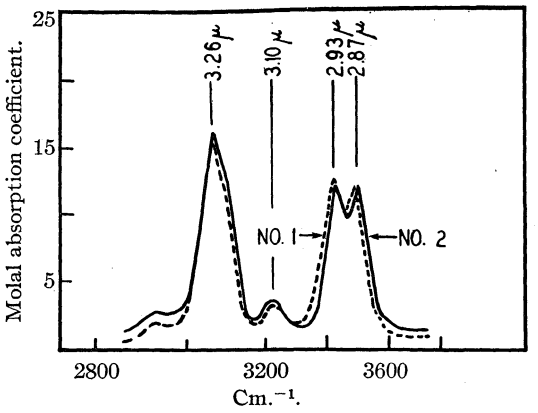

Fig. 4.—Aniline (in CCl_4): (1) 0.64 *M* in 0.158-cm. cell; (2) 0.01 *M* in 10.180-cm. cell.

One must assume that in the case of N–H the tendency toward bonding is small; the shift in frequency when a bond is found likewise small according to the rule of Venkateswaran and the increase in absorption is not comparable to that observed with O–H. Hence for all these reasons we do not expect to find a strong absorption characteristic of N–H ⟶ N or N–H ⟶ O bonding. The foregoing postulates will constitute the basis for some of our significant conclusions later on in this paper.

Since the tendency of aniline toward association appears non-existent it seemed desirable to investigate the tendency of *o*-nitroaniline toward chelation and in particular the acetanilide derivatives where an activation of the hydrogen sufficient to produce bonding might be expected. Acetanilide is itself only slightly soluble in carbon tetrachloride, as might be expected from its similarity to acetamide. *o*-Nitroacetanilide, on the other hand, is fairly soluble and shows no change in absorption with concentration. One must believe, therefore, that its tendency toward association is slight and that this is due perhaps to chelation since the N–H absorption is fairly strong and occurs at 2.96 μ (Fig. 5). One must, of course, consider the question as to whether this is N–H absorption at all. The molecule in question may enolize in two ways. Only one of these could lead to chelation but the 2.96 μ frequency is more nearly what we would expect from an OH ⟶ N bond. On the other hand, we must recognize that the rule of Venkateswaran predicts a small shift and a narrow absorption band for an inactive

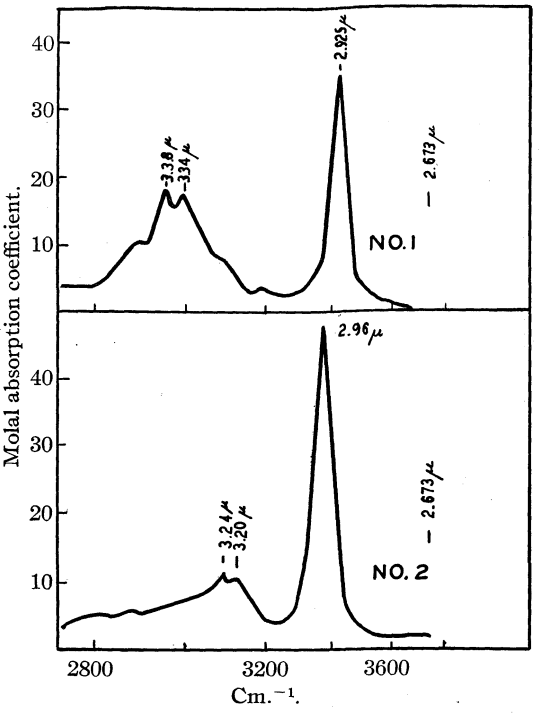

Fig. 5.—(1) 6-Methyl-2-nitroacetanilide (in CCl_4): 0.004 *M* in 5.070-cm. cell; (2) 2-nitroacetanilide (in CCl_4): 0.128 *M* in 0.158-cm. cell.

hydrogen. When the hydrogen of chloroform[5] is bonded, for example, the shift is scarcely observable but a considerable increase in absorption is noted. So here the N–H absorption of acetanilide is about 2.89 μ and the shift to 2.96 μ with increased absorption may well be taken as evidence for chelation. This conclusion seems more necessary when we consider the case of 2-nitro-6-

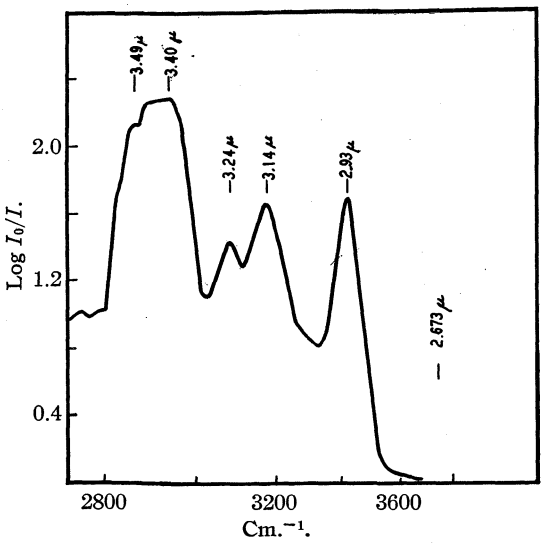

Fig. 7.—50% pyrrole–50% di-*n*-butylamine in ~0.005-cm. cell.

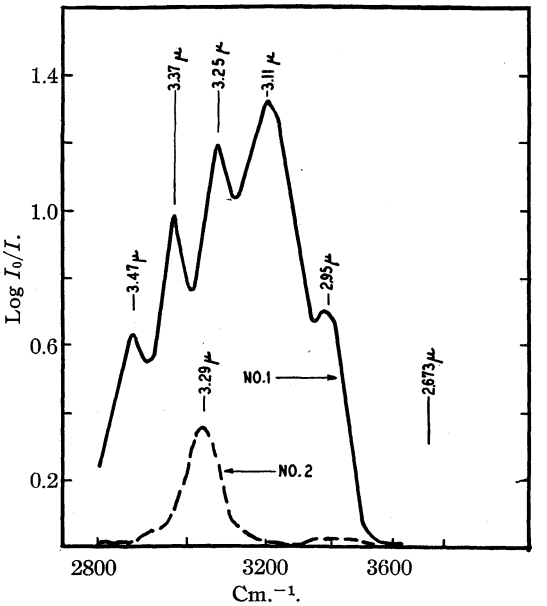

Fig. 8.—(1) 50% pyrrole–50% pyridine in ~0.005-cm. cell; (2) pyridine in ~0.005-cm. cell (half size).

methyl-acetanilide. Chaplin and Hunter[6] have collected a great deal of evidence to show that the methyl derivative is not chelated, presumably because of steric effects between the methyl group and the acetyl group. Certainly the high melting point and low solubility of the methyl derivative argue for association in the solid state into large polymers. The N–H frequency is shifted only a little from that of acetanilide and its absorption is not much stronger so that we assume there is only a slight tendency toward chelation. On the other hand, the obvious absence of association both in the solid state and in solution in the case of *o*-nitroacetanilide seems to have no other explanation than chelation. Acetanilide itself must be strongly associated in the crystalline phase since it is slightly soluble. N-Methylacetanilide shows considerable increase in solubility and in its basic properties presumably because of the disappearance of this association.

Two nitrogen compounds which contain a hydrogen of sufficient activity to form bonds are hydrogen azide and pyrrole.[7] The first of these will be discussed in detail elsewhere. Neither compound shows much tendency toward association. Liquid pyrrole has an absorption at 2.93 μ whereas in dilute solution the absorption is at 2.85 μ. With basic substances such as pyridine or dibutylamine, however, an absorption at 3.11 and 3.14 μ, respectively, can be attributed definitely to N–H ⟶ N bonding between molecules. This is characteristic of pyrrole only, however. Hydrogen azide has its fundamental frequency at 3.03 instead of 2.85 μ and the bonded frequency is shifted by a correspondingly greater amount. Each nitrogen compound therefore appears to be a law unto itself. Bonding takes place only when the hydrogen has somewhat of an acidic character and the shift in frequency is itself a variable quantity.

The Protein Problem.—In a previous publication we showed[2] that certain of the amides on association show an absorption similar to gelatine and that this absorption is characteristic of the linkage R—C(=O)—N(H)—R. If this linkage is continued it becomes identical with the peptide linkage. We suspect that the peculiar absorption noted in this type of molecule will be found characteristic of many of the proteins and will give information as to the cross linkage of the proteins through hydrogen bonding.[8] As a preliminary to this we have worked with various polypeptides, diketopiperazines, etc. The difficulties of solubility make it clear that this problem can be continued only by working with the crystalline material and we are developing the technique of measuring the absorption of thin crystalline films. Meanwhile we have prepared one or two dipeptides of sufficient solubility to obtain absorption curves. In

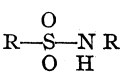
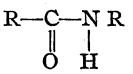
Fig. 9 the curves for glycylglycine ethyl ester show, as might of course be expected, a behavior very similar to the monosubstituted amides. The most characteristic thing about this absorption is the appearance at higher concentrations of a strong absorption a little beyond 3.0 μ which by its location and intensity suggests a bonded O–H rather than N–H. Since the possibility of enolization exists in all the compounds studied so far, we were anxious to investigate a compound where enolization could not occur. A promising compound in this respect is a sulfonamide and in Fig. 10 are shown curves obtained upon the benzenesulfonamide of cyclohexylamine. It is obvious at once that this molecule shows the striking behavior on association that is characteristic of the monosubstituted amides. Organic chemists believe that there is no possibility of enolization in the group



and there is of course no indication from infrared data that such enolization occurs in the single molecule. When association occurs, however, there is the same possibility of intermolecular enolization that exists with the group



At first thought it would appear strange that the hydrogen should be transferred to the oxygen but it must be remembered that the nitrogen in this molecule is almost exactly like the nitrogen of sulfamic acid. Sulfamic acid is a strong monobasic acid and in liquid ammonia becomes a dibasic acid. One must therefore assume that the NHR group is very acidic and that the possibility of intermolecular enolization has not been eliminated. It is hoped by further study to determine the exact mechanics of association which produces this type of absorption.

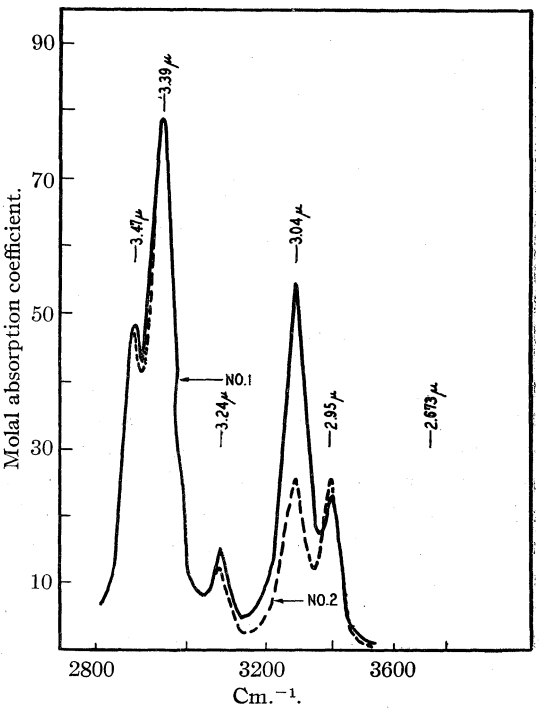


Fig. 10.—Benzenesulfonamide of cyclohexylamine (in CCl_4): (1) 0.008 *M* in 2.532-cm. cell; (2) 0.002 *M* in 10.180-cm. cell.

Summary

An extensive study of nitrogen compounds has been made in the region of the fundamental absorption of the N–H group. It is found that the absorption due to the N–H group is distinctly weaker than for the O–H group and there is a much greater variability in the characteristic frequency. Infrared absorption is a less reliable criterion for bonding of hydrogen attached to nitrogen than for hydrogen attached to oxygen. There is no positive proof of association involving the formation of N–H ⟶ N bonds but there is a strong tendency toward association if the hydrogen is somewhat acidic. The characteristic absorption produced by association of molecules containing the peptide linkage may be due to an enolized hydrogen.

Properties of Electrolytic Solutions. XXI. The Conductance of Tributylammonium Picrate in Ethylene Chloride at 25°

BY DARWIN J. MEAD[1] WITH RAYMOND M. FUOSS[1] AND CHARLES A. KRAUS

I. Introduction

A variety of electrolytes in non-aqueous systems have been studied, but very few examples of very weak electrolytes have been described. Kraus and Fuoss[2] measured tri-*i*-amylammonium picrate in benzene, in ethylene chloride and in a mixture of these two solvents. The purpose of this paper is to present some data of much higher precision than the earlier work, on tributylammonium picrate in ethylene chloride.

II. Apparatus, Materials and Method

The electrical equipment was the same as that described by Cox, Kraus and Fuoss.[3] Conductance cells were of the Erlenmeyer type described by Kraus and Fuoss,[2] having unplatinized electrodes. The cell constants were (I) 0.21299 and (II) 0.015357, as determined by comparison with a cell standardized using Jones and Bradshaw's[4] data on potassium chloride.

Tributylammonium picrate was prepared from tributylamine and picric acid in hot alcoholic solution. The salt was recrystallized from alcohol; m. p. 106.5°.

Ethylene chloride was purified in the usual manner.[5] Solvent conductances ($1.5–3.5 \times 10^{-11}$ mho) were negligible compared to solution conductance even for the most dilute solutions (1×10^{-7} mho).

For the more concentrated solutions the following procedure was used. A quantity (about 4 g.) of salt was weighed into the weighed conductance cell. About 20 cc. (sufficient to fill the electrode chamber) of ethylene chloride was placed in the cell. After dissolving and mixing thoroughly, the cap of the cell was lifted momentarily to release excess pressure. The cell and solution were then weighed and placed in an oil-bath held at 25.000 ± 0.002°. When temperature equilibrium had been established, the resistance of the solution was measured. To make the next solution about 10 cc. of solvent was added. This procedure was repeated until the volume of solution reached about 100 cc., which was the maximum convenient working volume of the cell. In the more dilute region, dilutions were made using a dilution pipet.[5]

Sorption effects in cell II and high resistance values in cell I prevented measurements on solutions more dilute than 10^{-4} *N*.

Polarization, as indicated by change of resistance with frequency, was noticed in the more concentrated solutions. In order to correct for polarization, all solutions were measured at 600, 1000, 2000 and 4000 cycles. Plotting observed resistance against $1/\sqrt{f}$ and extrapolating the resulting straight line gives the resistance corresponding to infinite frequency.[6] This extrapolated resistance was used in calculating the specific conductance of the solution. Figure 1, in which we have plotted the slope of the polarization curves, calculated as $(R_{1000\sim} - R_{\infty})/R_{\infty}$, against *c*, shows that this effect decreases approximately linearly with concentration.

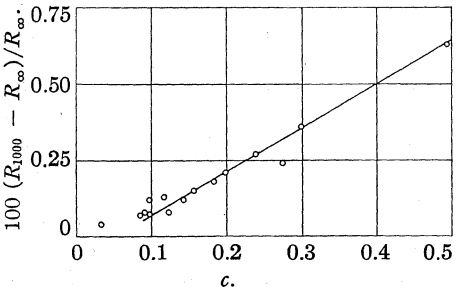

Fig. 1.—Dependence of polarization on concentration.

The solutions used were too concentrated to neglect the difference in density between the solution and the pure solvent in calculating normalities from the experimental weight concentrations. Density measurements were accordingly made at 25° with a Westphal balance. The results are given in Table I. Plotting density against moles of salt per kilogram of solvent gives the following straight line

$$d = 1.2455 - 0.022\,M \qquad (1)$$

where *d* is the density and *M* the molal concentration of the solution.

were made, each with independent initial weighings of salt. The conductance curve is shown in Fig. 2 where log Λ is plotted against log c. In

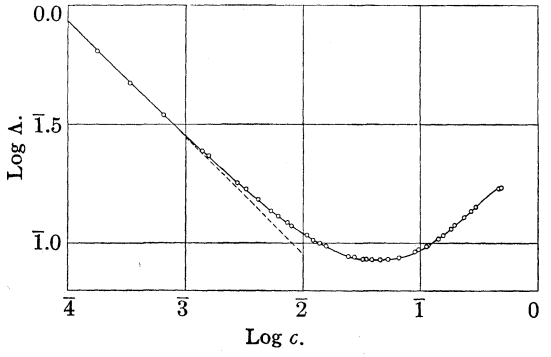

Fig. 2.—Conductance curve for tributylammonium picrate in ethylene dichloride at 25°.

the dilute region we have the usual linear dependence with slope $(-1/2)$, due to mass action.[7] The minimum, produced by triple ions,[8] occurs at $c \approx 4.5 \times 10^{-2} N$, with $\Lambda \approx 8.5 \times 10^{-2}$. In the more concentrated region the curve goes through an inflection point which suggests a maximum at still higher concentrations, due to the increased viscosity.

(7) Fuoss and Kraus, THIS JOURNAL, **55**, 476 (1933).
(8) Fuoss and Kraus, *ibid.*, **55**, 2387 (1933).

In the analysis of conductance data for strong electrolytes, F/Λ is plotted[5] against $c\Lambda f^2/F$. We have plotted the function for the more dilute points on tributylammonium picrate in Fig. 3.

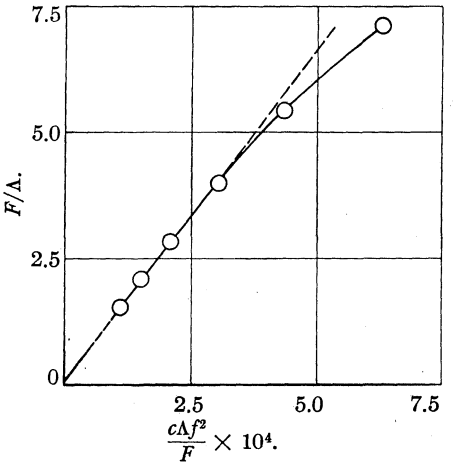

Fig. 3.—Mass action plot.

The intercept is too near zero to allow evaluation of Λ_0, because the salt is so weak. The slope $(1/K\Lambda_0^2)$ can be calculated from values of K and Λ_0 which follow. This calculated slope is shown as a dotted line in Fig. 3. It is obvious that the points approach a straight line with the proper slope as concentration decreases. The critical concentration[9] for ethylene chloride at 25° is 3.4×10^{-4}.

The triple ion function[7] $\Lambda \sqrt{c}\, g(c)$ is plotted against c in Fig. 4; it is linear up to about 0.06 N, where it begins to become concave down. The slope gives a value of 0.045 for the triple ion equilibrium constant. The intercept (8.70×10^{-3}) of the straight line is equal to $\Lambda_0 \sqrt{K}$. If we assume $\Lambda_0 = 60$ (tetrabutylammonium picrate

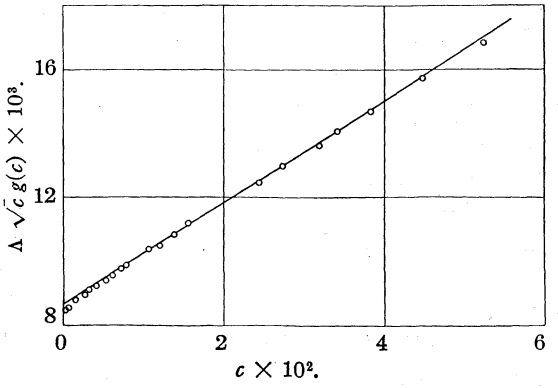

Fig. 4.—Triple ion plot.

(9) Fuoss, *ibid.*, **57**, 488 (1935).

has $\Lambda_0 = 57.40$ in ethylene chloride at 25°[4]) we find 2.10×10^{-8} for the dissociation constant of tributylammonium picrate. This value of K gives a value of 2.4 Å. for the parameter a (effective ion size),[10] which seems unexpectedly small.

(10) Fuoss and Kraus, THIS JOURNAL, **55**, 1019 (1933).

Summary

The conductance of tributylammonium picrate in ethylene chloride has been measured at 25°. The concentration range covered was 1.8×10^{-4} N to 0.5 N.

The Equilibrium and Kinetics of the Thermal Isomerization of Dichloroethylene Catalyzed by Iodine

BY REUBEN E. WOOD AND ROSCOE G. DICKINSON

The conversion of *cis*- into *trans*-cinnamic acid, catalyzed by iodine in benzene solution, has been found[1] to proceed at rates which can be interpreted in terms of iodine-atom catalysis just as can the photochemical conversion sensitized by iodine.[2] We have found that iodine similarly catalyzes the *cis–trans*-isomerization of dichloroethylene, and have measured reaction rates in the pure liquids and in various solutions. Since the isomerization comes to a measurable equilibrium, we have measured equilibrium constants as well as rates of conversion in both directions.

Materials.—The *cis*- and *trans*-dichloroethylenes were prepared by fractional distillation of mixtures of the isomers obtained from the Eastman Kodak Company. It was found desirable to carry out the distillations under carbon dioxide to avoid oxidation by air; pure *trans*-dichloroethylene was noticeably subject to air oxidation. The distillations were carried out with a five-foot (1.5-meter) column; the final products had boiling-point ranges of less than 0.1° and dielectric-constant ranges of 0.003. The boiling point of the *cis*-dichloroethylene was 59.6° at 745 mm.; the dielectric constant was 9.20 at 25°. The boiling point of the *trans*-dichloroethylene was 47.2° at 745 mm.; the dielectric constant was 2.14 at 25°. After purification the liquids were stored in flasks under an atmosphere of carbon dioxide; liquid for use was forced out by carbon dioxide when desired. The same method of storage was applied to stock solutions of the dichloroethylenes in the various solvents. The liquids thus stored were found to retain their original dielectric constants throughout the duration of the experiments (several months).

Thiophene-free benzene was fractionally crystallized, dried, and distilled.

Cyclohexane (Eastman "Practical") was shaken with fuming sulfuric acid, washed with sodium hydroxide solution, then with water, dried, and distilled. Its dielectric constant was found to be 2.013 at 25°.

Decalin (decahydronaphthalene) (Eastman "Practical") was shaken with anhydrous aluminum chloride and then treated similarly to the cyclohexane. It was found that if the treatment with fuming sulfuric acid was not sufficiently prolonged, the decalin added iodine in the subsequent experiments. The dielectric constant of the purified decalin was 2.150 at 25°.

The iodine was sublimed from potassium iodide–iodine mixture, and resublimed.

Dielectric Constant Measurement.—A method of analysis based on dielectric constant measurement was employed to determine the extent of isomerization. This measurement was made by a substitution method in which the capacitance of a cell containing the solution in question was compared with that of a variable precision condenser. The apparatus involved two oscillating circuits coupled to produce an audible heterodyne beat on a telephone receiver. A quartz crystal oscillating at 1.7 megacycles controlled the frequency of one of these circuits. The frequency-controlling part of the other circuit comprised inductance and capacitance, a part of the latter being furnished either by the cell containing the solution, or by the precision condenser. The essence of the measurement was the rapid substitution, by means of a switch, of the measuring cell for the precision condenser in this circuit; the precision condenser was adjusted so that no perceptible change in pitch of the heterodyne beat occurred when this substitution was made.

The precision condenser was a General Radio instrument; the capacitance range used was from 25 to 110 $\mu\mu$f. A calibration was made which gave corrections of the condenser readings to values linear with the capacitance.

The measuring cell was of glass and substantially of the type described by Doborzynski[3]; it was thermostated at 25°. For analytical purposes only a relation between composition of solution and precision condenser reading was necessary; nevertheless the apparatus was calibrated to give dielectric constants with the aid of a number of liquids of known dielectric constant.

Analytical Method.—The analytical problem was that of determining the fraction of dichloroethylene in the *cis*- or *trans*-form in a solution containing known amounts of solvent, iodine, and total dichloroethylene.

(1) R. G. Dickinson and H. Lotzkar, THIS JOURNAL, **59**, 472 (1937).

(2) A. Berthoud and Ch. Urech, *J. chim. phys.*, **27**, 291 (1930).

(3) D. Doborzynski, *Z. Physik*, **66**, 657 (1930).

Iodine was removed from the solution by inserting a clean, dry, helical coil of copper wire. Blank experiments showed that this method of deiodizing the solution brought about no isomerization of the dichloroethylene. After removal of iodine the solution contained a known ratio of total dichloroethylene to solvent so that a measurement of its dielectric constant enabled the fraction of dichloroethylene in each form to be determined from previous measurements on known solutions containing the same total dichloroethylene. Dielectric constants of some of these solutions are given in Table I.

TABLE I

Dielectric constants at 25° of solutions of *cis*- and *trans*-dichloroethylene undiluted (I), and diluted to ten mole per cent. of total (*cis* and *trans*) dichloroethylene in benzene (II), cyclohexane (III), and decalin (IV). Also shown are the measured dielectric constants of the solvents used.

% *cis* of total $C_2H_2Cl_2$	Dielectric constant I No solvent	II Benzene	III Cyclohexane	IV Decalin
0	2.14	2.256	2.018	2.149
20		2.347		
40	4.52	2.439		
50			2.192	2.274
60	5.93	2.530		
80	7.50	2.620		
100	9.20	2.714	2.375	2.405
Pure solvent		2.269	2.013	2.150

From the precision of the measurements it is estimated that the probable error of a determination of the ratio of *cis*- to total dichloroethylene is about 0.003 in a 10 mole per cent. solution in benzene; the error is, of course, somewhat larger in more dilute solutions.

Experimental Procedure.—Since the isomerizations were often carried out at temperatures considerably above the normal boiling points of the solutions, the reacting solutions were sealed up in thick glass ampoules. A stock solution of dichloroethylene in solvent, which had been made up by weight, was transferred to the ampoule, a weighed amount of iodine in a glass capsule was introduced, and the ampoule was sealed off. All fillings were carried out in such a way that oxygen was largely, although perhaps not completely, absent when the ampoules were sealed off. In the experiments without added solvent, this was accomplished either by filling the ampoule with carbon dioxide initially, or by boiling off considerable liquid after it had been introduced and cooling under carbon dioxide. In the rest, the solution usually was frozen down with solid carbon dioxide, and evacuated and sealed off while frozen. It was shown by blank experiments that no appreciable fractionation resulted from this treatment. In all manipulations care was exercised to keep moisture from the solutions because of the considerable effect of water on the dielectric constants.

After sealing off, the ampoules were placed in a light-tight thermostat. In some experiments this was an electric furnace with thermoregulator and in others a bath of vapor of a boiling liquid. In all rate experiments the average temperature was known to about 0.1°. At the conclusion of the experiment, the ampoule was removed from the thermostat and cooled and kept in the dark until analyzed. The duration of the experiments was sufficiently great so that errors in timing due to the initial heating and final cooling period could be shown to be negligible.

Blank experiments were carried out in which ampoules were made up and treated as usual with, however, the omission of iodine. Such ampoules were made up with the pure dichloroethylenes, and with solutions in each of the solvents. In the absence of iodine, the isomerization was negligible. Similar blanks made with iodine and solvent only gave scarcely appreciable changes in dielectric constant.

Equilibrium Experiments.—In Table II are summarized the results of experiments which were long enough so that equilibrium between the *cis* and *trans* isomers was substantially achieved. Some of these experiments were made with no added solvent; the rest were made with solutions of about ten mole per cent. dichloroethylene in benzene, cyclohexane, or decalin. The dichloroethylene at the start was always all *cis* or all *trans* as shown by the fourth column. The final composition shown in the seventh column is the percentage of the total dichloroethylene which was in the *cis* form at the end of the experiment. The equilibrium constant is given as the ratio of *trans* to *cis* isomer; its value is, of course, independent of whether concentrations or mole fractions are used. Mean values for various solvents and temperatures are given in the last column.

In the solutions studied here the values of the equilibrium constants are seen to depend relatively little either on the temperature or on the solvent. From the equation $-\Delta F^\circ = RT \ln K$, the following values for ΔF° for the conversion of *cis*- into *trans*-dichloroethylene in solution at 150° are obtained: in benzene, 750 cal.; cyclohexane, 630 cal.; decalin, 640 cal. Using the van't Hoff equation, $\frac{d \ln K}{dT} = \frac{\Delta H}{RT^2}$, and values of the equilibrium constant at different temperatures, ΔH may be calculated; the values obtained are, in benzene, 1200 cal.; cyclohexane, 1200 cal.; decalin, 600 cal. Since the probable error of these is at least 200 or 300 calories, it is not certain that the difference between the value for decalin and that for the other solvents is significant.

Values for the equilibrium constant for this reaction in the gaseous state have been given[4,5,6] which are of the same general magnitude as those found here.

The iodine-catalyzed conversion of *cis*- into *trans*-cinnamic acid has been found,[1] in dilute

* Since the starred experiments were not quite long enough, a small correction of the observed final composition to that at infinite time was made in computing the corresponding K; this required a rough knowledge of the rate constants.

solution in benzene, to proceed at rates which are first order with respect to cinnamic acid and half order with respect to iodine. The assumption of similar kinetics for the dichloroethylenes is found to be in agreement with the data provided that account is taken of the occurrence of reverse reaction. If k_1 and k_2 are specific rate constants for the reactions *cis*-$C_2H_2Cl_2 \underset{2}{\overset{1}{\rightleftarrows}}$ *trans*-$C_2H_2Cl_2$, and if $K = (trans)_{eq}/(cis)_{eq}$ be the equilibrium constant, then $K = k_1/k_2$. The assumption that each reaction is of first order with respect to the reacting isomer and of half order with respect to iodine leads to the integrated expression

$$k_1 = -\frac{K}{t(I_2)^{1/2}(K+1)} \ln \frac{(K+1)\alpha - 1}{K} \qquad (1)$$

for experiments in which the initial dichloroethylene is all *cis*, and to

$$k_1 = -\frac{K}{t(I_2)^{1/2}(K+1)} \ln [1 - (K+1)\alpha] \qquad (2)$$

for experiments in which the initial dichloroethylene is all *trans*. In both of these equations α is the fraction of dichloroethylene in the *cis* form at the time t.

The results of determinations of k_1 are given in Table III. Values of the equilibrium constant needed were taken from the results of Table II calculated to the desired temperature by means of the van't Hoff equation. The numerical values of k_1 in Table III were obtained expressing t in hours and (I_2) as mole fraction of I_2 in the reaction mixture.[7]

Inspection of the values of k_1 shows that these exhibit satisfactorily constant values in a given solvent at a given temperature. In each solvent, the iodine concentration was varied more than 10-fold (22-fold in the case of decalin). In Table III all experiments with added solvent had a total dichloroethylene mole fraction of about 0.1 except experiments 35 and 46. In these the mole fractions were made 0.2 and 0.01, respectively, without producing any significant change in rate constant. Indeed the experiments without added solvent gave values not much different from the others at the same temperature. It may be further noticed that the values found for k_1 are not dependent on which isomer was originally present; this is nearly true even when no added solvent was present so that the medium was largely different in the two cases. In fact the values of k_1 at a given temperature differ by less than 25% in the various media examined.

(7) If the value of K as well as the relation $K = k_1/k_2$ be assumed, it becomes arbitrary whether a given experiment be regarded as a determination of k_1 or of k_2.

The variation of the rate constant k_1 with the temperature is shown in Fig. 1 in which ln k_1 is plotted against $1/T \times 10^3$ for each of the solvents. From the slopes of these lines, the values of Q_1 in the Arrhenius equation $\mathrm{d} \ln k_1/\mathrm{d}T = Q_1/RT^2$ can be calculated. The values so obtained are, for benzene solutions 31,200 cal., for cyclohexane solutions 30,800 cal., for decalin solutions 30,200 cal. Values of k_2, the specific rate constant for the *trans* to *cis* reaction, may be obtained from the relation $k_2 = k_1/K$. Values of Q_2 may be obtained from the relation $Q_1 - Q_2 = \Delta H$; those values for Q_2 are 30,000, 29,600, and 29,600 cal., respectively. The probable experimental error is such that it is not certain whether the apparent changes in Q_1 and Q_2 with solvent are real.

In Table IV are given, for different solvents, average values at 150° of the equilibrium constant, and of the rate constants k_1 and k_2 for the *cis* to *trans* reaction and its reverse. It is desirable also to compute rate constants, k_1 and k_2, with (I_2) expressed as a volume concentration instead of a mole fraction. It is easy to show that $k' = kv^{1/2}$ where v is the volume of solution containing a total of one mole of substance. Estimated values of v at 150° for pure dichloroethylene, and for 10 mole per cent. solutions in the various solvents are given in the fifth column. These values were obtained from measurements on the pure substances at lower temperatures on the assumption of additivity of volumes and constancy of thermal expansion coefficient with temperature; their uncertainty probably does

TABLE IV

CONSTANTS IN VARIOUS SOLVENTS AT 150° COMPARING VALUES COMPUTED WITH (I_2) EXPRESSED IN MOLE FRACTIONS WITH THOSE IN VOLUME CONCENTRATIONS

Solvent	*K*	k_1 $\times 10^7$ sec.$^{-1}$	k_2 $\times 10^7$ sec.$^{-1}$	*v*, cc.	k_1' $\times 10^5$ moles$^{-1/2}$ cc.$^{1/2}$ sec.$^{-1}$	k_2' $\times 10^5$ moles$^{-1/2}$ cc.$^{1/2}$ sec.$^{-1}$
None	0.412	430	1044	92	41	100
Benzene	.410	425	1036	104	43	106

Decalin	.468	445	950	177	59	126

not affect the k's by more than 2%. It is interesting to notice that, in passing from one solvent to another, the k's in which (I_2) is expressed as a mole fraction are much more constant than the k's in which (I_2) is expressed as a volume concentration.

Discussion.—Just as was the case with the isomerization of cinnamic acid, the kinetics of the dichloroethylene isomerization can be accounted for in terms of iodine atom catalysis, and indeed in terms of the same mechanism as discussed in the case of cinnamic acid. In this mechanism atomic iodine is assumed to be in thermal equilibrium with molecular iodine so that proportionality of the rate[1] with the square root of the iodine concentration results.

The same proportionality would exist if the catalyst were iodine ions in equilibrium with molecular iodine, *e. g.*, $I_2 \rightleftarrows I^+ + I^-$. Evidence that an ionic mechanism is, however, not involved here has been obtained somewhat unexpectedly. It was originally planned to measure the dielectric constants of the reacted solutions without first removing iodine. When this was attempted with solutions of iodine in pure *cis*-dichloroethylene the electric oscillations in the dielectric constant apparatus were feeble, and with the more concentrated iodine solutions, entirely absent. On the assumption that this quenching of oscillation resulted from conductance of the solution some approximate conductance measurements were made. It was found that *cis*-dichloroethylene containing 0.02 g. per cc. of iodine had a specific conductance of 3×10^{-6} mho; this was 100 times the conductance of the dichloroethylene alone, and over 1000 times the conductance of a similar solution of iodine in benzene. Since the mobility of iodine ion in dichloroethylene could hardly be of a different order of magnitude from that in benzene, its concentration in benzene must be comparatively low; nevertheless, the specific rate constants are little different in dichloroethylene and benzene. An atomic rather than ionic catalysis accordingly is indicated here.

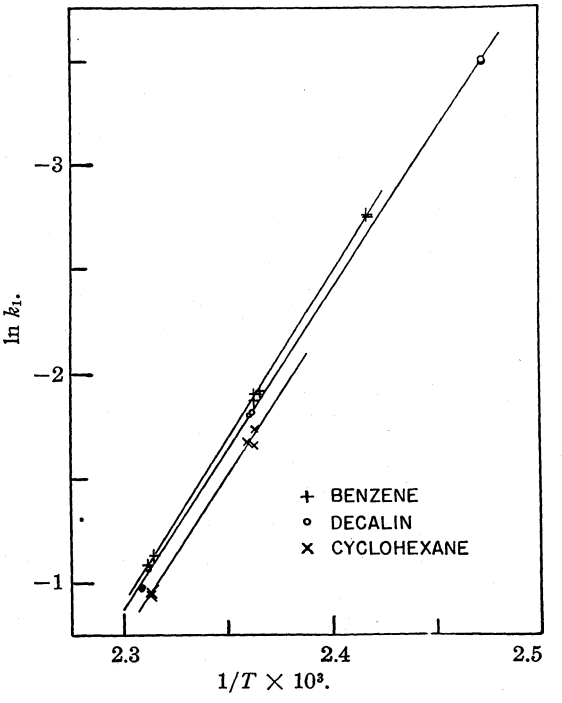

Fig. 1.—Dependence of rate constant on temperature: +, benzene; ○, decalin; ×, cyclohexane.

Summary

Dielectric constants of various liquid mixtures of *cis*- and *trans*-dichloroethylene and of their solutions in benzene, cyclohexane, and decahydronaphthalene have been measured.

Using iodine as a catalyst, equilibria between the *cis* and *trans* isomers have been established and measured in the pure liquids and in the solutions at various temperatures.

Rates of isomerization in the various media have been measured starting with each isomer. Neither the activation energies nor the actual rates vary much from one medium to another of those examined. The rate constants vary somewhat less from solvent to solvent when computed with the iodine expressed as a mole fraction than when computed with it expressed as a volume concentration.

The kinetics are compatible with an iodine-atom catalysis. Evidence against an ionic catalysis is mentioned.

The Molecular Structures of Sulfuryl Fluoride and Thiophosphoryl Fluoride

BY D. P. STEVENSON[1] AND HORACE RUSSELL, JR.

The relations between bond length and bond character in molecules containing bonds of the type sometimes called semipolar are not well understood. Among the compounds of phosphorus and sulfur there are a great number of such molecules, some of which have been investigated recently.[2,3,4] In this paper we give the results of an electron diffraction investigation of the structures of two such molecules containing fluorine atoms as well as semipolar double bonds.

Experimental.—The electron diffraction apparatus used in this investigation has been described by Brockway.[5] The camera distance was 10.84 cm., and the wave length of the electrons, determined in the usual fashion,[5] was 0.0611 Å.

Fifty cc. (S. T. P.) of pure thiophosphoryl fluoride was given to us by Professor H. S. Booth and Miss M. C. Cassidy of Western Reserve University, who have described the preparation and purification of the substance.[6] The sample was transferred to a bulb of about 150 cc. capacity which could be attached to the apparatus by means of a ground joint.

The preparation and purity of the sulfuryl fluoride used will be described in a separate paper on the Raman spectrum of this compound.[7] The pressure of the gas in the sample bulb was approximately 200 mm.

Interpretation.—Both the radial distribution method[8] and the correlation method[9] were used in interpreting the electron diffraction photographs. The modified radial distribution formula

$$D(l) = \sum_{n} C_n \frac{\sin s_n l}{s_n l} \quad C_n = f(I_n, s_n) \qquad (1)$$

has been discussed by Schomaker.[10]

It has been remarked in the literature[9,11] that the coefficients Z_iZ_j in the simplified theoretical scattering formula ordinarily used

$$I(s) = \sum\sum Z_iZ_j \frac{\sin l_{ij}s}{l_{ij}s} \qquad (2)$$

are not completely satisfactory when the atoms i and j are members of different rows of the periodic system, and that the more exact expression

$$I(s) = \sum\sum (Z_i - f_i)(Z_j - f_j) \frac{\sin l_{ij}s}{l_{ij}s} \qquad (3)$$

should be used. Since the corresponding coefficients in (2) and (3) differ by as much as 30% when $4 \leqslant s \leqslant 10$ for sulfuryl fluoride and thiophosphoryl fluoride, it was thought that it might be necessary to use (3) rather than (2) in the application of the correlation method to the interpretation of the photographs of these molecules. However, curves calculated according to (2) and (3) were found to be indistinguishable qualitatively and to have differences in the position of their maxima and minima of about 1% within the range of s indicated above. Since for $s \leqslant 12$ the coefficients of (2) and (3) are the same within 2%, it is thus satisfactory to use (2) rather than (3) in interpreting the photographs of sulfuryl fluoride and thiophosphoryl fluoride when $s > 12$. When $s < 12$ the photographs were compared with curves calculated according to (3).

Inasmuch as the two molecules under consideration are rather rigid, it was thought unnecessary to include a temperature factor[5] in the coefficients of the scattering formulas.

Sulfuryl Fluoride.—The photographs of this molecule show seven measurable maxima, six measurable minima, and two shelf-like features. The first shelf, designated a, is a shoulder on the inner side of the first maximum. The second shelf, feature b, is on the outside of the third maximum. The intensities of the maxima decrease uniformly from the first through the seventh. The only irregularity in the decreasing depth of the minima is that the fifth minimum is shallower than either

		Average of 11 features				1.002 ± 0.007		0.998 ± 0.008

[a] From curve for model with S − F/S − O = 1.56/1.43. F − O/S − O = 2.36/1.43. [b] From curve for model with S − F/S − O = 1.56/1.43, F − O/S − O = 2.38/1.43. [c] Omitted from average.

The radial distribution function (1), calculated with the coefficients C_n of column 4, Table I, is shown in Fig. 1, curve B. The first maximum at 1.48 Å. is an unresolved average of the sulfur–oxygen and the sulfur–fluorine distances. If one assumes the sulfur–oxygen distance to be 1.43 Å., the distance found in sulfuryl chloride,[4] one may estimate the sulfur–fluorine distance to be 1.52 Å. Since the term involving the fluorine–oxygen distance is four times as important in the scattering formula as the terms involving the fluorine–fluorine and oxygen–oxygen distances, the second peak at 2.37 Å. probably corresponds closely to the fluorine–oxygen distance.

If one assumes, as has been found to be the case for sulfuryl chloride,[4] that the sulfuryl fluoride molecule is a bisphenoid with symmetry C_{2v}, there are three parameters which determine the form of the intensity curves. These may be conveniently taken as ρ_1, the ratio of the sulfur–fluorine to sulfur–oxygen distance, ρ_2, the ratio of the fluorine–oxygen to sulfur–oxygen distance, and β, the fluorine–sulfur–fluorine angle.

The radial distribution function indicates that the value of ρ_1 is in the vicinity of 1.52/1.43 and the value of ρ_2 is near 2.37/1.43. Eighteen curves were calculated,[2] for models with the parameters ρ_1 and ρ_2 in the ranges $1.48/1.43 \leqslant \rho_1 \leqslant 1.60/1.43$ and $2.32/1.43 \leqslant \rho_2 \leqslant 2.44/1.43$.

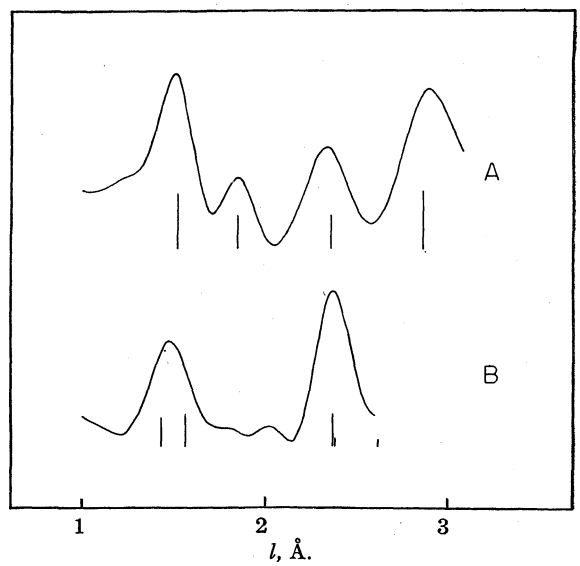

Fig. 1.—Radial distribution function, $D(l)$ *vs.* l: Curve A, thiophosphoryl fluoride; Curve B, sulfuryl fluoride. The vertical lines represent the internuclear distances found.

The parameter β was assumed to be 100° for all these curves. This is roughly the value found for the chlorine–sulfur–chlorine angle in sulfuryl and thionyl chlorides, and the qualitative and quantitative character of the theoretical curves is quite insensitive to variations in the value of this parameter. Some of these curves are shown in Fig. 2. Of these curves only the two with ρ_1 = 1.56/1.43 and ρ_2 = 2.36/1.43 or 2.38/1.43 are in agreement with the appearance of the photographs. Curves were then calculated for models with these values of ρ_1 and ρ_2 with β = 90 and 110°. The curves with β = 90° are unsatisfactory because feature b disappears while for β = 110° the fifth maximum is too low. This is illustrated by curves E_1 and E_2 of Fig. 2.

Quantitative comparison of the photographs with the curves for ρ_1 = 1.56/1.43, β = 100° and ρ_2 = 2.36/1.43 and 2.38/1.43 is made in Table I, columns 7 and 9. The agreement is quite satisfactory. The final results for the structure of sulfuryl fluoride are

S–F = 1.56 ± 0.02 Å.	∠F–S–O = 105 ± 2°
S–O = 1.43 ± 0.02 Å.	∠F–S–F = 100 ± 8°
F–O = 2.37 ± 0.02 Å.	∠O–S–O = 130 ± 10°

Thiophosphoryl Fluoride.—The photographs of thiophosphoryl fluoride were exceptionally clear, showing nine rings. The first and third maxima appear weaker than the second maximum, and the fifth maximum is weaker than the

fourth and sixth maxima. The fourth minimum is deeper than the third minimum and the sixth minimum is slightly deeper than the fifth minimum. The visually estimated relative intensities are given in Table II along with the values of $s_{obs.}$.

The radial distribution function calculated according to (1), with the coefficients C_n, given in column 4 of Table II, has four maxima (see curve A, Fig. 1) at 1.50, 1.85, 2.33, and 2.90 Å. These correspond to the four distances, phosphorus–fluorine, phosphorus–sulfur, fluorine–fluorine and fluorine–sulfur. The fluorine–phosphorus–fluorine and fluorine–phosphorus–sulfur angles computed from these distances are 100 and 118°, respectively.

If this molecule has the symmetry C_{3v}, two structural parameters determine the shapes of

[a] This distance was assumed.

appropriate models and the form of the theoretical intensity curves. These parameters are conveniently taken as the ratio ρ of the phosphorus–fluorine to the phosphorus–sulfur distance, and α the fluorine–phosphorus–fluorine angle.

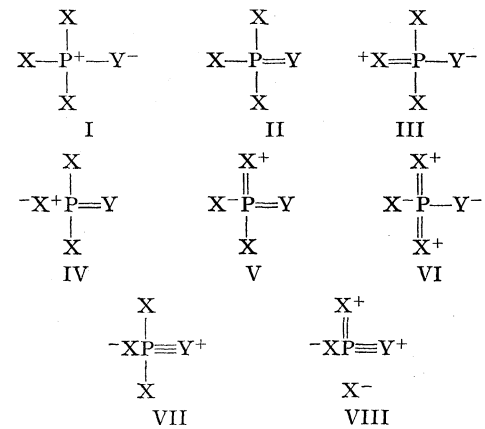
Curves were calculated for eighteen models, in which α was varied from 90–108° and ρ was varied from 1.54/1.85 to 1.46/1.85. A selection of these curves is shown in Fig. 3. All models with $96° \geqslant \alpha \geqslant 102°$ could be eliminated because the appearance of the third maximum on the curves is not that of the photographs and they show an asymmetry on either the outer side of the sixth maximum or the inner side of the seventh maximum while on the photographs these maxima appear quite symmetrical. The model with $\alpha = 99°$ and $\rho = 1.54/1.85$ is unsatisfactory because its fourth minimum is not deeper than its third and the sixth minimum is not deeper than the fifth. The curves for models with $\rho = 1.50/1.85$ and $\alpha = 99°$ show a shelf on the inner side of the ninth maximum and are unsatisfactory for this reason.

The curve calculated for the model $\rho = 1.52/1.85$ and $\alpha = 99°$ is in good qualitative agreement with the photographs. The quantitative comparison of this model with the photographs is shown in Table II. The final results for the structure of thiophosphoryl fluoride are P–F = 1.51 ± 0.02 Å., P–S = 1.85 ± 0.02 Å., ∠ F–P–F = 99.5 ± 2°, and ∠ F–P–S = 118 ± 2°.

Discussion.—Table III presents a summary of the structures found for molecules of the type X_3PY.

The distances predicted by the covalent radius table[13] are P–F (single bond) = 1.74 Å., P–Cl (single bond) = 2.09 Å., P–O (double bond) = 1.57 Å., and P–S (double bond) = 1.95 Å. The structure of thiophosphoryl fluoride presents two interesting differences from the structures of the other molecules in the group that have been studied, a decrease of 0.09 Å. in the phosphorus–sulfur distance and a small fluorine–phosphorus–fluorine angle.

An explanation for the first of these differences may be found from a consideration of the various resonating valence bond structures that may be written for molecules of this type.



The much greater shortening observed for the phosphorus–fluorine distance, 0.22 Å., than for the phosphorus–chlorine distance, 0.08 Å., has been explained by the assumption of a larger contribution of structures IV–VIII to the resultant structure of molecules containing fluorine, made possible by the larger electronegativity[14] of fluorine. Since the electronegativity of oxygen is so much larger than the electronegativity of phosphorus and sulfur, structures VII and VIII are unimportant in the molecules X_3PO. Thus we interpret the extra shortening of the phosphorus–sulfur bond in thiophosphoryl fluoride as due to considerable triple bond character made possible by the large electronegativity of fluorine and the small difference in the electronegativity between phosphorus and sulfur.

Although several explanations for the small fluorine–phosphorus–fluorine angle in thiophos-

phoryl fluoride present themselves, a satisfactory one cannot be advanced until more data have been acquired.

The sulfur–fluorine distance in sulfuryl fluoride, 1.56 Å., is 0.12 Å. less than the single bond distance predicted by the covalent radius table.[13] This shortening is not as great as is observed in the fluorine derivatives of phosphorus. A similar situation obtains for the corresponding chlorine compounds of sulfur and phosphorus.

It is of interest to note that, although there is much more shortening in the sulfur–halogen bond in sulfuryl fluoride than in sulfuryl chloride, the sulfur–oxygen distance in sulfuryl fluoride, 1.43 Å., is just that found for this distance in sulfur dioxide,[15] sulfur trioxide,[3] and sulfuryl chloride.[3]

In conclusion it should be remarked that the large uncertainty in the fluorine–sulfur–fluorine angle, ±8°, introduces an uncertainty of less than 0.1 E. U. into the calculation of the rotational entropy from the structure of the molecule.

Summary

The structures of sulfuryl fluoride and thiophosphoryl fluoride have been investigated by the electron diffraction technique. The interatomic distances and bond angles are: for sulfuryl fluoride, S–F = 1.56 ± 0.02 Å., S–O = 1.43 ± 0.02 Å., ∠ F–S–O = 105 ± 2°, and ∠ F–S–F = 100 ± 10°; and for thiophosphoryl fluoride, P–F = 1.51 ± 0.02 Å., P–S = 1.85 ± 0.02 Å., ∠ F–P–F = 99.5 ± 2°, and ∠ F–P–S = 118 ± 2°. The relationship between the structures found and the resonating valence bond structures is briefly discussed.

Solubility of Barium Iodate Monohydrate in Solutions of Uni-Univalent Electrolytes at 25°, and the Calculation of the Dissociation Constant of Iodic Acid from Solubility Data[1]

BY SOLOMON NAIDICH AND JOHN E. RICCI[2]

Barium iodate was one of the first salts to be used in the testing of theories of solutions of electrolytes through the effect of added electrolytes on the solubility of difficultly soluble salts. Such measurements for barium iodate were made by Harkins and Winninghoff,[3] in barium nitrate, potassium nitrate and potassium iodate solutions; by Polessitskiĭ[4] in potassium nitrate and calcium nitrate solutions up to very high concentrations; and by Macdougall and Davies,[5] in dilute solutions of potassium chloride, nitrate, chlorate and perchlorate, and of calcium chloride.

In the present work, at the expense of repeating some of the measurements already found in the literature, it was decided to attempt to calculate the dissociation constant of iodic acid through the relative effects on the solubility of barium iodate of the simple electrolyte potassium chloride and of the corresponding acid, hydrochloric, and, similarly, through the relative effects of the pair potassium nitrate and nitric acid on the same solubility. Measurements are therefore presented giving the effect of these four uni-univalent electrolytes on the solubility of $Ba(IO_3)_2 \cdot H_2O$ at 25°, calculation of the various Debye–Hückel parameters for the mean activity coefficient of $Ba(IO_3)_2 \cdot H_2O$ in these solutions, and, finally, calculation of the dissociation constant of iodic acid, based on the observed solubility data and certain assumptions to be stated.

Experimental

$Ba(IO_3)_2 \cdot H_2O$, C. P. grade, was washed eight to ten times with distilled water, the smaller particles being removed by a regulated process of sedimentation and decantation. Analysis of the product (dried at about 100°) before use, gave 96.5% $Ba(IO_3)_2$ as compared with the theoretical figure of 96.43% for the monohydrate. The analytical method here and in the solubility determinations themselves was the iodometric titration of the iodate by means of 0.05 *N* sodium thiosulfate solution, previously standardized against pure potassium iodate. The procedure, involving the use of weight burets, was standard; blanks were taken to correct for any iodate in the potassium iodide

used, and for any air oxidation of the excess iodide during the fixed time allowed for the titration.

The electrolyte solutions used as solvents were prepared, in the case of potassium chloride and nitrate, by weight, directly from C. P. recrystallized salts, followed by proper dilution, and by proper aliquoting and dilutions, for the very low concentrations. The hydrochloric acid solvents were made by a series of dilutions from a stock solution standardized gravimetrically; the nitric acid solutions, similarly, from a stock solution standardized volumetrically against pure sodium carbonate, using methyl orange as indicator.

The solubility determinations were carried out in Pyrex glass-stoppered bottles (250 ml. capacity), rotated for several days in a water-bath kept at 25 ± 0.01°. To ensure equilibrium and accuracy, the determinations, for each strength of solvent, were made both from under- and from super-saturation, the analyses moreover being repeated after a day or two in almost every case. Hence in most cases four determinations were made for each point of the reported solubility curves. The saturated solutions were analyzed by withdrawing by means of suction (after allowing some time for settling) a 50 or 100 ml. sample into a calibrated pipet, fitted with quantitative filter paper at the tip, delivering the sample into an Erlenmeyer, and titrating the iodate as described above.

Results

Table I lists the observed solubilities in the presence of various concentrations of potassium chloride, hydrochloric acid, potassium nitrate and nitric acid. The first column gives the molarity, m, of the solvent electrolyte; the second, the solubility, S, in moles per liter, averaged, in each case, from very closely agreeing results obtained from both under- and super-saturation; the third column lists the square root of the stoichiometric ionic strength, calculated on the assumption of complete dissociation for all electrolytes added.

Log S is plotted against $\sqrt{\mu}$ in Fig. 1. It will be observed that although the chloride curves are distinctly different from the nitrate curves, the relation of the acid to the salt effect is evidently very nearly the same for both cases. The increased solubility of the barium iodate in the presence of acid, as compared to its solubility in the corresponding concentration of potassium salt, evidently is due to the incomplete dissociation of iodic acid formed by double decomposition.

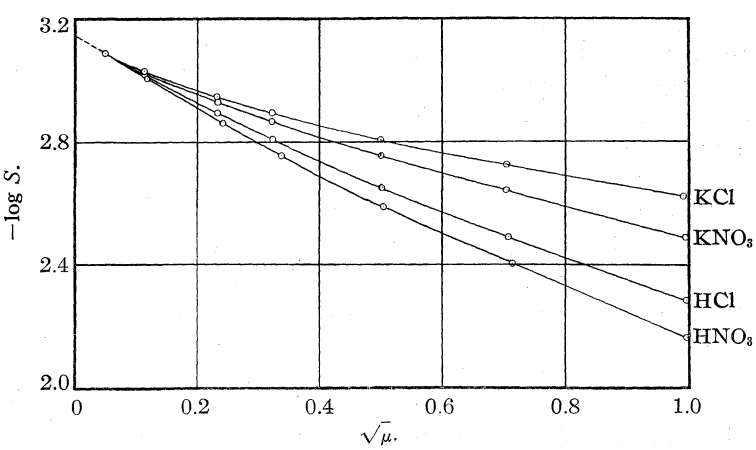

Fig. 1.—Solubility of $Ba(IO_3)_2 \cdot H_2O$ in electrolyte solutions.

Assuming the Debye–Hückel equation in the form

$$\log f_{\pm} = -\frac{B\sqrt{\mu}}{1 + A\sqrt{\mu}} \qquad (1)$$

to hold for the data involving the potassium salts as solvent electrolytes, the results can be used first to calculate, for the chloride and for the nitrate series separately, values of the parameter A, of S_0 (solubility in zero ionic strength) and of $f_{\pm}$, the mean activity coefficient, for the salt in its pure saturated solution. The coefficient $f_{\pm\mu} = S_0/S_\mu$; hence by solving successive sets of simultaneous equations of the form

$$\log S_0 - \log S_{\mu_1} = \frac{-1.01\sqrt{\mu_1}}{1 + A\sqrt{\mu_1}}$$
$$\log S_0 - \log S_{\mu_2} = \frac{-1.01\sqrt{\mu_2}}{1 + A\sqrt{\mu_2}} \qquad (2)$$

in which S_{μ_1} and S_{μ_2} are the observed solubilities in the ionic strengths μ_1 and μ_2, respectively, values of both S_0 and A are obtained. By omitting the determinations in very low concentration of added electrolyte, and combining the solubility in pure water, successively, with the determinations in the strengths shown in column 1 of Table II, the corresponding values of A are calculated.

TABLE II

VALUES OF A, CALCULATED

m	In KCl	In KNO_3
0.05	1.08	0.57
.10	1.10	.64
.25	1.06	.65
.50	1.03	.62
1.0	0.97	.56
Av.	1.05	.61

From these values the mean effective ionic diameter a may be calculated, through the relation $A = 0.328\ a$, yielding $a = 3.20$ Å. for the potassium chloride solutions, and $a = 1.86$ Å. for the potassium nitrate solutions. S_0 can also be calculated, through the solubility in pure water, by the relation

$$\log S_0 = 0.9126\text{–}4 - \frac{1.01(0.0495)}{1 + A(0.0495)}$$

Using $A = 1.05$ (KCl series), $S_0 = 7.33 \times 10^{-4}$ M; with $A = 0.61$ (potassium nitrate series), $S_0 = 7.31 \times 10^{-4}$. These values, averaging 7.32×10^{-4}, agree fairly well with the value obtained by the graphical extrapolation of the curves of Fig. 1 to zero μ; these curves, it is to be noted, give a limiting slope (observed -1.0_1 in each case) in agreement with the theoretical value of -1.01, and a value of S_0 of 7.31 (KCl curve) and 7.36×10^{-4} M (KNO_3 curve). The mean activity coefficient of barium iodate monohydrate in its pure saturated solution at 25° is then calculated to be

$$f_{\pm} = \frac{S_0}{S_w} = \frac{0.000732}{0.000818} = 0.895$$

where S_w is solubility in water; Brönsted and La Mer[6] calculated 0.894 from the data of Harkins and Winninghoff.[3]

Dissociation Constant of Iodic Acid

A.—The numerical results just presented can be used to evaluate the ionization constant of iodic acid, first, on the assumption that the only incompletely dissociated species present is iodic acid. As we shall see later, under B, the final result is changed to a negligible extent only if we correct further for the possible presence of undissociated $BaIO_3^+$ ion.

The assumption underlying the calculations is that the mean activity coefficient of the salt $Ba(IO_3)_2$ remains constant in solutions of the same total ionic strength, regardless of whether the principal electrolyte present is the acid or the potassium salt of a given anion; in other words, that $f_{\pm}$ for $Ba(IO_3)_2$ is the same in solutions of either potassium chloride or hydrochloric acid, at the same μ, and has a different but again a constant value in solutions of either potassium nitrate or nitric acid of the same μ. This amounts to assuming that the parameter A, in the Debye–Hückel expression for $\log f_{\pm}$, is the same, in respect to the effect on $f_{\pm}$ of $Ba(IO_3)_2$, for both the acid and the potassium salt of the same anion. For the particular reaction under consideration, of course, A for the two acids cannot be determined directly without, in fact, assuming a value for the dissociation constant of iodic acid. The equality of A for potassium chloride and for hydrochloric acid solutions therefore remains an assumption here. This assumption seems to be justified to some extent on the basis that the Debye–Hückel parameter A, for potassium chloride, in respect to other reactions, while differing rather regularly from that for potassium nitrate, is apparently the same for the corresponding acid, hydrochloric. Butler,[7] quoting the work of Harned and Åkerlöf[8] (electromotive force measurements), lists a for both potassium chloride and hydrochloric acid as 3.38 Å.

If $f_{\pm}$ is the same in hydrochloric acid and in potassium chloride solutions of the same ionic strength, then it follows that the mean ionic concentration $m_{\pm}$ ($= \sqrt[3]{4\ S^3}$) is also the same in the two solutions, since $f_{\pm}m_{\pm}$ = the mean ionic activity, which is constant. Consequently it follows that we can treat the solubility product likewise as constant in the two corresponding solutions. This last was the assumption made by Pedersen[9] in Bjerrum's laboratory, for the solubility product of calcium oxalate in solutions of either sodium chloride or magnesium chloride, in his recent similar calculation of the dissociation constant of magnesium oxalate; it can be seen of course that the assumption of the constant mean

8	.9894	68.78	32.34	44.36	93.20	.9801	1.0004	.6688

activity coefficient is implicit in that of the constancy of the solubility product, and that any uncertainty in the values of the various A parameters involved affects the applicability of the solubility product principle which must be used in the calculations.

Setting then the solubility product of barium iodate in solutions of hydrochloric acid equal to its solubility product in the corresponding potassium chloride solution of the same total ionic strength, the various ionic concentrations in the acid solutions can be calculated as follows. If S_S = the observed solubility in salt solution, and S_A that in acid (of the same μ)

$$m_{IO_3^-} = \sqrt{\frac{K_{SP}}{S_A}} = \sqrt{\frac{4S_S^3}{S_A}} \quad (3)$$

$$m_{HIO_3} = 2S_A - m_{IO_3^-} \quad (4)$$

$$m_{H^+} = m_{HCl} - m_{HIO_3} \quad (5)$$

$$\mu = S_A + m_{HCl} + m_{IO_3^-} \quad (6)$$

The value of $m_{IO_3^-}$ thus calculated is a first approximation, based on a value of S_S interpolated on the potassium salt curves to correspond to the uncorrected value of $\sqrt{\mu}$ for the acid solution yielding the observed S_A. On correcting the ionic strength for the undissociated iodic acid, μ now being equal to $m_{HCl} + S_A + m_{IO_3^-}$ (Equation 6), a second approximation was made in the calculation of IO_3^- by re-evaluating S_S to correspond to the corrected value of $\sqrt{\mu}$. The final concentrations thus obtained are given in Table III; the last two columns of this table give the corrected ionic strength (to the half power) and the logarithm of the ionization constant, K_m, of iodic acid in terms of concentrations.

It will be seen that the first two values (lowest concentrations) must be discarded in both the hydrochloric acid and the nitric acid series. This was probably to be expected, since the calculation is based essentially on the difference $S_A - S_S$, which becomes very small in this range and subject to too large a relative error. The thermodynamic constant, K_a, is now calculated from the remaining values of the mass constant, K_m, by an algebraic process similar to the calculation of S_0 from the values of S_μ in the foregoing part. Since, for iodic acid

$$K_a = K_m - \frac{f_{H^+} f_{IO_3^-}}{f_{HIO_3}} \quad (7)$$

we can, by assuming $f_{HIO_3} = 1$, set

$$\log K_a = \log K_m - \frac{1.01\sqrt{\mu}}{1 + A\sqrt{\mu}} \quad (8)$$

K_a can then be calculated by finding a proper value of the parameter A for the data to yield a constant value of K_a through the algebraic solution of successive sets of simultaneous equations of the form

$$\log K_a = \log K_{m_1} - \frac{1.01\sqrt{\mu_1}}{1 + A\sqrt{\mu_1}}$$

$$\log K_a = \log K_{m_2} - \frac{1.01\sqrt{\mu_2}}{1 + A\sqrt{\mu_2}} \quad (9)$$

After averaging the results ($\sqrt{\mu}$ and $\log K_m$) for both the hydrochloric acid and the nitric acid data into one series, combinations of values sufficiently far apart in respect to $\sqrt{\mu}$ were used as simultaneous equations, the calculated A parame-

ter having the values listed in Table IV, which shows also the degree of variability in this "constant."

Table V lists, in the last column, the values of K_a calculated (with $A = 1.25$) from the averaged values of $\sqrt{\mu}$ and of $\log K_m$ taken from Table III.

The average value of K_a thus calculated, without the consideration of the possible presence of undissociated $BaIO_3^+$, is then 0.163.

8	1.0	.9978	.447	.157
	Average			.165
	Average, omitting no. 3			.161

B.—Macdougall and Davies[5] showed that barium iodate cannot be considered to be completely dissociated even in very low concentrations; they calculated the equilibrium constant for the dissociation of the barium mono-iodate ion to be

$$\frac{m_{Ba^{++}} m_{IO_3^-}}{m_{BaIO_3^+}} = 0.08 \qquad (10)$$

As this circumstance would be expected to affect the final result for the dissociation constant of iodic acid to some extent, the calculations were repeated, taking into account therefore the formation of the ion $BaIO_3^+$. The concentration of this ion in the potassium salt solution, (x_s), can be calculated in the potassium chloride and nitrate solutions through the equation

$$\frac{(S_s - x_s)(2S_s - x_s)}{x_s} = K_{BaIO_3^+} \qquad (11)$$

which approximates to

$$x_s = \frac{2S_s^2}{K_{BaIO_3^+} + 3S_s} \qquad (12)$$

since x_s is small compared to S_s.

The value of $K_{BaIO_3^+}$ in terms of concentrations will vary markedly with the ionic strength, according to the expression

$$\log K_{BaIO_3^+} = \log (0.08) + \frac{2.02\sqrt{\mu}}{1 + A\sqrt{\mu}} \qquad (13)$$

(where 2.02 is the Debye–Hückel coefficient for a bivalent ion), and was evaluated accordingly for the various solutions by assuming $A = 1$; the magnitude of the effect here involved, on the final result, is so small that a value of 1 for A, which is reasonable, was taken merely for convenience.

The solubility product in any given salt solution is now given by

$$K_{sp} = (S_s - x_s)(2S_s - x_s)^2 \qquad (14)$$

Before calculating the concentrations in the acid solutions, required for the dissociation constant of iodic acid, it is also necessary to calculate the concentrations, x_A, of the $BaIO_3^+$ in the acid solutions, since, with

$$m_{Ba^{++}} = S_A - x_A \qquad (15)$$

then

$$m_{IO_3^-} = \sqrt{\frac{K_{sp}}{S_A - x_A}} \qquad (16)$$

To calculate x_A, we use

$$\frac{m_{Ba^{++}} m_{IO_3^-}}{m_{BaIO_3^+}} = K_{BaIO_3^+} \qquad (17)$$

or

$$\frac{(S_A - x_A)\sqrt{\frac{K_{sp}}{S_A - x_A}}}{x_A} = K_{BaIO_3^+} \qquad (18)$$

Since x_A is small compared to S_A, this simplifies to

$$x_A = \frac{\sqrt{K_{sp} S_A}}{K_{BaIO_3^+}} \qquad (19)$$

in which $K_{BaIO_3^+}$ is the mass constant calculated according to the earlier equation (13). The remaining quantities are calculated by

$$m_{HIO_3} = 2S_A - m_{BaIO_3^+} - m_{IO_3^-} \qquad (20)$$

$$m_{H^+} = m_{HCl} - m_{HIO_3} \qquad (21)$$

$$\mu = (S_A - x_A) + m_{HCl} + m_{IO_3^-} \qquad (22)$$

The calculations are summarized in Table VI, to which of course the first three columns of Table III should be added, for completeness.

It is interesting to note that the concentration of $BaIO_3^+$ in the salt solutions, x_s, remains constant, irrespective of the actual concentration of $Ba(IO_3)_2$, because of the effect of the ionic strength on $K_{BaIO_3^+}$. Although this sort of constancy was actually assumed as a general case, by Pedersen,[9] for undissociated calcium oxalate, in his calculation of the dissociation constant of magnesium oxalate, it is to be noted that at least in the pres-

ent case the same constancy does not hold as well in the acid solutions.

TABLE VI

CALCULATION OF K_m FOR IODIC ACID, INCLUDING CORRECTION FOR THE PRESENCE OF UNDISSOCIATED $BaIO_3^+$

No.	$x_S \times 10^4$ $m_{BaIO_3^+}$ in K^+ soln.	$x_A \times 10^4$ $m_{BaIO_3^+}$ in acid soln.	$m_{IO_3^-} \times 10^4$	$m_{HIO_3} \times 10^4$	m_{H^+}	$\sqrt{\mu}$	log K_m (+1)

7	.5	.7069	.395	.165
8	1	.9977	.447	.159
	Average			.164
	Average (omitting no. 3)			.162

It is to be pointed out that the dissociation constants calculated for the data in very low concentrations (perhaps including the concentration 0.01 N in acid) are highly variable and obviously not to be considered for the final value. This low reliability in the results is to be expected for low concentrations because of the nature of the method, which, as already stated, is a differential one, depending primarily on the observed difference between S_A and S_S (a measurement subject to very high relative error at the low acid concentrations) for the determination of the concentration of undissociated iodic acid, on which of course the ionization constant chiefly depends.

Discussion

The final value of K_a therefore, calculated from the solubility data, either with or without the correction for $BaIO_3^+$, is about 0.163. Whether or not the agreement is really to be expected, this value nevertheless agrees fairly well with the best values derived from conductivity work. All the values of the ionization constant of iodic acid in the literature are based on conductivity measurements:

Rothmund and Drucker[10] (1903)	K = 0.18–0.19 at 25°
Onsager[11] (1927)	K = .17 at 25°
Davies[12] (1933)	K = .18(.20?) at 25°
Fuoss and Kraus[13] (1933)	K = .1686 at 25°
Abel, Redlich and Hersch[14] (1934)	K = .26 at 0°
	.19 at 18°,
extrapolating to	.17 at 25°

The best value is accepted to be that of Fuoss and Kraus, 0.1686 at 25°, with which therefore the present value of 0.163 is to be compared. Pedersen,[9] it should be noted, likewise found agreement between values of the ionization constant of magnesium oxalate calculated from solubility data and from conductivity measurements, obtaining 3.8×10^{-4} and 3.9×10^{-4} in the two cases, respectively.

Summary

The solubility of $Ba(IO_3)_2 \cdot H_2O$ was measured at 25° in aqueous solutions of KCl, HCl, KNO_3 and HNO_3, the results being considered from the point of view of the Debye–Hückel equation.

The results are used to evaluate the ionization constant of iodic acid on the assumption of a constant mean activity coefficient for barium iodate in either the acid or the potassium salt solution of the same anion, at the same total ionic strength. Corrections are made for the possible existence of undissociated $BaIO_3^+$ in the solution; this effect however is found to be negligible.

The value of the thermodynamic constant K_a for iodic acid is found to be 0.163, in agreement with the best value (0.1686) derived from conductivity data.

Solubilities of Salts in Dioxane–Water Solvents[1]

BY T. W. DAVIS AND J. E. RICCI WITH C. G. SAUTER

As a study in the problem of the relations between dielectric constant and solubility of electrolytes, we have made measurements of the solubilities of three insoluble compounds, barium iodate, silver acetate and silver sulfate in dioxane–water mixtures at 25° over the complete range of concentrations from 0 to 100% dioxane in intervals of 10% by weight. The measurements extended over a dielectric constant range from 2.10 to 78.55 (the widest variation so far reported in solubility work) and the results have been treated in the light of the interionic attraction theory and of Born's theory of solvent interaction.[2]

I. Materials and Methods

Barium Iodate.—A C. P. grade of barium iodate monohydrate was washed eight to ten times with distilled water, sedimented in tall cylinders to remove smaller sized particles, and dried at 100° before use. Iodometric titration gave 96.5% $Ba(IO_3)_2$ compared with 96.43% theoretical for the monohydrate. The several preparations gave a constant solubility in water.

Silver Acetate.—A C. P. product was used without further treatment. Volumetric analysis for silver gave 64.72% silver compared with a theoretical 64.64%.

Silver Sulfate.—A preparation from Merck was employed without further purification. On the basis of silver content, the salt was 99.9% Ag_2SO_4.

Other Inorganic Salts.—Standard C. P. grade chemicals were used after drying at 100°.

Dioxane.—This solvent came from several sources. The first step in the purification was usually either a refluxing with metallic sodium for several hours or treatment with sodium wire at room temperature for several days. This sodium treatment was then followed by distillation through a 24-inch (61-cm.) packed distilling column. In some cases the dioxane was first treated with alkaline permanganate, distilled, refluxed with lime and then redistilled before being treated with sodium.[3] The density, refractive index and dielectric constant of the preparations checked closely with values to be found in the literature. The freezing points ran between 11.5 and 11.73°, somewhat lower than those reported by several others[3,4] (about 11.8). Such differences have been neglected in the present work since the effect on the calculated dielectric constant of the mixed solvents would be very small. The rapid deterioration of the material is ascribed by Hess and Frahm[4] to oxidation to give an aldehyde, peroxide and other subsequent products. Because of the unstable character of the liquid, it was prepared at frequent intervals during the course of the work.

Solubility Determinations.—The dioxane–water mixtures were made up by weight for each experiment, in glass-stoppered Pyrex solubility bottles of 250 ml. capacity. The liquid was rotated at 25 ± 0.02° with excess solid for one or more days.

Samples for analysis were withdrawn by suction through quantitative filters into calibrated 100-ml. pipets after allowing some time for the undissolved salt to settle. There was no evidence of colloidal character in any of the solutions. The silver-containing samples were titrated, after appropriate dilution in the case of high dioxane ratios, against standard 0.01 *N* potassium thiocyanate solution using weight burets. Some difficulty was encountered in fixing the end-point of this titration in the presence of varying quantities of dioxane; the precipitation of the silver thiocyanate is apparently slow near the equivalence point, and the color is also somewhat abnormal. Very vigorous and prolonged agitation is necessary to overcome the first difficulty, and comparison solutions were used as color standards to fix the final end-point in very high dioxane concentrations.

The iodate solutions were first evaporated to dryness to expel the dioxane which seriously interferes with the observation of the starch–iodine end-point, and which accelerates the liberation of iodine from an acidified potassium iodide solution. The titration of the iodate was performed with a carefully regulated procedure, using frequently standardized thiosulfate solutions delivered from weight burets, appropriate corrections being made for the blanks.

II. Solubilities in Presence of Dioxane

The solubility figures appearing in Tables II, III and IV are in every case the mean of one or more determinations from undersaturation and one or more from supersaturation.

In Table I we have collected the data on the properties of the solvents which are useful in interpreting our solubility figures. The dielectric constants are taken from the report of Åkerlöf and Short[3b]; the densities are interpolated from the measurements of Hovorka, Schaefer and Dreisbach.[5] The coefficients to be used in the Debye-Hückel equation at 25° are listed in the last two columns of the table. Column 5 of the table contains the differences between the reciprocal of the dielectric constants of the several media and the reciprocal of the dielectric constant of water.

The experimental figures on the solubilities of the three solutes investigated are presented in Tables II, III and IV both in moles per liter and in mole fractions, assuming normal molecular weights in the liquid. We have included the data in terms of both units because there is question as to which should be used in equilibrium studies. The general practice when dealing with media of different molecular composition is to use mole fractions as the more fundamental units. Scatchard[6] has shown, for example, that the reaction of thiosulfate ion with bromoacetate ion in mixed solvents[7] is in better agreement with prediction when the volume concentrations are corrected to a mole fraction basis. Bell and Gatty,[8] however, have come to the conclusion on theoretical grounds that volume concentrations should be used in calculations of interaction energies in solution. If this is correct, then all the data should appear in volume concentrations. We accordingly have listed the solubilities, in Tables II–IV, in terms of molarities and of mole fractions both, and have in fact carried out most of the subsequent calculations for both sets of units. The same tables also list the figures for the square root of the ionic strength in the several solutions calculated on the basis of 100% dissociation throughout.

Since the barium iodate is a hydrated salt, its activity and solubility must depend on the fugacity of water in the solutions. In every experiment the solid phase at saturation was the monohydrate, as proved by actual analysis, even when the solvent was dioxane, the stability of the solid in the last case being a result of the very low solubility of the salt. In no experiment with barium iodate as saturating phase, or with silver acetate or silver sulfate, was any double compound with dioxane formed. The activity of barium iodate monohydrate in solution being proportional to the activity of the water, we would find the solubility of the hydrate to be greater in solutions of lower water activity, other factors being the same. Accordingly all the solubility figures have been multiplied by the ratio of the aqueous pressure from the solution to that from pure water, using for this purpose the data of Hovorka, Schaefer and Dreisbach.[9] The resulting figure, which is that actually plotted, is the hypothetical solubility of barium iodate monohydrate in pure water of dielectric less than 78.55.

The measurements given in Tables II–IV are plotted in Figs. 1 and 2. The full curves of Fig. 1 show $-\log S$ (molarity) for the three salts studied, as a function of D and of $\left(\frac{1}{D}-\frac{1}{D_0}\right)$,

values for which are given in Table I; Fig. 2 shows the corresponding variations of $-\log X$.

Values reported in the literature for the solubility of $Ba(IO_3)_2 \cdot H_2O$ at 25° are

Trautz and Anschütz[10]	5.7×10^{-4} M
Harkins and Winninghoff[11]	7.895×10^{-4} M
Macdougall and Davies[12]	8.10×10^{-4} M
Polessitskii[13]	8.33×10^{-4} M
Present investigation	8.145×10^{-4} M

The numerous determinations of the solubility of silver acetate were reviewed by MacDougall and Bartsch,[14] who themselves found a value of 0.06634 M, as compared with the value here reported of 0.06663 M.

III. Theory of Solubility

Born[2] has given the following equation for the free energy of charging spheres of radius r_i, in a uniform medium of dielectric constant D, in terms of the charge, $z_i e$, of the spheres, e being the charge of an electron

$$E = \frac{1}{D}\frac{z_i^2 e^2}{2r_i} \qquad (1)$$

(15) K. Drucker, *Z. anorg. Chem.*, **28**, 361 (1901).

(16) V. Rothmund, *Z. physik. Chem.*, **69**, 523 (1909).

(17) A. E. Hill and J. P. Simmons, THIS JOURNAL, **31**, 821 (1909).

(18) W. D. Harkins, *ibid.*, **33**, 1807 (1911).

For a very dilute solution of an electrolyte considered as completely dissociated into spherical ions of radii r_+ and r_-, the energy of interaction of the ions with the medium per mole will be the sum of the individual energies

$$E_+ + E_- = \frac{N\nu_+ z_+^2 e^2}{D\ 2r_+} + \frac{N\nu_- z_-^2 e^2}{D\ 2r_-} = \frac{Ne^2}{D\ 2r}(\nu_+ z_+^2 + \nu_- z_-^2) \qquad (2)$$

independently of the concentrations as long as the solution is so dilute that interionic attractions can be neglected. In (2), r represents an averaged value of the two separate radii, and ν_+ and ν_- are the number of positive and negative ions, respectively, formed in the ionization of one molecule of the electrolyte. N is the Avogadro number.

Combining equation (2) with the ideal relation between free energies, activities and mole fractions, and rearranging the dielectric term, the solubilities in two different media will be related as follows

$$0 = RT \ln \frac{X''}{X'} + \frac{Ne^2}{2r}(\nu_+ z_+^2 + \nu_- z_-^2)\left(\frac{1}{D''} - \frac{1}{D'}\right) \qquad (3)$$

$$0 = RT \ln \frac{(\nu_+ X'')^{\nu_+}(\nu_- X'')^{\nu_-}}{(\nu_+ X')^{\nu_+}(\nu_- X')^{\nu_-}} + \frac{Ne^2}{2r}(\nu_+ z_+^2 + \nu_- z_-^2)\left(\frac{1}{D''} - \frac{1}{D'}\right) \qquad (4)$$

the primes and double primes referring to the two different media and the z's both being taken as positive numbers. On dividing by $RT\ (\nu_+ + \nu_-)$, equation (4) becomes

$$\ln X' = \ln X'' + \frac{Ne^2}{RT2r} z_+ z_- \left(\frac{1}{D''} - \frac{1}{D'}\right) \qquad (5)$$

The solubility of a slightly soluble electrolyte, however, is also dependent on the concentration of ions in the solution, including those from its own dissociation. The effect of the ionic atmosphere is to decrease the activity coefficients of the ions and hence to increase the solubility; and Born's equation should be applied only to solubilities which have been corrected for this ion–ion interaction effect. The magnitude of the correction at 25° is given by the familiar Debye–Hückel expression for the logarithm of the mean activity coefficient of the electrolyte

$$\log f_{\pm} = -\frac{\frac{352.6}{D^{3/2}} z_+ z_- \sqrt{\mu}}{1 + \frac{2.914}{D^{1/2}} a\sqrt{\mu}} \qquad (6)$$

where μ represents the ionic strength and "a" the distance of closest approach of the ions (twice the average radius).

If the solubility of the electrolyte in a solution of ionic strength μ is S_μ, then in a solution of zero ionic strength the solubility S_0 will be given by an expression of the form

$$\log S_0 = \log S_\mu - \frac{B\sqrt{\mu}}{1 + Aa\sqrt{\mu}} \qquad (7)$$

Combining this equation with the Born equation, we find the solubilities in two different media related by the equation

$$\log S' - \frac{B'\sqrt{\mu'}}{1 + A'a\sqrt{\mu'}} = \log S'' - \frac{B''\sqrt{\mu''}}{1 + A''a\sqrt{\mu''}} + \frac{Ne^2 z_+ z_-}{RT\ 2.303a}\left(\frac{1}{D''} - \frac{1}{D'}\right) \qquad (8)$$

Actually the effect of the Debye–Hückel corrections is rather small, as the two terms, being about equal in magnitude, nearly cancel each other. It proves to be empirically true in many cases that the mean activity coefficient of an electrolyte in saturated solution is almost independent of the dielectric constant of the medium. While no especial mention has been made of this fact, several examples may be found in the literature, and data presented later in this report (Table VIII) illustrate approximately the same principle.[14,19,20,21] This regularity and its possible application will be discussed in a later report.

Equations similar to (8) (without the general valence factor) have been used by La Mer and Goldman[19] in connection with their study of thallous iodate in alcoholic solutions, and by Brönsted, Delbanco and Volqvartz.[22] An equivalent valence factor appears in the equation for equilibrium constants in ionic processes, used by MacDougall and Larson,[20] while Dunning and Shutt[23] use a similar equation for solubilities but with a different valence factor. The equation modified for the interionic attraction effects, as given by the Debye–Hückel limiting law only, has been used by Flatt and Jordan.[24]

Brönsted, Delbanco and Volqvartz compared the solubilities of a number of electrolytes in water and in pure organic solvents. The unmodified Born equation was found to be in qualitative agreement with the actual "distribution

ratio of the ions" or the ratio of the solubility in water to that in the organic solvent; but quantitative tests were not made, and intermediate strengths of the mixtures were not used. The data of Flatt and Jordan were extremely limited (the solubility of the perchlorates of potassium, rubidium and cesium in 0, 50 and 75% alcohol, by volume). With only three points for the solubility curve of a given electrolyte, it is no surprise that the theory was found to be in "splendid agreement" with observation. What we are attempting here is a test of the combined Born and Debye–Hückel equations on a whole series of media of varying dielectric constant, using different types of electrolytes, and with a sufficient number of dependable determinations to furnish a drastic test of the mathematical predictions.

IV. Determination of "a" Values

With CARL G. SAUTER

In attempting to test the validity of equation (8), which we may call the "corrected" Born equation, the question immediately presents itself as to the correct values of a to be used in the several terms of the equation.

Ionic diameters for the three solutes examined in this investigation may be calculated from data on the solvent effects of strong electrolytes. Some of the data and computations are to be found in the literature. The values for silver acetate in water, alcohol–water and acetone–water solvents, in the presence of the various electrolytes shown in parentheses, given in Table IX below, are taken from the publications of MacDougall and coworkers.[14,20,25] That given for silver sulfate in the presence of potassium nitrate was calculated from some measurements of Harkins on the effect of potassium nitrate on the solubility of silver sulfate.[18] The value for barium iodate in the presence of potassium nitrate was calculated both from our own measurements and from the data given by MacDougall and Davies[12]; that for barium iodate in the presence of potassium chloride is taken from the measurements and calculations of Naidich.[26]

To supplement to some extent the data already found in the literature, we have made further similar determinations, studying the solubility of barium iodate monohydrate in water at 25° in the presence of varying concentrations of potassium nitrate, barium nitrate, magnesium chloride and potassium bromate; and that of silver acetate in 10% dioxane in the presence of potassium nitrate, sodium nitrate and potassium chlorate, and in 20% dioxane in the presence of potassium chlorate. The results are presented in Tables V, VI and VII; in these tables, $m_\pm$ is the mean ionic concentration of the saturating salt, *i. e.*, $\sqrt[(\nu_+ + \nu_-)]{(\nu_+S)^{\nu_+}(\nu_-S)^{\nu_-}}$, and μ is the ionic strength. S is the solubility in moles per liter of solution. The a values listed in these tables were calculated by the usual methods of applying equation (7).

The figures in Tables VI and VII are summarized in Table VIII, which shows S, the observed solubility, S_0, the solubility calculated at zero ionic strength, and f, the mean activity coefficient ($= S_0/S$). In agreement with the regularity pointed out above, the mean activity coefficient of silver acetate in its pure saturated solution seems to be roughly independent of the dielectric constant of the solvent.

The silver acetate solubilities in presence of salts, in various dioxane–water mixtures, are shown graphically in Fig. 3. The curve for silver acetate in water solvents is taken from the measurements of MacDougall and Rehner.[25] The

TABLE VIII

MEAN ACTIVITY COEFFICIENT OF SILVER ACETATE IN PURE SATURATED SOLUTION

Solvent	D	S_0	S	f
Water[14]	78.55	0.0531	0.0663	0.800
10% dioxane	69.71	.0396	.0503	.786
20% dioxane	60.81	.0279	.0361	.771

limiting slopes for the different dioxane solvents involved, namely, 0.505 for 0%, 0.606 for 10% and 0.744 for 20% dioxane are shown as dashed lines in the figure for comparison with the experimental curves. In the case of the barium iodate solubilities, in which the measurements extend down to a much lower value of the ionic strength, the observed limiting slope, as has been shown also by Brönsted and La Mer[27] and by Macdougall and Davies,[12] is in actual agreement with the theoretical value of 1.01.

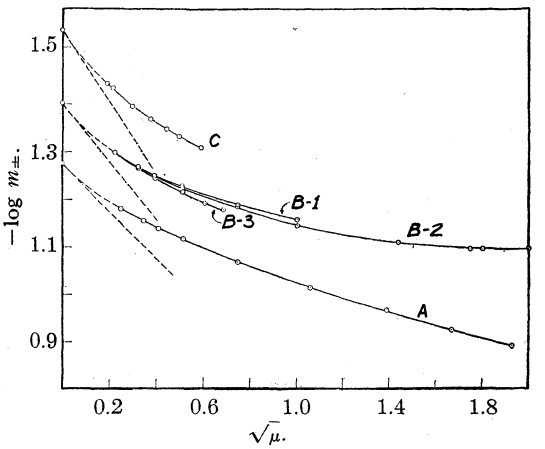

Fig. 3.—Solubility of silver acetate in dioxane–water mixtures in the presence of added salts: A, 0% dioxane, with $NaNO_3$; B, 10% dioxane, with (1) KNO_3, (2) $NaNO_3$, (3) $KClO_3$; C, 20% dioxane, with $KClO_3$.

The various Debye–Hückel values of the a parameter for silver acetate, silver sulfate and barium iodate are summarized in Table IX. Chloupek and Daneš[28] have reported another Debye–Hückel value of a for silver sulfate, determined, however, from studies on the e. m. f.'s of cells. Their values of 1 and 3 Å. for the diameters of the silver and sulfate ions, respectively, may be compared with the figure for this electrolyte given in the table.

TABLE IX

VALUES OF a FROM EFFECT OF SOLVENT SALTS ON SOLUBILITY

Solvent	$AgC_2H_3O_2$	Ag_2SO_4	$Ba(IO_3)_2 \cdot H_2O$
Water	4.35 (KNO_3)	2.43 (KNO_3)	1.80 (KNO_3)
	3.69 ($NaNO_3$)		3.20 (KCl)
			3.52 ($MgCl_2$)
			1.70 ($Ba(NO_3)_2$)
Alcohol (10–30%)	3.99 (KNO_3)		
	3.72 ($NaNO_3$)		
Acetone (10–30%)	3.99 (KNO_3)		
	3.87 ($NaNO_3$)		
Dioxane (10%)	4.48 (KNO_3)		
	4.03 ($NaNO_3$)		
	3.37 ($KClO_3$)		
Dioxane (20%)	3.52 ($KClO_3$)		

It is observed that the values are not and cannot be characteristic of the saturating salt itself

but are averages including the added solvent ions too. It is obvious that we cannot arbitrarily take an average of these parameters in applying Born's equation although we expect the a which should apply to be of the same order of magnitude. We have, therefore, thought it best to calculate a values by applying the "corrected" Born equation (Eq. 8) to solubilities experimentally observed in the several solvents. There may be some question whether the same a should be used in the Debye–Hückel terms as in the Born term, but inasmuch as the latter term far outweighs the others in numerical significance, appreciable variations in a have little effect on the Debye–Hückel corrections, and it seems reasonable to use a single figure for the ion diameters.

We have calculated the a values for the several solutions, combining the solubility in water with the solubility in the several mixed media as indicated in equation 8. The resulting a's are listed in Tables XI, XII and XIII. In each case the values increase with increasing proportion of dioxane. As a result of the mathematical transformations involved in the change of units the a's calculated from molarities are smaller than those based on mole fractions. But whichever units are used, the a values are of about the same magnitude and of the same relative consistency over the entire range; furthermore, they are comparable with a parameters appearing in Table VIII, at least in the water-rich solutions. For the purpose of comparison the various a values for the three separate salts which might possibly be used in testing the Born equation (Eq. 8) are collected in Table X.

The a's so determined and their variations as D changes, test and disprove the validity of the fundamental assumption made in the simple application to solubilities of Born's equation corrected for interionic attraction, namely, that there is a value for a (an effective ionic diameter) which

should remain constant from one medium to another and should be related to the solubility and dielectric by the equations given above.

At this point it may be appropriate to note that deviations from theoretical curves similar to those noted in this communication have been observed and reported by Tomlinson in a study of reaction velocities.[29]

We could proceed, on the other hand, on the more practical basis that the effective a changes as D changes. Then, assuming in the original equation that there is a characteristic value of a ($= a_0$) for the electrolyte in water (this could be taken as the value approached by the composite a when the percentage of dioxane decreases), an appropriate a ($= a_1$) representing the behavior in each successive solvent can be calculated using the modified Born equation

$$\log S' = \log S_0 + z_+z_-\left(\frac{B'\sqrt{\mu'}}{1 + A'a\sqrt{\mu'}} - \frac{B_0\sqrt{\mu_0}}{1 + B_0a\sqrt{\mu_0}} + \frac{242}{a_0D_0} - \frac{242}{a_1D_1}\right)$$

Since the a as already calculated (Tables XI–XIII) is in effect a composite of the diameters for each pair of media, although it is not an arithmetic average, the a values determined in the new way would be even larger than those already calculated. The principle, however, of an effective diameter varying with the medium would offer no possibility of testing the Born equation for the prediction of solubility, inasmuch as we have for the present no independent determination of the change of the diameter, a, for any given electrolyte with respect to change of dielectric. The a would in other words be an adjustable parameter only. We have consequently omitted such additional figures in the preparation of our tables.

(29) H. M. Tomlinson, "Influence of Dielectric Constant upon the Kinetics of the Bromoacetate-Thiosulfate Reaction," Thesis, Columbia, 1939; *cf.* also V. K. La Mer, *J. Franklin Inst.*, **225**, 709 (1939).

V. Solubilities Calculated from Born's Equation

While the variations of the a's cited in the last three tables themselves indicate the failure of Eq. 8 to account for our experimentally determined solubilities, a clearer picture of the extent of this failure may be drawn from a comparison of predicted and determined solubilities. The calculations have been made in terms of mole fractions using first the a values for the 0 and 10% dioxane solutions and again with the a for the 0 and 30% solutions. The calculations have been repeated on a volume–molar basis using the a which fits the 0 and 10% observed solubilities. The calculations, as before, involve successive approximations; first the solubility is computed without correcting for the interionic attraction, then with this preliminary value the interionic attraction terms are added to the equation and a new solubility is computed. Two approximations are all that are needed except for silver sulfate. The calculated solubilities using the a values just noted together with the ratio of the calculated to the experimental figures are given in the three tables. The calculated and observed curves for log S are plotted together in the two sets of concentration units in Figs. 1 and 2. As can be seen from these figures, the calculated values for log S for both molarity and mole fraction units lie in every case on a very nearly straight line with a slight curvature in the first two or three points due to interionic effects where the ionic strength is appreciable, and with a nearly constant slope, given by

$$\text{slope} = 242z_+z_-/a$$

where a has the value used in the given series of calculations. All the predicted values are too small except at a few points where the 30% a is used for the computations since here the straight line of the calculated values cuts through the curve of the observed solubilities at the point for 30% dioxane.

While there is general agreement as to order of magnitude of the solubility down to 40–50% dioxane computed on the basis either of mole fractions or of molarities, even this degree of concordance disappears for solutions containing more than 50% dioxane. This disagreement is a little worse for the two higher valence type electrolytes than for silver acetate. The use of a larger a improves the agreement in the high-dioxane mixtures but makes the figures for the low-dioxane solvents higher than the experimental, as already pointed out.

VI. Discussion

The disagreement between the observed and the calculated solubilities is seen to be substantially the same for either the volume or the mole fraction units of concentration. The question then of the proper concentration units to use would seem to involve factors of minor importance as compared to the larger discrepancies noted between observed and theoretical solubilities.

In seeking some explanation for the wide deviations between prediction and experiment in these solubilities, we observe that three assumptions involved in Eq. 8 may have to be modified in such a way as to bring about better agreement. These assumptions are (1) a constant diameter for the several electrolytes independent of the medium, (2) a homogeneous structureless character for the dielectric medium and (3) the absence of molecular or ionic associations.

While it may seem reasonable to suppose that variable solvation will lead to a changing effective diameter in different media, it is likely that ions in solutions containing even small percentages of water will be fully hydrated or nearly so, so that for practically the whole range of dioxane–water mixtures, a should be nearly constant for a given electrolyte. Moreover, if the extent of solvation is actually smaller in dioxane-rich solutions, smaller diameters should be expected, whereas, as already seen, the observed solubilities require much larger values to bring about agreement with the Born equation. There seems to be no independent method of estimating these ionic diameters in solution, so that our conclusions regarding them must remain speculative.

Scatchard[30] has shown that the e. m. f. of cells made up of hydrogen chloride in aqueous alcoholic solutions may be accounted for by taking a as equal to 4 Å. up to 50% alcohol and decreasing a to about 2 Å. in absolute alcohol. On the other hand, the values for sodium chloride and potassium chloride in aqueous alcohol are not much different from the a's for these salts in water.[27]

The observation also of rather constant values of a over a wide temperature range for cadmium sulfate and zinc sulfate in water[31] and the very small variation of a for hydrogen chloride in several dioxane–water solvent mixtures[32] may be noted as further evidence for the belief that for a given salt the values of a should be characteristic only of the electrolyte and independent of the medium. It would be pointless then to try to bring the Born equation into agreement with our experiments by artificial adjustments of the a's.

The assumption of continuous character of the solvent medium is apt to be a serious source of error in mixed solvents. The question is related to that of the effective diameter of solvated ions. It is to be expected that in a mixed solvent the more polarizable substance, water in the present case, will be preferentially oriented around the ions; with more soluble electrolytes such as sodium nitrate, this phenomenon may lead to the formation of two liquid layers. While this factor has often been mentioned (for example, by Scatchard[30] in 1925), few calculations of its consequences have been made. Using the Debye expression for the distribution of molecules in a dielectric mixture around a univalent ion,[33] in conjunction with Born's equation, Dunning and Shutt[23] report a calculation of the effective radius of silver chloride when dissolved in a one molar aqueous solution of urea, this radius agreeing more closely with crystallographic values than the radius determined from the Born equation alone. The calculation, however, is very tedious, and while the correction introduced will be in the right direction of increasing the solubilities calculated for a

given ion size, there is still doubt whether a constant a can be determined for the whole series of solvents, especially when ion association becomes important.

The effect of selective dipole concentration around the ions would not enter into solutions of salts in pure organic solvents of low dielectric; but in most of these liquids the solubility of electrolytes having slight solubility in water will be below the limit of quantitative estimation, and no tests can be applied. One may suggest that the small but detectable dissolving in 90% dioxane of such a difficultly soluble substance as barium iodate, while its solubility in a single solvent of the same dielectric capacity would probably be zero,[34] is evidence that the preferential adsorption of water around ions has a tremendous effect in determining solubility in solvents containing water.

Another effect particularly important in solvents of low dielectric constant is ion clustering in the Bjerrum sense.[35] Such clustering will result in an increased solubility over that calculated assuming complete dissociation. A formula for the formation of binary pairs for a uni-univalent electrolyte has been given by Fuoss and Kraus as a function of the diameter of the ions and the dielectric of the medium,[36] in the approximate and simplified form

$$\frac{1}{K} = \frac{4\pi N}{1000} a^4 \frac{DkT}{e^2} \exp.\left(\frac{1}{a}\frac{e^2}{DkT}\right)$$

where K is the dissociation constant and the other letters have their usual significance. Application of this equation gives approximately 3.1×10^{-6} and 1.1×10^{-12} as the values of K for silver acetate in 80 and 90% dioxane, respectively, where our value of a, namely, 3.05, is taken to define the corresponding value of K. Such results would indicate negligible quantities of silver acetate in molecular form when the ion concentrations are of the magnitudes given in column 3 of Table XI. Smaller a values in the Fuoss and Kraus equation will give, it is true, a K sufficiently small to account for observed solubilities. If a is taken as one-half of 3.05 Å., roughly correct solubilities are predicted. The magnitude of K calculated according to this equation is extremely sensitive to small changes in a. Uncertain, therefore, as a itself is, any value of K derived in the Fuoss and Kraus manner must be considerably in doubt. It is unlikely, furthermore, that the mean ionic diameter for silver acetate can be much smaller than 3.05 Å., for it usually has been found that the parameters fitted into the ordinary Debye–Hückel equation are smaller than expected in the sense that sometimes negative values are found, while a more extended treatment such as that of Gronwall, La Mer and Sandved[37] leads always to positive and hence physically plausible values of a. It is possible that the a's we have used, which are in general agreement with Debye–Hückel values, are too small also.

Several authors have declared that in media below about 60 in dielectric capacity, most of the divalent ions will be associated and that below a dielectric of about 30 univalent ions will be largely associated into neutral molecules. If this be the case in our experiments, the solutions should behave like non-electrolytes where the dioxane percentages exceed 50 approximately, and the solubilities should be nearly proportional to the mole fractions of water in the mixtures. This is not observed, as seen from the data in Tables II–IV, so that we may infer that the solutions of the un-ionized salts here studied are not ideal.

A complete prediction of solubilities in the light of modern theories would involve an estimation of the solubility by the corrected Born equation followed by a calculation of solvent segregation around the ions, a redetermination then of the ionic solubility and a determination of the Bjerrum ion association using the Kraus and Fuoss method of calculation. Such a series of calculations has not yet been made, but while laborious it would have some interest as a test of the combined theories.

Summary

The solubilities of silver acetate, silver sulfate and barium iodate have been determined at 25° in a series of dioxane–water solutions extending from 0 to 100% dioxane. The dielectric constants cover the range 2.1 to 78.55.

The solvent effect of potassium nitrate, barium nitrate, magnesium chloride and potassium bromate solutions on barium iodate in water has been examined experimentally. The solvent effects of potassium nitrate, sodium nitrate and potas-

(34) Thallous iodate has negligible solubility in alcohol, of much higher dielectric than 90% dioxane; *cf.* La Mer and Goldman, ref. 19.

sium chlorate on silver acetate in 10% dioxane solutions, and of potassium chlorate on silver acetate in 20% dioxane, have also been investigated. The corresponding Debye–Hückel a parameters have been calculated.

The Born equation even when corrected for interionic effects fails to account for the course of the solubilities as the percentage of dioxane increases, predicting in each case lower solubilities than those observed. The differences increase in media of higher dioxane content, prediction and observation disagreeing even as to order of magnitude in solvents containing more than 50% dioxane by weight. The disagreement is not diminished appreciably by substitution of mole fractions for volume concentrations, showing that this question is of minor importance as a factor in the application of the Born equation.

Modifications to be superimposed on the Born equation to bring it into line with the observations are discussed.

Kinetic Studies on Iodine Derivatives. I. The Thermal Decomposition of Acetyl Iodide[1]

BY J. LESLIE JONES

The thermal[2] and photochemical[3] decomposition of acetaldehyde into methane and carbon monoxide has been investigated by numerous authors. Since the deduction of a possible free radical mechanism for the thermal and photochemical decomposition of acetaldehyde by Rice and Herzfeld,[4] a great deal of controversy has arisen concerning its validity. The opposing theory[2c] assumes that the activation process, thermal or photochemical, is followed by a rearrangement of the acetaldehyde directly into the final products, methane and carbon monoxide.

On the basis of previous investigations[5] it seems probable that the thermal decomposition of alkyl iodides occurs by the breaking of the carbon–iodine bond (temperature range of 250–350°) as the primary process. This reaction is followed by the secondary reactions of the free radicals. By the substitution of an iodine atom for the hydrogen atom of the aldehyde group in acetaldehyde it is possible to study the thermal decomposition of the product, acetyl iodide, in the same temperature range as the alkyl iodides. Such a study casts light upon the mechanism of the thermal decomposition of acetaldehyde, supporting the free radical mechanism. In addition information is gained concerning the secondary reactions of the free radicals involved.

Experimental Section

The rate of decomposition of the acetyl iodide was followed by the pressure change method, employing essentially the apparatus of Jones and Ogg.[5] The quartz spiral manometer prevented the iodine evolved in the reaction from reacting with the mercury in the absolute manometer. A hollow barrel stopcock was employed to close the reaction vessel, employing a plasticizer as lubricant. The compound, di-*o*-xenzyl-monophenyl phosphate,[6] has a vapor pressure of 5 mm. at 285° and a viscosity of 170 centipoises at 60°. The liquid was warmed in a high vacuum system for several hours in order to remove all solvents. All observations indicated that it was unaffected by the iodine generated in the system, as its structure suggested. It was necessary to heat the stopcock closing the reaction vessel to about 110° in order to prevent condensation of iodine.

The acetyl iodide was prepared by the treatment of Eastman Kodak Co. acetyl chloride with an excess of dry hydrogen iodide gas at 0°. The brown crude product (90% yield) was protected from the air and vacuum distilled in an all-glass fractionating system two times, large amounts of the first and third fractions being discarded. A third fractionation was carried out in high vacuum, the product being distilled directly into the reservoir of the system employed for the study of the reaction rates. In

general about 30–40 g. of acetyl iodide was utilized as a middle fraction from 150–200 g. of crude acetyl iodide. Three different preparations were employed in the experiments and there was no difference in the behavior of each. The product colored brown in the presence of air. Light was excluded from the reservoir. The boiling point of the product was 60° at 145 mm.

Analysis of the gaseous products was done with a modified Bone–Wheeler apparatus handling a maximum of 3 ml. Bromine water was used to measure unsaturates, ammoniacal cuprous chloride for carbon monoxide, cupric oxide combustion for hydrogen and an explosion combustion for saturated hydrocarbons. A 5% sulfuric acid solution was kept in the measuring buret to maintain a constant vapor pressure. The apparatus was not satisfactory, but it was estimated that concentrations could be determined within 5%. Due to the simple products of the reactions, the apparatus was sufficiently accurate to indicate the main reaction involved.

Homogeneity of the Thermal Decomposition.—In order to determine the effect of packing upon the rate of thermal decomposition, a series of experiments were carried out in a 250-ml. spherical Pyrex flask packed with glass tubing to yield a surface–volume ratio of 5.1 cm.$^{-1}$. Experiments were also performed in the same bulb without glass packing, at a surface–volume ratio of 0.72 cm.$^{-1}$. A third series of experiments were carried out in a 1000-ml. flask of surface–volume ratio 0.44 cm.$^{-1}$. The experimental determination of the rate constant directly indicated that the rate of the decomposition was inhibited by packing the reaction vessel.

Further experiments were performed using helium and nitrogen as inert gases. The tank gases were purified by passage over copper screen heated to red heat and then through a liquid-air trap to remove condensable vapors. The gases were purified directly as needed and admitted to the reaction vessel.

Experimental Results

The Stoichiometric Reaction.—The average ratio of the final pressure, P_f, in the reaction to the extrapolated initial gas pressure of pure acetyl iodide, P_i, was 1.45. This value of P_f/P_i was apparently independent of the initial pressure and temperature of the reaction. Such a value indicated that three molecules of gaseous products were formed from two molecules of acetyl iodide. Free iodine was formed quantitatively from the acetyl iodide, as determined by titration of the iodine condensed in a liquid-air trap after an experiment. The residual gas on analysis was shown to consist of equal volumes of carbon monoxide and methane, within an error of ±5%. Observation of the reaction vessel after two or three experiments indicated that a solid product was being deposited on the surface of the vessel. After a half dozen experiments, the surface of the vessel was dark brown in color. The solid product was a closely adherent, non-crystalline substance. All of this evidence indicated that the stoichiometric reaction was probably

$$2CH_3COI = CH_4 + CO + I_2 + CH_2CO \text{ (solid polymer)}$$

The solid product was considered to be polymerized ketene. Because of its adherence to the glass surface, an amount sufficient for analysis could not be obtained. However, a material balance of the reaction products gave its empirical formula. The research of Rice and Greenburg[7a] indicated that the polymerization of ketene was a heterogeneous reaction at room temperature in a Pyrex vessel. Williamson[7b] found that ketene polymerized rapidly at 400–500°. An initial rapid lowering of the gas pressure was followed by a pressure increase. This phenomenon depended upon the initial gas pressure and thus indicated that the polymerization was not a unimolecular reaction.

Kinetics of the Reaction.—The data measuring the rate of decomposition of acetyl iodide fitted most closely the unimolecular expression

$$-d(CH_3COI)/dt = k(CH_3COI)$$

The pressure of acetyl iodide at any time t was given by

$$(CH_3COI) = (1.45P_0 - P_t)/0.45$$

The value of k, the rate constant, was obtained for each experiment by plotting the values of log (CH_3COI) against time. The graphs was straight lines for the experiments performed in unpacked flasks. The linearity of the graphs was maintained up to 65–76% decomposition at the lower temperatures (292–314°), while at 338° the rate constant was maintained up to 90–95% decomposition. The reaction rate constant was definitely a function of the initial pressure of acetyl iodide and, as Table I indicates, increased with the initial pressure. Other data indicated that the reaction was not a simple unimolecular reaction and therefore it was useless to apply the theory of Kassel–Rice–Ramsperger to the falling off of the value of k. If one considered the disappearance of acetyl iodide during the course of our experiment to occur to the extent of 80% before the value of k began to decrease, then the pressure of acetyl iodide fell to about 5–7 mm. before this effect occurred at 338°. Similar limiting pressures were obtained at lower temperatures. In view of the fact that the rate con-

(7) (a) Rice and Greenburg, THIS JOURNAL, **56**, 2132 (1934); (b) Williamson, *ibid.*, **56**, 2216 (1934).

stant for a particular experiment was maintained over a very large change in the concentration of acetyl iodide and yet is a function of the initial acetyl iodide pressure, one must conclude that the products of the decomposition are very efficient in maintaining the proposed chain mechanism over a wide pressure range.

[a] Initial acetyl iodide pressure.

The study of the effect of packing the vessel cast additional light upon the mechanism of the reaction. The 250-ml. reaction vessel was packed with Pyrex tubing, increasing its surface–volume ratio from 0.72 to 5.1 cm.$^{-1}$. Table II indicates the effect of packing on the rate constants. The values of k are approximately the same in packed and unpacked flasks over the greater portion of the decomposition. At 612°K. in the packed flask, the value of the rate constant began to fall off after about 60% decomposition and in the unpacked flask after about 90% decomposition. This falling off in the value of k is shown graphically in Fig. 1 for experiment number 25. It is evident that the effect of packing is of secondary importance in this reaction for at least 60% of the iodide is decomposed before departure from a first order reaction is noted. Such a departure indicates the existence of secondary chain reactions repressed by the walls of the vessel.

acetyl iodide, that the addition of inert gases had little effect on the values of k. Table III gives the values of k in the presence of the inert gases nitrogen and helium, indicating only a slight increase in the value of k on the introduction of an inert gas.

Discussion

All of the above experimental evidence indicates that a chain mechanism is involved in the thermal decomposition of acetyl iodide. The retardation of the decomposition by packing indicates that a chain propagating step is broken by the walls of the vessel. The effect of the products of the reaction in maintaining the rate of pyrolysis during a particular experiment supports the conclusion that the chains are propagated in the gas phase. Addition of the inert gases to acetyl iodide slightly increases the rate constants for the pyrolysis above the value corresponding to the initial pressure of the iodide alone.

In view of the role played by chain reactions, the value of the activation energy obtained by plotting log k vs. t may be of dubious utility unless the activation energies of the elementary chain reactions are known. However, in this particular study the value of the activation energy E has been obtained by plotting the log k against $1/T$ at several initial pressure values for the acetyl iodide (*cf.* Fig. 2). No claim can be made for high accuracy of the activation energy values but their concordance is satisfactory. The average value of E is 43,100 cal./mole.

Previous investigations[4] indicate that the strength of the carbon–iodine bond is approximately 43,000 cal./mole. Admittedly this is an approximation, disregarding the zero point energies of the atoms. However, the present experimental value of E is essentially the same. In view of this fact one can conclude that the primary rate determining step in the decomposition of acetyl iodide is the scission of the carbon–iodine bond. This primary process is then followed by a series of secondary processes best given by the mechanism shown.

		E, kcal./mole

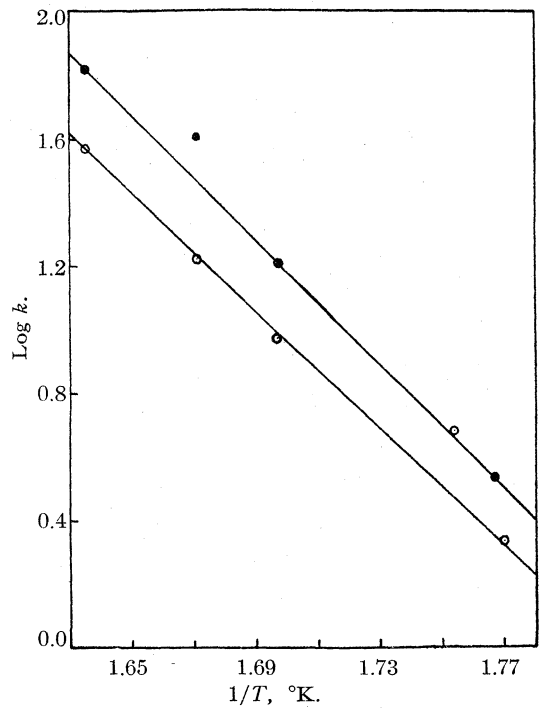

Fig. 2.—●, P_0 approximately 275 mm., E = 44,400 cal./mole; ○, P_0 approximately 100 mm., E = 41,800 cal./mole.

If one sets up in the usual manner equations expressing the stationary state concentrations of methyl and acetyl radicals and methyl iodide, then the rate of disappearance of acetyl iodide is given by the equation

$$-d(CH_3COI)/dt = 2k_1(CH_3COI)$$

The introduction of another possible elementary reaction

$$CH_3CO + I_2 \longrightarrow CH_3COI + I$$

results in a first power term with respect to iodine concentration as a denominator of the above equation. There is no evidence that iodine acts as an inhibitor, except possibly the results obtained in the packed flask and these are of secondary importance.

The evidence is insufficient to justify a statement as to the exact value of the carbon–iodine bond strength, but the value is not markedly affected by the presence of the carbonyl group. The stability of the acetyl radical is in dispute,[8] but the acetyl radical undoubtedly decomposes very rapidly in the temperature region employed in these experiments. Gorin,[8] on the basis of the photolysis of acetone in the presence of iodine,

(8) Gorin, *J. Chem. Phys.*, **7**, 256 (1939); Barak and Style, *Nature* **135**, 307 (1935); Spence and Wild, *J. Chem. Soc.*, 352 (1937).

ascribes a minimum activation energy of 17 kcal. to reaction (2).

The formation and dissociation of methyl iodide, as postulated by reactions (3) and (4), has been established by the work of Ogg[9] on the reduction of methyl iodide by hydrogen iodide. Similar reactions of other lower alkyl iodides have been demonstrated by Jones and Ogg.[10] Rollefson and Faull,[11] in order to account for the iodine-catalyzed decomposition of acetaldehyde, proposed a mechanism involving the above equilibrium. In addition, Etzler and Rollefson[12] in a recent note indicated that a liquid product thought to be methyl iodide had been isolated from the products of the photolysis of acetyl iodide at room temperature.

Rice and Herzfeld in their original paper[3] on the free radical mechanism of acetaldehyde pyrolysis postulated the reaction

$$CH_3CHO + CH_3 \longrightarrow CH_3CO + CH_4$$

ascribing to it an activation energy of 15 kcal. Akeroyd and Norrish[13] have deduced a value of 9.8 kcal. for the above apparent reaction by photochemical methods. However, Burton[14] has calculated a value of 115 kcal. for the strength of the carbon–hydrogen bond in the aldehyde group and thus renders improbable this proposed elementary reaction of Rice and Herzfeld. Taylor and Burton[15] have modified the Rice–Herzfeld mechanism, introducing the radical CH_2CHO as an intermediate instead of the radical CH_3CO. The present research is in agreement with their proposal for here the radical CH_2COI is involved. This radical is able to decompose in this temperature range to yield a stable molecule, ketene, and atomic iodine, in contrast to the inability of the CH_2CHO radical to lose a hydrogen atom. There is existing evidence[6,7] on the polymerization of ketene. Free radicals undoubtedly accelerate this process.

Smith and Taylor,[16] utilizing methyl radicals produced by the photolysis of mercury dimethyl, studied the reactions of hydrocarbons with the methyl radicals. They found a value of 8.3 kcal. for the activation energy of the reaction between ethane and methyl radical to form methane. This evidence supports the probability that the methane is formed essentially in this decomposition by the interaction of methyl radicals and acetyl iodide. Hence, it is also the methyl group of the acetaldehyde which is the principal donor of the hydrogen to form methane, not the aldehyde group.

Further research is in progress on the mechanism of the decomposition of other iodine substituted derivatives with particular reference to iodomethyl ether.

Summary

The thermal decomposition of gaseous acetyl iodide was studied in the temperature range 290–340°. The main products of the reaction were identified as carbon monoxide, methane, iodine and polymerized ketene. The decomposition was unimolecular with respect to the acetyl iodide and the rate constants were dependent upon the initial pressure of iodide. The effects of packing the reaction vessel and introducing inert gases were studied. A chain mechanism has been proposed for the decomposition and justified in terms of independent research. The mechanism involves as a primary step the scission of the carbon–iodine bond.

Electron Sharing Ability of Organic Radicals. X. Alpha-Substituted Tetrahydroquinolines

BY WILBUR OLDHAM AND I. B. JOHNS

A few measurements are recorded in the literature on the basicity of quinoline[1-5] and quinaldine.[1,3,6] With the exception of the constants found by Goldschmidt for these two heterocyclics, the results are in good agreement. However, the basic strength of the α-substituted tetrahydroquinolines has not been investigated. This manuscript reports the comparison of the ionization constants in absolute methanol of some members of the tetrahydroquinoline series with the constants of the α-substituted pyrrolidine series previously measured in this Laboratory.[7,8]

A most convenient and general method for the preparation of a series of α-substituted quinolines involves the reaction of an organometallic compound, such as $RMgX$[9] or RM,[10] with quinoline. The action of sodamide on quinaldine[11] was employed in the preparation of α-*n*-butylquinoline, this reaction being followed by treatment with *n*-propyl bromide.

Reduction to the tetrahydroquinolines was accomplished by means of metallic sodium in boiling ethyl alcohol,[12,13] since this method besides giving excellent yields is very easily carried out.

Synthesis of Compounds

Tetrahydroquinoline.—Eastman Kodak Co. synthetic practical quinoline, purified by fractionation, was reduced with a seven times excess of metallic sodium in boiling absolute ethyl alcohol. The resulting solution was diluted with water, made acidic with hydrochloric acid and the alcohol removed by heating under a water pump vacuum. The base was freed with solid sodium hydroxide and extracted with ether. Tetrahydroquinoline was recovered in a yield of 85%, b. p. 126° (18 mm.). The hydrochloride melted at 180–181°.

α-Methyltetrahydroquinoline.—Redistilled Eastman quinaldine was reduced exactly as was quinoline. A 70% yield of α-methyltetrahydroquinoline, b. p. 125° (17 mm.), was obtained. The hydrochloride melted at 195–196°.

α-Ethyltetrahydroquinoline.—α-Ethylquinoline was prepared in 20% yield byh eating 0.25 mole of ethylmagnesium bromide for three hours in a sealed bomb at 155° with 0.22 mole of quinoline.[9] The recovered product boiled at 110–112° at 6 mm. The picrate melted at 145–146°.

Reduction with sodium and alcohole gave a 62% yield of α-ethyltetrahydroquinoline, b. p. 110–113° (5 mm.).

Anal. Calcd. for $C_{11}H_{15}N$: N, 8.70; C, 81.90; H, 9.32. Found: N, 8.79, 8.90; C, 81.6, 82.0; H, 9.47, 9.47.

The picrate, prepared in absolute ether, melted at 119–120°. Reher[14] states that the salts of this base are amorphous but the picrate prepared here was not and gave melting point depressions when mixed with the picrate of α-ethylquinoline and with picric acid.

α - *n* - Butyltetrahydroquinoline.—α - *n* - Butylquinoline was prepared by the action of 10 g. of sodamide on 0.105 mole of quinaldine[11] followed by treatment with 0.105 mole of *n*-propyl bromide. The base was isolated in a yield of 42%, b. p. 145–146° (11 mm.). The picrate melted at 163–164°. Reduction with sodium and alcohol gave α-*n*-butyltetrahydroquinoline in 55% yield, b. p. 138° (6 mm.).

Anal. Calcd. for $C_{13}H_{19}N$: N, 7.41; C, 82.54; H, 10.05. Found: N, 7.32, 7.39; C, 82.6, 82.8; H, 9.97, 9.87.

The picrate would not precipitate. The *p*-bromobenzenesulfonamide, recrystallized from petroleum ether, melted at 160–160.5°.

α-Phenyltetrahydroquinoline.—Phenyllithium was prepared in ether according to procedure "C" of Gilman.[15] After filtering off the excess lithium by means of a glass wool plug, an equivalent amount (0.07 mole) of quinoline was added. Hydrolysis with aqueous ammonium chloride, extraction with ether and distillation yielded the 1,2-dihydro compound,[10] which was dehydrogenated to α-phenylquinoline by distillation from zinc dust. The yield was 85%, the base melting at 82.5° after recrystallization from alcohol. The picrate melted at 188.5–189° and the *p*-bromobenzenesulfonamide at 190–191°.

Sodium and alcohol reduction[16] gave α-phenyltetrahydroquinoline in 73% yield, b. p. 196° (8 mm.). The picrate, prepared by evaporating to dryness an ethereal solution of equivalent amounts of the base and picric acid and recrystallizing from alcohol, melted at 129°. The *p*-bromobenzenesulfonamide melted at 201–202°.

(16) Since the completion of this manuscript we have found that platinum on zirconium oxide catalyst, prepared by The American Platinum Works, will reduce α-phenylquinoline to α-phenyltetrahydroquinoline, while the platinum oxide of Adams and Shriner will reduce α-phenylquinoline to α-cyclohexyldecahydroquinoline.

α-*p*-Tolyltetrahydroquinoline.—In exactly the same manner as with α-phenylquinoline, α-*p*-tolylquinoline was prepared from *p*-tolyllithium and 0.13 mole of quinoline. Distillation from zinc dust and fractionation at 190° and 3 mm. pressure gave the base in the theoretical yield. After recrystallization from alcohol, crystals melting at 83° were obtained. The picrate melted at 198.7°.

α-*p*-Tolyltetrahydroquinoline was prepared for the first time by reduction of the corresponding quinoline in 73% yield. It was an almost colorless, viscous liquid, b. p. 210° (14 mm.).

Anal. Calcd. for $C_{16}H_{17}N$: N, 6.28; C, 86.10; H, 7.62. Found: N, 6.41, 6.39; C, 86.20, 86.25; H, 7.81, 7.58.

The picrate after several recrystallizations from alcohol melted at 134–134.5°.

α-*o*-Tolyltetrahydroquinoline.—α-*o*-Tolyllithium, prepared from 0.15 mole of *o*-iodotoluene and an excess of lithium, was treated with 19 g. of quinoline and gave α-*o*-tolylquinoline in 90% yield. Nitrobenzene was used for the dehydrogenation.[10] This base was a heavy oil that solidified on cooling, b. p. 197° (4 mm.). Purification was effected through the picrate. Regeneration with dilute sodium hydroxide yielded crystals that melted at 76–76.2° after being deposited from an ethereal solution.

Anal. Calcd. for $C_{16}H_{13}N$: N, 6.39. Found: N, 6.32, 6.30.

The picrate melted at 176°.

The corresponding tetrahydro compound solidified on cooling, b. p. 200–202° (6 mm.). Recrystallization from 70% alcohol gave α-*o*-tolyltetrahydroquinoline, in 85% yield, melting at 69.5°. A mixed melting point determination with α-*o*-tolylquinoline showed a depression to 45–48°.

Anal. Calcd. for $C_{16}H_{17}N$: N, 6.28; C, 86.10; H, 7.62. Found: N, 6.36, 6.27; C, 85.90, 85.90; H, 7.64, 7.75.

The picrate could not be obtained. The *p*-bromobenzenesulfonamide melted at 193–193.5°.

α-2-Mesityltetrahydroquinoline.—2-Mesityllithium, prepared from 0.166 mole of 2-bromomesitylene and lithium, was treated with 21 g. of quinoline in the way described. After dehydrogenation by means of nitrobenzene, α-2-mesitylquinoline was isolated in a yield of 25%, b. p. 200° (4 mm.). Considerable quantities of bromomesitylene were recovered. The base was recrystallized from petroleum ether and then melted at 69–69.5°.

Anal. Calcd. for $C_{18}H_{17}N$: N, 5.66. Found: N, 5.45, 5.65, 5.64.

The picrate prepared in absolute ether melted at 216.5°.

Reduction gave α-2-mesityltetrahydroquinoline in 83% yield as a heavy, very viscous liquid, b. p. 218° (6 mm.).

Anal. Calcd. for $C_{18}H_{21}N$: N, 5.57; C, 86.06; H, 8.37. Found: N, 8.50, 8.50; C, 86.10, 86.10; H, 8.20, 8.34.

The picrate melted at 164.5–165°.

Measurements of Ionization Constants.—The method used here is the same as that previously used by Goodhue[7] in this Laboratory. The hydrogen-ion concentrations of half-neutralized solutions of the bases in absolute methyl alcohol were determined by means of the normal hydrogen electrode in conjunction with a vacuum tube potentiometer.

The calomel half-cells employed were of the sealed Schollenberger type[17] and were prepared in duplicate using 0.1 *f* sodium chloride in absolute methanol. They were standardized by means of silver–silver chloride electrodes prepared in triplicate both by the method of Harned (type 2)[18] and by that of Rule and La Mer.[19] This latter method, involving the decomposition of a paste mixture of silver oxide and silver chlorate, was found to be more convenient although reproducible results were obtained by both procedures.

Platinum black was deposited on small platinum flags and used as the hydrogen electrodes. These were prepared and used in duplicate.

The purified bases were sealed in glass ampoules for weighing except the α-*o*-tolyltetrahydroquinoline which, being a solid, was weighed in a stoppered weighing bottle. All solutions were made by weight and the concentrations are expressed in molalities.

TABLE I

	.0450	.4460	5.63	11.08

[a,b] The e. m. f. values were measured using a calomel half-cell of 0.1134 v. except those marked "*a*" in which the value was 0.1174 and those marked "*b*" in which the value was 0.1171 when referred to the normal hydrogen electrode.

The results of the e. m. f. determinations are shown in Table I. The method of calculation is the same as for primary amines in water solutions. The hydrogen-ion activities were calculated from the equation

$$-\log a_H = (E - E_{calomel})/0.059$$

As noted in Table I, the potentials of the calomel cells were 0.1134, 0.1171, and 0.1174 volt.

Since in half-neutralized solutions of amines

(17) Schollenberger, *Ind. Eng. Chem.*, **17**, 649 (1925).
(18) Harned, THIS JOURNAL, **51**, 416 (1929).
(19) Rule and La Mer, *ibid.*, **58**, 2339 (1936).

the degree of hydrolysis becomes equal to the hydrogen-ion activity, then

$$K_{B_{CH_3OH}} = K_{CH_3OH/H \text{ ion activity}}$$

and

$$K_{B_{CH_3OH}} = -\log K_{CH_3OH} - (-\log a_H) = 16.71 - (-\log a_H)$$

The dissociation constant of methyl alcohol was taken as 1.95×10^{-17}.[20]

The ionization constants of the α-substituted quinolines could not be measured by this method because of reduction of the unsaturated bases. Goodhue encountered the same difficulty in attempting to use the hydrogen electrode in measuring the ionization constants of α-substituted pyrrolines in alcohol.[7] Reduction does not occur so readily in aqueous solutions. Felsing and Biggs[6] used the hydrogen electrode to measure the constants for some methylquinolines in water and Starr[21] used this method for some pyrrolines, also in aqueous solution.

Discussion

In Fig. 1 the ionization constants of the α-substituted tetrahydroquinolines have been plotted as functions of the electron sharing ability of the radicals. For purposes of comparison the curves are included for the primary amines measured by Goodhue[7] and for the α-substituted pyrrolidines measured by Goodhue[7] and by Kirchner.[8] The radicals have been placed along the x axis in the way that they were initially arranged by Hixon and Johns[22] from the ionization constants in water of a series of primary amines.

An inspection of these curves shows that the substitution of various groups in the tetrahydroquinoline nucleus affects the ionization constants in exactly the same manner as did substituting the same groups in the primary amines and in the pyrrolidine nucleus. This is to be expected if the substituent radicals affect the polar properties of these amines by means of their valence electrons.

Curve (1) for the pyrrolidines and curve (111) for the tetrahydroquinolines are of the same shape and their difference in slope from the primary amine curve represents the effect of having the substituent radical one carbon removed from the polar group.

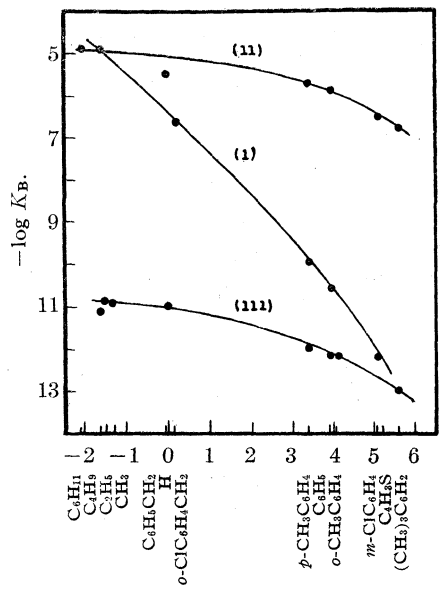

Fig. 1.—The ionization constants of various types of amines in absolute methanol plotted as functions of the electron sharing ability of the organic radicals. Curve (1) is for primary amines, (11) for α-substituted pyrrolidines, and (111) for α-substituted tetrahydroquinolines.

Summary

1. The ionization constants of a series of α-substituted tetrahydroquinolines have been determined in absolute methanol. The substituent radicals were: H, methyl, ethyl, *n*-butyl, phenyl, *o*-tolyl, *p*-tolyl and 2-mesityl.

2. These constants plotted against electron sharing ability functions give a curve similar to that for a series of α-substituted pyrrolidines previously reported.

3. α-Substituted quinolines prepared for the first time were the *o*-tolyl and the 2-mesityl. New α-substituted tetrahydroquinolines include *n*-butyl, *p*-tolyl, *o*-tolyl, and 2-mesityl.

Hydrogenation of Acetophenone to Cyclohexylmethylcarbinol in the Presence of Solvent

BY V. N. IPATIEFF AND B. B. CORSON

Acetophenone can be selectively hydrogenated in isopentane solution to a 70% yield of cyclohexylmethylcarbinol[1] but the conditions must be controlled carefully.

Experimental

A 3350 cc. bomb was charged with 200 cc. of acetophenone, 400 cc. of isopentane, 40 g. of nickel catalyst,[2] and 100 kg./sq. cm. of hydrogen. The bomb was rotated for six hours at 100°. The product was distilled through a Podbielniak column with a reflux ratio of 10/1. The isopentane was first evaporated. The residue consisted of 20% (by vol.) of ethylbenzene (b. p. 135–137°; $n^{20}D$ 1.4925), 7% of intermediate fraction (b. p. 137–189°; $n^{20}D$ 1.4874), 70% of cyclohexylmethylcarbinol (b. p. 189–190°; $n^{20}D$ 1.4688), and 3% of bottoms ($n^{20}D$ 1.4940).

The ethylbenzene fraction contained about 1% of ethylcyclohexane on the basis of its refractive index and solubility in cold 15% fuming sulfuric acid.

The redistilled cyclohexylmethylcarbinol showed the following constants: b. p. 189.4–189.8° at 761 mm.; $n^{20}D$ 1.4677; d^{20}_4 0.925. *Anal.* Calcd. for $C_8H_{16}O$: C, 74.9; H, 12.6; mol. wt., 128. Found: C, 74.8; H, 12.5; mol. wt., 126.

When an isopentane solution of acetophenone was heated for six hours at 75°, the product was a mixture of 8% of ethylbenzene and 92% of an approximately 50/50 mixture of phenylmethylcarbinol and cyclohexylmethylcarbinol, and when the hydrogenation temperature was 50° the product was mainly unchanged acetophenone.

In the absence of solvent, and using reduced copper as catalyst[3] at 225°, 95% of the product was ethylbenzene. Using cyclohexane as solvent at 100°, the product was a mixture of ethylbenzene, the two alcohols, and acetophenone.

Summary

Acetophenone has been selectively hydrogenated in isopentane solution to cyclohexylmethylcarbinol.

(1) Cyclohexylmethylcarbinol has previously been made through the Grignard reaction (Bouveault, *Bull. soc. chim.*, [3] **29**, 1049 (1903); Sabatier and Mailhe, *Compt. rend.*, **139**, 343 (1904).

(2) The catalyst was a kieselguhr supported nickel (about 70% of nickel) which had been reduced at 430°.

(3) Prepared by reduction in hydrogen at 225° and ordinary pressure of Kahlbaum–Schering granular copper oxide (nickel content, 0.1%).

RIVERSIDE, ILLINOIS RECEIVED SEPTEMBER 1, 1939

Pseudo-eleostearic Acid[1]

BY J. P. KASS AND G. O. BURR

Moore[2] has shown that prolonged saponification of linseed oil induces a partial isomerization of its spectroscopically inactive liquid linolenic acid to an absorptive crystalline substance, m. p. 77°, bearing a striking resemblance to the eleostearic acids in the position and intensity of its absorption band and in its failure to form an ether-insoluble hexabromide.

In the course of a spectroscopic study of isomerism in the fatty acids[3] we found it expedient to determine the constitution of this compound, the oxidation products of which, consisting of sebacic, oxalic and butyric acids, establish its structure as 10,12,14-octadecatrienoic acid-1. The shift to a conjugated configuration induced by alcoholic alkalies is thus analogous to the rearrangement of linoleic acid under similar treatment.[4] Like the eleostearic acids (9,11,13-octadecatrienoic acids),[5] the new isomer adds only two molecules of bromine easily, the introduction of the third requiring considerable time or exposure to ultraviolet light. However, its maleic anhydride addition product is not homogeneous and could not be separated into its clearly defined individual components. This points to the geometric configuration of the parent substance as the *trans-trans-trans* or *trans-cis-trans* isomer, either of which may form more than one condensation product.[6]

Since the completion of this investigation, we

(1) This work was supported by grants from the Hormel Foundation, the National Live Stock and Meat Board, and the Graduate School of the University of Minnesota.

have been informed[7] that in an independent preliminary study of the oxidation products of the new acid, designated by Moore[7] as "pseudo-eleostearic acid," Prof. T. P. Hilditch obtained sebacic acid and small amounts of monobasic acids having in impure condition an apparent equivalent of about 106. If the latter is assumed to be valeric acid (neutral equiv. 102), an allenic structure is suggested, which is contradicted by the pronounced absorption band at 270 mμ characteristic of the triply conjugated eleostearic acids.[8,9]

Moore[7] considers the spectroscopic activity and the production of sebacic acid indicative of the reorientation of the unsaturated linkages from the 9,12,15 positions of linolenic acid to the 10,12,14 configuration of pseudo-eleostearic acid.

Experimental

Formation of Pseudo-eleostearic Acid.—Moore's uncertain and prolonged saponification procedure, requiring the refluxing of the fatty acids with aqueous alcoholic potash for from seven to twenty-five days,[2] may be advantageously shortened to a matter of hours or minutes by the substitution of anhydrous butanol[4] or ethylene glycol, respectively, as the reaction medium, using approximately equal weights of the fatty acids and the alkali in four volumes of the solvent. The isomerization is completed in from six to twenty-four hours with the former and in from thirty to one hundred and twenty minutes with the latter, the reaction mixture then being acidified and the butanol removed by either steam or vacuum distillation and the glycol by simply washing the acids with water. The usual precautions against oxidation must be observed throughout, and the course of the reaction may be followed spectroscopically, dienometrically, or iodometrically, being considered complete when the absorption bands of the isolated aliquot samples of the mixed fatty acids reach a maximum at 230 and 270 mμ, their diene number exceeds 20, or their iodine number falls to about 150.

Six hundred and twenty-five grams of linseed oil fatty acids from which the solid acids were removed by two crystallizations from ligroin at −18° was refluxed under nitrogen for two hours with an equal weight of potassium hydroxide in 2.5 liters of anhydrous ethylene glycol. The mixture was then cooled, several hundred cc. of water added, and the refluxing resumed for a brief period to saponify the esters. (This step is essential when butanol is used as the solvent, since it shows a pronounced tendency toward esterification in the anhydrous state.) The soap solution was acidified, the fatty acids extracted with 1.5 liters of ligroin, and thoroughly washed with water. The dried ligroin solution was left overnight at −18°, when it deposited 25 g. of practically pure pseudo-eleostearic acid.

Pseudo-eleostearic Acid.—The acid precipitated easily from 85% alcohol as feathery crystals and from hexane as glistening scales. It was relatively insoluble in petroleum ether (30–35°), 1 g. requiring about 175 cc. for solution at 0°. Its m. p. was 77–79° (uncorr.), repeated crystallizations failing to narrow the melting point range, which was rapidly depressed and widened by exposure of the acid to air, so that three trials within two hours showed melting point ranges beginning successively at 75.5, 71.5, and 69° with a final maximum of 75°. The acid showed remarkable susceptibility to oxidation, quickly acquiring an acridly rancid odor and even its ligroin solutions becoming opalescent on boiling.

Anal.[10] Calcd. for $C_{18}H_{30}O_2$: C, 77.70; H, 10.79. Found: C, 77.78; H, 11.02.

The iodine number determinations by the Wijs or Hanus method gave values intermediate between two and three double bonds, rising with time and showing the recurring end-point and precipitation of iodine characteristic of the conjugated fatty acids.[11]

Hydrogenation of Pseudo-eleostearic Acid.—A mixture of the acid and platinum oxide catalyst in acetic acid was shaken for two hours in an atmosphere of hydrogen at room temperature and 40 lb. (3 atm.) pressure. The product was precipitated with water and after one recrystallization from 85% alcohol melted at 69.5–70°, showing no depression with a sample of authentic stearic acid.

Methyl Pseudo-eleostearate.—Ten grams of the acid was dissolved in 100 cc. of 4% methyl alcoholic sulfuric acid and left overnight at room temperature. The solution was then refluxed briefly and finally extracted with ligroin from which 7 g. of the methyl ester, m. p. 41° after recrystallization from methanol or ligroin, precipitated on cooling. The residue was a yellow oil which partially solidified at 0° and yielded an additional 1.5 g. of impure ester. Saponification of the sharply melting ester produced the parent acid, the m. p. of which again was 77–79°. This spread evidently is due to the greater susceptibility of the acid to oxidation.

Disruptive Oxidation of Methyl Pseudo-eleostearate.—A modification of the procedures of Armstrong and Hilditch[12] and of Haworth[13] was used; 5 g. of the ester was dissolved in 130 cc. of purified acetone and 75 g. of powdered potassium permanganate added carefully. The mixture was boiled under reflux and an additional 10 g. of the oxidizing agent added to produce a permanent pink coloration. After three hours, the acetone was evaporated completely, the residue extracted four times with dilute potassium hydroxide solution and the alkaline extract concentrated somewhat. The green extract was decolorized with gaseous sulfur dioxide, acidified with a small quantity of dilute sulfuric acid and distilled to the incipient precipitation of the salts. The residue was thoroughly extracted with ether, which on evaporation left 1.5 g. of a practically white solid contaminated with a yellowish oil, the latter being removed by crystallization from water and charcoal to give an acid with a neutral equivalent of 101.5 and m. p. 131–133°. One recrystallization narrowed the melting

point to 132–133°, no depression with authentic sebacic acid, m. p. 133°, neut. equiv., 101.07.

The aqueous residue was extracted repeatedly with benzene, then treated with a few drops of bromine, cooled, and the precipitated salts filtered off and discarded. The sulfates were precipitated with barium chloride, the filtrate made alkaline, then acidified with acetic acid and treated with purified calcium nitrate. After several hours the fine precipitate was filtered off, dissolved in hydrochloric acid and reprecipitated with ammonium hydroxide. The white powder, 0.76 g., reduced acid permanganate instantly and left a residue of 36.67% after ignition (calcd. for $CaC_2O_4 \cdot H_2O$, 38.38%).

The distillate, which possessed a pronounced odor of butyric acid, was made alkaline and evaporated to a small volume. It was then acidified, thoroughly extracted with ether, the ether extract washed once with water, and dried overnight with Drierite after preliminary drying over sodium sulfate. Evaporation of the ether left 0.5 g. of a liquid, 0.4 g. of which distilled at 165°. This distillate was miscible with water in all proportions, had a neutral equivalent of 80 and formed a *p*-toluidide, m. p. 69–71° (butyric acid, neut. equiv. 88, *p*-toluidide m. p. 73°).

Bromination of Pseudo-eleostearic Acid.—A solution of 1.5 g. of the acid in 250 cc. of petroleum ether cooled to 0° was brought to a distinct orange color with bromine and left at 0° for three hours. About 0.1 g. of a white powder precipitated, melting at 90–95° from hexane solution. Recrystallization from 1–5 ether–ligroin solution raised the m. p. to 90–100° and further fractionation of the powder from hexane showed its major component to be a crystalline substance, m. p. 104–104.5°.

Anal. Calcd. for $C_{18}H_{30}O_2Br_4$: C, 36.14; H, 5.02. Found: C, 35.73; H, 4.67.

The filtrate from the tetrabromides was treated with an additional portion of bromine and exposed to direct sunlight at room temperature. After twenty-four hours a partially crystalline precipitate appeared. Three successive extractions with boiling hexane yielded a total of 0.25 g. of white powders melting at (I) 125–135°, (II) 140–145°, and (III) 145–151°, respectively. The residue was taken up in ligroin (b. p. 90–95°) and finally recrystallized from ether, in which it is easily soluble, precipitating only in the ice–hydrochloric acid bath as scaly crystals, m. p. 152°. The ether mother liquor was evaporated and the residue combined with the hexane extract III, the mixture being recrystallized from ether to yield an additional crop of solid of m. p. 152°. Both portions were combined and recrystallized again from ether to yield 90 mg. of a crystalline material, m. p. 152–152.5°.

Anal. Calcd. for $C_{18}H_{30}O_2Br_6$: C, 28.50; H, 3.96. Found: C, 28.44; H, 4.17.

The hexane extracts I and II were combined and recrystallized from ligroin (b. p. 90–95°) without much improvement in melting point. However, 15 mg. of a crystalline substance of m. p. 148° was obtained from a 1 : 1 ether–petroleum ether solution. This was evidently the impure hexabromide, the mixed m. p. being 148–152°. Evaporation of the original ligroin mother liquor left only liquid bromides.

The hexabromide is apparently the only solid addition product obtained when pseudo-eleostearic acid is brominated in ultraviolet light; 0.4 g. of the acid in 15 cc. of purified carbon tetrachloride contained in a quartz test-tube was brominated at 0° to an orange color; an excess of one-third of the bromine consumed was added and the solution illuminated with a mercury arc at 50 cm. for one hour. The excess bromine was removed with amylene, the solvent evaporated at the vacuum pump, and the residual oil worked up with hexane. After twelve hours in the icebox, 50 mg. of a crystalline precipitate was obtained, melting at 145–148° after crystallization from ligroin (b. p. 90–95°). One recrystallization from ether raised the melting point to 152.5°. That ultraviolet light induces no isomerization of the parent acid was shown by the unaltered melting point and solubility behavior of a sample of pseudo-eleostearic acid similarly illuminated in a quartz container.

Addition of Maleic Anhydride.—An intimate mixture of equimolar quantities of pseudo-eleostearic acid and maleic anhydride was heated under nitrogen to 145°, when the yellow color of the melt was discharged. The reaction product set to a tacky, plastic mass on cooling. This was subdivided by repeated extraction with boiling hexane into a soluble granular solid and an insoluble sirup. The solid was redissolved several times in hexane, the less soluble sirup being removed each time. The final product was a white, poorly friable powder, sintering at 75° and melting at 77°, the melt becoming clear at 82°.

Anal. Calcd. for $C_{22}H_{32}O_5$: C, 70.21; H, 8.51. Found: C, 69.71; H, 8.21.

The residual sirup set to a brittle solid after complete evacuation of the solvent, and could then be ground to a coarse granular powder similar in melting point and appearance, except for a yellowish tinge, to the hexane extract. Both fractions were extremely soluble in alcohols, ether, acetic acid, and acetone, and were precipitated with ligroin as sirups that became solid on complete removal of the solvent. When the pseudo-eleostearic acid was heated with an excess of maleic anhydride either in the solid state or in a solvent, the reaction mixture remained liquid until the excess of reagent was removed either by distillation or with water, after which the characteristics of the product were those described.

Summary

Linolenic acid is partially converted by alcoholic alkalies into pseudo-eleostearic acid, 10,12,14-octadecatrienoic acid, m. p. 79°, methyl ester, m. p. 41°.

Pseudo-eleostearic acid forms mixed maleic anhydride addition products and mixed bromides, among them a tetrabromide, m. p. 104.5°, and a hexabromide, m. p. 152.5°.

The Preparation and Asymmetric Reduction of β-Methylcinnamic Acid

BY DAVID LIPKIN AND T. D. STEWART

H. Erlenmeyer[1] brominated the hydrocinchonine and glucamine salts of cinnamic acid and found that the cinnamic acid dibromide was optically active. The glucamine salt was brominated using only the solid salt, but the hydrocinchonine salt was brominated in chloroform solution as well, under which condition activity of the isolated dibromo acid corresponding to 8% asymmetric synthesis was observed. These experiments have been repeated by us and the results verified.

It is apparent that in chloroform solution the amine and acid are united in such a way as to produce a coupling of the electrical fields of both molecules which extends beyond the three atoms, –N–H–O–, involved in a possible hydrogen bond and includes the asymmetric center of the base and the olefinic bond of the acid. This is not surprising in view of the associated character of such salts in chloroform, but it indicates that the mutual electrical inductions in such salts may be as strong as the intramolecular induction in esters.[2] Vavon and Jakubowicz[3] studied the platinum-catalyzed hydrogenation of six optically active esters of β-methylcinnamic acid. They found that the β-phenylbutyric acid isolated after saponification had a specific rotation in benzene (λ = 5461 Å.) varying from +13.3 to −6.1°, corresponding to as much as 19% asymmetric synthesis.

The present paper describes improved syntheses of β-methylcinnamic and β-(α-naphthyl)-cinnamic acids, and their asymmetric reduction as hydrocinchonine salts.

Preparation of β-Methylcinnamic Acid.—The method of Stoermer, Grimm and Laage[4] has been modified to ensure reproducibility and greater purity of product. Acetophenone (240 g.), 20–30 mesh granulated zinc (196 g.) and sodium-dry benzene (850 ml.) were placed in a 3-liter three-necked flask fitted with a reflux condenser, mercury-sealed stirrer and a dropping funnel. All outlets to the air were closed by drying tubes. The mixture was heated to gentle refluxing on a steam-bath and then the addition of 234 g. of freshly distilled ethyl bromoacetate dissolved in 150 ml. of dry benzene started. This addition was carried out over a period of ten to twelve hours, with continual refluxing and stirring; the heating and stirring were then continued for another six hours. Under these conditions one mole of zinc reacts per mole of the other reagents.

$$C_6H_5COCH_3 + BrCH_2CO_2R \xrightarrow{Zn} C_6H_5C(OZnBr)(CH_3)CH_2CO_2R$$

A competing condensation reaction using one-half this amount of zinc, producing succinic ester, is inhibited by keeping a low concentration of bromoacetic ester and through the use of a large excess of zinc. Similarly reaction of the intermediate zinc derivatives with the ester group likewise is retarded by the slow addition of the ester.

The cooled reaction mixture was decanted from the unused zinc and washed with 400 ml. of 6 *N* hydrochloric acid and 200 ml. of water. Without drying, the mixture was then refluxed by means of an oil-bath in a 3-liter flask fitted with a Dean and Stark[5] tube which was equipped with a stopcock to remove water collected from the reflux. When the water level in the tube had remained constant for half an hour, the water was drawn off and 5 ml. of phosphorus oxychloride added to the flask. Refluxing was then continued until the water collected was again constant (about one-half hour). This portion of water represents the water formed in the catalytic dehydration of the ester and is a good indication of the eventual yield. The benzene was now allowed to distil off, taking care that the oil-bath did not rise above 130° and that prolonged distillation was avoided.

The ester residue was hydrolyzed by adding two liters of 1 *N* methanolic potassium hydroxide and 45 ml. of 40% aqueous potassium hydroxide and refluxing for one and one-half hours. The methanol was then removed by steam distillation and the cooled aqueous residue extracted with ether to remove alkali-insoluble by-products. The latter represented a large portion of the reaction products and contained little acetophenone as such. The aqueous layer was added to one liter of ether and then acidified with 450 ml. of ice-cold 6 *N* sulfuric acid. Two additional ether extracts of 200 ml. each were made and the combined ether extracts dried and the ether distilled off. The crude β-methylcinnamic acid was distilled at 1 mm. pressure, or less, using a 500-ml. Claisen flask with a wide side arm: b. p. (0.6 mm.) 124–127°; b. p. (1 mm.) 135–136° uncorr.; yield 133.6 g. or 41%.

The vacuum distilled product was a slightly yellowish, crystalline solid containing a considerable amount of low-melting material, probably a solid solution of *cis* and *trans* isomers. To remove this, the product was placed in a 500-ml. wide-mouthed flask fitted with a reflux condenser and thermometer whose bulb rested on the bottom of the flask.

About 35 ml. of pentane was added and refluxed until the boiling point was constant. After cooling, the liquid phase was removed through an immersion filter and the pentane extraction repeated several times until successive extracts had the same boiling point. The remaining solid (the *trans* isomer) was dissolved in ligroin (b. p. 90–100°), using 225 ml. of solvent per 100 g. of acid, charcoal treated, and recrystallized; m. p. 98.4–98.7° corr.; yield, 89 g. or 27%. To remove any possible catalyst poison the product was recrystallized from aqueous methanol, 560 ml. of methanol and 720 ml. of water per 100 g. of acid.

None of the acid fractions gave the lemon-yellow color or intense violet color in concentrated sulfuric acid noted by the above authors and attributed to the stable and labile acids, respectively.

Preparation of β-(α-Naphthyl)-cinnamic Acid.—This acid was prepared by essentially the same procedure as used for the methyl derivative, substituting α-naphthyl phenyl ketone prepared by the method described by Fieser[6] for the acetophenone. The crude yield varied from 55–72%, and it is significant that the alkali-insoluble saponification product was nearly pure α-naphthyl phenyl ketone. The yield of acid was virtually 100% based on the ketone actually consumed. It was purified by crystallization from carbon tetrachloride, acetic acid or absolute ethanol; m. p. 213.1–214.0° corr.

Hydrocinchonine was prepared by catalytic hydrogenation of cinchonine, using palladous chloride as catalyst;[7] crystallization was from dioxane, m. p. 275° corr. (dec.); $[\alpha]^{22}D$ +214° (0.0223 *M* hydrocinchonine in 0.024 *M* aqueous HCl).

Reduction of Hydrocinchonine β-Methylcinnamate by Hydrogen.—The first reduction was carried out in an 0.0434 *M* solution of the salt in absolute ethanol, using 0.076 g. of Adams platinum oxide per each 100 ml. of solution. The catalyst was forty-eight days old. Hydrogen was introduced at a pressure of 41 lb. (3 atm.) per square inch, with vigorous shaking; the reaction was complete in four and one-half hours at room temperature. Special care was used to remove the dextrorotatory hydrocinchonine from the acid. After removing the ethanol by vacuum distillation, the residue was treated with benzene and excess dilute sulfuric acid at room temperature. Three successive acid extracts eventually showed no optical activity nor a test for alkaloid with $KBiI_4$. The optical activity of the benzene solution, assuming a quantitative reduction and recovery, indicated $[\alpha]^{20}_{5461}$ +5°. An alkaline extract of the benzene solution, using 0.1 *N* NaOH, gave an observed rotation of +0.062°, corresponding to $[\alpha]^{20}_{5461}$ +3°. Finally the free acid was recovered in benzene again and the benzene evaporated. The residue at constant weight amounted to 1.07 g. of sirupy liquid; dissolved in benzene at a dilution of 0.065 g./ml., α = +0.629° in a 2-dm. tube or $[\alpha]^{20}_{5461}$ +4.5°. This corresponds to about 8–9% asymmetric synthesis.

A second reduction was made under approximately the same conditions except that the hydrogen pressure was 760 mm., the temperature 25.0°, and using a catalyst twenty-four days old. The recovered β-phenylbutyric acid had an activity of $[\alpha]^{20}_{5461}$ +0.64° in benzene.

(7) Heidelberger and Jacobs, THIS JOURNAL, **41**, 817 (1919).

Reduction of Hydrocinchonine β-(α-Naphthyl)-cinnamate.—The reduction was carried out in 0.05 *M* ethanol solution using 0.106 g. of catalyst in 100 ml. of solution. The temperature was 25.0° and the pressure of hydrogen 760 mm. The recovered reduced acid had an activity corresponding to $[\alpha]^{20}_{5461}$ −0.5° in chloroform solution.

Discussion

The poor and sometimes erratic yields in the Reformatsky reaction employed in these preparations may be attributed to condensations of the bromoacetic ester with itself, producing eventually water-soluble products after saponification. This is clearly indicated in the condensation using α-naphthyl phenyl ketone, in which the unsaponifiable fraction was largely unchanged ketone. The yield of desired condensation product was quantitative on the basis of used ketone, with complete disappearance of the bromoacetic ester and the quantitative consumption of zinc. In the case of acetophenone further side reactions are self-condensation to *sym*-triphenylbenzene (recovered in some experiments) and possibly Claisen-type condensation with the bromoacetic ester to form ketonic products. In this case the alkali-insoluble saponification product was not simply unused ketone, and the yields are uniformly poorer than in the condensation with the purely aromatic ketone. The slow addition of bromoacetic ester to the reaction mixture produces a consistent and apparently nearly maximum yield; the procedure is employable on any scale of operation.

The fact that heterogeneous hydrogenation of these alkaloid salts in alcohol solution leads to partial asymmetric synthesis of the reduced acids indicates that adsorption of these polar substances has not prevented the molecular inductions responsible for the specificity.

The authors wish to acknowledge the careful preparative work done on this problem by Mr. Wilbur Pearlson.

Summary

A procedure for the Reformatsky condensation of aromatic ketones and bromoacetic ester leading to maximum yields and applicable to any scale of operation is given.

The hydrocinchonine salts of β-methylcinnamic acid and β-(α-naphthyl)-cinnamic acid are catalytically reduced in ethanol solution by hydrogen to produce optically active β-phenylbutyric acid and β-(α-naphthyl)-hydrocinnamic acid, respectively.

The Asymmetric Reduction of β-Methylcinnamic Acid by *d*-Glucose in the Presence of Raney Nickel

BY T. D. STEWART AND DAVID LIPKIN

The reduction of β-methylcinnamic acid by *d*-glucose in alkaline solution[1] offers the possibility that the β-phenylbutyric acid produced is optically active. Using Raney nickel as a catalyst, and carefully controlled conditions, we have found the specific rotation of the product to be reproducible and to vary from $[\alpha]^{25}_{5461}$ +0.31° to −0.42° (benzene). The highest specific rotation observed for β-phenylbutyric acid is given by H. Rupe for D light, from which we estimate[2] the specific rotation of the pure *levo* form to be $[\alpha]^{20}_{5461}$ −68.5° (benzene). The present paper concerns itself with the factors producing these small but significant changes in the degree of asymmetric synthesis.

A summary of the results obtained and the experimental conditions is given in Table I. The table headings indicate the initial concentrations of the reactants and the order in which they were added. Columns 2, 3, and 4 give, respectively, the amount of Raney nickel used, expressed in grams per liter of reacting solution, and the time and temperature employed in its preparation from the nickel–aluminum alloy. The temperature specified is that of the oil-bath used for the digestion of the alloy with sodium hydroxide; the catalysts are correspondingly called "hot" or "cold," in reference to this temperature. The relative rates of reaction are shown in column 5, and the specific rotation of the product given in column 6.

Reproducibility of the results is shown in Expts 16, 24, and 26. A plot of the alkali consumed *vs.* time in these experiments showed absolute consistency of reaction rate. Polarimeter readings were accurate to 0.01° and the specific rotation is accurate to 0.03–0.04°. Experiments 2 and 17 differed in catalyst preparation, and to a minor extent in reagent concentrations.

Amount of Catalyst.—In Fig. 1 are plotted the data for two series of runs, Expts. 12, 8, 9, and Expts. 18, 24, 13, 21, in each of which the amount of identically prepared catalyst is varied. In the first series the "hot" catalyst was employed; in the second, the "cold" catalyst. It appears anomalous that increased amount of a given surface catalyst should alter the course of the reaction.[3]

TABLE I

EXPERIMENTAL CONDITIONS AND RESULTS

Expt.	Catalyst amt. (g./l.)	Prep. and amt. Time, hr.	Prep. and amt. Temp., °C.	Reaction time for 75% completion	Specific rotation $[\alpha]^{20}_{5461}$
Part A. Concentration and order of mixing: β-methylcinnamate 0.220 *M*; potassium hydroxide 0.330 *M*; *d*-glucose 0.440 *M*; nickel. Temperature of reaction 25°C.					
12	15	2	118	16 hr.	+0.02
8	30	2	118	2.3	− .35

2	15	7	>118	6.5(62%)	+ .31
Part E. Concentrations one-half those of Part A, except that glucose was 0.165 *M* in Expt. 14. Temperature 25°					
14	30	2	118	1.4	−0.32
11	30	2	118	1.1	− .42

(1) Delépine and Horeau, *Compt. rend.*, **204**, 1605 (1937); *Bull. soc. chim.*, [5] **4**, 1524 (1937).

(2) H. Rupe, *Ann.*, **369**, 323 (1909), gives $[\alpha]^{20}_{D}$ −57.23° (benzene) as determined by resolution through the menthyl ester. Levene and Marker, *J. Biol. Chem.*, **93**, 761 (1931); **100**, 685 (1933), obtained $[\alpha]^{25}_{D}$ −46.8° (benzene) from the cinchonidine salt. After laborious crystallization of the quinine salt we have obtained a sample of acid of $[\alpha]^{25}_{D}$ −47.92 and $[\alpha]^{25}_{5461}$ −45.40° (benzene, 0.3280 g./10 ml.).

(3) It is obviously possible as Wieland, *Ber.*, **46**, 3327 (1913), pointed out, that catalytic dehydrogenation of an alcohol may be followed by catalytic hydrogenation of an acceptor of the hydrogen, and in the present case this could result in a symmetric rather than asymmetric reduction. The effects studied here are conceivably concerned with only a small fraction of the total reaction, or may represent the balance between two concurrent stereochemical processes.

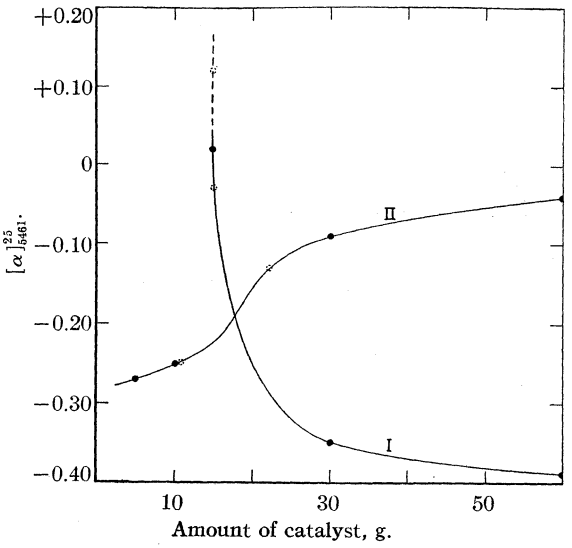

Fig. 1.—Curve I, data from Expts. 12, 8, 9; Curve II, data from Expts. 18, 24, 13, 21. Broken circles plot the specificity only found in Expts. 17, 6 (curve I) and Expts. 20, 22 (curve II), indicative of relative amount of effective catalyst present.

In an attempt to see whether actual concentrations rather than relative concentrations of the reactants were important, all concentrations (and amounts of catalyst) were halved (Expts. 9 and 11) without affecting the specificity appreciably. In all the experiments the ratio of catalyst to reactants increases during the reaction, and the ratio of reactants to each other changes; we are here concerned only with the integrated effect as measured.

A tentative explanation of the effect described in Fig. 1 is as follows. Consider two processes leading to dextro and levo products, P_d and P_l, respectively.

$$\text{Catalyst} + \beta\text{-methylcinnamate} \rightleftarrows C_1 \xrightarrow{\text{glucose}} P_d \quad \text{(A)}$$

$$\text{Catalyst} + \text{glucose} \rightleftarrows C_2 \xrightarrow{\beta\text{-methylcinnamate}} P_l \quad \text{(B)}$$

where C_1 and C_2 are reversibly adsorbed molecules. The ratio of the two products will depend upon the equilibrium or steady state values of C_1 and C_2 and the specific rates of the follow reactions. If the two adsorption processes are of such different rates compared to each other or to the rates of the respective follow reactions that the times required for the achievement of equilibrium or steady state values of C_1 and C_2 differ, then the time required for the over-all reaction becomes important. This is so because if the reaction time is short (large amount of catalyst) the reaction could be complete before the steady states are reached; but if the reaction time is long (small amounts of catalyst) both steady states could be established, leading to a different proportion of the two processes. A seeming independence of the specificity with amount of catalyst at high and low amounts displayed in Fig. 1 could be explained on this basis. The data cannot be used to make a rigid test of this hypothesis, partly because of the factor[3] mentioned above which obscures many effects such as induction periods and absolute rates of reaction, but there are some confirming facts yet to be mentioned. The two curves of Fig. 1, on this basis, suggest that the catalyst will differ in its relative rates of adsorption for the two reactants depending upon the mode of preparation. Thus the "hot" catalyst will be considered provisionally to adsorb glucose the more rapidly (process B) while the "cold" catalyst adsorbs cinnamate the more rapidly. There is no evidence that the "cold" catalyst produces a dextro product (process A) and it may lead only to a levo product when used in small amount and to a racemic product in large amount. On the other hand, the "hot" catalyst apparently participates in both processes.

Time of Catalyst Digestion.—In two series, Expts. 6, 7, 8, and Expts. 17, 28, 15, the nickel alloy was digested for periods of two, four, and seven hours. Concentrations of reactants differed in the two series but were constant within each series. In both cases the negative specific rotations of the products decrease linearly with the digestion time; in the second series this decrease actually results in a positive specific rotation (Expt. 17). This result can be correlated with the facts of the previous section through the simple assumption that continued digestion results in a sintering process that in effect reduces the amount of the catalyst. The destruction of the catalyst may be estimated, for Expts. 6 and 7, from Fig. 1, as amounting to about 50% and 30%, respectively.

Order of Mixing.—In two pairs of identical experiments the order of addition of the glucose and nickel was reversed. In one pair, Expts. 8 and 20, the addition of the sugar last produced a faster reaction and lower specificity in the reaction; in the other pair, Expts. 6 and 22, that order produced a slightly faster reaction but higher specificity (see Fig. 1). In fact, the changes in

specificity were identical in degree, 0.22°, but different in sign.

This behavior may be explained by assuming that the "hot" catalyst, through prior exposure to the β-methylcinnamate, subsequently behaves as would a catalyst which adsorbs that reagent the faster, *i. e.*, a "cold" catalyst. Accordingly in Fig. 1 the specific activities of the products obtained from Expts. 20 and 22 are plotted on Curve II, Fig. 1, and from this the apparent amounts of catalyst present may be read from the plot as 22 g. and 11 g., respectively. As a two-hour "hot" catalyst, the former was 30 g. (Curve I, Fig. 1), or an apparent decrease of 27% effected through change in order of addition of reagents. The latter (Expt. 22) as a seven-hour "hot" catalyst was estimated in the previous section to correspond to only 15.5 g. of two-hour "hot" catalyst, and through the same change in order has decreased 29% (15.5 g. to 11 g.).

Further evidence of the essential identity, aside from effective amount, of the two-hour and seven-hour catalysts, is to be found in the two pairs of experiments, Expts. 8, 15 and 6, 17. In each pair ratios of reactants and catalysts have been similarly changed, in one case with a change in specificity of +0.16° and in the other of +0.15°. This change has been produced by a decrease in the relative glucose concentration and an increase in the dilution (compare the identity of results in Expts. 9, 11), and is in the direction to be expected by a retardation in the rate of adsorption of glucose. A similar effect of decreasing initial glucose concentration is found in Expts. 11, 14.

Effect of Temperature.—Expts. 13 and 23 were identical except for the reaction temperatures, which were 25 and 0°, respectively. The observed decrease in specificity with lower temperature would be expected on the above considerations, because for this catalyst cinnamate is adsorbed the more rapidly, implying that glucose adsorption has a higher activation energy and therefore cinnamate adsorption would be even more highly favored at the lower temperature.

Effect of Platinum Oxide Catalyst.—The use of Adams platinum oxide as catalyst, instead of Raney nickel, results in evolution of some hydrogen gas (dehydrogenation of the sugar) and production of an acid, but virtually no reduction of the cinnamate ion. Different amounts of catalyst were used in two experiments; the order of addition was the same as in Part A, Table I.

Reduction by Means of Monohydric Secondary Alcohols.—*d*-Hexanol-2 and *l*-menthol in the presence of alkali and Raney nickel reduced the unsaturated acid as readily as did glucose, but the reduction product was completely racemic. The catalyst used was digested for seventy-two hours at 20° and was not varied in amount. The reaction time was of the same order as in the case of glucose. With menthol, the solvent used was 65% dioxane in water.

It is possible that any one or all of the alcohol groups in glucose are responsible for the reduction of the β-methylcinnamate ion; in fact, it seems plausible that oxidation of the glucose proceeds first to the osone and then, through an internal Cannizzaro reaction, to gluconate ion. We have ascertained by trial that this last step is rapid compared to the rate of the β-methylcinnamate reduction.

All of the experiments performed under carefully controlled conditions are reported. In addition to these, trials using galactose and lactose were made under conditions which with glucose gave a large negative rotation. These sugars gave products with small positive rotations.

Comparison with Enzyme Reactions.—It should be noted that similar variations in enzyme stereo-specificity have been observed in which the same variables of amount of enzyme, order of mixing, etc., have influenced the optical activity of the product of the enzyme reaction even to an inversion of sign. These studies can only be referred to.[4]

Experimental Part

Materials.—The preparation of β-methylcinnamic acid has been described.[5] The potassium hydroxide solution and water used for dilution were carbonate-free. The *d*-glucose was Baker C. P. analyzed material. For the *d*-hexanol we are indebted to Mr. J. K. Holmes. It was resolved by Pickard and Kenyon's method[6] and had a rotation $[\alpha]^{18}D$ +11.68° (homogeneous). *l*-Menthol from McKesson and Robbins, $[\alpha]^{23}_{5461}$ −58.9° (95% alcohol), was used.

The preparation of Raney nickel was carried out in two ways. The desired amount of 20% sodium hydroxide was

placed in a round-bottomed flask and then at room temperature the 50% nickel–50% aluminum alloy was added as rapidly as foaming permitted (one-half to one hour). The alloy was weighed to yield a given amount of nickel upon the assumption of complete removal of the 50% of aluminum. Actually it was found that the aluminum is not completely removed. After completing the addition of the alloy to the alkaline solution, the flask was placed in a glycerol-bath and heated at 115–120° for the desired time interval, after which it was cooled and the nickel washed by decantation an additional five times after the washings first became neutral to litmus. The second procedure differed in that the alloy was added while cooling the alkali in an ice-bath. The flask was then closed with a Bunsen valve and allowed to stand at room temperature for seventy-two hours with occasional shaking. The catalyst was always prepared just prior to use.

Procedure.—The weighed sample of β-methylcinnamic acid was placed in a volumetric flask and known amounts of potassium hydroxide solution added. When the thermostat temperature was reached, the glucose and catalyst, in either order, were added and the flask filled to the mark and shaken. Zero time was taken when the fourth component was added. The reaction mixture was transferred to a specially designed flask to permit vigorous continuous shaking in the thermostat, with provision for sweeping out the air with pure nitrogen and the taking of periodic samples for titration for alkali concentration. The initial alkali concentration was calculated from the amount of acid and base added; completion and rate of the reaction were indicated by the alkali used up.

After completion of the reaction the nickel was filtered off and discarded and the filtrate acidified and extracted with benzene. The benzene layer, after water washing, was filtered through filter paper moistened with benzene, evaporated to constant weight and the residue taken up in 25 ml. of dry benzene for polarimetric observation and titration. To remove any unreduced β-methylcinnamic acid, the benzene solution was extracted by 50 ml. of 0.5 *N* sodium hydroxide and the alkaline extract neutralized to phenolphthalein. Known amounts of 0.020 *M* potassium permanganate were then added until a small addition gave a color persisting for fifteen minutes; 10 ml. of 1 *N* sodium hydroxide was then added and a benzene extraction made to remove any acetophenone; after this the solution was acidified and the reduced acid recovered as before. In all but three experiments the unreduced acid present, as shown by the permanganate reaction, amounted to less than 0.3%. In these cases the following amounts were present: Expt. 12, 28%; Expt. 17, 15%; Expt. 18, 17%. The rotations reported are for the permanganate-treated acid, although in most cases the activity of the treated and untreated samples was identical within experimental error. Vacuum distillation of one sample did not change the rotation; vacuum distillation of 35 g. of accumulated samples resulted in a product which crystallized on standing, b. p. (10 mm.) 150–156°, uncorr.; yield 34 g.

Summary

The reduction of β-methylcinnamate ion by *d*-glucose in alkaline solution, catalyzed by Raney nickel, has been studied with variations in amount of catalyst, temperature, order of mixing, method of preparation of the catalyst, and relative concentrations of solutes. The optical activity in benzene of the resulting β-phenylbutyric acid varied from $[\alpha]_{5461}$ +0.31° to −0.42°, corresponding to about 0.5% asymmetric synthesis. The specificity changed with each variable and a tentative explanation of all of the variations has been presented based upon a simple hypothesis of relative rates of adsorption. Attention is called to the analogous behavior of enzyme catalyzed reactions.

The Redistribution Reaction. IV. Interchange between Triethyllead Chloride and Radioactive Tetraethyllead

BY GEORGE CALINGAERT, HAROLD A. BEATTY AND LEWIS HESS

In the preceding papers of this series[1] it was shown that R_4Pb compounds in general undergo the redistribution reaction in which the intermolecular interchange of R groups leads to the formation of random equilibrium mixtures. Among the effective catalysts for this reaction are the R_3PbX salts, where X is Cl, Br, or I. It is obviously of interest to determine whether these R_3PbX salts also enter directly into this reaction, and whether both the R and X groups are capable of being interchanged with each other. In the first paper of this series it was indicated that such is the case; the present paper gives the experimental details of the study of the simplest possible reaction of this type, that between R_4Pb and R_3PbX, where all the R groups are identical and no new compounds can be formed; a subsequent paper will describe the more general examples wherein compounds containing different R groups are used.

(1) Calingaert and Beatty, THIS JOURNAL, **61**, 2748 (1939); Calingaert, Beatty and Neal, *ibid.*, 2755; Calingaert and Soroos, *ibid.*, 2758.

Study of the present reaction is possible only by the use of some special "tracer" method such as that of radioactive indicators. In the present work, the "tracer" used was lead containing radium D. The β radiation of radium D is so weak that it is desirable to measure instead only the β radiation of its first disintegration product, the bismuth isotope, radium E. The amount of radium E originally present is largely separated from the lead in the course of the chemical reactions used here, but its half-life is short compared with that of radium D. As a result, starting with a preparation containing radium D and no radium E, the concentration of the latter will be within 0.5% of its maximum value after thirty-five days, and will remain so for sixty-five days thereafter.

Procedure.—A solution was made containing equimolecular proportions of radioactive tetraethyllead and inert triethyllead chloride, and was kept at room temperature. Samples were removed at intervals of time from two hours to seven days, and the tetraethyllead and the triethyllead chloride were separated and converted individually to lead sulfate. After the build-up of radium E in each sample was substantially completed, measurements of radioactivity were made.

The data for two duplicate runs given in Table I show that the random distribution of the chlorine atoms between the two lead compounds present takes place rapidly and reaches equilibrium in less than twenty-four hours. Both tetraethyllead and triethyllead chloride are relatively stable compounds under the conditions used, and it is accordingly somewhat surprising to find so rapid an interchange of the chlorine atoms and ethyl radicals.

TABLE I

RADIOACTIVITY OF Et_4Pb AND Et_3PbCl

	Radioactivity, counts per minute			
	Expt. 1		Expt. 2	
Time, hr.	Et_4Pb	Et_3PbCl	Et_4Pb	Et_3PbCl

24	1704	1684	1922	1838
72	1659	1669		
96			1887	1808
168	1673	1679	1887	1703

Experimental.—Lead sulfate which contained about 2×10^{-8} g. of radium D sulfate per g. was reduced to metallic lead by smelting with metallic iron and coke, and this lead was used to prepare the sodium–lead alloy, NaPb, from which radioactive tetraethyllead was synthesized.[2]

To carry out the redistribution reaction, 0.082 mole each of radioactive tetraethyllead and ordinary triethyllead chloride[3] were placed in a small flask under nitrogen, and diluted with sufficient benzene, 77 ml., to dissolve the salt. The solution was maintained at room temperature for one week, with occasional shaking. The reversible side reaction[4] of triethyllead chloride in accordance with the equation $2Et_3PbCl \rightleftarrows Et_2PbCl_2 + Et_4Pb$ was effectively minimized by the low temperature employed, together with the high ratio of ethyl radicals to chlorine. This was evidenced by the very slight precipitation of the nearly insoluble diethyllead dichloride.

Samples were removed for analysis after periods of two hours, and one, three, and seven days, and were treated as follows: most of the benzene was removed by vacuum evaporation at room temperature, 25 ml. of hexane was added to precipitate the triethyllead chloride, the mixture was filtered, and the residue was washed with three 10-ml. portions of hexane, adding the washings to the filtrate. The filtrate and residue were brominated separately with an excess of a solution of bromine in carbon tetrachloride, and the resulting bromides were dissolved in nitric acid and converted to sulfates, which were filtered, washed, dried, and later were measured for radioactivity. The experiment was performed in duplicate.

Measurement of Radioactivity.—The counting system consisted of a scale-of-one counting circuit excited by a Geiger-Müller tube, as described by Duffendack and coworkers.[5] The tube had a background count of less than 20 per minute. Each sample was measured once only, from thirty-two to forty days after its preparation. Each measurement covered a period of twenty minutes, during which the counter was switched off by a time switch for twelve seconds out of each minute, to provide leisure time for recording the count.

The procedure in general was designed to avoid errors from extraneous sources. However, the counts obtained from a considerable number of presumably identical samples showed variations substantially larger than expected, the reason for which was not evident. Such variations also appear in the data in Table I, but do not affect the general conclusions derived from the experiments.

Acknowledgments.—We are indebted to M. Marcel Pochon of Eldorado Gold Mines, Ltd., for a supply of radioactive lead sulfate, to Dr. Oscar E. Harder of the Battelle Memorial Institute for the smelting of this lead sulfate, and to Professor O. S. Duffendack and Dr. Harold Lifschutz of the University of Michigan for advice and assistance in the measurement of radioactivity.

Summary

Using radium D as an indicator, it is shown that an interchange of chlorine atoms and ethyl radicals between tetraethyllead and triethyllead chloride takes place, and reaches equilibrium in less than one day at room temperature.

Solubilities of Sodium and Potassium Salts of Nitrophenols and Related Acids[1]

BY O. C. DERMER AND V. H. DERMER

Aqueous solubilities of salts of 2-chloro-3-nitrotoluene-5-sulfonic acid and some similar acids already have been determined in a search for a better precipitant for potassium.[2] The present paper reports results of a like study of salts of a variety of other organic acids, chosen because their potassium salts were either known or hoped to be slightly soluble.

Experimental

Synthesis of Salts.—Picric acid, 2,4,6-trinitro-*m*-cresol (methylpicric acid), picrolonic acid, 5-nitrobarbituric acid, and 2,4-dinitronaphthol-7-sulfonic acid were Eastman Kodak Co. products. Styphnic acid, dipicrylamine, N,2,-4,6-tetranitroaniline, 3-chloro-2,4,6-trinitrophenol (chloropicric acid), 2,3,4,6-tetranitrophenol, and nitranilic acid were made by nitrating resorcinol, 2,4-dinitrodiphenylamine,[3] picramide,[4] *m*-chlorophenol,[5] *m*-nitrophenol,[6] and diacetylhydroquinone,[7] respectively. 1-Phenylbarbituric acid was prepared by condensing malonic acid with phenylurea[8] and was nitrated according to the directions given in "Organic Syntheses" for 5-nitrobarbituric acid.[9] Efforts to prepare pure 1,5-dinitronaphthol-7-sulfonic acid derivatives by nitrating sodium 2-naphthol-7-sulfonate according to the meager directions of Volochneva[10] were abandoned after several failures. 2-Chloro-1,4-dimethyl-3-nitrobenzene-5-sulfonic acid (2-chloro-3-nitro-*p*-xylene-5-sulfonic acid) was prepared from *p*-xylene by the general method described in the first paper of this series;[2] most of the steps were also those employed by Wahl.[11] The successive intermediate stages were 2-chloro-1,4-dimethylbenzene, 2-chloro-1,4-dimethylbenzene-5-sulfonic acid, the corresponding sulfonyl chloride (m. p. 47°, Wahl gave 50°), and 2-chloro-1,4-dimethyl-3-nitrobenzene-5-sulfonyl chloride. 2-Chloro-3-nitrotoluene-5-arsonic acid was synthesized by arsonating *o*-toluidine,[12] introducing a chlorine atom by the Sandmeyer reaction, and nitrating the product.

The salts were made by neutralizing the acid with the calculated amount of the appropriate alkali and recrystallizing the product repeatedly from alcohol or water. The di-metal salts of flavianic acid had to be recrystallized from dilute alkali to prevent hydrolysis, and those containing only one metallic atom per molecule could not be obtained pure. This verifies the statement of Clark and Willits[13] that the dipotassium salt is the one precipitated, but casts some doubt on Volochneva's[10] report that monopotassium 1,5-dinitronaphthol-7-sulfonate is the stable form.

Salts of N,2,4,6-tetranitroaniline, 2,3,4,6-tetranitrophenol, 2-chloro-3-nitrotoluene-5-arsonic acid, and 1-phenyl-5-nitrobarbituric acid were not investigated further after qualitative tests showed their potassium salts to be too soluble to precipitate readily. The others were dried at 105° in a vacuum oven, to reduce the danger of an explosion.[14]

Analysis and Determination of Solubility.—The purity of each salt was tested and the solubility determined by the methods previously used.[2]

Discussion of Results

Table I shows the results of our experimental work. The only reagents in this group useful as potassium precipitants have already been suggested for that purpose: dilituric acid[15] and especially dipicrylamine.[16] Little relation can be traced between structure and solubility of salts; dilituric acid is useful, but the addition of a phenyl group destroys its value. The substitution of a methyl group in the 5-position on the ring in 4-chloro-3-nitrobenzenesulfonic acid makes the potassium salt far less soluble,[2] but addition of another methyl group to the ring yields 2-chloro-1,4-dimethyl-3-nitrobenzene-5-sulfonic acid, which is worthless as a potassium precipitant. The same ruinous effect of a methyl group, or indeed of any group at all in this case, is seen among relatives of picric acid, including also 3,3′-azo-*bis*picric acid (3,3′-dihydroxy-2,4,6,2′,4′,6′-hexanitroazobenzene).[17] It is improbable, therefore, that substituted dipicrylamines would exceed or even equal the parent compound in usefulness.

Summary

The sodium and potassium salts of ten possible potassium precipitants, mostly nitrophenols, have been synthesized and their solubilities at 30°

[a] Average of two values with a mean deviation of 0.3%. [b] Average of two or three values with a mean deviation of 1.4%. [c] Dibasic. [d] Monohydrate. [e] Perhaps the best literature value is given by Fischer, *Z. physik. Chem.*, **92**, 581 (1918), as 4.30 at 25°. [f] Fischer gives 0.645 at 25°. [g] There is disagreement on the names for salts of dipicrylamine; this one is sometimes called "potassium dipicrylaminate." We prefer the name "potassium dipicrylamide" as best indicating the structure of a substituted potassium amide. [h] Kielland, *Ber.*, **71**, 220 (1938), gives the solubility as 0.0025 molar at 25°, which is equivalent to 0.12 g./100 g. H_2O. Kolthoff and Bendix (ref. 16) give the value 0.088 for the same temperature. [i] Fredholm (ref. 15) gives the value as 0.049 molar at 18°. [j] Fredholm gives 0.0022 molar at 18°.

determined. The most sensitive reagents in the group were dipicrylamine and dilituric acid. Introduction of additional groups into the molecules of such potassium reagents as picric acid, dilituric acid, and 2-chloro-3-nitrotoluene-5-sulfonic acid is more likely to decrease than to increase their value.

STILLWATER, OKLAHOMA RECEIVED JULY 20, 1939

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

Hydrogenation of 1,3-Diketones to Ketols

BY PAUL S. STUTSMAN AND HOMER ADKINS

Sprague[1] obtained the ketol $(CH_3)_3CC(O)CH_2CHOHCH_3$ in 68% yield by the hydrogenation of $(CH_3)_3CC(O)CH_2C(O)CH_3$. This rather unexpected result was no doubt due to the relative resistance to hydrogenation of a carbonyl group adjacent to a tertiary butyl group. The study reported herewith was directed toward finding conditions under which other ketols, less resistant to hydrogenation, could be obtained by the partial hydrogenation of the corresponding 1,3-diketones.

Eight diketones, in which R was methyl, ethyl, a propyl or a butyl radical in compounds of the formula $RCOCH_2COCH_3$, were prepared and subjected to hydrogenation over Raney nickel under various conditions in attempting to obtain the optimum yield of the various ketols.

Hydrogenation at 100° over Raney nickel of the diketones dissolved in methanol gave in general the highest yield of ketols. The yields of ketol were where R was methyl 35%, ethyl 51%, *n*-propyl 58%, isopropyl 50%, *n*-butyl 66%, isobutyl 49%, *s*-butyl 64%. Hydrogenation of the diketone dissolved in ether, dioxane or ethanol gave in several cases lower yields, though this difference may have been due more to differences in the losses during isolation rather than to the effect of the solvent upon the rate or course of hydrogenation. The differences between solvents were in most cases negligible, as for example where R was *t*-butyl the yields of the ketol were 66, 68 and 70% in methanol, ether and ethanol, respectively. The 68% yield in ether confirms the yield reported by Sprague referred to above.

The most important consideration, for a given diketone, in determining the yield of ketol is the amount of hydrogen which is absorbed before the reaction is stopped. In order to obtain the yields given above, the shaking of the reaction vessel was stopped after 0.9 to 1.0 mole of hydrogen per

(1) Sprague and Adkins, THIS JOURNAL, **56**, 2669 (1934).

mole of diketone had been absorbed. Since the hydrogenation proceeds rapidly it is not always easy to stop the reaction when the proper amount of hydrogen has been taken up.

Improved yields have been obtained by making use of the technique recently described for the partial hydrogenation of phenanthrene.[2] In this procedure the hydrogenation is carried out under nitrogen with a limited amount of hydrogen. The diketone, methanol and catalyst were placed in the reaction vessel and nitrogen added to a pressure of about 100 atmospheres. One mole of hydrogen per mole of diketone was then added. The mixture was then shaken at 100° until the pressure was constant. The pressure of nitrogen kept the contents of the bomb in the liquid phase even after all the hydrogen had reacted. This procedure enables exactly the proper amount of hydrogen to be added to the diketone and in the three cases in which it was tried raised the yields by 4, 20 and 17%, respectively. The method was tried where R was methyl, *i*-butyl and *s*-butyl. The hydrogenations required about one hundred and ten minutes due to the low pressure of hydrogen, as compared with about twenty minutes under 125 atmospheres of hydrogen.

Hydrogen did not react at the carbonyl next to R until the carbonyl next to the methyl group had been hydrogenated, as the ketols obtained were in each case methylcarbinols, *i. e.*, $RCOCH_2CHOHCH_3$. The structure of the ketols was ascertained by dehydrating each one over oxalic acid[3] to the corresponding unsaturated ketone $RCOCH{=}CHCH_3$, which was then hydrogenated to $RCOCH_2CH_2CH_3$. Solid derivatives of the ketone so prepared were compared by mixed melting points with derivatives of a sample of a ketone of known structure.

The 2,4-dinitrophenylhydrazones of the unsaturated ketones were prepared in six cases. The same derivative was obtained from the ketol as from the unsaturated ketone since the ketol is dehydrated during the process of forming the hydrazone.

The hydrogenation of 1,3-diketones may be continued beyond the ketol stage to give good yields of the glycols of the type $RCHOHCH_2CHOHCH_3$.[1] Glycols where R is ethyl, *n*-propyl, *n*-butyl or *s*-butyl have been prepared for the first time in yields of 92, 94, 94 and 80%, respectively. These hydrogenations were made at 100 to 125° during the course of one and a half to three hours under approximately 100 atm. of hydrogen over 4 g. of Raney nickel. Approximately 25 g. of the diketone was dissolved in 80 ml. of dry methanol and the glycols obtained by fractionation after hydrogenation.

Sprague noted that the hydrogenation of certain 1,3-diketones resulted in the cleavage of the chain with the formation of ketones and aldehydes, *i. e.*

$$t\text{-BuCOCH}_2\cdots\text{COCH}_3 \xrightarrow{H_2} t\text{-BuCOCH}_3 + \text{CH}_3\text{CHO}$$

The splitting was ascribed to cleavage by hydrogen of the carbon to carbon linkage indicated by the dots in the formula. It seemed possible that hydrogenation of the carbonyl group, rather than hydrogenolysis of the carbon to carbon linkage, might have taken place to give a ketol, which might then undergo disproportionation to give the ketone and aldehyde, *i. e.*

$$t\text{-BuCOCH}_2\text{CHOHCH}_3 \longrightarrow t\text{-BuCOCH}_3 + \text{CH}_3\text{CHO}$$

The disproportionation might have occurred in the reaction vessel under the conditions of hydrogenation or during the separation and purification of the products. To test this hypothesis the ketol indicated just above was heated in ether solution at 60° in the bomb in the presence of Raney nickel for twelve hours. No disproportion products were formed and the ketol was recovered unchanged. Since alkali would tend to facilitate disproportionation during the process of working up the reaction products after a hydrogenation, Sprague's procedure was modified in that potassium carbonate was not used for drying the solution of the products before fractionation. Ethylbenzoylacetylmethane, $C_6H_5CO\cdots CH(Et)COCH_3$, was subjected to hydrogenation as by Sprague but the products were isolated without drying them over potassium carbonate. The results showed a 27% cleavage at the linkage indicated by dots in the formula. Ethylbenzoylacetylmethane was used in this experiment in preference to $t\text{-BuCOCH}_2\text{COCH}_3$ because the former undergoes cleavage to a greater extent according to Sprague's results.

There is therefore no evidence that the cleavage observed by Sprague was due to disproportionation of a ketol, but rather it may be regarded as dependent upon hydrogenolysis of the diketone.

The 1,3-diketones were made by condensing ethyl acetate with the proper ketone using sodium

(3) Pastreau and Zamenhof, *Compt. rend.*, **182**, 323 (1926).

ethoxide as the condensing agent. The procedure was essentially that previously described and labeled "B."[4] Methyl *i*-propyl[5] and methyl *t*-butyl ketones[6] were made by the methods described in "Organic Syntheses." Methyl ketones containing *n*-propyl, *n*-butyl and *s*-butyl groups were made through the use of acetoacetic ester, the hydrolysis being made as given in "Organic Syntheses."[7] The other monoketones used were commercial products.

Hydrogenations were carried out in various reaction vessels but all those reported herewith were made in a steel bomb having a void of 270 ml. The general procedure was as follows. The diketone (0.15 to 0.35 mole) dissolved in 40 to 80 ml. of dry methanol was placed in the reaction vessel with 3 to 5 g. of Raney nickel. Hydrogenation under a pressure of 100 to 200 atmospheres was allowed to proceed at 100° until one mole of hydrogen per mole of diketone had been absorbed. The time of reaction was in general from five to thirty minutes. The reaction vessel was then cooled to room temperature, the excess hydrogen released, the vessel opened and the reaction mixture and washings filtered. The solvent was then distilled through a fractionating column at atmospheric pressure and the products separated by fractional distillation at a convenient pressure. Both a Widmer and a modified Widmer column were used.[8] The modified Widmer containing a spiral 15 cm. in length with 12 turns of the helix was preferable. Since all the yields reported were isolated by fractionation they represent minimum rather than maximum values. In particular the mechanical losses in the case of the viscous glycols were relatively large.

The ketols (10 to 20 g.) were dehydrated to the unsaturated ketones by slow distillation through the modified Widmer column from a flask containing 0.3 to 0.6 g. of oxalic acid. The water layer in the distillate was discarded, the ketone dried over sodium sulfate and fractionated through the modified Widmer column. The yields were 70 to 90% of the theoretical quantity. The unsaturated ketone (4 to 9 g.) was then hydrogenated over Raney nickel at 30–40° under 100 atm. of hydrogen in a small steel reaction vessel.[9]

The 2,4-dinitrophenylhydrazones of the ketones and ketols were made by the method of Allen[10] or Brady.[11] When R was ethyl, *n*-propyl, *i*-propyl, *n*-butyl, *i*-butyl or *t*-butyl the ketol gave the same derivative as the corresponding unsaturated ketone. The bisphenylurethans of the glycols were prepared as by Tessmer.[12]

The colors of the 2,4-dinitrophenylhydrazones of ketones, after recrystallization from the indicated solvent were as follows: hexene-4-one-3 and heptene-2-one-4, red needles from dry ethanol; 2-methylhexene-4-one-3, orange needles from methanol; octene-2-one-4, orange needles from 95% alcohol; 6-methylheptene-2-one-4, red plates from 95% alcohol; and 2,2-dimethylhexene-4-one-3, yellow needles from a methanol–water mixture. The melting points and analytical data for these and other derivatives are given in Table I.

TABLE I

MELTING POINTS AND ANALYSES OF VARIOUS DERIVATIVES

Compound	M. p., °C.	Nitrogen, % Calcd.	Found
Hexene-4-one-3[a]	164–165	20.14	20.40
Heptene-2-one-4[a]	142–143	19.18	19.29

Summary

Ketols of the type $RCOCH_2CHOHCH_3$ have been prepared in yields averaging above 50% by the hydrogenation over Raney nickel of 1,3-diketones where R is a methyl, ethyl, a propyl or a butyl group. In order to obtain good yields of the ketols it is necessary to interrupt the hydrogenation after the absorption of one mole of hydrogen per mole of ketone. This is most satisfactorily accomplished by having in the reaction vessel no more than the required amount of hydrogen, and adding a sufficient amount of nitrogen to obtain the desired pressure. All of the eight ketols obtained were methylcarbinols, showing that hydrogenation proceeds to completion at the acetyl group before it begins at propionyl, butyryl or valeryl groups.

Evidence is presented that the cleavage of diketones previously reported is really a hydrogenolysis and not a disproportionation of a ketol subsequent to hydrogenation.

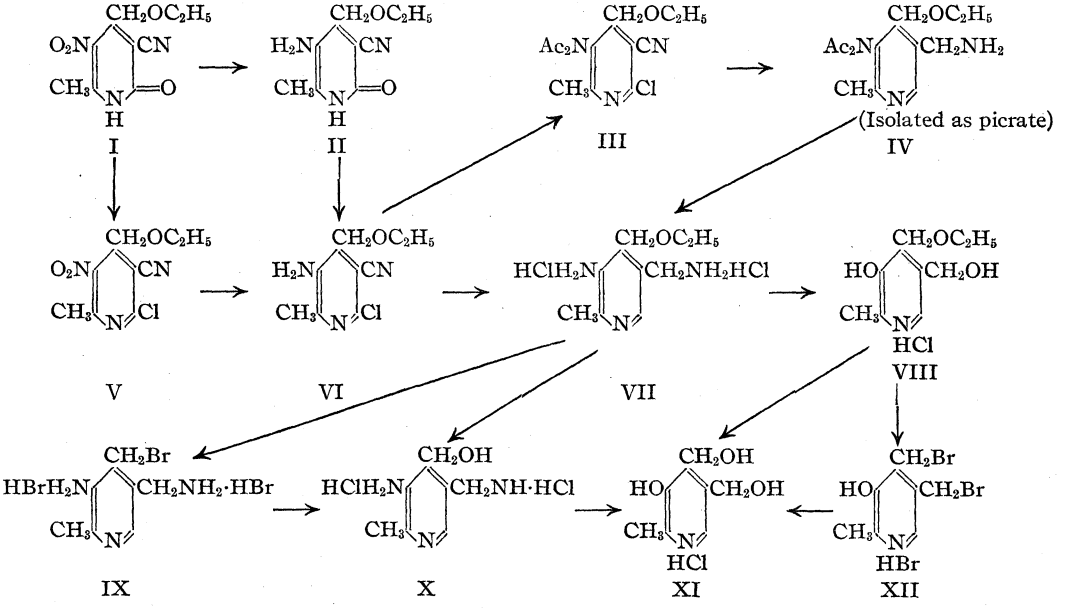
Synthesis of Vitamin B_6. II[1]

BY STANTON A. HARRIS AND KARL FOLKERS

In a previous article[2] a complete synthesis of vitamin B_6 was described. The present paper describes some variations and improvements in this synthesis, along with new derivatives of some of the intermediate compounds. These variations are shown in the set of reactions, I–XII.

The original synthesis is represented by the reactions I → V → VI → VII → VIII → XII → XI. The nitropyridone, I, was prepared by the nitration of 3-cyano-4-ethoxymethyl-6-methyl-2-pyridone, which in turn was prepared by the condensation of ethoxyacetylacetone and cyanacetamide.

The ethoxy-diamine, VII, is the key compound in all these syntheses. This compound was prepared by two new variations of these reactions: I → II → VI → VII and I → II → VI → III → IV → VII. These variations are limited by the low yield in reaction II → VI. Compounds III and IV are not essential to the success of the synthesis of the ethoxy-diamine, VII.



Acetylation of the aminopyridone, II, and the chloroaminopyridine, VI, gave a mono and a diacetate in each case. The question of the position of the second acetyl group in the diacetate of the aminopyridone, II, was settled only by analogy. Since the chloro-aminopyridine, VI, also formed a diacetate and the original pyridone, namely, 3-cyano-4-ethoxymethyl-6-methyl-2-pyridone, did not form an acetate when boiled with acetic anhydride, it was deduced that the diacetate of II had both acetyl radicals attached to the amino group.

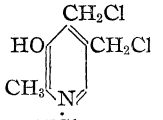
The important variations in the synthesis start with the ethoxy-diamine, VII. The first variation is represented by the reactions VII → VIII → XI. It was found that the ethoxy group of VIII could be split with dilute hydrochloric acid in a bomb tube reaction at 150°. This reaction eliminated the use of constant boiling hydrobromic acid and the necessity for the subsequent hydrolysis of the intermediate dibromide, XII. A second variation is shown by the steps VII → IX → X → XI. These steps also were shortened by another bomb tube reaction to give the third and most practical series of reactions, VII → X → XI. The hydroxy-diamine, X, was more easily isolated and recrystallized than was the 4-ethoxymethyl derivative, VIII, of vitamin B_6.

The 4-ethoxymethyl derivative, VIII, also was deëthylated with concentrated hydrochloric acid

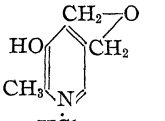
(1) The material in this paper was presented to the Organic Division of the American Chemical Society at Boston, Mass., on September 11, 1939.

(2) Harris and Folkers, THIS JOURNAL, 61, 1245 (1939).

in a bomb tube at 132° to form 2-methyl-3-hydroxy-4,5-*bis*-(chloromethyl)-pyridine hydrochloride, XIII, which was, in turn, hydrolyzed to vitamin B_6 hydrochloride, XI.



XIII



XIV

In the original synthesis,[2] vitamin B_6 hydrochloride, XI, was obtained by hydrolyzing the dibromide, XII, with hot water and removing the bromide ions with silver chloride. On recrystallizing the product from alcohol, a by-product was found in the mother liquors which proved to be an inner ether of the vitamin. This ether, 2-methyl-3-hydroxy-4,5-(epoxydimethyl)-pyridine hydrochloride, XIV, was also obtained by treating both vitamin B_6, XI, and its ethyl ether, VIII, with 50% sulfuric acid. Unlike the ethyl ether, VIII, this new ether was stable toward hydrolysis with dilute hydrochloric acid at 175°. However, it was reconverted to the dibromide, XII, by boiling with 48% hydrobromic acid, which can, in turn, be converted to vitamin B_6 hydrochloride, XI.

Experimental Part

Reduction of 3-Cyano-4-ethoxymethyl-5-nitro-6-methyl-2-pyridone, I.—The reduction was carried out with hydrogen in the presence of Adams catalyst, both in ethyl alcohol and acetic acid. From 22.5 g. of I, the yield of 3-cyano-4-ethoxymethyl-5-amino-6-methyl-2-pyridone, II, was 12.5 g. (63.6%); m. p. 250–255° with decomposition after recrystallization from ethyl alcohol.

Anal. Calcd. for $C_{10}H_{15}N_3O_2$: C, 57.96; H, 6.32; N, 20.28. Found: C, 58.15; H, 6.19; N, 20.67, 20.61.

The reduction of the nitropyridone, I, also was carried out in acetic anhydride and yielded the monoacetate of II. From 23.5 g. of I, dissolved in 200 cc. of acetic anhydride, the yield of 3-cyano-4-ethoxymethyl-5-acetylamino-6-methyl-2-pyridone was 13.3 g. (53.4%); m. p. 260° after recrystallization. An additional 8–9 g. of crude material was obtained from the mother liquor. It was difficultly soluble in acetic anhydride and ethyl alcohol, from which latter it was recrystallized.

Anal. Calcd. for $C_{12}H_{15}O_3N_3$: C, 57.82; H, 6.07; N, 16.85. Found: C, 57.80; H, 6.11; N, 16.99.

The aminopyridone, II, also was acetylated by boiling in an excess of acetic anhydride. In one experiment a small amount of the monoacetate was obtained in addition to a larger quantity of a more soluble product which proved to be a diacetate. After the removal of the acetic anhydride under reduced pressure the residue was oily but, on standing, it gradually crystallized to a solid mass. After three recrystallizations from ethyl alcohol, the diacetate of 3-cyano-4-ethoxymethyl-5-amino-6-methyl-2-pyridone melted at 176°.

Anal. Calcd. for $C_{14}H_{17}O_4N_3$: N, 14.43; CH_3CO, 29.5. Found: N, 14.6; CH_3CO, 28.92, after refluxing in strong alkali for 25.5 hours.

Chlorination of 3-Cyano-4-ethoxymethyl-5-amino-6-methyl-2-pyridone, II.—Two grams of the aminopyridone, II, was treated with 15–20 cc. of phosphorus oxychloride and 4 g. of phosphorus pentachloride and allowed to stand overnight at 30°. The phosphorus oxychloride was removed under reduced pressure and the residue decomposed with ice water. On neutralization with ammonia, a substance crystallized which, after three recrystallizations from alcohol, melted at 146–147° and showed no depression of melting point with a pure sample of 2-methyl-3-amino-4-ethoxymethyl-5-cyano-6-chloropyridine, VI.[2] The yield of crude material was 0.38 g. (16.5%). A large proportion of unchanged starting material was obtained by extracting the aqueous mother liquor with chloroform.

Acetylation of 2-Methyl-3-amino-4-ethoxymethyl-5-cyano-6-chloropyridine, VI.—Two grams of the chloro-aminopyridine, VI, was dissolved in 10 cc. of warm acetic anhydride and then allowed to crystallize. One gram of starting material was recovered. The acetic anhydride solution was decomposed with cold water from which the acetylation product was extracted with chloroform. After washing the solution with sodium bicarbonate and with water and drying over calcium chloride, the chloroform was evaporated. The residue was recrystallized from alcohol and yielded 2-methyl-3-acetylamino-4-ethoxymethyl-5-cyano-6-chloropyridine; m. p. 134–136°.

Anal. Calcd. for $C_{12}H_{14}O_2N_3Cl$: C, 53.83; H, 5.27; N, 15.70. Found: C, 53.65; H, 5.40; N, 15.90.

In a second experiment, 3.8 g. of the chloro-aminopyridine was acetylated by boiling with 25 cc. of acetic anhydride for thirty minutes. The acetic anhydride was removed by distillation under reduced pressure and the residue was treated with 20 cc. of alcohol and 10 cc. of water. After a few minutes, crystallization took place. The crystals were recrystallized by dissolving them in the least possible amount of alcohol and adding water until the solution was slightly cloudy. The yield was 4.3 g. (82.5%) of 2-methyl-3-diacetylamino-4-ethoxymethyl-5-cyano-6-chloropyridine, III; m. p. 90–92°.

Anal. Calcd. for $C_{14}H_{16}O_3N_3Cl$: C, 54.28; H, 5.20; N, 13.57. Found: C, 53.98; H, 4.92; N, 13.34.

Reduction of 2-Methyl-3-diacetylamino-4-ethoxymethyl-5-cyano-6-chloropyridine, III.—A solution of 100 cc. of glacial acetic acid containing 3.09 g. of the chlorodiacetylaminopyridine, III, and 0.82 g. of sodium acetate was shaken with hydrogen in the presence of 10 g. of palladium charcoal and 0.5 g. of Adams catalyst until three moles of hydrogen had been absorbed. The solution was filtered, concentrated, taken up in absolute alcohol, and filtered from the separated sodium chloride. A solution of 2.5 g. of picric acid in hot alcohol was then added and after several minutes crystallization took place. The product was twice recrystallized from alcohol. The yield of the monopicrate of 2-methyl-3-diacetylamino-4-ethoxymethyl-5-aminomethylpyridine, IV, was 1.85 g. (36.4%); m. p. 190–191°.

Anal. Calcd. for $C_{20}H_{24}N_6O_{10}$: C, 47.24; H, 4.75; N, 16.53. Found: C, 47.04; H, 4.72; N, 16.64.

Deacetylation of 2-Methyl-3-diacetylamino-4-ethoxymethyl-5-aminomethylpyridine, IV.—The picrate of IV was decomposed with hydrochloric acid (1:1) and the picric acid was extracted first with nitrobenzene and finally with ether. An attempt was then made to diazotize the free amino group by the addition of one mole of sodium nitrite. The solution was then hydrolyzed by boiling for one and one-half hours with 15% hydrochloric acid, after which it was concentrated to dryness, taken up in absolute alcohol, and treated with acetone. The only product which was isolated was the dihydrochloride of 2-methyl-3-amino-4-ethoxymethyl-5-aminomethylpyridine, VII; m. p. 193–195°.[2] Dr. J. van de Kamp of this Laboratory reported that drying of this compound at 100° under a vacuum from an oil pump raised the m. p. to 204–205°. Recrystallization of the ethoxy-diamine, VII, from 95% alcohol yielded a monohydrate; m. p. 127–129°.

Anal. Calcd. for $C_{10}H_{21}O_2N_2Cl_2$: C, 41.97; H, 7.39; N, 14.68. Found: C, 42.02; H, 7.41; N, 14.93.

Deëthylation of the Dihydrochloride of 2-Methyl-3-amino-4-ethoxymethyl-5-aminomethylpyridine, VII.—The ethoxydiamine, VII (1.55 g.), was treated in a distillation flask with 20 cc. of boiling 48% hydrobromic acid until about one-half of the acid had been distilled. On cooling and scratching the concentrated solution, crystallization took place. The product was recrystallized by dissolving it in a small amount of water and adding 8–10 volumes of alcohol, which yielded the dihydrobromide of 2-methyl-3-amino-4-bromomethyl-5-aminomethylpyridine, IX; m. p. 260–265° with decomposition.

Anal. Calcd. for $C_8H_{14}N_3Br_3$: C, 24.51; H, 3.60; N, 10.72. Found: C, 24.97, 24.90; H, 3.71, 3.62; N, 10.66.

This bromomethyl-diamine, IX, was heated with hot water and then stirred with silver chloride until the bromide ions were completely removed. The solution was concentrated to dryness under reduced pressure and the residue was recrystallized from 95% alcohol. The product was the dihydrochloride of 2-methyl-3-amino-4-hydroxymethyl-5-aminomethylpyridine, X; m. p. 235–237°.

Anal. Calcd. for $C_8H_{15}N_3OCl_2$: C, 40.01; H, 6.30; N, 17.50. Found: C, 39.81; H, 6.14; N, 17.48.

It was found later that the ethoxy-diamine, VII, could be hydrolyzed directly to the hydroxy-diamine, X. A solution of 2.24 g. of VII in 34 cc. of 2.5 *N* hydrochloric acid was heated in a bomb tube for four hours at 175–180°. The slightly colored solution was filtered with charcoal and concentrated to dryness under reduced pressure. The product was recrystallized from water and alcohol. The yield of the hydroxy-diamine, X, was 1.44 g. (76.7%); m. p. 235–237°. There was no depression of mixed melting point with a sample of X obtained above.

Diazotization of the Dihydrochloride of 2-Methyl-3-amino-4-hydroxymethyl-5-aminomethylpyridine, X, to form Vitamin B_6, XI.—A solution of 1.28 g. of the hydroxy-diamine, X, in 22 cc. of water was added simultaneously with a solution of 2.24 g. of sodium nitrite to 45 cc. of hot (90–95°) 2.5 *N* hydrochloric acid. The yellow solution was concentrated to dryness under reduced pressure and the residue washed with acetone, which removed some of the color. The vitamin hydrochloride was extracted from the sodium chloride with hot absolute alcohol. This solution was filtered with charcoal and concentrated to a small volume. On addition of acetone the vitamin B_6 hydrochloride crystallized; m. p. 208°. The yield was 0.5 g. (45.4%).

Anal. Calcd. for $C_8H_{11}NO_3Cl$: C, 46.72; H, 5.88. Found: C, 46.51; H, 5.70.

Conversion of 2-Methyl-3-hydroxy-4-ethoxymethyl-5-hydroxymethylpyridine, VIII, to Vitamin B_6 Hydrochloride.—This ethyl ether of vitamin B_6, VIII, has now been obtained in a purer form with a slightly higher melting point than was reported in a previous paper.[2] It was most easily purified as the free base in acetone solution by the addition of ether and filtration with charcoal. The nearly colorless solution was then treated with dry hydrogen chloride. The precipitated salt was recrystallized from alcohol by the addition of an equal volume of acetone. Washing with acetone gave colorless crystals of 2-methyl-3-hydroxy-4-ethoxymethyl-5-hydroxymethylpyridine hydrochloride, VIII; m. p. 135–136°.

Anal. Calcd. for $C_{10}H_{16}NO_3Cl$: C, 51.38; H, 6.90; N, 6.00. Found: C, 51.20; H, 6.81; N, 6.25, 6.20.

A solution of 4 g. of the ethyl ether, VIII, in 20 cc. of water and 1 cc. of 2.5 *N* hydrochloric acid was heated in a bomb tube at 155–160° for six hours. The slightly colored solution was treated with charcoal, filtered, and concentrated to dryness under reduced pressure. The yield of slightly yellow crystals was 2.92 g. (83%). After recrystallization from absolute alcohol, with the use of charcoal for decolorization, pure white vitamin B_6 hydrochloride was obtained; m. p. and mixed m. p. 208–209°.

The cleavage of the ethoxy group of VIII also was accomplished by dissolving 0.2 g. of this substance in 6 cc. of concentrated hydrochloric acid and heating in a bomb tube at 132° for one hour. On cooling in ice water, crystals separated and were recrystallized from a little concentrated hydrochloric acid. The yield of 2-methyl-3-hydroxy-4,5-*bis*-(chloromethyl)-pyridine hydrochloride, XIII, was 0.09 g. (45%), m. p. 206° with preliminary darkening around 200°.

Anal. Calcd. for $C_8H_{10}NOCl_3$: C, 39.62; H, 4.16; N, 5.78. Found: C, 39.48; H, 3.98; N, 5.94.

This dichloride, XIII (50 mg.), was converted to vitamin B_6 hydrochloride by heating in 10 cc. of water on the steam-bath for one hour. The water was evaporated and the material recrystallized from alcohol and acetone. The first crop of vitamin B_6 hydrochloride (10 mg.) melted at 202–203° and showed no depression of melting point with a pure specimen of the vitamin.

2-Methyl-3-hydroxy-4,5-(epoxydimethyl)-pyridine Hydrochloride, XIV.—In recrystallizing vitamin B_6 prepared by the hydrolysis of 2-methyl-3-hydroxy-4,5-*bis*-(bromomethyl)-pyridine hydrobromide, XII, a by-product was found in the mother liquors. After the pure vitamin hydrochloride crystallized out, a mixture of substances melting at about 195° was obtained. When acetone was added to the final mother liquor a substance melting above 230° was formed. Recrystallization from alcohol yielded 2-methyl-3-hydroxy-4,5-(epoxydimethyl)-pyridine hydrochloride; m. p. 239–240° with decomposition.

Anal. Calcd. for $C_8H_{10}O_2NCl$: C, 51.21; H, 5.37; N, 7.47. Found: C, 51.13; H, 5.21; N, 7.62.

This epoxy compound, XIV, was obtained in small yields when 1-g. quantities of vitamin B_6, XI, and its ethyl ether, VIII, were treated with 15 cc. of 50% sulfuric acid for one hour on the steam-bath. The sulfuric acid was neutralized with sodium hydroxide, the water was evaporated, and the product was extracted with acetone as the free base. The addition of dry hydrogen chloride gave a product which, after crystallization from alcohol, was identical with the by-product described above.

Cleavage of the Epoxydimethyl Group.—2-Methyl-3-hydroxy-4,5-(epoxydimethyl)-pyridine resisted hydrolysis on heating with 2.5 *N* hydrochloric acid at 175° for four hours. However, the ether group was split when 3.7 g. of the epoxydimethyl derivative, XIV, was distilled with 60 cc. of 48% hydrobromic acid until the volume was reduced to 30 cc. After cooling and filtering, the yield of 2-methyl-3-hydroxy-4,5-*bis*-(bromomethyl)-pyridine hydrobromide, XII, was 6.42 g. (86.5%); m. p. 228.5°. This melting point was 5° higher than previously reported.[2]

Anal. Calcd. for $C_8H_{10}NOBr_3$: C, 25.53; H, 2.66; N, 3.72. Found: C, 25.71; H, 2.89; N, 3.73.

Acknowledgment.—The authors are indebted to Messrs. D. F. Hayman and W. Reiss for the microanalyses and to Mr. A. N. Wilson for technical assistance.

Summary

Variations and improvements in the synthesis of vitamin B_6 have been made. The compounds 2-methyl-3-hydroxy-4-ethoxymethyl-5-hydroxymethylpyridine and 2-methyl-3-amino-4-ethoxymethyl-5-aminomethylpyridine have been hydrolyzed directly to the corresponding hydroxy derivatives by heating with dilute hydrochloric acid at 150–175° under pressure. Derivatives of some of the intermediates and a new inner ether of vitamin B_6 have been described.

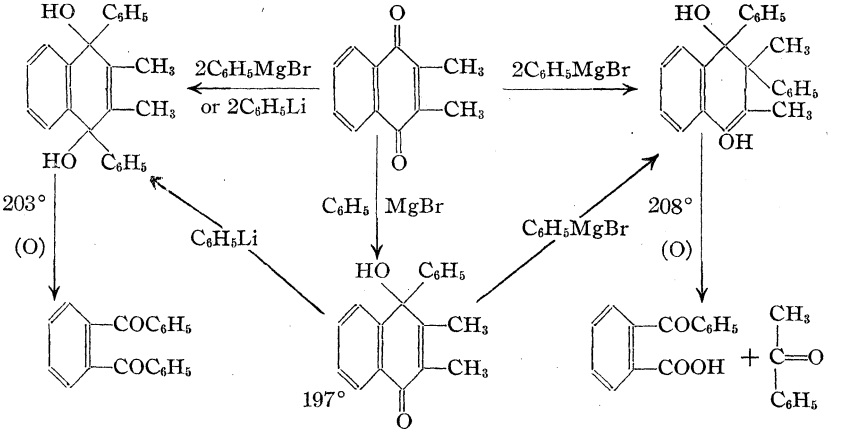
The Reaction between 2,3-Dimethyl-1,4-naphthoquinone and Phenylmagnesium Bromide. II[1]

BY H. MARJORIE CRAWFORD

In an earlier paper[2] it was shown that phenylmagnesium bromide reacts with 2,3-dimethyl-1,4-naphthoquinone to give all of the expected reduction and addition products. These solids accounted for about 30% of the starting material, the other product being a dark, thick oil. No amorphous materials were encountered. Four addition products were described, two resulting from the 1,2- and 1,4-addition of one molecule of phenylmagnesium bromide to one molecule of the quinone, and two resulting from the 1,2-1,2- and 1,2-1,4-addition of two molecules of phenylmagnesium bromide to one molecule of the quinone.

Further reactions of the two di-addition products are described in this paper.

The structures of the two di-addition products were established as shown by the following equations.



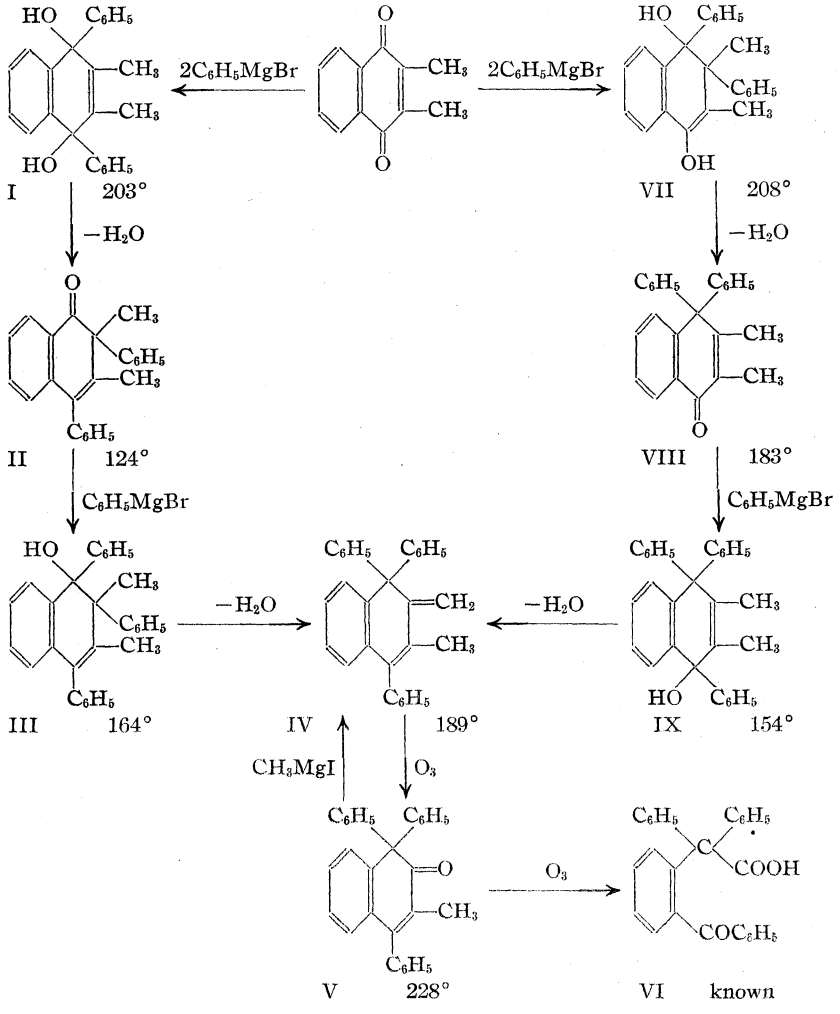
In the Grignard machine, both di-addition compounds showed two active hydrogens. Oxidation of both compounds gave known products which served to locate the phenyl groups. The 203° compound gave *o*-dibenzoylbenzene and the 208° compound gave acetophenone and *o*-benzoyl-

(1) Reported at the fall meeting of the American Chemical Society at Boston, Mass., September, 1939.

(2) Crawford, THIS JOURNAL, **57**, 2000 (1935).

benzoic acid. The 203° compound was also formed by the reaction of phenyllithium on either the 197° mono-addition compound or the original quinone. Phenylmagnesium bromide reacted with the 197° mono-addition compound to give the 208° compound.

Starting with these two di-addition products, parallel series of reactions led to the same product, a hydrocarbon.



The dehydration and rearrangement of I led to the formation of the 124° compound (II). II was oxidized easily to acetophenone and *o*-benzoylbenzoic acid. The formation of these products indicated that the formation of II from I involved the shift of one phenyl group from a carbon next to the ring to a carbon holding a methyl group. Very small amounts of II were available and the only other reactions investigated were those with phenyllithium and with phenylmagnesium bromide. In both of these reactions, decomposition of the metallic product with acid led to the formation of a hydrocarbon (IV). Careful decomposition of the metallic compound with water gave an intermediate carbinol (III) which, in the presence of acid, easily lost a molecule of water and gave the hydrocarbon. This hydrocarbon was difficult to oxidize with ordinary oxidizing agents, but was attacked readily by ozone to give formaldehyde and a ketone (V). When the ketone was treated with methylmagnesium iodide followed by acid, the hydrocarbon was formed again, so no rearrangement occurred during the reaction with ozone. Ozonization of the ketone (V) gave a known keto acid (VI). The structure of this known keto acid located the three phenyl groups in the hydrocarbon (IV) and in the ketone (V).

The same hydrocarbon (IV) was obtained by starting with the other di-addition product (VII) and carrying out the same series of reactions. Dehydration of VII gave the 183° compound (VIII) which was extremely unreactive. VIII was recovered unchanged after attempts at oxidation with potassium dichromate or chromium trioxide in glacial acetic acid, with basic potassium permanganate, with hydrogen peroxide and with ozone. The only reactions which VIII could be made to undergo were reduction with zinc and acetic acid (which gave very small amounts of two reduction products) and the reaction with organo-metallic reagents. When phenylmagnesium bromide or phenyllithium was added to VIII and the metallic compound was decomposed with acid, the hydrocarbon (IV) resulted, but if ammonium chloride was used for the decomposition, an intermediate carbinol (IX) could be isolated. Both ozonization of this carbinol and oxidation with potassium

dichromate in acetic acid gave the same products that would have been obtained from the hydrocarbon, so the first reaction was apparently dehydration and this was followed by oxidation.

Knowing the structures of I, II, IV and VII, the structure proposed for VIII seems the only reasonable one, although all attempts to break it up by oxidation and all attempts to synthesize it have so far proved unsuccessful.

The reactions involved in these dehydrations and rearrangements are all of the pinacol and allylic types. Cases of dehydration accompanied by the migration of a phenyl group are not unusual. The researches of Ramart and Amagat,[3] Bachmann,[4] and Kleinfeller and Eckert[5] showed that, in the cases studied, the phenyl group was the only one to migrate. The tendency of phenyl groups to migrate in preference to methyl groups is shown by the work of McKenzie and Myles[6] and of Orekhov and Tiffeneau.[7]

In most attempts at oxidation of the carbinol (IX) and of the hydrocarbon (IV), either by potassium permanganate, potassium dichromate or ozone, there resulted small amounts of a hydrocarbon, melting at 235°, which was isomeric with the hydrocarbon (IV). An oil was formed when this hydrocarbon was treated with ozone and no structure can be suggested for it at this time.

Experimental

All combustions were carried out using the semi-micro method of Lauer and Dobrovolny.[8] Molecular weight determinations were made by the lowering of the freezing point of benzene or of camphor.

1,4 - Dioxy - 2,3 - dimethyl - 1,4 - diphenyldihydronaphthalene, I, m. p. 203–204°.—Because of its great solubility, this white di-addition product was obtained only occasionally from the mixture of products resulting from the reaction between phenylmagnesium bromide and 2,3-dimethyl-1,4-naphthoquinone. When it was obtained from this mixture, it was in the form of a pale yellow double compound which contained two molecules of the quinone to one molecule of the 203° compound. The quinone could be steam distilled from a solution of the double compound leaving the 203° compound (I). I was obtained in much better yields (20%) by the reaction of 0.2 mole of phenyllithium[9] on 0.1 mole (18.6 g.) of the quinone. The green solid formed in this reaction looked very much like the solid formed during the reaction between phenylmagnesium bromide and the quinone. After standing for two hours, the mixture was decomposed with ice and dilute hydrobromic acid. The organic material was extracted with ether. Evaporation of the ether gave 10 g. of white solid which after recrystallization from 50% alcohol yielded 6.85 g. of I. This compound was also formed, in 50% yield, by the reaction of 0.02 mole of phenyllithium on 0.01 mole of the 197° mono-addition compound.

The Grignard machine showed two active hydrogens. The other analytical data are included in the earlier paper[2] (in which the 203° compound was numbered IX).

Potassium permanganate was not decolorized and heating 1.0 g. of I for one and one-half hours with potassium dichromate gave a small amount of solid melting at 140–143°. Better results were obtained by adding 2.0 g. of I to 2.0 g. of chromium trioxide in 10 cc. of glacial acetic acid and boiling for five minutes. Pouring the mixture immediately into water gave a precipitate which on crystallization from alcohol melted at 145–148° and was identical with a known sample of *o*-dibenzoylbenzene.

Heating I with hydrochloric acid in methyl alcohol or with zinc chloride and hydrochloric acid in benzene caused it to lose a molecule of water and to be transformed almost quantitatively into the 124° compound (II).

1 - Oxo - 2,3 - dimethyl - 2,4 - diphenyldihydronaphthalene, II, m. p. 124°.—This compound was obtained once in the crystallization of the yellow double compound of I and quinone. Later it was easily obtained, in practically quantitative yields, by the dehydration of I.

Oxidation of 1.0 g. of II by boiling for five hours with 3.0 g. of potassium dichromate in glacial acetic acid gave acetophenone and *o*-benzoylbenzoic acid. II decolorized bromine in carbon tetrachloride slowly, but failed to give a semicarbazone. It reacted readily with phenylmagnesium bromide and phenyllithium. When the metallic product was decomposed by acid (after fifteen minutes of standing) there resulted a hydrocarbon (IV). When the metallic product was decomposed carefully with water, a carbinol (III) was obtained.

The analytical data for II are contained in the earlier paper[2] (in which the 124° compound was numbered XI).

1 - Oxy - 2,3 - dimethyl - 1,2,4 - triphenyldihydronaphthalene, III, m. p. 164–174°.—This carbinol was prepared by adding phenylmagnesium bromide in excess to 0.7 g. of II, decomposing the product with water, and extracting with ether. The small amount of solid from the ether solution was crystallized from alcohol, in which it was quite soluble, and melted at 164–174°. Heating in benzene for one hour with a few crystals of zinc chloride and five drops of concd. hydrochloric acid caused 0.2 g. of III to lose water with the formation of the hydrocarbon (IV).

Anal. Calcd. for $C_{30}H_{26}O$: C, 89.51; H, 6.51. Found: C, 88.92, 88.83; H, 6.80, 6.65.

3 - Methyl - 2 - methylene - 1,1,4 - triphenyldihydronaphthalene, IV, m. p. 189–190°.—This hydrocarbon was obtained by the dehydration of either of the carbinols, III or IX. Addition of methylmagnesium iodide to 0.25 g. of the ketone (V) and decomposition of the reaction mixture with hydrochloric acid also gave the hydrocarbon in 76% yield. The best method of preparation, giving practically quantitative yields, was the addition of phenylmagnesium bromide to the 183° compound (VIII) and decomposition

of the reaction mixture, after about an hour, with hydrochloric acid. The hydrocarbon was then extracted with ether, the solvent evaporated, and the solid crystallized from a mixture of alcohol and benzene. It was only slightly soluble in isopropyl ether, alcohol and ethyl acetate but was very soluble in benzene. It decolorized bromine in carbon tetrachloride rapidly.

Potassium permanganate in acetone was not decolorized by IV at room temperature. When the hydrocarbon was boiled for four hours with potassium dichromate in glacial acetic acid, a small amount of benzoic acid was isolated along with a neutral oil which could not be crystallized. Ozonization of IV in chloroform or in carbon tetrachloride gave varying results. The solution of the ozonide was poured into water and allowed to stand overnight. The main product from the ether extract was always the ketone (V) with sometimes small amounts of the keto acid (VI) and sometimes small amounts of a hydrocarbon, m. p. 235°. In one case the ozonide was dropped into boiling water containing zinc dust and traces of hydroquinone and silver nitrate. The resulting gases were passed into a solution of methone and there were formed white needles of formaldimethone, identical with synthetic formaldimethone.

Anal. Calcd. for $C_{30}H_{24}$ (384.2): C, 93.71; H, 6.29. Found: C, 93.71, 93.26; H, 6.28, 6.66; mol. wt. (benzene) 360, (camphor) 398, 416.

2 - Oxo - 3 - methyl - 1,1,4 - triphenyldihydronaphthalene, V, m. p. 228°.—This ketone was formed by ozonizing the hydrocarbon (IV) and the carbinol (IX). It is only slightly soluble in alcohol, glacial acetic acid and pyridine, but is fairly soluble in hot benzene. It decolorized bromine in carbon tetrachloride rapidly. Fusion with potassium hydroxide, treatment with semicarbazide and boiling for three hours with potassium dichromate in glacial acetic acid gave only unchanged material. Addition of excess methylmagnesium iodide to 0.25 g. of the ketone and decomposition of the mixture with ice and hydrochloric acid gave 0.19 g. (76%) of the hydrocarbon (IV). Ozonization of 1.0 g. of the ketone in carbon tetrachloride and decomposition of the ozonide with water gave 0.6 g. of a white acid (VI) which decomposed at 218°.

Anal. Calcd. for $C_{29}H_{22}O$: C, 90.11; H, 5.74. Found: C, 90.16; H, 5.95.

Diphenyl-(*o*-benzoylphenyl)-acetic Acid, VI.—This keto acid was obtained by ozonizing the ketone (V). It was recrystallized from benzene and acetone and decomposed at 218°. The acid was transformed into the methyl ester by boiling about 0.3 g. of the acid with 5 cc. of methyl alcohol and two drops of concd. sulfuric acid. A white precipitate formed after forty minutes and the solution was cooled and filtered. The ester melted at 189–190°. This keto acid was then synthesized by the oxidation of 1,1,3-triphenylindene.[10] The methyl ester of this acid had not been reported before and was made by boiling 1.0 g. of the synthetic acid with 20 cc. of methyl alcohol and six drops of concd. sulfuric acid. As in the other case, solid separated after about forty minutes of heating. The solid melted at 188–189° and after recrystallization from methyl alcohol and benzene finally melted at 192–193°. The mixed melting point of this ester with that from the acid resulting from the ozonization of the ketone, was 190.5–192°.

Anal. Calcd. for $C_{28}H_{22}O_3$: C, 82.73; H, 5.45. Found: C, 82.63; H, 5.56.

1,4 - Dioxy - 2,3 - dimethyl - 1,2 - diphenyldihydronaphthalene, VII, m. p. 208–209°.—This compound was the main solid product from the reaction between phenylmagnesium bromide and 2,3-dimethyl-1,4-naphthoquinone.[2] It also resulted from the reaction of phenylmagnesium bromide on the 197° mono-addition compound. It was oxidized easily to acetophenone and *o*-benzoylbenzoic acid by boiling for five hours with potassium dichromate and glacial acetic acid. The Grignard machine showed two active hydrogens. The most interesting reaction of VII was the loss of a molecule of water to give the 183° compound (VIII). This reaction could be brought about by treatment with various reagents. Heating on the steam-bath for two hours with phosphorus tribromide in bromoform, heating for six hours in benzene with about 3 g. of zinc chloride and 3 cc. of concd. hydrochloric acid or heating for one hour with 0.5 g. of iodine in 50 cc. of glacial acetic acid transformed 1.0 g. of VII into VIII in 90% yields. VII was not changed by one-half hour of heating with 20% sulfuric acid nor by warming on the steam-bath with acetic anhydride and sodium acetate.

Other properties and analytical data are included in the earlier paper[2] (in which this compound was numbered VI).

4 - Oxo - 2,3 - dimethyl - 1,1 - diphenyldihydronaphthalene, VIII, m. p. 183°.—This compound was formed in about 90% yields by the loss of a molecule of water from compound VII. It is very soluble in most organic solvents and separates from hot alcohol in glistening white leaflets. Its extreme inertness is its most outstanding characteristic. It was recovered unchanged from boiling for one hour with constant boiling hydrobromic acid, from boiling for seven hours with hydroxylamine, from warming for one hour with semicarbazide, from warming with phenylhydrazine and 2,4-dinitrophenylhydrazine, from warming with aluminum isopropylate, from warming with potassium permanganate and potassium hydroxide, from boiling for five hours with potassium dichromate in glacial acetic acid, from boiling for one hour with chromium trioxide in glacial acetic acid, from warming for six hours with 30% hydrogen peroxide, and from ozonizing for one hour in carbon tetrachloride. It does not decolorize bromine in carbon tetrachloride.

Reduction of 3.2 g. of VIII by boiling for four hours with 5 g. of zinc and 25 cc. of glacial acetic acid gave very small amounts of two neutral products. One melted at 142–143° and analyses corresponded to the addition of two atoms of hydrogen to give the compound $C_{24}H_{22}O$. The other melted at 176–177° and is a hydrocarbon.

The only reactions that took place readily were those with phenylmagnesium bromide and phenyllithium. The Grignard machine showed the addition of one molecule of methylmagnesium iodide and no active hydrogens. When the mixture from the reaction of either phenylmagnesium bromide or phenyllithium on VIII was decomposed with hydrochloric acid, the hydrocarbon (IV) was isolated in 90% yields from the ether extract. If the magnesium compound was carefully decomposed, after about twenty

(10) Kohler, *Am. Chem. J.*, **40**, 231 (1908).

minutes, with ammonium chloride and water, the ether extract gave 90% yields of the carbinol (IX).

Other analytical data on this compound are contained in the earlier paper[2] (in which this compound was numbered VIII).

4 - Oxy - 2,3 - dimethyl - 1,1,4 - triphenyldihydronaphthalene, IX, m. p. 154°.—This carbinol was formed in 90% yields by the addition of phenylmagnesium bromide to VIII. It is very unstable in the presence of acid and when an alcohol solution of the carbinol was treated with hydrochloric acid, a molecule of water was lost with the formation of the hydrocarbon (IV). IX melts at 154° with the loss of a molecule of water and the formation of the hydrocarbon (IV). Warming with zinc chloride and concd. hydrochloric acid in benzene also converted IX to the hydrocarbon (IV). The Grignard machine showed one active hydrogen. Boiling for one hour with potassium permanganate and potassium hydroxide gave 90% of unchanged material. Boiling for one hour with potassium dichromate in glacial acetic acid gave a solid from which, after many recrystallizations from alcohol and ethyl acetate, it was possible to isolate a small amount of the 235° hydrocarbon. Ozonization of IX in chloroform gave the ketone (V), so dehydration to the hydrocarbon (IV) probably occurred before the reaction with ozone.

Anal. Calcd. for $C_{30}H_{26}O$: C, 89.51; H, 6.51. Found: C, 89.31, 88.95; H, 6.80, 6.75.

The 235° Hydrocarbon.—This compound, isomeric with the 189° hydrocarbon (IV), was formed in small amounts in many attempts to oxidize the hydrocarbon (IV) with potassium dichromate or potassium permanganate in glacial acetic acid or with ozone, and to oxidize the carbinol (IX) with potassium dichromate in glacial acetic acid.

Heating the hydrocarbon (IV) with acetic acid alone or with iodine in acetic acid did not convert it into the high melting isomer. Ozone converted 0.4 g. of the 235° compound into an oil from which no solid material could be obtained. The 235° compound was only slightly soluble in alcohol and in ethyl acetate, but could be crystallized from benzene.

Anal. Calcd. for $C_{30}H_{24}$ (384.2): C, 93.71; H, 6.29. Found: C, 93.84, 93.23; H, 6.29, 6.07; mol. wt. (camphor), 360.

The author wishes to thank the University of Minnesota for the courtesy shown her as an Honorary Fellow of the University while on leave from Vassar College in the spring of 1938.

Summary

Starting with the two di-addition products from the reaction between phenylmagnesium bromide and 2,3-dimethyl-1,4-naphthoquinone, parallel series of reactions lead to the same product, a hydrocarbon.

Structures have been assigned to these two di-addition products, to the two compounds resulting from the dehydration and rearrangement of these compounds, and to four new compounds obtained in these series of reactions.

Sterols. LXXVI. Oxidation and Reduction Products of Equilenin

BY RUSSELL E. MARKER AND EWALD ROHRMANN

In previous work[1] from this Laboratory it was observed that equilenin when reduced with Adams catalyst in acidic ethanol gave approximately a 70% yield of 5,7,9-estratrienol-17. No other reduction products were isolated. Ruzicka, Müller and Mörgeli[2] in a somewhat similar reduction obtained this same product in addition to some α-dihydroequilenin. By modifying the reduction technique these workers were able to obtain a 5,7,9-estratrienediol-3,17 which was identical with one of the diols obtained by the reduction of equilenin with sodium.[2,3,4]

When the hydrogenation of equilenin is carried out in a neutral medium with Adams catalyst, the essential product is α-dihydroequilenin, a product first isolated from the phenolic fraction of mares pregnancy urine by Wintersteiner and co-workers[5] and later prepared by Marker and co-workers[1] by the reduction of equilenin with aluminum isopropylate. The hydrogenation of α-dihydroequilenin in acidic ethanol yields the same 5,7,9-estratrienol-17 as was obtained from equilenin, indicating that the hydroxyl group at C-17 is of the α-configuration.

In a previous comprehensive investigation of the carbinol fraction of mares pregnancy urine[6] we reported the isolation (from the chromic anhy-

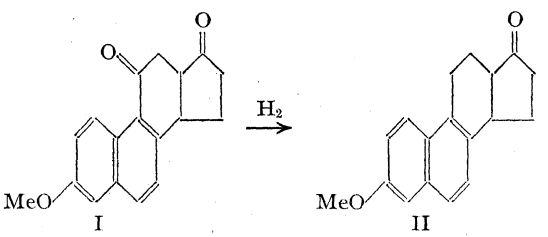
dride oxidation products of a crude carbinol fraction) of a diketone of the composition $C_{18}H_{16}O_2$. This substance formed a mono-semicarbazone, which suggested the presence of a hindered carbonyl group. We now have strong indications that this product is 3-desoxy-11-keto-equilenin. On catalytic hydrogenation in acidic ethanol, it gave a good yield of 5,7,9-estratrienol-17(α) identical with that obtained from equilenin. The fact that the reduction in acidic medium removes the carbonyl group at C-11 is in accordance with the fact that carbonyl groups adjacent to benzenoid ring systems are usually removed on hydrogenation under the proper conditions.

The properties of 3-desoxy-11-ketoequilenin resemble those of the methyl ether of 11-keto-*nor*-equilenin (I) prepared synthetically by Koebner and Robinson.[7] This product (I) formed only a mono-carbonyl derivative and on reduction with a platinum–charcoal catalyst in the presence of palladium chloride yielded the methyl ether of *nor*-equilenin (II).

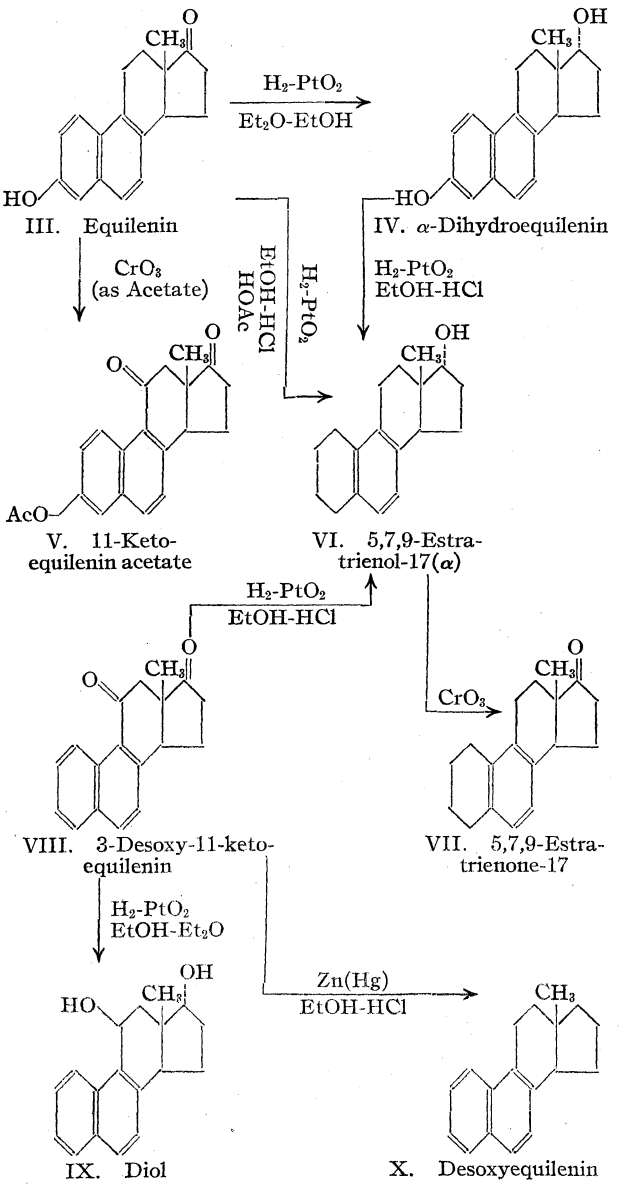


I II

When the hydrogenation of 3-desoxy-11-keto-equilenin was carried out in a neutral medium the product appeared to be a compound in which the two carbonyl groups were reduced to hydroxyl groups. A mild Clemmensen reduction (unamalgamated zinc) of 3-desoxy-11-keto-equilenin yielded a mono-keto derivative while more vigorous reduction (amalgamated zinc) gave desoxyequilenin.

Inasmuch as the 3-desoxy-11-keto-equilenin was obtained from the oxidation of a ketone free (*i. e.*, non-hindered ketones) carbinol fraction, some question might be raised concerning the nature of the compound before oxidation. It now seems highly probable that the carbonyl group at C-11 was introduced during the chromic anhydride oxidation of the carbinol fraction, inasmuch as equilenin acetate upon oxidation with chromic anhydride yields a product which appears to be 11-keto-equilenin acetate. The substance forms only a mono-semicarbazone. The 11-keto-equilenin acetate was obtained in rather poor yields apparently due to the lability of the product to further oxidation under the conditions used.

The introduction of a carbonyl group into the C-11 position by oxidation of equilenin derivatives with chromic anhydride strongly suggests that the 3-desoxy-11-keto-equilenin obtained from the oxidation of the mares urine carbinol fraction was actually formed by the oxidation of 3-desoxy-dihydroequilenin, thus indicating the presence of this substance in mares pregnancy urine.



Equilenin resembles estrone in that it reacts

(7) Koebner and Robinson, *J. Chem. Soc.*, 1994 (1938).

readily with ethyl chloroacetate and sodium ethylate to yield the acetic acid derivative.[8] Catalytic hydrogenation of equilenin-3-oxy-acetic acid in acidic ethanol yielded largely 5,7,9-estratrienol-17(α) and very little acidic material was obtained.

This investigation was supported by a grant from the Committee for Research in Problems of Sex, National Research Council. We also wish to thank Parke, Davis and Company for the supply of urine concentrate and equilenin and for their generous assistance in various phases of this work.

Experimental Part

Hydrogenation of Equilenin and α-Dihydroequilenin.—A mixture of 500 mg. of equilenin, 500 mg. of Adams catalyst, 300 cc. of ether and 10 cc. of absolute ethanol was shaken with hydrogen at three atm. and 25° for fifteen hours. The product was crystallized from 80% ethanol to give compact white crystals, m. p. 245–247°. This gave no depression with an authentic sample of α-dihydroequilenin. It gave a 30° depression with a sample of equilenin of m. p. 257–258°.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.55; H, 7.5. Found: C, 80.8; H, 7.6.

A mixture of 250 mg. of α-dihydroequilenin, 120 cc. of absolute ethanol, 2 cc. of hydrochloric acid and 200 mg. of Adams catalyst was shaken with hydrogen at three atm. for twelve hours at 25°. The product was crystallized from ether–pentane as white needles, m. p. 144–146°. This gave no depression with a sample of 5,7,9-estratrienol-17(α), m. p. 144–146°, obtained from equilenin.

Anal. Calcd. for $C_{18}H_{24}O$: C, 84.3; H, 9.4. Found: C, 84.0; H, 9.5.

5,7,9-Estratrienone-17.—To a solution of 300 mg. of 5,7,9-estratrienol-17(α) in 30 cc. of acetic acid was added a solution of 300 mg. of chromic anhydride in 20 cc. of 80% acetic acid. After standing for one hour at 25°, the mixture was diluted with water and extracted with ether. The ethereal solution was washed with sodium carbonate solution and the ether removed. The residue was crystallized from aqueous methanol as thick white needles, m. p. 107–109°.

Anal. Calcd. for $C_{18}H_{22}O$: C, 85.0; H, 8.7. Found: C, 84.7; H, 8.8.

With hydroxylamine hydrochloride the product yielded an **oxime** which crystallized from acetone as white needles, m. p. 203–205° dec.

Anal. Calcd. for $C_{18}H_{23}ON$: C, 80.25; H, 8.6. Found: C, 80.5; H, 8.3.

Reduction of 3-Desoxy-11-keto-equilenin. (a) By Catalytic Hydrogenation in Acidic Medium.—A mixture of 250 mg. of 3-desoxy-11-keto-equilenin, 120 cc. of absolute ethanol, 200 mg. of Adams catalyst and 2 cc. of concentrated hydrochloric acid was shaken with hydrogen at two atm. for five hours at room temperature. After treatment with Norite the product was crystallized from ether–pentane to give 150 mg. of white needles, m. p. 144–146°. This gave no depression with a sample of 5,7,9-estratrienol-17(α), m. p. 144–146°, prepared by a similar reduction of equilenin.

Anal. Calcd. for $C_{18}H_{24}O$: C, 84.3; H, 9.4. Found: C, 84.2; H, 9.5.

When refluxed for thirty minutes with an excess of acetic anhydride the reduction product yielded an **acetate** which crystallized from methanol as white needles, m. p. 101.5–102.5°. This gave no depression with a sample of the acetate of 5,7,9-estratrienol-17(α), m. p. 102–103°.

Anal. Calcd. for $C_{20}H_{26}O_2$: C, 80.5; H, 8.8. Found: C, 80.5; H, 8.9.

(b) **By Catalytic Hydrogenation in Neutral Medium.**—A mixture of 200 mg. of 3-desoxy-11-keto-equilenin, 60 cc. of ether, 60 cc. of absolute ethanol and 200 mg. of Adams catalyst was shaken with hydrogen at three atm. at room temperature for four and one-half hours. The product was crystallized from ether–acetone as white needles, m. p. 209–212°.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.55; H, 7.5. Found: C, 80.5; H, 7.7.

(c) **By Clemmensen Reduction with Unamalgamated Zinc.**—A mixture of 250 mg. of the 11-keto compound, 40 cc. of 95% ethanol and 10 g. of 20-mesh zinc was refluxed for three and one-half hours during which time 7 cc. of hydrochloric acid was added. The solution was decanted into water and the resulting mixture extracted with ether. The reaction product was sublimed in high vacuum at 130–140° to give a product which crystallized from ether–pentane as needles, m. p. 156–158°.

Anal. Calcd. for $C_{18}H_{18}O$: C, 86.35; H, 7.25. Found: C, 86.3; H, 7.3.

(d) **Clemmensen Reduction with Amalgamated Zinc.**—To a boiling mixture of 100 mg. of the ketone, 25 cc. of ethanol and 5 g. of amalgamated zinc (20-mesh) was added 15 cc. of hydrochloric acid over a period of two hours. The product was sublimed in high vacuum at 60–65° and the sublimate crystallized from methanol and acetone to give white crystals, m. p. 73–75°.

Anal. Calcd. for $C_{18}H_{20}$: C, 91.5; H, 8.5. Found: C, 91.2; H, 8.5.

11-Keto-equilenin Acetate.—To a solution of 2 g. of equilenin acetate (m. p. 158–160°) in 75 cc. of acetic acid was added a solution of 2.5 g. of chromic anhydride in 40 cc. of 80% acetic acid. The mixture was allowed to stand at 25° for five hours, when it was diluted with water and extracted with ether. The ethereal extract was washed well with water and sodium carbonate solution and the ether evaporated. The residual sirup was crystallized first from ether–pentane and then from ether to give compact white crystals, m. p. 195–197°.

Anal. Calcd. for $C_{20}H_{18}O_4$: C, 74.5; H, 5.6. Found: C, 74.7; H, 5.7.

With semicarbazide acetate under the usual conditions the substance yielded a **mono-semicarbazone** which crystallized from aqueous methanol, m. p. 238–241° decomp.

Anal. Calcd. for $C_{21}H_{21}O_4N_3$: C, 66.5; H, 5.6. Found: C, 66.3; H, 5.8.

Equilenin-3-oxyacetic Acid.—To a mixture of 1 g. of equilenin, 50 cc. of absolute ethanol and 3.5 cc. of ethyl chloroacetate was added a solution of 600 mg. of sodium in 20 cc. of ethanol. The mixture was refluxed for sixteen hours, when 1 g. of potassium hydroxide was added and the mixture refluxed for an additional hour. Upon dilution with water a white precipitate separated which was taken up in ether.

The water layer was acidified with hydrochloric acid and the white solid taken up in a large volume of ether. The ethereal extract was washed twice with sodium carbonate solution. Evaporation of the ether yielded about 200 mg. of unreacted equilenin. The sodium carbonate washings were acidified with hydrochloric acid and the precipitated solid collected and crystallized from acetone–ether as white needles, m. p. 233–236°.

Anal. Calcd. for $C_{20}H_{20}O_4$: C, 74.05; H, 6.2. Found: C, 73.7; H, 6.3.

The neutral fraction which separated upon first dilution of the reaction mixture with water was crystallized from aqueous acetone to give white crystals, m. p. 141.5–143°.

Anal. Calcd. for $C_{22}H_{24}O_4$: C, 75.0; H, 6.8. Found: C, 75.4; H, 7.1.

Hydrolysis of this neutral material with an excess of ethanolic potassium hydroxide yielded an acid which when crystallized from acetone–ether, m. p. 232–235°, gave no depression with equilenin-3-oxyacetic acid. The neutral product was very probably the ethyl ester.

With diazomethane equilenin-3-oxyacetic acid yielded a **methyl ester** which crystallized from acetone–methanol as white plates, m. p. 180–182°.

Anal. Calcd. for $C_{21}H_{22}O_4$: C, 74.5; H, 6.6. Found: C, 74.4; H, 6.5.

Hydrogenation of Equilenin-3-oxyacetic Acid.—A mixture of 800 mg. of equilenin-3-oxyacetic acid, 120 cc. of absolute ethanol, 500 mg. of Adams catalyst and 2 cc. of hydrochloric acid was shaken with hydrogen at two atm. at room temperature for five hours. The reaction products contained no appreciable acidic material. Crystallization from ether–pentane gave white needles, m. p. 144–146°, which gave no depression with a sample of 5,7,9-estratrienol-17(α), m. p. 144–146°.

Anal. Calcd. for $C_{18}H_{24}O$: C, 84.3; H, 9.4. Found: C, 84.0; H, 9.5.

Summary

Equilenin derivatives upon mild oxidation with chromic anhydride yield 11-keto derivatives.

Catalytic hydrogenation of equilenin derivatives in acidic medium gives 5,7,9-estratrienol-17(α).

Sterols. LXXVII. The Oxidation of Pregnanetriol-3,4,20(α) and of Coprostanediol-3,4

BY RUSSELL E. MARKER, EUGENE L. WITTLE, LOUIS PLAMBECK, JR., EWALD ROHRMANN, JOHN KRUEGER AND PAUL R. ULSHAFER

Gardner and Godden[1] oxidized coprosterol and coprostanone with cleavage of the 2,3-bond to a dicarboxylic acid of m. p. 247°. Windaus[2] confirmed Gardner and Godden's work and also oxidized *epi*-coprostanol with chromic oxide to the same acid. Windaus and Riemann[3] oxidized this dibasic acid to isolithobilianic acid which has been proved to have the carboxyl groups in the 2- and 3-positions. We have repeated the oxidation of coprostanone and obtained an acid of m. p. 247°, which appears to be the acid described above. The major oxidation product in the coprostane series, coprostane-2,3-dicarboxylic acid, is therefore formed by cleavage of the 2,3-bond.

On the other hand, oxidative degradations of compounds with the coprostane configuration in the bile acid series result in cleavage of the 3,4-bond as the major reaction. Wieland, Dane and Scholz[4] found that the oxidation of lithocholic acid proceeded with the formation of a 50% yield of lithobilianic acid and a 15% yield of isolithobilianic acid. Thus the oxidative cleavage in this compound took place chiefly at the 3,4-bond, and the substance formed by cleavage of the 2,3-bond was a by-product. Also J. Sawlewicz and T. Reichstein[5] obtained deoxybilianic acid as the major product in the oxidation of α-3-hydroxy-12-keto-cholanic acid. The same is true in the oxidation of other cholic acid derivatives.

Because the major oxidative cleavage in the bile acids of coprostane configuration is at the 3,4-bond, whereas the bile acids of the *allo* series are attacked at the 2,3-bond, it has been generally assumed that all coprostane and cholestane derivatives will behave in the same way. Confusion has resulted in the literature because of this

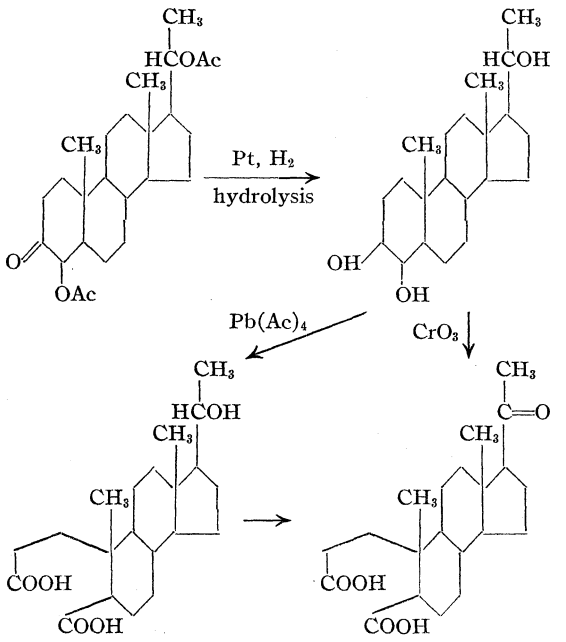
generally accepted but erroneous rule. Sobotka[6] gives the structure of the acid obtained by the oxidation of coprostanone as if a 3,4-cleavage had taken place in spite of the fact that Windaus[3] oxidized the side chain of this acid and obtained isolithobilianic acid, which could only have been formed if the first oxidation had resulted in a 2,3-cleavage in the coprostanone molecule.



Butenandt[7] oxidized pregnanedione with cleavage in ring A and obtained a dibasic acid to which he later assigned the 3,4-dicarboxylic acid structure.[8] We have repeated this oxidation and obtained the acid described by Butenandt. However, when pregnanetriol-3,4,20(α) (prepared by bromination of pregnanedione, followed by potassium acetate treatment, and finally by reduction and hydrolysis of the resulting ketoacetate) was oxidized, the major product was a ketodibasic acid (m. p. 216°), which was different from the acid of m. p. 270° (our melting point 281°) prepared by direct oxidation of pregnanedione with chromic anhydride. The same acid of m. p. 216° was obtained by lead tetraacetate oxidation followed by chromic anhydride treatment. Obviously the oxidation product of pregnanetriol-3,4,20(α) must have been obtained by cleavage of the 3,4-bond which lies between two hydroxyl groups.

We also carried out an analogous series of reactions on coprostanone. This compound was brominated, and the 4-bromocoprostanone was converted to 4-acetoxycoprostanone by potassium acetate. The resulting compound, by catalytic reduction and hydrolysis, yielded 3,4-dihydroxycoprostane. This diol, on cold oxidation with chromic anhydride in acetic acid, yielded a 3,4-diacid, m. p. 217°, which was different from the 2,3-diacid, m. p. 247°, obtained as the major product of direct cleavage of coprostanone by chromic anhydride in acetic acid. This acid, the 3,4-coprostane-dicarboxylic acid, also gave a large depression in melting point with dihydro-Diels acid of m. p. 251°.

Thus, the point of cleavage of Ring A of the sterols on oxidation is highly dependent on the nature of the group attached to C-17, even though this group is far removed from the point of oxidative attack.

We wish to thank Parke, Davis and Company for their generous support and assistance rendered in the various phases of this work.

Experimental Part
