N-Benzoyl-2-nitro-*p*-toluidine.—Five grams of 2-nitro-*p*-toluidine was dissolved in 3 ml. of pyridine, treated with 5 g. of benzoyl chloride, and warmed on a steam-bath for ten to fifteen minutes. The product was washed with water, dilute alkali, water, dilute acid, and water, respectively. Dilute alcohol was used for crystallization; m. p. 174–175°.

The authors wish to acknowledge the kind counsel of Professor A. S. Wheeler, who directed this problem for several weeks prior to his retirement due to illness.

Summary

1. The dinitration of *p*-cymene has been studied at −3 to −5°, −5 to −7°, and −10 to −12°.

2. The preparation of 6-nitrocarvacrylamine from *p*-cymene has been improved.

3. The chemical method of separation of the nitration products of *p*-cymene is far superior to the methods previously used.

The Synthesis of *dl*-β-Cyclohexylalanine

BY DAVID SHEMIN AND ROBERT M. HERBST

While studying the preparation of *dl*-β-phenylalanine by the reduction of α-acetaminocinnamic acid[1] in the presence of Adams platinum oxide catalyst, the occasional formation of *dl*-β-cyclohexylalanine (hexahydrophenylalanine) was observed. Generally an unsaturated linkage in the side chain of an aromatic compound may be hydrogenated by catalytic methods without reduction of the aromatic nucleus. The rate of hydrogenation of the aromatic nucleus is so much slower than that of the unsaturated side chain that there is a sharp break in the rate of hydrogen uptake when the latter has been completely saturated.

When freshly prepared and still moist Adams catalyst was employed for the reduction of α-acetaminocinnamic acid, the rate of hydrogenation of even the phenyl group was so great that on numerous occasions no break in the rate of hydrogen uptake was apparent until the compound was completely hydrogenated. The reduction of the compound, both of the unsaturated side chain and of the phenyl group, was complete in about an hour and a half. After the same preparation of catalyst had been dried and allowed to stand in a desiccator for a week or longer, it showed the usual differential rate of hydrogenation of the side chain unsaturation and of the aromatic nucleus.

In view of the fact that *dl*-β-cyclohexylalanine has not been described, a brief characterization of the compound may be of value. Waser and Bräuchli[2] have described *l*-β-cyclohexylalanine (*l*-hexahydrophenylalanine), which they obtained by catalytic hydrogenation of *l*-tyrosine. A certain amount of confusion was introduced by their failure in an earlier paper[3] to realize that the hydroxyl group of the tyrosine was at least partially eliminated during the hydrogenation.

Experimental

N-Acetyl-*dl*-β-cyclohexylalanine.—A solution of 10 g. of α-acetaminocinnamic acid[1] (p. 1) in 75 cc. of glacial acetic acid containing about 0.25 g. of freshly prepared Adams platinum oxide catalyst was shaken with hydrogen under two to three atmospheres pressure in a Burgess–Parr hydrogenation apparatus. The theoretical amount of hydrogen (4 mols) was taken up in from one to two hours. After removal of the catalyst the solution was evaporated to dryness *in vacuo*. Recrystallization of the residue from hot water gave 9.5 g. of N-acetyl-*dl*-β-cyclohexylalanine as needles, m. p. 178°.[4,5]

Anal. Calcd. for $C_{11}H_{19}O_3N$: C, 62.0; H, 9.0; N, 6.6. Found: C, 62.0; H, 8.9; N, 6.6.

***dl*-β-Cyclohexylalanine.**—The amino acid was prepared by hydrolysis of the acetyl derivative with twenty parts of boiling normal hydrochloric acid for eight hours. The hydrochloric acid was removed as completely as possible by vacuum distillation. The remainder of the chloride was removed by treatment with silver oxide followed by hydrogen sulfide to remove silver ion. *dl*-β-Cyclohexylalanine was obtained by evaporation of the clear aqueous solution. On recrystallization from hot water it separated in the form of needles that tended to group together in bunches.

Anal. Calcd. for $C_9H_{19}O_2N$: C, 63.1; H, 10.0; N, 8.2. Found: C, 63.0; H, 9.8; N, 8.2.

The compound showed similarity to phenylalanine in its water solubility. It usually was necessary to employ relatively large volumes of boiling water to dissolve the compound completely, and evaporation of some of the solvent was necessary before crystallization took place.

N-Benzoyl-*dl*-β-cyclohexylalanine.—Benzoylation of *dl*-β-cyclohexylalanine was carried out in aqueous solution with benzoyl chloride in the presence of sodium bicarbonate. The benzoyl derivative crystallized from aqueous alcohol as plates, m. p. 182–183.5°.

Anal. Calcd. for $C_{16}H_{21}O_3N$: C, 69.8; H, 7.7; N, 5.1. Found: C, 69.6; H, 7.6; N, 5.1.

α - Phenylureido - β - cyclohexylpropionic Acid.—The phenyl isocyanate derivative of β-cyclohexylalanine was prepared by shaking an aqueous solution of the amino acid with a slight excess of phenyl isocyanate. The derivative crystallized from aqueous alcohol as prisms, m. p. 177.5° with decomposition.

Anal. Calcd. for $C_{16}H_{22}O_3N_2$: C, 66.2; H, 7.6; N, 9.6. Found: C, 66.1; H, 7.5; N, 9.5.

3-Phenyl-5-cyclohexylmethylhydantoin.—The phenylureido derivative was converted into the corresponding hydantoin by boiling in a mixture of equal parts of absolute alcohol and concentrated hydrochloric acid for several hours. After removal of the alcohol by distillation *in vacuo* the product separated from the reaction mixture in the form of needles or long prisms, m. p. 172.5° after recrystallization from aqueous alcohol.

Anal. Calcd. for $C_{16}H_{20}O_2N_2$: C, 70.6; H, 7.4; N, 10.3. Found: C, 70.7; H, 7.4; N, 10.2.

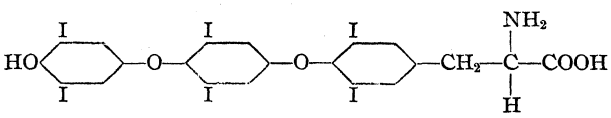
An Analog of Thyroxine

BY M. BOVARNICK, K. BLOCH AND G. L. FOSTER

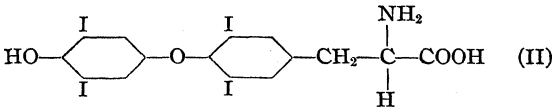
There have been numerous studies on the chemical constitution of thyroxine in relation to its physiological activity. A full discussion of this subject is given by Harington[1] in his monograph on thyroxine. He observes that the presence of certain chemical features in the molecule seems to be responsible for its specific physiological activity, namely, its iodine content, the special orientation of two of the iodine atoms in the ortho position to a phenolic group, the presence of the diphenyl ether linkage, and the α-amino acid residue.

It therefore seemed of some interest to see whether the following compound (I) might possess thyroxine activity.



(I)

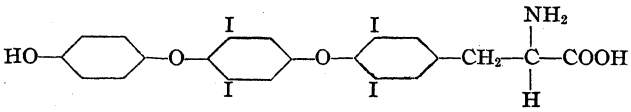
Comparing this with thyroxine (II) the chemical similarities are shown.



(II)

Physiologically, however, the three-ringed amino acid showed no significant activity.

One of the intermediate products in the synthesis is the following



(III)

Because of the parallel relationship between this and our final product (I) on the one hand, and 3,5-diiodothyronine and thyroxine on the other, it was thought worth while to test this physiologically. It showed no more activity than that displayed by the fully iodinated compound (I).

(1) Harington, "The Thyroid Gland," Oxford University Press, London, 1933, Chapter VII.

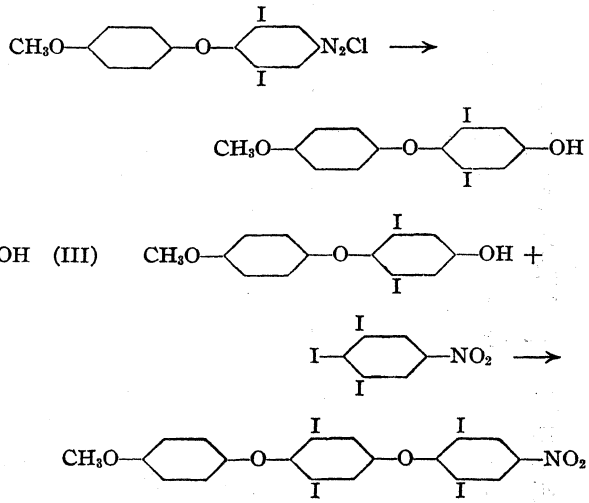
Experimental

Bio-assay.—Since the preliminary estimations, which were done by comparing the weight curves of test animals with thyroxine treated and normal controls, showed so little activity, the more complicated and tedious assay by basal metabolic rates was not undertaken.

Guinea pigs of about 300 g. weight were used. All animals were fed the same adequate diet *ad lib.* The results are shown in Chart I. Each curve represents a group of six animals. Injections and weighings were done daily. The controls received 1 cc. of warm water; the thyroxine and new substances were injected as sodium salts in 1 cc. of warm water. The dosage of thyroxine was 0.05 mg. per animal per day, that of the new compounds 2 mg. per animal per day. The injections were given intraperitoneally.

Since the animals tested with the new substances, although not gaining weight quite as rapidly as the untreated controls, showed no effects comparable to the thyroxine controls, and since the molecular dosage of new substances was about thirty times that of thyroxine, it seems safe to conclude that there is very little, if any, thyroid activity in either of the new compounds.

The synthetic procedure was similar to that followed by Harington and Barger[2] for thyroxine. The only new steps introduced were the following



A 20% solution of 3,5-diiodo-4-(4′-methoxyphenoxy)-benzene diazonium chloride in glacial acetic acid was pre-

(2) Harington and Barger, *Biochem. J.*, **21**, 169 (1927).

pared according to Harington and Barger.[2] This was added to a hot (100–110°), vigorously stirred 50% (by weight) sulfuric acid solution and both temperature and stirring maintained for twenty to thirty minutes, when the β-naphthol test for diazonium salts became negative. The orange mixture turned yellow-gray, and a dark brown sediment separated out. After cooling and standing overnight the solid was filtered off and extracted with 0.5 *N* sodium hydroxide. On addition of an equal volume of 4 *N* sodium hydroxide to the resulting solution the crystalline sodium salt of the phenol separated out. This was centrifuged, washed with 2 *N* sodium hydroxide, dissolved in water, and the solution was made acid to congo with hydrochloric acid. The precipitate was recrystallized from aqueous alcohol or acetic acid. The phenol crystallized as slightly brown, short needles or rods, m. p. 160–163°, yield 48%.

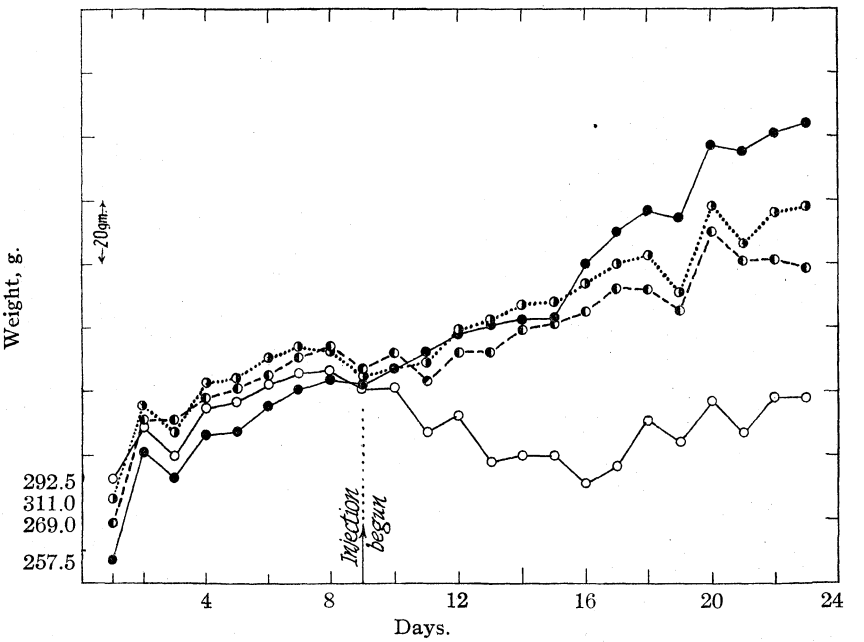


Fig. 1.—●—●, Control; ○—○, thyroxine; ◑···◑, thyroxine *p*-hydroxy phenyl ether; ◐--◐, thyroxine 4-hydroxy-3,5-diiodo phenyl ether.

Anal. Calcd. for $C_{18}H_{10}O_3I_2$: C, 33.3; H, 2.12; I, 54.0. Found: C, 33.2; H, 2.18; I, 53.7.

3,5 - Diiodo - 4 - [3′,5′ - diiodo - 4′ - (4″ - methoxyphenoxy)-phenoxy]-nitrobenzene.—A mixture of 26 g. of the phenol, 8.8 g. of anhydrous potassium carbonate, 31.2 g. of 3,4,5-triiodonitrobenzene, and 125 cc. of dry methyl ethyl ketone was refluxed for fifteen hours on the steam-bath. The hot mixture of salt and yellow product which precipitated out of solution was filtered and washed with the ketone and then with water; 60 g. of almost pure product was left on the filter. The mother liquors on cooling yielded 12 more grams, and still more on dilution with water. The product crystallized in long yellow needles or rods, m. p. 190–192°; yield 87%.

Anal. Calcd. for $C_{19}H_{11}O_5NI_4$: C, 27.0; H, 1.30; I, 60.4; OCH_3, 3.7. Found: C, 27.0; H, 1.35; I, 60.3; OCH_3, 3.6.

3,5 - Diiodo - 4 - [3′,5′ - diiodo - 4′ - (4″ - methoxyphenoxy)-phenoxy]-aminobenzene.—Dry hydrogen chloride was bubbled through a solution of 150 cc. of hot acetic acid containing 15 g. of the trinitro compound and 17 g. of crystallized stannous chloride. The reaction flask was kept hot on the steam-bath. After a while the crystalline stannichloride of the amine began to separate out (one hour). The mixture was cooled and allowed to stand in the icebox overnight. The crystalline precipitate was filtered off and washed with a little cold acetic acid. Then in small portions it was shaken vigorously in a separatory funnel with saturated potassium hydroxide and a large volume of peroxide-free ether containing a little stannous chloride. If no stannous chloride is added, colored products are formed on shaking with alkali, which apparently can be reduced by addition of stannous chloride. The amine is sparingly soluble in ether and large quantities were used, each portion of ether being siphoned off when saturated. The ether solution was filtered and concentrated, whereupon the amine came out as white needles. When hydrochloric acid was passed into the ethereal solution of amine, the hydrochloride separated out as prisms. These were unstable and on being dried lost hydrochloric acid to give the free amine, m. p. 185–187°; yield 87%.

Anal. Calcd. for $C_{19}H_{13}O_3NI_4$: C, 28.1; H, 1.6; I, 62.6. Found: C, 28.0; H, 1.8; I, 62.4.

3,5 - Diiodo - 4 - [3′,5′ - diiodo - 4′ - (4″ - methoxyphenoxy)-phenoxy]-benzonitrile.—Diazotization of the amine was done most conveniently in small lots. To each solution of 1.8 g. (4 *M*) of ethyl nitrite in 40 cc. of glacial acetic acid at room temperature was added slowly and with occasional shaking a 5-g. portion of dry amine. The amine dissolved slowly as the reaction proceeded. The resulting clear orange solutions were combined and added dropwise, at room temperature, and with continuous stirring, to a cuprous cyanide solution prepared by adding, for each 20 g. of amine, 160 g. of potassium cyanide in 280 cc. of water to 120 g. of cupric sulfate in 520 cc. of water. After completion of the reaction as indicated by absence of positive naphthol test for diazonium salt, the mixture was filtered. The light brown solid was dried over phosphorus pentoxide *in vacuo*, and then extracted with benzene solution. The dark brown benzene solution was passed through an aluminum oxide column, losing most of its color and coming out pale yellow. This solution was evaporated to dryness *in vacuo* and redissolved in acetone. On diluting the acetone solution with one-fourth its volume of water and allowing it to stand overnight, a flocculent yellow precipitate came out. This was filtered off and the practically colorless filtrate on further dilution yielded the nitrile as long colorless needles. On purification by crystallization

from acetone–water these melted at 225–226°; yield 64%.

Anal. Calcd. for $C_{20}H_{11}O_3NI_4$: C, 29.2; H, 1.34; N, 1.7; I, 61.8. Found: C, 29.1; H, 1.34; N, 1.8; I, 61.8.

3,5 - Diiodo - 4 - [3′,5′ - diiodo - 4′ - (4″ - methoxyphenoxy)-phenoxy]-benzaldehyde.—To a solution of 6.9 g. of freshly fused, anhydrous stannous chloride in 35 cc. of anhydrous ether saturated with dry hydrogen chloride gas was added 5 g. of nitrile dissolved in 40 cc. of anhydrous chloroform. There was a slight evolution of heat and hydrogen chloride gas, after which the container was tightly stoppered and allowed to stand at room temperature. A yellow, flocculent precipitate soon began to form. After twenty-four hours the heavy yellow precipitate was filtered off, washed with a little cold, dry ether, and suspended in dilute hydrochloric acid. The mixture was brought to boiling and kept there for five minutes. The precipitate became white and granular. It was filtered off and recrystallized from a water–acetone mixture, coming out as clusters of lancets, m. p. 196–198°; yield 70%.

Anal. Calcd. for $C_{20}H_{12}O_4I_4$: C, 29.1; H, 1.54; I, 61.7. Found: C, 28.9; H, 1.50; I, 61.3.

Azlactone of β-3,5-Diiodo-4-[3′,5′-diiodo-4′-(4″-methoxyphenoxy) - phenoxy] - phenyl - α - acetaminoacrylic Acid.—An intimate mixture of 2 g. of aldehyde, 0.28 g. of acetylglycine, 1.2 g. of freshly fused anhydrous sodium acetate, and 4 cc. of acetic anhydride was refluxed on the oil-bath for one hour. After cooling the yellow solid was filtered off, washed with cold acetic anhydride, then with water till the washings came through neutral, dried and recrystallized from acetic anhydride; glistening golden plates, m. p. 264–265°; yield 80%.

Anal. Calcd. for $C_{24}H_{15}O_5NI_4$: C, 31.8; H, 1.76; I, 56.1. Found: C, 31.8; H, 1.65; I, 55.9.

Thyroxine-*p*-hydroxyphenyl Ether.—To a suspension of 2 g. of red phosphorus in a mixture of equal parts (by volume) of acetic anhydride and 57% hydriodic acid was added 2.8 g. of azlactone and the mixture refluxed on the oil-bath for one and one-quarter hours. The phosphorus was removed by filtering the hot mixture through asbestos. Occasionally the hydroiodide of the amino acid separated out of the hot solution during the course of the reaction, but was brought into solution previous to removal of the phosphorus by addition of more hot dilute acetic acid. After removal of the acetic acid and hydriodic acid as completely as possible by repeated addition of small amounts of water and evaporation *in vacuo*, the insoluble light brown solid was filtered off, washed with a little dilute alcohol, suspended in a large volume of hot alcohol, and brought into solution by the addition of a few drops of *N* sodium hydroxide. On acidification with acetic acid and cooling the amino acid came out as clusters of long colorless needles; 1.75 mg. was obtained. This product was very difficult to purify. There was some loss of iodine during the reduction and hydrolysis, the analysis at this point always being 1 to 2% too low. On repeated recrystallization as described above, the product gradually approached analytical purity, but the yield suffered greatly; 200 mg. of pure material was prepared for analysis and bioassay, m. p. 267–268° with decomposition.

Anal. Calcd. for $C_{21}H_{15}O_5NI_4$: C, 29.0; H, 1.7; N, 1.61; I, 58.46. Found: C, 28.9; H, 1.9; N, 1.67; I, 58.30.

Thyroxine-4-hydroxy-3,5-diiodophenyl Ether.—Because of the very slight solubility of the tetraiodo compound in aqueous ammonia, the iodination was carried out in a methyl alcohol–aqueous ammonia mixture.

To a solution of 869 mg. of tetraiodo compound in a mixture of 140 cc. of methyl alcohol and 200 cc. of 25% aqueous ammonia was added dropwise 8 cc. of 0.5 *N* iodine in 0.1 *M* potassium iodide. If more than the calculated amount of iodine was used, there was an increase in destruction, probably due to oxidation. The iodine was taken up rapidly. After addition of the iodine the solution was put in the icebox for several hours. Most of the ammonia was then removed by distillation *in vacuo* at room temperature, and the solution was acidified with acetic acid. The white precipitate obtained weighed 1.1 g. A portion of this, 415 mg., was extracted with hot 95% ethyl alcohol, the solution filtered and diluted to 70% with water. A crop of fine white needles came out. This was filtered off, redissolved in 100 cc. of hot alcohol and diluted with 30 cc. of water; 130 mg. of fine white needles was thus obtained. This compound was rather unstable, coloration and loss of iodine occurring on heating both in solution and in the dry state. It could only be thoroughly dried by heating in high vacuum, and even when kept dry and unexposed to light, there was brown coloration and loss of iodine. Because of these properties it was difficult to purify. Decomposition starts at 210° without melting.

Anal. Calcd. for $C_{21}H_{13}O_5NI_6$: C, 22.48; H, 1.16; N, 1.25; I, 67.9. Found: C, 22.26; H, 1.23; N, 1.34; I, 67.5.

Summary

The synthesis of the 3,5-diiodo-4-hydroxyphenyl ether of thyroxine is described. The product is physiologically inactive.

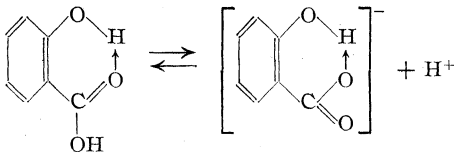
Relation between Resonance Stabilized Chelate Rings and Acidity

BY RICHARD T. ARNOLD AND JOSEPH SPRUNG

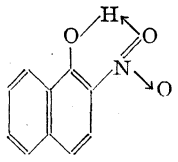
The general effects of chelate rings on the physical properties of organic molecules are well known.[1]

It has been shown recently[2] that the abnormally high acidity of salicylic acid is readily explained by an increased resonance in the anion formed by ionization. Thus



This increased possibility of resonance is brought about by hydrogen bond formation.

It has been assumed[3] that the formation of a chelate ring stabilizes the nuclear double bonds in the aromatic ring to which the chelate ring is attached. We have consistent data which seem to prove the corollary of this idea, *i. e.*, that the amount of hydrogen bond formation is greater around a stabilized double bond. The following molecule will serve as an example



Since resonance of the hydrogen atom among the three oxygen atoms of this chelate ring stabilizes the structure, one could expect a higher degree of resonance and consequently greater stability when the steric factors between the hydroxyl and nitro groups are most favorable. This "locking-up" of the ionizable hydrogen should decidedly decrease the acidity of the molecule.

The inductive effect here however is large and is easily transmitted across the double bond.[4] The decreased acidity predicted above is obvious from the values listed in Table I.

Solvent Effect.—The parallel change in "*pK*" with solvent as shown above indicates that the order of acidity discussed here is not affected by the interaction of solute and solvent.

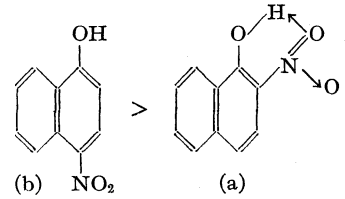
o-Nitrophenol	8.55	8.15	7.85	7.68	7.58

[a] $T = 35°$.

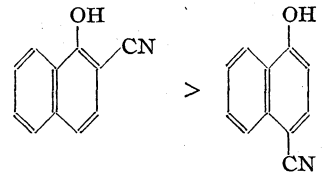
Discussion

It is to be noticed that while the large inductive effect would tend to make (a) more acidic than (b), the reduction caused by chelate ring formation completely overshadows this effect. Thus

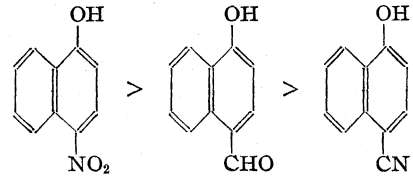


The same situation holds for the corresponding hydroxyaldehydes.

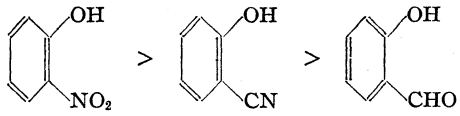
With the cyanonaphthols (no chelate rings) the normal inductive effect becomes important. Thus



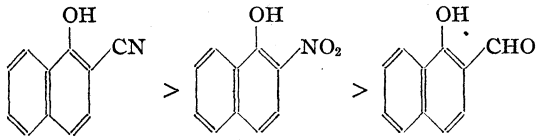
When only the inductive effect is operative the order of acidity is $-NO_2 > -CHO > -C{\equiv}N$. Consequently



When some hydrogen bond comes into play this order changes. Thus



When the hydrogen bond becomes very strong a further change takes place as shown.



All of the above observations are explained readily by assuming stronger hydrogen bond formation around a stabilized double bond. The fact that the order of acidity is not the same in the naphthalene and benzene series as shown above clearly proves this point (since all the other factors involved are constant).

We wish to stress that the low acidity of 2-cyano-3-naphthol is in accord with our ideas concerning the structure of naphthalene.[5]

We have shown that the method considered above will locate stabilized double bonds. We will publish soon our work on the Mills-Nixon[6] problem using the above attack.

Experimental

Apparatus.—The general method was that described in an earlier paper[5] except that the glass electrode was used throughout.

1-Hydroxy-2-naphthonitrile.—Eleven grams of potassium hydroxide was dissolved in 350 cc. of dried glycerol contained in a three-necked flask equipped with a sealed stirrer. Fifty grams of sodium 1-sulfonate-2-naphthonitrile was added and the stirred solution heated for two hours at 140°. The mixture was poured into a liter of water and acidified with hydrochloric acid. The white precipitate was filtered, dried, and refluxed with 25 cc. of acetic anhydride for thirty minutes. The crude 1-acetoxy-2-naphthonitrile was purified by recrystallization, m. p. 87°; yield 7 g. The hydroxy compound was obtained by hydrolysis with dilute sodium hydroxide. After five recrystallizations from ethanol it melted at 178–179°.

Anal. Calcd. for $C_{11}H_7ON$: C, 78.09; H, 4.17. Found: C, 78.18; H, 4.25.

4-Acetoxy-1-naphthaldehyde.—Attempts to follow the literature gave disappointing results.[7] Fifty grams of 4-hydroxy-1-naphthaldehyde was dissolved in a solution of 250 cc. of acetic acid, 50 cc. of acetic anhydride and 20 g. of sodium acetate and refluxed for two hours. The solution was poured into ice water and the precipitate recrystallized from ethanol; yield 4.5 g., m. p. 103–105°. The material was not quite pure.

4-Hydroxy-1-naphthaldehyde Oxime.—Five grams of 4-acetoxy-1-naphthaldehyde was dissolved in 125 cc. methanol and 60 cc. of water. Three and one-half grams of hydroxylamine hydrochloride, 3.5 g. of sodium acetate and 2.0 g. of sodium bicarbonate were added and the mixture refluxed for fifteen minutes. The methanol was removed until crystallization started. Two hundred cubic centimeters of water was added and the temperature raised to 100°. After cooling slightly, the solution was filtered quickly to remove a resinous portion and crystallization completed in an ice-bath; yield 3 g. (68%), decomposition point 150°.

Anal. Calcd. for $C_{11}H_9O_2N$: C, 70.57; H, 4.84. Found: C, 71.03; H, 4.95.

The acetyl group is hydrolyzed in the course of the reaction. An attempt to prepare the oxime directly led to unfavorable results.

4-Hydroxy-N-acetoxy-1-naphthaldehyde Oxime.—Thirteen grams of 4-hydroxy-1-naphthaldehyde oxime was dissolved in 100 cc. of glacial acetic acid and 25 cc. of acetic anhydride added. After one hour the precipitate was filtered and washed with dilute acetic acid; yield 14 g. (88%); decomposition point 155°.

Anal. Calcd. for $C_{13}H_{11}NO_3$: C, 68.11; H, 4.83. Found: C, 67.97; H, 4.86.

4-Hydroxy-1-naphthonitrile.—Fourteen grams of the above compound was heated in 140 cc. of ethanol and 30 cc. of dry pyridine for two hours. The solution was evaporated to one-half volume and poured into dilute hydrochloric acid. The yield of crude nitrile was 9.5 g. (92%); m. p. 173–175°. After recrystallization, m. p. 176–176.5°.

Anal. Calcd. for $C_{11}H_7ON$: C, 78.09; H, 4.17. Found: C, 77.96; H, 4.21.

This compound also was obtained by the decomposition of the diazonium borofluoride[8] of 4-cyano-1-aminonaphthalene.

All of the other compounds measured can be produced easily by methods discussed in the literature.

The authors wish to thank the du Pont Company for generous gifts of isomeric aminonaphthalene sulfonic acids.

Summary

1. It has been shown that chelate rings formed around stabilized double bonds are abnormally strong.

2. A method for finding stabilized double bonds has been developed and its limitations completely recognized.

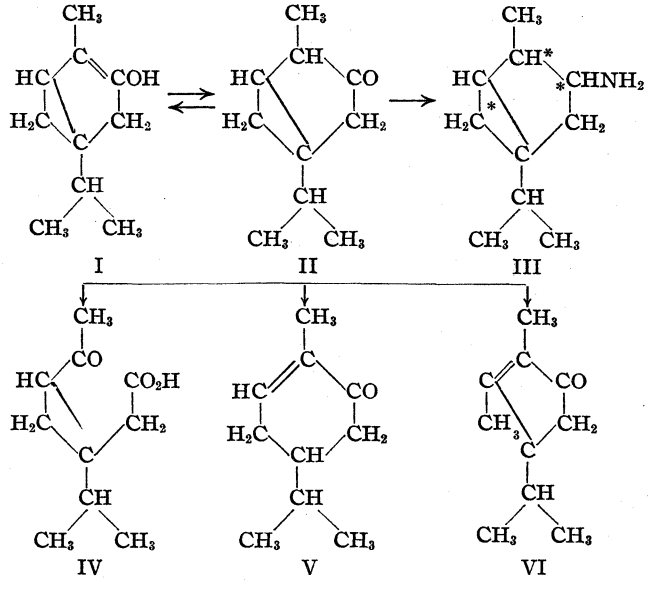
The Terpenoid Amines. I. The Isomeric Thujylamines

BY H. L. DICKISON[1] AND A. W. INGERSOLL

The purpose of this investigation is to characterize the stereoisomeric amines derivable from the five important dicyclic systems represented by thujone, pinocamphone, fenchone, isofenchone and camphor. The various amines are being studied as to their possible value as resolving agents and as to their suitability as derivatives for the analytical determination of the parent terpenoid substances. The present paper is concerned principally with the isomeric thujylamines, the first family that has been fully characterized thus far.

The Isomeric Thujylamines.—Two so-called thujylamines were known when the present work was begun. The more fully characterized amine was first obtained by Semmler[2] by reduction of an oxime, m. p. 51.5°, prepared from dextro-rotatory β-thujone (tanacetone), the principal ketone of tansy oil. The preparation was repeated by Wallach[3] and by Tschugaeff[4] and the amine was reported to have b. p. 195°, $[\alpha]_D$ +101°. It formed a sparingly soluble nitrate and very soluble hydrochloride. The second amine was contained in a mixture which Wallach[5] obtained by heating crude levorotatory α-thujone from thuja oil with ammonium formate and hydrolyzing the resulting formyl derivative. The amine was stated to form a sparingly soluble sulfate but was not completely separated from stereoisomers or from the accompanying fenchylamine.

Wallach[6] later showed that the α- and β-forms of thujone (II) are interconvertible in the presence of either alkaline or acidic reagents, presumably through the common enol (I). The β-form predominates at equilibrium. Both forms yield the same dextrorotatory thujaketonic acid (IV) upon oxidation. Hence the two thujones have the same configuration except for an interchange of H and CH_3 on the upper ring carbon. Wallach also demonstrated the isomerization of both thujones, by heating with strong acids, into *dl*-carvotanacetone (V) and the so-called *dl*-isothujone (VI).



These transformations were of primary importance for the proposed preparation of the thujylamines (III), which it was hoped to accomplish on a large scale by heating the thujone fraction of thuja oil with ammonium formate–formamide reagent. Although this fraction (b. p. 196–200°, α_D −18°) consists largely of α-thujone, together with some levorotatory fenchone, the α–β isomerization undoubtedly would be induced by prolonged heating in the mildly alkaline reaction mixture and could result in the formation of all four of the diastereoisomeric thujylamines—one antipode from each pair. In addition it was possible that amines derived from *l*-fenchone, *dl*-carvotanacetone and *dl*-isothujone might likewise be formed under the conditions used.

Application of this process, followed by alkaline hydrolysis of the crude formyl derivative, actually gave 55–60% yields of mixed amines, b. p. 193–202°, α_D +23°. This material was then converted to salts with a variety of acids and these were gradually and completely separated by prolonged fractional crystallization. In this way there were finally obtained five distinct amines for which the principal properties are given in Table I.

TABLE I

PROPERTIES OF THE AMINES

Amine	B. p., °C.	$\alpha^{25}D$[a]	Characteristic salts	M. p., benzoyl deriv., °C.
A	199.6	+27.80°	Sulfate–*p*-Toluene-sulfonate	73.0
B	193.4	+94.94°	Nitrate–Acid oxalate	131.5
C	196.7	−14.15°	Sulfate–Normal oxalate	94.5
D	202.2	−22.07°	*l*-Malate–sulfate	Glassy
E	195.3	+22.19°	*d*-Mandelate–*l*-Malate	90.2

[a] Rotation for 1 dm. without solvent.

The amine E was identified as (+)-fenchylamine, which had been partially characterized previously. The absence of optically inactive amines excluded the presence of amines derived from *dl*-carvotanacetone or *dl*-isothujone. The four remaining amines were therefore probably the theoretically possible thujylamines.

In a supplementary series of experiments, undertaken in an effort to correlate two of these amines with β-thujone, pure crystalline β-thujoneoxime, m. p. 53°, was reduced with sodium and alcohol and the product converted to salts and fractionated. In this way there were obtained 83.7% of an amine identical with B above, 6% identical with A and 4% identical with D. Aside from a trace of C, no other amines were present. These results confirmed the identification of the four thujylamines and indicated with considerable certainty that A and B were derived from β-thujone while the small amounts of C and D were derived from α-thujone, whose oxime must have been formed by an inversion occurring during the reduction.

When this work was practically complete, there appeared a paper by Short and Read[7] dealing in part with two thujylamines. One of these, which these authors named *d*-isothujylamine ($\alpha^{12}D$ +94.82°), likewise was obtained by reduction of β-thujoneoxime, m. p. 53°, and is clearly identical with the less pure amine previously prepared in the same way by Semmler,[2] Wallach[3] and Tschugaeff[4] and with the amine B described above. The other amine, which was named *l*-thujylamine ($\alpha^{13}D$ −24.32°), was obtained by reduction of the crude liquid oxime of α-thujone and purification through the hydrochloride. This amine was probably present in the impure preparation of Wallach and is identical with the amine D described above. Amines corresponding to A and C were not described.

(7) Short and Read, *J. Chem. Soc.*, 2016 (1938).

In view of the constants and relationships that have now been established for the entire group of four amines, it would seem advantageous to systematize their nomenclature. All four amines as well as both thujones have the same configuration at the junctions of the two rings and hence may be regarded as belonging to the same configurational series. It will not be possible to decide whether this is the *d*- or the *l*-series until a suitable derivative can be correlated with some substance of known configuration. However, in order to name the four diastereoisomers in each series it is proposed that the prefixes α- and β-, which have long been used for the two natural thujones, be retained in the names of the derived pair of amines and that the prefix iso- be assigned provisionally to that member of each pair which has the higher numerical rotatory power. With the addition of the sign of rotation, the amines A and B then become (+)-β-thujylamine and (+)-iso-β-thujylamine, respectively, while C and D become (−)-α-thujylamine and (−)-iso-α-thujylamine, respectively. These names are used in the remainder of this paper.

Characterization of the Amines.—The four thujylamines and also fenchylamine have been characterized rather completely as free amines and as salts and other derivatives. The most important data are recorded in the Experimental part. In each instance some six or seven of the most readily crystallizable salts were prepared from each amine and the crystal habit, solubility, rotatory power and other constants were carefully determined. It is expected that, should any of the amines be encountered again in other parts of the present program or by other workers, it should be possible to separate and recognize them readily by reason of their sharply distinctive properties.

Application as Resolving Agents.—This portion of the program has been studied thus far only incidentally to the separation of the isomeric amines, in the course of which *dl*-mandelic acid and *dl*-malic acid were employed. It was found that *dl*-mandelic acid was resolved readily by either (+)-β-thujylamine or (−)-α-thujylamine and that *dl*-malic acid was resolved by (−)-iso-α-thujylamine. Also both of these acids were readily resolved by (+)-fenchylamine. Preliminary experiments have shown further that all of these amines form well crystallized salts with several other types of organic acids and it is ex-

pected that various other resolutions can be carried out. Work is being continued in this direction.

Experimental

α-Thujone.—This was obtained in the crude state by distilling commercial oil of *Thuja occidentalis*, α_D −12.8°, through a jacketed 60-cm. Vigreux column. The fraction b. p. 196–199° (745 mm.), 78–82° (12 mm.), $\alpha^{25}D$ −18° (l = 1), was used for the Leuckart synthesis of amines. This fraction (55% of the oil) contained also considerable levorotatory fenchone. Pure α-thujone is reported[7] to have $\alpha^{18}D$ −19.94°.

β-Thujone.—This was obtained similarly from oil of tansy, $\alpha^{25}D$ +39°. The fraction b. p. 80–82° (12 mm.), $[\alpha]^{25}D$ +59.7° (c = 4, ether) was used to prepare the oxime. This fraction (38% of the oil) contained also some α-thujone and levorotatory camphor. Pure β-thujone is reported to have $\alpha^{15}D$ +72.46°[7] (l = 1), $[\alpha]D$ +76.16 in ether[6] and $[\alpha]D$ +77.45° in hexane.[8]

β-Thujoneoxime.[9]—Crude β-thujone (55 g.), hydroxylamine hydrochloride (28 g.) and sodium acetate trihydrate (60 g.) were dissolved in 85% ethanol (600 cc.) and allowed to remain overnight. It was hoped that mild conditions would minimize the oximation of camphor. The alcohol was evaporated and the liquid oxime extracted with benzene and distilled. The principal fraction (65%), b. p. 117–118° (6 mm.), $[\alpha]^{25}D$ +82° (c = 4, methanol), largely solidified after several days. The liquid portion smelled strongly of camphor. The solid was drained by suction and redistilled with rejection of a small forerun. After solidification this process was repeated on the product. The oxime then had m. p. 53°, $[\alpha]^{25}D$ +105.3° (c = 4, methanol). Short and Read[7] report $[\alpha]^{12}D$ +98.14° (c = 2, ethyl alcohol). The observation of these authors that the crystalline oxime could not be made satisfactorily from fractions containing considerable (liquid) α-thujoneoxime was confirmed. Repeated distillation of material with specific rotation +45° or less produced only slight enrichment of β-thujoneoxime in the higher boiling fractions. In this connection it was found that oximation of β-thujone in the presence of alcoholic pyridine[10] gave a non-crystallizable liquid of low dextrorotation. Partial isomerization of the β- to the α-configuration apparently occurs readily under these conditions.[11]

Leuckart Synthesis of Mixed Thujylamines.—Crude α-thujone (537 g., 3.53 moles) and solid ammonium formate (895 g., 14.2 moles) were heated in a 2-l. flask equipped with an automatic separator arranged to reject the distilled aqueous ammonium carbonate solution and return the ketone. The mixture, which darkened considerably, became homogeneous after two hours and was then heated at 175–185° for seven hours longer. The heating period was purposely made somewhat shorter than usual with the hope that the less reactive fenchone would be incompletely converted. The mixture of crude formyl derivatives, unchanged ketone and condensation products was extracted with benzene and hydrolyzed by refluxing for eight hours with 285 g. of sodium hydroxide in 3 l. of 85% alcohol. A little water was then added to dissolve sodium formate and most of the alcohol distilled through a long column. The crude amine was then distilled with steam, *cautiously* neutralized with cold, dilute hydrochloric acid and extracted with benzene to remove neutral volatile substances. The amine was then liberated with alkali, extracted and dried. The benzene was removed through an efficient column and the amine then distilled through a short column. The mixed amines weighed 314 g. (58% yield) and had b. p. 195–201°, $\alpha^{25}D$ +22.53° (l = 1), d^{25}_4 0.880, $n^{25}D$ 1.4615.

The volatile neutral material (45 g.) was examined briefly. The main fraction, b. p. 69–75° (12 mm.), had $\alpha^{25}D$ −40.2 (l = 1) and smelled strongly of fenchone. The non-volatile condensation products remaining after the steam distillation were not examined.

Several additional runs were made as described above, or by substitution of an equivalent amount of 95% formamide for the ammonium formate, with substantially similar results. In preliminary experiments[12] attempts were made to hydrolyze the formyl derivatives with 20% hydrochloric acid in the usual way. In one experiment brief heating, followed by isolation of the amine as described above, gave a 45% yield of mixed amines having $\alpha^{25}D$ about +15°. With longer heating the yield was much smaller. A somewhat similar result was observed by Short and Read.[7] When purified amine, obtained by alkaline hydrolysis, was neutralized exactly with dilute aqueous hydrochloric acid, the solution at once acquired a violet color. This rapidly deepened and changed to black on long standing or brief heating and much of the amine could not be recovered. No similar coloration or decomposition was noted when other acids were used, but care was always taken in the later work to avoid any excess of strong acid. The amine mixture obtained by acid hydrolysis was not used for the experiments described below.

Fractional Separation of Mixed Amines.—The combined product of several runs (650 g., b. p. 193–200°, $\alpha^{25}D$ +23.0°, $n^{25}D$ 1.4650) was separated eventually by the fractional crystallization of a variety of salts. The principal steps in this long and tedious process are outlined below. Full descriptions of the various salts and amines are reserved for a later section.

The mixture was first subjected to a preliminary fractionation as sulfates. The amine was combined with slightly less than the amount of acid calculated for the normal salt in 2 liters of hot water. The dense crystal mass was filtered after cooling and then heated with 500 cc. of water and again filtered after cooling. The amine (270 g.) recovered from these two filtrates was called Fraction IV. The crystalline portion was then boiled with three successive 1-liter portions of water and the solutions filtered at 60° from undissolved solid. The latter was called Fraction I. The warm filtrates on cooling gave crystalline crops. These were combined into Fraction II and the filtrates into Fraction III.

The sulfate fraction I was found to yield almost com-

pletely pure amine A, subsequently called (+)-β-thujylamine. The very sparingly soluble sulfate was recrystallized in portions from large volumes of water. The amine was then recovered and converted to the *p*-toluenesulfonate, which could be recrystallized more conveniently. The pure salt (195 g.) had $[\alpha]^{25}D$ +27.91°. The amine (5.5 g.) recovered from the final mother liquor was combined with that from Fraction II.

Fraction II was converted to the amine (90 g.) and this to the *p*-toluenesulfonate. Brief fractionation gave 20 g. more of the *p*-toluenesulfonate of amine A and mother liquors from which the mixed amines were recovered. Fraction III was also converted to the amine (168 g.) and this to the nitrate. Fractionation gave 24 g. of a characteristic nitrate, $[\alpha]^{25}D$ +70.48°, of the amine B, subsequently called (+)-iso-β-thujylamine. The residual amine was recovered from the mother liquor and combined with that recovered from Fraction II.

The combined amines were then converted to mandelates by the use of *dl*-mandelic acid. Prolonged fractionation of the crystalline portion finally gave two apparently homogeneous fractions, (a) 65 g. having $[\alpha]^{25}D$ +23.4° and (b) 82 g. having $[\alpha]^{25}D$ +1.3°. Actually, neither fraction proved to be uniform. The amine recovered from the portion (a) on fractionation as nitrate gave more of the amine B, and the soluble portion of the nitrate series, on conversion to sulfate, gave a new, rather sparingly soluble sulfate having $[\alpha]^{25}D$ +3.47°. Alternate crystallization as nitrate and sulfate gave exclusively 14.5 g. of amine A and 16.5 g. of the new amine C, subsequently called (−)-α-thujylamine.

The crystalline mandelate fraction (b) yielded an amine which was then converted to the malate by means of *dl*-malic acid. It was found that the principal constituent resolved *dl*-malic acid, giving a sparingly soluble acid *l*-malate, $[\alpha]^{21}D$ −14.73°. In order to obtain the maximum amount of this salt the *dl*-acid was taken in twice the equivalent amount so that at least one equivalent of the *l*-acid was present. The mother liquor gave an amine consisting almost entirely of the amine A. Alternate fractionation as the *p*-toluenesulfonate and malate gave 7 g. of A and 35 g. of the new amine D, subsequently called (−)-iso-α-thujylamine.

The mother liquors of the original mandelate series (containing the unseparated remainder of fractions II and III) gave an amine which was then combined with an excess of *dl*-malic acid. Fractionation gave a small amount of a crystalline malate which was distinctly different from that of the amine D, and a very soluble portion remaining in the mother liquors. A similar behavior had been observed in the meantime with certain parts of Fraction IV (see below). The two malate series were therefore combined and their further fractionation is described later. The crystalline malate proved to be the acid *l*-malate of a fifth amine E, subsequently identified as (+)-fenchylamine.

Since the amines from the sulfate fraction IV distilled over a moderate range, this material was separated into four sub-fractions, (a), (b), (c) and (d), in that order of decreasing volatility. These fractions were examined separately while some of the work described above was still in progress. The fraction (a) (18.3 g.) was combined with *dl*-malic acid and yielded a little of the crystalline malate of E and mother liquors containing very soluble malates. The amine was recovered from the mother liquors and later converted to oxalates. The fraction (b) (76 g.) was combined with *dl*-mandelic acid and yielded a small crystalline crop. The amine recovered from this was further fractionated as nitrate and gave more of the nitrate of amine B already described. The amines in the mother liquors of the mandelate and nitrate were then combined with *dl*-malic acid. Fractionation gave 36 g. more of the *l*-malate of D. The amines in the mother liquors were later converted to oxalates.

The fraction (c) (144.2 g.) was converted to the *d*-tartrate. The crystalline portions of this series could not be obtained uniform. The amine was therefore recovered from it and fractionated alternately as malate and nitrate. This gave more of the pure *l*-malate of D and the nitrate of B. The amines in the tartrate mother liquors were also combined with *dl*-malic acid and the crystals thus obtained were combined with similar material from the foot of fractions II and III and from IV (a). Fractionation gave 60 g. of the pure acid *l*-malate of (+)-fenchylamine. This salt has no observable rotation, apparently because the rotatory effect of each ion is cancelled. The salt was identical with that prepared from the pure amine and pure *l*-malic acid. This acid had therefore been resolved by fenchylamine.

The amines remaining in the mother liquors of the malate series were combined with similar material already mentioned and with IV (d) (32 g.). This material (all that remained of the original mixture) was then fractionated as oxalates. This gave 55 g. of the pure acid oxalate of B and 36 g. of less pure oxalate of D. The latter was purified by conversion to the *l*-malate. The amines in the mother liquors of the oxalate and malate (about 7 g.) were further separated into small additional amounts of the salts already described. No trace of any other amine was discovered.

In summary, there were obtained as pure amines or salts 137.5 g. of A, 54 g. of B, 34.9 g. of C, 54 g. of D, and 53.6 g. of E. The total (334 g.) is slightly over 50% of the original mixture. With the information now in hand concerning the salts it would undoubtedly be possible to separate a similar mixture much more systematically and with very little loss.

Amines from β-Thujoneoxime.—The oxime already described (33.8 g.) was reduced in 550 cc. of absolute alcohol by rapid addition of 47 g. of sodium. This process gave 28.6 g. (92%) of an amine mixture of b. p. 193–195°, $[\alpha]^{25}D$ +75.58° (c = 4, benzene), +93.94° (c = 3.7, ethanol). The entire amount was converted to nitrates and brief fractionation gave 32.4 g. of the characteristic nitrate of amine B. The amine recovered from the mother liquors then gave in succession 1.5 g. of the oxalate of B, 3.6 g. of the *p*-toluenesulfonate of A and 2.5 g. of the *p*-toluenesulfonate of D. The residual amine (1.3 g.) was converted to oxalates. Because of the small amount, pure salts were not obtained from this portion but the rotation data and crystalline appearance of the various fractions indicated a trace of the amine C and small additional amounts of A and D. From the weights of all of the salts it was calculated that the original mixture con-

tained (at least) 6.0% of A, 83.7% of B, 4.0% of D and a trace of C. It may be noted that the previous separation and characterization of the various amine salts enabled the above separation to be carried out rapidly and almost quantitatively. The separation was facilitated considerably by the absence of fenchylamine.

Characterization and Analysis.—Each amine was isolated, in the order already mentioned, as an apparently uniform salt. This was recrystallized to constant properties and decomposed with alkali. The amine was extracted with benzene (sometimes after steam distillation) and distilled and characterized. In each instance the amine was then converted to another salt and the entire process repeated as a check. In no instance did this process or distillation at ordinary or reduced pressures produce any significant change in properties. The distillations under low pressures were made in a flask filled with glass wool with omission of the customary capillary bubbler, and carbon dioxide was excluded as much as possible at all times.

Each pure amine was then converted to various salts and all of these that could be made to crystallize readily were purified and characterized. The properties thus observed were used as guides for the separation of the remaining mixture. The principal data and analyses are recorded in the following sections and in Table II. Additional data and details are recorded in the original thesis.

(+)-β-Thujylamine. (Amine A.)—B. p. 199.6°[13] (750 mm.), 77.0° (12 mm.); $n^{25}D$ 1.4654; $\alpha^{25}D$ +27.8° (l = 1); $[\alpha]^{25}D$ +51.27° (c = 3, ethanol), +35.31° (c = 5.6, benzene). The amine was purified and analyzed as normal sulfate and *p*-toluenesulfonate.

Anal. Calcd. for $(C_{10}H_{19}N)_2 \cdot H_2SO_4$: SO_4, 24.38.

(13) All temperatures in this paper were taken with reliable short range thermometers without further correction.

Found; SO_4, 24.33. Calcd. for $C_{10}H_{19}N \cdot C_7H_8SO_3$: N, 4.31. Found: N, 4.27.

(+)-Iso-β-thujylamine. (Amine B.)—B. p. 193.4° (737 mm.), 76.8° (11 mm.); $n^{25}D$ 1.4564; d^{25}_4 0.860; $\alpha^{25}D$ +94.94° (l = 1); $[\alpha]^{25}D$ +107.9°, +108.4° (c = 1.6, ethanol), +103.6° (c = 3.3, benzene). The amine was purified as nitrate and oxalate; analyzed as oxalate.

Anal. Calcd. for $C_{10}H_{19}N(COOH)_2$: N, 5.76. Found: N, 5.76.

This amine has been partially described previously.[2-4] The constants recorded above agree closely with those given for an amine named *d*-isothujylamine by Short and Read.[7]

(−)-α-Thujylamine. (Amine C.)—B. p. 196.7° (756 mm.), 77.6° (12 mm.); $n.^{26.5}D$ 1.4590; $\alpha^{27.5}D$ −14.15° (l = 1); $[\alpha]^{27}D$ −1.41° (c = 6.3, ethanol), −13.25° (c = 5.8, benzene). The amine was purified as sulfate and normal oxalate; analyzed as sulfate.

Anal. Calcd. for $(C_{10}H_{19}N)_2H_2SO_4$: N, 6.93. Found: N, 6.87.

(−)-Iso-α-thujylamine. (Amine D.)—B. p. 202.2° (748 mm.), 86.2° (15.5 mm.), 81.1° (12 mm.); $n^{26}D$ 1.4640; $\alpha^{27}D$ −22.07° (l = 1); $[\alpha]^{26}D$ −23.29° (c = 2.6, ethanol), −26.92° (c = 2.3, benzene). The amine was purified as *l*-malate and *p*-toluenesulfonate; analyzed as normal oxalate and acid malate.

Anal. Calcd. for $(C_{10}H_{19}N)_2(COOH)_2$: $(COOH)_2$, 22.7. Found: $(COOH)_2$, 22.6. Calcd. for $C_{10}H_{19}N \cdot C_4H_6O_5$: N, 4.88. Found: N, 4.55.

The properties of this amine agree closely with the one named *l*-thujylamine by Short and Read.[7]

(+)-Fenchylamine. (Amine E.)—B. p. 195.3° (730 mm.), 73.4° (11.5 mm.); $\alpha^{27}D$ +22.19 (l = 1); $[\alpha]^{26}D$ +25.89° (c = 5, ethanol), +19.11° (c = 4.6, benzene). This amine was purified as *l*-malate and *d*-mandelate; analyzed as malate.

Anal. Calcd. for $C_{10}H_{19}N \cdot C_4H_6O_5$: N, 4.88. Found: N, 4.85.

This amine and its antipode have been partially characterized by Wallach.[14] Further description of the various isomeric fenchylamines is reserved for a later paper.

Resolution Experiments.—It was observed in the course of the separation of the amines that (+)-β-thujylamine resolved *dl*-mandelic acid. The process was therefore studied on a larger scale with pure amine. Fractionation of the salts with the *dl*-acid gave alternate crops with distinctive rotations and crystalline appearance. Both salts were purified quickly by combining similar crops and recrystallizing systematically. The principal constants of these salts already have been given in Table II.

The resolution of *dl*-mandelic acid with (−)-α-thujylamine was studied similarly. The less soluble salt (−B + A type) was purified readily and had $[\alpha]^{23}D$ +65.23° (c = 1.2, water). The more soluble salt was not purified completely.

Attempted resolution of *dl*-mandelic acid with (+)-iso-β-thujylamine gave three successive crystalline crops having specific rotations +68.9, +61.9 and +48.2°, respectively. Since it appeared that prolonged fractionation would be necessary for the resolution, the attempt was abandoned. Somewhat similar results were obtained with (−)-iso-α-thujylamine, except that the fractions were more distinctly different. This resolution has not been completed.

The resolution of *dl*-malic acid with (−)-iso-α-thujylamine was employed in the original separation of this amine from the mixture. In separate experiments the pure amine was combined with two equivalents of *dl*-malic acid. Fractionation readily gave a good yield of the pure acid *l*-malate, $[\alpha]^{21}D$ −14.78° (c = 4, water). The mother liquor contained principally *d*-malic acid. The identity of this salt was confirmed by its preparation from the amine and pure *l*-malic acid. The much more soluble *d*-malate was not purified. The malates of the other three thujylamines were too soluble for convenient crystallization and the resolutions were not studied.

The use of active fenchylamines as resolving agents has shown that they are probably the most convenient agents yet employed for the resolution of *dl*-malic acid and *dl*-mandelic acid. This work will be described in a later paper.

(14) Wallach, *Ann.*, **263**, 140 (1891).

Summary

The four diastereoisomeric thujylamines derived from the natural thujones have been prepared and their separation from each other and from fenchylamine described. All of these amines have been characterized fully. A preliminary study of the use of these amines as resolving agents is reported.

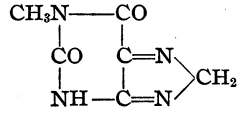
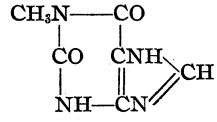
Desmotropism of Xanthine Derivatives[1]

BY TREAT B. JOHNSON AND JOSEPH C. AMBELANG[2]

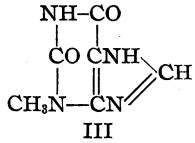
The conclusion of vanVeen[3] that *toxoflavin*[4] is to be assigned the empirical formula $C_6H_6O_2N_4$ and represented structurally by formula (I), or an isomer of a monomethylxanthine (II) or (III), has stimulated a renewed activity by this Laboratory in the study of new purines, and the relationship of such constructions to the field of chemotherapy for infectious disease.[5] If vanVeen's postulation is correct, then *toxoflavin* (I) assumes a position of immediate scientific interest to workers in the field of purines, and presents the first chemical evidence in support of the desmotropic formulation for purine (IV) to be recorded in the chemical literature.[6]



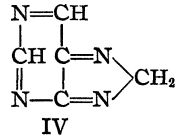
I



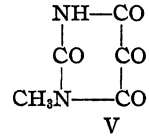
II



III



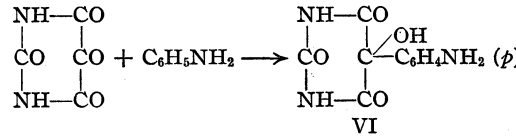
IV



V

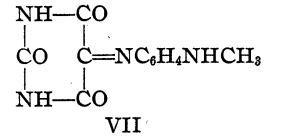
The purpose of this communication is to draw attention to specific reactions which characterize the differences in behavior of the pyrimidine alloxan toward cyclic and acyclic mono- and dibasic amines. The interesting facts that *toxoflavin* gives the murexide reaction, and when oxidized with potassium chlorate and hydrochloric acid yields methylalloxan (V),[5] suggest the possibility of new heterocyclic condensations being brought about by interaction of alloxan with aliphatic diamines. The authors are not aware that the action of such diamines on alloxan has been investigated previously.

The condensation reactions of aromatic amines with alloxan can be divided into two distinct groups as follows: 1, condensations involving addition of alloxan to the nucleus of the aromatic amine used giving derivatives of dialuric acid (VI). This characteristic behavior was first described by Pellizzari[7] and applies to monoamines of the aniline type or its nitrogen substituted derivatives. The same type of reaction applies when phenols are allowed to react with alloxan.

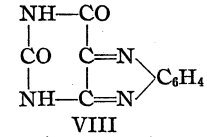


VI

2, Condensations of the anil type which result by interaction of alloxan with diaminobenzene derivatives as illustrated by the formation of the two anils (VII) and (VIII) from *o*-methylphenylenediamine and *o*-phenylenediamine, respectively.[8]



VII



VIII
(Alloxazine)

No anils of either type (VII or VIII) obtained by the action of aliphatic amines on alloxan have been described thus far. This pyrimidine (alloxan) functions as a strong oxidizing agent when allowed to react in aqueous solution with acyclic

(4) A name given by vanVeen and Mertens to the prosthetic group of a natural pigment formed in the culture of *Bacterium bongkrek*. This substance (toxoflavin) formed by the action of *Bacterium cocovenenans* is the cause of the well-known bongkrek and semaji-poisonings met with in Java.

(5) VanVeen seems to have demonstrated conclusively that *toxoflavin* is a pyrimidine compound closely related structurally to alloxan. It is impossible, however, to conclude from the present experimental evidence whether the methyl group functioning in its formula occupies position 1 or 3 in the supposed purine molecule (I).

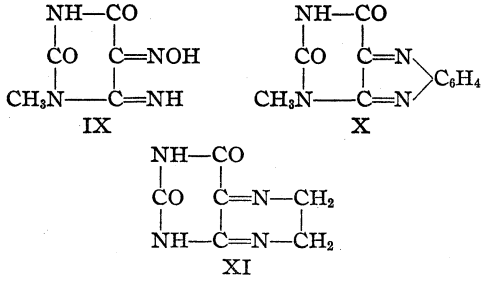
(6) "Harnsäure und Xanthine," H. Biltz, *J. prakt. Chem.*, **145**, 83 (1936). "The 4,5-double bond in xanthines does not exhibit the same unsaturation value as that in the uric acids. Conjugation with the 8,9-double bond in a xanthine, or with the 7,8-double bond in an isoxanthine, bestows on the imidazole ring of the purine an aromatic character [Biltz and Sauer, *Ber.*, **64**, 752 (1931)], thereby destroying the influence of unsaturation exercised by the double bond. This aromatic system exhibits, as might be expected, an influence favorable for substitution in the 8-position of the purine molecule."

(7) Pellizzari, *Gazz. chim. ital.*, **17**, 412 (1887).

(8) (a) Piloty and Finkh, *Ann.*, **333**, 41 (1904); (b) Mohlau and Litter, *J. prakt. Chem.*, **73**, 453 (1907); (c) Kuhling and Kaselitz, *Ber.*, **39**, 1319 (1916); (d) also recent work of Rudy and Cramer, *ibid.*, **72**, 227 (1939).

monoamines leading to complicated molecular changes with formation of the corresponding amine salts of purpuric acid, which finally undergo conversion to murexide.[8a] Strecker[9] first disclosed this remarkable behavior of alloxan in a study of its action on α-amino acids, and observed that such acids are oxidized by alloxan to the corresponding aldehydes with formation of murexide.[10]

The authors are now able to report that the reactivity of alloxan toward methylenediamine and ethylenediamine has been investigated, and that neither diamine was found to be productive of any changes of immediate biochemical interest. Methylenediamine showed no tendency to react with alloxan to form xanthine or any desmotropic modification of a purine (IV) corresponding to the constitution proposed for toxoflavin (I). Also ethylenediamine failed to react with alloxan in a manner corresponding to that of *o*-phenylenediamine with formation of a cyclic anil (XI).



IX

X

XI

A description of the reactions revealed in this study is given in the experimental part of this paper. It is also of especial interest to note here that the imido-oxime derivative of methylalloxan (IX), which is characterized by the same anil type of unsaturation as is expressed in van-Veen's proposed formula for toxoflavin (I), does not react with *o*-phenylenediamine to form *methylalloxazine* (X). VanVeen and Baars[3] report that *toxoflavin* is not methylated further by the action of diazomethane or methyl iodide and undergoes complete destruction by energetic action.

Experimental Part

Attempts at Condensation of Alloxan with Methylenediamine.—The methylenediamine dihydrochloride used in this research was prepared according to the method described by Knudsen.[11]

(9) Strecker, *Ann.*, **123**, 363 (1862).

(10) Leucine = isovaleraldehyde; alanine = acetaldehyde; glycine = formaldehyde. See also Hurtley and Wootten, *J. Chem. Soc.*, **99**, 288 (1911).

(11) Knudsen, *Ber.*, **47**, 2698 (1914).

1. In Glacial Acetic Acid Solution.—One gram (0.009 mole) of pulverized methylenediamine dihydrochloride was added to an acetic acid solution (20 cc.) of 0.8 g. (0.01 mole) of fused sodium acetate. After standing for three hours with occasional shaking, the mixture was refluxed a few minutes and allowed to stand until cold. The acid solution was then filtered to remove undissolved sodium chloride and mixed with a solution of 0.3 g. (0.0028 mole) of alloxan anhydride in 10 cc. of glacial acetic acid. A deep red color developed immediately. After four days of standing the acid solution was heated at 90–100° for one and one-half hours, when the red coloration became somewhat lighter. On cooling, a small amount of crystalline material separated. It was washed carefully with dry ether and dried *in vacuo* over concentrated sulfuric acid; yield 0.12 g. This showed no sharp m. p. and slowly decomposed when heated above 253°. It was identified as alloxan. This experiment was repeated but without securing any evidence of the formation of a purine condensation product. The recovered alloxan was highly discolored, due apparently to admixture of a small amount of murexide.

Anal. Calcd. for $C_4H_2O_4N_2$: N, 20.00. Found: N, 19.73.

2.—No formation of a purine was observed by interaction of methylenediamine dihydrochloride with alloxan in aqueous solution in the presence of sodium acetate. The solution took on a deep red color due to slow formation of murexide, and the odor of formaldehyde was detected easily.

3.—Attempts also were made to bring about a condensation in absolute alcohol solution. In an acidified solution (with hydrochloric acid) ammonium chloride was precipitated, and formaldehyde generated. Alloxan alcoholate was used also for condensation with methylenediamine but without success. Interaction of the diamine with alloxan in pyridine solution led to the production of a black tar. It is of interest to note here that methylenediamine dihydrochloride as well as trioxymethylene reduce Fehling's solution after gentle warming of the alkaline solution.

Condensation of Alloxan with Ethylenediamine. 1. In Acid Solution.—One and six-tenths grams (0.01 mole) of alloxan monohydrate dissolved in 10 cc. of water was added to a solution of 0.75 g. (0.012 mole) of ethylenediamine in 7 cc. of 6 *N* hydrochloric acid (0.042 mole). The characteristic murexide coloration did not develop and a small quantity of colorless crystals finally separated on standing. The yield was only 0.5 g. and this was not increased by warming the solution. This reaction product contained chlorine and was dried for analysis *in vacuo* over concentrated sulfuric acid; m. p. 225–230° with decomposition. The crystals were colored slightly pink, indicating the possible admixture of a trace of murexide. The results of analysis indicated a constitution conforming to that of a hydrochloride of alloxan-[ethylenediamine-anilhydrate]-5.

Anal. Calcd. for $C_6H_{10}O_4N_4 \cdot HCl$: C, 30.1; H, 4.6; N, 23.4. Calcd. for $C_6H_{10}O_4N_4 \cdot HCl \cdot H_2O$: C, 29.1; H, 4.4; N, 22.7. Found: C, 29.7; H, 3.80; N, 22.74.

The filtrate from the preceding experiment was diluted with acetone until no further precipitation of solids took place (1.44 g.). This substance was identified as the di-

hydrochloride of ethylenediamine equivalent to 87% of the diamine originally used.

Anal. Calcd. for $C_2H_{10}N_2Cl_2$: N, 21.1. Found: N, 21.2.

2. In Alcohol Solution.—Alloxan anhydride (0.4 g. or 0.0028 mole) was dissolved in 15 cc. of absolute alcohol, and dry hydrogen chloride gas bubbled into the solution until it was decolorized to a pale yellow. After cooling in a refrigerator (two days) and finally filtering, 0.2 g. (0.0033 mole) of ethylenediamine in 10 cc. of absolute alcohol was added. A colorless, granular precipitate deposited, and took on a pink color on exposure to the air. It was separated, washed with absolute alcohol and ether and then dried *in vacuo* over concentrated sulfuric acid. The yield was only 0.5 g. The compound was free from chlorine. It was very soluble in water and attempts to purify it by precipitation from aqueous solution with acetone or pyridine, or by diluting an acetic acid solution with chloroform, were unsuccessful. A specimen dried to constant weight at 100° over phosphoric anhydride melted at about 214° with decomposition.

Anal. Calcd. for alloxan-[ethylenediamine-anilhydrate]-5, $C_6H_{10}O_4N_4$: C, 35.64; H, 4.9; N, 27.71. Found: C, 35.27, 36.2; H, 4.28, 4.53; N, 26.89, 28.1.

Two-tenths gram of the above condensation product was dissolved in 11 cc. of 0.1 *N* hydrochloric acid and combined with 22 cc. of water containing 0.3 g. of picric acid. After concentrating the solution *in vacuo*, and cooling, the picrate of ethylenediamine separated. This salt was purified by crystallization from water and melted at 227–235° with decomposition. When mixed with pure ethylenediamine picrate, no depression of the melting point was observed.

Anal. Calcd. for $C_{14}H_{14}O_{14}N_8$: N, 21.62. Found: N, 21.82.

Ethylenediamine gives an intense crimson coloration when added to an aqueous solution of alloxan. The dihydrochloride of the amine produces no coloration under the same experimental conditions. Furthermore, the presence of ethylenediamine dihydrochloride did not interfere with the formation of *alloxazine* by interaction of *o*-phenylenediamine dihydrochloride with alloxan in aqueous solution.

Interaction of *o*-Phenylenediamine Dihydrochloride with Methylalloxan-4-imino-5-oxime.—Toxoflavin and methylalloxan[12] react with *o*-phenylenediamine dihydrochloride in aqueous solution on warming to give methylalloxazine $C_{11}H_{18}O_2N_4$ (X). The above oxime derivative (IX)[13] does not interact with the *o*-diamine in a similar manner to form this alloxazine derivative. Combination in boiling water solution leads to the formation of an amorphous, brown substance which is soluble in hot acetic acid, and is reprecipitated in an amorphous condition by addition of water. We were unable to isolate any product of crystalline character from the reaction mixture.

Summary

1. Attention is called to the characteristic differences in chemical behavior of the pyrimidine alloxan toward aromatic and aliphatic amines.

2. Methylenediamine and alloxan do not interact to form xanthine or any tautomeric modification of this purine.

3. Ethylenediamine shows a different behavior toward alloxan than its aromatic analog *o*-phenylenediamine, and does not interact to form the corresponding aliphatic alloxazine analog. A simple addition product is formed without cyclization.

4. The oximido-imide (4,5) derivative of methylalloxan does not interact with *o*-phenylenediamine to form an alloxazine.

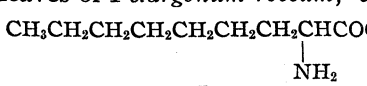
Synthesis of α-Aminopelargonic Acid

BY TREAT B. JOHNSON

At the urgent request of a group of workers in experimental medicine the author consented to undertake the synthesis of this unknown α-amino acid (I). Polypeptide combinations of this amino acid are believed to occur in the degradation products of the proteins of beet roots and in leaves of *Pelargonum roseum;* and several



I

dipeptide derivatives containing this amino acid have been described previously by Hopwood and Weizmann[1] in 1911.

The fact that pelargonic acid itself is known to influence certain physiological changes of interest to medicine, lends interest in the possible physiological behavior of the unknown amino acid and its derivatives. The fatty acid is characterized, for example, by its physical capacity as a surface-active substance and may act, depending upon the percentage present, as an accelerator or an

TABLE I

Oenanthol, g.	Hydantoin, g.	Glac. acetic acid, cc.	Sod. acetate, g.	Time, hrs.	Temp., °C.	M. p., °C.	Hydantoin yield, g.
6	5	30	15	8	140–150	156–158	0.75
6	5	30	30	9	140–150	156–158	0.65
11.4	10	40	50	9	140–150	156–158	2.60
6	5	30	30	9	140–150	156–158	1.8
26	22.8	120	120	9	140–150	156–158	6.3
14	11.6	60	60	10	140–150	156–158	2.4

inhibitor of fermentation.[2] It also has been shown to be bactericidally effective toward certain organisms due to its marked surface-tension depressant action.[3] Addition of pelargonic acid to washed blood cells is known to increase their glucolytic activity to a marked degree. The acid exhibits also a characteristic physiological influence when incorporated into ester constructions of the procaine type (II). In the quantitative comparisons of a series of aliphatic procaine analogs it was shown that the narcotic effect of such esters increases in a normal series until the pelargonate derivative (II) is reached, when toxicity is enhanced to a maximum.[4]

$CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_2COOCH_2CH_2N(C_2H_5)_2 \cdot HCl$

II

For the preparation of this amino acid (I) the author has applied successfully the aldehyde–hydantoin method of synthesis of α-amino acids originally developed in this Laboratory by Wheeler.[5] The different steps of this method are expressed below (III–VI).

$$\underset{\text{III}}{RCHO} \longrightarrow \underset{\text{IV}}{RCH{=}\overset{\displaystyle\frown}{C}CONHCONH} \longrightarrow$$

$$\underset{\text{V}}{RCH_2\overset{\displaystyle\frown}{C}HCONHCONH} \longrightarrow \underset{\text{VI}}{RCH_2CH(NH_2)COOH}$$

While this method of synthesis finds very general application when applied with aromatic aldehydes (R = C_6H_5, etc.), it has proved of no practical value, from a synthetic point of view, for the utilization of aliphatic aldehydes in α-amino acid synthesis. It is, therefore, of special interest to report that the author has succeeded in applying this technique of α-amino acid synthesis successfully with the aliphatic aldehyde—*oenanthol*. This aldehyde condenses with hydantoin to form the oenantholal-hydantoin (IV).[6] The latter compound is reduced easily to the saturated hydantoin (V); and this undergoes a normal hydrolysis by digestion with alkali yielding the desired α-aminopelargonic acid I.

(6) R = $CH_3(CH_2)_5CH{=}$.

Experimental Part

Oenanthol, $CH_3(CH_2)_5CHO$.—All the oenanthol used in this work, with the exception of 10 g. of a Kahlbaum stock specimen, was manufactured by destructive distillation *in vacuo* of a high grade of castor oil. Heating this oil at an oil-bath temperature of 290–300° a fraction was collected which distilled from 60–68° at a pressure of 23–30 mm. This fraction of crude oenanthol was then purified by distillation at ordinary pressure and a fraction of oenanthol was finally collected boiling at 152–155°. Pure oenanthol boils at 155° at 760 mm. The average yield of oenanthol was 14 g. of the pure aldehyde from 280 g. of castor oil.

Condensation of Oenanthol with Hydantoin

Formation of $CH_3(CH_2)_5CH{=}C(\text{—}NH\text{—}CO\text{—}CO\text{—}NH\text{—})$, **Oenantholal-hydantoin.**—This hydantoin was obtained by digesting molecular proportions of hydantoin and oenanthol in glacial acetic acid solution with anhydrous sodium acetate. The results of the different condensations and the experimental conditions are recorded in Table I.

The yields of hydantoin condensation products were irregular and were not increased by incorporating acetic anhydride with the acetic acid and sodium acetate. After the end of the digestion period the reaction mixture was mixed with water and cooled. The unreacted oenanthol was extracted with ether, leaving behind the insoluble hydantoin derivative. This compound is purified easily by recrystallization from boiling absolute alcohol. It separates on cooling in the form of colorless rosets which melt at 157–159°.

Anal. Calcd. for $C_{10}H_{16}O_2N_2$: C, 61.22; H, 8.16; N, 14.28. Found: C, 61.01; H, 7.98; N, 14.31, 14.50.

The hydantoin dissolves easily in dilute sodium hydroxide solution and is reprecipitated by acidifying the alkaline solution with hydrochloric acid.

Reduction of Oenantholal-hydantoin

Formation of $CH_3(CH_2)_6CH(\text{—}NH\text{—}CO\text{—}CO\text{—}NH\text{—})$, **Hydantoin of α-Aminopelargonic Acid.**—For reduction of the above oenantholal-hydantoin the following reaction mixture was prepared: 5.5 g. of hydantoin, 12.5 g. of $SnCl_2 \cdot 2H_2O$, 75 cc. of 20% hydrochloric acid and 50 cc. of alcohol. This mixture was heated at boiling water-bath temperature for one and one-half hours and the excess of alcohol then

evaporated at 100°. The residue left behind was then triturated with water, filtered and the insoluble precipitate saved (see below). The aqueous filtrate was then saturated with hydrogen sulfide gas to precipitate tin as sulfide. After filtering off this tin sulfide precipitate and evaporating the filtrate to dryness no organic residue was recovered.

The insoluble precipitate (above) proved to be the desired reduction product. It was very insoluble in cold water, but separated from boiling water in colorless crystals melting at 142–143°. The total yield of pure crystallized hydantoin was 3.0 g. In a second experiment 8.8 g. of oenantholal-hydantoin was reduced under exactly the same conditions and yielded 8.8 g. of the desired reduced hydantoin.

Anal. Calcd. for $C_{10}H_{18}O_2N_2$: N, 14.14. Found: N, 14.17, 14.09.

Hydrolysis of the Reduced Hydantoin to α-Aminopelargonic Acid, $CH_3(CH_2)_6CH(NH_2)COOH$.—This hydantoin proved to be very resistant to hydrolysis by the action of barium hydroxide. Three grams of the pure reduced hydantoin was suspended in 1000 cc. of a hot, saturated solution of barium hydroxide and the mixture refluxed at its boiling point until the evolution of ammonia gas ceased. This actually required a digestion for fifty-six hours. The barium was then exactly precipitated as barium sulfate by adding the required amount of sulfuric acid, and bringing the solution to an exact neutral point to litmus. After filtering from barium sulfate, the clear aqueous solution was evaporated to dryness when we obtained 2.4 g. of the required α-aminopelargonic acid or 92.3% of the theoretical.

This α-amino acid is very difficultly soluble in hot water, alcohol, benzene and glacial acetic acid. It was purified for analysis by dissolving in hot, dilute hydrochloric acid, and cooling, when the hydrochloride of the amino acid crystallized out as fine colorless needles. This salt showed no definite melting point but slowly underwent decomposition on heating. It was dried for analysis over phosphorus pentoxide in an Abderhalden vacuum drier.

Anal. Calcd. for $C_9H_{20}O_2NCl$: N, 6.68; Cl, 16.94. Found: N, 6.90, 6.52; Cl, 16.81.

In order to obtain the free α-aminopelargonic acid (I) 1 g. of the above hydrochloride was dissolved in hot water and the solution allowed to cool slowly. The amino acid separated in the form of colorless, flaky crystals. This acid did not show a definite melting point and underwent decomposition when heated between 236 and 256°, giving off dense vapors. The yield of free acid was 0.63 g. The crystals gave no test for chlorine, indicating complete dissociation of the hydrochloride in aqueous solution.

Anal. Calcd. for $C_9H_{19}O_2N$: C, 62.42; H, 10.98; N, 8.10. Found: C, 62.23; H, 10.83; N, 8.40, 7.90.

Summary

1. Oenanthol can be utilized with success for the synthesis of α-aminopelargonic acid by application of the aldehyde-hydantoin method of amino acid synthesis.

Synthesis of 2-*n*-Butyl-α-naphthol

BY YUOH-FONG CHI[1]

In this short paper is described a method of synthesizing 2-*n*-butyl-α-naphthol, which promises to have practical value as an antiseptic. This compound is formed by reducing 2-*n*-butyryl-α-naphthol, which is in turn obtained by condensing α-naphthol with *n*-butyric acid in the presence of fused zinc chloride.

It has long been known that fatty acids react in a characteristic manner with phenols and resorcinol in the presence of fused zinc chloride giving hydroxy-ketones.[2] α-Naphthol also condenses with glacial acetic acid in the presence of acetic anhydride and zinc chloride giving 2-acetyl-α-naphthol.[3] The author finds that α-naphthol reacts likewise with *n*-butyric acid giving 2-*n*-butyryl-α-naphthol, m. p. 85–86°, which is identified by formation of its oxime and semicarbazone. A secondary product of the reaction is α-naphthol *n*-butyrate.

The hydroxy-ketones, such as 2-acetylhydroquinone, 4-acetylresorcinol, 4-propionylresorcinol, 2-propionylhydroquinone, 4-*n*-butyrylresorcinol, 4-acetylanisole, 4-acetylphenetole, 4-propionylphenetole, 2,5-dimethoxypropiophenone, 3,4-dimethoxypropiophenone, etc., which contain the hydroxyl or alkoxyl group in the benzene ring, have been shown to undergo reduction to their corresponding alkyl derivatives by digesting with zinc amalgam and strong hydrochloric acid.[4] In like manneer 2-*n*-butyryl-α-naphthol is reduced

to 2-*n*-butyl-α-naphthol according to the Clemmensen technique.

Experimental Part

2-*n*-Butyryl-α-naphthol.—Fifty-eight and four-tenths grams of α-naphthol was digested with 105.6 g. of *n*-butyric acid in the presence of 108 g. of fused zinc chloride for one minute. The mixture, while still warm, was then poured in a fine stream into 1200 cc. of cold water with stirring, whereupon the oil solidified to a brownish crystalline mass. After being filtered and dried, this reaction product was purified by fractionating in a vacuum. The following three fractions: (a) b. p. 135–150° at 3 mm., (b) b. p. 150–165° at 3 mm., and (c) b. p. 165–170° at 3 mm., were collected. Each fraction was redistilled at 1 mm. pressure, whence two main subfractions: (a) b. p. 125–130°, and (b) b. p. 145–152°, were finally obtained. The yield of the high boiling fraction (b. p. 145–152° at 1 mm.) was 34.3 g. It crystallized from hot petroleum ether in yellow rhombic crystals melting at 85–86°. The ketone also can be recrystallized from ether.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.46; H, 6.59. Found: C, 78.51, 78.39; H, 6.65, 6.73.

The low boiling fraction (b. p. 125–130° at 1 mm.) was proved to be α-naphthol *n*-butyrate. It was purified by recrystallization from a mixture of benzene and petroleum ether, separating in colorless needles, melting at 95.5–96.5°. The yield was 11.6 g. On treatment with hydroxylamine, it was changed into naphthol.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.46; H, 6.59. Found: C, 78.22, 78.35; H, 6.35, 6.50.

Oxime.—One and seven-hundredths grams of 2-*n*-butyryl-α-naphthol dissolved in a small volume of alcohol was treated with 0.7 g. of hydroxylamine hydrochloride and 0.53 g. of sodium carbonate dissolved in a small volume of water, and sufficient alcohol was added to obtain a uniform solution. This was then refluxed for four hours, and finally diluted with a large volume of water, whereupon the impure oxime precipitated. It was filtered, dried, and recrystallized from benzene and petroleum ether in the form of yellow needles, melting at 119° to a clear oil.

Anal. Calcd. for $C_{14}H_{14}O_2N$: N, 6.11. Found: N, 6.26, 6.33.

Semicarbazone.—One and seven-hundredths grams of 2-*n*-butyryl-α-naphthol dissolved in a small volume of alcohol was treated with 1.12 g. of semicarbazide hydrochloride and 0.53 g. of sodium carbonate dissolved in a small volume of water, and sufficient alcohol to obtain a uniform solution. This was heated on a water-bath for four hours, and water added to precipitate the semicarbazone. This was purified by dissolving in a mixture of alcohol, benzene and petroleum ether, and allowing to stand in a vacuum desiccator over sulfuric acid, whereupon the semicarbazone crystallized in microscopic crystals and melted at 201–202° to a clear oil. The yield was 0.3 g.

Anal. Calcd. for $C_{25}H_{17}O_2N_3$: N, 15.50. Found: N, 15.70, 15.61.

2-*n*-Butyryl-α-naphthol Methyl Ether.—Ten and seven-tenths grams of 2-*n*-butyryl-α-naphthol and 2.8 g. of potassium hydroxide were dissolved in 500 cc. of alcohol, and 5 cc. of dimethyl sulfate was added gradually drop by drop, while the solution was shaken vigorously. This was then heated at 50° for four hours to complete the reaction and the solution boiled for five minutes in order to destroy the excess of dimethyl sulfate and remove the excess of alcohol. This solution was then extracted with a large volume of benzene, the benzene solution dried with anhydrous sodium sulfate, filtered, and heated on a water-bath to remove the solvent. The oil left behind solidified on cooling and distilled at 155–157° at 1 mm. pressure. The yield was 6.5 g. After recrystallization from petroleum ether, it melted at 80–81°.

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 78.90; H, 7.07. Found: C, 78.77, 78.83; H, 7.01, 6.94.

2-*n*-Butyryl-α-naphthol Ethyl Ether.—Ten and seven-tenths grams of 2-*n*-butyryl-α-naphthol dissolved in 500 cc. of alcohol was heated for eight hours with 6.5 g. of ethyl bromide and 2.8 g. of potassium hydroxide. After distilling off the alcohol the residue was extracted with a large volume of benzene; the solution was dried with anhydrous sodium sulfate, filtered, and finally heated on a water-bath to remove the solvent. The oil left behind solidified and distilled at 158–159° under 1 mm. pressure. After recrystallization from petroleum ether, it melted at 79–81°.

Anal. Calcd. for $C_{16}H_{18}O_2$: C, 79.29; H, 7.49. Found: C, 79.11; H, 7.57.

2-*n*-Butyl-α-naphthol.—Ten and seven-tenths grams of 2-*n*-butyryl-α-naphthol was digested with 50 g. of zinc amalgam suspended in a mixture of 50 cc. of concentrated hydrochloric acid and 50 cc. of water for seventeen hours. After each hour's boiling, 10 cc. of concentrated hydrochloric acid was added, until a total volume of 150 cc. of hydrochloric acid was used for the reaction. After the acid solution, with a layer of brown oil floating on the surface, was separated from the unreacted zinc amalgam and cooled, the crude 2-*n*-butyl-α-naphthol solidified. It was dried and distilled at 140–149° at 1 mm. pressure. The yield was 6.5 g. After purification by recrystallization from petroleum ether, it separated in colorless needles, melting at 73–74°. On keeping for two months it becomes colored.

Anal. Calcd. for $C_{14}H_{16}O$: C, 83.95; H, 8.06. Found: C, 83.99, 83.84; H, 8.24, 8.19.

Summary

1. α-Naphthol condenses normally with *n*-butyric acid giving 2-*n*-butyryl-α-naphthol.

2. 2-*n*-Butyl-α-naphthol is obtained by reduction of 2-*n*-butyryl-α-naphthol by Clemmensen's method.

3. The bactericidal properties of this new naphthol are under investigation.

Fluorinated Derivatives of Propane. III

BY ALBERT L. HENNE AND MARY W. RENOLL

Introduction.—In the preceding paper of this series,[1] the fluorination of C_3Cl_8, of *a*-C_3HCl_7, and of *s*-C_3HCl_7 was described. Formulas for the mono- and the difluorides were demonstrated and plausible formulas were presented for the trifluorides. The present paper proves the correctness of the trifluoride assumptions and describes newly prepared tetrafluorides, for which it offers plausible formulas.

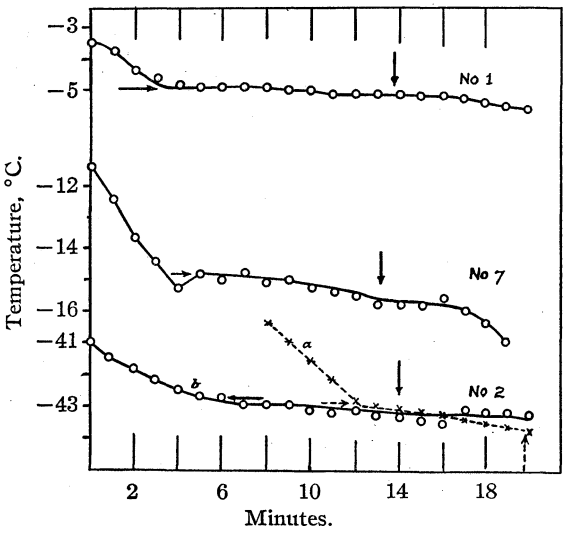

Fig. 1.—Horizontal arrows show the temperature at which crystals were unmistakably seen. Vertical arrows denote end of stirring. a, b and c denote different rates of cooling.

Procedure.—The methods of fluorination and chlorination were the ones used in the preceding papers. So also were the methods of purification and the physical measurements. The analyses for chlorine and fluorine were made after decomposing the organic fluorochlorides over red hot calcium oxide, in a small steel bomb. The freezing curves required a great deal of perseverance because the latent heat of fusion of polyfluorides is small, and because the mushy crystals create a viscous mass, difficult to stir adequately. The rate of cooling must be slow, and the best results were obtained with a cooling bath kept about 5° below the freezing point under measurement. These difficulties are illustrated graphically in Fig. 2.

(1) Henne and Ladd, THIS JOURNAL, **60**, 2491 (1938).

Results.—The actual experimental results appear in the table and diagrams. Figure 1 gives the freezing curve of $CCl_2FCCl_2CClF_2$ (no. 1), of $CCl_3CClFCClF_2$ (no. 7) and of $CClF_2$-CCl_2CClF_2 (no. 2) taken at two different rates of cooling (a and b). Figure 2 refers to CCl_3-$CClFCF_3$ (no. 8), taken at three different rates of cooling (a, b and c); it illustrates the difficulties prevailing when a small sample is used; on both curves b and c, the crystals were seen at −15.8°, and this was adopted as the freezing point, although it is quite probable that the true point may be as much as one degree higher.

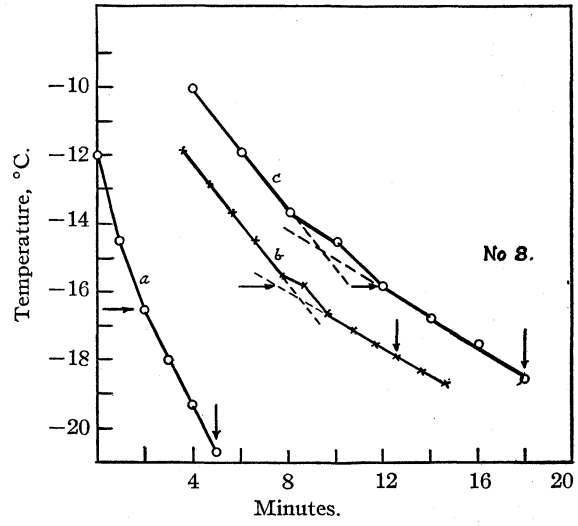

Fig. 2.—Horizontal arrows show the temperature at which crystals were unmistakably seen. Vertical arrows denote end of stirring. a, b and c denote different rates of cooling.

In the table, no comments are required except for no. 4. In this case the analysis result is explained by the presence of trichloroethylene.

Determination of the Formulas.—The procedure used follows that of the preceding paper. Specifically, the trifluorides were obtained from known difluorides, and since no reason exists to expect rearrangements of halogen atoms during fluorination, there are only a limited number of places available for the third fluorine atom. The same reasoning holds true for the fourth fluorine atom of the new tetrafluorides. Reactions with zinc in alcohol gave additional information as

to the nature of the halogens attached to adjacent carbon atoms. Finally, the heptahalogenated derivatives (which form glasses at low temperature) were chlorinated in sunlight to crystallizable octahalogenated derivatives and the crystals were compared. The experimental evidence thus obtained was sufficient to establish definitely the formulas of the trifluorides. In the case of the tetrafluorides this did not suffice, as the experimental evidence could only reduce the choice to a limited number of possibilities, and establish a gradation as to their plausibility. The final choice was based on the agreement between predicted and observed melting points, a procedure which can be defended in this particular case on two counts: (a) there is a marked parallelism between the melting points on the one hand, and the number and place of the fluorine atoms on the other hand, which can be seen in the preceding papers on ethane and propane derivatives, and hence it is possible to predict melting points within 2 or 3°. (b) The final choices are to be made between alternates with widely separated melting points, that is, at least 40° apart. This is a consideration of paramount importance and in no case should a choice be made between melting points which can be considered as in the same range.

It should again be emphasized that in the following discussion, a clear cut distinction is always made between demonstrated formulas and plausible formulas, and in the latter case an effort is made to rate the degree of plausibility.

(1) **$CCl_2FCCl_2CClF_2$, m. p. −4.9°.**—This trifluoride was obtained from $CCl_3CCl_2CClF_2$ as well as from $CCl_2FCCl_2CCl_2F$, and in neither case was there another trifluoride formed. Consequently, the proposed formula is experimentally demonstrated.

(2) **$CClF_2CCl_2CClF_2$, m. p. −42.9°.**—This tetrafluoride was easily obtained from the preceding compound. Besides the proposed formulation, it can have only two alternates, namely, $CCl_2FCClFCClF_2$, or $CCl_2FCCl_2CF_3$. The choice results from the following reasons, based on general analogies: (a) the fluorination course and the regularity of the freezing point depression recalls the case of CCl_3CCl_3, whose trifluoride CCl_2FCClF_2 (m. p. −36°) freezes 60° below the difluoride CCl_2FCCl_2F (m. p. 24°) and whose tetrafluoride $CClF_2CClF_2$ (m. p. −94°) freezes 58° lower than the trifluoride. (b) The alternate formulas call for widely different melting points, namely, about −80° for $CCl_2FCClFCClF_2$, and not lower than −5° for $CCl_2FCCl_2CF_3$. The formula adopted is therefore a plausible hypothesis.

(3) **$CCl_2FCHClCClF_2$.**—This compound was obtained from the established $CCl_2FCHClCCl_2F$, with much decomposition. To prove its structure, it was proposed to remove one molecule of hydrogen chloride by means of an alcoholic alkali, then to chlorinate the resulting olefin to obtain a fully halogenated trifluoride. The latter was expected to freeze at −4.9°, thereby proving identical with $CCl_2FCCl_2CClF_2$ (no. 1) and establishing the correctness of the proposed formula. However, the reaction did not follow the expected course, and hydrolysis occurred: the only reaction product that could be isolated boiled at 104–109° at 7 mm., had a density d^{20}_4 1.1794, and a refractive index $n^{20}D$ 1.4320. Its analysis indicated 5.62% H, 42.28% C, 18.87% Cl, and no fluorine. This information, and an experimental determination of the molecular magnitude as about 190, indicated that the compound was the diethyl ester of chloromalonic acid, and this was confirmed by the good agreement between the computed molecular refraction (42.54) and the experimental value (42.80) and by the literature. The chloromalonic ester proves that the central chlorine atom is still unreplaced by fluorine, and demonstrates therefore that the proposed formula of the trifluoride no. 3 is correct.

Efforts to replace the hydrogen atom by chlorine in sunlight, and directly to manufacture $CCl_2FCCl_2CClF_2$ (no. 1) failed completely on account of complete decomposition, an unpredicted behavior.

(4) **$CClF_2CHClCClF_2$.**—This compound, obtained with much decomposition from the preceding trifluoride, proved unstable and never was purified adequately. The best preparations were shown by analysis to be not better than 75% pure. Complete decomposition occurred during chlorination, or during a treatment with alkalies, and it was therefore impractical to link the formula with that of the tetrafluoride no. 2. The formula proposed rests merely on the assumption that fluorination takes place in a symmetrical fashion.

(5) **$CHCl_2CClFCClF_2$.**—This trifluoride was obtained with great ease from the known difluoride $CHCl_2CCl_2$-

$CClF_2$. By chlorination in sunlight it gives a compound $C_3Cl_5F_3$, melting at $-15°$ and different from $CCl_2FCCl_2CClF_2$ (no. 1), a fact which excludes $CHClFCCl_2CClF_2$ as its possible formulation. The choice is thus restricted to the proposed formula, or else to $CHCl_2CCl_2CF_3$. The alternate is not considered plausible, because its chlorination would yield $CCl_3CCl_2CF_3$, a compound which should melt at 20° or higher (CCl_3CF_3 melts at 13°, and a lengthening of the chain by a $-CCl_2-$ group raises the melting point by more than 10°). To conclude, the proposed formula should be regarded as a very plausible hypothesis.

(6) **$CHCl_2CClFCF_3$.**—This compound was obtained from the preceding trifluoride (no. 5) at high temperature and with appreciable decomposition, in sharp contrast with the previous steps. Chlorination in sunlight gave a compound $C_3Cl_4F_4$, which melts at $-15.5°$, and which yields quantitatively an olefin $C_3Cl_2F_4$ and zinc chloride, when treated with zinc in alcohol. This proves that the central carbon atom still bears a chlorine atom. The choice is therefore restricted to $CHClFCClFCClF_2$ and $CHCl_2CClFCF_3$, if the formula of the parent trifluoride (no. 5) is accepted as proposed. The decision to select the second formula is based on the melting point of the compound obtained after chlorination, because the other formula would call for $CCl_2FCClFCClF_2$ after sunlight chlorination, a compound which should freeze at about $-70°$.

For the sake of completeness, it might be added that by starting from the implausible formula of the parent compound, no. 5, *i. e.*, from $CHCl_2CCl_2CF_3$, the tetrafluoride no. 6 could only be $CHClFCCl_2CF_3$ or $CHCl_2CClFCF_3$, and the second formula (identical with that adopted in the preceding paragraph) could not be preferred to the first one because the compounds obtained after sunlight chlorination would have to be written $CCl_2FCCl_2CF_3$ or $CCl_3CClFCF_3$, respectively, and both formulas would call for melting points in the vicinity of $-15°$.

The conclusion is therefore that the proposed formula is acceptable.

(7) **$CCl_3CClFCClF_2$** was synthesized by chlorination of no. 5, and is discussed above, together with the formula of no. 5.

(8) **$CCl_3CClFCF_3$** was obtained from no. 6 and is discussed together with it; its freezing curve was taken on a sample of a few grams only.

(9) **$CCl_2{=}CFCF_3$** was obtained by the action of zinc on no. 8.

(10) **$CCl_2BrCFBrCF_3$** resulted from the bromination of the preceding ethylenic compound. The freezing point was taken on 10 cc. of material obtained by three fractional crystallizations from a batch melting originally at 28°.

Discussion.—The experimental results show, in confirmation of the preceding paper, that $-CCl_3$ groups are by far the most sensitive to fluorination, that $CHCl_2-$ groups are exceedingly resistant, and that —CHCl— groups undergo decomposition before being fluorinated. They show also that $-CCl_2-$ groups are quite resistant to fluorination and require severe conditions to go from the —CClF— to the $-CF_2-$ stage. This last observation applies only to $-CCl_2-$ groups surrounded by halogenated groups and contrasts with the fact that $-CCl_2-$ groups surrounded by hydrogen-bearing carbons are exceedingly easily fluorinated.[2]

The behavior of the compounds containing a —CHCl— group was novel on two counts, the breakage of the molecule at that point and the hydrolysis of the adjacent trihalogenated groups.

The synthesis of a $-CF_3$ group, despite the fact that it was adjacent to a halogen-bearing carbon atom, is a feature which has only one analogous but not identical precedent, namely, the fluorination of $CHCl_2CHF_2$ to CH_2ClCF_3.[3] In other cases where $-CF_3$ groups were obtained, the adjacent group bore hydrogen exclusively.[4] Besides showing the behavior of highly fluorinated compounds, the experimental results fortify the idea that (from the practical standpoint) high molecular polyfluorides should be synthesized by condensation of smaller highly fluorinated molecules, rather than by the fluorination of high molecular compounds obtained by condensation.

Summary

Ten new compounds listed in Table I have been synthesized, and their structural formulas have been discussed.

Photochemical Studies. XXIX. The Decomposition of Diethyl Ketone at Short Wave Lengths. A Comparison of Acetone, Ethyl Methyl Ketone and Diethyl Ketone Near 3000 Å.

BY VICTOR R. ELLS[1] AND W. ALBERT NOYES, JR.

The photochemical decompositions of acetone[2] and of ethyl methyl ketone[3] in the wave length region 1850–2000 Å. have been studied. The salient facts of these investigations may be summarized as follows.

(a) The quantum yield of carbon monoxide formation from acetone is about 0.50 at moderate pressures, increases with decreasing pressure, and attains a value of about 0.66 at a pressure of 0.2 mm. In the presence of foreign gases (CO_2, N_2, C_2H_6) this quantum yield is raised.

(b) The quantum yield of carbon monoxide formation from ethyl methyl ketone is about 0.70 at moderate pressures and becomes approximately 0.90 at low pressures.

(c) While for both compounds the ratio of carbon monoxide to hydrocarbons in the products is not far from 1:1, it was shown that diketones are produced upon irradiation of ethyl methyl ketone, both at these short wave lengths and in the near ultraviolet. The quantum yield expressed in terms of molecules of ethyl methyl ketone disappearing was shown to approach a value not far from unity at low pressures.

(d) The yield of methane from ethyl methyl ketone increases with temperature.

The photochemical decomposition of ethyl methyl ketone in the near ultraviolet has been investigated by Norrish and Appleyard,[4] who found the main reaction to give carbon monoxide and a mixture of ethane, propane, and butane. A small amount of decomposition to ethylene and acetaldehyde was also reported.

With ethyl methyl ketone two primary dissociations may be visualized

$$CH_3COC_2H_5 + h\nu = CH_3 + COC_2H_5 \quad (1)$$
$$CH_3COC_2H_5 + h\nu = C_2H_5 + COCH_3 \quad (2)$$

If the primary dissociations of simple ketones have quantum yields of unity, variations in yield are to be associated with the secondary reactions.

Since diethyl ketone can only give propionyl radicals upon rupture of a single carbon–carbon bond adjacent to the carbonyl group, the behavior of this substance upon irradiation may furnish information concerning such radicals.

As shown by Matheson and Zabor,[5] the major portions of the fluorescences of diethyl ketone and of propionaldehyde are identical when excited by near ultraviolet radiation. Thus bipropionyl is probably one of the decomposition products in this region. Unfortunately, no satisfactory method of analyzing for small amounts of this diketone is now available so that quantum yields in the present article are merely those of carbon monoxide formation.

Experimental Procedure and Results

The diethyl ketone (Eastman Kodak Co.) was fractionally distilled several times, both at atmospheric pressure and at reduced pressure. Vapor pressures of this substance have been measured by Rintelen, Saylor and Gross[6] at 10, 30, and 50°, the values being 16.9, 46.1, and 117 mm., respectively. The maximum pressure attainable in the present work (at 27°) is about 38 mm.

The light source has been described,[2] and the method of gas analysis was essentially that of Manning,[7] which has been used with the other ketones.[2,3]

Liquid nitrogen was used first as a refrigerant, the only uncondensed gaseous product being carbon monoxide together with traces of ethane and ethylene. Ethane, butane, and ethylene were pumped off from pentane mush at a temperature between −150 and −155°. A slight hydrocarbon deficiency is again observed in spite of all precautions, indicating that such substances are soluble in the ketone and are difficult to remove.

The hydrogen bromide actinometer was used for measuring the number of quanta absorbed.

Table I shows gas analyses for four runs, two in which radiation from the full aluminum spark was used and two in which the region 1850–2000 Å. obtained through focal isolation was alone present.

TABLE I

ANALYSES FOR HYDROCARBONS AND CARBON MONOXIDE

Pressure $(C_2H_5)_2CO$, mm.	31	28	35	35
Total hydrocarbons, mm.	0.0048	0.0043	0.0236	0.0121
C_4H_{10}, mm.	.0038	.0027	.0161	.0081
C_2H_6, mm.	.0005	.0008	.0038	.0022
C_2H_4, mm.	.0005	.0008	.0037	.0018
CO, mm.	.0045	.0039	.0217	.0108
$CO/[C_4H_{10} + \frac{1}{2}(C_2H_6 + C_2H_4)]$	1.05	1.11	1.09	1.07
% C_2H_5 giving C_4H_{10}	88	77	81	80
Conditions	1850–2000 Å.		Full spark	

From the data in Table I it is evident that most of the ethyl radicals combine to form butane although about 20% disproportionate to give ethane and ethylene. The excess of carbon monoxide is not definite evidence against the formation of bipropionyl because of the difficulty in pumping off the hydrocarbons completely.

Table II shows data for the quantum yield of carbon monoxide formation from diethyl ketone in the wave length region 1850–2000 Å. All runs were made at room temperature (25 ± 2°).

6	60	36.9	.00513	.00561	.91
4	60	36.6	.00371	.00389	.95

The figures in the fifth column are corrected for the thermal decomposition of hydrogen bromide and for the transmission of the windows. When multiplied by Avogadro's number these figures would give the number of quanta absorbed.

There seems to be a slight tendency for quantum yields to increase with decreasing pressure. The results scatter so much that an extrapolation has little meaning, but a value of unity at zero pressure would be compatible with the data. At comparable pressures the quantum yield of carbon monoxide formation is definitely higher for diethyl ketone than for ethyl methyl ketone[3] and for acetone.[2] Table III shows a comparison at even pressures of the values for the three ketones.

Since quantum yields of carbon monoxide formation increase with complexity of ketones in the region 1850–2000 Å. and since the quantum yield of carbon monoxide formation from acetone is considerably higher than in the near ultraviolet, it was deemed interesting to make a comparison of the ketones at the longer wave lengths.

TABLE III

COMPARISON OF QUANTUM YIELDS OF CARBON MONOXIDE FORMATION AT SHORT WAVE LENGTHS FOR ACETONE, ETHYL METHYL KETONE AND DIETHYL KETONE 25 ± 2°

Pressure, mm.	$(CH_3)_2CO$	$CH_3COC_2H_5$	$(C_2H_5)_2CO$
20	0.52	0.76	0.88
8	.56	.78	.90
4	.59	.78	.95
1	.62	.82	(.98)
0.3	.64	.86	(.99)

Values in parentheses are obtained by rough graphical extrapolation.

An aluminum spark was used in conjunction with a red-purple corex filter for this comparison. The main lines absorbed by the ketones lie between 3050 and 3100 Å., but the radiation was not strictly monochromatic. At the low pressures used longer wave lengths would not be appreciably absorbed. The fractions of the incident radiations absorbed by the various ketones were determined with the aid of a photoelectric cell and proved to be nearly the same. While too great stress cannot be placed on absolute values, relative values are of interest in the present discussion.

The quantum yields given in Table IV are based on an assumed value of 0.095 ± 0.01 for that of carbon monoxide production from acetone at 25°.[8]

Based on the assumed value of 0.095 for acetone, the average quantum yield of carbon monoxide formation from ethyl methyl ketone is 0.11 and that from diethyl ketone is 0.97. Therefore, while the yields of the first two are low and nearly the same at 3000 Å., that of the latter is about the same at long as at short wave lengths.

(8) This figure is an average of a large number of runs made by one of us (W. A. N., Jr.) during 1931 using an absolute method with a thermopile calibrated by a standard light source. It agrees well with values which will be published in the near future from this Laboratory. The quantum yields obtained by Damon and Daniels [THIS JOURNAL, **55**, 2363 (1933)] and by Norrish, Crone, and Saltmarsh [*J. Chem. Soc.*, 1456 (1934)] are slightly higher but were obtained at higher temperatures. Since Leermakers [THIS JOURNAL, **56**, 1899 (1934)] has shown the yield to be unity at 163°, the value cited at 25° is a reasonable one in comparison with the others. At 3130 Å. and a temperature of 56° Damon and Daniels found a considerable falling off of yield with pressure. In the unpublished work just cited little change with pressure between 5 and 16 cm. could be found. Pressures in Table IV are below 5 cm. so that some doubt exists concerning absolute values.

TABLE IV

COMPARISON OF QUANTUM YIELDS OF CARBON MONOXIDE FORMATION FROM THREE KETONES NEAR 3000 Å.

Assuming yields to be 0.095 for acetone. The values at 10 mm. pressure are least accurate because of the small amount of absorption.

Ketone	Pressure, mm.	Press. CO formed (V = 531 cc.), mm.	Quantum yield of CO formation
CH_3COCH_3	10	0.0007	(0.095)
$CH_3COC_2H_5$	10	.0006	.082
$C_2H_5COC_2H_5$	10	.0049	.67
CH_3COCH_3	10	.0006	(.095)
$CH_3COC_2H_5$	10	.0007	.11
$C_2H_5COC_2H_5$	10	.0062[a]	.98
CH_3COCH_3	21	.0009	(.095)
$CH_3COC_2H_5$	21	.0011	.12
$C_2H_5COC_2H_5$	21	.0092	.97
CH_3COCH_3	36	.0013	(.095)
$CH_3COC_2H_5$	36	.0016	.12
$C_2H_5COC_2H_5$	36	.0142[b]	1.04

[a] Pressure of butane + ethane + ethylene in this experiment is 0.0060. 0.93 of the ethyl groups form butane, and the remainder disproportionate to ethane and ethylene. [b] Total pressure of hydrocarbons 0.0136 mm. in this experiment.

Discussion of Results

The details of the mechanism of photochemical acetone decomposition in the near and far ultraviolet have not yet been elucidated completely. Since the quantum yield of carbon monoxide formation is appreciably greater at 1850–2000 Å. than at longer wave lengths, it is evident either that the acetyl radical separates with enough energy to make it inherently unstable or that secondary reactions leading to carbon monoxide formation are, for some reason, more probable under the conditions under which the short wave experiments were carried out.

From a variety of sources it is quite certain that the quantum yield of the primary process

$$CH_3COCH_3 + h\nu = CH_3 + COCH_3 \qquad (3)$$

is very close to unity in the near ultraviolet.[9] The low yield of carbon monoxide formation may be due to the reactions

$$CH_3CO + CH_3CO = (CH_3CO)_2 \qquad (4)$$

and

$$CH_3CO + CH_3 = CH_3COCH_3 \qquad (5)$$

The mechanism by which carbon monoxide is produced is uncertain, but two possibilities suggest themselves

$$CH_3CO = CH_3 + CO \qquad (6)$$

$$CH_3 + CH_3CO = C_2H_6 + CO \qquad (7)^9$$

Gorin believes that (6) has too high an activation energy to be important at ordinary temperatures and ascribes carbon monoxide production to (7). While no adequate evidence for or against this choice is available as regards the work in the near ultraviolet, a comparison of the yield at 1850–2000 Å. with that at longer wave lengths makes it appear probable that (6) is important in the former region. It should be noted that (3) followed by (6) would be difficult to distinguish clearly from a primary dissociation into two methyls and carbon monoxide.

If the energy required to produce reaction (3) is assumed to be 70 kcal., a wave length of 3130 Å. provides an excess of 21 kcal. per gram molecule. If the excess appears merely as translational energy, the acetyl radicals would possess 5.5 kcal. of energy per gram molecule in that form. Since, however, they have more degrees of freedom than methyl radicals, they might be expected to retain more than half if all were in the form of vibrational energy. Nevertheless, sufficient energy to cause dissociation would scarcely be available if the activation energy (17 kcal.) assumed by Gorin for (6) is correct. At 2536 Å. the acetyl radicals would acquire 10 kcal. if the energy were all translational. This would still be inadequate to evoke (6) except in a few collisions where thermal energy could supply the deficiency. At 1900 Å., however, 20 kcal. would be given to the acetyl radical as kinetic energy. This could cause dissociation at the first impact by reaction (6). The high quantum yield of CO formation at short wave lengths can be explained in this way. In ethyl methyl ketone, the acetyl radical would acquire more kinetic energy of translation than from acetone, assuming no energy in vibrational degrees of freedom. No account is taken of electronic excitation in these simple calculations.

A quantum yield expression derived from (3), (4), (5), (7), and (8)

$$CH_3 + CH_3 = C_2H_6 \qquad (8)$$

shows no variation with either intensity or with pressure as long as all reactions occur in the homogeneous gas phase and third bodies are unimportant. The inclusion of (6) would mean necessarily that the quantum yield of carbon monoxide formation would increase at low intensities although the formal expression is very complex. While no very good evidence exists on this point at present, such as is available favors this sort of variation with intensity.[10]

(9) See Gorin, *J. Chem. Phys.*, **7**, 256 (1939).

(10) Damon and Daniels, THIS JOURNAL, **55**, 2363 (1933).

At short wave lengths the main portion of carbon monoxide must be formed by a spontaneous dissociation of the acetyl radical. All combination reactions of free radicals which would reduce carbon monoxide formation must be relatively unimportant. Only in this way can the lack of intensity effect on the yield be accounted for unless one wishes to admit a peculiar enhancement of the rate of (7) for at present unknown reasons.

When attention is turned to ethyl methyl ketone, the situation becomes very difficult to understand unless some spontaneous dissociation of the radicals CH_3CO and C_2H_5CO is allowed. It is not very satisfactory, although it may prove necessary to postulate nearly all possible types of primary dissociation of this molecule,[9] including a production of propane and carbon monoxide in one step.

In the decomposition of diethyl ketone, either in the near or in the far ultraviolet, the quantum yield of carbon monoxide formation is not far from unity. If the primary process is

$$(C_2H_5)_2CO + h\nu = C_2H_5 + C_2H_5CO \qquad (9)$$

the propionyl radical must either be very unstable, or it must undergo a very probable reaction analogous to (7). The recombination reactions

$$C_2H_5CO + C_2H_5 = C_2H_5COC_2H_5 \qquad (10)$$
$$C_2H_5CO + C_2H_5CO = (C_2H_5CO)_2 \qquad (11)$$

cannot be important. Some evidence for a slight occurrence of (11) is found from a study of the fluorescence of diethyl ketone.[5]

Without considering for the moment the mechanism by which carbon monoxide may be produced from propionyl radicals, let us assume merely that 90% of such radicals yield carbon monoxide. The acetyl radical may be expected to give carbon monoxide (in the near ultraviolet) not more than one-tenth of the time. Therefore if primary processes (1) and (2) are equally probable, the quantum yield of carbon monoxide production from ethyl methyl ketone should be 0.50 in the near ultraviolet. The data in Table IV show that this is not the case, the actual yield being little greater than for acetone.

It seems necessary to conclude, therefore, that primary process (2) predominates.[11] If one assumes that the low yield of carbon monoxide from ethyl methyl ketone is due to the recombination

$$C_2H_5 + COCH_3 = C_2H_5COCH_3 \qquad (12)$$

and that 0.1 of the acetyl radicals and 0.9 of the propionyl radicals yield carbon monoxide, it can be shown that 0.98 of the primary dissociation goes by (2) and 0.02 by (1). A slight combination between methyl and acetyl radicals would alter these figures somewhat, and acetone would be predicted to appear among the products. The amount of diethyl ketone produced should be negligible, but, on the other hand, biacetyl should result from combinations between acetyl radicals. Since the main part of the fluorescence of ethyl methyl ketone is identical with those of acetaldehyde, acetone, and biacetyl, the occurrence of biacetyl among the products is probable.

The fact that approximately equal quantities of ethane, propane, and butane are produced both in the near and far ultraviolet is difficult to explain with any distribution of methyl and ethyl radicals and must be due to peculiarities in the rates of production of these gases from free radicals.[3] With the above mechanism approximately equal numbers of the two free radicals should form hydrocarbons.

In the far ultraviolet if 0.55 of the acetyl radicals yield carbon monoxide, 0.9 of the propionyl radicals yield carbon monoxide, and the over-all yield of carbon monoxide is 0.80, it can be shown that primary process (1) is slightly more probable than (2). However, variations in the ratio are quite sensitive to the quantum yield figures. Since an amount of energy considerably in excess of that necessary to cause dissociation is absorbed at these wave lengths, slight differences in bond strength might be expected to make little difference in the nature of the dissociation.

The fact that butane is the principal hydrocarbon resulting from the photochemical decomposition of diethyl ketone is not surprising. The extents to which ethyl radicals combine to form butane and disproportionate to ethane and ethylene have not been determined satisfactorily. Perhaps one or the other or both of these reactions occurs on the walls. The results of Meinert[12] on the thermal decomposition of tetraethyllead indicate a high probability of butane formation. The 1:1 ratio of ethane to ethylene is evidence, although not proof, against other reactions intervening in the production of ethane and ethylene.

(11) Professor G. B. Kistiakowsky suggested at a symposium held at Stanford University, August 8–11, 1938, that much of the work on photochemistry of ketones could be explained by assuming that the molecules usually split on the side of the carbonyl group toward the heaviest radical.

(12) Meinert, THIS JOURNAL, **55**, 979 (1933).

Summary

1. The quantum yield of carbon monoxide formation from diethyl ketone in the wave length region 1850–2000 Å. is quite high and seems to approach unity as the pressure is lowered.

2. With an assumed quantum yield of 0.095 at 3000 Å. for carbon monoxide formation from acetone it has been shown that the yield from ethyl methyl ketone is only slightly higher and that that of diethyl ketone is about one.

3. These facts indicate either a high intrinsic instability of propionyl radicals or very probable reactions involving them which lead to carbon monoxide.

4. Ethyl methyl ketone probably dissociates almost but not quite solely to give ethyl radicals in the near ultraviolet. At short wave lengths methyl and ethyl radicals are produced in nearly equal amounts from the primary process.

5. Most of the ethyl radicals form butane, but a small fraction yield ethane and ethylene.

The Palladium–Deuterium Equilibrium

BY LOUIS J. GILLESPIE AND WILLIAM RICHARD DOWNS

The purpose of this investigation has been to study the absorption of deuterium by palladium black in the region of temperature and pressure in which hydrogen and palladium have been found by Brüning and Sieverts[1] and by Gillespie and Galstaun[2] to exhibit a critical solution temperature, and inclusive of the region at 200° and above in which hydrogen and palladium exhibit a tendency toward compound formation—in short, to obtain part of the phase diagram for deuterium and palladium analogous to that of Gillespie and Galstaun for hydrogen and palladium.

Sieverts and Zapf[3] studied the solubility of hydrogen and of deuterium in a palladium wire. The ratio of the solubility of deuterium to that of hydrogen was 0.67 at 300° and increased to 0.91 at 1000°.

Sieverts and Danz[4] studied the absorption of deuterium by palladium black from 20 to 350° at various low pressures (less than 2 atm.). Isotherms at 80 and 100° gave evidence of two solid phases, but in all cases, even for the corresponding curves for hydrogen, there was considerable hysteresis. Sieverts and Danz[5] have also studied the electrical resistance and magnetic susceptibility of palladium wire charged with deuterium.

Since the early work of Oxley[6] the magnetic susceptibility of palladium charged with hydrogen has also been studied by Aharoni and Simon,[7] Svensson,[8] and Michel and Gallissot.[9] The latter have also studied the variations of the lattice parameter, the Brinell hardness and the electrical resistance as hydrogen is added to the metal.

There are recent X-ray studies of the system palladium–hydrogen by Kruger and Gehm[10] and by Owen and Jones.[11] The latter, as well as Michel and Gallissot, found in agreement with the early experience of Wolf[12] that simple degassing of palladium that has been well charged with hydrogen—to the formation of the second (beta) solid solution—does not entirely restore the original physical constants of the palladium, but that high temperature annealing (*e. g.*, 450° for one-half hour[11]) is necessary and sufficient.

This finding is of two-fold interest in connection with the equilibrium of either hydrogen or deuterium with palladium. In the first place, one need not expect the whole of an isotherm containing a horizontal portion to be reversible, since the palladium would appear not to be the same for the first rising portion when traced upward from zero concentration as when later traced downward after formation of the beta phase and its subsequent decomposition. This effect seems, however, to be rather theoretical than actual. In the second place, one might expect that any reluctance to form the beta phase, if once over-

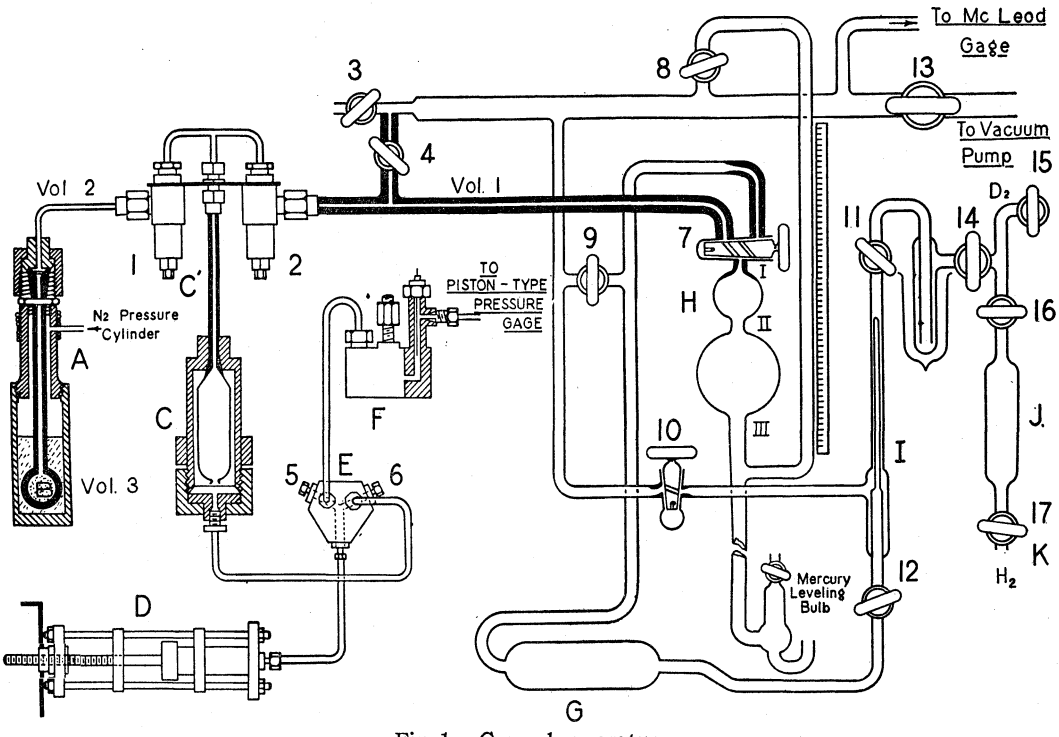

Fig. 1.—General apparatus.

come, might disappear on repetition of the experiment, since the alteration in the physical state of the metal may serve as well as the presence of "nuclei" (or perhaps actually constitute such), about which the new phase may freely form. This expectation has been borne out in the present work with deuterium.

Lacher[13] has derived with the aid of statistical theory an approximate equation to represent the results of Gillespie and Galstaun for palladium and hydrogen. If we remember the arbitrary nature of the fundamental assumption that was made, which did not permit representation of compound formation, we may consider the semi-quantitative success of the representation very gratifying.

Apparatus and Procedure.—The apparatus of Gillespie and Galstaun was used, after redetermination of the dead-space volumes and recalibration of the pressure gage, and the same procedure for the measurements was used. The only modifications were as follows. After we found that the critical solution pressure was to prove much higher than that for hydrogen we installed a steel jacket around the Pyrex reaction bulb and part of its capillary lead, within which jacket a compensating pressure of nitrogen can be maintained. For fear of excessive heat loss along the jacket and consequent unknown stem-correction we have used melted Wood's metal within the jacket to transfer heat to the reaction bulb. Measurements with hydrogen and palladium, with and without the jacket, showed that the stem-correction was zero or the same in both cases. The design is such that without the jacket the stem-correction should be the same as for the platinum thermometer. This jacket and the associated apparatus are shown in Fig. 1. A change was made in the procedure for freeing the palladium black from ammonium chloride, and this will be discussed later.

Deuterium is prepared by electrolysis of a dilute solution of anhydrous potassium sulfate in heavy water in the apparatus shown in Fig. 2. By adjustment of the mercury in the bulb B the volume of bulbs A and B can be made exactly half the volume of the deuterium bulb E, so that electrolysis can take place without attention to the levels in the U-tube at D. Ice was used in a Dewar flask about the U-tube for cooling during electrolysis.

Heavy water guaranteed 99.9% pure was obtained from

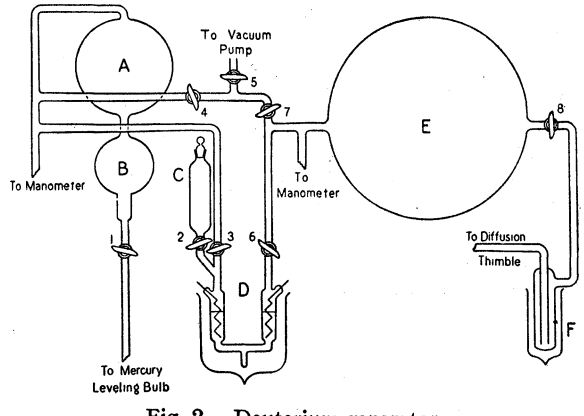

Fig. 2.—Deuterium generator.

(13) Lacher, *Proc. Roy. Soc.* (London), **A161**, 525 (1937).

the California Isotope Company in sealed ampoules. The water was exposed to air only long enough to break off the tip and introduce the liquid into the tube C. The cell was evacuated before introducing any heavy water, and rinsed out before final filling.

Deuterium was not passed over phosphorus pentoxide, but passed through the hot (300°) palladium diffusion thimble (I of Fig. 1) after freezing out the oxide at F with liquid nitrogen.

Precautions were taken at all times to avoid contamination of the deuterium with hydrogen, all parts of the apparatus being well pumped and repeatedly rinsed with deuterium. That this was successful is indicated by the reproducible character of the curves and especially by the horizontal character of the flat portions.

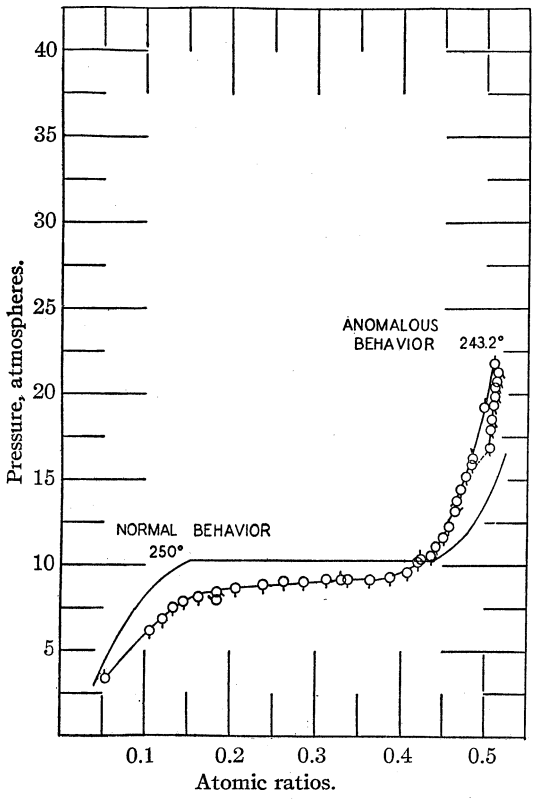

Fig. 3.—Anomalous and normal behavior of hydrogen with palladium black.

The palladium was prepared from ammonium chloropalladate obtained through the kindness of the National Bureau of Standards. This salt was converted into the chloride, then into palladosammine chloride, which was reprecipitated repeatedly from ammoniacal solution, well washed, dried, and converted to metal in a boat in a stream of hydrogen at about 150°. The hydrogen was replaced with carbon dioxide before cooling and then the metal allowed to cool in carbon dioxide. At the temperatures at which 1 atm. of hydrogen was in contact with the metal no beta phase could have been formed, a consideration that proves to be of importance.

For the first experiment the ammonium chloride, formed with the metal upon reduction of the palladosammine chloride, was largely removed by substantially the same procedure used by Gillespie and Galstaun (heating *in vacuo*).

For all the other experiments the ammonium chloride was better removed by thorough washing with hot distilled water until disappearance of chloride ion, after washing for several minutes in boiling 3 *N* ammonium hydroxide to dissolve any unreduced ammine. After being dried at 105°, the metal was then heated between 360 and 380° for an hour or more under vacuum and allowed to cool in a vacuum before weighing. Two portions of metal prepared in this second way were available. After joining the reaction bulb to the apparatus and just before starting an experiment with hydrogen or deuterium, the sample was conditioned by admitting the gas at about 2 atm. at bath temperature and then exhausting, this procedure being repeated several times.

In the calculation of the average compositions of the solid phases, corrections were applied for the deviation of deuterium from the ideal gas law, under the assumption that the equation of state for deuterium is the same as for hydrogen. It should be noted that the sensitiveness of the calculations of composition to small errors of volume, to the allocation of dead space between bath and room temperature along the capillary lead from the reaction bulb, and to uncertainty of the density of the palladium (assumed to be 11.774) increases with the pressure. Therefore the compositions at the highest pressures may not be so exact as those at 20 atm.

Experiments.—Before proceeding to the study of deuterium it was thought well to check with hydrogen some of the results of Gillespie and Galstaun. The first experiment was with palladium prepared substantially as by them, but which stood without exclusion of air for nine months after preparation and before the experiment. The results at 243.2° are shown in Fig. 3, labelled *Anomalous Behavior*, together with the curve of Gillespie and Galstaun at a nearby temperature, 250°, labelled *Normal*. Tails on the circles distinguish points obtained by addition of hydrogen (tails pointing up) from those obtained by withdrawal. It is evident that the hysteresis is slight and the curve within the hysteresis region is lacking in a truly horizontal portion. Gillespie and Galstaun saw such a result but once, and the palladium was then found to be heavily contaminated with mercury (10% or more). Therefore this preparation was examined for mercury by very strong heating in a boat, but none could be detected. The loss of weight on heating, due in part or whole to expulsion of ammonium chloride, was 0.23%, about the same as for the preparation used for the final results of Gillespie and Galstaun. This preparation was not studied further.

Because of the experience of Holt, Edgar and Firth[14] with active and inactive palladium it seems possible that the nine months of storage (and not in an atmosphere of hydrogen) allowed an "inactivation." Our next experiments showed the propriety of the labelling.

For all subsequent experiments the palladium was freed from chloride by washing, as described above, and was recently prepared from the palladosammine chloride.

With such material, hydrogen isotherms were deter-

(14) Holt, Edgar and Firth, *Z. physik. Chem.*, **82**, 513 (1913).

mined at 250 and 280°. The manipulation was isothermal, no "heat treatment" being used at any time in this work. The results are shown by the centers of the circles in Fig. 4. The lines are those by Gillespie and Galstaun. The check is good. The first rising portion of the 250° curve lies underneath the old curve, but a plot of log p against $1/T$ indicates that the new points are more consistent with the earlier results at other temperatures than are the old 250° points. No particular effort was made to fix the exact compositions at the ends of the horizontals, but the confirmation of the earlier results is good so far as it goes; indeed, it seems better for these compositions than for the pressures.

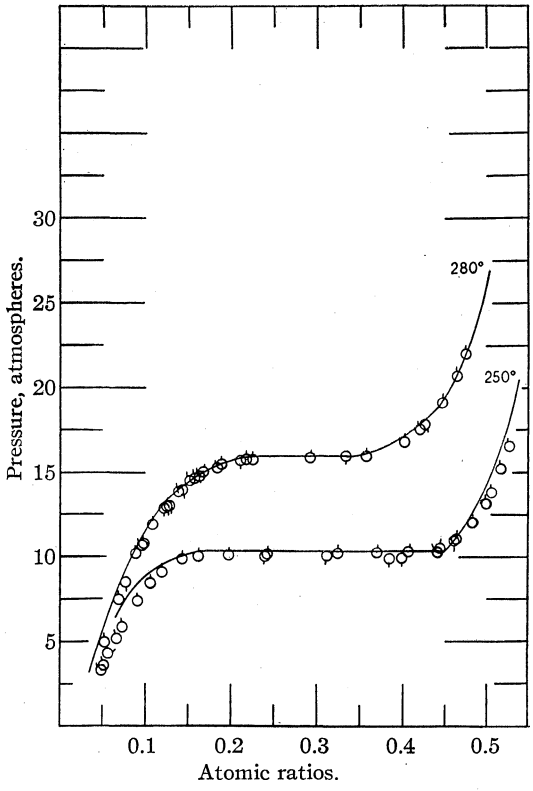

Fig. 4.—Comparison of new hydrogen data (circles) with old (lines).

Figure 4 gives a check of all apparatus constants except the volume of the gas buret and the delta value of the platinum thermometer (the ice-point agreed with the earlier value and also did the settings of the thermostatic control). It proves that the queer result at 243.2° is in fact anomalous.

In the next experiment we determined deuterium isotherms at 200 and 250°. Figure 5 shows by circles the points for deuterium at these temperatures, with the best lines. At 250° circles of two sizes show two experiments. For comparison, the curve for hydrogen of Gillespie and Galstaun is added, as well as their points at 200° (but not at 250°), so that the spread of the points in the horizontal region can be compared. The spread is greater for D_2 at 200° than for H_2. The spread decreases with rising temperature in both cases.

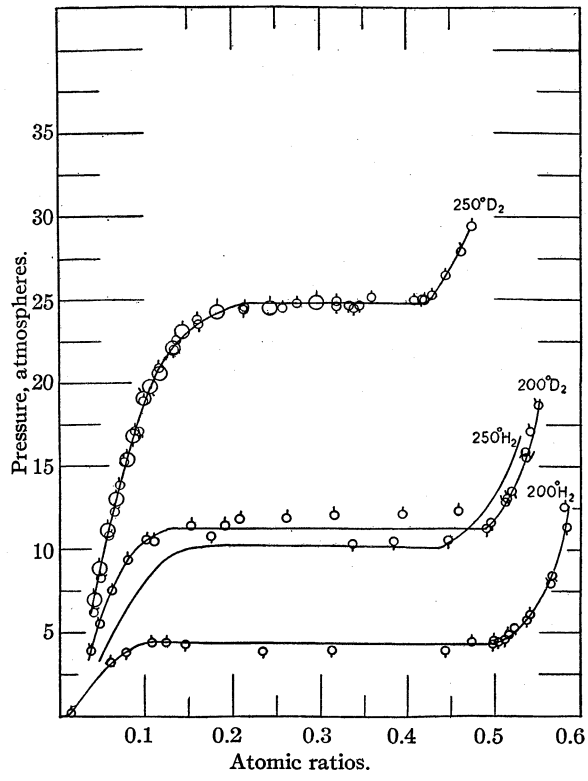

Fig. 5.—H_2:Pd and D_2:Pd at 200 and 250° (normal behavior).

It was at this point that the jacket was installed to protect the reaction bulb and the second portion of the palladium was also placed in the bulb, a portion that had not been exposed to hydrogen so as to form beta phase. The resulting curve is shown at the left of Fig. 6, labelled *Virgin Pd, Sample B*. All the points represent additions. They are so far from the curve previously obtained and here labelled *Normal Curve* that the deuterium was removed, fresh deuterium added to a pressure of about 6 atm. (at 250°) and the system evacuated. This pressure is only one-quarter of that required for beta phase formation under equilibrium conditions, but had some effect on the palladium. This is shown in the same Fig. 6 by the curve labelled *Virgin Pd, Sample B'*. The hysteresis is considerable and the loop does not enclose the normal curve shown without points. If the additions had been extended to high enough pressures the loop might well have enclosed the normal curve or perhaps coincided with it in part.

In the next experiment the deuterium was removed and replaced with hydrogen, and the points of a hydrogen isotherm at 250° determined as shown in Fig. 7 along with the line of the earlier experiment (of Fig. 4). The agreement of the points with the line shows that the metal was like that used before. After removal of hydrogen and flushing with deuterium, the points for a deuterium isotherm were determined as shown in the same Fig. 7 along with the line previously determined (of Fig. 4).

These experiments showed us that there is a reluctance toward formation of the deuterium beta phase, which has

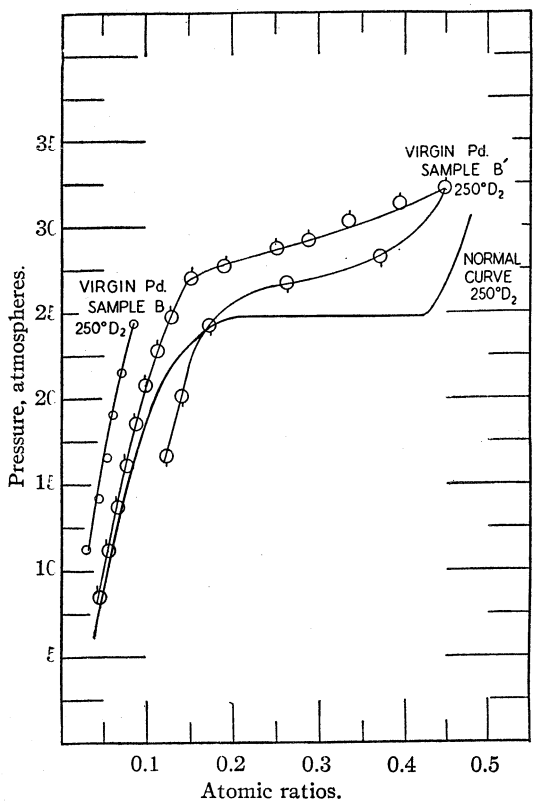

Fig. 6.—Deuterium in virgin Pd and in Pd previously used for hydrogen ("normal curve").

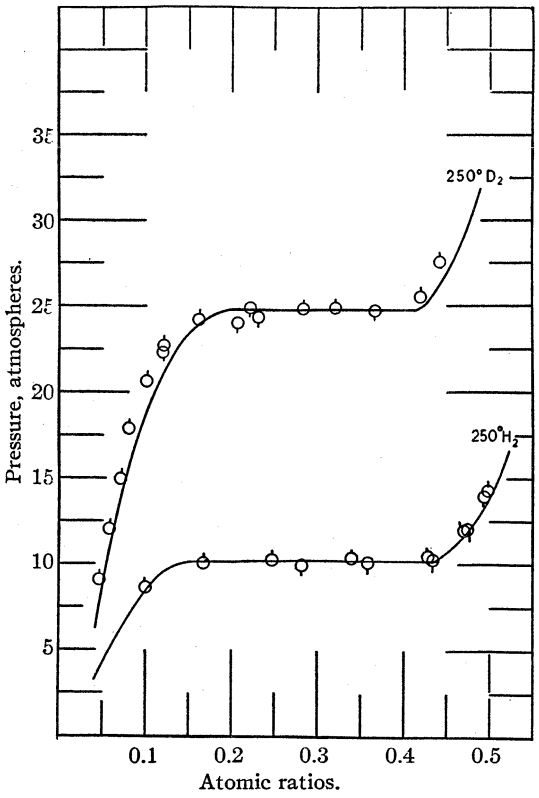

Fig. 7.—Normal H_2 curve followed by normal D_2 curve in the sample of Fig. 6.

seldom been observed by us in the case of hydrogen, but is serious in the case of deuterium. We think that the loop of Fig. 6 indicates the formation of some beta phase at moderate pressures of deuterium (in material within which no beta phase of hydrogen had ever been produced), but that in this case beta phase was not formed in all portions of the metal.

Once beta phase is formed throughout the metal by the use of hydrogen, an effect persists after evacuation. In the X-ray experiments distortion of the diffraction pictures remains and here the material seems to retain enough structure to serve as nuclei for subsequent beta phase formation. We have not hesitated therefore to proceed to extend the study of the deuterium–palladium diagram by the use of palladium thus conditioned with hydrogen.

Our complete phase diagram of the system Pd:D_2 is shown in Fig. 8. The anomalous results quoted above are not included, and no further anomalous results were seen. There is a critical solution temperature at about 276°. The corresponding pressure is 35 atm. to within 0.5 atm., and the composition is about 0.25 atom of D per atom of Pd.

Sieverts and Danz[4] suggested from the course of some low pressure measurements that the critical solution temperature might possibly be lower than for hydrogen, but they did not show that one exists for deuterium.

The pressures along the horizontals for deuterium are given in the following table, as observed directly without regard to temperature consistency, and as calculated from the equation

$$\log_{10} p_{\text{atm.}} = 4.6330 - 1696.11/(t + 273.13) \quad (1)$$

TABLE I

PRESSURES ALONG THE HORIZONTALS FOR D_2 AND Pd IN ATM.

Temp., $t°$	200	250	260	270
Obsd.	11.4	24.5	28.25	32.5
Calcd.	11.7	24.5	28.3	32.4

The calculated pressures agree with the points of each isotherm as well as the directly observed, and should be regarded as the final best values.

From Eq. (1) and the simple Clapeyron equation (with ideal gas assumptions) the heat evolved when 1 mole of deuterium is added to palladium to convert the alpha (first) to the beta (second) solid solution is calculated to be 7760 cal. The corresponding result for hydrogen is 8590 cal. from the previous work.[2] This heat is therefore 10% less for deuterium. Its value is more uncertain, being determined from only four points between 200 and 270°.

As in the case of hydrogen, the fictive heat effect upon adding 1 mole of gas to palladium is least along the first rising portions of the iso-

therms, greater along the horizontals, and greatest along the second rising portions of the isotherms. The fictive heat above the critical point at the critical composition seems to be greater for deuterium than the heat along the horizontals.

Ten weeks after the completion of the isotherms shown in Fig. 8 another isotherm was determined at 260° and also a few points at 280°. These last results did not check exactly with the previous. The pressure of the horizontal at 260° was correct as judged by Eq. (1) and as shown in Table I, but the compositions were lower at both temperatures by about 0.01 in the atomic ratio. This suggests an error in the reading of the gas buret at the beginning of this last experiment, but in any case the check is sufficient to exclude the possibility that the results of Fig. 8 (in which the 260° isotherm is not included) suffer from aging of the palladium, and the results speak definitely against a tendency toward compound formation in the neighborhood of Pd_3D.

The locus of the compositions of the coexistent solid phases, alpha and beta, as shown by the broken line in Fig. 8, discloses no tendency toward compound formation—indeed, seems to exclude the possibility of compound stability. The results shown are not completely convincing as regards a hypothetical Pd_3D, but the 260° isotherm completes our conviction that no compounds are in evidence above 200°, our lowest temperature.

A final analysis was made of the last palladium sample studied, introduced with the jacket as mentioned above, and no mercury could be detected. The loss of weight after very severe heating in a stream of nitrogen was only 0.03%, within the experimental error.

On a large diagram of Fig. 8 new horizontals were drawn at the pressures given by Eq. (1) and with their aid the compositions of the alpha and beta phases determined at the ends of the horizontals. The values are given in Table II.

TABLE II

COMPOSITIONS OF COEXISTENT ALPHA AND BETA PHASES

Temperature, t°	200	250	260[15]	270
Atomic ratio D/Pd, alpha phase	0.130	0.173	0.195	0.215
Atomic ratio D/Pd, beta phase	0.495	0.418	0.365	0.310

The ratio of p_D, the pressure along a horizontal for deuterium at any temperature, to p_H, the pressure along the horizontal for hydrogen at the same temperature, is given by Eq. (2) up to the critical point for deuterium.

$$\log_{10}(p_D/p_H) = 0.0312 + 181.71/(t + 273.13) \quad (2)$$

In our publications we have never presented our reasons (some of which are based on indirect evidence) for believing that our degassing technique has been sufficient to ensure that our compositions really start at zero as is assumed in all our phase diagrams. Mercury diffusion pumps have always been used—the metal was in the finely divided black form—the temperature of degassing in the early work[16] was never less than 360° and in the later work[2] and the present work never less than 200° (the lowest bath temperature). Recent special degassing experiments by Bennett[17] on massive palladium richly charged

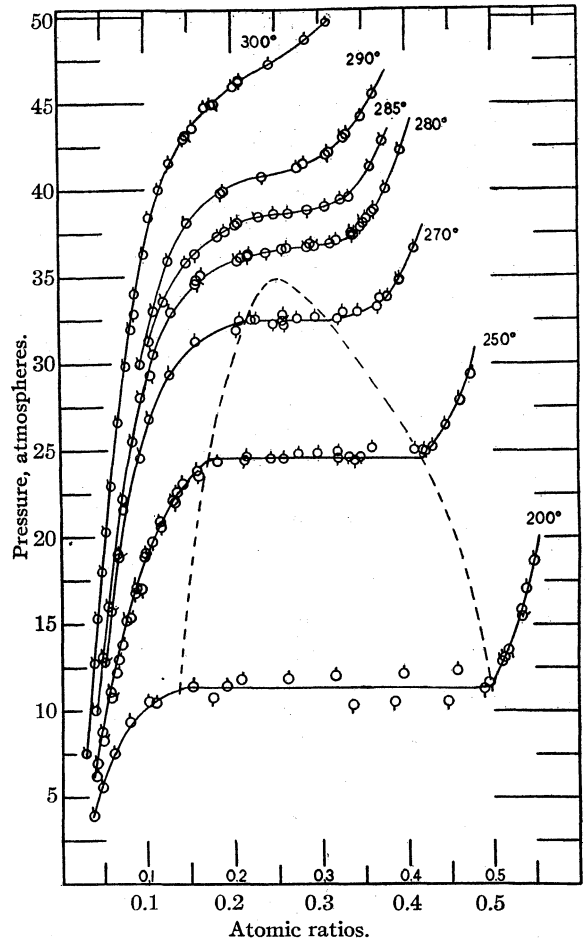

Fig. 8.—Phase diagram of deuterium and palladium.

(15) Estimated by applying the correction of 0.01 to the results of the 260° isotherm.

(16) Gillespie and Hall, THIS JOURNAL, **48**, 1207 (1926).

(17) F. D. Bennett, *ibid.*, to be published. We wish to thank Mr. Bennett and Professor W. R. Ham, through whose courtesy we were able to see the paper in advance of publication.

with hydrogen by electrolysis show no difficulty at 300° (which is above the critical solution temperature) and not too much at 200°. This work seems to close the question and to make it unnecessary to discuss the indirect evidence.

Summary

The isotherms of Gillespie and Galstaun for palladium and hydrogen at 250 and 280° have been confirmed.

A series of isotherms for deuterium and palladium black has been obtained from 200 to 300°, including a critical solution point. A difficulty due to reluctance to formation of the second solid phase was overcome by first forming the beta phase of hydrogen–palladium by pretreatment with hydrogen.

After such pretreatment the isotherms of deuterium are thoroughly reproducible, and after prolonged treatment of palladium with deuterium the hydrogen isotherms are again reproducible.

For a given temperature and pressure, the absorption of deuterium is less than that of hydrogen, but at all the temperatures studied there is not much difference in the maximum absorption of the two gases at the highest practicable pressures after the second solid phase has been formed. Horizontal lines appear in the deuterium isotherms at pressures about 2.3 to 2.5 times the pressures of the corresponding hydrogen horizontals.

The critical solution temperature for deuterium and palladium is found to be 276°, the critical pressure 35 atm., and the critical composition 0.25 atom D per atom Pd.

The heat of solution per mole of deuterium increases regularly with increasing deuterium content and is 7760 cal. per mole for the conversion of the first to the second solid phase.

The phase diagram is given. The locus of the compositions of coexistent solid solutions is smooth and continuous without rising steeply at any simple atomic ratio. This indicates that no palladium deuterides exist in the region above 200°. As the composition of the second solid phase is practically that of Pd_2D at 200° (like the H_2 system), further work at lower temperatures will be required to determine the possible existence of this compound.

The palladium black was prepared by reduction of palladosammine chloride and studied at once.

The Reduction of Metal Oxides in Liquid Ammonia. I. Preliminary Communication

BY GEORGE W. WATT[1] AND W. CONARD FERNELIUS

Recent studies have shown that bismuth oxyiodide is reduced completely by solutions of sodium and potassium in liquid ammonia.[2] The removal of oxygen from the oxyiodide appears to involve the formation of alkali monoxide and its subsequent ammonolysis to alkali hydroxide and alkali amide. These experiments suggest that some oxides, like almost all halides,[3] may be reduced by liquid ammonia solutions of the alkali metals.

There have been recorded in the chemical literature certain observations which suggest that mercurous oxide,[4] zinc oxide,[5] ferric oxide,[6] and cobaltous-cobaltic oxide[6b] may be reduced under similar conditions. In none of these cases, however, has it been proved that oxygen may be removed *quantitatively* from a heavy metal oxide by means of these reducing agents.

Experimental[7]

Bismuth Trioxide.—One-half gram of bismuth trioxide in the presence of 15 cc. of liquid ammonia[8] was treated with a solution containing 0.25 g. (six equivalents) of potassium in a like volume of ammonia. The characteristic blue color of the potassium solution was discharged immediately and the yellow trioxide was reduced to a gray

(6) (a) Bergstrom, THIS JOURNAL, **53**, 3037 (1931); (b) Burgess and Kahler, *ibid.*, **60**, 191 (1938).

(7) The experimental methods employed were those developed by Franklin and co-workers. All reactions were carried out in Faraday tubes at or near room temperature. For details see: Franklin, "The Nitrogen System of Compounds," Reinhold Publishing Corporation, New York, N. Y., 1935, pp. 317–30; Johnson and Fernelius, *J. Chem. Educ.*, **6**, 447–50 (1929).

(8) All of the oxides studied appeared to be insoluble in and unreactive toward liquid ammonia. However, there appears to be some evidence to indicate that cuprous and cupric oxides are slightly soluble; see Franklin and Kraus, *Am. Chem. J.*, **20**, 827 (1898).

metallic solid. At the same time there appeared a small quantity of a white flocculent precipitate (potassium hydroxide). The insoluble reaction product was washed ten times with liquid ammonia. The solvent was vaporized, the tube was evacuated, weighed, opened for analysis, and the insoluble product (0.5795 g.) was washed with water to remove potassium hydroxide.

Anal. Found: Bi, 0.4385 g.

The above weight of bismuth corresponds to 97.7% of the bismuth (as bismuth trioxide) used in the reaction and to 98.4% of the ammonia-insoluble reaction product after allowance is made for the presence of potassium hydroxide.

The aqueous washings were analyzed for potassium hydroxide and nitrogen.

Anal. Found: KOH, 0.1339 g.; N, trace.

The ammonia-soluble product was analyzed for potassium and nitrogen.

Anal. Found: K, 0.1688 g.; N, 0.0415 g.

The weight of nitrogen found in the soluble product is equivalent to 0.16 g. of potassium amide as compared to the 0.18 g. of potassium amide calculated on the assumption that one-half of the potassium used in the reaction should be converted to the amide. The combined analyses for potassium (results from analysis of both soluble and insoluble products), account for a total of 0.26 g. as compared to the 0.25 g. of potassium used in the reaction.

Cuprous Oxide.—One-half gram of cuprous oxide was treated with 0.27 g. (two equivalents) of potassium. After a few minutes a non-adherent copper mirror formed on the walls of the reaction tube. Within one-half hour the blue color was discharged and the liquid ammonia was colored pale yellow (due to dissolved potassium amide). There was no marked change in the color of the oxide. After washing the insoluble material several times with ammonia, the tube was opened and a sample (0.3820 g.) taken for analysis.

Anal. Calcd. for Cu_2O: Cu, 88.8%. Found: KOH, 0.0873 g.; Cu, 0.2628 g. or 89.2% after allowance is made for potassium hydroxide present in the insoluble product.

Cupric Oxide.—One-half gram of cupric oxide was treated with 0.49 g. (two equivalents) of potassium. The black color of the oxide was replaced immediately by the color characteristic of cuprous oxide and after a few minutes a non-adherent copper mirror formed on the walls of the tube. After washing five times with ammonia, a sample (0.1264 g.) was taken for analysis.

Anal. Calcd. for CuO: Cu, 79.9%; for Cu_2O: Cu, 88.8%. Found: KOH, 0.0415 g.; Cu, 0.0732 g. or 86.2% after allowance is made for potassium hydroxide.

Silver Oxide.—One-half gram of silver oxide was treated with 0.17 g. (two equivalents) of potassium. The black oxide was immediately converted to a gray solid. After removal of ammonia- and water-soluble materials, a sample (0.4518 g.) was taken for analysis.

Anal. Found: Ag, 0.4505 g. or 99.7%.

Germanic Oxide.—One-fourth gram of germanic oxide was treated with 0.37 g. (four equivalents) of potassium. The alkali metal was converted to the amide in ten hours. After allowing the apparently unchanged oxide to stand in the presence of the liquid ammonia solution of potassium amide for several hours, the white solid was washed thoroughly with liquid ammonia and analyzed.

Anal. Calcd. for GeO_2: Ge, 69.4. Found: Ge, 68.0.

Other Oxides.—Preliminary studies of the possibility of reduction of the following oxides have also been made: zinc oxide, cadmium oxide, stannous oxide, stannic oxide, lead monoxide, lead dioxide, arsenic trioxide, antimony trioxide. *In every case, reduction has been found to occur.* The reduction products appear to include the elemental metals and (or) soluble or insoluble intermetallic compounds of potassium. These reactions are being investigated further.

Discussion

The results of this investigation show that some metal oxides are reduced by solutions of potassium in liquid ammonia. The primary action involved in such reduction is undoubtedly the removal of oxygen. Subsequently, the resulting alkali monoxide is ammonolyzed to potassium amide and potassium hydroxide.

The formation of potassium hydroxide, which is insoluble in liquid ammonia, prevented the isolation of a single insoluble reduction product. Accordingly it was necessary to correct the analytical data for the heavy metal in the light of results of analyses for potassium hydroxide. This difficulty was obviated in the cases of bismuth trioxide and silver oxide since in these instances the metal formed in the reduction reaction was unreactive toward water and the hydroxide could be removed by washing with water prior to analysis.

When a liquid ammonia solution of an alkali or alkaline earth metal is brought into the presence of a metal oxide, the oxide *may* act as a catalyst[9] for the reaction

$$K \rightleftharpoons K^+ + e^-$$
$$e^- + NH_3 \longrightarrow NH_2^- + {}^1/_2H_2$$

Thus, in the presence of a limited quantity of potassium, an oxide having a marked catalytic activity toward the foregoing reaction might not be reduced to any appreciable extent because of the rapid conversion of potassium to potassium amide; or, more properly, because of the elimination of electrons by virtue of the concomitant formation of molecular hydrogen. The reduction of cupric oxide, for example, appears to be a two-step process. The rate of reduction to cuprous oxide is greater than the rate of interaction between potassium and ammonia. Hence, cupric

(9) For primary references see Fernelius and Watt, *Chem. Rev.*, **20**, 198 (1937).

oxide is reduced to cuprous oxide and it follows that cupric oxide is a relatively poor catalyst for the foregoing reaction. Cuprous oxide, on the other hand, seems to be a very good catalyst and is therefore only slightly reduced when only an equivalent quantity of potassium is used. The ease of reduction of bismuth trioxide and silver oxide precludes the possibility of their exerting any appreciable catalytic effect. Germanic oxide exhibits no marked catalytic effect toward the reaction between potassium and ammonia.

The formation of insoluble or soluble intermetallic compounds of potassium (by the interaction of potassium and the metal liberated from the oxide in the reduction reaction) might have been anticipated, particularly in the case of bismuth.[2] Such reactions were suppressed by the utilization of only that quantity of potassium required for the removal of oxygen, and by the fact that the velocity of the reduction reaction proved to be much greater than that of intermetallic compound formation.

Summary

1. A study of the action of liquid ammonia solutions of potassium on certain metal oxides has shown that: (a) cupric oxide is largely reduced to cuprous oxide; (b) cuprous oxide is reduced to elemental copper to a slight extent; (c) silver oxide and bismuth trioxide are reduced quantitatively to the corresponding elemental metals; and (d) germanic oxide is not reduced.

2. Germanic oxide is not acted upon by a liquid ammonia solution of potassium amide at room temperature.

The Partial Pressure of Hydrogen Chloride from its Solutions in Ethylene Glycol and Other Solvents at 25°

BY S. JAMES O'BRIEN, CHRISTOPHER L. KENNY AND ROBERT A. ZUERCHER[1]

It has been pointed out by Rodebush and Ewart[2] that the measurement of the partial pressure of a volatile acid solute provides a means of estimating the extent of the acid–solvent base reaction. More recently, Zellhoefer and co-workers[3] have shown that measurements of the solubility of halogenated hydrocarbons at various pressures in a number of solvents may be interpreted in terms of a solute–solvent reaction, involving the formation of a hydrogen bond, and in terms of the association of the medium. It would seem, then, that a similar study employing a solute like hydrogen chloride, which is at the end opposite to that of the halogenated hydrocarbons, on the scale of hydrogen activity, should be interesting from this point of view. Data of this kind for hydrogen chloride solutions, however, are quite limited. With the exception of a few measurements of the solubility at pressures of about one atmosphere the only direct measurements of the partial pressure of hydrogen chloride from its solutions recorded in the literature are those from water at 25°,[4] glacial acetic acid at the same temperature,[2] and benzene at 30°.[5] Additional information of this kind is also indirectly available for benzene and nitrobenzene solutions at 25° from distribution studies.[6] It is believed that further studies of this kind would be worth while.

Since the work of Zellhoefer and co-workers[3b,3c] shows the solubility of monofluorodichloromethane to be less in ethylene glycol than in nitrobenzene and in acetic acid, while it is to be expected that the solubility of hydrogen chloride in ethylene glycol is greater than that in either of these two solvents, considering the high solubility of hydrogen chloride in alcohols in general, it was decided to make a study of the partial pressure of hydrogen chloride from its ethylene glycol solutions in order to provide concrete evidence concerning this point. It is the purpose of this paper, then, to report the results obtained in this study, and to discuss the available data in terms of the acid–solvent base reaction.

Experimental

Apparatus and Method.—Since the apparatus and method are almost identical with those employed by Saylor,[5] details will not be given here. However, preliminary experiments were performed using solutions of known vapor pressures which showed that the solution–vapor equilibria were established within twenty-four hours. Consequently, the time allowed for the glycol solutions to come to equilibrium with their vapor was approximately two days instead of the longer periods suggested by Saylor.

The constant temperature bath was regulated at 25.00 ± 0.02°.

Materials.—The ethylene glycol used was an Eastman Kodak Co. product of good grade. It was not purified further since the method employed is not of sufficient accuracy to give results that would be seriously affected by the traces of impurities present.

The hydrogen chloride was generated in an all-glass apparatus using C. P. grade potassium chloride and sulfuric acid. It was passed through a drying tower of phosphorus pentoxide before being introduced into the ethylene glycol.

Results

The results obtained are given in Table I in which the first column contains the molalities of the solutions, the second the partial pressure of hydrogen chloride from the solutions and the third, values for the quantity,[7] $k'\gamma$, which will be considered below.

TABLE I

THE PARTIAL VAPOR PRESSURE OF HYDROGEN CHLORIDE FROM ETHYLENE GLYCOL SOLUTIONS AT 25°

m	p, atm.	$k'\gamma$
1.33	0.0008	0.0212
2.27	.0025	.0220
2.45	.0032	.0231
2.72	.0046	.0250
3.02	.0074	.0285
3.07	.0075	.0282
3.11	.0086	.0298
3.13	.0079	.0284
4.66	.0357	.0406
6.57	.135	.0558
6.63	.139	.0562
6.92	.172	.0598
8.78	.424	.0742

A logarithmic plot of the data in Table I, together with those for water, acetic acid, benzene and nitrobenzene solutions, is given in Fig. 1. The data for water solutions were taken from those given by Randall and Young[4]; that for glacial acetic acid solutions from the investigation of Rodebush and Ewart[2]; and those for the benzene and nitrobenzene solutions are direct measurements of the hydrogen chloride pressure above the solutions at 25°, which were taken from unpublished studies made in this Laboratory.[8,9] Since these seem to be the only direct measurements made in these solvents at 25°, some representative data are also given in Tables II and III.

.225	.428	.030	.059

Discussion

From Fig. 1 it is evident that hydrogen chloride solutions in the solvents considered, fall into two groups. In one, which includes benzene, nitro-

(8) Schmelzle, Master's Thesis, The Creighton University, 1938.
(9) Westfall, Master's Thesis, The Creighton University, 1938.

benzene, and acetic acid, its solubility is low, and the law of Henry in the form

$$p = km \quad (1)$$

is followed.[10] In the second, which includes water and ethylene glycol solutions, its solubility is high, and the law of Henry, in the form of equation (1), does not hold, but, as is customary for aqueous solutions, the data can be treated in terms of the law of Henry (or a law similar to it) in the form[7]

$$p^{1/2} = k'\gamma m \quad (2)$$

It seems logical to consider this possible treatment of the data in terms of two forms of the law of Henry, as an indication of two different acid–solvent reactions. Equation (1) corresponds to a reaction which may be represented by

$$HCl + S = S \longrightarrow H—Cl \quad (I)$$

where S represents the solvent and S ⟶ H—Cl is written to indicate the formation of a hydrogen bond with some atom in the solvent. Equation (2) would correspond to the reaction

$$HCl + S = SH^+ + Cl^- \quad (II)$$

where SH^+ represents the solvated proton.

Also, the extent to which these acid–base reactions proceed may be determined, if it can be assumed that the unreacted molecular hydrogen chloride in the solutions corresponds to the law of Raoult[6] (p. 1070)

$$f = f_0 N_u \quad (3)$$

where f is the fugacity of the hydrogen chloride in solution, f_0 is the fugacity of pure liquid hydrogen chloride, and N_u is the mole fraction of unreacted hydrogen chloride. First, however, it should be pointed out that since reaction (I) takes place to some extent, equation (1) should be written

$$p = k(m_u + m_r) \quad (4)$$

where m_u represents the molality of unreacted hydrogen chloride, m_r, reacted hydrogen chloride, and

$$m = m_u + m_r \quad (5)$$

Equation (2), of course, could be written in a similar manner, but since the molality of unreacted solute is negligible in comparison with that which has reacted, in all the cases so far considered which fit into this group, it is only necessary to set

$$m = m_r \quad (6)$$

in order to follow through in equation (2) the notation adopted in equation (4).

(10) Compare Heston and Hall, THIS JOURNAL, **56**, 1462 (1934).

The equilibrium constant of the reaction represented by (I) is given by

$$K_a = a_r/a_u \quad (7)$$

where the a's refer to activities and the subscripts have the same significance as in the previous equations. Using equation (3) and setting $p = f$, it is found that[11]

$$m_u = m_s p/f_0 \quad (8)$$

where m_s is the number of moles of solvent in 1000 g. Assuming that activities are equal to molalities in this case, and making use of equations (4), (5) and (8), equation (7) becomes

$$K_a = (f_0 - km_s)/km_s \quad (9)$$

In like manner, making use of equations (2), (6) and (8), and assuming that the activity coefficients of unreacted hydrogen chloride are equal to unity, the equilibrium constant for reaction (II) becomes

$$K_d = f_0/m_s k'^2 \quad (10)$$

In Table IV are given values of these constants for hydrogen chloride solutions in benzene, nitrobenzene, acetic acid, glycol and water. In obtaining these constants, the value of $f_0 = 30.3$ atm. at 25° was calculated from the vapor pressure of liquid hydrogen chloride, interpolated from the data in "International Critical Tables,"[12] using the approximate method of Lewis and Randall[7] (pp. 197–199), and assuming that the deviation of hydrogen chloride from the perfect gas law at 25° is the same as that indicated by the work of Gray and Burt[13] at 0°; the Henry's law constants given in the second column of this table were obtained from the same data used in constructing Fig. 1, for benzene, nitrobenzene, and acetic acid; that for water is from Lewis and Randall[7]; that for glycol was obtained by extrapolating a plot of m against $k'\gamma$ (Table I) to $m = 0$, where, as in the case of aqueous solutions, it is assumed that $\gamma = 1$. The

TABLE IV

EQUILIBRIUM CONSTANTS FOR THE HYDROGEN CHLORIDE SOLVENT BASE REACTIONS AT 25°

Solvent	k	K_a
Benzene	2.04	0.16
Nitrobenzene	1.98	0.88
Acetic acid	0.347	4.25
	k'	K_d
Ethylene glycol	0.02	4.68×10^3
Water	0.000664	1.23×10^6

(11) The denominator of equation (8) is, of course, $f_0 - p$, but p is neglected since in most cases it is small in comparison with f_0. In the more concentrated solutions of hydrogen chloride, however, this simplification introduces an error of about 3%.

(12) "International Critical Tables," Vol. III, p. 228.

(13) Gray and Burt, *J. Chem. Soc.*, **95**, 1633 (1908).

partial pressure data could not be carried to low enough concentrations by the method employed to make the extrapolation with any great degree of certainty, but the curve was well enough defined so that the value given should be of the correct order of magnitude and may be accepted tentatively until activity data at lower concentrations are available.

The values for K_a and K_d given in this table indicate the relative basicities of the solvents, and the method of their derivation seems to be additional confirmation of the opinion that the basicity of a solvent is determined by the strength of the hydrogen bond formed with some atom in the solvent molecule acting as an electron donor.[14] When the bond formed is weak, the hydrogen chloride remains in the solution in the form of hydrogen bond compound, although the bond distance between the proton and the negative constituent of the acid is increased, as indicated by infrared absorption studies[14d] (p. 224). In solvents forming such bonds, the solubility of hydrogen chloride is low. When the bond formed is relatively strong, the bond between the proton and the negative constituent is so weakened that more or less complete ionization takes place, and when this occurs the solubility of hydrogen chloride is high.

While the formation of a complex between benzene and hydrogen chloride is indicated in Table IV, it should be pointed out that the magnitude of the deviation from the law of Raoult, which leads to the value given for K_a, may be of the same order as the uncertainty involved in the calculation of f_0. In other words, it is not possible to conclude definitely from this work that reaction (I) takes place in this case, although such a process might serve as the explanation for the increased dielectric polarization of hydrogen chloride in benzene solutions,[15] and the apparent slight shift toward longer wave lengths of the vibrational band occurring in the infrared spectra of hydrogen chloride at 3.46 μ.[16] In addition, Hantzsch[17] has considered such a possibility as the explanation for the catalytic action of hydrogen chloride in toluene solutions on the decomposition of diazoacetic acid ester.

The results obtained in this study of ethylene glycol solutions also definitely establish the inverted order of solubility of hydrogen chloride in nitrobenzene, acetic acid and glycol, compared to the solubility of monofluorodichloromethane. This appears to be an indication that the solute itself is an important factor in determining the basicity of the solvent, insofar as it may affect the hydrogen bonding between the molecules of the solvent. The solubility of hydrogen chloride in ethylene glycol is greater than expected from the law of Raoult, while that of monofluorodichloromethane is less. That this is due to a reduction in the amount of association of the glycol in the presence of hydrogen chloride seems quite likely, since the converse case of reduction of hydrogen bonding of solutes in the presence of other solutes that have a strong tendency to form hydrogen bonds, is fairly well established.[18] However, further studies are in progress in this Laboratory and since these may give additional information concerning this point, further discussion will be postponed until the results of these investigations can be given.

Summary

1. The partial vapor pressure of hydrogen chloride from its solutions in ethylene glycol at 25°, over the concentration range, 1.33 to 8.78 *m*, has been measured. Also, data from unpublished studies on the partial pressure of hydrogen chloride from benzene and nitrobenzene solutions at 25° are included.

2. The available data on the partial pressure of hydrogen chloride from solutions in various solvents have been considered in terms of two different acid–base reactions. A method of calculating the equilibrium constants for these reactions has been given.

3. The importance of hydrogen bonding, and the nature of the solute, in determining the basicity of the solvent is indicated.

The Structure of Formaldehyde from Electron Diffraction

BY D. P. STEVENSON,[1] JAMES E. LUVALLE[2] AND VERNER SCHOMAKER

Introduction

The structure of monomeric formaldehyde is of particular interest since it is the simplest molecule containing a carbon–oxygen double bond. Bru[3] found the carbon–oxygen distance to be 1.15 ± 0.05 Å. by electron diffraction. The accuracy, ±0.05 Å., of this determination is very much less than is now obtainable in determining the size of simple molecules.[4] Furthermore, this value for the carbon–oxygen distance is about 0.1 Å. smaller than that predicted by the covalent radius table[5] for the carbon–oxygen double bond, 1.24 Å., and that found for the carbon–oxygen distance of acetaldehyde,[6] 1.22 Å., and glycine,[7] 1.24 Å. Badger's rule[8] applied to the carbon–oxygen frequency gives 1.21 Å.[9] for the distance.

The moments of inertia have been determined very accurately[10] but are insufficient by themselves to determine the structure uniquely. This will be discussed below. Since the carbon–oxygen distance appeared definitely to be shorter than predicted, we were led to redetermining it by the electron diffraction technique.

Experimental

Dieke and Kistiakowsky[10] found it possible to maintain a pressure of 100 mm. of H_2CO by heating paraformaldehyde. For this reason we first attempted to obtain photographs by heating Eastman Kodak Company White Label paraformaldehyde from 150 to 200° in the "high temperature nozzle." Some of the photographs obtained in this fashion had the expected pattern, namely, that of a diatomic molecule, while others showed a much more complicated pattern. The latter were probably due to small polymers (*e. g.*, trimer). In order to eliminate the possibility of polymer in the vapor we prepared 10 cc. of the monomeric liquid according to the method of Spence and Wilde.[11] The liquid was held at −25° in the side-arm of a 200-cc. flask attached to the apparatus. This gave an effective pressure of nearly one atmosphere. Since air was excluded carefully from the preparation, polymerization was delayed long enough to obtain photographs of the monomer. The photographs so obtained were excellent, having a pattern similar to that of a diatomic molecule.

The camera distance was 10.84 cm. and the wave length of the electrons was 0.0611 Å. based on transmission pictures of gold, the structure of which is known (a = 4.070 Å.).

Interpretation.—Only the photographs obtained by the second technique will be considered since polymers may have been present in the gas in the high temperature photographs. The photographs showed five minima and five maxima of gradually decreasing intensity. The measured values of $s\left(s_0 = \frac{4\pi}{\lambda}\sin\frac{\vartheta}{2}\right)$ are given in the third column of Table I. Comparison with a simple $\sin x/x$ curve indicated the carbon–oxygen distance to be about 1.20 Å. This distance and the moments of inertia (see below) give a carbon–hydrogen distance of 1.09 Å. and a hydrogen–carbon–hydrogen angle of 120°. A theoretical intensity curve was then calculated for the corresponding model. In place of the commonly used coefficients Z_iZ_j, $\overline{(Z_i - f_i)(Z_j - f_j)}e^{-A_{ij}}$ was used in the expression

$$I(s) = \sum_i\sum_j \overline{(Z_i - f_i)(Z_j - f_j)}e^{-A_{ij}}\frac{\sin l_{ij}s}{l_{ij}s}$$

The use of the "temperature factor," "$e^{-A_{ij}}$," will be discussed by one of us.[12] The atomic scattering factors "f" were obtained from Pauling and Sherman.[13] The curve so obtained is shown in Fig. 1, curve C, along with a common visual curve calculated for the same molecular dimension and the curve $\sin 1.20x/1.20x$. The vertical lines indicate the position of the measured maxima and minima. Quantitative comparison with the curve calculated with temperature fac-

Average of 9 features 1.011 ± 0.008

Carbon–oxygen distance = 1.20 × 1.011 = 1.213 ± 0.008 Å.

[a] From curve calculated with C–O = 1.20, C–H = 1.09, ∠H–C–H = 120°, with temperature factor. [b] Omitted from average.

Discussion

Dieke and Kistiakowsky[10] have determined values for the moments of inertia of formaldehyde from the analysis of the rotational structure of six ultraviolet bands. Since the molecule is planar, there are only two independent moments of inertia while there are three parameters which determine the structure of the molecule, namely, the carbon–oxygen and carbon–hydrogen distances and the hydrogen–carbon–hydrogen angle. An independent determination of any one of these structural parameters along with the moments of inertia suffice to determine the other two structural parameters. In Fig. 2 we have plotted the values of the carbon–oxygen and carbon–hydrogen distances which are consistent with the moments of inertia as a function of the hydrogen–carbon–hydrogen angle. Our value of 1.213 Å. for the carbon–oxygen distance (marked by a circle on the graph) corresponds to an angle of 120° and a hydrogen–carbon distance of 1.086 Å. Ebers and Nielsen[14] from an incompletely resolved infrared band at 4.5 μ have determined rough values for the moments of inertia of deuteroformaldehyde. Although their value for the small moment of inertia is in good agreement with that of Dieke and Kistiakowsky[10] for light formaldehyde, their value for the large moment is not sufficiently accurate to be used in determining the structure of formaldehyde.

Thompson and Linnett[9] using the frequencies of Nielsen[15] and a five constant potential function have found $k_{C-O} = 12.3 \times 10^5$ dynes/cm. and $k_{C-H} = 4.3 \times 10^5$ dynes/cm. With these values Badger's rule[8] leads to a carbon–oxygen distance of 1.21 Å. and a carbon–hydrogen distance of 1.09 Å. in good agreement with our determination. Very little significance can be assigned to the agreement in the case of the carbon–oxygen bond distance since Thompson and Linnett[9] find the

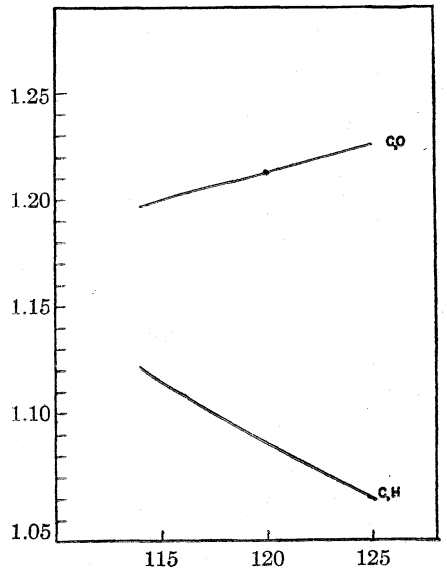

Fig. 2.—Graph of distances and angles consistent with the moments of inertia of formaldehyde: $I_1 = 2.941 \times 10^{-40}$ g. cm.²; $I_2 = 21.39 \times 10^{-40}$ g. cm.²

same distance for ketene, which has been found by electron diffraction to have a carbon–oxygen distance equal to 1.17 Å.[16]

The large value of the hydrogen–carbon–hydrogen angle, 120°, may be interpreted as indicating that the bonding in formaldehyde is primarily of the sp^2, π type which gives three coplanar bonds at 120°. It has been found that in acetaldehyde[6] a similar situation obtains, the carbon–carbon–oxygen angle being 122 ± 2°. The carbon–oxygen distance in formaldehyde is definitely shorter than that predicted by the covalent radius table for a carbon–oxygen double bond.

Summary

Electron diffraction photographs of monomeric formaldehyde have been obtained using fast electrons. Their interpretation leads directly to a carbon–oxygen distance equal to 1.21 ± 0.01 Å. Using this distance and the accurately known moments of inertia one finds the carbon–hydrogen distance to be 1.09 ± 0.01 Å. and the hydrogen–carbon–hydrogen angle to be 120 ± 1°.

The Hydrolysis of Ethylal[1]

BY PAUL M. LEININGER[2] AND MARTIN KILPATRICK

In a study of the inversion of sucrose[3] it was shown that the parameters of the Arrhenius equation

$$\ln k = B - (E_A/RT) \qquad (1)$$

depended upon electrolyte concentration and temperature. The present paper extends the study to the hydrolysis of ethylal. This reaction was chosen because the velocity constant can be determined conveniently over similar ranges of hydrochloric acid concentration and temperature.

Skrabal and Schiffrer[4] measured the rate of hydrolysis of ethylal in aqueous hydrochloric acid solutions by indirectly determining the amount of formaldehyde present at suitable intervals. The formaldehyde was oxidized to formic acid and titrated. In 1926 Skrabal and Eger[5] continued the work at 25°, using a modification of the sulfite method of Lemme[6] to determine the quantity of formaldehyde.

Subsequently the hydrolysis of ethylal was studied at 25 and 35° by Salmi[7] and by Palomaa and Aalto[8] using analytical methods. In 1934 Palomaa and Salonen[9] measured the reaction rate dilatometrically. Löbering and Fleischmann[10] investigated the hydrolysis at 10, 20 and 30° in sulfuric acid solutions.

If the claim of an accuracy of ±4% in the measurement of the rate constant, made by one of the authors,[8] can be regarded as typical, it is apparent that for this reaction the data in the literature are insufficiently accurate for a study of the parameters of the Arrhenius equation. In addition, both the temperature and concentration ranges investigated are too limited to enable one to observe possible variations in the parameters, E_A and B.

The present investigation extends over a range of hydrochloric acid concentration from 0.5 to 3.0 molar, at 0, 10, 15, 20, 25, 30, 35 and 40° (concentrations resulting in too rapid reaction being omitted at the higher temperatures).

Experimental

Ethylal.—Ethylal from the Eastman Kodak Company was purified by fractional distillation, the fraction boiling between 87.0 and 88.0° (760 mm.) being used. That the preparation was free of acidic impurities was established by titration of an aqueous solution in an atmosphere of nitrogen using brom thymol blue as indicator. A further check upon the purity of the product was made by determining the refractive index by means of a Zeiss dipping refractometer. At 17.5° different preparations gave values of n_D varying from 1.3736 to 1.3745 as compared with

1.3760 in the literature.[11] An examination of the experimental results reveals no difference in the velocity constants for the various preparations.

Hydrochloric Acid.—Baker C. P. analyzed hydrochloric acid was used. Experiments made with solutions prepared from constant-boiling acid checked the others within the experimental error.

Apparatus.—The dilatometers and thermostats were the same as in the study of the inversion of sucrose.[3]

Determination of Temperature.—Temperature regulation was slightly better than in the previous work,[3] the determination of temperature being carried out as previously described.

Determination of Concentrations.—The weight of ethylal used in an experiment was calculated from its density[12] and volume at the temperature of the experiment. The molarity of the ethylal was obtained from the weight of ethylal, the density of the reacted mixture, and the weight of hydrochloric acid solution. This procedure permits the calculation of molalities as well as molarities. The molarity of the hydrochloric acid was determined directly for each solution at the temperature at which the experiment had been performed by titration of the reacted mixture. The validity of the method was established by titrating a blank in the absence of ethylal. The concentration of acid was known to 0.1%.

Determination of the Rate.—A definite volume (150 cc.) of a hydrochloric acid solution of known concentration was introduced into the mixing chamber of the dilatometer and subjected to reduced pressure to prevent subsequent bubble formation. To this solution, at the temperature of the thermostat, 5 cc. of ethylal was added. The mixture was stirred until the solution became homogeneous, sealed off in the dilatometer and the rate of contraction noted. Velocity constants were evaluated by the Guggenheim method.[13]

Results

The hydrolysis of ethylal is represented conventionally as taking place in two steps: first hydrolysis, then the decomposition of the hemi-acetal.

$$CH_2(OC_2H_5)_2 + H_2O = CH_2(OC_2H_5)(OH) + C_2H_5OH$$
$$CH_2(OC_2H_5)(OH) = CH_2O + C_2H_5OH$$

The results of the present work indicate that the reaction is of the first order over the entire range of temperature and concentration investigated. Because of the great difficulty, if not impossibility, of preparing hemi-acetals, Skrabal[4] has concluded that the first of the above steps involves the rate determining process. The actual existence of hemi-acetals seems to be indicated, however, by some work of Adkins and Broderick.[14]

The validity of the dilatometric method is based upon the agreement of the results obtained in the present investigation with the values of other workers at 25° using analytical methods (see Fig. 1). As in the case of the other formals,[9] the reaction is accompanied by a contraction.

average of the average deviations for these experiments has been calculated and is 0.7%.

An examination of Table I shows that the bimolecular constant increases with concentration of hydrochloric acid. In Fig. 1 values of log $k_{H_3O^+}$ have been plotted against the molarity of the hydrochloric acid. The curves reading from top to bottom are for 25, 20, 15, 10 and 0°, respectively. The straight lines obtained indicate that the effect obeys the equation

$$\log k_{H_3O^+} = \log k^0_{H_3O^+} + \beta C \qquad (2)$$

at each temperature for the concentration range considered. The following equations were obtained from the above data.

$$\log k_{H_3O^+} = \bar{4}.2001 + 0.3760\ C \text{ (at } -0.01°) \qquad (2A)$$
$$\log k_{H_3O^+} = \bar{4}.9066 + 0.3612\ C \text{ (at } 10.00°) \qquad (2B)$$
$$\log k_{H_3O^+} = \bar{3}.2458 + 0.3529\ C \text{ (at } 15.00°) \qquad (2C)$$
$$\log k_{H_3O^+} = \bar{3}.5790 + 0.3444\ C \text{ (at } 20.00°) \qquad (2D)$$
$$\log k_{H_3O^+} = \bar{3}.8914 + 0.3478\ C \text{ (at } 25.00°) \qquad (2E)$$

The effect of ethylal concentration upon $k_{H_3O^+}$ is small, as evidenced by the value in Table I with superscript "*a*". A further examination of Fig. 1, however, shows that the value of $k_{H_3O^+}$ reported by Skrabal and Eger[5] is considerably higher (*ca* 20%) than one would expect for that concentration of hydrochloric acid. Since the only difference between this experiment and all the others is the fact that the molarity of ethylal was about 0.02 instead of 0.2, one would conclude that the bimolecular constant increased with decreasing ethylal concentration. This conclusion is further substantiated by the experiment reported in Table I with a superscript "*b*". In this case another portion of ethylal was added to the reacted mixture from a previous run (which might be considered equivalent to increasing the concentration of ethylal). Here a marked decrease in $k_{H_3O^+}$ was noted.

In Table II are recorded the values of E_A calculated from the data of Table I by the equation

$$E_A = \frac{RT_1T_2}{(T_1 - T_2)} \ln \frac{k_{T_1}}{k_{T_2}} \qquad (3)$$

The maximum error, ΔE_M, in E_A is calculated from the relation

$$\Delta E_M = \Sigma(\delta E_x) \qquad (4)$$

where δE_x represents the change in E_A due to the variation, δ_x, in the quantity x (x representing in turn T_1, T_2, ΔT, $k_{H_3O^+(T_1)}$ and $k_{H_3O^+(T_2)}$). The values assigned to δT_1 and δT_2 are 0.01°, to $\delta(\Delta T)$ 0.01° and to δk_1 and δk_2 = 0.7%. ΔE_M is approximately ±300 cal. A calculation of the

$$\Delta E_{PM} = \sqrt{\Sigma(\delta E_x)^2} \qquad (5)$$

precision measure, ΔE_{PM}, yields ±200 cal. Two things become apparent: E_A increases with increase in temperature, and decreases with increase in hydrochloric acid concentration. The concentration effect is also indicated by the decrease in the slope of the equations (2A) to (2D) as the temperature increases.

TABLE II

SUMMARY OF ACTIVATION ENERGIES

Temp. range, °C.	HCl, moles/liter	k_{T_1}/k_{T_2}	E_A, cal.
−0.01 to 10.00	0.4950	4.996	24,690

25.00 to 35.00	.4997	3.996	25,290
30.00 to 40.00	.4948	3.952	25,920

There are only three values of E_A available in the literature for the hydrolysis of ethylal by hydrochloric acid. From the work of Salmi[7] one calculates an activation energy of 25,760 cal., from that of Palomaa and Aalto[8] 24,620 cal., and from that of Palomaa and Salonen[9] 25,910 cal. An average value of 25,430 cal. is thus obtained for solutions approximately 0.4 molar with respect to hydrochloric acid and 0.2 molar with respect to ethylal. In this investigation the value of E_A at 30° for solutions 0.5 molar with hydrochloric acid was found to be 25,290 cal.

The effect of hydrochloric acid concentration is illustrated by a plot of values of E_A (taken from Table II) against molarity of acid.

In similar fashion, one can show the effect of temperature by plotting E_A against the midpoint of the temperature interval. This is done in Fig. 3, using values from Table II for 0.5 molar solutions of hydrochloric acid. The position of the line in Fig. 3 was determined by least squares.

Values of E_A for 0, 1 and 2 molar solutions of acid (read from Fig. 2) and for 0.5 molar acid (read from Fig. 3) are summarized in Table III. Values of E_A for zero molarity were likewise checked by calculation from the intercepts of equations (2A) to (2E).

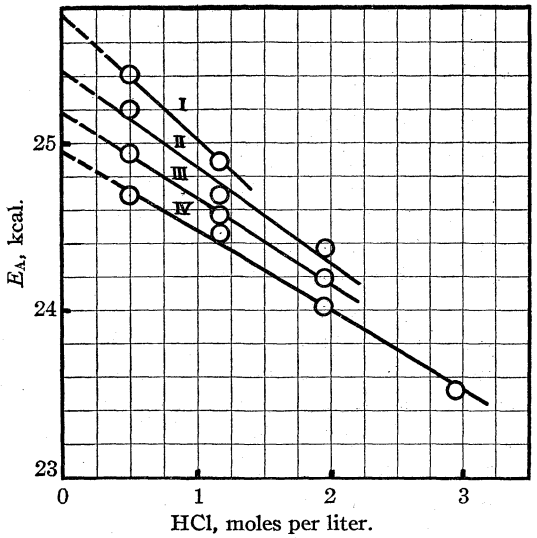

Fig. 2.—Electrolyte effect on energy of activation: I, 15.00 to 25.00°; II, 10.00 to 20.00°; III, −0.01 to 20.00°; IV, −0.01 to 10.00°.

TABLE III

VARIATION OF THE ENERGY OF ACTIVATION WITH TEMPERATURE AND ACID CONCENTRATION

	E_A, cal.			
Temp. range, °C.	0 molar HCl	0.5 molar HCl	1 molar HCl	2 molar HCl
−0.01 to 10.00	24,960	24,760	24,480	24,010
−0.01 to 20.00	25,180	24,920	24,670	24,160
10.00 to 20.00	25,440	25,070	24,860	24,280
15.00 to 25.00	25,760	25,220	25,020	....
20.00 to 30.00	....	25,370	....	....
25.00 to 35.00	....	25,530	....	....
30.00 to 40.00	....	25,680	....	....

Values of B calculated by equation (1), $k_{H_3O^+}$ being expressed in reciprocal seconds, are summarized in Table IV.

TABLE IV

VARIATION OF B WITH TEMPERATURE AND ACID CONCENTRATION

	B			
Temp. range, °C.	0 molar HCl	0.5 molar HCl	1 molar HCl	2 molar HCl
−0.01 to 20.00	33.54	33.50	33.47	33.39
10.00 to 20.00	34.00	33.76	33.80	33.60
15.00 to 25.00	34.56	34.04	34.08	...
20.00 to 30.00	...	34.28	...	...
25.00 to 35.00	...	34.53	...	...
30.00 to 40.00	...	34.79	...	...

From Table IV it appears that B increases with increasing temperature. The variation of B with concentration is within the experimental error, which is calculated to be ±0.3 of a B unit.

Discussion

From the results it is evident that the energy of activation decreases with increasing hydrochloric acid concentration, as in the case of the inversion of sucrose, but that the effect of temperature on E_A is in the opposite direction to that for the inversion of sucrose, dE_A/dT being positive and equal to 31 cal. per degree. The effect appears to be linear with temperature.

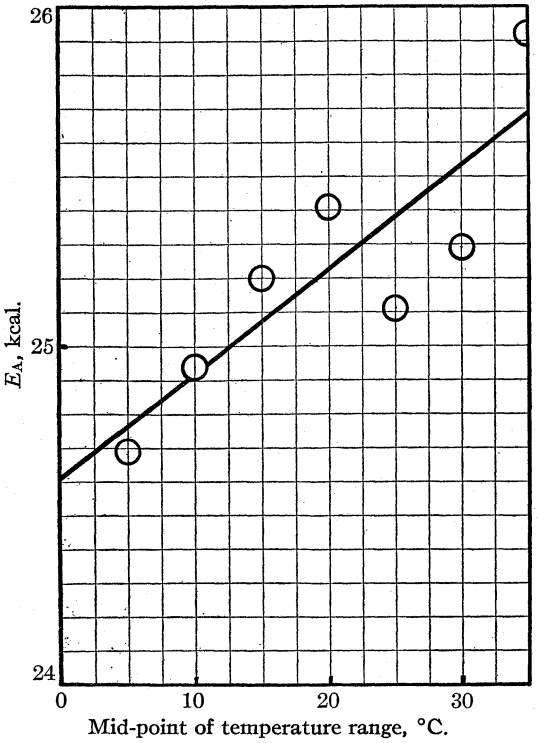

Fig. 3.—Effect of temperature on energy of activation (0.5 molar HCl).

In a recent paper Moelwyn-Hughes[15] reviews the examples of the change of E_A with temperature and reports experiments on the hydrolysis of methyl halides. He finds that the temperature coefficient of the apparent activation energy is always negative in the region explored. This is not the case for the hydrolysis of ethylal.

Even though the variation of E_A and B with temperature has been established definitely, it is still possible to write an expression of the form of equation (1) which holds for the data in 0.5 molar hydrochloric acid solution. In fact it is possible to calculate values of $k_{H_3O^+}$ from the following equation, over the range of temperature studied, which on the average agree with the observed values to ±1.2%, the maximum deviation being 3.8%. The equation

$$\ln k_{H_3O^+} = 34.175 - (25{,}304/RT) \qquad (6)$$

(15) Moelwyn-Hughes, *Proc. Roy. Soc.* (London), **A164**, 295 (1938).

was determined by considering ln $k_{H_3O^+}$ as a linear function of $1/T$ and determining the intercept and slope of the line by least squares. The constancy of E_A and B cannot be judged from the conventional plot of log k *vs.* $1/T$.

In similar fashion the data for the inversion of sucrose[3] at zero hydrochloric acid concentration can be represented by the equation

$$\ln k_{H_3O^+} = 35.33 - (26{,}250/RT) \quad (0\text{–}40°) \qquad (7)$$

The average deviation of the values of $k_{H_3O^+}$ from this equation is 3%, the maximum deviation 6%. Moelwyn-Hughes[16] reports equations of this type for 0.2 molar hydrochloric acid for three temperature ranges.

$$\ln k_{H_3O^+} = 34.19 - (25{,}430/RT) \quad (15.45\text{–}27.26°) \qquad (8A)$$
$$\ln k_{H_3O^+} = 32.55 - (24{,}470/RT) \quad (27.26\text{–}41.00°) \qquad (8B)$$
$$\ln k_{H_3O^+} = 30.12 - (22{,}950/RT) \quad (41.00\text{–}57.10°) \qquad (8C)$$

As already pointed out, the values for E_A and B are lower than the values of Leininger and Kilpatrick.[3] Jackson and Gillis,[17] in a study of the Clerget method, measured the velocity of inversion of sucrose at temperatures from 20 to 90° and conclude that the results are in agreement with the exponential law first proposed by Arrhenius. The exponential equation for 0.01 normal hydrochloric acid may be put in the form

$$\ln k_{H_3O^+} = 34.61 - (25{,}705/RT) \quad (30\text{–}90°) \qquad (9)$$

where B is calculated at 49.85°, E_A calculated by equation (3) for each interval shows no trend with increasing temperature, the average deviation being 330 cal. These results, however, are not in disagreement with those of Leininger and Kilpatrick,[3] who found dE_A/dT to approach zero in the range 30–40°. Moelwyn-Hughes, on the other hand, observed no decrease in dE_A/dT at higher temperatures.

In considering a possible theoretical explanation of the variation of E_A with electrolyte concentration, it becomes necessary to decide whether the rate determining step is bimolecular or unimolecular. Unfortunately the kinetic measurements of this investigation permit no decision. In the following discussion the rate determining mechanism is to be considered unimolecular. This latter view seems the more probable in the light of recent investigations of reaction rates in heavy water.[18]

Hornel and Butler[19] noted that the hydrolysis of acetal proceeded more rapidly in heavy water than in ordinary water. One would logically expect that the substitution of deuterium for hydrogen would slow down the process if the rate determining mechanism involved a proton transfer. The only possible explanation of the effect observed, therefore, seems to be in the consideration of a preëquilibrium.

In a previous discussion[3] the change in E_A with electrolyte concentration was related to a corresponding change in the difference in heat content between the collision complex and the reactants. A comparison of the observed variation of E_A with electrolyte concentration, and the corresponding value of ΔH_2, is given in Table V. ΔH_2 is the heat of dilution of the hydrogen ion between the two solutions. For comparison, the results for the inversion of sucrose are included.

TABLE V

COMPARISON OF ΔH_2 AND ΔE_A

C_2 (moles per liter)	C_1	ΔH_2	(Calories per mole) ΔE_A, 20° Sucrose	ΔE_A, 15° Ethylal
4	3	300	610	...
3	2	300	620	...
2	1	300	630	580
1	0.5	200	...	210
0.5	0	300	...	370
1	0	500	630	580

From these calculations it appears that the change in energy of activation is understandable on the basis of a preëquilibrium.

Summary

1. The velocity constant, $k_{H_3O^+}$, for the hydrolysis of ethylal has been measured from 0 to 40° over a range of hydrochloric acid concentration.

2. Equations for the effect of the electrolyte, hydrochloric acid, on $k_{H_3O^+}$ are given at −0.01, 10.00, 15.00, 20.00, and 25.00°. The effect of electrolyte decreases with increasing temperature.

3. The energy of activation calculated from the Arrhenius equation shows that E_A and B increase with increasing temperature.

4. A decrease in the energy of activation with increasing concentration of the electrolyte, hydrochloric acid, has been noted.

5. A plausible explanation of the effect of electrolyte concentration upon E_A has been given on the basis of a preëquilibrium.

Pressure–Volume–Temperature Relations in Solutions. II. The Energy–Volume Coefficients of Aniline, Nitrobenzene, Bromobenzene and Chlorobenzene

BY R. E. GIBSON AND O. H. LOEFFLER

Recent measurements have shown[1] that the compressions of benzene and a number of its monosubstituted derivatives over considerable ranges of pressure may be well represented by the Tait equation[2]

$$k = C \log [(B + P)/(B + P_0)] \qquad (1)$$

where k is the decrease in volume per unit volume when the pressure is raised from P_0 to P kilobars. B, a function of the temperature, is a constant characteristic of the liquid or liquid mixture, and C is a constant independent of temperature and the same for all the derivatives of benzene we have examined. In this paper we shall give data on the thermal expansions of the liquids mentioned in the title, give more complete compressibility data, and discuss some of the thermodynamic quantities derivable from these measurements, including the pressure–temperature coefficient $(\partial P/\partial T)_V$ which, following Hildebrand,[3] we shall denote as γ, and especially the energy–volume coefficient $(\partial E/\partial V)_T$.

Experimental

The compressions of the liquids to various pressures up to 1000 bars were measured at 25, 45, 65 and 85° in vitreous silica piezometers in our latest pressure apparatus,[4] and depend on the same constants for vitreous silica and mercury that were employed in the investigation of benzene.[5]

The specific volumes of the liquids at atmospheric pressure were measured at intervals of 10° between 25 and 85° in a weight dilatometer of the type used by Burlew[6] and by Pesce and Hölemann.[7] The dilatometer, made of vitreous silica, is shown diagrammatically in Fig. 1. Its chief merits are simplicity and ease of manipulation. By following Burlew's design of having the open end of the capillary above the dilatometer, we were able to avoid the complicated thermostat used by Pesce and Hölemann, and by having an opening at the top of the dilatometer bulb we were able to fill it readily with solutions whose composition would have changed if evacuation had been necessary. The opening in the dilatometer was closed by a silica glass plate. The faces of this plate and of the supporting flange were ground flat and polished to an optical quality. No trouble from leakage occurred after we had acquired the technique of bringing the optically flat surfaces together. During an experiment the dilatometer was immersed in a well-stirred oil-bath and the tip of the capillary dipped into mercury contained in a small glass cup. The temperature was controlled "by hand" to ±0.01° and measured with the help of a 5-junction copper–constantan thermoelement[8] calibrated at the inversion point of sodium sulfate decahydrate (32.384°)[9] and at the steam point. The departures from L. H. Adams' table[10] were, respectively, +1 and −1 microvolt on the 5-junction element.

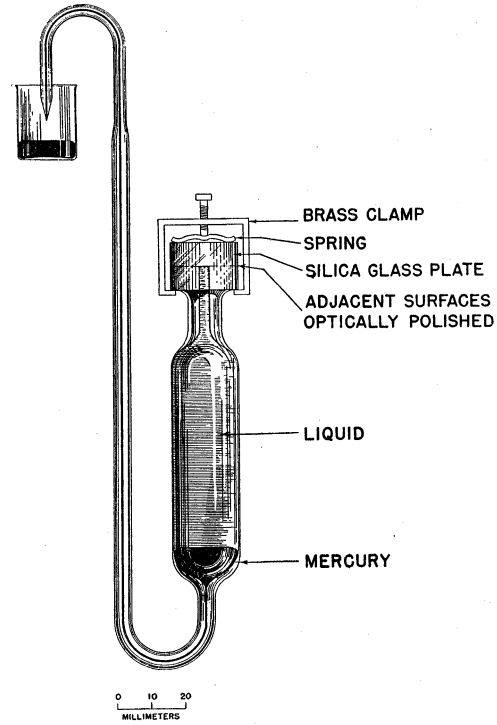

Fig. 1.—Diagrammatic sketch of weight-dilatometer made of vitreous silica for the determination of the thermal expansions of solutions over considerable temperature ranges.

After the temperature had been held constant (within 0.01°) for an adequate time, the small glass cup was

removed and weighed. From the mass of mercury deposited in or taken from the cup during a given change of temperature, the thermal expansion was computed. Readings made with rising and with falling temperature indicated no hysteresis in the thermal expansion of the dilatometer itself. Over 10° intervals the thermal expansions were reproducible within 0.05%.

The volume of the dilatometer at different temperatures was determined from experiments with water and mercury confined in it, the volume–temperature data for these substances being taken from the "International Critical Tables."[11] After approximate corrections had been made for the volume of mercury in the emergent stem of the dilatometer, we computed the mean cubic expansion coefficients of vitreous silica in the form $(v_t - v_{25})/v_{25}(t - t_{25})$. At 45, 65, 85 and 95° this expression multiplied by 10^6 had the values: 1.43 (1.34), 1.46 (1.43), 1.57 (1.49), 1.63 (1.51). The figures in parentheses represent values of the same expression interpolated linearly from the mean coefficients of cubic expansion of vitreous silica given by Sosman.[12] The agreement is satisfactory.

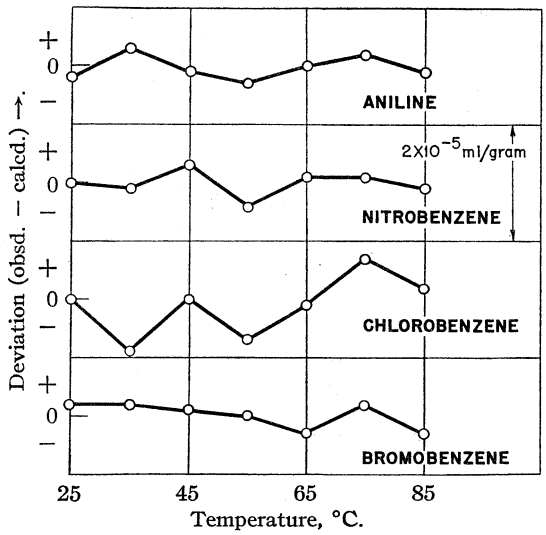

Fig. 2.—Differences between the observed thermal expansions of different liquids and those computed by cubic equations of the type of equation (2).

Aniline, nitrobenzene, chlorobenzene and bromobenzene were obtained from the Eastman Kodak Company. The three first-named were distilled under reduced pressure and the middle fractions were used. The original sample of bromobenzene was fractionated in a small column packed with glass beads. The second and third fractions were used. In Table I the specific volumes at 25° of the samples of liquid[13] we used are compared with apparently reliable ones found by other investigators. We concluded that the agreement indicated that our samples were sufficiently pure for the work in hand.

It was possible to use the dilatometer for direct measurements of the specific volumes of the liquids at 25°. Weighed amounts of mercury and solutions were introduced into the dilatometer and the whole warmed until the mercury completely filled the capillary. Mercury was then allowed to flow in from one of the weighed cups until the dilatometer and its contents were in equilibrium at 25.00°. From a knowledge of the total amount of mercury in the dilatometer, the mass of the solution—the total volume (determined from similar experiments with water)—it was easily possible to measure the specific volume to 1 in the fifth decimal place. At the end of each run all the mercury in the dilatometer was removed, cleaned and weighed. Such a method possesses distinct advantages when one is dealing with volatile liquids.

Results

The specific volumes were represented as functions of the temperature by cubic equations written for convenience in the form

$$v = v_{55} + a(t - 55) + b(t - 55)^2 + c(t - 55)^3 \quad (2)$$

TABLE II

COEFFICIENTS IN EQUATION 2 REPRESENTING THE SPECIFIC VOLUMES OF DIFFERENT LIQUIDS AS FUNCTIONS OF THE TEMPERATURE AT 1 ATMOSPHERE. THE CONSTANT v_{55} REFERS TO OUR SAMPLE (SEE TABLE I)

Substance	v_{55}	10^4a	10^7b	10^9c
Chlorobenzene	0.935873	9.589	13.229	4.38
Bromobenzene	.690481	6.498	7.602	1.875
Nitrobenzene	.855751	7.274	6.931	1.528
Aniline	1.008746	8.874	9.292	2.083

Our results are presented, therefore, in Table II, which gives the values of v_{55}, and the other coefficients in the equations for the four liquids. The excellent way in which these equations fit our data is shown in Fig. 2 where the differences between the observed specific volumes and those

calculated by equation (2) are plotted at different temperatures. It should be noted that the values of v_{55} refer to the samples we used. The expansion equations may be adapted to give the specific volumes of purer samples merely by adjusting the value of v_{55}. By differentiation of equation (2) we were able to compute the expansion coefficient $(\partial v/\partial T)_P$ at any temperature, and these computed values were used in any subsequent calculations without any reference to the deviations.

To test the validity of these equations for extrapolation beyond the observed range, we computed the specific volumes at 0°, which are given in parentheses in Table I. These were compared with the measured values obtained by Timmermans and his colleagues, also in parentheses.

The results of the compressibility experiments are summarized in Table III, which gives the

TABLE III

CONSTANTS IN THE TAIT EQUATION FOR BENZENE AND SOME OF ITS DERIVATIVES AT DIFFERENT TEMPERATURES. FOR ALL THE LIQUIDS AT ALL THE TEMPERATURES C = 0.2159$_1$

Substance	B in kilobars 25°	45°	65°	85°
Benzene	0.970	0.829	0.701	
Chlorobenzene	1.2491	1.0978	0.9609	0.8350
Bromobenzene	1.4044	1.2473	1.1033	0.9720
Nitrobenzene	1.8652	1.6788	1.5045	1.3416
Aniline	2.0066	1.7983	1.6056	1.4294

values of B in the Tait equation for the different liquids at different temperatures, and in Fig. 3 where the deviations are plotted. It should be noted that although the chlorobenzene results at 500 bars deviated most widely, the values of the compressibilities at 1 atmosphere calculated from the Tait equation agreed within 1% with those obtained from sound velocities by Freyer, Hubbard and Andrews.[14] We already have commented[1] on the fact that the constant C has the value 0.2159$_1$ for all the liquids discussed in this paper and apparently it does not change with temperature.

The Pressure–Temperature Coefficient $(\partial P/\partial T)_V$.—To compute the coefficient $(\partial P/\partial T)_V$ at atmospheric pressure we used the relation

$$\gamma \equiv \left(\frac{\partial P}{\partial T}\right)_V = -\left(\frac{\partial v}{\partial T}\right)_P \Big/ \left(\frac{\partial v}{\partial P}\right)_T = \frac{1}{v_t}\left(\frac{\partial v}{\partial T}\right)_P \times \frac{(B+P)}{0.4343C} \quad (3)$$

where v_t is the specific volume of the liquid at temperature t and one bar pressure,[15] with the values of $(\partial v/\partial T)_P$ at 1 bar computed from equation (2). Two methods were used to compute $(\partial v/\partial T)_P$ at higher pressures. (a) The specific volumes at a given pressure were calculated from the compressions at each temperature, *i. e.*, 25, 45, 65 and 85°, and then expressed as a function of temperature by empirical cubic or quadratic equations—the latter being quite adequate at the higher pressures. From these empirical equations $(\partial v/\partial T)_P$ was computed at each pressure. (b) From a consideration of the Tait equation it readily may be seen that

$$\left(\frac{\partial v}{\partial T}\right)_{P=P} = \left(\frac{\partial v}{\partial T}\right)_{P=P_0}(1-k) + 0.4343Cv_t\frac{P}{B+P}\frac{1}{B}\left(\frac{dB}{dT}\right) \quad (4)$$

This equation enables us to compute the expansion coefficient at any pressure, $(\partial v/\partial T)_{P=P}$, if we know its value at 1 atmosphere (P_0), the constants

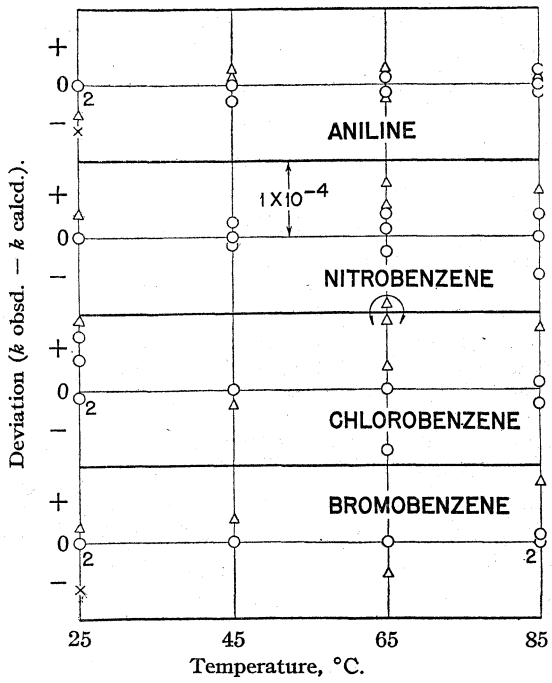

Fig. 3.—Differences between the observed compressions of different liquids and those calculated from the appropriate Tait equation (coefficients in Table III). The open circles ○, triangles △ and crosses × refer to compressions at 1000, 500 and 750 bars, respectively. All the experimental results except those of the compressions to 250 bars are included in the diagram.

(14) E. B. Freyer, J. C. Hubbard and D. H. Andrews, THIS JOURNAL, 51, 759 (1929).

(15) The symbols generally used in this paper are summarized as follows. The specific volume is denoted by v, the molal volume by V, t is the temperature in °C., T the absolute temperature, E is the internal energy, P is the pressure in bars, 10^6 dynes/sq. cm., or kilobars, 10^9 dynes/sq. cm.

in the Tait equation and the change of B with temperature. This last quantity, which was obtained from empirical equations of the form

$$B = B_{25} + a_1(t - 25) + b_1(t - 25)^2 \quad (5)$$

values of a_1 and b_1 being given in Table IV for B

TABLE IV

COEFFICIENTS IN EQUATION 5 REPRESENTING B AS A FUNCTION OF TEMPERATURE

Substance	B_{25}	10^3a_1	10^5b_1
Chlorobenzene	1.2491	− 7.897	1.66
Bromobenzene	1.4044	− 8.179	1.62
Nitrobenzene	1.8652	− 9.616	1.48
Aniline	2.0066	−10.813	1.99

expressed in kilobars, is the weakest part of the whole calculation.[16] We used method (*a*) to compute $(\partial v/\partial T)_{P=P}$ at 1 bar and at 1000 bars, and method (*b*) at 250, 500, 750 and 1000 bars. Except in the case of chlorobenzene both methods gave essentially the same results.

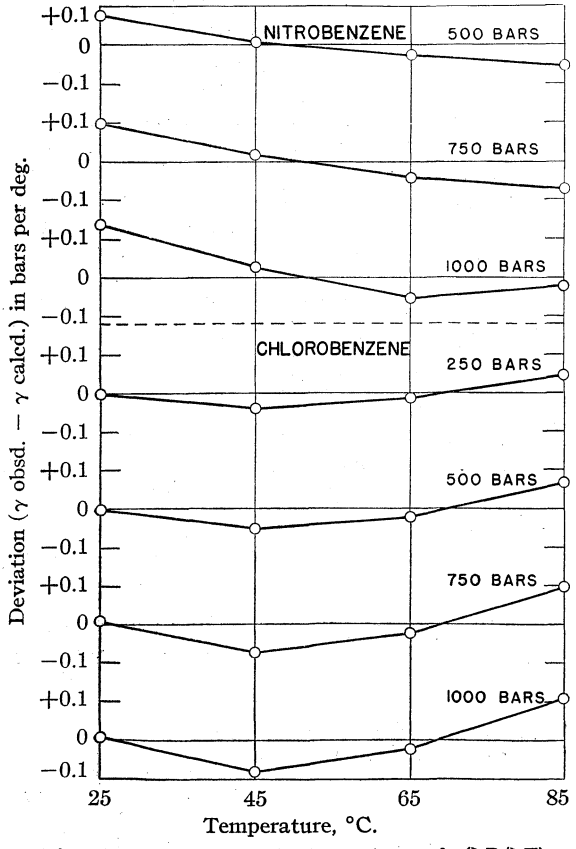

Fig. 4.—Deviations of the values of $(\partial P/\partial T)_V$ computed by the empirical equation (6) from the "observed" values.

(16) Carl[2] proposed the simple equation $B = T_c/T - constant$, where T_c is the critical temperature, to represent B as a function of T. This equation does not fit our data, and even if T_c is taken as an adjustable constant, it does not represent the data over the observed range as well as equation (5).

The coefficient γ increases with pressure at constant temperature, decreases with temperature at constant pressure, and decreases with temperature at constant volume. This last change is not large but is undoubtedly real and very significant. It is in accordance with Bridgman's general conclusions.[17]

We found empirically that the variation of γ over the temperature range at any pressure could be represented most simply by making γ a linear function of $(B + P)$, and, moreover, that the coefficient of $(B + P)$ is independent of pressure. At present no significance is attached to this relation, but to summarize our results in a concise and readily available form we give in Table V the constants l and m in the equation

$$\gamma = l + m(B + P) \quad (6)$$

TABLE V

CONSTANTS IN EQUATION 6 REPRESENTING THE PRESSURE–TEMPERATURE COEFFICIENTS AS FUNCTIONS OF $(B + P)$ (SEE TABLE III)

		The coefficient l				
Substance	m	1 bar	250 bars	500 bars	750 bars	1000 bars
Chlorobenzene	8.17	2.85	1.59	0.28	−1.08	−2.47
Bromobenzene	7.79	2.65	1.42	.16	−1.14	−2.47
Nitrobenzene	7.35	2.73	1.56	.36	−0.86	−2.11
Aniline	7.37	3.43	2.29	1.12	− .75	−1.29

for the different liquids and a deviation curve in Fig. 4 for those cases where the difference between the observed and calculated values is greater than ±0.04 bar/degree. The fact that equation (6) holds so well is interesting because it means that the expansion coefficient is simply related to B by equation (7)

$$\frac{1}{v_t}\left(\frac{\partial v}{\partial T}\right)_P = 0.4343C\left\{\frac{l}{(B + P)} + m\right\} \quad (7)$$

and, as the compressibility of the liquid is given by $0.4343C/(B + P)$, it means further that over a range of temperature at a given pressure the expansion coefficient $(\partial v/\partial T)_P/v_t$ varies approximately linearly with the compressibility. The coefficient l as a function of the pressure decreases somewhat less rapidly than linearly as P increases. It is of interest to note that at constant volume the expansion coefficients $(\partial v/\partial T)_P$ and the compressibilities of all these liquids decrease as the temperature is raised.

The Energy–Volume Coefficient $(\partial E/\partial V)_T$

From the thermodynamic relation $(\partial E/\partial V)_T = T\gamma - P$ we computed the energy–volume coefficients for the various liquids at different temperatures and pressures. The results are given in

(17) P. W. Bridgman, *Rev. Modern Phys.*, **1**, 12 (1935).

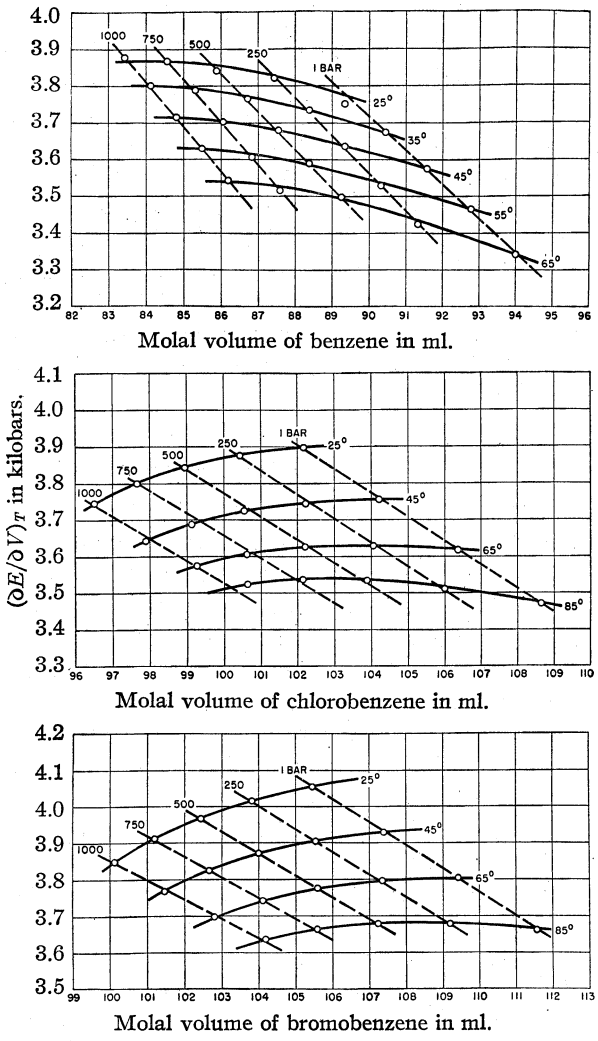

Fig. 5.—The internal pressures $(\partial E/\partial V)_T$ of benzene, chlorobenzene and bromobenzene as functions of the molal volumes at different temperatures.

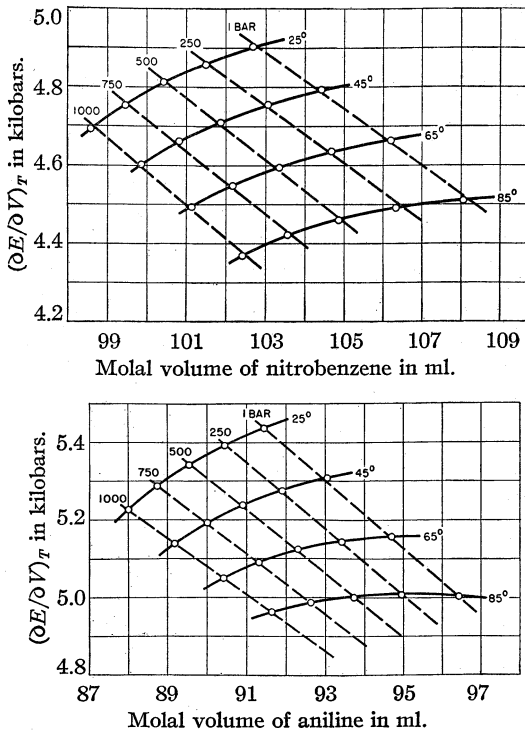

Fig. 6.—The internal pressures $(\partial E/\partial V)_T$ of aniline and nitrobenzene as functions of the molal volumes at different temperatures.

Figs. 5 and 6, where $(\partial E/\partial V)_T$ is plotted against the molal volume of the liquid, the isotherms and isobars being drawn. No special significance is attached to the apparent rectilinearity of the isobars. The results for benzene were computed from the data of Gibson and Kincaid.[5] We wish to call attention to two significant features of the curves in Figs. 5 and 6. (1) Our results cover the interesting but not much studied region in the neighborhood of the pressure and temperature where $(\partial^2 E/\partial V^2) = 0$, a region where such simple formulas as $(\partial E/\partial V)_T = constant/V^n$ certainly do not apply.[18] (2) At constant volume $(\partial E/\partial V)_T$ diminishes as the temperature rises. The coefficient $(\partial E/\partial V)_T$ is positive and quite large for these liquids, ranging from 3.5 to 5.5 kilobars (84 to 131 cal. per cc.) and the changes of $(\partial E/\partial V)_T$ at constant volume illustrated in the diagrams are relatively small, being only about 10% of the total value. We believe, however, that these changes are real. At a given temperature $(\partial E/\partial V)_T$ increases from liquid to liquid in the order benzene, chlorobenzene, bromobenzene, nitrobenzene, aniline. The introduction of the polar group increases $(\partial E/\partial V)_T$ and at the same time makes $(\partial^2 E/\partial V^2)_T$ more positive.

Where classical mechanics are applicable, the total energy of a fluid may be regarded as the sum of a term dependent only on the temperature, $E(T)$, the mean kinetic energy of the molecules at their equilibrium positions together with energy associated with rotation or internal degrees of freedom, and terms giving the potential energy due to intermolecular forces of attraction and repulsion,[19] E_A and E_R. Thus $E = E_R + E_A +$

(19) For expressions giving the energies of fluids containing spherical molecules see J. O. Hirschfelder and W. E. Roseveare, *J. Phys. Chem.*, **43**, 15 (1939), or J. H. Hildebrand, ref. 18a, Chap. V. The authors express the total potential energy in terms of the potential energies of pairs of molecules and the distribution function for the molecules in the liquid. A fundamental treatment of the subject

$E(T)$ and $(\partial E/\partial V)_T = (\partial E_R/\partial V)_T + (\partial E_A/\partial V)_T$. If, following common usage,[20] we call $(\partial E/\partial V)_T$ the internal pressure P_i, we may call $(\partial E_R/\partial V)_T$ and $(\partial E_A/\partial V)_T$ the repulsive and attractive pressures P_R and P_A, respectively. It will be noted that P_R is negative and P_A is positive. In the region we are studying $-(\partial P_R/\partial V)_T$ increases more rapidly than $(\partial P_A/\partial V)_T$ as the volume is diminished along an isotherm and at the maximum where the observed $(\partial P_i/\partial V)_T = 0$, $(\partial P_A/\partial V)_T = -(\partial P_R/\partial V)_T$; at lower volumes further increase of repulsive pressure causes P_i to fall as the volume decreases.[21]

Our second observation that $(\partial E/\partial V)_T$ diminishes with temperature at constant volume is equivalent to the statement (which is obvious from Figs. 5 and 6) that $(\partial E/\partial V)_T$ increases more rapidly as the volume is diminished along an isobar than along an isotherm. We may explain this result by the hypothesis that increase of temperature increases the randomness of the distribution of the molecules in the liquid and that this increase of randomness increases the repulsive internal pressure. Lennard-Jones and Devonshire[22] have developed quantitatively the idea that when a solid melts the disorder introduced increases the free energy and causes an excess repulsive pressure. It is now generally assumed that the molecules are not distributed at random in a liquid, especially near its melting point, but that there persists an order (short range at least) in the arrangement of the molecules,[23] which is a function of pressure and temperature. As the temperature is raised the arrangement of the molecules in the liquid becomes more random.[23] If this happens when the volume of the liquid is kept constant, an additional disorder term is added to the repulsive pressure as in the melting phenomenon discussed by Lennard-Jones and Devonshire. The forces which determine the attractive pressure vary much less rapidly with distance than do those determining the repulsive pressures. It seems plausible to assume, therefore, that at constant volume the attractive pressure is unchanged by changes in the molecular distribution function[24] and that it is the increase in repulsive pressure which lowers the observed value of $(\partial E/\partial V)_T$. In other words, a simple consequence of the decrease of $(\partial E/\partial V)_T$ with temperature at constant volume is that $(\partial^2 P/\partial T^2)_V$ is negative or that the P–T curves at constant volume are concave to the temperature axis and that $T(\partial P/\partial T)_V$ rises less rapidly with temperature at constant volume than does the external pressure. This abnormal increase in the external pressure is a result of the increase in repulsive pressure due to increase of randomness.[25]

The Attractive Internal Pressure

From our previous work with the Tait equation[1,5] we have adopted the working hypothesis that $(B + P)$ at any pressure represents the difference between the thermal and attractive pressures or is equal to the repulsive pressure. It might be expected, then, that the increase of $(B + P)_V$ with temperature should just be equal to the decrease of $(\partial E/\partial V)_T$ with temperature at constant volume, and calculations show that this is approximately true in all the liquids we have studied. It will be seen at once that this result is expressed by the statement that $(T\gamma + B)$, which represents the attractive pressure P_A, is the same function of the volume for all temperatures, and, indeed, we have found that we may express $(T\gamma + B)$ in the form $a'V^{-n}$ over the whole range of pressures and temperatures we have investigated. In Fig. 7 we have plotted log $(T\gamma + B)$ against log V, the slopes of the curves give $-n$ and the intercepts on the ordinates give log a'. It will be seen that the

has been given by J. G. Kirkwood [*J. Chem. Phys.*, **3**, 300 (1935)]. A complete formula for a mixed fluid in which the relative orientations of the molecules are taken into account is given by G. Scatchard, *Trans. Faraday Soc.*, **33**, 160 (1937).

(20) T. W. Richards, THIS JOURNAL, **46**, 1419 (1924).

(21) For discussions of the complete $(\partial E/\partial V)_T$–$V$–curves for liquids, see J. H. Hildebrand, ref. 18a, Chap. V; O. K. Rice, *J. Chem. Phys.*, **5**, 492 (1937).

(22) J. E. Lennard-Jones and A. F. Devonshire, *Proc. Roy. Soc.* (London), **A169**, 317 (1939).

(23) J. D. Bernal, *Trans. Faraday Soc.*, **33**, 27 (1937).

(24) Changes in the relative orientation of the molecules may produce changes in the attractive potential energy at constant volume. This will be discussed later.

(25) That the repulsive potential energy of a liquid increases with temperature at constant volume may also be seen from the following considerations. It has been found convenient and, indeed, necessary in the explanation of many phenomena in fluids to assume that the repulsive energy of a pair of molecules rises rapidly as the molecules approach one another but that the slopes of the repulsive energy–distance curves are not infinite as would be the case for hard spheres [P. W. Bridgman, ref. 17, p. 10; J. Hirschfelder, D. Stevenson and H. Eyring, *J. Chem. Phys.*, **5**, 896 (1937)]. This is all that is implied by the brief but loose statement that it is assumed that the molecules are compressible. Hence, as their kinetic energy increases, the distance of closest approach of the molecules decreases. Curves giving the distribution functions of the atoms in liquid potassium [C. D. Thomas and N. S. Gingrich, *J. Chem. Phys.*, **6**, 411 (1938)] and sodium [F. H. Trimble and N. S. Gingrich, *Phys. Rev.*, **53**, 278 (1938)] show that the probability of finding atoms at very short distances from a given atom increases as the temperature increases. As the repulsive potential energy varies exponentially with the distance between molecules, it must rise considerably as the probability of finding molecules at short distances increases. It is not yet clear, however, how this temperature effect is modified by volume changes.

points for all temperatures lie substantially on the same straight line.[26]

It will be seen that n is approximately the same for aniline, nitrobenzene, bromobenzene and chlorobenzene, the slopes of the curves being -2.70, -2.69, -2.78 and -2.78, respectively. These give an average of -2.74 so that we may write

$$P_A = (T\gamma + B) = a'V^{-2.74} \qquad (8)$$

The values of $10^{-6}\ a'$ for P in kilobars and V in cc. per mole are as follows: chlorobenzene, 1.621; bromobenzene, 1.870; nitrobenzene, 2.163; aniline, 1.730. The curve for benzene, which is not a straight line, indicates that n diminishes as the volume increases. Over most of the range we have studied, however, P_A for benzene is given by $3.38 \times 10^6/V^3$, indicating that at low volumes the attractive potential energy is proportional to V^{-2}, which is in qualitative agreement with the theory of van der Waals forces.[27] In the polar derivatives the longer-range forces may be responsible for making the exponent of V less than that of benzene. It is certain that the linear relation between log $(T\gamma + B)$ and log V does not hold over a large range of volume for any of these liquids. At high volumes the attractive pressure in fluids is proportional to $1/V^2$ no matter what the law of force is.[28] The quantity $E_A = -V(T\gamma + B)/1.74$ should be larger than the heat of evaporation of the liquid, as it neglects entirely the repulsive potential energy. Actually E_A so computed is lower than the values of the heat of evaporation given in the literature, although these are not concordant,[29] indicating that P_A decreases less rapidly at the higher volumes than it would if equation (8) held over the whole range.

In the study of benzene[5] it was pointed out that $(B + P)_V$ was a linear function of the temperature

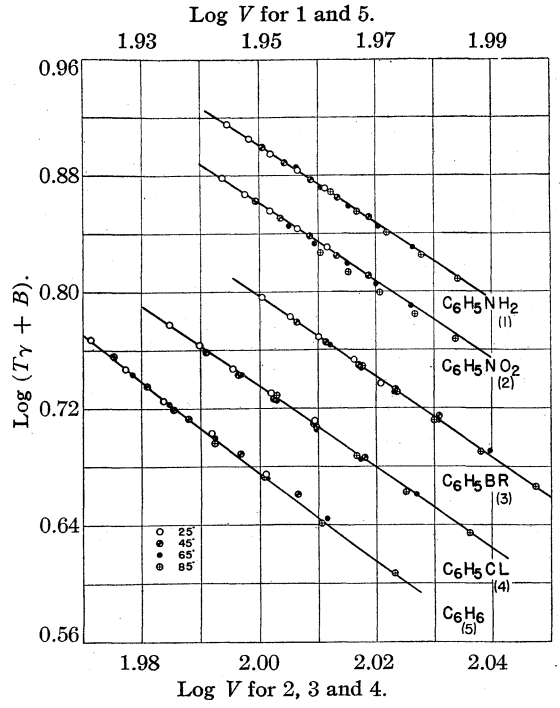

Fig. 7.—The logarithm of the attractive internal pressures of different liquids as functions of the logarithm of the molal volume. Note the points at different temperatures all lie on one curve for each liquid.

and that the extrapolated values of $(B + P)_V$ at 0°K. were approximately inversely proportional to the square of the volume. Over the range we have investigated, $(B + P)_V$ is also a linear function of T for nitrobenzene, but the extrapolated values at 0°K. increase as the volume increases. It will be noticed that the slopes of the $(\partial E/\partial V)_T - V$ curves for these two substances are opposite in sign. For the other liquids $(B + P)_V$ is not a linear function of the temperature, the slope decreasing as the temperature is raised. From the foregoing argument it will be seen that where $(B + P)_V$ increases linearly with T, $(\partial E/\partial V)_T$ decreases linearly with T at constant volume. The linear relation we found holds because over a relatively short range of temperature the "disorder" part of the repulsive pressure is proportional to the thermal energy of the molecules.

A consideration of Figs. 5 and 6 suggests that, for a given change in volume, variation of temperature at constant pressure produces a larger change in the distribution of molecules in a liquid than does the corresponding variation of pressure at constant temperature. The coefficient $(\partial P/\partial T)$ along the melting curve might be regarded as

(26) In this work we are dealing with molecules that are not spherically symmetrical and are also polar. Doubtless changes in the orientation of the molecules occur as the temperature is changed, but our results indicate that changes in P_A arising from changes in orientation make a contribution to the change of $(\partial E/\partial V)_T$ with temperature at constant volume which is small compared with the contribution due to the distribution of the molecules. We find, however, that at constant volume $(T\gamma + B)$ decreases slightly with temperature, indicating a possible decrease of P_A due to change in the distribution function, but the difference is so close to the over-all uncertainty of our calculations that further discussion of it is undesirable. For instance, in the extreme case of nitrobenzene $(\partial E/\partial V)_T$ for $v = 0.8345$ decreases by 525 bars from 25 to 85°, whereas under the same conditions $(T\gamma + B)_V$ decreases by 104 bars. With other liquids the total change in $(T\gamma + B)_V$ over the same temperature range was less than 50 bars.

a measure of the change in pressure which must be applied to counteract the change in randomness produced by a given rise of temperature. Here we may suppose that the distribution of the molecules is constant, being that existing in the crystal. We have recently measured $(\partial P/\partial T)_V$ for solid benzene; it is approximately 23 bars per degree. The coefficient $(\partial P/\partial T)$ along the melting curve is approximately 36 bars per degree.[30] For a given rise of temperature, the pressure change necessary to keep constant the distribution in the solid is, according to this argument, more than 1.5 times the pressure change required to keep constant the volume of the solid.

Summary

From measurements of the specific volumes at 25°, the thermal expansions and the compressions of aniline, nitrobenzene, chlorobenzene and bromobenzene, we have been able to compile a table of the volumes of these liquids at any temperature and pressure in the region 25 to 85° and 1 to 1000 bars. Suitable equations for computing the first and second derivatives also are given. From these data the coefficients $(\partial P/\partial T)_V$ and $(\partial E/\partial V)_T$ were computed. Our data enable us to discuss the variation of these and other thermodynamic functions with temperature at constant volume. Both $(\partial P/\partial T)_V$ and $(\partial E/\partial V)_T$ decrease as the temperature increases at constant volume. It is suggested that this effect is due to an increase in the repulsive internal pressure which follows from an increased randomness in the distribution of the molecules in the liquids at higher temperatures. The quantity $(B + P)$ in the Tait equation for the compressibility of the liquids is identified empirically as the repulsive internal pressure. It increases with temperature at constant volume and, when it is combined with the total internal pressure, an estimate of the attractive pressure is made. The attractive pressure so computed is expressible as $P_A = a'V^{-n}$ and is dependent only on the volume within the limits of our experimental error. The exponent n has the value 3 for benzene and 2.74 for the polar liquids.

A weight dilatometer of vitreous silica suitable for the rapid and precise measurements of the thermal expansions of solutions is described.

A Lead–Iodine Voltaic Cell

BY W. C. VOSBURGH AND VERNON H. DIBELER

Among the cells made by Gerke[1] the cell

$$Pb(Hg)/PbI_2, Pb(ClO_4)_2/Pb(ClO_4)_2, PbI_2, I_2/(Pt)$$

is outstanding in that its temperature coefficient $(\Delta E/\Delta T)$ is as small as that of the saturated Weston cell and the two cells that he made agreed unusually well. These results suggested that the cell might have some value as a standard cell. A number of cells were made and they agreed unusually well with Gerke's cells. They were constant in electromotive force as long as observed and were superior to the Weston cell with respect to recovery from polarization.

The cells were set up in vessels of the type used by Vosburgh and Craig.[2] Lead amalgam, about 5% lead, was prepared electrolytically. In some of the cells a more dilute amalgam was used by mistake. The iodine was resublimed. Lead iodide and lead chloride were precipitated from dilute solutions. Lead nitrate was recrystallized. Lead perchlorate solution was prepared by the addition of an excess of lead oxide to a perchloric acid solution, followed by filtration and the addition of enough perchloric acid to give a clear solution.

In the construction of the iodine electrodes, equal quantities of dry lead iodide and iodine were ground, mixed thoroughly and placed in one leg of the cell vessel. Lead perchlorate solution was then introduced to a depth of several centimeters and then lead iodide was allowed to fall through the solution to form a layer about one centimeter thick above the iodine–iodide mixture. A platinum electrode sealed into the end of a glass tube was then introduced carefully into the mixture. In some of the cells a platinum wire in the form of a helix was used for the electrode, but usually the electrode was of platinum foil about 1 sq. cm. in total surface area. The area of the amalgam electrode was about 1 sq. cm. also.

The cells may be divided into three groups. In the first group, Cells 3–16, the materials were not free from oxygen, and air was not excluded. Six of these cells agreed well with each other. Four others were rejected

(1) Gerke, THIS JOURNAL, **44**, 1684 (1922).
(2) Vosburgh and Craig, *ibid.*, **51**, 2012 (1929).

because of accidents and four because of disagreement. The disagreement of the last group may be ascribed at least partly to inexperience. In the second group, Cells 17–24, there were no cells rejected. In the construction of these cells the solution was freed from dissolved air and vacuum-nitrogen technique was used for the exclusion of oxygen from the vessel and other materials. In Cells 21 and 22 a saturated lead nitrate solution with excess of solid lead nitrate was used for the electrolyte instead of a lead perchlorate solution, and in Cells 23 and 24 saturated lead chloride solution with excess of solid was used. No significant dependence of the electromotive force on the nature or concentration of the electrolyte was observed. Cells 21–22 and 23–24 became variable when it was attempted to change their temperatures, but they were constant at 25° for over a week and during that time agreed with the perchlorate cells.

Most of the above cells had amalgams that were more dilute than intended. While satisfactory at temperatures below 30°, measurements at higher temperatures showed that the amalgams became unsaturated. Therefore Cells 25–31 were made, and more care was taken that the amalgam was 5% lead. Vacuum technique was not used in their construction, but no cells were rejected. The electromotive forces of the six cells agreed within 0.1 mv. The electromotive forces of all of the satisfactory cells over a period of time are shown in Table I. The average electromotive force agrees well with the value of 0.89363 at 25° found by Gerke.

TABLE I

CONSTANCY OF ELECTROMOTIVE FORCE

Cells	Electrolyte M	E − 893.00 mv., 25° 1–2 wks.	1 mo.	3	5–6	10
3	0.2	0.54	0.58	0.60	0.59	0.60

25–31	1.0	.60	..	.65	.61[c]	

[a] Lead nitrate solution. [b] Lead chloride solution. [c] Calculated from measurement at 28.5°.

Two series of measurements were made at temperatures other than 25°. Cells 3, 14–16 and 18–20 were measured at 20, 10, 15, 20 and again at 25°, but some of the cells disagreed at 30° and others at higher temperatures, presumably because the amalgams became unsaturated. Cells 25–31 were later measured at 40, 35, 30, 25, 20 and again at 25°. The results are given in Table II. The average change in electromotive force with temperature was 0.000042 v. per degree, which is the value found by Gerke.

TABLE II

CHANGE IN ELECTROMOTIVE FORCE WITH TEMPERATURE

Cells	$E_{25} - E_t$, mv. 10°	15°	20°	30°	35°	40°
3–20	−0.65	−0.43	−0.22	..	..	..
25–31	....	....	− .20	0.20	0.42	0.65

It was found by Niederhauser and Hulett[3] that practically all of the polarization of the Weston cell takes place in the mercury limb. Since no mercury salt is present in the lead–iodine cell, it was of interest to test its polarization.

Cell no. 7 was discharged through a resistance of about 150,000 ohms (current 5.3 microamperes) for thirty minutes and the potential drop across the resistance was measured periodically. After fifteen minutes a steady potential difference of 0.89100 v. was attained, which was 2.58 mv. less than the electromotive force of the cell. On breaking the circuit, the electromotive force returned to its original value in twenty minutes. This is typical of the results for several cells discharged through various resistances from 0.1 to 2.5 megohms. Cell 3, discharged for thirty minutes through 9000 ohms, recovered to within 0.01 mv. of its original electromotive force in thirty minutes.

After charging one of the lead–iodine cells for forty-five minutes with a current of 5 microamperes, the cell recovered its original electromotive force in twenty minutes. Measured immediately after the charging was stopped, the electromotive force was 0.3 mv. too high. A normal Weston cell containing a small concentration of acid in the electrolyte when treated in the same manner was still 0.34 mv. too high in electromotive force at the end of thirty minutes. These experiments were repeated on other cells and are believed to be typical.

One cell of larger capacity with electrode areas of about 54 sq. cm. was constructed. The electrode systems were separated by a porous cup. It came to good agreement in electromotive force with the other cells, but later disagreed, presumably because of unequal evaporation of the electrolyte. On discharging through 4000 ohms a constant potential drop across the resistance was attained in twenty minutes and was maintained until measurements were discontinued ten minutes later.

Summary

The cell $Pb(Hg)/PbI_2$, $PbClO_4(m)$,/$PbClO_4(m)$, PbI_2, I_2/(Pt) has been found to be easily reproducible and to remain constant in electromotive force over periods of at least several months. It recovers its original electromotive force after charge or discharge more quickly than the Weston cell.

Aromatization of *n*-Octane and *n*-Decane in the Presence of Nickel–Alumina Catalyst

BY V. I. KOMAREWSKY AND C. H. RIESZ

In a previous article[1] the alkylation of aromatic and naphthenic hydrocarbons with olefin in the presence of nickel–alumina catalyst was described. In the attempt to perform the same reaction with paraffin hydrocarbons it was necessary to study first the behavior of paraffins alone toward the same catalyst. It was found that the paraffin hydrocarbons *n*-octane and *n*-decane undergo dehydrogenation, accompanied by cyclization, the final products being aromatic hydrocarbons. Thus, *n*-octane at 300° yielded a liquid stable toward permanganate. From this liquid, 10% (by weight of *n*-octane charged) of toluene was isolated. The gases from the reaction contained hydrogen and methane (no olefins). These facts show that *n*-octane undergoes dehydrogenation and aromatization to ethylbenzene and the latter decomposes to toluene and methane, as it was shown in another paper.[2] Similarly *n*-decane at 350° over the same catalyst gave a liquid from which 2% toluene was isolated, together with a higher boiling fraction which was not identified. In the reaction gases hydrogen and methane were found. These facts show that *n*-decane also undergoes dehydrogenation and cyclization with splitting of the aromatic formed to toluene and methane. In addition iso-paraffins (1.6%) were found in the aromatic-free product by the antimony pentachloride method.[3]

Comparing these results with the work of Kazansky and Plate[4] and Moldavsky and Kamusher,[5] a definite difference in the action of nickel–alumina catalyst must be noticed. Thus, the platinum charcoal used by Kazansky and Plate produced from *n*-octane at 300° a mixture of ethylbenzene and *m*-xylene. Chromium oxide catalyst used by Moldavsky and Kamusher produced at 460° the same aromatic hydrocarbons and olefins. Nickel–alumina produced toluene.

Only traces of aromatization were observed with isoöctane and diisoamyl over nickel–alumina catalyst at 300–350° and, in addition, olefins were formed.

Experimental Part

Apparatus and Procedure.—The paraffin hydrocarbons were passed at the rate of 3–4 cc. per hour through a glass tube of 14 mm. inside diameter filled with 40 g. of 8–10 mesh catalyst. The slow stream of nitrogen simultaneously was passed through the tube. The tube was placed in a horizontal electric furnace. The liquid products were fractionated by a micro-Podbielniak column The gases were analyzed by the Göckel method.

Material.—*n*-Octane, *n*-decane, and diisoamyl were synthesized by the Wurtz method from *n*-butyl bromide and *n*-amyl bromide, respectively. *n*-Octane, b. p. 124.5–125°, $n^{25}D$ 1.3950; *n*-decane, b. p. 169–170.5°, $n^{25}D$ 1.4098, diisoamyl, b. p. 156–158°, $n^{25}D$ 1.4067. Isoöctane was Röhm and Haas Co. product, b. p. 99–100°, $n^{25}D$ 1.3866. Nickel–alumina catalyst was prepared according to the procedure of Zelinsky and Komarewsky.[6]

Aromatization

***n*-Octane.**—At 300°, 50.0 g. of *n*-octane yielded 48.5 g. of liquid, $n^{25}D$ 1.4130, stable toward permanganate. Distillation gave fractions of the following weight, boiling point and refractive index: (1) 5 g., 110–115°, $n^{25}D$ 1.4750; (2) 2.2 g., 115–123°, $n^{25}D$ 1.4050; (3) 37.0 g., 123–126°, $n^{25}D$ 1.3950; (bottoms) 1.0 g., no boiling point, $n^{25}D$ 1.4120. Nitration of the first fraction gave crystals of 2,4-dinitrotoluene, m. p. 70°.

Anal. Calcd. for $C_6H_5 \cdot CH_3$: C, 91.3; H, 8.7. Found: C, 91.1; H, 8.9.

***n*-Decane.**—At 350°, 39.9 g. of *n*-decane yielded after two passages 25.6 g. of a liquid, $n^{25}D$ 1.4122, stable toward permanganate. Distillation of 22.9 g. gave fractions of the following weight, boiling point and refractive index: (1) 0.5 g., 105–120°, $n^{25}D$ 1.4790; (2) 0.5 g., 120–165°, $n^{25}D$ 1.4150; (3) 2.2 g., 165–169°, $n^{25}D$ 1.4105; (4) 14.5 g., 169–170.5°, $n^{25}D$ 1.4108; (5) 3.2 g., 170.5–172°, $n^{25}D$ 1.4125; (bottoms) 2.0 g., no boiling point, $n^{25}D$ 1.4590. Nitration of the first fraction gave crystals of 2,4-dinitrotoluene, m. p. 70°. The gas from the reaction contained 25% hydrogen and 75% paraffin (index 1.0). 9.4% of aromatics were found on the total product with fuming sulfuric acid. Distillation of 16.9 g. of the aromatic-free product gave fractions of the following weight, boiling point and refractive index: (1) 3.7 g., 165–169°, $n^{25}D$ 1.4085; (2) 12.8 g., 169–170.5°, $n^{25}D$ 1.4098; (bottoms) 0.4 g., no boiling point, $n^{25}D$ 1.4100. The boiling range of fraction (1) is lower than that of the original material. Since this fraction does not contain any olefins or aromatics, iso-paraffins must be present. By the antimony pentachloride method[3] 11.6% of isoparaffins was found in fraction (1).

(6) Zelinsky and Komarewsky, *Ber.*, **57**, 667 (1924).

Isoöctane produced at 350° a liquid with $n^{25}D$ 1.3880, traces of reaction with nitrating mixture.

Diisoamyl produced at 300, 325 and 350° a liquid with $n^{25}D$ 1.4080, 1.4090 and 1.4090, respectively. The combined product contained 9.7% of olefins and traces of aromatics.

Summary

In the presence of nickel–alumina catalyst, the normal paraffins *n*-octane and *n*-decane undergo dehydrogenation accompanied by cyclization to aromatic hydrocarbons. A splitting forming toluene and methane also takes place which is not observed with catalysts of platinum charcoal or chromium oxide. Isomerization of the normal paraffins also was noted.

Aromatization of Fatty Alcohols

BY V. I. KOMAREWSKY, C. H. RIESZ AND GEORGE THODOS

The role of various substituents of mixed catalysts in heterogeneous catalysis such as promoter and carrier (support) action has assumed prime importance in our present knowledge of the subject. While in many cases it may be difficult to distinguish between catalyst, promoter, and carrier phenomena, the fact remains that only one reaction is catalyzed in one specific direction. There are, however, mixed catalysts which accomplish two or more different reactions, due to the action of each component of the mixed catalyst working in its own specific direction. It is proposed to call such catalysts "complex-action" catalysts.

In such cases the resulting reaction is a series of parallel or consecutive steps leading to the formation of desired product.

Thus, by combining nickel oxide and alumina, it was possible to obtain directly from camphor, isocamphane by simultaneous reduction, dehydration and hydrogenation.[1,2] By combining a polymerizing and hydrogenating catalyst, isooctane was obtained in one step from isobutylene and hydrogen (hydropolymerization).[3,4] The dehydropolymerization of ethylene[5] represents another example of these types of reactions.

In the development of these ideas a simultaneous combined reaction of dehydration and dehydrogenation of aliphatic alcohols was carried out. The dehydration of fatty alcohols results in the formation of olefin hydrocarbons which by further dehydrogenation can produce more unsaturated material such as diolefins and acetylenes. It was of particular interest to perform this type of simultaneous reaction with the fatty alcohols containing a chain of six or more carbon atoms in order to see whether a more complete dehydrogenation of this chain could take place causing cyclization and formation of aromatic hydrocarbons. For these reactions a mixed dehydrating–dehydrocyclizing catalyst was required.

In this work an alumina-chromium oxide catalyst was used; alumina was the dehydrating and chromium oxide the dehydrogenating and cyclizing catalyst. The simultaneous dehydration and dehydrocyclization of *n*-hexyl, *n*-heptyl and *n*-octyl alcohols, and di-*n*-propylcarbinol was performed. As expected it was found that the simultaneous reaction took place with the production of aromatic hydrocarbons according to the scheme

$$C_nH_{(2n+1)}OH \longrightarrow C_nH_{2n} + H_2O \longrightarrow C_nH_{2n-6} + 3H_2$$

In addition to this reaction, dehydrogenation of the alcohols to aldehydes also took place as shown by the presence of carbon dioxide and carbon monoxide in the reaction gases.

For the fatty alcohols containing six and seven carbon atoms, cyclization of the olefin produced gave the corresponding aromatic hydrocarbon. When *n*-octyl alcohol was subjected to this reaction, a more complex reaction product was obtained. As expected, the eight-carbon chain cyclized to *o*-xylene and ethylbenzene. In addition, however, *m*- and *p*-xylene and toluene were identified. Thus, with this alcohol it is evident that isomerization occurs and *m*- and *p*-xylene are produced by the migration of a methyl

group. Toluene probably is formed by splitting off of a methyl group. Besides, higher boiling unidentified aromatics were found in the reaction product.

The dehydration of alcohols over alumina catalyst takes place with measurable velocities even at 200–300°; however, the dehydrogenation of the olefin produced requires higher temperatures. Therefore the experiments were conducted at 450° and higher. At these temperatures the dehydration takes place with non-measurable speed so that the total reaction might be considered kinetically as being a simple monomolecular (found experimentally) dehydrogenation of olefin hydrocarbons. Due to excellent constancy and reproducibility of the reaction speed an attempt was made to evaluate the energy of activation.

Experimental Part

Apparatus and Procedure.—The alcohols were passed at a rate of 7–10 cc. per hour through a 14-mm. inside diameter glass tube filled with 50 g. of 8–10 mesh catalyst, in a slow stream of nitrogen. The tube was contained in a horizontal electric furnace. The liquid products were condensed by means of a water condenser and an ice trap.

Alcohols.—*n*-Hexyl alcohol, b. p. 153–156°, $n^{25}D$ 1.4170; *n*-heptyl alcohol, b. p. 172–176°, $n^{25}D$ 1.4222; *n*-octyl alcohol, b. p. 196.0–197.0°, $n^{25}D$ 1.4295; di-*n*-propylcarbinol, b. p. 151–154°, $n^{25}D$ 1.4159.

Catalyst.—The catalyst was prepared by the simultaneous precipitation of chromium and aluminum hydroxides from an alkaline solution of aluminate and chromite by nitric acid. The precipitate was washed anion free, dried and reduced at 450° in a stream of hydrogen. The chromium oxide content was 25%.

Analysis of the Products.—The first exploratory experiment indicated that:

1. A complete decomposition of the alcohols took place, since no traces of alcohols could be detected in the product.

2. The formation of carbon monoxide and dioxide in the gases showed that a certain amount of the alcohol charged underwent a dehydrogenation to aldehyde with a consecutive decomposition of the latter. The decomposition of the aldehyde formed is complete since no undecomposed aldehyde was detected in the liquid reaction product by the sodium bisulfite method. Thus the amount of the aldehyde formed can be calculated from the amount of oxygen evolved in the gas in the form of carbon monoxide and dioxide. Consequently, the amount of hydrogen formed in the reaction gas belongs to two reactions: (a) alcohol dehydrogenation to aldehyde; and (b) olefin cyclization to aromatics.

3. The boiling points of the liquid reaction products are always lower than those of the charged alcohol and usually correspond to the boiling points of the mixture of corresponding olefin and aromatic hydrocarbons. Small

(about 5%) higher boiling bottoms probably are formed due to polymerization of unsaturated and hydrocarbon fragments from aldehyde decomposition. These bottoms have a very high refractive index (incomparably higher than the corresponding aldehyde or alcohols) which indicates that unreacted alcohol, or undecomposed aldehyde, is absent in the liquid reaction product.

Taking these facts into consideration, the following analytical procedure was applied.

Gas Analysis.—The gas was analyzed by the Göckel method. The amount of alcohol dehydrogenated to aldehyde (or ketone) and the amount of aromatic hydrocarbon formed was calculated, as follows.

Total gas evolved, 5520 cc.; carbon dioxide content, 10.0%; carbon monoxide content, 2.90%. Oxygen, as calculated from carbon dioxide and carbon monoxide, 0.903 g. This oxygen corresponds to 6.55 g. of alcohol dehydrogenated to ketone, producing 1265 cc. of hydrogen. Total hydrogen evolved, 2820 cc. (N. T. P.). Hydrogen evolved from toluene formation 2820 − 1265 = 1555 cc. This corresponds to 2.12 g. of toluene or 13.0% in the product, or 8.2% on alcohol charged.[6]

Liquid Analysis.—The liquid products of the reaction were separated from water (formed on dehydration), dried with calcium chloride (since no undecomposed alcohol was found in the product) and fractionated by means of a 36-inch (91-cm.) distilling column of the Podbielniak type. As mentioned previously, the boiling point of the product was typical of a mixture of corresponding unsaturated and aromatic hydrocarbons. The combined fractions were analyzed for olefins by sulfuric acid. The amount of aromatics formed was checked also by the refractive indices of the product (without the bottoms) using refractive index curves. In the case of octyl alcohol the product was hydrogenated selectively before fractionation in order to eliminate the olefins. The results of the experiments are given in Tables I and II.

Kinetics of the Reaction

Experiments 3, 4, 5, and 6 were carried out under carefully controlled conditions, each time with a freshly regenerated catalyst. The reaction took place with a constant speed during a sufficiently long time (two to four hours). Thus it was possible to evaluate the kinetic constants and calculate the energy of activation.

(6) Data from Experiment 4.

Calculations from the experimental data showed that the reaction of aromatization is of the first order and the formula $K = \frac{2.303}{t} \log \frac{a}{a - x}$ (t, time, a, the amount taken into the reaction; and x, the amount of product in per cent.) can be applied. The energies of activation, Q, were calculated using the formula

$$2.303 \log \frac{K_2}{K_1} = \frac{Q}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

where K_1 and K_2 were the velocity constants, and T_1 and T_2 the corresponding absolute temperature. The constants were determined for two reactions: (1) alcohol aromatization, and (2) alcohol dehydrogenation to aldehyde (or ketone).

Table III presents the results of these calculations.

TABLE III

Alcohol	Cal./mole, Q for aromatization	Q for aldehyde (or ketone) formation
n-Heptyl alcohol	59,700	
Di-*n*-propylcarbinol	57,600	31,100
n-Hexyl alcohol	62,000	14,200

Summary

1. Under the action of a mixed, chromic oxide–alumina catalyst, the fatty alcohols undergo a complex reaction involving dehydration, dehydrogenation, and cyclization producing aromatic hydrocarbons.

2. The reaction was accomplished with alcohols containing six, seven, and eight carbon atoms.

3. Each component of the chromic oxide–alumina catalyst influenced the reaction in its own specific direction, alumina acting as dehydration and chromium oxide as a dehydrogenation and cyclization catalyst.

4. It is proposed to name this type of mixed catalysts "complex-action catalysts."

Hydroxyl and Amino Derivatives of Dehydroabietic Acid and Dehydroabietinol

BY LOUIS F. FIESER AND WILLIAM P. CAMPBELL[1]

The objective of our work in the resin acid field has been to utilize abietic acid as a starting material for the synthesis of hydrophenanthrene derivatives having a sufficient structural similarity to certain other important natural products of this group to offer promise of exhibiting some of their physiological actions. A foundation for this project was laid in the first investigation[2] by the isolation and characterization of the partially aromatized dehydroabietic acid, and later a practical method was found for the preparation of the pure acid in quantity.[3] On investigating methods for the introduction of the hydroxyl and amino groups into the aromatic ring, it was found that nitration proceeds too readily to the stage of disubstitution and that the readily prepared sulfodehydroabietic acid on alkali fusion gives an intractable mixture containing products of degradation and dehydrogenation. An analogous dehydrogenation has been observed by Mosettig and Stuart[4] who found that 9,10-dihydrophenanthrene-2-sulfonic acid gives 2-phenanthrol on fusion with alkali.

The Friedel and Crafts reaction of methyl dehydroabietate was observed to proceed smoothly in nitrobenzene solution to give as the chief product a substance characterized as the 6-acetyl derivative[3] (III), and this has now proved a suitable intermediate for the preparation of the compounds desired. In the preparation of large quantities of the substance there accumulated an adequate amount of the previously observed by-product for further characterization. This sharply melting substance formerly was thought to be a different crystalline modification of the 6-acetyl derivative, for it has the same composition and gives an identical oxime, but it is now recognized as a molecular compound of the 6- and 8-isomers. No separation could be accomplished by crystallization, but it was found that the more hindered 8-acetyl compound (VI) is unattacked by hydroxylamine even under rather drastic conditions and may be separated from the oxime of the 6-derivative by mechanical segregation of the crystals. The structure VI was established by oxidation with nitric acid and identification of the product as prehnitic acid (1,2,3,4-acid).

On treatment with hydrogen chloride in acetic acid–anhydride in the cold the oxime of methyl 6-acetyldehydroabietate rearranges very smoothly to give a mixture consisting largely of the desired acetyl amine ester IV but containing an appreciable quantity of the methyl amide ester V. A separation is not practical at this stage but can be accomplished after partial hydrolysis. Short boiling with hydrochloric–acetic acid results in complete hydrolysis of the ester group of V without attacking the methyl amide substituent, giving the alkali-soluble methyl amide acid Va. The acetyl amine ester IV under these conditions is converted largely into the corresponding amine ester VII, which is found in the neutral fraction along with a small amount of the unchanged acetyl compound. With this isomer (IV) there is but little hydrolysis of the ester group, and as this apparently occurs after elimination of the acetyl group the material carried into the alkaline extract can be separated from Va by precipitation of the hydrochloride from ether. To obtain pure methyl 6-aminodehydroabietate the partially hydrolyzed neutral fraction is submitted to further treatment with hydrochloric–acetic acid to destroy the remaining acetyl compound. After separation of a quantity of the free amino acid with alkali, the amino ester is obtained easily in a pure, crystalline condition.

The separations indicated were all sharp, and the total yields of pure end-products based upon the oxime used were as follows: methyl 6-aminodehydroabietate (VII), 62%; 6-aminodehydroabietic acid, 26%; 6-methylamidodehydroabietic acid (Va), 4%. The last-named substance was characterized by saponification to 6-carboxydehydroabietic acid, the 1-methyl ester of which was described previously.[3] Various derivatives of the amino acid and ester of the other series were prepared, and the amine VII was converted by diazotization with nitrosylsulfuric acid in pyridine[5] and by hydrolysis into methyl 6-hydroxydehydroabietate. There is a possibility that this phenolic

substance is structurally related to podocarpic acid, for on the basis of the evidence adduced by Sherwood and Short[6] it is conceivable that the phenolic acid isolated from resins of Java and New Zealand differs from the acid corresponding to VIII only in the absence of the isopropyl group in the 7-position.

(6) Sherwood and Short, *J. Chem. Soc.*, 1006 (1938).

Having developed satisfactory methods for the introduction of the amino and hydroxyl group into the aromatic nucleus, we next sought to modify the functional group in the alicyclic part of the molecule, and the way was paved in model experiments using methyl dehydroabietate. Bouveault reduction of the ester with sodium and amyl alcohol was tried briefly but found to result chiefly in hydrolysis. Satisfactory results were obtained, however, by high pressure hydrogenation over copper chromite catalyst,[7] dehydroabietinol (II) being obtained in 73% yield. The carbinol is a liquid giving a crystalline dinitrobenzoate. The hydrogenation of methyl 6-aminodehydroabietate presented the further complication that ammonia was liberated if the temperature was raised too high, but under carefully controlled conditions the amino alcohol XI was obtained in excellent yield as a crystalline solid. The reduction of methyl 6-hydroxydehydroabietate gave unpromising results in the first trials, but the desired carbinol X was obtained easily from the amino alcohol XI by the diazo reaction.

6-Hydroxydehydroabietinol (X) is one end-product envisioned in the original plan of our research,[2] for it is a hydrophenanthrene derivative with one aromatic ring having a phenolic hydroxyl group at one end of the molecule and an alcoholic hydroxyl group at the other. The substance therefore possesses some of the structural features of oestradiol and it is being tested for oestrogenic activity.[7a]

It also seems possible that in the resin acid series suitable amino derivatives may be found to have a morphine-like action. As a start in this direction one such compound has been prepared in consultation with Dr. L. F. Small, who has kindly agreed to submit the substance for pharmacological tests. Like morphine, 6-aminodehydroabietinol (XI) is an amino alcohol derivative of a hydrophenanthrene having one benzenoid nucleus, and in analogy with the extensive observations of Small, Eddy, and associates[8] it was thought that the substance might have some activity but that the quality would be improved by methylation, preferably of both the amino and the hydroxyl groups. Methylation was accomplished moderately well in some experiments with dimethyl sulfate and ammonium hydroxide, but the results were erratic. A better method was found in exhaustive treatment with methyl iodide and silver oxide in ether, which gives a water soluble product apparently consisting of the methohydroxide of XII. The aqueous extract on treatment with ammonium iodide gave a precipitate of the methiodide and this decomposed smoothly on heating in vacuum, giving the amine XII as a viscous oil. The substance was isolated as the crystalline hydrochloride and the presence of the ether group established by a methoxyl determination. Both functional groups are thus covered by methylation and the substance is of the type sought.

(7) Compare the hydrogenation of abietic acid esters, Hercules Powder Co., U. S. Patent 1,901,630 (1933).

(7a) Assays of X kindly conducted at the Squibb Institute for Medical Research are reported as follows by Dr. G. A. Harrop. When given at a dose level of 20 γ to 45 castrated rats, 23% of the animals showed a completely cornified smear, while at a level of 5 γ 60% of 40 rats gave a full oestrous response. The difference suggests that the substance may be rather toxic at the higher dosage. In another series a 2.5-γ dose produced full oestrus in 24% of 100 rats and and at a level of 5 γ the response in 40 rats was 55%. Under the conditions of these experiments oestrone produces a high oestrous response at a level of 7.5 γ. The resin acid derivative thus appears to possess marked oestrogenic activity.

Experimental Part[9]

Preparation of Dehydroabietic Acid.—In preparing further quantities of this substance by the previously described procedure[3] it was found that purification of the starting material by the Palkin process can be dispensed with an entirely satisfactory material obtained from crude Steele's abietic acid, once crystallized as the acid sodium salt. The hydrolysis of sulfodehydroabietic acid is conveniently modified by using 60% sulfuric acid (480 cc. of concentrated acid and 500 cc. of water) and stirring the mixture at 135° with a Hershberg tantalum stirrer. The yield in this step (with 80-g. batches) was better, averaging 80%, and the over-all yield of pure dehydroabietic acid from the crude acid sodium salt was the same as that previously reported using pure salt (43%).

Acetylation of Methyl Dehydroabietate.—By the previous method,[3] 46.7 g. of the ester gave 33.0 g. of **methyl 6-acetyldehydroabietate** (m. p. 133.5–134°) in the first crop of crystals (prisms) from ether, and the mother liquor afforded 5.3 g. more of this substance, m. p. 132–134° (total yield 75%) and 3.8 g. (7%) of the substance, m. p. 119.5–120° (needles), which is now recognized as a complex.

Isolation of Methyl 8-Acetyldehydroabietate.—One gram of the complex, m. p. 119.5–120°, was refluxed for four hours with 0.5 g. of hydroxylamine hydrochloride in 2.5 cc. of pyridine and 5 cc. of alcohol and the mixture was poured into water and extracted with ether. After washing with dilute acid and with sodium bicarbonate solution and drying the solvent was evaporated and the product crystallized from ether–petroleum ether. Two kinds of crystals were deposited simultaneously and a mechanical separation could be accomplished rather easily. There was obtained in all 0.35 g. of fine needles of the oxime of methyl 6-acetylabietate, m. p. 151.5–152°, identified by

(9) All melting points are corrected. Microanalyses by Lyon Southworth, with the exceptions noted.

mixed melting point determination, and 0.28 g. of methyl 8-acetyldehydroabietate. This substance crystallizes in clusters of diamond-shaped tablets and melts on rapid heating at about 133°, resolidifies above this temperature, and remelts sharply at 153–153.5°; $[\alpha]^{25}D$ + 40° (1.0% in alcohol). The substance contains no nitrogen.

Anal. Calcd. for $C_{23}H_{32}O_3$: C, 77.47; H, 9.03. Found: C, 77.69; H, 9.02.

The substance exists in two forms which are easily interconvertible. When the above low-melting tablet form was heated in a test-tube at 140° it melted and resolidified; on immersing this material in a capillary tube in a bath at 140° it showed no change and melted sharply at 153–153.5°. This high-melting form was then melted on a watch glass and cooled rapidly to room temperature, giving a glass. When seeded with the low-melting form and warmed slightly, crystals were formed which melted when immersed in a bath at 137°, or sintered at 132° when heated slowly, and then showed the higher m. p.

For proof of structure 0.1 g. of the 8-acetyl compound was heated with 1 cc. of concentrated nitric acid and 2 cc. of water at 190° for twenty hours and the resulting clear yellow solution evaporated to dryness. The residue was dissolved in hot water and caused to crystallize by adding concentrated nitric acid, giving a product, m. p. 236–238° with gas evolution. This was identified as **prehnitic acid** (1,2,3,4-acid) by conversion with excess diazomethane to the tetramethyl ester, which crystallized from methanol as colorless needles, m. p. 130–130.5°, giving no depression when mixed with an authentic sample.[10] We can confirm Smith and Carlson's[11] observation concerning the purple color which this ester acquires on exposure to light and the recovery of colorless material on recrystallization.

The **oxime of methyl 6-acetyldehydroabietate** exhibits an interesting property in forming what appears to be a molecular compound with glacial acetic acid. On shaking 0.55 g. of the oxime with 2 cc. of this solvent at room temperature the substance dissolved completely in a few seconds and the complex then promptly separated. After bringing this into solution by heating and then allowing crystallization to proceed slowly, there was obtained 0.45 g. of product, m. p. 121.5–122.5°, $[\alpha]^{25}D$ + 76° (1.4% in alcohol). The m. p. is not changed by recrystallization.

Anal. Calcd. for $C_{23}H_{33}O_3N \cdot CH_3CO_2H$: C, 69.58; H, 8.64; neut. equiv., 431.5. Found: C, 69.70; H, 8.83; neut. equiv., 431.

The free oxime is recovered on neutralization or on heating the complex for some time at 125°.

Beckmann Rearrangement of the Oxime of Methyl 6-Acetyldehydroabietate and Hydrolysis.—A solution of 0.5 g. of the oxime in 2 cc. of warm glacial acetic acid was cooled, treated with 1 cc. of acetic anhydride, and saturated with dry hydrogen chloride. The reaction product soon began to separate in the form of colorless plates, and after twenty-four hours this was collected, washed with acetic acid and dried; yield 0.5 g., m. p. 179–183°. This apparently is a mixture of the $ArNHCOCH_3$ and $ArCONHCH_3$ compounds in which the former predominates, but separation at this point by crystallization is not practical. The yield and character of the mixture was the same in larger runs (40 g.) and on using three times the specified quantities of acetic acid and anhydride.

For partial hydrolysis facilitating a separation of products, the crude, undried material from 37.1 g. of oxime was refluxed for one hour with 250 cc. of acetic acid and 125 cc. of 6 *N* hydrochloric acid; the solution was poured into 1.5 liters of cold water and the colorless precipitate was collected and combined with that obtained by neutralizing the acid liquor with alkali. The total moist solid was stirred with excess alkali and extracted with ether, and after separation of the ether layer the alkaline liquor was acidified with acetic acid, giving 3.0 g. of an **acid mixture B,** which subsequently was worked up as described below. The ethereal solution (800 cc.) was dried, concentrated to a volume of about 200 cc., and saturated with dry hydrogen chloride. The precipitated material, washed with ether and air dried at 50°, weighed 35 g. and will be referred to as **mixture A.** This consists largely of the hydrochloride of methyl 6-aminodehydroabietate but contains a sufficient amount of the unhydrolyzed acetate of this amine to interfere with the isolation of the amine in a pure, crystalline condition unless removed by further hydrolysis. The presence of the acetate was ascertained on submitting mixture A to diazotization. On dissolving the diazonuim salt in water an insoluble residue remained, and when purified by distillation and crystallization from methanol this formed flat needles, m. p. about 90°, having the characteristics of the 6-acetylamino ester described below. It is odd that this acetate should be carried down from an ethereal solution by hydrogen chloride, but this behavior was noted with an analytical sample prepared from the pure amine as described below.

Methyl 6-Aminodehydroabietate (VII).—A solution of 5 g. of the partially hydrolyzed mixture A in 40 cc. of acetic acid and 20 cc. of 6 *N* hydrochloric acid was refluxed for four hours, cooled, and poured into a solution of 36 g. of sodium hydroxide in 400 cc. of water. The liberated amine was extracted with ether (saving the **alkaline liquor C,** see below) and after drying and concentrating the solution it was obtained crystalline; the yield of satisfactory material was 2.9 g. (62%, based upon the oxime). Crystallized from ether–petroleum ether, it formed diamond-shaped plates, m. p. (evacuated capillary) 137–137.5°, $[\alpha]^{25}D$ +81° (1% in alcohol).

Anal. Calcd. for $C_{21}H_{31}O_2N$: C, 76.54; H, 9.48. Found: C, 76.36; H, 9.33.

The **hydrochloride** was prepared by saturation of an ethereal solution of the amino ester with dry hydrogen chloride. For crystallization 0.25 g. of the salt was warmed with 2–3 cc. of 6 *N* hydrochloric acid and enough alcohol to bring the material into solution at the boiling point. The substance separated as colorless leaves which sintered at about 160° and melted at about 250°, dec.; $[\alpha]^{25}D$ +61° (1% in alcohol). Immersed in a bath at 245°, the sample melted with loss of water, resolidified and melted at 250–260°, dec. The substance, dried at 80° and 9 mm., appears to be a monohydrate; after heating at 245° and evacuating the capillary the product remained unmelted at 290°.

(10) Fieser and Peters, THIS JOURNAL, **54**, 4347 (1932).

Anal. Calcd. for $C_{21}H_{32}O_2NCl \cdot H_2O$: C, 65.69; H, 8.93. Found: C, 65.47, 66.06; H, 8.77, 8.70.

The salt was also isolated from mixture A by crystallization from acid-alcohol and showed the same characteristics on heating.

6-Aminodehydroabietic Acid.—The alkaline liquor C mentioned above on acidification with acetic acid gave 1.1 g. (24% from the oxime) of this acid as a white solid. Crystallization from alcohol gave pure material separating in laths, m. p. (vacuum) 214.5–215°; $[\alpha]^{25}D$ + 82° (1% in alcohol).

Anal. Calcd. for $C_{20}H_{29}O_2N$: C, 76.15; H, 9.27. Found: C, 76.29; H, 9.09.

The **hydrochloride** was prepared by passing dry hydrogen chloride into an ethereal solution of the amino acid and crystallized from a mixture of alcohol and 6 *N* hydrochloric acid. It is unmelted at 295°.

Anal. Calcd. for $C_{20}H_{30}O_2NCl$: C, 68.26; H, 8.59. Found: C, 68.06; H, 8.63.

6-Methylamidodehydroabietic Acid (Va).—The 3 g. of the acid mixture B separated after partial hydrolysis of the rearrangement product on crystallization from aqueous alcohol afforded 2.7 g. of material melting in the range 210–240°. About one-third of this was found to consist of 6-aminodehydroabietic acid, which was dissolved by extraction of the solid with 150 cc. of boiling ether in two portions, precipitated from the ethereal extract with hydrogen chloride, reconverted to the amino acid (0.8 g.), crystallized from alcohol, giving 0.7 g. of pure material (2% yield from the oxime).

A little of the amide-acid (0.2 g.) was recovered from the remaining ether solution by extraction with alkali and precipitation with acid, and this was combined with the material which did not dissolve in the ether (1.5 g.). Crystallization of the total V from aqueous alcohol gave 1.5 g. (4% from the oxime) of shiny leaves, m. p. 253–254°, and the fully purified substance melted at 254–255°; $[\alpha]^{25}D$ +82° (0.9% in alcohol).

Anal. Calcd. for $C_{22}H_{31}O_3N$: C, 73.90; H, 8.74; N, 3.93; neut. equiv., 358. Found: C, 74.30, 73.77; H, 8.78, 8.38; N (Kjeldahl), 4.12; neut. equiv., 359.

6-Carboxydehydroabietic Acid (IX).—A solution of 0.2 g. of the amide-acid V in 5 cc. of *n*-butyl alcohol containing 0.5 g. of potassium hydroxide was refluxed for four hours, the solvent was removed by steam distillation, and the clear aqueous solution remaining was acidified with hydrochloric acid, giving 0.2 g. of an amorphous white solid which did not melt at 280°. This remained undissolved when boiled with 15 cc. of alcohol, but on adding a few cc. of water it dissolved readily. After adding more water at the boiling point the solution became turbid and on cooling the dibasic acid separated as the monohydrate in the form of colorless needles (0.18 g.). The sample was further purified by crystallization from aqueous acetone and gave $[\alpha]^{25}D$ +71° (0.9% in 80% alcohol).

Anal. Calcd. for $C_{21}H_{28}O_4 \cdot H_2O$: C, 69.59; H, 8.33; neut. equiv., 181. Found: C, 69.41; H, 8.54; neut. equiv., 181.

Acetylation of Methyl 6-Aminodehydroabietate.—The **diacetyl derivative** was obtained by heating the amine recovered from 0.5 g. of the hydrochloride with 5 cc. of acetic anhydride at the boiling point for a few minutes Water was added and the mixture warmed to hydrolyze the excess reagent, cooled, and the product extracted with ether. Crystallization from ether–hexane and then from methanol yielded 0.25 g. of the pure derivative in the form of thick prisms, m. p. 150–151°; $[\alpha]^{25}D$ +75° (1.7% in alcohol).

Anal. Calcd. for $C_{25}H_{35}O_4N$: C, 72.60; H, 8.53. Found: C, 72.78, 72.40; H, 8.47, 8.82.

The **monoacetyl compound** (IV) was made by allowing a solution of 0.3 g. of the free amine in 5 cc. of pyridine and 2 cc. of acetic anhydride to stand at 35–40° for two days and pouring the mixture into 30 cc. of water containing excess hydrochloric acid. The oily product soon solidified and was crystallized twice from methanol. The substance forms characteristic flat needles but does not melt normally or sharply. At 93–95° it changes gradually to a transparent but very viscous liquid which does not flow to the bottom of the capillary. The rotation was $[\alpha]^{25}D$ +79° (1.0% in alcohol).

Anal. Calcd. for $C_{25}H_{33}O_3N$: N, 3.77. Found (Kjeldahl): N, 3.87.

6-Acetylaminodehydroabietic acid was prepared from the amino acid (0.4 g.), pyridine (5 cc.) and acetic anhydride (2 cc.). After twenty-four hours at 35°, 100 cc. of water was added and the product slowly crystallized (0.4 g.). One crystallization from methanol gave 0.32 g. of thick hexagonal plates, m. p. 255–256°, $[\alpha]^{25}D$ +80° (1.2% in alcohol).

Anal.[12] Calcd. for $C_{22}H_{31}O_3N$: C, 73.90; H, 8.74; N, 3.93. Found: C, 74.00; H, 8.65; N (Kjeldahl), 3.97.

Methyl 6-Hydroxydehydroabietate (VIII).—One gram of powdered sodium nitrite was added to a stirred mixture of 10 cc. of concentrated sulfuric acid and 5 cc. of water at 0°; the mixture was warmed gradually to 35–40° with stirring until a nearly clear solution resulted. This was cooled to −5° and a solution of 2 g. of methyl 6-aminodehydroabietate in 6 cc. of pyridine was added dropwise with stirring, keeping the temperature below 0°. Sufficient ice and water was added to the thick cream-colored paste to permit good stirring, and after forty-five minutes the volume was made up to about 200 cc., 0.6 g. of urea was added, and stirring was continued for one-half hour. The suspension of the diazonium salt was then poured rapidly into 300 cc. of boiling water and boiling was continued for a few minutes. The phenol separated as a granular precipitate and was collected after cooling. Crystallization from ether–hexane yielded 1.0 g. of diamond-shaped plates, m. p. 157–157.5° and a second crop of 0.5 g., m. p. 156–157°; total yield 68%. Further crystallization did not change the m. p. of the first crop; the rotation was $[\alpha]^{25}D$ +71° (1.2% in alcohol).

Anal. Calcd. for $C_{21}H_{30}O_3$: C, 76.63; H, 9.15. Found: C, 76.32; H, 9.15.

Dehydroabietinol (II).—Methyl dehydroabietate (5 g.) was reduced to the carbinol in dioxane (5 cc.) using copper chromite catalyst (0.5 g.) with hydrogen at 1310–1070 lb. (87–71 atm.) pressure at 250°. After forty-eight hours

(12) Analysis by the Arlington Laboratories.

there was no further absorption of gas. After dilution with water the product was extracted and dried in ether and obtained as a stiff resin consisting largely of the carbinol but containing some unreduced ester. It was refluxed for four hours with 1.5 g. of potassium hydroxide in 15 cc. of *n*-butyl alcohol, the solvent was removed with steam, and the neutral fraction extracted and dried in ether. On distillation the carbinol fraction boiled almost completely at 177° at 1 mm.; yield 3.3 g. (73%). The rotation was $[\alpha]^{25}D$ +53° (2.4% in alcohol).

Anal. Calcd. for $C_{20}H_{30}O$: C, 83.87; H, 10.55. Found: C, 84.25; H, 10.91.

Acidification of the alkaline liquor gave 0.6 g. (12.5%) of dehydroabietic acid.

For characterization the carbinol was converted into the 3,5-dinitrobenzoate by warming it with the corresponding acid chloride in benzene–pyridine at 35–40° for seventeen hours. The substance crystallized from ether–hexane in clusters of prisms, m. p. 123–124°.

Anal. Calcd. for $C_{27}H_{32}O_6N_2$: C, 67.49; H, 6.71. Found: C, 67.58; H, 6.87.

6-Aminodehydroabietinol (XI).—A mixture of 3.3 g. of methyl 6-aminodehydroabietate, 1 g. of copper chromite catalyst, and 25 cc. of dioxane was shaken at 200° with hydrogen at 2400–2100 lb. for seventeen hours, when approximately two moles of gas had been absorbed and the reaction was stopped. The solution was filtered through a thin layer of Norite, washed through with methanol, and the colorless solution concentrated to 40–50 cc., and diluted with water while hot. On cooling, the amino alcohol crystallized in long, shining laths, m. p. 135–137°; yield 2.2 g. (73%). From the mother liquor 0.2 g. more of the product (total yield 80%) was obtained after removing the solvent with steam and removing unchanged ester by saponification of the resin (0.78 g.) with potassium hydroxide (1 g.)–*n*-butyl alcohol (10 cc.) by boiling for four hours. The amine was extracted with ether, converted with aqueous acid to the hydrochloride (0.3 g.), recovered, and crystallized from ether–petroleum ether.

On thorough purification from ether–petroleum ether the amine separated both as flat needles and as leaves of the same m. p. (and mixed m. p.) 139.5–140°; $[\alpha]^{25}D$ +72° (1% in alcohol).

Anal. Calcd. for $C_{20}H_{31}ON$: C, 79.68; H, 10.37. Found: C, 79.97; H, 10.39.

The **hydrochloride** can be purified by crystallization from aqueous hydrochloric acid, forming fine white needles; $[\alpha]^{25}D$ +63° (1.0% in alcohol).

Anal.[12] Calcd. for $C_{20}H_{32}ONCl$: C, 71.08; H, 9.55; Cl, 10.49. Found: C, 71.16; H, 9.49; Cl, 10.35.

The yield in several hydrogenations conducted as above varied from 75 to 85% using pressures from 1000 to 2500 lb. (67 to 167 atm.). The yield was lower at higher temperatures; in one run at 250° ammonia was formed (green color, test with litmus), while in another, using crude starting material, no ammonia was produced but in four and one-half hours the yield of amine was only 45 and 41% of acid was recovered on saponification. A longer reaction time at 200° (forty-eight hours) gave a lower yield (68%).

6-Dimethylaminodehydroabietinol Methyl Ether (XII) Hydrochloride.—A solution of 0.3 g. of 6-aminodehydroabietinol in 10 cc. of dry ether was treated with 5 cc. of methyl iodide and 0.3 g. of silver oxide and refluxed for forty-four hours in a Soxhlet apparatus containing anhydrous sodium sulfate in the thimble to absorb the water formed. During the refluxing two 5-cc. portions of methyl iodide and five 0.3-g. portions of silver oxide were added. The solvent was evaporated and the residue was digested with three 10 to 15-cc. portions of water on the steam-bath. Each aqueous extract was treated while hot with 1 g. of solid ammonium iodide and the resulting gel converted to the crystalline methiodide by heating and shaking. This gave in all 0.45 g. of colorless needles, m. p. 152–152.5° with evolution of gas. For decomposition to the tertiary amine the methiodide was placed in a tube with a constriction providing two compartments and heated in a furnace at 140° and 1–2 mm. pressure, when the amine slowly distilled as a very viscous, clear oil. This was dissolved in ether and treated with dry hydrogen chloride, giving 0.3 g. of the hydrochloride, m. p. (vacuum) 226–227°, with gas evolution. The salt crystallized from a mixture of about equal parts of methanol and 6 *N* hydrochloric acid in the form of colorless laths of the same m. p. (which is somewhat dependent on the rate of heating), yield, 2.7 g. (71%), $[\alpha]^{25}D$ +78° (0.8% in alcohol).

Anal. Calcd. for $C_{23}H_{38}ONCl$: C, 72.70; H, 10.08; OCH_3, 8.17. Found: C, 72.97; H, 10.07; OCH_3, 8.22.[12]

In methylating a 3-g. portion of the amine (eighty hours) it was found expedient during the extraction with water to add 2 g. of silver oxide with each 50-cc. portions of water in order to complete conversion to the water soluble methohydroxide. In this case the methiodide contained a small amount of infusible solid but this did not alter the m. p. of the methiodide or interfere with its decomposition, being left as a white, non-volatile residue. The yield of pure hydrochloride was 68%.

6-Hydroxydehydroabietinol (X).—Attempted preparation of this substance by high pressure hydrogenation of methyl 6-hydroxydehydroabietate gave a product which could be obtained only as a gel or an amorphous solid.

A solution of 1 g. of crude 6-aminodehydroabietinol, m. p. 136–137°, in 100 cc. of hot water containing 0.9 cc. of 6 *N* hydrochloric acid was filtered, cooled to 0–5°, and the hydrochloride precipitated as a fine suspension by adding 10 cc. of 6 *N* acid. A solution of 0.24 g. of sodium nitrite in a little water was added all at once. The salt rapidly dissolved and a flocculent, light yellow precipitate separated. After thirty minutes 0.5 g. of urea was added, and in ten minutes more the precipitate (0.3 g.) was removed by filtration and washed with cold water. The cloudy filtrate and wash water (250 cc. in all) was poured into a solution of 400 cc. of 3 *N* sulfuric acid at 85° and heating was continued for twenty minutes. After cooling, the crude phenol was collected as a light yellow resin (0.65 g., 65%). Crystallization from ether–hexane yielded in all 0.42 g. (42%) of faintly yellow prisms, m. p. 180–181.5°, $[\alpha]^{25}D$ +72° (1.1% in alcohol). The behavior on melting is like that of camphor, liquid appearing at the lower temperature indicated and the crystal skeleton disappearing at the higher temperature.

Anal. Calcd. for $C_{20}H_{30}O_2$: C, 79.42; H, 9.99. Found: C, 79.52; H, 10.25.

Summary

Pure dehydroabietic acid can be prepared very conveniently by the previous process but starting with Steele's abietic acid. The Friedel and Crafts reaction of the ester with acetyl chloride gives chiefly the 6-acetyl derivative, but this is accompanied by a small amount of the 8-isomer with which it forms a stable molecular compound resolvable by preferential reaction with hydroxylamine.

The oxime of methyl 6-aminodehydroabietate rearranges smoothly on treatment with hydrogen chloride in acetic acid–anhydride and gives chiefly the acetylamine derivative, along with a small amount of the isomeric methyl amide. After suitable hydrolysis, derivatives of these substances can be separated efficiently and pure 6-aminodehydroabietic acid and its ester can be obtained by this route in good yield.

By hydrogenation over copper chromite catalyst methyl dehydroabietate and its 6-amino derivative can be converted smoothly to the carbinols. The amino alcohol on methylation with methyl iodide–silver oxide gives 6-dimethylaminodehydroabietinol methyl ether, which is being tested for possible morphine-like actions. The phenols methyl 6-hydroxydehydroabietate and 6-hydroxydehydroabietinol were prepared from the amines by the diazo reaction; the latter substance has some of the structural features of oestradiol.

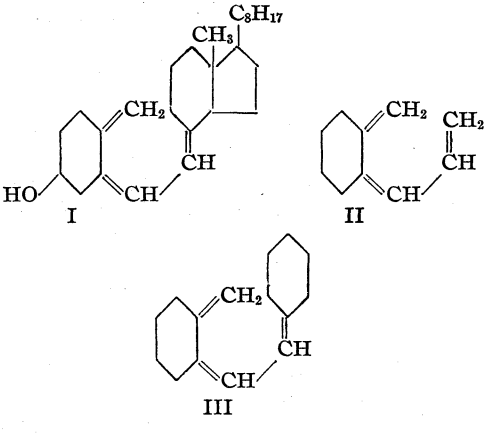
Studies in the Synthesis of the Antirachitic Vitamins. I. The Synthesis of 3-[2′-Methylenecyclohexylidene-1′]-propene-1

BY NICHOLAS A. MILAS AND W. LYSLE ALDERSON, JR.

Although the structure of the antirachitic vitamins has been fairly well elucidated, ultimate proof is lacking because they have not yet been synthesized from simple substances. Some time ago we undertook the problem of synthesis, but in view of its complexity we decided first to synthesize the most unstable portion of the vitamin molecule, then to build the other parts together with the necessary functional groups around this portion. The most unstable portion of an antirachitic vitamin, represented by structure I, is that which includes the three conjugated double bonds. This is known to be responsible for the characteristic spectrum of the vitamin and, together with the hydroxyl group and the side chain,[1] contributes to its antirachitic action.

Two of the simplest configurations which represent this portion of the antirachitic molecule are indicated by structures II and III. After a number of attempts on various reactions which would lead to the synthesis of II and III, we have found that in the case of II the reactions outlined by the equations below led to the expected product in fairly good yields. In view of similar work



undertaken in other laboratories,[2,3] we are publishing at present the synthesis of II which will be followed shortly by that of III and other portions of the antirachitic molecule.

The ultraviolet absorption spectra of II and VII have been plotted side by side in Fig. 1. It may be seen readily that the amine VII absorbs rather strongly in the region of 236 mμ. Its extinction coefficient has been calculated to be 10,500, which is of the right order of magnitude

(1) Milas and Milone, unpublished work which indicates that the side chain of the antirachitic vitamins plays an important role.

for substances of this type having two conjugated double bonds. The triene II has a very prominent band with a maximum at 255 mμ which is slightly displaced toward the short ultraviolet as compared with the important maximum of calciferol at 265 mμ. However, its molecular extinction coefficient agrees remarkably well with that of calciferol, vitamin D_3 and vitamin D_4 as shown in Table I.

TABLE I

THE MOLECULAR EXTINCTION COEFFICIENT, ε, OF THE ANTIRACHITIC VITAMINS

	ε
Calciferol[4] (Vitamin D_2)[5]	19,200 (18,200)
Vitamin D_3[5]	19,200
Vitamin $_4$[5]	18,700
Triene II	19,000

Experimental Part

2-Dimethylaminomethyl Cyclohexanone-1 (IV).—In the preparation of this ketone the procedure of Mannich and Braun[6] was followed. A mixture of 49 g. of cyclohexanone (b. p. 155–156°), 9 g. of 39% formaldehyde solution (Merck) and 9 g. of dimethylamine hydrochloride was heated slowly over a free flame until refluxing commenced. The flame was then removed as the heat evolved by the reaction was sufficient to cause vigorous refluxing which subsided after about two minutes. After the reaction product was allowed to cool to room temperature, it was shaken with 50 cc. of water, the aqueous layer extracted several times with ether to remove any unconverted cyclohexanone, made alkaline with potassium hydroxide and the liberated amine extracted with ether, the ethereal solution dried over anhydrous sodium sulfate, filtered and the ether removed under reduced pressure. Finally, the amine was fractionally distilled and the fraction, 10 g., boiling at 91–92° (7 mm.) collected. The b. p. of this was redetermined at 13 mm. and found to be 97–100°. Mannich and Braun[6] report the b. p. of 2-dimethylaminomethylcyclohexanone-1 to be about 100° (13 mm.).

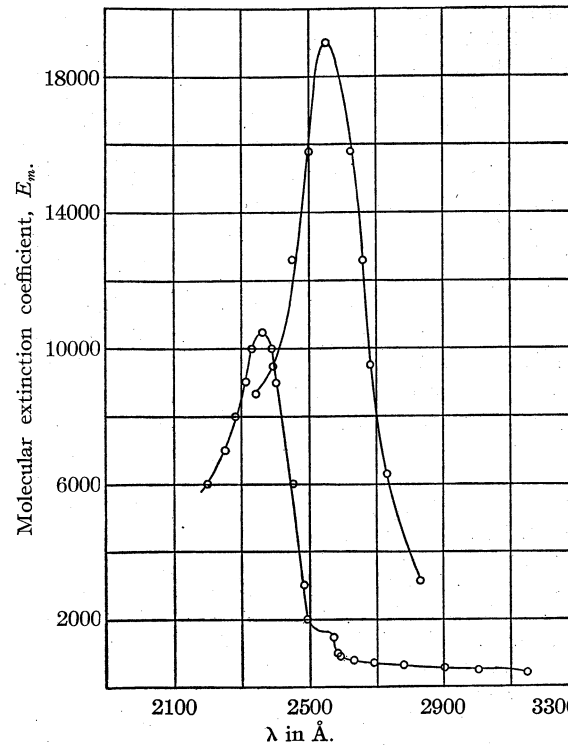

Fig. 1.—The absorption spectra of II and VII.

2-Dimethylaminomethyl 1-Allylcyclohexanol-1 (V).—A solution of 41.5 g. of 2-dimethylaminomethyl-cyclohexanone-1 in 100 cc. of anhydrous ether was added over a period of four hours to an efficiently stirred solution of allylmagnesium bromide[7] in 500 cc. of dry ether. A white precipitate was formed which remained insoluble in ether. After all the ketone had been added, stirring was continued for twelve hours, then the mixture was poured on ice which was mixed with ammonium chloride to decompose the addition product. The ether layer was separated, dried over anhydrous sodium sulfate, filtered, the ether removed under reduced pressure, the residue fractionated,

and the fraction boiling at 112–117° (5 mm.) collected; yield 34.3 g. This substance was a colorless oil with a rather unpleasant odor.

Inasmuch as it was nearly impossible to obtain this alcohol free from the diene, the dehydrated alcohol, and in order to identify it definitely, it was decided to prepare the acetate. Three grams of the dimethylamino alcohol was refluxed with 6 g. of acetic anhydride for one and a half hours. The product was then poured on cracked ice, neutralized with dilute potassium hydroxide, the resulting mixture extracted several times with ether and the ether extracts dried over anhydrous sodium sulfate, filtered and the ether removed in vacuum. The residue was then fractionated and the fraction, 1.8 g., boiling at 129–130° (9 mm.) collected and analyzed.

Anal. Calcd. for $C_{14}H_{25}O_2N$: N, 5.85. Found: N, 5.8, 5.9.

The acetate is a colorless viscous oil of a sharp, rather pleasant odor, having the physical constants: d^{25}_4 0.9596; $n^{25}D$ 1.4740. When exposed to air for long periods of time, it turns brown.

3 - [2′ - Dimethylaminomethylcyclohexylidene - 1′]-propene-1 (VII).—Potassium acid sulfate, phenyl isocyanate, oxalic acid, phthalic anhydride, methylmagnesium iodide and the xanthate method of Tschugaeff were used for the dehydration of 2-dimethylaminomethyl-1-allylcyclohexanol-1. All gave varying yields of the dehydrated amine, but it was found that a purer product could be obtained in higher yields by first converting the alcohol into the bromide and eliminating hydrogen bromide with solid potassium hydroxide.[7b] Although the use of potassium acid sulfate led to satisfactory yields of a dehydrated product, its b. p. of 100–103° (9 mm.) was considerably lower than that produced by the use of the other reagents. This was probably the undesirable product in which the double bond migrated into the ring, a reaction which Wallach[8] has shown to take place readily with similar compounds under the influence of acid reagents.

2-Dimethylaminomethyl-1-allylcyclohexyl Bromide-1 (VI).—In view of its high instability this bromide was not isolated but was prepared as follows. Two grams of freshly distilled phosphorus tribromide dissolved in 5 cc. of anhydrous benzene was added slowly to a vigorously stirred and well cooled solution of 3 g. of the dimethylaminocarbinol dissolved in 10 cc. of dry benzene. The temperature of the reaction mixture while the bromide was added was never allowed to exceed +5°. After all of the bromide had been added, the reaction mixture was stirred at room temperature for six hours longer, whereby the phosphorous acid salt of the amine began to crystallize. To this mixture was then added 6 g. of finely powdered solid potassium hydroxide and the mixture distilled under reduced pressure using an oil-bath. After the benzene distilled over, the oil-bath was heated rapidly to 175°, whereupon the salt of the dimethylamino bromide began to decompose and 2 g. of the crude dimethylaminodiene distilled over at 116–126°. When 2 g. of this amine was fractionated from finely divided sodium, 1.8 g. of pure product was obtained boiling at 126.5–128° (10 mm.).

Anal. Calcd. for $C_{12}H_{21}N$: N, 7 Found: N, 7.6, 7.5.

This amine is a colorless liquid, with a sharp but not unpleasant odor, having the following physical constants: d^{26}_{26} 0.8776; $n^{26}D$ 1.4909, $n^{25}D$ 1.4910; *MR*, calcd. for $C_{12}H_{21}N$, 2F, 58.43, found, 59.03; exaltation, 0.6. That the two double bonds in this amine are conjugated is shown by the presence of an exaltation and also by its absorption spectrum shown in Fig. 1 (VII). This was determined in pure ethyl alcohol and found to have a prominent band in the ultraviolet region with a maximum at 236 mμ. The molecular extinction coefficient was calculated to be 10,500, a value which is of the same order of magnitude as that calculated for substances of this type having two conjugated double bonds.

3 - [2′ - Methylene - cyclohexylidene-1′]- propene - 1 (II).—Three grams of the dimethylaminodiene was converted into the methylammonium iodide by allowing it to react for twenty-four hours at room temperature with excess methyl iodide. The white solid formed was dissolved in water and converted into the methylammonium hydroxide by shaking the aqueous solution for three hours with twice the theoretical amount of freshly precipitated silver oxide. The mixture was then filtered and the filtrate concentrated under reduced pressure in an atmosphere of nitrogen using an oil-bath. After most of the water had been removed, the pressure was reduced to 5 mm. and the temperature of the oil-bath slowly raised to 60° at which temperature the ammonium base began to decompose with considerable foaming. One gram of a pleasant smelling product distilled over. This was taken up in ether and the ethereal solution washed several times with a solution of 50% acetic acid followed by a concentrated solution of sodium bicarbonate, dried over anhydrous sodium sulfate, filtered, the filtrate fractionated under reduced pressure in an atmosphere of nitrogen and the fraction, 0.8 g., boiling at 62–63° (7 mm.) collected and analyzed.

Anal. Calcd. for $C_{10}H_{14}$: C, 89.5; H, 10.5. Found: C, 89.5, 89.4; H, 10.9, 10.5.

The triene is a colorless liquid, with a very characteristic terpene-like odor, having the physical constants: d^{27}_{27} 0.8744; $n^{15}D$ 1.5281, $n^{20}D$ 1.5255, $n^{27}D$ 1.5224; *MR*, calcd. for $C_{10}H_{14}$, 3F, 43.57, found, 46.82; exaltation, 3.24. It is highly reactive and when allowed to remain in contact with oxygen it polymerizes rapidly into a white solid. When hydrogenated in ethyl alcohol using platinum oxide as the catalyst, it was found to absorb 2.98 and 3.3 moles of hydrogen as against the theoretical value of 3 showing the presence of three double bonds.

The ultraviolet absorption spectrum of the triene was then determined in pure ethyl alcohol and the results plotted in Fig. 1 (II). This shows a prominent band with a maximum at 255 mμ and a molecular extinction coefficient of 19,000, a value which is of the right order of magnitude for systems containing three conjugated double bonds one of which is joined to an exomethylene group.

That this triene had not cyclized to form one of the hexahydronaphthalenes is further shown by the work of Morton and de Gouveia[9] and of Huber.[10] These investigators have found that the hexahydronaphthalenes absorb in the region 234–239 mμ and show practically no exaltation.

(8) Wallach, *Ann.*, **360**, 29 (190).

(9) Morton and de Gouveia, *J. Chem. Soc.*, 916 (1934).

(10) Huber, *Ber.*, **71**, 729 (1938).

The authors are indebted to Dr. Robert Heggie for valuable suggestions and aid in the spectroscopic measurements. This is the first article of a program of research on the synthesis of vitamins A and D, support of which is derived through contributions from Abbott Laboratories, Eli Lilly and Company, Merck and Co., Inc., Parke, Davis and Company, and the United Drug Company, such contributions being made through the Research Corporation of New York.

Summary

1. A successful synthesis has been accomplished for the triene, 3-[2′-methylenecyclohexylidene-1′]-propene-1, which possesses a conjugated system identical with that present in all antirachitic vitamins.

2. The molecular extinction coefficient of this triene is nearly identical with that reported for the antirachitic vitamins.

3. Work is being continued with the ultimate goal of synthesizing an antirachitic vitamin.

Sterols. LXX.* The Steroid Content of Mares Pregnancy Urine

BY RUSSELL E. MARKER AND EWALD ROHRMANN

In a previous paper[1] from this Laboratory it was pointed out that the ratios of pregnanediol-3(α)-20(α), *allo*-pregnanediol-3(α)-20(α) and *allo*-pregnanediol-3(β)-20(α) which occurred in human and cows pregnancy urine and in bulls urine appeared to be constant. The figures reported for mares pregnancy urine were arbitrarily based upon the amount of *allo*-pregnanedione[2] obtained from the oxidation of the total carbinol fraction and from this it was assumed that the observed ratio of the occurrence of the various pregnanediols held for all pregnancy urines. Both pregnanediol-3(α),20(α)[2] and *allo*-pregnanediol-3(β)-20(α)[3] have been isolated while *allo*-pregnanediol-3(α),20(α) was assumed to be present from the amount of *allo*-pregnanedione obtained by oxidation of the total carbinol fraction.

Because of the large amount of tar present in mares pregnancy urine the isolation of the pregnanediols by the methods used to work up other urines is extremely difficult and this fact has greatly delayed a quantitative investigation of this urine. Recently we have obtained indications that mares pregnancy urine differs considerably from the other urines studied, especially in regard to the ratio of pregnanediols present. In order to obtain more quantitative information concerning these substances we have undertaken the present investigation of the carbinol fraction from 10,000 gallons of mares pregnancy urine.

The results obtained show a remarkable difference between mares pregnancy urine and other urines as is shown in the following table.

APPROXIMATE AMOUNTS INDICATED IN MG. PER GALLON OF URINE

	Pregnanediol-3(α), 20(α)	*allo*-Pregnanediol-3(α), 20(α)	*allo*-Pregnanediol-3(β), 20(α)
Human pregnancy	50	25	6
Cow pregnancy	25	15	3
Bull	100	50	12
Mare pregnancy	3	2	25

The crude carbinols from 10,000 gallons of hydrolyzed mares pregnancy urine from which the ketones were previously removed with Girard's reagent were separated from the hydrocarbons by means of the half phthalates and the entire carbinol fraction precipitated with an excess of digitonin to separate the steroids epimeric at C-3. The material precipitated by digitonin consisted largely of uranediol-3(β),11[4] and *allo*-preganediol-3(β),20(α) together with a new substance of the composition $C_{48}H_{82}O_3$. This latter substance appears to be a molecular compound of cholesterol and uranediol-3(β),11 since oxidation of the product yielded uranedione while treatment with acetic anhydride yielded cholesteryl acetate.

The carbinol fraction which did not precipitate with digitonin was oxidized under mild conditions with chromic anhydride and the ketones separated with Girard's reagent. The ketonic material yielded some pregnanedione and *allo*-pregnane-

dione in addition to a new compound of the composition $C_{18}H_{16}O_2$, m. p. 214°. This substance which is evidently an unsaturated diketone formed only a monosemicarbazone, which suggests that the substance may be 3-desoxy-11-keto-equilenin. We are planning to investigate the nature of this compound and its possible origin more fully when more of the substance becomes available.

We have also obtained evidence of the presence of urenetriol and of a new *allo*-pregnanetriol in the digitonin precipitable fraction (*cf.* flow sheet, ref. 4, p. 1563). The bromination and mild oxidation with chromic anhydride of two fractions of non-sublimable carbinols[4] gave in one case urenetrione identical with that prepared from uranetrione[5] while the other fraction yielded a new trione, m. p. 129°. This trione upon Clemmensen reduction gave *allo*-pregnane.

Examination of the ligroin soluble fraction referred to in a previous paper (*cf.* flow sheet, ref. 4, p. 1563) yielded the characteristic urinary hydrocarbon of the composition $C_{28}H_{58}$ identical with that previously reported from other urines,[6,7] together with cholesterol and equistanol.[1,3,8]

It seems strange that cow pregnancy urine and bull urine should resemble human pregnancy urine so closely in regard to the ratio of the various pregnanediols present, while mares pregnancy urine, which one might expect to resemble cow pregnancy urine in composition, is so widely different from all the urines so far studied. Mares pregnancy urine differs from the other urines studied not only in regard to the ratio of the pregnanediols present but also by its extreme complexity, as is shown by the large number of substances which have been isolated from it and from the large amount of tarry products of unknown nature which are present. In view of these facts we feel that the investigation of the urines of a number of animal species may give highly interesting results. The fact that equistanol appears to be present in most animal urines but not in human urine may be of great importance and a further investigation of the occurrence and nature of this substance seems highly desirable.

This investigation was supported by a grant from the Committee for Research in Problems of Sex, National Research Council. We wish to thank Parke, Davis and Company for the supply of urine concentrate used and their coöperation in various phases of this work.

Experimental Part

Digitonin Precipitation.—The neutral extract of 10,000 gallons of mares pregnancy urine after hydrolysis with hydrochloric acid, followed by steam distillation with an excess of sodium hydroxide and removal of the ketones by Girard's reagent, weighed 5.2 kg. The pregnanetriol and uranetriol were removed as previously described.[9]

The residue was dissolved in 2 liters of hot acetic acid and poured into 50 liters of ether. The ethereal solution was washed well with water and then stirred with an excess of aqueous sodium hydroxide solution. A large amount of tar, which upon burning left a large inorganic residue, separated out and was discarded. The ethereal solution was washed well with water and the ether removed. The residue was dried by distilling benzene from it. This was then heated on a steam-bath with 1500 cc. of pyridine and 1500 g. of phthalic anhydride for one hour. Ether and ice were added, and the pyridine removed by shaking with hydrochloric acid. The ethereal solution was shaken with an excess of potassium carbonate solution to remove the phthalic esters. These were hydrolyzed by refluxing with alcoholic potassium hydroxide. The carbinol fraction weighed 2.3 kg.

This was dissolved in alcohol and a 2% solution of alcoholic digitonin added until no more digitonide separated. This required a total of 2100 g. of digitonin for the complete precipitation. The digitonides were washed well, dried and decomposed by heating on a steam-bath with 10 liters of dry pyridine until dissolved. This was poured into an excess of ether and filtered from the precipitated digitonin. The pyridine was removed by washing with dilute hydrochloric acid and the ether was evaporated. The residue consisting of digitonin precipitable sterols was dissolved in 500 cc. of benzene.

The Carbinol Fraction Non-Precipitable by Digitonin.—The filtrate from the digitonide precipitation was evaporated, but due to the large amounts of aliphatic carbinols present resisted separation. The concentrate was dissolved in acetic acid and vacuum evaporated several times to remove any alcohol. The residue was then dissolved in 20 liters of acetic acid, cooled to 20° and 3 kg. of chromic anhydride dissolved in 3 liters of water and 5 liters of acetic acid slowly run in with stirring over a period of two hours, keeping the temperature at 20°. It was stirred for an additional hour. Ether and water were added and the ethereal solution washed with water and dilute alkali. The ether was removed and the ketones separated by means of Girard's reagent to give 215 g. of material. Upon steam distillation 75 g. of volatile ketones was removed. The ketones which did not steam distil were extracted with ether and upon concentration to 300 cc. and cooling 5.2 g. of material was obtained. This was sublimed in high vacuum at 140° and the sublimate was crystallized from acetone, methyl alcohol and ethyl alcohol to give a product of m. p. 212–214°. It

(9) Marker, *et al.*, *ibid.*, **60**, 210 (1938).

gave a depression in melting point when mixed with uranetrione and *allo*-pregnanedione.

Anal. Calcd. for $C_{18}H_{16}O_2$: C, 81.8; H, 6.1; mol. wt., 264. Found: C, 82.0, 81.6; H, 6.1, 6.0; mol. wt., (Rast), 248.

Upon heating with semicarbazide hydrochloride and sodium acetate in alcohol for two hours, it gave a semicarbazone which was crystallized from 80% ethanol to give a product, m. p. 255–260° dec. It analyzed for a monosemicarbazone.

Anal. Calcd. for $C_{19}H_{19}N_3O_2$: C, 71.0; H, 5.9. Found: C, 71.4; H, 5.9.

The ketones from the mother liquors of the above product were sublimed in high vacuum, collecting the fraction from 100–220°. These were dissolved in two liters of alcohol and refluxed for two hours with 100 g. of semicarbazide hydrochloride and 120 g. of sodium acetate. The extremely insoluble semicarbazone decomposed at about 320°. This product (21 g.) was hydrolyzed with sulfuric acid and the product crystallized from methanol, ethanol and acetone to give white crystals, m. p. 200–201°; yield 12 g. It gave no depression in melting point when mixed with *allo*-pregnanedione.

The filtrates from the above semicarbazone were combined and recrystallized. The first fraction upon acid hydrolysis gave a further quantity of 1.4 g. of *allo*-pregnanedione. The next fraction of semicarbazones gave only oily products which could not be separated. The following fraction, after hydrolysis of the semicarbazone and sublimation, was crystallized from dilute ethyl alcohol after seeding with a crystal of pregnanedione. It was recrystallized to give 21 g. of pregnanedione, m. p. 117–119.5°, which gave no depression in melting point when mixed with an authentic sample of pregnanedione.

The Digitonin Precipitable Sterols.—This fraction was dissolved in an equal quantity of benzene and allowed to stand at room temperature for one week. The precipitate which formed was filtered and crystallized from acetone. After treatment with Norite this product was crystallized from methanol to give 25 g. of compact white crystals, m. p. 210–212°. This gave no depression with a sample of uranediol obtained previously from mares urine.

The filtrate remaining after the separation of the crude uranediol was evaporated and the semicrystalline product crystallized repeatedly from ethyl acetate to give white flaky needles, m. p. 191–192.5°. The mixture with uranediol melted from 189 to 205°. The product sublimed unchanged in high vacuum at 120–160°.

Anal. Calcd. for $C_{21}H_{36}O_2 \cdot C_{27}H_{46}O$: C, 81.5; H, 11.7; mol. wt., 706. Found: C, 81.6, 81.5, 81.5, 81.4; H, 11.8, 11.5, 12.0, 11.9; mol. wt. (Rast), 363.

When refluxed for thirty minutes with acetic anhydride the product yielded an **acetate** which crystallized from aqueous acetone as white plates, m. p. 111–113°. This gave no depression with an authentic specimen of cholesteryl acetate.

Anal. Calcd. for $C_{29}H_{48}O_2$: C, 81.2; H, 11.3. Found: C, 81.2, 81.5, 81.2; H, 11.6, 11.3, 11.4.

When oxidized with chromic anhydride in acetic acid at room temperature for one hour the substance yielded a product which after treatment with Norite crystallized from ether–pentane as white crystals, m. p. 177–178°. This gave no depression with a sample of uranedione.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 79.4; H, 10.0.

The total sterol fraction remaining after removal of the uranediol and most of the uranediol–cholesterol compound was sublimed in high vacuum, the material distilling at 100–220° being collected. The sublimate was dissolved in 5 liters of acetic acid and the solution oxidized with 200 g. of chromic anhydride at 20° for three hours. The mixture was diluted with water and the precipitated solid taken up in ether and washed with sodium carbonate solution. Partial evaporation of the ether gave 205 g. of solid which after crystallization from methanol and acetone gave 165 g. of white crystals, m. p. 197–200°. This gave no depression in melting point with *allo*-pregnanedione.

The combined filtrates from the above yielded an additional 44 g. of *allo*-pregnanedione as well as a small amount of material which was crystallized from ethanol, acetic acid, methanol and acetone to give white crystals, m. p. 245–248°. Upon heating to 255° gas was evolved. The product, which analyzes for a hydroxy ketone, was recovered unchanged after refluxing with acetic anhydride.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.8. Found: C, 79.2, 79.2; H, 11.1, 11.2.

Oxidation of Residue from Carbinol Mixture C. (*Cf.* flow sheet, ref. 4, p. 1563.)—The portion of carbinol mixture C which would not sublime at 200° was dissolved in acetic acid and a slight excess of bromine added to prevent oxidation of unsaturated compounds. To this solution was added an excess of chromic anhydride in 90% acetic acid and the mixture was allowed to stand at room temperature for ninety minutes, after which 10 cc. of methanol and 5 g. of zinc dust was added. After heating for thirty minutes on the steam-bath the mixture was filtered and the filtrate diluted with water. The precipitated solid was taken up in ether and the product sublimed in high vacuum, the product distilling at 140–160° being collected and crystallized from methanol to give short thick needles, m. p. 127–129°.

Anal. Calcd. for $C_{21}H_{30}O_3$: C, 76.3; H, 9.2. Found: C, 76.2; H, 9.1.

When treated with semicarbazide acetate under the usual conditions, the substance yielded a **semicarbazone** melting above 300°.

Anal. Calcd. for $C_{23}H_{36}O_3N_6 \cdot {}^1/_2H_2O$: C, 60.9; H, 8.3; N, 18.6. Found: C, 60.9, 60.8; H, 8.4, 8.3; N, 19.3.

A solution of 75 mg. of the ketone in 25 cc. of acetic acid was treated with 10 g. of amalgamated zinc and 25 cc. of concentrated hydrochloric acid and the mixture refluxed for three hours. The mixture was extracted with ether and the product crystallized from acetone–methanol to give white crystals, m. p. 80–82°. This gave no depression with an authentic sample of *allo*-pregnane.

Urenetrione from Residues of Carbinol Mixture A. (*Cf.* flow sheet, ref. 4, p. 1563).—The residue remaining after the high vacuum sublimation of carbinol mixture A at 200° was dissolved in 50 cc. of glacial acetic acid. A slight excess of bromine was added and the solution was oxidized with 3 g. of chromic anhydride as described in the

previous experiments. The oxidation product was sublimed in high vacuum at 130° and the sublimate crystallized from methanol as pale yellow plates, m. p. 192°. This gave no depression with a sample of urenetrione (m. p. 195°).

Anal. Calcd. for $C_{21}H_{28}O_3$: C, 76.8; H, 8.6. Found: C, 76.7; H, 8.5.

Ligroin Soluble Fraction.—The ligroin soluble material corresponding to 1000 gallons (3700 liters) (*cf.* flow sheet, ref. 4, p. 1563) was used. The ligroin was evaporated *in vacuo* and the residual tar taken up in 350 cc. of hot 95% ethanol. The solution was cooled at 0° and the white crystals collected, washed with ethanol and crystallized from ethyl acetate after treatment with Norite to give greasy white plates, m. p. 64°. This gave no depression with samples previously reported from human and cows pregnancy urine.

Anal. Calcd. for $C_{28}H_{58}$: C, 85.3; H, 14.8. Found: C, 85.1; H, 14.8.

The filtrate from the above containing the ethanol soluble material was made up to a volume of 500 cc. with 95% ethanol and the solution was precipitated with digitonin (13 g.) to yield 12 g. of dried digitonide. This was decomposed with pyridine in the usual manner and the product was crystallized from ethyl acetate to give white plates, m. p. 146°, which gave no depression with a sample of cholesterol.

The filtrate remaining after removal of part of the cholesterol was made up to a volume of 50 cc. with 95% ethanol and treated with a slight excess of bromine in ethanol solution. To the resulting solution at 25° was added a solution of 2 g. of digitonin in 40 cc. of ethanol and 8 cc. of water at 25°. The mixture was kept at 3° for twelve hours. The digitonide was collected, washed, dried and decomposed with pyridine. The product was crystallized from acetone to give white plates, m. p. 132°. This gave no depression with a sample of β-equistanol.

Summary

Mares pregnancy urine has been found to differ from other urines in the proportion of the three pregnanediols present, *allo*-pregnanediol-3(β),20-(α) being present in considerable amounts while only small amounts of pregnanediol-3(α),20(α) and *allo*-pregnanediol-3(α),20(α) are present.

The Sorption of Methylene Blue by Curd Fibers of Sodium Palmitate

By J. W. McBain, Josephine M. McDowell and Margaret E. Worden

Soap curd fibers account for the whiteness and much of the opacity of many commercial soaps. They are formed in characteristic manner when a solution of pure sodium palmitate is cooled and sets to a solid white mass, or curd, consisting of a fine mesh of these fibers of hydrated neutral soap enmeshing any excess of liquid or solution. They possess some remarkable properties. X-Ray examination clearly shows them to be crystalline, with rows of double molecules placed at right angles to the long axis of the fiber. However, although they may grow to be as much as several centimeters long, microscopic and ultramicroscopic examination shows them to be made up of bundles of very much finer fibers.

It is the purpose of the present study to obtain information as to the actual size of these curd fibers by measuring the superficial area available for the sorption of methylene blue from solution. It is also of interest to find whether such a dye is incorporated within the fibers or, as seems to be the case, lies upon their external surface. Furthermore, this method of study yields information as to changes, such as aging, that take place in curd fibers. Some progress also has been made toward characterizing the differences between curd fibers separating from concentrated and from dilute solution.

Materials.—The sodium palmitate was the special preparation by Kahlbaum, found by analysis to be exactly neutral, that was used by McBain, Vold and Jameson[1] in their recent phase rule study. It was dried at 105° and all solutions were made up by weight. The methylene blue chloride was from the Eastman Kodak Company. Its concentration in the aqueous liquid was determined colorimetrically.

Sodium palmitate although highly soluble at temperatures above 60 to 70° is almost completely insoluble at room temperature, the mother liquor containing only the slightest trace of palmitate in addition to a few thousandths or a few hundredths normal sodium hydroxide as will be described later. Its hydration although large and variable does not appreciably affect the calculation of the amount of sorption. The mother liquor enmeshed in the curd is readily released by mechanical means when the concentration is 0.025 *N* or less. In higher concentrations it is generally possible to cause the apparently hard curd to soften and syneresе by merely rotating the bottle to and fro for a short time, a striking (as yet unnamed)[2] phenomenon which is the opposite of "rheopexy."

(2) *Cf.* ultrasonic effects on sodium stearate curds; Freundlich and Gillings, *Trans. Faraday Soc.*, **34**, 657 (1938).

Method.—Two general types of experiment were employed. In the first or "*in situ*" experiments the dye is added to the hot solution so that the fibers form on cooling to 25° in the presence of the dye. In the more usual type of experiment with "preformed" fibers the curd is first made and only then is the dye presented to the already formed curd. The solution of the dye is mixed as well as possible with the white curd. Both procedures could be varied because in the *in situ* experiments the curd fibers could be formed either from concentrated solution in the presence of the methylene blue and subsequently diluted for observation and analysis, or all of the three constituents could be added initially in one homogeneous solution. Similarly with preformed fibers, these can be kept to any desired age before adding methylene blue and may be diluted either before or afterward. The final dilution was generally $N/20$, $N/24$ or $N/40$. Seventy-three experiments were set up (mostly by J. M. M.) and the observations then extended from the period of initial mixing up to an age of as much as a year.

A standard solution of methylene blue did not fade on prolonged standing; but all experiments were made up from solid dye. A blank experiment showed that addition of sodium hydroxide to make the *p*H equal to 10 does not affect the color of methylene blue. As will be seen later, however, it does affect the amount of sorption.

The Experimental Results

In the first few experiments only 0.086 g. of methylene blue was added to 0.695 g. of sodium palmitate, the initial concentration for the preformed soap being $N/20$, being diluted with the methylene blue solution to $N/24$, the concentration of the *in situ* solutions from the beginning. Practically all (99.6%) of the methylene blue was sorbed in all cases, the final value of x/m being 0.123 g. of methylene blue per gram of sodium palmitate, leaving a concentration of 0.0006 g. of methylene blue per 100 g. of water in solution, but at least four months were required for the final value to be obtained. When the amount of methylene blue was raised to 0.43 g., again the sorption was almost complete ($x/m = 0.617$) with but little difference between *in situ* and preformed experiments, except that the former reached equilibrium more quickly. After the first few weeks noticeable desorption set in again in both cases.

In most of the experiments subsequent to the first four groups just summarized, 1.25 to 2.5 g. of methylene blue was used with 0.695 g. of sodium palmitate, and the methylene blue was found to be fairly divided between the curd fibers and the solution. All these experiments were carried out at 25.0°.

In Situ Experiments.—It is very interesting that sorption by the *in situ* fibers is not completed as soon as the fibers are fully formed in the presence of the methylene blue. Instead, it required a period of hours or days for maximum sorption which afterward fell off again during the next few months.

It may therefore be concluded that sorption in *in situ* fibers does not consist of incorporation of methylene blue within the interior or as an integral part of the fiber. It must be upon the external surfaces of the fiber. This is borne out by the fact that there is little difference between the results with *in situ* and with preformed curds. This is in contrast with the finding of Brocklesby and Kuchel[3] that the oil-soluble vitamin A is sorbed to the extent of 39% by soaps formed *in situ* as compared with only 6% by preformed soaps. Finally, it is clear that the *in situ* curds first formed are unstable in respect either to composition or to size or to both, and that they then recrystallize with less surface.

A typical *in situ* experiment (no. 28) gave the following results: 2.5 g. of methylene blue in 25 g. of water with the *p*H adjusted to 10 by addition of solid sodium hydroxide was added to 0.695 g. of sodium palmitate in 25 g. of water, the $N/20$ solution after cooling to room temperature being diluted to $N/40$. The *p*H of the diluted mixture was also found to be 10. The values of x/m in grams of methylene blue sorbed per gram of sodium palmitate were

15 min.	4.5 hrs.	1 day	3 days	5 days
1.5	1.8	2.0	2.0	1.8
7 days	14 days	23 days	31 days	159 days
1.7	1.4	1.5	1.4	0.8

The maximum value averaged from three series with $N/20$ curd was 2.2 attained after several days, the concentration of equilibrium liquid being 1.01 g./100 g. of water, and the total methylene blue sorbed being 60%. In another experiment x/m had fallen to the value 1.2 in eighty-five days and to 0.4 in one hundred and eighty-one days; but in yet another it was still 1.2 at two hundred and one days.

Without alkali the maximum value of x/m is much less; namely, for solutions originally $N/20$ then diluted as above to $N/40$, it is 1.5. With the solution originally $N/4$ diluted to $N/40$, it is 2.1, and if originally N it is 2.8. In all cases the maximum value is attained after a few days, experiments being quicker than those with preformed curds, partly because in the latter experiments the

(3) H. N. Brocklesby and C. C. Kuchel, *J. Biol. Chem.*, **123**, xvi, May (1938).

methylene blue had to diffuse into the interstices of the solid mass.

The value finally attained after several months with $N/20$ and $N/4$ diluted to $N/40$ is 1.3 in equilibrium with a concentration of 1.6 g. of methylene blue per 100 g. of water, only 36% of the total dye being sorbed. Thus 7 and 24%, respectively, has been desorbed, since the middle of the first week. On the other hand, the solution that was originally normal desorbs the same amount in three months, but x/m is still at the high value of 2.1. Bennett[4] has proved that the curd that separates from a normal solution of sodium palmitate is for some time definitely different from that separating from the more dilute solutions (*cf.* final section of this paper).

Preformed Curd.—All the remaining experiments were carried out with preformed curd. Sorption reaches a maximum in seven days and falls off again for several months.

With 0.43 g. of methylene blue practically the whole of the dye is sorbed, making x/m 0.62. The initial stages are slower when the curd is more concentrated or when more alkali is added. It is significant that desorption is inappreciable, x/m retaining 99.6% of its maximum value even after one hundred and fourteen days, and 99% after two hundred and forty-five days, showing that there is not more than enough dye to saturate the new curd formed by recrystallization. The same result is observed with *in situ* experiments.

With 1.25 g. of methylene blue and solutions originally $N/20$, $N/4$ and N diluted to $N/40$ typical results for x/m were:

Original	15 min.	19 hrs.	1 day	7 days
$N/20$	0.4	1.0	1.0	1.1
$N/4$	.15	0.9	0.9	1.1
N	.05	1.0	1.0	1.1
Original	14 days	84 days	197 days	382 days
$N/20$	1.0	0.76	0.72	0.55
$N/4$	1.0	.76	.70	.57
N	1.0	.76	.66	.56

With 1.8 g. of methylene blue the values of x/m were:

Original	10 min.	2 hrs.	1 day	
$N/20$	0.75	0.99	1.0	
$N/4$	.16	.74	1.1	
N	.002	.28	0.8	
Original	7 days	21 days	140 days	216 days
$N/20$	1.1	0.8	0.75	0.25
$N/4$	1.1	.7	.70	.56
N	1.1	.8	.58	.23

(4) H. B. Bennett, *J. Chem. Soc.*, **125**, 1971 (1924); see also M. Laing McBain, *ibid.*, **117**, 1524 (1920).

Solutions with 2.5 g. of methylene blue were studied more thoroughly with and without added alkali, again using N, $N/4$ and $N/20$ curds diluted to $N/40$. Without alkali, the maximum reached in seven days was $x/m = 1.2$, in every case, falling to a value of 0.4 after six or seven months. At twenty-four days the *p*H was 7.56. With added alkali the maximum value is increasingly larger, being 1.4 for addition of 0.12 N sodium hydroxide, 1.6 with 0.024 sodium hydroxide (*p*H of the mixture being 7.83 at two hundred days), 1.8 for *p*H maintained at 10, and 2.2 for *p*H of the added methylene blue being 11.5. The final value, however, with alkali, is not so increased, but again tends to 0.4 or less.

For $x/m = 1.2$ the concentration of the equilibrium solution is 1.66 and only 34% of the methylene blue is sorbed.

Discussion

It appears that the sorption of dye by sodium palmitate curd fibers is largely or wholly external, as is evident from the time required for sorption even with curds formed *in situ* in presence of the dye, and the similarity of the maximum sorption with preformed and *in situ* curds. Acid soap formed by interaction with the methylene blue hydrochloride sorbs less than soap that has been preserved by keeping the *p*H sufficiently high. The effect of added alkali is to increase the sorption even when no acid soap is present. Most of the excess dye is sorbed until the surface is nearly saturated and thereafter any excess added accumulates in the solution.

Some idea of the extent of the surface may be derived from the numerical results for the saturation value of x/m. Methylene blue has been used since the experiments of Paneth and collaborators to measure approximately the extent of accessible surface on the assumption that 1 mg. of methylene blue indicates 1 square meter. although Bancroft and Barnett[5] have shown that at least over a certain range the results are much affected by the value of *p*H. Gorter[6] found at *p*H 1 and again at the isoelectric point 1 mg. of various proteins cover 1 square meter. Voet[7] found 1.25 mg. of Night Blue to be sorbed per square meter.

The exterior surface of fibrous colloids is of special significance. For example, when 70%

of a cellulose fiber is acetylated, it has been calculated[8] that all of the triacetate would be on the micellar surface as a monomolecular layer.

Similarly, Dr. F. Olsen (private communication) has found that the solubility of nitrocellulose depends solely upon the adjustment of the nitrogen on the exterior.

Size and Shape of Palmitate Curd Fibers.—The data here obtained enable us to reach rather definite conclusions as to the size and shape of the sorbing solid in sodium palmitate curd.

It appears that we must conclude that if x/m can be as great as 1.5, it would require sheets of sodium palmitate to be only 13 Å. thick, an impossibly low value when it is remembered that to satisfy the X-ray data the molecules would have to be laid end to end almost normal to the surface. However, if the fibers are square rods, the indicated area corresponds to breadth and thickness each of 27 Å. It is clear therefore that the fibers are not more than two molecular lengths thick and they must be rod-like or even narrower and lath-like. Even if the methylene blue molecules lay parallel to the exposed sodium palmitate molecules, this would indicate that the cross section of the rod would consist of not over twenty-two sodium palmitate molecules. The subdivision of the curd into fibers is thus carried to an excessive extent, which is still so great even after very many months of standing that one must conclude that sorption occurs on the primary ultramicroscopic fibers.

A similar result follows from the assumption (Dr. M. J. Vold) that the methylene blue molecules are attached in a continuous coating in vertical orientation to the exposed carboxylate ends of the soap molecules; one methylene blue (mol. wt. 319) to each soap molecule (mol. wt. 278). However, as has been noted, especially in the presence of alkali, the amount of methylene blue may sometimes be twice even this value.

Similarly, Mrs. McBain[9] found that 7% of the molecules in insoluble curd fibers from 1 N_W sodium palmitate are ionized and conducting; this would appear to set a minimum value for the exposed molecules unless the conduction could occur through the lattice also.[10]

The reduction of available area of a crystalline precipitate of colloidal dimensions has been ascribed to one or all of three causes: (a) perfection of an originally imperfect surface of a primary particle, improbable in the present case, (b) cementing of the primary fibers to ultramicroscopic bundles, and (c) actual recrystallization to coarser particles.

The Solubility and Hydrolysis-Alkalinity of Sodium Palmitate Curds of Different Concentrations and Ages.—Since Bennett[4] had shown that solubility and hydration of sodium palmitate curd fibers initially obtained from 1.0 and 0.25 N solution differed greatly, a few further determinations of solubility were made. First it was shown that the mother liquors differed in refractive index, but they contained sodium hydroxide as well as soap. Hence the method adopted was to isolate a known quantity of mother liquor by filtration using suction or a Carver press as necessary. This mother liquor was then analyzed by treating with a known amount of standard hydrochloric acid, filtered and the filtrate treated to give total sodium and the residue titrated in neutralized 80% alcohol with sodium hydroxide to measure total fatty acid. The results are given in Table I. It may be noted that the fibers began to form at about 67° from the 1.0 N_W solution, 58° from 0.25 N_W and 50° from 0.05 N_W.

more dilute solution. However, the solubility of all the curds definitely decreases with time, being on an average 0.0020, 0.00145 and 0.0012 N for one day, one week and one and one-half months, respectively, all four curds being then 0.0012 N with respect to total palmitate in solution.

The solubilities recorded by Bennett[4] were the mean of total palmitate and total sodium, but it is now clear that these two quantities should have been kept separate since alkalinity and solubility change independently, and are very different for different curds.

The alkalinity is most striking. Since 1910 we have had occasional indications that the formation of curd is accompanied by the development of alkali. The mother liquors of the stronger curds are now found to be more alkaline than any actual solution of soap is ever found to be, and the alkalinity is maintained. The alkalinity of a 1 N curd is ten times and that of a $N/4$ curd twice that of a dilute curd. Furthermore, the alkalinity increases with time for all the stronger curds. The sodium palmitate from which the curds were derived was exactly neutral in composition. Hence curding is accompanied by definite and appreciable hydrolysis, possibly an example of membrane equilibrium or ion exchange on the exposed surface of the fibers. The pH of a fifteen-year old specimen of $N/20$ sodium palmitate was 9.2.

Summary

Curd fibers of sodium palmitate sorb methylene blue to about the same extent when dye is added to fibers already formed and to those which form in presence of the dye. Since in both cases time is required to complete the sorption, it is evident that sorption is largely external upon the surface of the excessively fine primary ultramicroscopic crystalline fibers. After a week the weight and number of dye molecules sorbed exceeds the weight and number of sodium palmitate molecules. Thereafter the sorption distinctly diminishes and after a year may be only one-third, without any indication that a final value is yet attained, although the fibers must still be less than 100 Å. in diameter.

The solubility of curd fibers formed from concentrated solution is at first only slightly greater than those from dilute solutions, but all diminish to about the same extent with time.

The alkalinity of the stronger curds is far greater than that of any soap solution and it is ten times larger for a 1 N curd than for a 0.05 N curd, although the latter falls in the course of years to pH 9.2.

Pectic Enzymes. IV. Structural Considerations in Connection with the Enzymic Hydrolysis of Pectins[1]

BY Z. I. KERTESZ

The high viscosity of aqueous solutions of pectins attracted attention over a hundred years ago but no satisfactory theory has been proposed as yet to explain the physical properties of pectins in the light of our present knowledge of their chemical composition. The final disproval of Ehrlich's tetragalacturonic acid theory[2] paved the way for renewed activity in this field. By the use of various concentrations of ethanol,[3] arabans and galactans[4] may be removed from the crude pectin preparations. The resulting compound (a true pectin composed almost exclusively of galacturonic acid anhydride residues with CH_3O present as ester in most carboxyl groups) lends itself well for investigations of the relation between physical and chemical properties.

Without having conclusive evidence on hand and reasoning mostly by analogy, the chains of galacturonic acids have been regarded by most investigators as being responsible for the viscosity of pectins. Accordingly the loss of viscosity under certain conditions has been attributed to the decomposition of the polygalacturonic acid chains.

(4) Hirst and Jones, *J. Chem. Soc.*, 454–460 (1939).

Based upon such reasoning Mehlitz and Scheuer[5] proposed a method for the determination of the enzymic hydrolysis of pectins by the changes which occur in the viscosity.

A study of the enzymic decomposition of pectins has been in progress at this Laboratory for several years.[6] The results obtained here never indicated a close relationship between changes in the viscosity and the decomposition as measured chemically. A systematic study of this problem was therefore undertaken to explain this discrepancy. The results obtained are presented herewith.

Experimental Methods

The viscosity determinations were performed at 30.0°, using Ostwald viscosity pipets. In the experiments yielding the data presented in Fig. 1 and Fig. 3 the viscosity determinations were made as follows. When the

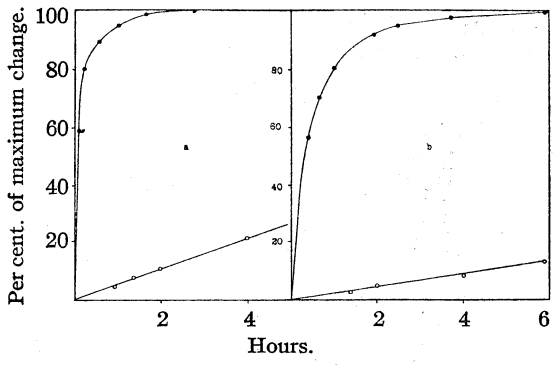

Fig. 1.—Changes in the viscosity (●), and reducing power (○), of pectin solutions during hydrolysis by 0.10% enzyme (a) and 0.05% enzyme (b).

reaction mixtures were made up from the prewarmed components and mixed, 3 cc. was pipetted immediately into the Ostwald pipet, which had been placed in the bath more than half an hour earlier. The determinations were started about three minutes later. The values obtained for the relative viscosity represent the average value for the period required for the outflow. In constructing the viscosity curves in Fig. 1 and Fig. 3 the viscosity values were taken as representing this average viscosity at the time of starting of the viscosity determination plus half of the time needed for the outflow.

In the case of the experiments demonstrated in Figs. 2 and 3 the pectin solution was heated in a bath of boiling water. To obtain the viscosity values for Fig. 2 the volumetric flasks holding the pectin solution were cooled at the end of the heating period and the contents made up to the original volume.

The reaction mixtures were composed of 100 cc. of pectin solution of *p*H 3.2 plus 10 cc. of 1% (filtered) commercial pectinase.[7] Only 10 cc. of 0.5% enzyme was used in obtaining Fig. 1b. Experiments reported in this paper have been repeated with different pectins giving essentially the same results. The data presented herein have been obtained on purified citrus pectin. The concentrations of the solutions used in Figs. 1, 2, and 3 were 0.854, 0.686, and 0.849%, respectively.

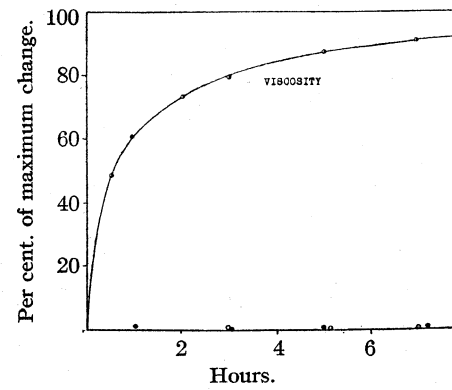

Fig. 2.—Changes in the viscosity (◑), reducing power (○), and methoxyl content (●), of a pectin solution upon heating.

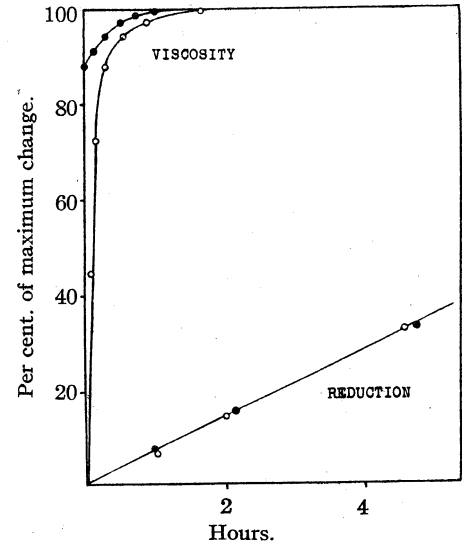

Fig. 3.—Changes in the viscosity and reducing power of unheated (○), and heated (●), pectin solutions upon enzymic hydrolysis.

The Willstätter–Schudel hypoiodide method[8] was used for the determination of the increase in the reducing power resulting from the activity of the pectin-polygalacturonase. It is essential to keep the limitations of this method in mind[9] in order to obtain dependable results. The enzymic demethoxylation was followed by titrating 10-cc. samples

of the reaction mixture with 0.1 *N* sodium hydroxide, using phenolphthalein indicator and adding 5 cc. more alkali. The excess of the alkali was titrated after one hour's standing at room temperature. One cc. of alkali consumed for the saponification equals 3.1 mg. of CH_3O split off.

The pectic enzymes available at this time are mostly mixtures of several enzymes acting upon pectin. In spite of the attempts made in this Laboratory and elsewhere,[10] no method is available as yet for the quantitative separation of the enzymes present in commercial pectinases. As a result, the action of several enzymes upon pectins is proceeding simultaneously in the reaction mixtures. The most important known chemical change occurring during the enzymic decomposition of pectins is the hydrolysis of the polygalacturonic acid chains by the pectin-polygalacturonase. Another enzyme which is present and may influence the viscosity as well as the velocity of the hydrolysis is pectin-methoxylase,[11] an esterase responsible for the splitting off of the CH_3O groups attached to most COOH groupings of pectins. It is not held likely that at the *p*H of the reaction mixtures the demethoxylation would have had a significant effect on the changes in viscosity. Furthermore, the changes which may have been caused by this enzyme would be negligible as compared with those caused by the pectin-polygalacturonase. As will be discussed later in this paper, a 1% hydrolysis of the polygalacturonic acid chains would cause approximately 33% reduction in the viscosity. A 1% demethoxylation on the other hand will cause only about 1% loss of the viscosity caused by the presence of the methyl esters.

Results and Discussion

To study the relation between the changes which occur in the viscosity and reducing power during enzymic hydrolysis, pectin solutions were exposed to the action of a commercial pectinase in two different concentrations. The results presented in Fig. 1 are expressed as percentages of the maximum possible changes. Complete hydrolysis of the structure into galacturonic acid would cause a reduction of 100, while the low initial reduction was taken as 0. Similarly the difference between the time of outflow of the original reaction mixtures and those completely decomposed was taken as 100 and the decrease observed as a fraction thereof. There is an abrupt change in the viscosity of the mixtures in the first few minutes of the reaction. The reducing power is increasing slowly and (up to the extent of decomposition shown in the figure) at a constant rate.

It is necessary at this time to consider briefly the interrelation of the changes followed by the determination of the viscosity on the one hand and by the increase in the reducing power on the other. In pectin as well as in the case of other polysaccharides some heterogeneity must be assumed with regard to the size of the molecules present (in whatever sense the word molecule may be understood). This heterogeneity is even more increased upon a limited degree of cleavage of the chains and the "average" values calculated will depend on the method of measurement as well as on the method of calculation. Determinations of the increase in the reduction (as well as all other end-group methods and also freezing point and osmotic pressure determinations) give averages defined by the expression[12]

$$M_n = \frac{1}{\Sigma f_i/M_i}$$

where f_i is the fractional weight of the constituent of molecular weight M_i and the summation is to be applied to all constituents present. This is the "number average." On the other hand, viscosity measurements give an average value for the size of the molecule according to the expression

$$M_w = \Sigma f_i M_i$$

This is a "weight average." Calculations with the possible degradation products of homogeneous polymers (as pectin is thought of, for instance) indicate that upon hydrolysis the "weight average" molecular weight or chain length as measured by the viscosity will decrease slower than the "number average" measured by reduction. A mathematical consideration of this problem will be presented elsewhere, but it may be cited here that a 1% increase in the reduction in the case of pectin should result in a halving of the "number average" molecular size while the "weight average" (and thus according to Staudinger the viscosity) should decrease only about 33%. As stated before, the experimentally observed decrease in the viscosity is more rapid than the corresponding change in the reducing power would allow according to the calculations.

If the observed changes in the viscosity are actually caused by the changes in the size of the polygalacturonic acid chains, then any decrease in the viscosity should be accompanied by a corresponding increase in the reducing power. It is known that the viscosity of pectin solutions decreases upon heating.[13] To obtain information on this matter pectin solutions were heated (at *p*H 3.2) to 100° and the changes in the viscos-

ity (as determined at 30.0°) and reducing power and methoxyl content followed. The results, shown in Fig. 2, prove conclusively that there is no correlation between the changes in the viscosity and reducing power. There is no indication that polygalacturonic acid chains were split during the heating of the pectin solution.

There also appeared some possibility that the decrease of the viscosity may be caused by progressive demethoxylation of the pectin. It has been shown by von Fellenberg,[14] and more recently by the author,[15] that the viscosity of pectin solutions will decrease upon extensive demethoxylation. Tests conducted during the heating and shown in Fig. 2 proved that there was no demethoxylation whatsoever during the period of heating used in this experiment.

If the viscosity is not a property of the chemical polygalacturonic acid chains, the velocity of the enzymic hydrolysis of a pectin solution in which the viscosity has been lowered by heat should be identical with the velocity of hydrolysis of the original unheated pectin solution. That this indeed is the case is shown in Fig. 3 where "reduction" represents the hydrolysis of both the original pectin solution and that heated for five hours to 100° before the enzyme was added. The viscosity changes are also indicated in the figure, showing that there was some additional decrease in the viscosity of the heated solution "b" during the hydrolysis. Determinations of the progress of changes in the reducing power of the heated and unheated solutions showed that the changes were identical in both mixtures. The progress of demethoxylation, not shown in the figure, was also identical. These observations make it even more probable that no chemical changes are induced by the heating of the pectin solution. In other words, the viscosity is not directly associated with the chemical structure of pectin.

It is obvious, therefore, that changes in the viscosity may not be used as a measure of enzymic decomposition.[16] The changes occur only in the early part of the hydrolysis. In the case of many pectins of "low quality" or of those which are degenerated by heat treatment, there would be but little change at all in the viscosity upon enzymic decomposition.

(14) Von Fellenberg, *Biochem. Z.*, **85**, 118 (1918).

(15) Kertesz, *Food Research*, **3**, 481 (1938).

(16) The measurement of the viscosity of a pectin solution may nevertheless give valuable information concerning its usefulness for various practical purposes where its colloidal properties are important [Baker, *Food Ind.*, **6**, 305 (1934)].

Assuming for the present that all aldehyde groups which are set free during the enzymic hydrolysis show the reduction characteristic of galacturonic acid, the conclusion must be drawn that the viscosity is not directly caused by the polygalacturonic acid molecules. The formula $[(G)_m]_n$ presents a possible explanation of this observation. The polygalacturonic acids $(G)_m$ containing m galacturonic acid anhydride residues form a secondary aggregate or polymer by the association of n polygalacturonic acid chains. The viscosity of pectins is mostly caused by the aggregate $[(G)_m]_n$ which is destroyed by heating. The units of $(G)_m$ show no additional reducing power when n is lowered to approach 1. On the other hand, if the galacturonic acid chains $(G)_m$ are attacked by the enzyme, the secondary structure falls apart. It is reasonable to assume that the formation of aggregates from the $(G)_m$ units is a property of polygalacturonic acid chains of certain minimum length. With the disturbance of this primary structure by reducing the size of the chemical unit, the secondary polymer is automatically destroyed.

This hypothesis explains why the viscosity in enzyme hydrolyzed pectin solutions decreases more rapidly than one would expect from the molecular size and the viscosity calculated therefrom by Staudinger's method. It also accounts for the observed decrease in the viscosity of heated pectin solutions without an increase in the reducing power, *i. e.*, without splitting of the polygalacturonic acid chains $(G)_m$.

From the trend of the viscosity curves obtained during this work one may draw the conclusion that the polygalacturonic acid structure $(G)_m$ also possesses some viscosity higher than that corresponding to a solution of galacturonic acid of equal concentration (see Fig. 2). This is indicated also when pectin is hydrolyzed by low concentrations of pectin-polygalacturonase, but its viscosity is relatively low when compared to that of the complete structure $[(G)_m]_n$.

It is of interest to note that a similar double structure has been found to exist in the case of starches. Baird, Haworth and Hirst[17] reported the disaggregation of starch without decomposing the chemical unit. Later Hassid and Dore[18] isolated a natural starch which showed low viscosity and appeared to be composed of unaggre-

(17) Baird, Haworth and Hirst, *J. Chem. Soc.*, 1201 (1935).

(18) Hassid and Dore, THIS JOURNAL, **59**, 1503 (1937).

gated starch molecules. From the work reported in this paper it seems likely that the structure of the large pectin molecule is similar to that of certain starches. On the other hand, Schneider and Fritschi[19] claim that pectin has a "macro molecule" bound with main valences only and is not an aggregate of the chemical units. The observations made at this Laboratory are not in favor of their contention.

There is no information available on the relative reducing power of polygalacturonic acids containing different numbers of galacturonic acid anhydride residues. The formula proposed for polygalacturonic acid by Morell, Baur and Link[20] is generally accepted and if true would indicate a direct proportionality between the number of molecules in the polymer and its reducing power. In case of starch the presence of non-reducing aldehyde groups has been assumed[21] but without conclusive evidence to that effect. The low reducing power observed in purified pectins is believed by the author to be a characteristic property of the pectin molecule. In spite of many attempts made at this Laboratory, no pectin preparation entirely free of reducing power has been obtained as yet. The significance of the natural reducing power of pectins will be the subject of a later contribution.

Assuming that the aldehydic reducing groups are tied up or masked in some manner in higher polymers of galacturonic acid, this would only modify and not eliminate the postulated secondary structure. Until evidence of this fact is presented, it seems more likely that the aggregates of polygalacturonic acid molecules are held together by means of secondary valence attractions not affecting the reducing power of the terminal aldehydic groups of the chemical polygalacturonic acid units.

(21) See a discussion of this matter in Hanes, *The New Phytologist*, **36**, 101 (1937).

Summary

1. When pectin solutions are enzymatically decomposed the viscosity decreases more rapidly than corresponds to the increase in reducing power.

2. The viscosity of pectin solutions can be reduced by heat without any increase in the reducing power. This heat-degenerated pectin is decomposed by enzymes at the same velocity as the original unheated pectin solution.

3. These results are explained by postulating a structure $[(G)_m]_n$ for pectin in which $(G)_m$ is a polygalacturonic acid. The n units of polygalacturonic acids form a secondary aggregate which is mostly responsible for the viscosity of pectin.

The Action of Chlorine on Thiocyanates

BY TREAT B. JOHNSON AND IRWIN B. DOUGLASS[1]

This paper is contributed as a report of an investigation carried out recently in this Laboratory on the development of new methods for synthesis of sulfonyl chlorides. The recent interest in the chemotherapy of sulfanilamide and related compounds has stimulated a demand for new and improved methods of synthesizing sulfonyl chlorides. We have reported previously on a method of formation of chlorides of this type by interaction of chlorine with isothioureas,[2] and also the action of chlorine on other types of sulfur combinations.[3]

Observations on the chemical action of anhydrous chlorine on the lower alkyl thiocyanates have been made by Cahours,[4] Riche,[5] and James,[6] but none of the workers identified a sulfonyl chloride among the various reaction products described. Cahours mentioned obtaining by the chlorination of methyl thiocyanate a heavy yellow oil which solidified in contact with ammonia. If the experimental conditions employed by him

were not strictly anhydrous, this oil may have contained some methyl sulfonyl chloride, but it was undoubtedly a mixture of reaction products. A careful search of the literature has failed to disclose other instances in which a sulfonyl halide may have been produced directly from a thiocyanate by treatment with a halogen.

We have found that aliphatic thiocyanates can be transformed readily into sulfonyl chlorides in excellent yields by the action of aqueous chlorine at low temperatures. The reaction has proved to be one of very practical technique in most of the applications made of the chlorination process. In addition to the sulfonyl chlorides, cyanogen chloride (CNCl) is also a product of the chlorination reaction. Cahours,[4] Riche,[5] and James,[6] all reported obtaining crystals of the trimolecular form of this chloride $(CNCl)_3$.

The behavior of benzyl thiocyanate (I) on chlorination was very puzzling until it was discovered that there was an intermediate formation of benzylsulfinic acid (II), which was only slightly soluble in water and comparatively unreactive toward chlorine at the low temperature of the reaction. This formation of benzylsulfinic acid is very interesting because it affords probably the easiest method yet available for the preparation of this unstable compound, and also because of the light it throws on the mechanism of the reaction leading to the formation of the sulfonyl chloride (III). Benzyl sulfinyl chloride, $C_6H_5CH_2SOCl$, is a possible intermediate of this reaction, and could be the precursor of either benzylsulfinic acid, II, or benzylsulfonyl chloride, III. This will be discussed more fully in a future paper from this Laboratory. In none of our chlorination experiments with thiocyanates have we obtained any evidence of the formation of intermediate sulfur compounds of the *sulfenic* acid type (—SOH or —S(OH)).[7]

$C_6H_5CH_2SCN$	$C_6H_5CH_2SOOH$	$C_6H_5CH_2SO_2Cl$
I	II	III

In a patent application now pending,[8] based partially on this work, examples are given of the preparation of fifteen different sulfonyl chlorides by the action of aqueous chlorine on thiocyanates, and of *n*-butoxyethoxyethyl sulfonyl bromide by the action of aqueous bromine on the corresponding thiocyanate. The reaction is of general application whether the nucleus linked to the —SCN group is substituted or unsubstituted, and whether it is alkyl, aralkyl, aryl, alicyclic or heterocyclic in nature.

(8) Serial No. 201728, "Sulfonyl Chlorides," Filed in U. S. Patent Office April 13, 1938; Application allowed March 7, 1939.

Experimental Part

Methylsulfonyl Chloride, CH_3SO_2Cl.[9]—Twelve and one-half parts of methyl thiocyanate (CH_3SCN) and 100 parts of water are mixed in a vessel immersed in an ice-bath. The mixture is agitated thoroughly while chlorine gas is bubbled into the solution at a rate such that the temperature is kept at 5° or lower. The passage of the chlorine is continued until the yellow color of the reaction mixture shows that an excess of chlorine is present. This takes about two to two and one-half hours. The oil which separates is extracted with ether, the resulting ether solution washed first with sodium bisulfite solution and then with sodium bicarbonate solution, and finally dried over anhydrous calcium chloride. The methylsulfonyl chloride is distilled at reduced pressure and boils at 55° under 11 mm. This chloride is converted easily to methyl sulfonic acid (CH_3SO_2OH) by acid hydrolysis, and to the corresponding sulfonamide ($CH_3SO_2NH_2$) by the action of ammonia;[10] yield 75%.

Ethylsulfonyl Chloride[11] ($C_2H_5SO_2Cl$).—Twenty grams of ethyl thiocyanate (C_2H_5SCN) suspended in 200 cc. of water is stirred vigorously at a temperature of 0–5° during the addition of chlorine gas at a rate of 2–3 liters per hour. Treatment with chlorine is continued until a permanent greenish-yellow color is produced, indicating an excess of the halogen. Air is then blown gently through the mixture to remove the excess of chlorine, after which an oil separates and is extracted with ether. After washing with sodium bisulfite and sodium bicarbonate solutions, and drying the ether extract over calcium chloride, the ethylsulfonyl chloride was obtained in a yield of 79%. It was identified by its boiling point (71–72° at 20 mm.) and refractive index.

Cyanogen chloride (CNCl) was identified in the water layer after the removal of the sulfonyl chloride by extraction with ether. The solution was heated and a gentle stream of air was blown through it and into 5 cc. of aniline oil. The aniline was then washed with dilute sodium hydroxide to remove the phenylcyanamide formed and the alkaline solution, after neutralization of the excess of sodium hydroxide, was shaken with a few drops of benzoyl chloride. Benzoyl phenylcyanamide precipitated and after recrystallization from alcohol melted at 124–125°. The melting point of this product mixed with an authentic sample was not lowered.

Benzylsulfinic Acid ($C_6H_5CH_2SOOH$), and Benzylsulfonyl Chloride from Benzyl Thiocyanate ($C_6H_5CH_2SCN$).—

(9) Billeter, *Ber.*, **38**, 2019 (1905).

(10) Helferich and Gnüchtel [*ibid.*, **71**, 712 (1938)] and Helferich and Mittag [*ibid.*, **71**, 1480 (1938)] have found this sulfonyl chloride (CH_3SO_2Cl) is of practical use in preparing characteristic derivatives for identifying certain carbohydrates and α-amino acids. They write, however, as follows regarding the experimental difficulties in preparing pure methanesulfonyl chloride: "In the preparation of methanesulfonyl chloride from the sodium salt of methanesulfonic acid by the action of phosphorus pentachloride, it is very difficult to separate the sulfonyl chloride from the phosphorus oxychloride. Only by repeated fractional distillation can this be accomplished, and then with great losses."

(11) Gerhardt and Chancel, *Jahresberichte*, 434 (1852); Spring and Winssinger, *Ber.*, **15**, 447 (1882).

Benzyl thiocyanate (10 g.), freshly crystallized and finely pulverized, was suspended in 200 cc. of water and chlorinated as described above at a temperature of 0–2°. In two to three hours the contents of the flask consisted of a yellow pasty mixture which was filtered through an ice cold Büchner funnel. The solid was washed with ice water to remove chlorine hydrate and sucked as dry as possible. The filtrate gave a heavy precipitate with barium chloride and smelled strongly of cyanogen chloride. The latter was identified by the formation of benzoylphenylcyanamide as described above.

The solid product of reaction was spread on filter paper to dry in the air, but after three to four hours of exposure it had decomposed with the evolution of sulfur dioxide and had absorbed into the filter paper. From the paper were extracted unchanged starting material, and a white solid which contained sulfur but no halogen or nitrogen. This was insoluble in acid or alkali, evolved sulfur dioxide on heating and melted at 108–109°. Since these properties are those that might be expected of a disulfone or a disulfoxide, and since the melting point corresponded to that recorded for $C_6H_5CH_2SOSOCH_2C_6H_5$,[12] the original reaction product that spontaneously decomposed was suspected of being benzyl sulfinic acid, $C_6H_5CH_2SOOH$.

To establish this conclusion the chlorination experiment was repeated and the white solid formed was treated immediately with sodium bicarbonate solution, in which most of it dissolved. The residue, consisting chiefly of unchanged benzyl thiocyanate, was removed by washing with ether. The alkaline solution was then treated with 1 cc. of benzyl chloride and heated on the steam-bath for one hour. On cooling, colorless crystals separated having a melting point of 151–152°, which corresponds with the melting point recorded for dibenzylsulfone.

Anal. Calcd. for $C_{14}H_{14}O_2S$: S, 13.02. Found: S, 13.22.

In another experiment 10 g. of benzyl thiocyanate was chlorinated at 0–2° to apparent saturation, then the temperature was raised to 15–20° and the chlorination continued. The products of the reaction were $C_6H_5CH_2SO_2Cl$ in 45% yield, benzyl chloride, cyanogen chloride, and positive evidence of the formation of sulfate ion by interaction with barium chloride to form barium sulfate. Again when chlorination of 10 g. of pure benzyl thiocyanate was carried out at 20–30°, 9.33 g. of impure benzylsulfonyl chloride melting at 84–88° was obtained. This smelled distinctly of benzyl chloride and the aqueous filtrate gave a heavy sulfate ion test.

To determine whether the benzyl chloride and sulfate ion resulted from the action of chlorine water on the benzyl thiocyanate or on the benzylsulfinic acid, 10 g. of benzyl thiocyanate was chlorinated at 0–2° and the white solid product was treated quickly with sodium bicarbonate solution. After extracting with ether to remove all undissolved material from which was recovered unchanged thiocyanate and a few milligrams of benzylsulfonyl chloride, the solution was acidified with an excess of hydrochloric acid and immediately chlorinated at 20–25° to saturation. The product consisted of 5.75 g. of benzylsulfonyl chloride which melted at 92° without further purification. Although the water in which the original chlorination was carried out reacted strongly for sulfate ion, the final filtrate after removing the sulfonyl chloride gave only a slight cloudiness with barium chloride.

The amount of benzyl chloride and sulfate formed seemed to be increased if the benzyl thiocyanate was impure or if the temperature during chlorination was not kept under rigid control. A chlorination experiment carried out in 80% acetic acid solution resulted in the formation of benzyl chloride almost to the complete exclusion of benzylsulfonyl chloride.

The Formation of Benzylsulfonyl Chloride by Chlorination of Benzyl Isothiourea Hydrochloride.—This hydrochloride was chlorinated under conditions identical to those employed in the treatment of benzyl thiocyanate. There was no evidence of the formation of benzylsulfinic acid and benzylsulfonyl chloride which melted at 92° without purification was obtained in 76% yield. Barium chloride solution formed only a slight precipitate in the aqueous filtrate.

Chlorination of Phenyl Thiocyanate (C_6H_5SCN).—This aromatic thiocyanate is much more resistant to the action of chlorine than the aliphatic compounds. Chlorination for eight hours under the usual experimental conditions gave a product that contained less than half the calculated amount of chlorine required for benzenesulfonyl chloride. Chlorination for even sixty hours at room temperature failed to yield a product free of the starting material. Some benzenesulfonyl chloride was formed, however, for when the product was treated with aniline and the reaction mixture extracted with sodium hydroxide, benzenesulfonyl anilide was obtained by acidifying the alkaline solution.

Summary

1. Organic thiocyanates can be employed with success for the synthesis of sulfonyl chlorides.

2. Chlorination of such thiocyanates in aqueous suspension and at low temperatures leads to a transformation of —SCN to —SO_2Cl.

3. Benzyl thiocyanate can be changed by chlorination at low temperatures into benzylsulfinic acid. On chlorination in aqueous suspension at higher temperature, benzylsulfonyl chloride is formed in excellent yield.

4. The question of the mechansim of the different chlorination reactions thus far reported from this Laboratory will be discussed in a future paper.

NOTES

Optical Properties of Sulfamic Acid

By W. M. D. Bryant

Sulfamic acid, $NH_2 \cdot SO_3H$, has been the subject of crystallographic studies at widely different times by at least two experimenters.[1,2] Only very meager optical data incidental to goniometric observations were reported, and these were inadequate for purposes of identification. Recently M. E. Cupery[3] described a new process for industrial scale preparation of pure sulfamic acid and kindly placed some of this substance at the writer's disposal for optical crystallographic examination.

The methods employed in this study were those described in an earlier paper.[4] The refractive indices and optic axial angles were measured in green monochromatic light (5461 Å.) from the mercury arc. Due to the weak dispersion optic axial angles in white light were not appreciably different. The observed optical data are tabulated.

Refractive indices at 25 ± 3°: $\alpha = 1.553$; $\beta = 1.563$; $\gamma = 1.568$ all ±0.003.

Optic axial angle: $2H_a = 65 \pm 1°$; $2H_0 = 120 \pm 5°$; $2V = 64°$ (calculated from $2H_a$ and $2H_0$ by the tangent relation); $2V = 63°$ (calculated from $2H_a$ and β).

Dispersion: weak, indeterminate.

Optical character: negative.

Crystal system: orthorhombic bipyramidal, according to both Fock and Jaeger. However, these investigators each used a different setting, so that the crystallographic *b*- and *c*-axes are transposed in their respective treatments.

Crystal habit: tablets and compact prisms from cold aqueous solution; large lozenge-shaped plates on cooling hot aqueous solution; the fused material is glassy.[5]

Optical orientation: the optic axial plane coincides with the principal pinacoid, which is 001 according to Jaeger or 010 according to Fock. The obtuse bisectrix apparently coincides with the *a*-axis for both settings.

The only numerical optical constant found in the earlier literature is the optic axial angle reported by Fock[1] as $2E$ = *circa* 85°. $2E$ calculated from the present $2H_a$ value is about 109 ± 2°. Since no indications of a second crystal modification of sulfamic acid have been obtained to date, it is believed that Fock's $2E$ value is erroneous.

A Method of Coupling Organic Radicals by Means of the Grignard Reagent: A Correction

By John H. Gardner and Lionel Joseph

In a paper of this title published in 1929[1] the statement was made that when iso- and *s*-butylmagnesium bromides were allowed to react with silver bromide, there is formed a mixture from which no pure compound could be isolated. In connection with some other work in progress in this Laboratory, some results were obtained which led us to doubt the correctness of this statement. Consequently, the experiments were repeated using more effective distilling apparatus than was available at the time the earlier work was done. In this way, we obtained the dimethylhexanes which would be expected from the coupling of the radicals in high purity but in rather poor yield. The other products were gases, very likely the corresponding butanes and butenes, although definite proof of their identity has not as yet been obtained. It is thus definitely established that in all cases so far studied of the action of Grignard reagents on silver bromide, there is no rearrangement.

Experimental

Reaction of Iso- and *s*-Butylmagnesium Bromides with Silver Bromide.—To an ethereal solution of 1 mol of the Grignard reagent in a flask provided with a mechanical stirrer and two reflux condensers, and cooled in an ice–salt bath, there was added a slight excess of silver bromide, with continual stirring. The mixture was stirred in the cooling bath for a half hour and then for an hour at the boiling point. After the addition of very dilute hydrochloric acid, the organic products were separated by steam distillation, dried over calcium chloride and distilled through a 70-cm. Vigreux column. In both cases, after

(1) J. H. Gardner and P. Borgstrom, This Journal, **51**, 3375 (1929).

the ether had distilled, the distillation curve rose sharply and the hydrocarbon fraction was collected over an approximately 5° range. The products were boiled for an hour over metallic sodium to remove any alkyl halide and redistilled. There was thus obtained from isobutylmagnesium bromide, 20 g. (37.5%) of 2,5-dimethylhexane, b. p. (755 mm.) 107–108.5°, d^{20}_4 0.6911, $n^{21}D$ 1.3922. Egloff[2] gives b. p. (760 mm.) 109.3°, d^{20}_4 0.6949, $n^{20}D$ 1.39295 as the preferred values. Similarly, from *s*-butylmagnesium bromide, there was obtained 7.5 g. (13%) of 3,4-dimethylhexane, b. p. (757 mm.) 116–117°, d^{22}_4 0.7199, $n^{26}D$ 1.4040. Egloff[2] (p. 54) gives as the preferred values, b. p. (760 mm.) 117.8°, d^{20}_4 0.7195, $n^{20}D$ 1.4045.

Morpholine Condensations

BY CHESTER B. KREMER, M. MELTSNER AND L. GREENSTEIN

In the course of researches dealing with the condensation of secondary amino alcohols with *o*- and *p*-chloronitrobenzenes, we also investigated the condensing ability of the secondary amine, morpholine. The products obtained have been described by others in a recent article,[1] but were prepared in a manner somewhat different from ours. We are therefore recording our procedures and at the same time including data for one compound as yet unreported.

The general method of procedure was to reflux molar quantities of morpholine and the chloronitrobenzene in the presence of anhydrous sodium carbonate for approximately four hours. The reaction mixture was then steam distilled to rid it of unreacted material. A dark oil, slowly solidifying, remained in the distillation flask in the run with *o*-chloronitrobenzene, an orange-red solid remaining in the case of the para compound. These were recrystallized from benzene: N-(*o*-nitrophenyl)-morpholine, light orange product, m. p. 40–41°; N-(*p*-nitrophenyl)-morpholine, yellow in color, m. p. 149–150°.

Another method used in preparing N-(*p*-nitrophenyl)-morpholine was as follows: 1.0 g. of phenylmorpholine was added to 4 cc. of concentrated sulfuric acid and 4 cc. of concentrated nitric acid added dropwise. The reaction mixture turned red and foamed violently. When the reaction was complete, the mixture was poured onto ice and finally filtered. The filtrate yielded orange crystals of the desired product.

Reduction of the nitro compounds with tin and hydrochloric acid yielded the previously reported N-(*p*-aminophenyl)-morpholine[2] and the new compound, N-(*o*-aminophenyl)-morpholine, m. p. 98–98.5°; calculated N, 15.73; found, 15.87.

N-(*o*-Aminophenyl)-morpholine can be purified by sublimation, yielding beautiful white platelets. In the pure state the compound is quite stable, but when somewhat impure discolors fairly rapidly on standing.

The present work proves that the compound formed in treating *o*-chloronitrobenzene with diethanolamine is not N-(*o*-aminophenyl)-morpholine as had been tentatively advanced[3] in a previous publication.

Hydrogen and Deuterium Exchange between Nitramide and Water

BY V. K. LA MER AND SEYMORE HOCHBERG

On the basis of measurements of the decomposition rate of proto-nitramide dissolved in mixtures of H_2O and D_2O, La Mer and Greenspan[1] suggested two mechanisms for the decomposition. The first assumed that only one H of nitramide exchanges promptly on being dissolved in D_2O; the second that both H atoms of nitramide exchange promptly.

On the basis of the data then available it was impossible to decide whether the decomposing substrate was HDN_2O_2 or $D_2N_2O_2$ when proto-nitramide is dissolved in D_2O.

We now present evidence based upon two independent procedures that both H atoms are exchanged promptly for D atoms in a solvent of high deuterium content, and that the rate-determining step in D_2O involves $D_2N_2O_2$.

I. Decomposition Rate of $D_2N_2O_2$.—Deutero-nitramide was prepared by the reaction of potassium nitrocarbamate with 99% D_2O and SO_3. On reaction of this nitramide with water (0.01 *N* hydrochloric acid) the observed rate constant, based upon manometric measurement[2] of

(1) La Mer and Greenspan, *Trans. Faraday Soc.*, **197**, XXXIII, Part 9, 1266 (1937).

(2) Greenspan, La Mer and Liotta, THIS JOURNAL, **59**, 1606 (1937).

the nitrous oxide formed, is $k^* = 387 \times 10^{-5}$ min.$^{-1}$ (decadic logs) at 35°, in excellent agreement with Baughan and Bell's[3] $k^* = 386 \times 10^{-5}$ min.$^{-1}$ obtained for proto-nitramide in H_2O.

Partially deuterized nitramide prepared from 48% D_2O and sulfur trioxide yielded $k^* = 125.5 \times 10^{-5}$ min.$^{-1}$ at 24.84° in 0.01 *N* hydrochloric acid in H_2O. La Mer and Greenspan[1] obtained $k^* = 126.6 \times 10^{-5}$ min.$^{-1}$ under the same conditions for proto-nitramide in H_2O.

II. Direct Exchange.—Proto-nitramide was dissolved in D_2O (temp., approx. 5°). The nitramide produced by exchange was extracted with ether (dried over sodium) by the freezing method of Marlies and La Mer.[4,5] The exchange and extraction required less than one hour.

To ensure the complete removal of possible traces of deutero-solvent, the nitramide was kept over phosphorus pentoxide for one week. It was then decomposed by gentle heating in the presence of a trace of anhydrous sodium carbonate. The liberated water was redistilled and the density determined by the falling drop method.[6]

The following results show that the deuterium content of the nitramide approximated the deuterium content of the water from which it had been extracted.

Mole fraction of D in the solvent water in which exchange takes place	0.28	0.87	0.97
Mole fraction of D in the water from the decompn. of the extracted nitramide	.25	.65	.94

There is no point in calculating an exchange constant because, due to the method of extraction, the equilibrium temperature and the equilibrium concentration of D_2O cannot be held constant. Since deutero-nitramide decomposes in water at the same rate as proto-nitramide and since deutero-nitramide containing more than one atom of D per molecule may be extracted from a solution of proto-nitramide in D_2O, it is evident that both atoms of hydrogen in nitramide exchange with D_2O before decomposition occurs.

Ferric Chloride as a Condensing Agent

BY W. M. POTTS AND R. J. DODSON

A further investigation[1] of anhydrous ferric chloride as a condensing agent in the alkylation of benzene has been carried out using butyl alcohols.

1. Condensation products were not formed with *n*-butyl alcohol and benzene. This agrees with the results reported by Huston and Hsieh[2] using aluminum chloride and primary alcohols up to and including *n*-hexyl alcohol.

2. *s*-Butyl alcohol gave evidence of a reaction but no product was identified. With aluminum chloride under the same conditions, a 69% yield of *s*-butylbenzene was obtained. Huston and Hsieh[2] reported a 25–28% yield, while Tzukervanik and Tokareva[3] reported a 70% yield. The *s*-butylbenzene was identified by its physical constants and the diacetamino derivative, m. p. 193°.[4]

3. At room temperature, one mole of *t*-butyl alcohol, one mole of ferric chloride and five moles of benzene gave an 82% yield of *t*-butylbenzene. With aluminum chloride under the same conditions a 50% yield of *t*-butylbenzene was obtained. Using two moles of *t*-butyl alcohol, one mole of benzene and one mole of ferric chloride, a 24% yield of mono-*t*-butylbenzene and 64% of 1,4-di-*t*-butylbenzene was obtained. The acetamino derivative of the former melted at 168°.[4] The latter was identified by the method reported by Potts and Carpenter.[1]

Better yields of *t*-butylbenzene were obtained with ferric chloride than with aluminum chloride, but ferric chloride does not effect the condensation of primary and secondary alcohols with benzene. Higher temperatures and larger quantities of ferric chloride lower the yields of *t*-butylbenzene.

α-Hydrindone

BY CHARLES C. PRICE AND FREDERICK M. LEWIS

Although ring closures of many β- and γ-aryl butyric acids to the corresponding cyclic ketones have been accomplished successfully by the ac-

tion of sulfuric acid, it has been reported[1] that this reagent will not effect such a ring closure for the simplest β-arylpropionic acid, hydrocinnamic acid, to yield α-hydrindone.

By varying the conditions for the reaction of hydrocinnamic acid in sulfuric acid it has been found possible to obtain a very pure product rapidly and conveniently although in only moderate yield.

The concentration of acid was varied from 15% fuming to 85% sulfuric acid, the time of heating from one minute to three hours and the reaction temperature from 100 to 160°. Optimum conversion was obtained by using 5% fuming sulfuric acid at 140° for five minutes. In each case the sulfuric acid (20 cc.) was heated to the desired temperature in an oil-bath, the hydrocinnamic acid (5 g., m. p. 49–50°) added with stirring and, at the end of the specified time, the reaction mixture poured over cracked ice (100–150 g.). The α-hydrindone was extracted with two 25-cc. portions of benzene. After drying over sodium sulfate, the benzene was removed by evaporation on a steam plate, leaving a pale yellow oil which crystallized on cooling to room temperature, maximum yield 1.2 g. (27%), m. p. 40–41°. A mixture of these crystals with the starting material was liquid at room temperature. The identity of the product was established further by preparation of the 2,4-dinitrophenylhydrazone, m. p. 254–255°. No starting material was isolated in any case.

The addition of boron fluoride or aluminum chloride to the sulfuric acid lowered the yield considerably.

Some Schiff Base Hydrochlorides. A Test for Arylamines[1]

BY J. V. SCUDI, H. D. RATISH AND J. G. M. BULLOWA[2]

In the course of certain studies,[3] a very simple color test was devised for the estimation of sulfanilamide and other arylamines. The test is not as sensitive (1 part in 200,000) as diazotization procedures,[4,5] but its simplicity has made it useful in following various concentrates in a semi-quantative way. Recently the Ehrlich reagent has been more rigorously standardized[6] for the determination of sulfanilamide, although the reaction mechanism was left in doubt. It was therefore decided to record our observations.

The test consists in adding 1 cc. of 10% hydrochloric acid to 5 cc. of a 1% solution of cinnamaldehyde in alcohol followed by 5 cc. of a 2–4 mg. % solution of the arylamine. A yellow color is instantly formed. This is stable for several days, but unstable to alkali. Other aldehydes may be used, but not benzaldehyde. Toluenesulfonamide does not give the test. The sensitivity is increased ten-fold by performing the test in absolute alcohol in the presence of concentrated sulfuric acid.

The color producing substances were shown to be the somewhat labile hydrochlorides of the Schiff bases of sulfanilamide and sulfapyridine. These were converted to the free bases. In accord with the finding of Dimroth and Zoeppritz[7] and Moore and Gale,[8] the color appears to be produced by the halochromic effect of the acid upon the Schiff base. The compounds reported are not submitted as crystalline derivatives for the characterization of the arylamine, but as evidence of the mechanism of the color development.

Experimental

Schiff Base Hydrochlorides.—These were prepared essentially by the method of Dimroth and Zoeppritz[7] with the exception that one mole of cinnamaldehyde was dissolved in alcohol prior to addition to the arylamine in dilute hydrochloric acid. Yields of 85–95% of the products were precipitated instantly as golden-orange plates. The cinnamylidene sulfanilamide hydrochloride, melting at 203–205° dec., was recrystallized with some hydrolysis from dilute hydrochloric acid. Calculated for $C_{15}H_{14}O_2N_2S\cdot HCl$: Cl, 11.01. Found: Cl, 11.35.

The cinnamylidene sulfapyridine hydrochloride was too labile to be crystallized. Washed with a minimal amount of alcohol and ether, the product melted at 178–180° dec. Calculated for $C_{20}H_{17}O_2N_3S\cdot HCl$: N, 10.52; Cl, 8.90. Found: N, 10.15; Cl, 9.65.

Free Bases.—Crystallization of cinnamylidene sulfanilamide hydrochloride from water gave 70–80% yields of the base, m. p. 213–215° dec. The melting point was unchanged when mixed with an authentic sample,[9] although

The Directive Influence of the Electric Moment on Substitution in the Benzene Ring

BY W. J. SVIRBELY

A few years ago[1] a comparison of the electric moments of the monosubstituted benzene derivatives which direct substitution to the ortho and para positions with those which direct substitution to the meta position resulted in the following rule: *in general, if the electric moment of a monosubstituted benzene derivative is greater than ~2.07D, the next substituted group will be directed to the meta position; if the moment is less than ~2.07D, the next group will be directed to the ortho and para positions.*

In Table I there are listed the monosubstituted benzene derivatives whose moments have been determined since 1935. The compounds are divided into two groups depending upon whether the second substituted group is directed to the ortho and para or to the meta position. An examination of the data shows that in all of these compounds the rule is obeyed. Compounds which contained unsaturated bonds in the monosubstituted group such as the styrenes, diazoaminobenzenes, cinnamyl derivatives, etc., where the side chain is first attacked, have not been included in the table although their moments are listed in the literature.

(1) Svirbely and Warner, THIS JOURNAL, **57**, 655 (1935).

In a search for practical solvents for silicon tetrafluoride, its solubility in a number of organic solvents at room temperature (27–33°) has been determined. Saturated solutions were prepared by circulating the purified gas through the various solvents, contained in an absorption tower or an Orsat pipet, in a closed system at atmospheric pressure until saturation appeared to be attained. The non-aqueous solvents, except absolute ethyl alcohol, were used as purchased without additional purification. The rate at which the gas dissolved seemed to depend largely on the fluidity of the solvent. The concentration of silicon tetrafluoride in the solutions was calculated from the determination of fluorine in weighed samples. The saturated solutions remained clear, showing no precipitation of silica, when allowed to stand overnight out of direct contact with air. The results obtained are given in the table below. Owing to lack of temperature control and the possibility that the more viscous solutions may have been incompletely saturated, the results are regarded as approximate, but of practical value.

The data show that the solubility of silicon tetrafluoride in the homologous series of monohydroxy alcohols decreases definitely and quite regularly with an increase in the number of carbon atoms and for the same number of carbon atoms with an increase in the number of hydroxyl groups. Compounds containing ether groups (diethylene glycol), carbonyl groups (acetone and pyruvic acid), and carboxyl groups (acetic and pyruvic acids) were found not to be very good solvents for silicon tetrafluoride.

The Solubility of Silicon Tetrafluoride in Organic Solvents. Behavior of Such Solutions

BY GRADY TARBUTTON, E. P. EGAN, JR., AND S. G. FRARY

TABLE I

SOLUBILITY OF SILICON TETRAFLUORIDE AT ROOM TEMPERATURE (27–33°) AND TOTAL PRESSURE OF 750–760 MM.

Solvent	G. SiF_4/100 cc. solvent	Wt. % of SiF_4 in soln.
Methyl alcohol, absolute	..	32.8
Methyl alcohol, 94% by wt.	..	39.0
Ethyl alcohol, absolute	57.2	36.4
Ethyl alcohol, 96.1% by wt.	60.8	37.8
Ethyl alcohol, 95% (U. S. P.)	61.4	38.1
Ethyl alcohol, 94.3% by wt.	61.5	38.1
Ethyl alcohol, 92.6% by wt.	63.4	38.8
Ethyl alcohol, 91.0% by wt.	63.9	39.0
Isopropyl alcohol, 98%	39.4	28.2
n-Butyl alcohol, 98% (U. S. P.)	30.4	23.4
Amyl alcohols (fusel oil)	20.9	17.3
Glycol, C. P.	..	26.2
Diethylene glycol, C. P.	..	17.6
Glycerol, C. P.	..	5.7
Acetone, C. P. anhyd.	3.2	3.1
Acetic acid (glacial)	1.1	1.1
Pyruvic acid, tech. (38–45%)	..	4.4

In addition to these quantitative data, it was found that silicon tetrafluoride is sparingly soluble in benzene and trichloroethylene, and insoluble in carbon tetrachloride at room temperature.

On the addition of 9% by weight of water to the saturated solution in 95% alcohol (U. S. P.), a gelatinous precipitate of hydrated silica was formed. However, when the original solution was subjected to vacuum distillation at room temperature, silicon tetrafluoride was evolved until a solution containing approximately 26.5% of the gas remained, which corresponds to a mole ratio of alcohol to silicon tetrafluoride of approximately 6:1. On adding an equal volume of water to the residual solution from the vacuum distillation, no precipitate formed, possibly because the silicon tetrafluoride had combined chemically with the ethyl alcohol. Subsequent addition of a soluble barium salt precipitated 95% of the fluorine as pure barium fluosilicate. This reaction offers a convenient method for preparing barium fluosilicate of high purity.

When saturated solutions in glycol were distilled in a vacuum at room temperature, 50 and 100°, the residual solutions contained fluorine equivalent to 26.2, 24.5, and 2.8% silicon tetrafluoride, respectively; on addition of water to them, a precipitate was formed in each case.

The above information is of interest in that such solutions in organic solvents may furnish the basis for the synthesis of organic fluorine compounds as well as a means of preparing pure fluorine salts. However, the authors do not plan to pursue the investigation further and, therefore, wish to relinquish the problem to others who may be interested in it.

WILSON DAM, ALABAMA RECEIVED MAY 8, 1939

Occurrence of the Syringyl Radical in Plant Products

BY EINAR WEST, A. S. MACINNES, JOSEPH L. MCCARTHY AND HAROLD HIBBERT

It has now been shown that treatment of jute fiber, rye straw and corn stalks with a 2% solution of hydrogen chloride in anhydrous ethanol, according to the method described for the ethanolysis of spruce and maple woods,[1] gives rise to typical ethanolysis products, namely, ethanol lignin and a mixture of volatile oils. The yields of ethanol lignin and volatile oils are of the same order of magnitude as those obtained from spruce and maple woods. The presence of the syringyl radical has been established in the volatile oils from each of these fibers. Thus, following the procedures previously described,[2] α-ethoxypropiosyringone as the *p*-nitrobenzoate (m. p. 141–142°), syringoylacetaldehyde as the monosemicarbazone (m. p. 207–208°), and syringaldehyde as the 2,4-dinitrophenylhydrazone (m. p. 235–235.5°), were isolated. Mixed melting points with authentic specimens showed no depression.

These, and previous results with hard woods,[1,2] would seem to point to the presence of syringyl derivatives in the lignin constituents of all angiosperms, for example as indicated in corn and rye (monocotyledons) and in jute and maple (dicotyledons).

Reaction of *p*-Fluorophenol with Benzene and Aluminum Chloride

BY ARTHUR W. WESTON[1] AND C. M. SUTER

Recently it was found[2] that in the deëthylation of *p*-fluorophenetole with aluminum chloride in benzene solution a by-product was obtained in

(1) Sharp and Dohme Post-Doctorate Fellow 1938–1939.

(2) Suter, Lawson and Smith, THIS JOURNAL, **61**, 163 (1939).

considerable amount. This was phenolic in nature and in an impure condition melted at 153–156°. It has now been determined that the same substance results from heating *p*-fluorophenol with benzene and aluminum chloride. When purified it melted at 163.5–164° and upon oxidation gave a high yield of benzoic acid. No depression of the melting point occurred when a sample of the unknown was mixed with *p*-hydroxybiphenyl. Hence

$$C_6H_6 + FC_6H_4OH \xrightarrow{AlCl_3} C_6H_5C_6H_4OH\ [+ HF]$$

p-fluorophenol must react as shown and the *p*-hydroxybiphenyl obtained in the deëthylation of *p*-fluorophenetole also results from this reaction.

Attempts to extend the reaction in various directions have been without success. Because aromatic fluorine may be under some conditions replaced by chlorine,[3] it seemed possible that *p*-chlorophenol was an intermediate in the reaction. However, *p*-chlorophenol showed no activity toward benzene in the presence of aluminum chloride. None of the corresponding hydroxybiphenyl was isolated when *p*-fluorophenol and aluminum chloride were heated with toluene or chlorobenzene.

By heating a mixture of 3 g. of *p*-fluorophenol, 7 ml. of benzene and 7 g. of aluminum chloride under reflux for two and one-half hours there was obtained about 1 g. of *p*-hydroxybiphenyl, m. p. 164°. The 51 g. obtained in the deëthylation of *p*-fluorophenetole[2] corresponds to 13% of the *p*-fluorophenol reacting with the benzene.

COMMUNICATIONS TO THE EDITOR

SYNTHETIC AND NATURAL ANTIHEMORRHAGIC COMPOUNDS

Sir:

In our last communication [THIS JOURNAL, **61,** 1923 (1939)] the reported antihemorrhagic activity of 2-methyl-1,4-naphthoquinone was a minimum assay result. The total comparative activity of this compound is given in Table I. It is by no means as active as vitamin K [Ansbacher and Fernholz, *ibid.*, **61,** 1924 (1939)] or as low in activity as reported by Thayer, *et al.*, [*ibid.*, **61,** 1932 (1939)] and would seem to provide an effective, cheap, synthetic substitute for vitamin K. This compound, like phthiocol and others, is capable of maintaining the prothrombin level of chick blood at a normal value when sufficient is given.

We have purified or synthesized and tested a number of naphthoquinones and related compounds (Table I). Assays were conducted and results expressed as noted previously [*ibid.*, **61,** 1923 (1939)]. Entirely negative results were obtained with 1,4-benzoquinone, naphthalene, 1,4-naphthoquinone, anthraquinone, 1,2-dihydroxyanthraquinone, and hydrolapachol at levels of 100 mg. or more per kg. of diet. Thayer, *et al.*, [*ibid.*, **61,** 1932 (1939)] have reported some activity in 1,4-naphthoquinone. Fieser, *et al.*, [*ibid.*, **61,** 1925 (1939)] have indicated activity in lomatiol, lapachol and hydrolapachol. We have previously found lomatiol and lapachol to be inactive [*ibid.*, **61,** 1923 (1939)]. These other workers employ assay methods which require only twenty-four hours or less but which are, in our experience, likely to give misleading results.

TABLE I

ANTIHEMORRHAGIC ACTIVITY OF NAPTHOQUINONES

Substance	Level fed per kg. of diet, mg.	Activity in terms of cc. of ref. standard per g.[a]
2-Methyl-1,4-naphthoquinone	10	> 2400
2-Methyl-1,4-naphthoquinone	2.5	5150
2-Hydroxy-1,4-naphthoquinone	75	139

Phthiocol ethyl ether	15	100
Phthiocol octadecyl ether	20	95
Phthiocol phytyl ether	20	< 50
Phthiocol monoacetate	15	420
Phthiocol triacetate	15	192
Alfalfa concentrate	0.5	>53600
Alfalfa concentrates[b]	0.2 to 0.3	63000

[a] Standard hexane extract of dried alfalfa representing 1 g. per cc. [b] From preliminary assays of alfalfa preparations (E. A. Doisy, P. Karrer).

We have made the observation that solutions of the vitamin, the purified pigment derived from the vitamin by alkaline hydrolysis, the low temperature distillate from the molecular still (contains no vitamin K), and pure phytol all exhibit a characteristic white fluorescence when exposed to the light from an argon lamp. The same fluorescence was noted in samples of vitamin K obtained from Professor E. A. Doisy and Professor P. Karrer. The active nucleus, 2-methyl-1,4-naphthoquinone, does not show this fluorescence.

We prepared 2-methyl-3(?)-phytyl-1,4-naphthoquinone by condensation of 2-methyl-1,4-naphthoquinone with phytol. Purification was effected by repeated molecular distillation. *Anal.* Calcd. for $C_{31}H_{46}O_2$: C, 82.6; H, 10.3. Found: C, 82.5; H, 10.6. The product has the color, oily form and solubilities similar to those of vitamin K from alfalfa and sublimes in the molecular still under the same temperature and pressure. It shows the characteristic white fluorescence previously mentioned and gives the color changes of the natural vitamin in sodium methylate [*ibid.*, **61,** 1610 (1939)], although the transient purple is rather weak. When administered orally to vitamin K deficient chicks three weeks old at a level of 0.2 mg. per chick the compound restored blood clotting power to normal within a few hours. Quantitative assays have not been completed [see *Biochem. J.*, **33,** 1055 (1939)].

THE CONSTITUTION AND SYNTHESIS OF VITAMIN K_1

Sir:

In a previous communication [THIS JOURNAL, **61,** 1928 (1939)] we reported some experiments on the oxidation of vitamin K_1, in which we obtained phthalic acid, a quinone acid, and a ketone $C_{18}H_{36}O$. The ketone was identified as 2,6,10-trimethylpentadecanone-14 by means of the semicarbazone, melting point 66–67°. An authentic specimen of this semicarbazone was not available at the time but we have subsequently prepared it from the ketone which we obtained by the oxidation of phytol [F. G. Fischer and K. Löwenberg, *Ann.*, **464,** 69 (1929)]. The melting point was 64–66° and the mixed melting point 64–66°.

The amount of quinone acid obtained was so small (3.5 mg.) that only one analysis was possible, and the results indicated the formula $C_{14}H_{12}O_4$. On the basis of this, it was tentatively suggested that the acid was 2-ethyl-1,4-naphthoquinone-3-acetic acid. When this acid was synthesized and found to be different, we prepared an additional amount of the quinone acid from the vitamin and converted it to the methyl ester (melting point 121–122°). This was found to be identical with a synthetic specimen of the methyl ester of 2-methyl-1,4-naphthoquinone-3-acetic acid. *Anal.* Calcd. for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95. Found: C, 68.55; H, 5.22. The synthetic ester melted at 121.5–122.5° and the mixture showed no depression.

These results have been confirmed by further experiments with the diacetate of dihydro vitamin K_1 [THIS JOURNAL, **61,** 1612 (1939)]. Oxidation of this with chromic acid gave a good yield of a colorless diacetate acid melting without decomposition at 205°. *Anal.* Calcd. for $C_{17}H_{16}O_6$: C, 64.55; H, 5.10. Found: C, 64.40, 64.56; H, 5.09, 5.16. Treatment with diazomethane gave the methyl ester which melted at 127.5–128.5°. *Anal.* Calcd. for $C_{18}H_{18}O_6$: C, 65.45; H, 5.49. Found: C, 65.12; H, 5.36. This was found to be identical with a synthetic specimen of the methyl ester of 1,4-diacetoxy-2-methylnaphthalene-3-acetic acid (melting point 125–126°). The mixed melting point was 126–127°. Chromic acid oxidation of the diacetate acid from the vitamin converted it to the quinone acid which gave a methyl ester identical with the methyl ester of 2-methyl-1,4-naphthoquinone-3-acetic acid. These experiments demonstrate conclusively that the structure of vitamin K_1 is correctly represented by the formula 2-methyl-3-phytyl-1,4-naphthoquinone.

Confirmation of this structural formula for vitamin K_1 has been obtained through synthesis which was easily accomplished through direct alkylation by the method of Claisen [*Ann.*, **442,** 210 (1925)] for direct carbon alkylation of phenols. The reaction of phytyl bromide with a benzene suspension of the monosodium salt of 2-methyl-1,4-naphthohydroquinone produced the hydroquinone of the vitamin which was oxidized by the air to the quinone. This was purified by chromatographic adsorption and by high-vacuum distillation and was then subjected to reductive acetylation. The diacetate obtained in this man-

ner was crystallized from methyl alcohol. *Anal.* Calcd. for $C_{35}H_{52}O_4$: C, 78.33; H, 9.77. Found: C, 78.06; H, 9.81. The mixed melting point with an authentic specimen of diacetate from the natural vitamin showed no depression.

SYNTHETIC APPROACH TO VITAMIN K1

Sir:

In seeking a method for the introduction of the phytyl group into the 3-position of 2-alkyl-1,4-naphthoquinones we have investigated various procedures for condensing 2-methyl-1,4-naphthohydroquinone with phytol, geraniol and simpler β-unsaturated alcohols, and with dienes. In the work on vitamin E such condensations have been brought about in the presence of mineral acids (either added or liberated in the reaction) or zinc chloride and have been attended with cyclization to compounds of the tocopherol type. Since cyclization introduces a complication in the case at hand, trial was made of less powerful agents and it was found that, with anhydrous oxalic acid in dioxane solution, methylnaphthohydroquinone can be condensed with simple β-unsaturated alcohols and dienes to give considerable amounts of the uncyclized substituted hydroquinones. With 2,3-dimethylbutadiene, after refluxing for twenty-four hours, there was obtained 29% of the substituted hydroquinone, characterized as the diacetate (m. p. 119–120°, found: C, 74.04; H, 7.23), and 13% of a stable substance, m. p. 73–73.5°, which appears to be of the tocopherol type (found: C, 79.95; H, 7.63). The crude hydroquinone was converted quantitatively on oxidation to 2-methyl-3-(β,γ,γ-trimethylallyl)-1,4-naphthoquinone, m. p. 95–95.5° (found: C, 80.33; H, 7.25); this gives the above diacetate on treatment with pyridine, acetic anhydride, and zinc dust. Condensation with cinnamyl alcohol gave a hydroquinone (extracted with 10% sodium hydroxide) which formed a diacetate, m. p. 167.5–168° (found: C, 77.17; H, 6.09) and a quinone, m. p. 127–127.5° (found: C, 83.63; H, 5.71).

The reaction is being extended to other examples, including the isoprenoid alcohols, and the use of esters and ethers of the hydroquinone is being investigated. We have ascertained that phytol enters into the condensation under the above conditions or at 140°, and viscous oils have been obtained of the composition of the substituted hydroquinone or tocopherol. One preparation, purified by rather drastic treatment with alkali and by high vacuum distillation, gave C, 82.62; H, 10.52 ($C_{31}H_{48}O_2$ requires C, 82.24; H, 10.69); another after distillation gave C, 82.36; H, 10.71. The general character of the distilled material suggests that it is the tocopherol. In the geranyl series a similar product was oxidized with lead tetraacetate to a substance having the composition of the acetoxyquinone (found: C, 74.92; H, 8.15; $C_{23}H_{28}O_4$ requires C, 74.93; H, 7.69), and this route is under investigation.

Synthesis by the addition of a Grignard reagent to a 2-alkyl-1,4-naphthoquinone oxide does not appear promising. Such oxides (2-methyl, 2,6- and 2,7-dimethyl) are conveniently prepared by adding aqueous sodium carbonate to an alcoholic solution of the quinone and excess hydrogen peroxide. The 2,6-dimethyl compound, m. p. 97–98° (found: C, 71.23; H, 5.07), with either allylmagnesium bromide or magnesium bromide in ether gave a considerable amount of the bromohydrin, m. p. 146–148° (found: C, 51.05; H, 4.18; Br, 28.33), characterized by conversion to the bromodimethylnaphthoquinone, m. p. 114–114.7° (found: C, 54.64; H, 3.61).

RECEIVED JULY 25, 1939

SYNTHESIS OF 2-METHYL-3-PHYTYL-1,4-NAPHTHOQUINONE

Sir:

When equivalent amounts of phytol and 2-methyl-1,4-naphthohydroquinone are heated in dioxane solution in the presence of anhydrous oxalic acid at the reflux temperature, condensation occurs readily but the methylphytylnaphthohydroquinone produced is cyclized about as rapidly as formed and the chief reaction product appears to be the naphthotocopherol. By using a large excess of methylnaphthohydroquinone to accelerate the bimolecular condensation reaction and by operating at a temperature (75°) where cyclization is slow, it is possible to produce a considerable amount of the substituted hydroquinone.

The unchanged hydroquinone is removed by extraction from ether with dilute alkaline hydrosulfite and the phytyl-substituted hydroquinone is separated from the ether residue as a waxy, white solid by digestion with petroleum ether and centrifugation. The white sludge is oxidized in dry ether with silver oxide, and evaporation gives 2-methyl-3-phytyl-1,4-naphthoquinone as a pure yellow, rather mobile oil (Calcd. for $C_{31}H_{46}O_2$: C, 82.61; H, 10.29. Found: C, 82.76; H, 10.53). The preparation has been completed successfully ten times under slight variation of the conditions and the pure quinone obtained in yields up to half the weight of the phytol employed. Trichloroacetic acid has been used satisfactorily in place of oxalic acid and the procedure has been applied to the preparation of 2,6-dimethyl-3-phytyl-1,4-naphthoquinone (M. D. Gates, Jr.) and 2-methyl-3-geranyl-1,4-naphthoquinone (yellow oils).

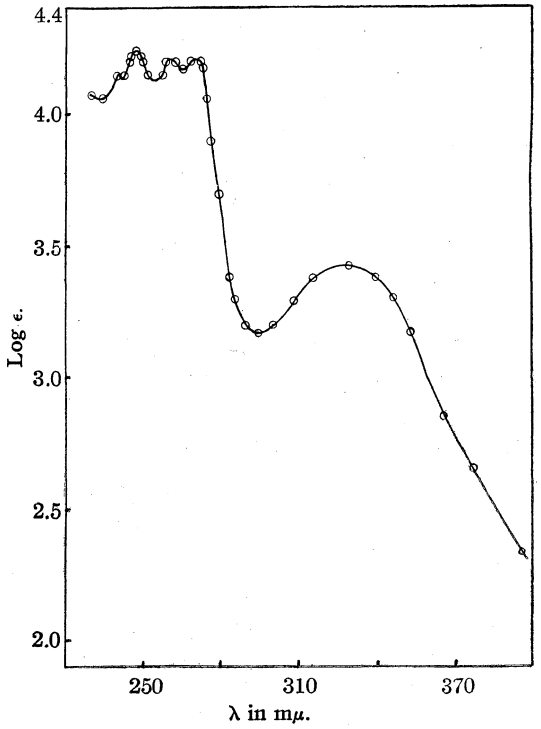

Fig. 1.—2-Methyl-3-phytyl-1,4-naphthoquinone in absolute alcohol. Maxima in mμ (with log ε values in parentheses): 241 (4.15), 248 (4.24), 260.5 (4.20), 270.5 (4.20), 328 (2.42).

In the Dam–Karrer test with alcoholic alkali, 2-methyl-3-phytyl-1,4-naphthoquinone gives striking purple or deep blue colors, depending upon the concentrations. The absorption spectrum, kindly determined by D. M. Bowen, closely resembles that reported for vitamin K_1, the curve being practically identical in form with that given by Dam, Karrer, *et al.* [*Helv. Chim. Acta*, **21**, 310 (1939)]. The positions of the maxima correspond closely with the values given for the vitamin by Dam, Karrer, *et al.*, and by Doisy, *et al.*, THIS JOURNAL, **61**, 1295, 1612 (1939), although the high extinction coefficient reported by Doisy has not been observed.

Dr. W. L. Sampson has found synthetic 2-methyl-3-phytyl-1,4-naphthoquinone to have marked antihemorrhagic activity. The substance was administered in 0.1 cc. of peanut oil to chicks which had been on a vitamin K deficient diet for two weeks and the blood clotting time determined eighteen hours after administration. The control birds all showed a clotting time of more than two hours and the following assays were made on the same day with the same group of chicks. With the Walker–Gordon standard alfalfa 75 mg. reduced the clotting time of 90% of the birds below ten minutes (av. 6.1 min.). With 2-methyl-3-phytyl-1,4-naphthoquinone a dose of 4 γ reduced the c. t. below ten minutes in 90% of the birds (av. 5 min.), while 2 γ was effective in 50%; thus 2–4 γ of the quinone is equivalent to approximately 75 mg. of alfalfa. Doses of 1 γ and 0.5 γ of 2-methyl-1,4-naphthoquinone were effective in 90% (av. c. t. 5 min.) and 30%, respectively, indicating an activity definitely greater than that of the phytyl derivative.

That the phytyl group very probably is linked through the terminal carbon atom is inferred from (1) analogy to the synthetic compounds of the vitamin E group, (2) analogy to similar condensations observed with cinnamyl alcohol and benzyl alcohol, and (3) the color reaction, which is interpreted as requiring an enolizable hydrogen on the α-carbon of the unsaturated side chain. Reductive acetylation gave the hydroquinone diacetate as a nearly colorless oil (Calcd. for $C_{35}H_{52}O_4$: C, 78.31; H, 9.77. Found: C, 78.43; H, 10.01), which resisted first attempts to effect crystallization but which eventually separated in part from methanol as colorless nodules after exposure of the solution in a Pyrex flask to sunlight, although it is not yet established that this treatment is essential. Recrystallized from methanol, the diacetate melted at 57–59° (Found: C, 78.34; H, 9.87). The hydroquinone dibenzoate, obtained as a solid after exposure to sunlight, melted at 85–86° (Calcd. for $C_{45}H_{56}O_4$: C, 81.77; H, 8.54.

Found: C, 81.63; H, 8.59). For the corresponding diacetyl derivative of natural vitamin K_1 Doisy (*loc. cit.*) found the m. p. 59°.

RECEIVED AUGUST 12, 1939

IDENTITY OF SYNTHETIC 2-METHYL-3-PHYTYL-1,4-NAPHTHOQUINONE AND VITAMIN K_1

Sir:

A comparison of the synthetic product described earlier with the natural vitamin was made possible by Dr. Byron Riegel, who generously supplied me with a highly purified 3–5% alfalfa concentrate [Riegel, Schweitzer and Smith, *J. Biol. Chem.*, **129**, 495 (1939)]. An alcoholic suspension of 5.3 g. of this oil was shaken with aqueous hydrosulfite and the vitamin hydroquinone taken into petroleum ether, extracted with Claisen's alkali containing hydrosulfite, and recovered from the yellow liquor by dilution with water and extraction with ether. Digestion with petroleum ether and centrifugation, following the procedure of the synthesis, gave a white solid yielding on oxidation 60 mg. of vitamin K_1 as a yellow oil (Found: C, 82.64; H, 10.20). The substance gives the characteristic Dam–Karrer color test, the spectrum agrees very closely with that of the synthetic quinone (T. J. Webb), and in antihemorrhagic activity the two substances appear identical within the limit of error (W. L. Sampson). Reductive acetylation gave a diacetate, m. p. 58.5–60° (Found: C, 78.13; H, 10.11) showing no depression when mixed with synthetic 2-methyl-3-phytyl-1,4-naphthohydroquinone diacetate (purified sample, m. p. 60–61.5°, remelting at 60–60.5°). Subsequent to my comparison, this finding has been confirmed by Dr. E. A. Doisy, who kindly examined my synthetic diacetate and found that it did not depress the m. p. of a purified sample of his diacetate from natural vitamin K_1. The sample was sent, at Dr. Doisy's stipulation, at the conclusion of his own work (sample received August 21, examined August 22). In contrast to the behavior noted with the synthetic compound of the methyl series and with the natural vitamin, synthetic 2-ethyl-3-phytyl-1,4-naphthohydroquinone did not separate from petroleum ether even after considerable purification had been effected by extraction with Claisen's alkali, and a sample of the quinone showing a strong color test was found inactive in fairly high dosage. The conclusion from this work is indicated by the title. A further observation, made with a sample of the synthetic material, is that the Dam–Karrer reaction results in the formation of phthiocol, m. p. 171–172°, mixed m. p. 171.5–172.5°.

In a clinical trial Drs. H. A. Frank and A. M. Seligman of the Beth Israel Hospital, Boston, found that 10 mg. of the synthetic vitamin given by mouth with 3 g. of ox bile to a patient with a complete malignant biliary obstruction reduced the prothrombin clotting time (method of Quick) from 37.5 to 17 seconds on one occasion and from 55 to 28 seconds on another. Intravenous injection of the quinone (10 mg.) in dispersion in 10% glucose solution (1 liter) was also successful and the patient was carried through operation without abnormal bleeding.

NEW THERMODYNAMIC DATA FOR THE CYCLOHEXANE–METHYLCYCLOPENTANE ISOMERIZATION

Sir:

The equilibria at several temperatures in the isomerization reaction Cyclohexane (liq.) $\rightleftarrows$ Methylcyclopentane (liq.) have been studied carefully by Glasebrook and Lovell [THIS JOURNAL, **61**, 1717 (1939)]. From their measurements on this reaction they have calculated the thermodynamic data at 25° which appear in the second column of Table I and then have compared these results with similar ones (Column 3) derived from the free energy studies of Parks and Huffman ["The Free Energies of Some Organic Compounds," The Chemical Catalog Co., New York, 1932, p. 90]. Here the Parks–Huffman value for ΔS, which should be quite reliable, is in fairly good agreement with the value derived indirectly by Glasebrook and Lovell but the ΔH and $\Delta F°$ values differ even in sign. These discrepancies are undoubtedly due to the fact that the Parks–Huffman ΔH value (and therefore also their $\Delta F°$) is based on early and somewhat uncertain combustion data for these two hydrocarbons. Indeed an error of only 0.25% in the two heats of combustion might conceivably account for this difference.

TABLE I

THERMODYNAMIC DATA FOR THE REACTION: CYCLOHEXANE (liq., 25°) ⟶ METHYLCYCLOPENTANE (liq., 25°)

	Calcd. from equil. meas.	Calcd. from Parks and Huffman	Calcd. by Moore and Parks
ΔH, cal.	3510	−1100	3930
ΔS, e. u.	7.9	10.0	10.0
$\Delta F°$, cal.	1150	−4100	950

In view of this situation we recently included these two substances in an extensive and very precise investigation of the heats of combustion of organic compounds which is in progress in this Laboratory. We have now obtained the following values, in terms of the "defined" calorie, for the heats of combustion of the liquid hydrocarbons per gram (*in vacuo*) at 25° and 1 atm. constant pressure: cyclohexane, 11,126.7 (±2.1) cal.; methylcyclopentane, 11,173.4 (±3.6) cal. From these data we find for the cyclohexane–methylcyclopentane isomerization $\Delta H_{298.16} = 46.7$ (±4.2) cal. per gram or 3930 (±350) cal. per mole. Taking $\Delta S = 10.0$ (±0.8) e. u. and using the relation $\Delta F = \Delta H - T\Delta S$, we next obtain $\Delta F°_{298.16} = 950$ (±420) cal. per mole. This new third law value for the free energy of isomerization is thus in good agreement with that derived from the equilibrium study of Glasebrook and Lovell.

The new thermodynamic data are now recorded in Column 4 of the table. They serve to emphasize the necessity of very precise combustion data in any accurate free energy calculations based on the third law.

Before concluding, we wish to thank the Shell Development Company for the preparation of extremely pure samples of these hydrocarbons and for the financial support which made this study possible.

SYNTHESIS OF 2-METHYL-3-β-HYDROXY-ETHYL-N-[(2-METHYL-6-AMINOPYRIMIDYL-(5))-METHYL]-PYRIDINIUM BROMIDE HYDROBROMIDE

Sir:

In view of the marked specificity of thiamin with respect to the loading of the heterocyclic rings, it seemed of interest to synthesize the isosteric 2-methyl-3-β-hydroxy-ethyl-N-[(2-methyl-6-aminopyrimidyl-(5))-methyl]-pyridinium bromide hydrobromide. This has been accomplished in ten steps, starting with 6-amino-3-nitro-2-picoline [Seide, *J. Russ. Phys.-Chem. Soc.*, **50,** 542 (1920)]. This was converted into the 6-hydroxy-3-nitro-2-picoline according to the method of Seide (*ibid.*, p. 540). From the hydroxy compound the 6-chloro-3-nitro-2-picoline was obtained by treatment with phosphorus pentachloride. Chlorine was eliminated and the nitro group simultaneously reduced to the amino group with hydrogen and a palladium catalyst [Binz and von Schickh, *Ber.*, **68,** 320 (1935)]. The 3-amino-2-picoline (m. p. 113°) was converted into the corresponding nitrile (m. p. 58°) by a Sandmeyer reaction at *p*H 4.5. The nitrile was converted into the 2-picolyl methyl ketone (b. p. 75–78°, 2 mm.) by a modified LaForge procedure [THIS JOURNAL, **50,** 2480 (1928)]. The ketone was brominated, the reaction product without isolation being converted into the acetyl derivative by treatment with potassium acetate in alcohol. The acetylated ketol was reduced without isolating it to 2-methyl-3-β-hydroxyethylpyridine (b. p. 125°, 3 mm.), picrate (m. p. 125°). (*Anal.* Calcd. for $C_{14}H_{14}O_8N_4$: C, 45.95; H, 3.81; N, 15.3. Found: C, 46.04; H, 3.66; N, 15.37). This compound was acetylated using the method described by Kuhn [*Z. physiol. Chem.*, **259,** 50–51 (1939)] (b. p. 90–92°, 3 mm.). (*Anal.* Calcd. for $C_{10}H_{13}O_2N$: N, 7.82; CH_3CO, 24.02. Found: N, 7.9; CH_3CO, 24.4, 24.2.) The β-hydroxyethyl derivative was condensed with 2-methyl-5-bromomethyl-6-aminopyrimidine hydrobromide [THIS JOURNAL, **59,** 1052 (1937)] and the 2-methyl-3-β-hydroxyethyl-N-[(2-methyl-6-aminopyrimidyl-(5))-methyl]-pyridinium bromide hydrobromide (m. p. 247°) was obtained. (*Anal.* Calcd. for $C_{14}H_{20}ON_4Br$: C, 40.00; H, 4.76; N, 13.33; Br, 38.09. Found: C, 39.72; H, 4.97; N, 13.83; Br, 37.75.)

Owing to the difference between the pyridine and thiazole rings, the new derivative permits synthesis of isomers not possible for a thiazole and, therefore, the corresponding 2-methyl-5-β-hydroxyethyl-N-[(2-methyl-6-aminopyrimidyl-(5))-methyl]-pyridinium bromide hydrobromide (m. p. 245°?) was synthesized in a similar manner starting from the corresponding ketone [*Ber.*, **57,** 832 (1924)]. The 2-methyl-5-β-hydroxyethylpyridine is a low melting solid (b.p. 103°, 2 mm.). (*Anal.* Calcd. for $C_8H_{11}ON$: C, 70.00; H, 8.03; N, 10.21. Found: C, 69.60; H, 7.77; N, 10.08.)

A detailed report of our work will be presented in the future.

We acknowledge gratefully valuable suggestions of Dr. H. Gilman and Dr. F. B. LaForge. We are also indebted to Merck & Co., Inc., for generously furnishing us with a supply of the pyrimidine derivative used in this work. The analytical work was carried out by Dr. Carl Tiedcke of New York City.

VITAMIN K POTENCIES OF SYNTHETIC COMPOUNDS

Sir:

In view of the failure of the absorption of many patients in which vitamin K therapy is highly desirable, we have been examining various compounds which could be administered intravenously in aqueous solution. The most active compound found is 1,4-dihydroxy-2-methylnaphthalene which has a potency of approximately 1000 Thayer–Doisy units per milligram. It can be prepared readily by the reduction of the highly potent 2-methyl-1,4-naphthoquinone. Since this preparation is soluble in dilute alkali and has a high degree of potency (approximately equal to the potency of 2-methyl-1,4-naphthoquinone), it seems that this compound may prove very important for intravenous vitamin K therapy.

Supplementing our previous preliminary report [THIS JOURNAL, **61**, 1932 (1939)], we have reassayed several quinones to determine their optimum potency values. Except for 2-methyl-1,4-naphthoquinone, these more recent data agree with our previous findings. The assay of this compound was carried out by the Thayer–Doisy method, making a concurrent test, at six, eighteen and seventy-two hours. The standard was also run at varying levels at the same time for each series. The data are given in Table I. The details as to the method of feeding, care of the chicks, length of test period, manner of bleeding, etc., were essentially the same as described previously.

TABLE I

Assay period	Thayer–Doisy units per mg.
6 hours	1110
18 hours	970
72 hours	1070
Average	1050

The potency of 2-methyl-1,4-naphthoquinone (Thayer–Doisy units) agrees with the value previously assigned to the natural K_1, namely, 1000 units per milligram [*Proc. Soc. Exp. Biol. Med.*, **41**, 194 (1939)]. These results also confirm the findings of Ansbacher and Fernholz [THIS JOURNAL, **61**, 1932 (1939)].

Incidentally, in view of these observations and the lack at this time of a suitable standard, it is suggested that 2-methyl-1,4-naphthoquinone should be adopted as a basic standard for the assay of vitamin K. This compound has the desirable qualities of a standard in that it can be obtained readily in a satisfactory state of purity, has a definite melting point for characterization, and when protected from excessive exposure to light is relatively stable. The unit could then be defined in the terms used by the League of Nations committee as the specific vitamin K activity of one microgram of pure 2-methyl-1,4-naphthoquinone.

ANTIHEMORRHAGIC ACTIVITY OF SIMPLE COMPOUNDS

Sir:

In connection with our investigation of vitamin K, we have tested recently a large number of derivatives of α-naphthoquinone, many of which have been prepared and reported by Professor Fieser and his collaborators[1] and some of which were synthesized in this Laboratory. At this time we wish to report our findings of the antihemorrhagic activity of 2-methyl-1,4-naphthoquinone and of some other related substances of significance.

One of the first quinones we assayed was 2-methylnaphthoquinone and, because it did not appear at that time to be as active as 2,3-dimethyl-1,4-naphthoquinone,[1] we did not determine its minimum dose.

Following the appearance of the extremely interesting report of Ansbacher and Fernholz,[2] we reinvestigated the activity of 2-methyl-1,4-naphthoquinone, and we are now in complete agreement with them.

(1) Fieser, *et al.*, THIS JOURNAL, **61**, 1925, 1926, 2206 (1939).
(2) Ansbacher and Fernholz, *ibid.*, **61**, 1924 (1939).

The assay method we employed was as follows: Day old chicks were placed on a vitamin K free diet and kept on this diet for fourteen to seventeen days. When a preliminary determination of clotting time showed that at least 90% of the chicks had clotting times above thirty minutes, the samples, dissolved in 0.1 cc. of peanut oil, were administered orally. Eighteen hours later, the clotting times on the dosed birds were determined. Usually ten chicks were used at each dose level.

In the course of six weeks, nine assays were run on 2-methylnaphthoquinone. Following is a typical protocol of our results:

Substance	Dose	No. birds	Clotting time in min. 0–5	6–10	11–30	>30	Per cent. under 10 min.
2-Methyl-naphtho-quinone	1 γ	10	5	4	1	0	90
2-Methyl-naphtho-quinone	0.75 γ	9	4	3	1	1	77
2-Methyl-naphtho-quinone	0.5 γ	9	3	1	3	2	44
Alfalfa extract	≏75 mg.	9	3	3	2	1	67
Negative controls	0	10	0	0	0	10	0

In all over 120 chicks were used in testing 2-methyl-1,4-naphthoquinone at levels of 0.5 to 1.0 γ and the results in every case were essentially the same as above.

From the results of Ansbacher and Fernholz and from ours, it would appear that, in the chick at least, 2-methylnaphthoquinone possesses antihemorrhagic activity of the same order of magnitude as the vitamin K_1 reported by Thayer, *et al.*[3] These results are particularly striking inasmuch as hitherto no simple compounds corresponding in chemical structure to the chemically identified vitamins exhibit the same order of activity as the vitamins themselves. It is also noteworthy that 2-ethylnaphthoquinone (activity above 200 γ) and 2-*n*-propylnaphthoquinone[4] (inactive at 400 γ) are decidedly less effective than the methyl homolog. While 2,3-dimethylnaphthoquinone has some antihemorrhagic activity (effective at 50 γ), 2,6- and 2,7-dimethyl-1,4-naphthoquinone[1] exhibit little, if any (inactive at 400 γ), notwithstanding the fact that the substituents about the quinone systems of the latter two compounds are similar to 2-methylnaphthoquinone.

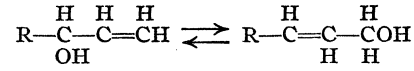
THE INTERCONVERSION OF CROTYL ALCOHOL AND METHYLVINYLCARBINOL IN AQUEOUS SULFURIC ACID

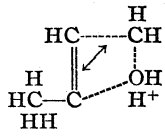
Sir:

According to the generally accepted ideas [Burton and Ingold, *J. Chem. Soc.*, 1907 (1928); J. W. Baker, "Tautomerism," pages 241–7, Routledge, London, 1934], carbinol systems of the type



are the least mobile of the allylic systems, exhibiting little or no tendency to isomerize. Although the system has been reported to be mobile when R = phenyl [Valeur and Luce, *Bull. soc. chim.*, **27,** 611 (1920)], Burton and Ingold [*loc. cit.*] were unable to verify the observation. Another example of isomerization was reported by Prévost [*Ann. chim.*, [10] **10,** 147 (1928)], who found that crotyl alcohol was formed during the dehydration of methylvinylcarbinol over alumina at high temperatures.

However, work on the mechanism of the reaction of the butenols with solutions of hydrogen bromide [Young and Lane, THIS JOURNAL, **60,** 847 (1938)] convinced us that crotyl alcohol and methylvinylcarbinol should be interconvertible in the presence of acids to form equilibrium mixtures even at room temperatures. This predicted interconversion was based on a postulate that activation of the oxonium ion of either crotyl alcohol or methylvinylcarbinol might lead to the same resonating molecule



in which the oxygen is bonded weakly to both carbons 1 and 3 [Young and Nozaki, paper in process of publication]. Consequently 50-ml. portions of crotyl alcohol and methylvinylcarbinol are being treated with mixtures of water and sulfuric acid adjusted so that the normality of acid in 228 ml. of reaction mixture is 7.4, 3.7, and 1.9. With methylvinylcarbinol after one week at room temperature the 7.4 *N* acid had caused the production of 4.5 g. of crotyl alcohol and 5 g. of a fraction which appears to be a mixture of crotyl and methylvinylcarbinyl ethers. With crotyl alcohol after two weeks the 7.4 *N* acid had produced 22 g. of the ether fraction and equal quantities, 4 g., of methylvinylcarbinol and

crotyl alcohol, while the 3.7 *N* acid had produced less ether and more alcohol, 7 g. of each. Since the problem requires a careful study of the effect of the acid concentration on the proportion of hydration, ether formation and alcohol rearrangement, we wish to record the fact that mobility may be induced in this supposedly stable allylic system even at low temperatures. The possibility that butenyl sulfates are involved in the rearrangement is being investigated.

NEW BOOKS

Lehrbuch der organischen Chemie. (Textbook of Organic Chemistry.) By PAUL KARRER, Professor in the University of Zurich. Sixth, revised and enlarged edition. Georg Thieme Verlag, Rossplatz 12, Leipzig C 1, Germany, 1939. xxiii + 689 pp. 6 figs. 17.5 × 24 cm. Price, RM. 34; bound, RM. 36.

The sixth German edition is practically identical with the English edition recently reviewed in these pages [THIS JOURNAL, **61**, 756 (1939)]. The new subject matter in the sixth edition (which is also incorporated in the English translation) includes only the section on organic deuterium compounds (five pages), a page on ergot alkaloids and half a page on phthalocyanins. Other topics have been brought up to date, especially in the active fields of natural products. In the preface the author calls attention to a greater inquiry into reaction mechanisms than in previous editions. The change in this regard seems slight, the text retaining its almost purely descriptive character.

PAUL D. BARTLETT

The Oxidation States of the Elements and their Potentials in Aqueous Solutions. By WENDELL M. LATIMER, Ph.D., Professor of Chemistry, University of California. Prentice-Hall, Inc., 70 Fifth Avenue, New York, N. Y., 1938. xiv + 352 pp. 16 × 24 cm. Price, $3.00.

The usefullness of thermodynamic data is determined by the carefullness with which they have been obtained, the clearness with which they are presented and the convenience with which they may be used. Judged by these criteria Latimer has achieved a remarkably successful volume. The author has endeavored to include references to all works published up to 1938. The results of these investigations are presented concisely in a series of tables in the appendix. The first two give E^0 values for several hundred half cell reactions, one for acid solutions and one for alkaline solutions. Then follows a table of free energies of formation and one giving equilibrium constants, arranged alphabetically by the elements. The next table gives values for the activity coefficients of strong electrolytes and the last gives values for the entropy of elements, compounds and ions. If the volume contained only these thirty pages of tables it would be invaluable.

For the convenience of students who are not working in the field of physical chemistry, the first two chapters give an introduction to the use of the tables. These chapters discuss the subject of units, conventions, general methods employed in the determination of oxidation–reduction potentials, ionization potentials, electron affinities, lattice energies, and their relation to standard oxidation–reduction potentials. A section of the appendix serves as a guide in the use of activity coefficients and the concept of the ionic strength. Although these chapters of a general nature are designed to make the remainder of the volume useful they will also serve as a convenient review of the most often used portions of thermodynamics for students of organic and inorganic chemistry.

Nineteen chapters follow these first two general sections, taking up in detail the chemistry of the elements arranged by families. Here an investigator interested in any particular element will find gathered together the available thermodynamic data and references to the literature. These data are interpreted and applied to the chemical behavior of the element. Where no data are available the author frequently has given estimates, which will be useful guides to those without a background of long experience in this field.

This volume will not only constitute an essential part of every chemist's reference library but will also introduce students who wish to use physico-chemical data to the elements of thermodynamics.

HENRY E. BENT

Inorganic Quantitative Analysis. By HAROLD A. FALES, Ph.D., Columbia University, and FREDERIC KENNY, Ph.D., St. Francis College. Second edition. D. Appleton-Century Company, Inc., 35 West 32nd Street, New York, N. Y., 1939. xiii + 713 pp. 132 figs. 15 × 22.5 cm. Price, $4.00.

The educational philosophy of this excellent book is contained in the following sentences from the preface: "It has been the aim of the authors, in preparing this work, to apply the principles of Physical Chemistry to the theory of Quantitative Analysis in a detailed and thorough manner. In stressing this point of view, it has not been forgotten, however, that the two other

aspects of the subject, namely, technique and methods, play an equally important part in the education of the analyst." This is the pattern of nearly all the recent books in Analytical Chemistry and therefore such a book must be judged by the ratio of theory to techniques and methods. No one, however, knows what the correct ratio is, and therefore authors should not be criticized for using a given ratio. In this book there is a full measure of theory and as far as possible the techniques and method of analysis are presented from the standpoint of theory. This is also followed in the arrangement of the subject matter, as is shown by the departure from the traditional division into gravimetric and volumetric analysis.

The general techniques and the detailed procedures for carrying out the laboratory exercises are well done. At the end of each chapter is a list of problems, and there is a long appendix with a table of five-place logarithms, specific gravity tables and tables of equivalent units of the metric and English systems of weights and measures. The appendix also contains such mathematical derivations as are deemed too advanced for the text.

The chapters on precision, weighing and calibration of weights are particularly good in the wealth of information they contain. The use of organic reagents and solvents is presented in a chapter of 22 pages, and 38 pages are given to a chapter on Photometry. So much space to these subjects is unusual in a book of this kind, and, to the reviewer at least, the chapter on Photometry seems out of balance. It is nearly all theory with only one laboratory exercise, the determination of free ammonia in water. There are no exercises in turbidimetric or nephelometric methods. In the excellent chapter on electrometric methods there is no mention of the simple and accurate differential and dead-stop end-point systems of titration which require scarcely more electrical equipment than a galvanometer. The old method of determining sodium by difference is given but there is merely a literature reference to one of the triple acetate methods. These points, however, are but differences of opinion between the reviewer and the authors. Perhaps the authors are right. At any rate the reviewer likes the book and commends it heartily to students of analytical chemistry.

C. W. FOULK

Kinetik der Phasenbildung. (Kinetics of Phase Formation.) By Dr. MAX VOLMER, Professor and Director of the Division of Physical and Electrochemistry of the Institute of Technology of Berlin. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1939. xii + 220 pp. 61 figs. 15.5 × 22.5 cm. Price, RM. 14.25; bound, RM. 15.

This book presents a new case—older ones are the phase rule, the Donnan equilibrium, the galvanic cell, the correlation between adsorption and surface tension—where a seed sown by Willard Gibbs and fallen, as it were, on barren land, begins to grow after many years, when touched by the moisture of true understanding. An equation given by Gibbs for the formation of a first droplet of a second liquid phase in the interior of an infinite mass of another one, which was independently re-derived by Volmer, is one fundament on which the book is based. Some others are: a molecular kinetic formulation of the continuous formation and growth of liquid nuclei and of the discontinuous formation and growth—already preconceived by Gibbs—of crystalline nuclei.

As important results of this theoretical treatment may be mentioned: a quantitative agreement as to the rate of nuclei formation in vapors of different liquids on adiabatic expansion and as to the influence of pressure upon the temperature to which a liquid may be overheated; Wilhelm Ostwald's "metastable limit" and his frequently observed rule, that the newly formed phase is generally an instable one, may be understood; the production of nuclei is enormously favored at interfaces;—this explains that "cavitation," *i. e.*, the disrupture of a liquid under the influence of supersonic waves, also occurs mainly at interfaces (reviewer's remark).

It may be hoped that many puzzling phenomena in meteorology and, particularly, in the formation of Liesegang's rings (*e. g.*, the influence of light, the similarity of complicated ring systems with wave patterns) will soon become clearer, when attacked by these new methods.

Volmer's most interesting book is very lucidly arranged: 1, a historic survey; 2, the transport of molecules from one phase to another; 3, general theory of supersaturation and of nuclei formation; 4, special kinetic treatment and comparison with experimental results (droplets in gases, bubbles in liquids, formation of crystalline nuclei in the interior of phases and at interfaces, etc.); 5, nature of new phase (primary formation of instable phases); 6, structure of new phase (growth of nuclei, etc.). Nevertheless, this book is no easy reading, because exactness of theoretical conception and derivation is the author's first law and because his "thermodynamical dialect," mainly based on Gibbs' thermodynamical potential μ, is somewhat unusual.

H. FREUNDLICH

Lehrbuch der anorganischen Chemie. (Textbook of Inorganic Chemistry.) By Prof. Dr. ERNST H. RIESENFELD. Second, revised edition. Verlag von Franz Deuticke, Helferstorferstrasse 4, Wien, Germany, 1939. xxvii + 706 pp. 90 figs. 17.5 × 25.5 cm. Price, M. 14; bound, M. 16.

The reviewer found this textbook most useful when looking up recent developments of general and inorganic chemistry. Chapters which have been treated with particular thoroughness are those on the structure of atoms (isotopes, natural and artificial radioactivity, etc.), on metals and their compounds, on crystal structure, and on complex salts. The author frequently refers to the biochemical importance of the elements. Many recent technical applications are described.—The age in which the book has been published has left a rather curious mark: gas masks are mentioned no less than five times in different chapters.

The book is well arranged and well written; an abundance of facts has been collected. There were only very few, where the reviewer did not find the information he looked for: the polarographic method, now used more and more in analytical chemistry, is not mentioned; Brönsted's conception of acids and bases has been treated rather too briefly.

H. FREUNDLICH

The Chemistry of Organic Compounds. A Year's Course in Organic Chemistry. By JAMES BRYANT CONANT, President of Harvard University, Revised with the Assistance of MAX TISHLER, Ph.D., Merck and Co. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1939. x + 658 pp. 35 figs. 15 × 22 cm. Price, $4.00.

This admirable text, the first edition of which appeared six years ago, has now been revised with due consideration, not only to the useful newer chemical reactions, but also to the trends of organic chemistry in the direction of industry, and of biological chemistry and physical chemistry. Actually there have been added but thirty-five additional pages, yet this fact does not in any sense indicate the extent of revision, as the book has been modernized in a very effective and pleasing manner. There is a commendable choice of industrial applications. The electron theory of valence has been extended. The concept of resonance has been interestingly introduced in connection with the guanidinium ion, and elaborated further in the treatment of aromatic compounds. Indeed, wherever appropriate, there has been shown the importance of physical chemistry to organic chemistry. New and interesting information has been given on topics of biochemical significance including hormones, vitamins, sugars and proteins. The chapter on heterocyclic compounds has been enlarged. The last two chapters dealing with "Plant Pigments" and with "Advanced Topics in Stereochemistry" should certainly be provocative of interest and thought to students looking forward to advanced courses.

This is a scholarly, well-written book, which should take a front rank position among the newer organic chemistries. It is refreshing to read a text which, like the present one, departs from the stereotyped.

ARTHUR J. HILL

Photochemistry and the Mechanism of Chemical Reactions. By GERHARD K. ROLLEFSON, Ph.D., Associate Professor of Chemistry, University of California, and MILTON BURTON, Ph.D., Instructor in Chemistry, New York University. Prentice-Hall, Inc., 70 Fifth Avenue, New York, N. Y., 1939. xiv + 445 pp. 58 figs. 16 × 23.5 cm. Price, $5.75.

An excellent comprehensive survey of modern photochemistry. Following a brief introductory chapter, the authors summarize those portions of the quantum theory of atomic and molecular spectra which are necessary for an empirical understanding of spectral notation, selection rules, and potential energy curves. Fluorescence and photodissociation are discussed in two well-written chapters on the physical and chemical effects following the absorption of light. A chapter on photochemical kinetics summarizes the principles and methods used in the determination of secondary reaction mechanisms, and gives particular attention to the reactions of free atoms and radicals. In the next chapter, on photolysis in the solid state, the authors assume the de Boer "perforated lattice" model and interpret existing data, chiefly on the alkali and silver halides, on the basis of this model. The remaining two-thirds of the book is devoted to a critical summary and discussion of existing data on a large number of photochemical reactions. Most of the cases discussed involve reactions in gases, but chapters on reactions in solution and on heterogeneous reactions are included. Photography and photosynthesis, considered as photochemical processes, are interestingly discussed in the chapter on heterogeneous reactions. Useful appendices on spectral notation, bond and dissociation energies, and activation energies are included.

The experimental technique of photochemistry is not systematically discussed, although certain specialized techniques are referred to at various places in the book. Owing to the order of discussion which the authors have adopted, certain reactions will be found treated in part in one chapter and in part in another. Thus, the mercury sensitized dissociation of hydrogen is discussed in chapter 3 and again in chapter 10, the photolysis of hydrogen bromide is taken up in chapter 7, its synthesis in chapter 11, and the discussion of the photographic latent image is divided between chapters 6 and 15.

The book reflects very clearly the extent to which modern photochemistry is interrelated with spectroscopy on the one hand, and the elementary reactions of free atoms and radicals on the other, and the change in emphasis in the subject during recent years is illustrated by the fact that the law of photochemical equivalence is mentioned at only two places, while these interrelations receive much attention throughout. The book is authoritatively and clearly written and the reviewer agrees with the contention of the authors that it is possible for a person using it to "find himself with a working understanding of what has been done and an appreciation of what is still needed" in photochemistry.

PHILIP A. LEIGHTON

Calculations of Quantitative Chemical Analysis. By LEICESTER F. HAMILTON and STEPHEN G. SIMPSON. Third edition. McGraw-Hill Book Company, Inc., 330 West 42d Street, New York, N. Y., 1939. 293 pp. Price, $2.50.

Among the more difficult parts of chemistry for the elementary student to grasp thoroughly are the calculations involved in analytical work. Hamilton and Simpson have attempted to remedy this by presenting all the types of calculation concerned in a clear and concise manner under one cover, with such success that the previous editions of this book achieved wide popularity. Almost every imaginable type of problem is covered, both in explanation and in the many problems which accompany the text.

The present third edition retains the good features of the old with many improvements. The chapter on oxidation and reduction has been considerably modernized, and the sections dealing with electrolytic processes and with indicators have undergone a needed expansion. A discussion of methods of weighing also has been added, which omits, however, the method of single swing weighing. The calibration of weights also has been left out. One might also have wished for some consideration of the relative concentration of ions in solution at the end-point in oxidation–reduction titrations. The rules for balancing equations seem needlessly complicated and do not appeal to me.

On the whole, however, the book is excellently written, and should continue to be a standard text for teaching and student reference in this field.

J. C. MORRIS

Experimental Methods in Gas Reactions. By A. FARKAS and H. W. MELVILLE. The Macmillan Co., 60 Fifth Ave., New York, N. Y., St. Martin's Street, London, 1939. 389 pp. Price $7.50.

Until now the graduate student and research worker in the field of gaseous reaction kinetics have had to depend largely upon verbal exchange and chance gleanings from the literature for their information as to the techniques available in the field. Too often valuable methods have been confined to individual laboratories or have suffered untimely burial in the back files of magazines. It is true that there have been monographs on special phases such as the technique of achieving and measuring vacua, but before this there has been no attempt to provide a volume on technique in this entire field in which technique plays such an important role.

Because of this the present book by A. Farkas and Melville is an important and noteworthy one, the more especially so when the general excellence of the work is considered. Hardly a stone has been left unturned to make it a complete compendium. All the common problems of experimental method in connection with homogeneous, photochemical, and catalytic gas reactions, and many of an unusual nature have been covered. The chapter headings, Kinetical Gas Theory, Apparatus for Control of Pressure and Temperature, Preparation and Analysis of Gases, Photochemical Technique, and Experimental Methods for the Investigation of Chemical Reactions, do not give an adequate picture of the wealth and variety of material contained in the book. For example, the last chapter covers such widely varied and important topics as the construction of reaction vessels, measurement of the progress of the reaction, the theory and operation of flow systems, production and reactions of free radicals, preparation of catalysts and operation of catalytic systems, electrical activation, and the investigation of explosions and flames. Other chapters are as rich in the material considered. The procedure of the book is to present some of the major methods in considerable detail and to give many others in concise, though generally adequate form, with appropriate literature references in case further information is wanted. This allows a greater coverage than would be otherwise possible. The value of the book is further increased by the inclusion of many tables of properties of gases and gaseous systems, arranged in convenient form for the kineticist.

It is naturally difficult in a book of wide scope to maintain the same high plane throughout, particularly in one which is a pioneer. In the present instance the discussions on the construction of furnaces for high temperature work, and the automatic control of high temperatures is rather inadequate. For example, the use of solid metallic blocks for attaining even temperature distribution at elevated temperatures is not considered, nor are photoelectric devices for the regulation of temperature, of which at least one excellent type is on the market. In some instances the methods given for the preparation of gases seem not the best available, or are rather incomplete. There are other less important omissions. All these, however, are minor flaws.

One's guess is that graduate students should welcome this book with open arms, and that more mature research workers should find it of considerable inspiration and assistance. Although by its nature it will serve chiefly as a reference work for the solution of specific problems, nevertheless a straight through reading gives a fine conception of general possibilities, and may, as in the case of the reviewer, furnish suggestions for improvement of technique in unexpected places.

The book is quite free from typographical errors in the text itself, but it should be noted that in several instances the labelling on diagrams does not agree with the text explanation of them.

J. C. MORRIS

Respiratory Enzymes. Compiled under the direction of C. A. ELVEHJEM and P. W. WILSON, University of Wisconsin. Burgess Publishing Company, Mimeoprint and Photo Offset Publishers, 426 South Sixth Street, Minneapolis, Minn., 1939. x + 236 pp. 21.5 × 27.5 cm. Price, $3.28.

Different individuals in several Departments at the University of Wisconsin, interested in respiratory enzymes, were assigned, for seminar purposes, topics such as, the oxidases, dehydrogenases, hydrogen-carriers, coenzymes, etc. Their reports make up the different chapters in the book.

In gathering together the material from the current literature sufficient background from older work has been included so as to furnish an appropriate perspective for setting forth that which seems most significant in recent contributions. The presentation is well done and quite complete bibliographies are given. The authors have rendered a valuable service in bringing together in one volume a convenient survey of the current knowledge in this field of research.

J. M. NELSON

Textbook of Organic Chemistry. By E. WERTHEIM, Professor of Organic Chemistry in the University of Arkansas. P. Blakiston's Son and Company, 1012 Walnut Street, Philadelphia, Pennsylvania, 1939. xiv + 830 pp. Illustrated. 16.5 × 24 cm. Price, $4.00.

There is need for a variety of textbooks of different kinds so that the teacher may select the one adapted to his particular needs. At one end we have an outline which is to be filled in and supplemented by the teacher as he wishes; at the other end a book which comprises a large amount of information from which the teacher may select. The present text is an example of the latter kind. Comprehensiveness is its outstanding characteristic. In its 800 well-printed pages there is a deal of information, much more than can possibly be assimilated by any one student in his first year. This gives the teacher the opportunity for selection and provides the exceptional student with additional information which will interest him and

lead him on. The book is succinctly but clearly written; its size is due to the amount of material included.

The first 374 pages deal with aliphatic compounds, the next 230 with aromatic. Then come terpenes, dyes (36 pp.), alicyclic, heterocyclic, alkaloids, proteins, chemistry of the human body (12 pp.) and identification of organic compounds (14 pp.). There are a number of features not usually found in textbooks. Scattered throughout the book, without any relation to the context, are pictures with biographical sketches of 46 chemists besides Emil Fischer as a frontispiece. These are mostly moderns. The U. S. is represented by Remsen, Franklin, Baekeland, Gomberg, Stieglitz, Bogert, G. N. Lewis, Nieuwland, Whitmore, Adams, Adkins, Conant, Gilman and Kharasch.

At the back of the book there are flow sheets of a number of industrial processes, a list of books on organic chemistry, a glossary of chemical terms and a table of physical properties of some 600 organic compounds. At the end of each chapter there are a number of review questions and also literature references.

The book will make a useful text for teachers who like an abundance of material and will be useful to students and others as a compendium of information on organic chemistry. It includes many new developments such as vitamins and sex hormones.

E. EMMET REID

Fortschritte der Chemie organischer Naturstoffe. Eine Sammlung von Zusammenfassenden Berichten. (The Chemistry of Natural Products. A Collection of Review Papers.) Edited by L. ZECHMEISTER. Vol. I. Verlag von Julius Springer, Linkstrasse 22–24, Berlin W 9, Germany, 1938. vi + 371 pp. 41 figs. 16 × 24 cm. Price, RM. 28.

This timely collection contains comprehensive surveys to the middle of 1938 of the following subjects: Neuere Richtungen der Glykosidsynthese, by G. Zemplén, The Component Glycerides of Vegetable Fats, by T. P. Hilditch, Recent Advances in the Chemistry of Sterols, by I. M. Heilbron and F. S. Spring, Cozymase, by F. Schlenk and H. v. Euler, Nucleinsäure, by H. Bredereck, Chlorophyll, by H. Stoll and E. Wiedemann, and Anwendung physikalischer Methoden zur Erforschung von Naturstoffen, by O. Kratky and H. Mark.

It fills a real need for an organ for the presentation of current advances in that field of organic chemistry closely related to physiological processes. Although the chemistry of such investigations gradually finds its way into advanced organic texts, this normally occurs after the topic has been fully developed. For the presentation of subjects still in a fluid and developing state this medium is well suited.

The reviewer feels that more emphasis might be placed on the biological functions of the compounds considered, the few pages devoted to this phase of cozymase or coenzyme I being quite inadequate for the proper presentation. But he might well turn to the more biological publications, as the Ergebnisse der Enzymforschung, for their detailed treatment, and leave this publication for their chemical consideration. Thus have the editors, perhaps wisely, decided.

The fortunate choice of authors to discuss each of the fields selected for the first volume, supported by the good workmanship of the publisher, makes certain the scientific success of this volume, and it is sincerely hoped by the reviewer that it may be feasible to continue the series.

WILLIAM F. ROSS

Handbuch der Lebensmittelchemie. A. BÖMER, A. JUCKENACK and J. TILLMANS. Fünfter Band. **Getreidemehle, Honig, Zucker, Früchte, Gemüse.** (Handbook of Food Chemistry. Vol. V. Flour, Honey, Sugar, Fruits, Vegetables.) Edited by A. JUCKENACK, F. BAMES, B. BLEYER AND J. GROSSFELD. Verlag von Julius Springer, Linkstrasse 22–24, Berlin W 9, Germany, 1938. 1048 pp. 332 figs. 17.5 × 26 cm. Price: RM. 135; bound, RM. 138.60.

This volume represents the collaborative efforts of ten authors, all of them well known as contributors to *Zeitschrift für Untersuchung der Lebensmittel.* Eight chapters are devoted to the five foods which form the subject matter of this member of the *Handbuch.* Four are unique in that there is appended to each a sub-chapter on the microscopy of the food, or food product, in question. This feature is the work of one author, C. Griebel, who has written also the separate chapter (29 pages) on the microscopical examination of vegetables, potherbs and edible mushrooms.

The chapter headings and the authors responsible for the contents of each are: cereals, legumes and flour (116 p.) and bakery products (42 p.) by K. Täufel; alimentary pastes (37 p.) by R. Strohecker and R. Vauble; fruits and fruit products (198 p.) by A. Beythien; honey and imitation honey (63 p.) by W. Bartels; sugar and sugar products (121 p.) by J. Grossfeld; vegetables and vegetable products (78 p.), and fungi and mushrooms (15 p.) by O. Windhausen. Griebel, besides his contribution already noticed, treats in a masterly manner the microscopy of the starches and flours (93 p.), honey (18 p.), bakery products and baker's yeast (9 p.), and fruits, fruit products and the diseases of fruits (35 p.). The book closes with digests, written by F. Bames, of the foreign (31 p.) and Austrian food laws (7 p.). At greater length are presented the pertinent German laws (108 p.) by H. Holthöfer.

Space does not permit of a critical review of each chapter; all constitute in themselves a literary accomplishment and an authoritative presentation of the subject with a liberal use of literature citations and illustrations. Comment on a typical one, however, will suffice to illustrate the general excellence of this work.

Bartels has done food chemistry, and the honey industry in particular, a grateful service by bringing together the scattered and often times not readily accessible, newer information on the composition of honey. Griebel's use here of his original microphotographs of pollen grains adds greatly to the value of the whole chapter. The analytical aspects of the subject are given full treatment to the end that the whole constitutes an invaluable aid to the analyst.

This volume, also, rightfully deserves a place among its six predecessors in the series, for by collecting and collating the vast amount of authoritative scientific and technical matter on the several subjects in question it has performed a service not only for food chemistry in

particular, but for its allied fields of botany, biology, physiology, and agriculture as well.

H. A. SCHUETTE

Annual Review of Biochemistry. Vol. VIII. Edited by JAMES MURRAY LUCK and JAMES H. C. SMITH. Annual Reviews, Inc., Stanford University P. O., California, 1939. ix + 676 pp. 16 x 23 cm. Price, $5.00.

Volume VIII of this very useful publication continues the high standard that has been set by the previous volumes. The editor and editorial committee have shown excellent judgment in their choice of topics and have been unusually successful in their efforts to keep the size of the individual articles within reasonable bounds without sacrificing clarity of presentation or omitting mention of papers of real importance. Several of the contributors point out that exhaustive review is quite impossible within the space available, but add lists of papers not otherwise mentioned which serve to extend the ground actually covered. In spite of their deprecatory statements, little that is of moment to the average biochemist has been overlooked.

The excellent policy of frequent change in the authorship of the reviews has been continued. Owing to the appearance of a companion volume, Annual Review of Physiology, reviews of purely physiological topics are this year restricted in number while the field of biochemical topics is extended. Thus the present volume contains articles on Polysaccharides and Lignin, by K. Freudenberg; Ruminant Nutrition, by H. R. Marston; X-Ray Studies of the Structure of Compounds of Biological Interest, by W. T. Astbury; Growth Hormones in the Higher Plants, by F. W. Went; The Biochemistry of Yeast, by E. I. Fulmer; and Animal Poisons, by C. H. Kellaway; none of which has been dealt with recently if at all. The field of enzymes is divided, K. Linderstrøm-Lang having prepared the review of the Proteolytic Enzymes and K. Myrbäck that on Nonproteolytic Enzymes.

It is interesting to note the increase in space occupied by the proteins. Whereas in Volume III, in 1934, two articles were sufficient, in the present volume there are five if the two enzyme reviews may be included in this field with Astbury's paper already mentioned, A. Tiselius' article on The Chemistry of Proteins and Amino Acids, and R. W. Jackson and J. P. Chandler's on the Metabolism of Proteins and Amino Acids.

Several subjects receive attention every two years. In Volume VIII, these are The Chemistry and Metabolism of the Compounds of Sulfur, by G. Medes; Metabolism of Brain and Nerve, by J. H. Quastel; The Alkaloids, by L. Small; Chemical Aspects of Photosynthesis, by H. Gaffron; Mineral Nutrition of Plants, by J. W. Shive and W. R. Robbins; and Immunochemistry, by M. W. Chase and K. Landsteiner. Mineral Metabolism, by D. M. Greenberg has not been reviewed since 1936 and is restricted to Calcium, Magnesium, and Phosphorus, and choline has not been dealt with since 1935: the present review by C. H. Best and J. H. Ridout of Choline as a Dietary Factor is of particular interest since most of the work on this aspect of choline chemistry has been accomplished since that date.

The lipids are discussed in two sections, that on Lipid Metabolism by W. M. Sperry and that on The Chemistry of the Acyclic Constituents of Natural Fats and Oils, by R. J. Anderson and L. F. Salisbury. Carbohydrate Metabolism is reviewed by I. L. Chaikoff and A. Kaplan, Hormones by J. Freud, E. Lacqueur and O. Muhlbock, The Water-Soluble Vitamins by C. G. King, and the Fat-Soluble Vitamins by E. M. Nelson and C. D. Tolle. The review of Biological Oxidations and Reductions was prepared by M. Dixon.

A subject and an author index are included, and an errata sheet for several previous volumes is prefixed. The Editors regret that a review of Nucleic Acids, Purines and Pyrimidines failed to arrive in time for inclusion. The international aspect of this publication is emphasized by the fact that only 13 of the 25 contributions are from American laboratories; three are from English, two from Australian, and one from a Canadian source, while Germany and Sweden each provide two, Denmark and Holland each one.

H. B. VICKERY

An Introduction to Crystal Chemistry. By R. C. EVANS, M.A., Ph.D., B.Sc., Demonstrator in the Department of Mineralogy and Petrology, University of Cambridge. Cambridge University Press: The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1939. xi + 388 pp. 113 figs. 14.5 × 22.5 cm.

Since von Laue's discovery of the diffraction of X-rays by crystals in 1912, the study of atomic arrangement in solids has gone through three stages. In the first stage the laws of X-ray diffraction were developed and methods of structure analysis established. Next, the structures of an enormous number of crystalline materials were worked out, and the most important features of each structure tabulated in reference works such as Wyckoff's "Structure of Crystals" and the "Strukturbericht." In the third stage, an attempt is made to find correlations in these results, to seek out the fundamental principles which determine the structures, to relate the structures to fundamental properties of the atom and theories of chemical bonding, and to find the relationship between crystalline structure and physical properties. It is this third stage of the work which is called crystal chemistry.

The present book is an excellent introduction to this field. The author has carefully avoided making it a Strukturbericht, that is, describing structures, and as a secondary matter pointing out principles. Instead he has written the book around fundamental principles, and described only those structures which are well adapted to illustrate the principles. It is very evident that the author has put in a great deal of care and thought in the organization of the material. In a book on crystal chemistry, which is to remain of reasonable size, it is obviously impossible to include everything which various readers might desire. The Pauling–Slater theory of directed valence bonding could have been given in more detail, and a number of examples, which are here treated from the purely ionic point of view, could be shown to be equally amenable to treatment as homopolar bonding with the bond directions given by the theory. The intricate arrangement of the hydrogens in ice proposed by Bernal and Fowler is presented, but no mention is made of Paul-

ing's result that a randomness in the arrangement gives the correct entropy discrepancy.

The book is very readable, and the figures and printing are clear. It can be highly recommended as a textbook or for reading by anyone interested in the present status of the structural chemistry of solids.

B. E. WARREN

Crystalline Enzymes. The Chemistry of Pepsin, Trypsin and Bacteriophage. By JOHN H. NORTHROP, Rockefeller Institute for Medical Research. Columbia University Press, 2960 Broadway, New York, N. Y., 1939. xv + 176 pp. Illustrated. 16 × 23.5 cm. Price, $3.00.

Dr. Northrop's book is an elaboration of his Jesup Lectures, delivered at Columbia University in 1938. It brings together for the first time the studies by which he and his associates have fundamentally clarified the nature and kinetics of enzyme action. The book should be reviewed by a chemist as well as by a biologist, since the latter must take much for granted which his experimental experience is not adequate to appraise with precision. However, in the case of an investigator of Dr. Northrop's distinction, such blind acceptance is not a risk.

The part of Northrop's work which has aroused the greatest interest among biologists is that which deals with the isolation and crystallization of enzymes. After Willstätter's preparations of highly purified enzymes in 1928, it was generally believed that, since his active solutions did not give protein or carbohydrate reactions, neither of these substances was concerned with enzyme activity. But since that time, much evidence has been presented which indicates that Sumner's crystallized urease, Northrop's crystallized pepsin, trypsin and chymo-trypsin, and Anson's carboxypeptidase, as well as the amylase, papain and lysozyme preparations of other investigators, are simple proteins. Warburg's respiratory ferment is a conjugated protein and, unlike the others, has been shown to contain a prosthetic group.

Northrop is, of course, more than others less experienced in protein chemistry, aware of the fact that constant composition after repeated crystallization is not alone proof of purity in the case of proteins, and that the usual criterion of purity—melting point determination—is not applicable, since proteins decompose before melting. He has, therefore, added to his crystallization studies solubility measurements, based on Willard Gibbs' phase rule (for the conclusiveness of which this bacteriologist is unfortunately compelled to take Dr. Northrop's word); rate of sedimentation in the ultracentrifuge; quantitative relation between protein and proteolytic activity; parallelism between alkali-denaturization and loss of activity; proportionate recovery of activity with reversal of alkali-denaturization on standing near neutrality (Anson and Mirsky); constancy of activity per milligram of protein as pepsin solution is slowly inactivated at 50° and *p*H 1.8, conditions under which protein is rapidly hydrolyzed; and parallelism between inactivation and loss of native protein under ultraviolet light. He has thus followed Pasteur's historic advice and neglected no available methods to prove himself wrong—that is, to disprove the identity of his crystallized enzymes and the protein molecules comprising them. To the present reviewer it appears that there is no question of the truth of his conclusions and, indeed, their validity is no longer disputed except by isolated critics who must assume the "burden of disproof" against a mass of affirmative evidence adduced with precise experimentation and authoritative knowledge of protein chemistry.

Among the most significant of Northrop's results are his experiments on the reactivation of purified enzymes after inactivation by simple chemical and physical procedures. The most interesting of these are the acetylation experiments with pepsin. Purified pepsin was acetylated by treatment with ketene and the activity observed to decrease as the acetylation proceeded. An acetylated preparation was obtained in crystalline form which had only 60% of the original activity. When such material was subjected to treatment with $N/1$ sulfuric acid under suitable conditions the specific activity increased to the value of pure pepsin while the acetyl contents decreased from nine to four acetyl groups per molecule. The experiments, which cannot be dealt with in detail, appear to indicate that acetylation of the primary amino groups changes the activity by 10% or less, whereas addition of acetyl groups in other places causes marked decrease.

The demonstration that enzyme activity—which, in the last analysis, is the fundamental factor of metabolic activity and therefore of life processes—depends upon molecular alterations of apparently pure proteins (of molecular weights ranging from 35,000 to 70,000), is obviously a matter of fundamental importance to science in general. To the bacteriologist, however, who is dealing with problems of parasitism and with infections by ultramicroscopic virus agents, these studies are of particular importance. There can, of course, be no question that these "active" enzyme proteins are products of synthetic cell metabolism. And considering the specific nature of the enzymes produced by cells in various locations of the animal body, one must assume a chemical "director" which in each cell type determines the nature of the synthesis which leads to the building up of each particular enzyme. From this, considering the crystallization of at least one type of virus agent ("mosaic," by Stanley), it is not an intellectual trapeze act to postulate the possibility that virus agents, which have been shown experimentally to depend for multiplication on the metabolism of the living susceptible cell, may be products of abnormal autocatalytic action initiated by seeding an active enzyme system (a living cell) with small amounts of the end-product. The conception of such a "directed" synthesis is actually demonstrable in the study of bacterial dissociation; the best example being that observed with pneumococci. It has been possible in this group, for instance, to suppress by suitable manipulation the synthesis of the type specific carbohydrate of the virulent organisms, producing thereby a relatively non-virulent "rough" organism. By subjecting this rough culture to contact with dead virulent organisms containing its own or another type carbohydrate, these organisms can be made to resume the synthesis and grow out as virulent cultures of the original type or of some other, according to that of the dead organisms added. In other words,

carbohydrate synthesis is re-established and chemically directed by the addition of the respective "type" polysaccharide under suitable conditions. There is much that points in the same direction for virus agents, which play such an increasingly important role in medicine and which exhibit many of the properties of enzymes—except that they are immensely larger (10,000,000 molecular weight and above) and have not so far been observed to increase except by "seeding" living cells with pre-existing virus. Northrop has worked along these lines with bacteriophage, the formation of which—probably a nucleoprotein—from the bacterial cell he compares to the rapid increase of pepsin when small amounts of pepsin are inoculated into pepsinogen solutions. The analogy is an apt one, though as far as virus agents are concerned, the crucial experiments are still lacking. Moreover, among the virus agents, where the variation of size and chemical complexity ranges from the crystallizable probably pure protein of Stanley to the visible elementary bodies of vaccinia (mμ 200+) which appear to contain protein, carbohydrate and lipin, it is by no means clear whether we are confronted with synthetic or polymerized cell products, or with parasites that have degenerated to the extent of losing their own enzyme systems. However, until decisive experiments can be devised, it is wise to discourage speculative garrulousness which, in this zone between the "animate" and "inanimate" too often spreads from the legitimate ground of the biochemical or biophysical into what we may call the bio-metaphysical.

In pursuit of the analogy between enzymes and virus agents, immunological phenomena are of considerable importance, since there is no longer any doubt about the fact—whether one favors the intrinsic autocatalytic origin of virus or conceives them as extraneous parasites degenerated to the point of "borrowing" their metabolic enzymes, that these agents are "antigenic"—that is, sufficiently alien to the body chemistry as a whole to stimulate antibody response. Enzymes have long been regarded as possessing such "antigenicity," resembling in this sense "organ specific" proteins such as those of the lens of the eye, spermatozoa, etc. For Kunitz and Northrop's trypsin, Ten Broeck has shown such antigenic activity, as has Seastone for crystallized pepsin. These experiments, while not entirely satisfactory, still indicate adequately that, in producing enzymes, the cells are capable of building up within themselves a protein antigenically foreign to the general species antigen.

A review of this book by anyone except an experienced protein chemist must necessarily be incomplete. To the biologist it represents an achievement that cannot help making him happy to be living in an era in which biochemistry and biophysics are carrying biology out of its vagueness into the precision of chemical definition and quantitative methods.

Søren Peter Lauritz Sørensen

Honorary Member of the American Chemical Society

JOURNAL OF THE
AMERICAN CHEMICAL SOCIETY

VOLUME 61 OCTOBER 9, 1939 NUMBER 10

SØREN PETER LAURITZ SØRENSEN

1868–1939

Denmark has contributed many great figures to the world of Science since the time of Ørsted but few have left their impress on the fields in which they labored to a greater extent than Søren Peter Lauritz Sørensen, who died in Copenhagen on the twelfth of February, 1939. His seventieth birthday had been celebrated by a jubilee just over a year before his death. On that occasion a Jubilee Volume had been published to which contributions had been made by more than seventy-five students and friends working in the fields which Sørensen had influenced in Denmark and in twelve other countries of Europe and Asia, Africa and America.

Born on January 9, 1868, at Havreberg, Slagelse, the son of a farmer, Hans Sørensen, he left high school at Sorø in 1886 and went to the University of Copenhagen. Three years later, in 1889, he received the Gold Medal of the University for a paper on the conception of the chemical radical. His experimental work, however, was largely in the field of analytical chemistry and included studies on pure strontium compounds, for which he again received the Gold Medal of the University in 1896, and "Studies on Cobaltic Oxalates," which was the subject of his doctor's dissertation in 1899. Meanwhile, from the time he received the degree of Master of Science, in 1891, he was assistant at the chemical laboratory of the Danish Polytechnical Institute under Professor S. M. Jørgensen (1892–1901) and chemical consultant at the Royal Naval Dock Yard (1892–1901).[1]

In 1901, at the age of thirty-three, Sørensen was appointed Director of the Chemical Department of the Carlsberg Laboratory in Copenhagen in succession to Johann Kjeldahl. From this time on, his interest never veered from the study of amino acids and peptides, proteins and enzymes. Sørensen never doubted that the chemistry of these nitrogenous molecules was interdependent and concerned with one fundamental problem.

Sørensen began his studies of this complex field by investigations for which he was completely prepared by his earlier training. On the one hand he explored methods for the synthesis of amino acids, on the other methods for the more accurate determination of nitrogen and other analytical procedures. Then came the "Studies on Enzymes." The first of these in 1907, "Om Kvantitativ Maaling af Proteolytiske Spaltninger" was concerned with following enzyme action with the formal titration method, the second with the electromotive force method of

(1) I am indebted to Dr. K. Linderstrøm-Lang, the present Director of the Chemical Department of the Carlsberg Laboratory, for some of the information regarding Sørensen's early studies.

measuring hydrogen ion concentration. Both represent exhaustive, painstaking standardizations of procedures of such value in the study of changes in biochemical systems that the methods are still in general use and these classical papers are still constantly consulted.

The advantages of an acidimetry in terms of the negative logarithm of the hydrogen ion concentration, a quantity linear in the electromotive force, were clearly stated by Sørensen and the symbol, pH, defined in this second paper. Chemical and medical students, zoölogists, physiologists, bacteriologists, public health workers, agricultural and industrial chemists have by now become familiar with the symbol pH. In the more than thirty years since Sørensen's great paper appeared, but very few workers have seen the field more clearly in all its ramifications. In this first paper he considered the electromotive force and colorimetric methods, the choice of indicators and of standard buffer solutions, and, finally, the use of these methods in the study of enzyme action.

The methods having been developed to this point Sørensen's next great contribution was the characterization as a chemical individual of a member of the class of large nitrogenous compounds, the proteins. In 1917, there was published from the Carlsberg Laboratory a description of the crystallization of egg albumin, of its dialysis, its purification and standardization, of the estimation of its molecular weight by osmotic pressure measurements, of its acid and base combining capacity by electromotive force measurements and of the influence of neutral salts upon this and upon its solubility. A classicist by temperament and training, he began the study of proteins with a consideration of Henry's law and of the phase rule and ended it by demonstrating that even such complex molecules as the proteins could be prepared and studied with such care as had previously not been lavished upon them.

Beccari and Denis, Bence-Jones and Scherer, Ritthausen, Hofmeister, Hardy, Hopkins, Pauli, Mellanby, T. B. Osborne and a host of others had prepared and studied proteins. Conditions for the crystallization of certain of them had been described. With Sørensen the physical chemistry of the proteins passed from the stage of qualitative observation and the description of phenomena to accurate quantitative characterization in terms of laws and constants.

Sørensen subsequently studied many proteins other than egg albumin. In 1924 when he visited the United States he described in various lectures and in the *Journal of the American Chemical Society* the investigations on serum proteins on which he spent many years. On that occasion, too, he was elected an honorary member of the American Chemical Society, the first of many honors conferred upon him by American institutions. Indeed, following the war, during which his magnificent study on egg albumin appeared, Sørensen's connections with America became far closer than they had previously been. He learned English and had numerous American followers. His influence upon the approach to the study of biochemical systems by means of physico-chemical methods can scarcely be exaggerated.

The great contributions of Sørensen to science, the revolutions that he brought about, depended in the last analysis on his faith that the classical methods of chemistry could be applied to the most complex biochemical systems without sacrifice of accuracy, provided patience and understanding were constantly employed in the slow, orderly development of methods and the unfolding of problems.

During the last years of his life although his interest in the laboratory did not diminish, his concern with the role of science in industry, agriculture and the state occupied much of his time. He was a president of the Danish Scientific Society and an honored member of learned societies in Norway, Sweden, Belgium, England, France, the United States, Germany, Finland, Poland and Spain. His counsel was widely sought and his influence as a scientist upon the affairs of Denmark and of the other Scandinavian countries will be missed. His influence upon the men that he trained and upon the fields of science to which he contributed will, however, continue, for he sought the enduring qualities of precision and perfection.

X-Ray Investigation of the Decamethylene Series of Polyesters

BY C. S. FULLER AND C. J. FROSCH

In two previous papers[1,2] results of X-ray studies on several members of the ethylene series of polyesters have been reported. The present investigation deals with the decamethylene series of polyesters and is a continuation of this work, the general aim of which is to clarify the structures of substances composed of chain molecules of high molecular weight.

The previous work has shown that polyesters of sufficiently high average molecular weight are capable of producing sharp X-ray fiber patterns when oriented specimens[3] are employed. An analysis of the fiber patterns obtained from the ethylene esters and the self ester of ω-hydroxydecanoic acid[2] has shown that in general two types of fiber patterns are present. One type found in the case of polyethylene succinate gives a much shorter fiber period than that calculated for this ester on the assumption of a planar zigzag model[1] and agrees best with a helical or coiled form of the long-chain molecules present. The other type of pattern, the one usually observed, gives fiber periods which are only slightly less (0.3 to 0.4 Å.) than the values calculated for a planar zigzag model.

In the ethylene polyesters showing the zigzag type of pattern the ester groups apparently play a part in the alignment of the chain molecules with respect to one another. The previous work on the ethylene polyesters indicated that in the odd esters studied, *i. e.*, those containing an odd number of chain atoms in the repeating unit, the chains were arranged so that the carbonyl groups of adjacent chains fell in planes perpendicular to the fiber axis. In the even esters, however, evidence favored an arrangement whereby these groups fell in planes inclined to the fiber axis. For the three even esters studied the inclination of this plane to the fiber axis was calculated to be approximately 65°.

All the members of the decamethylene series of polyesters examined in the present work show the zigzag type of fiber pattern. These patterns differ from those obtained on the ethylene series in several respects, however, and indicate that the laws determining the manner in which the chains associate are perhaps not as simple as heretofore expected. As will be shown later, however, most of the present results can be explained, qualitatively at least, by a theory proposed recently by T. Schoon.[4]

Compounds Examined.—The preparation of the polyesters and the X-ray technique employed already have been described.[1] In the present experiments decamethylene glycol reacted with the successive members of the aliphatic dicarboxylic acid series up to and including sebacic with the exception of pimelic. Polyesters suitable for X-ray investigation were obtained in all cases except that of malonic acid. The average molecular weight in each case was above 10,000 as determined by viscosity measurements. The purity of the final polyesters in view of the small amount of cyclic ester theoretically produced was considered sufficient without fractionation. Table I lists the compounds studied and their melting points.

TABLE I

SOFTENING POINTS OF DECAMETHYLENE POLYESTERS

	Compound	Softening point, °C.
1	Oxalate	77
2	Succinate	69
3	Glutarate	60
4	Adipate	74
5	Suberate	75
6	Azelate	66
7	Sebacate	73

X-Ray Results.—Highly oriented specimens of the various esters were employed in order to secure sharp X-ray fiber patterns. Characteristic copper X-radiation filtered free of beta was employed. The interplanar spacings were calculated on the basis of the known spacings in sodium chloride, which was applied as a powder directly to the specimens. The patterns corresponding to the compounds listed in Table I are shown in Fig. 1, A to G inclusive. Figure 1H illustrates the type of picture obtained when sodium chloride powder is applied to the sample of Fig. 1G. The results of the measurement of these fiber patterns are shown in Tables II and III. Table II

gives the interplanar spacings and Table III gives the observed fiber periods and the fiber periods calculated on the basis of a planar zigzag chain for comparison.

Several reflections not reported in Table II have also been found. At least four inner equatorial spots have been observed in the various decamethylene compounds which were not observed in the ethylene compounds. Some of these, however, may be caused by the Ag or Br

absorption edges or by copper beta radiation. Further work is necessary before their presence can be considered proved.

Discussion of Results

(1) **The Fiber Periods.**—Examination of Table III shows that in the case of all the decamethylene polyesters studied, the observed fiber periods and the fiber periods calculated on the basis of a planar zigzag chain agree within 0.2 Å. The chains in these compounds therefore conform very closely indeed to the planar zigzag model. A somewhat greater deviation (0.4 Å.) has been reported previously[1] for the higher members of the ethylene series of polyesters. This is in support of the view advanced at the time that the ethylene glycol portion of these esters may vary somewhat from the planar configuration. The closeness of these differences to the experimental error, however, makes further investigation of this point desirable. It is entirely possible that a slight shortening of the identity periods can occur as a result of atomic vibrations in the plane perpendicular to the chains as Huggins[5] has suggested. A value of 1.51 Å. for the C–C distance would likewise bring about agreement between the calculated and observed results.

In view of the possibility of resonance in the oxalate ester a shortening of the fiber period due to a shortening of the C–C bond between the two carbonyl groups is to be expected.[6] Table III shows, however, that the oxalate fiber period deviates no more than the other esters. This is probably explained by the small magnitude of the shortening and by the fact that the increased angle between the C–C and C–O bonds partially compensates for the smaller C–C distance.

(2) **The Equatorial Reflections.**—As pointed out in a previous paper[2] the equatorial reflections for the modification of the ethylene polyesters possessing the zigzag type of chain configuration agree well in spacing with those corresponding to the (*hk*0) planes reported for the lower molecular long-chain paraffins[7,8] and esters.[9,10] This is in general true of the decamethylene polyesters also and indicates that the chain molecules pack together in the plane perpendicular to the chain axes in the same fashion in all of these cases. There are, however, certain deviations from this rule for the oxalate, as can be seen from Table II. This indicates that the distribution of polar groups along the chains influences to some extent the effective cross-section of the chains. With the exception of the oxalate, however, the interchain spacings are constant for all the esters within the experimental error and practically the same as have been found for aliphatic hydrocarbon chains ($ab \sin \beta = 37.0$ Å.^{2}).

(3) **Layer-Line Reflections.**—In the decamethylene series as in the ethylene series strong second-order meridian reflections are observed in the case of the odd esters (Fig. 1C and F). These in the case of decamethylene azelate fall very close to the primary beam and are barely visible in the reproduction. These reflections agree with the twofold screw axis present in the structure and constitute further proof of the zigzag chain configuration. Unlike polyethylene azelate, however, polydecamethylene azelate shows, in addition to the second-order meridian reflections, reflections of large spacing which arise from planes inclined to the fiber axis (IV_1 Table II). Since the presence of the strong second-order meridian reflection requires an alignment of the carbonyl groups of neighboring chains in planes perpendicular to the fiber axis, these strong layer-line reflections indicate that in the case of some of the chains the carbonyl groups fall in planes inclined to the fiber axis. This also is true of decamethylene glutarate in which pyramidal spacings (II_1 Table II) occur on the same layer-line as the meridian reflections. The best interpretation of these patterns at present is that the chain molecules fit two forms of lattice. In one of these the C=O groups are aligned in planes perpendicular to the fiber axis, whereas in the other they lie in planes which form an angle with this axis.

In the case of the even decamethylene esters (Fig. 1 A, B, D, E and G) certain differences as compared with the ethylene esters are also evident. The oxalate, succinate, and sebacate behave normally in that no low-order meridian reflections are present. The adipate and suberate esters, however, show second-order reflections on the meridian. These reflections are weak in the case of the adipate and are accompanied by pyramidal reflections on the first layer-line. The suberate is unique in possessing very strong meridian reflections on the second layer-line together with weak pyramidal reflections on the third layer-line.

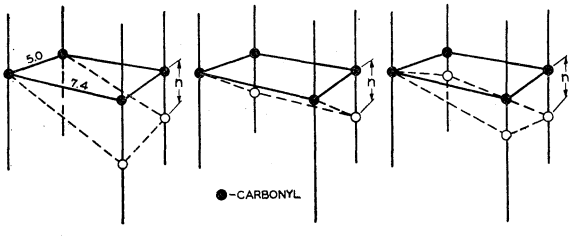
In view of the fact that the zigzag structure of the chain holds in the case of the suberate, as shown by the agreement of the observed and calculated fiber periods, we are forced to assume that in this ester a twofold screw axis or a glide plane exists but that it does not coincide with the chain axis. In other words, a displacement of one-half the fiber period parallel to the chain direction must occur in the case of some of the chains. Because of the high intensity of this reflection it is probable that half of the chains are shifted this amount. An analogous situation exists in the adipate. The much lower intensity of the corresponding meridian reflection in this case suggests that the halving of the fiber period may not occur as often. However, the general fuzziness of the pattern indicates that the chain arrangement is less perfect than in the case of the suberic ester.

As in the case of the odd esters the best interpretation of the fiber patterns produced by the adipate and suberate esters is that more than one form of crystalline arrangement is present. It is possible that the sebacate ester also is complicated by more than one form. The patterns of the oxalate and succinate on the other hand can be explained on the basis of one form of crystal (monoclinic). In the case of these patterns the strong pyramidal planes arise from the fact that all of the carbonyl groups fall in inclined planes. As will be seen in the next paragraph, these findings are capable of a general interpretation.



(a) (b) (c)

Fig. 2.—Possible types of gliding in polyesters.

The patterns of the even esters other than the adipate and suberate agree with the behavior of the even ethylene polyesters in showing no low order meridian reflections.[11] The pyramidal planes observed in these compounds are best interpreted as arising from the fact that a predominance of carbonyl oxygen atoms fall together with chain carbon atoms in these planes.

General Theory of the Crystalline Structure of Polyesters.—The determination of the positions of the atoms in the crystals composing the polyesters is too complex an undertaking to be solved by means of the present X-ray data. Because of the known chemical structure and the zigzag nature of the chains, however, the problem is simplified considerably. The X-ray results show that the polyester chains having the zigzag type of structure assume the same relative positions in the plane perpendicular to their long axes as do the lower molecular long-chain compounds.[12] As mentioned previously, this is strong evidence that the long chains in the polyesters have the same cross-sectional area and shape as in these lower molecular chain structures and that they behave like rigid rods in so far as packing in the crystal is concerned. Because of the great length of the chains in the polyesters and therefore the negligible influence of the end-groups on the structure, we may consider the repeating unit as the unit of packing, and attempt to work out the crystal structure on this basis.

In a bundle of chain molecules all having a common repeating unit it is evident that various crystal structures will arise depending on the relative displacement of the repeating units in the direction of the chain axis. Thus, corresponding atoms in adjacent parallel chains will assume various positions in the structure depending on the amount of gliding these chains undergo with respect to one another in the direction of their lengths. In this manner orthorhombic, monoclinic and triclinic lattices may arise. If no gliding occurs in the case of identical chains, an orthorhombic cell is possible. If, on the other hand, a glide parallel to the *ac* plane takes place as shown in Fig. 2a, a monoclinic cell may be formed. An alternative monoclinic cell may be produced by a glide parallel to the *bc* plane (Fig. 2b). Finally, a glide parallel to the diagonal plane as illustrated in Fig. 2c may result in a triclinic cell. It is possible, therefore, that all of these lattices will be observed in crystals composed of chain structures of this nature.[13]

In order to show that the crystalline polyesters

(11) Compare K. H. Storks, THIS JOURNAL, **60**, 1753 (1938). As pointed out in ref. 2, most of the polyesters undoubtedly possess meridian reflections on the layer-line corresponding to the number of chain atoms in the repeating unit. Because of the comparatively long wave length employed, however, these reflections are not observed in this work.

(12) As pointed out, in the oxalate ester the interchain spacings are somewhat different from the higher decamethylene esters.

(13) It is possible to draw up unit cells in which the chain axis is always perpendicular to one face. These large cells, however, turn out to be multiples of the smaller cells considered in the present treatment. The latter are, therefore, to be regarded as the true unit cells.

so far examined can be explained on the basis of the theory briefly outlined above, let us consider those chain structures which are essentially zigzag in form and in which the chains fall on a Müller net ($a = 5.0$, $b = 7.4$). The assumption is made that when gliding occurs, its magnitude is always an integral multiple of the distance between chain atoms as measured parallel to the chain. In the case of the esters this distance is obtained by dividing the observed identity period along the fiber axis by the number of bonds composing the repeating unit. For the ethylene polyesters[14] the distance averages 1.19 Å., whereas for the decamethylene polyesters the average distance is 1.23 Å. Decamethylene oxalate[15] has a slightly lower value, 1.21 Å. By multiplying this distance by n the total displacement in the chain direction is obtained.

TABLE IV

Ester	Reflection	Obsd.	Calcd. for Glide n

			64.7	2(bc)
ω-Hydroxy-decanoic ester	II_0	90	90.0	Zero

[a] (ac) designates glide parallel to *ac*-plane. [b] In these cases as noted in the text a screw axis non-coincident with the chain is supposed to be present.

Table IV shows the agreement obtained between the observed angles and angles calculated on the basis of the above glides. In the second column are given important low order reflections for each of the esters employing the designations of Table II. Reflections for the ethylene polyester and ω-hydroxydecanoic ester taken from previous publications are also included. The angles which the planes causing these reflections make with the fiber axis are given in the third column. These angles have been calculated from the observed fiber periods and the *d*-values corresponding to the planes in question. In column 4 are listed the angles calculated on the basis of the glides in column 5. Only values of n which agree best with the observations are recorded. Glides parallel to the diagonal planes as shown in Fig. 2c have not been considered since the angles corresponding to these cannot be calculated on the basis of the available data. The possible solutions in column 5 therefore are not to be considered as inclusive. The agreement between the observed and calculated angles is, however, confirmatory of the gliding theory. The choice of the proper lattice and unit cell from among the various possibilities must await more complete experimental results. It is planned to present a more detailed analysis in the case of some of the structures in a later publication.

The general theory given above to account for the various polyester structures is essentially that given by T. Schoon[4] to explain the various polymorphic forms of the lower molecular weight chain compounds. In this way Schoon accounts nicely for the various monoclinic and orthorhombic forms shown by these compounds. On this same basis one might expect that the polyesters would also exhibit a variety of stable modifications in the case of each compound. From the results presented above on the decamethylene polyesters this appears to be the case.

The authors wish to thank Mr. N. R. Pape for his assistance in the X-ray work.

Summary

1. Decamethylene polyesters of average molecular weight above 10,000 have been prepared from the following acids: oxalic, succinic, glutaric, adipic, suberic, azelaic and sebacic.

2. X-Ray fiber patterns have been obtained on oriented fibers of these compounds. Complete measurements of the patterns are given and it is shown that in all cases the molecules conform closely to the planar zigzag model. Except in the

(14) The present argument applies only to zigzag chain configurations.

(15) For the oxalate $a = 5.28$ Å., $b = 7.00$ Å. have been employed.

case of the oxalate ester, all of the structures conform to the same lateral packing as is shown by the lower molecular chain compounds.

3. A discussion of the origin of the various fiber patterns is given. It is shown that in the case of certain esters the presence of different crystal forms is indicated. A general interpretation of these forms on the basis of the theory of Schoon is presented.

Kinetics of the Exchange of Oxygen between Benzoic Acid and Water[1]

BY IRVING ROBERTS AND HAROLD C. UREY

The organic compounds which thus far have been found to exchange their oxygen with that of water are aldehydes, ketones, carboxylic acids, and a few very reactive alcohols.[2] A kinetic study of the exchange of oxygen between acetone and water in the medium 90% acetone-10% water was made by Cohn and Urey,[3] who demonstrated a general acid catalysis which is significant for the mechanisms of both the hydration and the enolization of acetone. The obvious structural similarity of the acid catalyzed esterification and ester hydrolysis reactions to the oxygen exchange reactions of carboxylic acids indicates that a kinetic study of the latter should yield results at least as interesting as those obtained in the acetone exchange.

Benzoic acid exchanged both its oxygen atoms with that of water, the reaction being catalyzed by acids, as is the case for the exchange of carboxylic acids in general.[4-6] The usual method for following exchange, that of mixing comparable amounts of the reacting substances, cannot be used at ordinary temperatures in the case of benzoic acid since the compound is not sufficiently soluble in water to cause an appreciable change in the heavy oxygen content of the water. Rather than introduce the complication of a mutual solvent, we have devised a method of determining the heavy oxygen content of benzoic acid and have carried out the kinetic experiments in dilute aqueous solution.

(6) The present work shows that the statement of Koizumi and Titani [*Bull. Chem. Soc. Japan*, **13**, 607 (1938)] that only one oxygen atom of benzoic acid is readily exchangeable cannot be correct. Such a statement is quite unreasonable in the light of our present knowledge of the rapid dissociation of the hydrogen ion from a carboxylic acid and of the symmetrical structure of a carboxylate ion.

Experimental

Decarboxylation Apparatus.—The determination of the O^{18} content of benzoic acid depends upon the observation of Sabatier and Mailhe[7] that benzoic acid will be converted almost quantitatively into benzene and carbon dioxide when passed over reduced copper at 500°. For the present work, it was necessary to construct an apparatus which would perform the decarboxylation of a few milligrams of benzoic acid in a stream of nitrogen gas, and which would be free of traces of oxygen, carbon dioxide, water, or copper oxide. In addition, after each conversion, the apparatus should be easily made ready for the succeeding one, since many samples must be converted for each kinetic experiment.

The apparatus finally used is shown in Fig. 1. Tank nitrogen was admitted at the left through a flowmeter (A) and successively through a tube of copper at 350° (B), a bubbler containing sulfuric acid (C), and tubes D and E, filled with potassium hydroxide and anhydrous calcium sulfate, respectively. At this point the nitrogen can be made to take one of two paths; if stopcock K is closed, it can pass through J into the decarboxylation tube (I) containing copper at 500° and into the air through stopcock F. On the other hand, with stopcock J closed, the nitrogen could enter tube I through stopcock F and pass successively through K, a trap (L), and into the air through stopcock O. Tube I was made of temperature-resistant glass (Corning 172), and sealed directly to the Pyrex tubing at either side. Tube H was 1.5 cm. in diameter and contained a ring seal with an opening of about 2 mm. diameter. The apparatus also contained a safety seal (G), a manometer (M), a sample tube fitted with a break seal (N), and a trap (P) surrounded with solid carbon dioxide to protect a Hyvac pump connected at the right.

After sweeping out with hydrogen gas to reduce the oxides of copper, the entire apparatus was evacuated and filled with nitrogen. Trap L was surrounded with liquid nitrogen. The nitrogen stream was then adjusted to 30 cc./min., and directed through J, through tubes I and H and into the air through F (stopcocks K and O being closed). The plug in tube H was removed, the tube containing the benzoic acid inserted around the ring seal and the plug replaced. The benzoic acid sample tubes, which were 10 mm. in diameter and of the shape shown in the upper left of Fig. 1, were first wiped with chamois to

(7) Sabatier and Mailhe, *Compt. rend.*, **159**, 219 (1914).

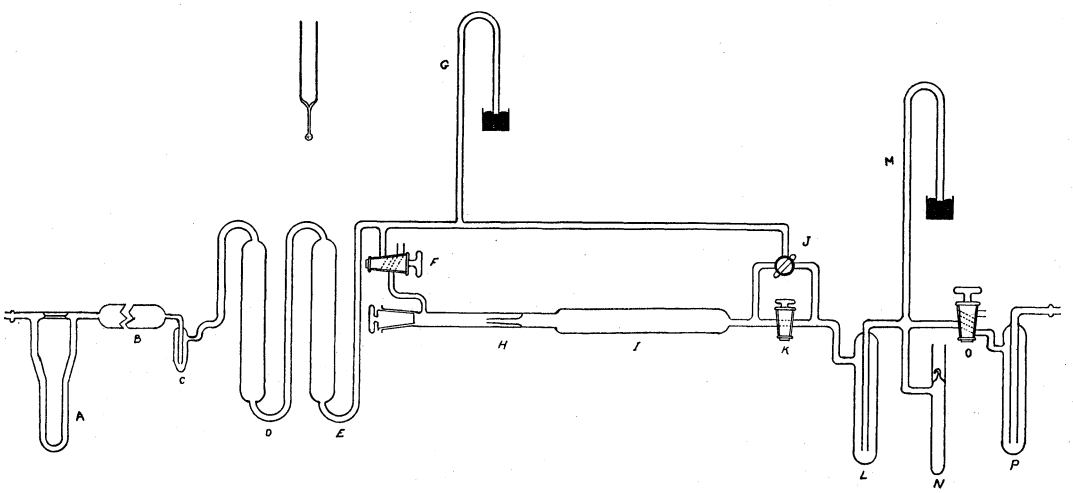

Fig. 1.

remove any organic material which would produce carbon dioxide on being heated. The purpose of the inner seal of tube H was to direct the stream of nitrogen into the benzoic acid sample tube when it was put into place.

After sweeping out the air introduced with the tube for four minutes, the nitrogen stream was reversed by turning stopcock F, closing stopcock J, opening stopcock K, and opening stopcock O to the air. The benzoic acid was then sublimed into I with an ordinary Bunsen flame, both the benzene and the carbon dioxide produced being caught in trap L. After allowing the nitrogen stream to continue for fifteen minutes, stopcocks O and K were closed, and the gas was again directed through J, I, H, and F, into the air. The nitrogen gas remaining in the portion of the apparatus to the right of stopcocks J and K was then pumped out through O and P. Stopcock O was turned off and the liquid nitrogen around trap L was removed and replaced with solid carbon dioxide–acetone mixture, thus keeping the benzene frozen while allowing the carbon dioxide to vaporize. After observing the pressure on the manometer (M), the carbon dioxide was distilled into the sample tube (N) by cooling it to liquid nitrogen temperature, the sample tube being then sealed off at the side-arm and set aside for mass spectrometer analysis.

To prepare the apparatus for the next conversion, the first benzoic acid sample, stopcock O was opened to the air and a new carbon dioxide sample tube sealed on. The air was then pumped out, liquid nitrogen placed around trap L, and the evacuated space filled with nitrogen through stopcock J (stopcock F having been closed). In this way no air was admitted to tube I at any time. The nitrogen stream was again directed from left to right through tube I and the process carried out as before. The time elapsed between the beginning of one conversion to the beginning of the next was about fifty-five minutes.

Materials and Solutions.—Benzoic acid, recrystallized twice from alcohol and water and once from water, was dried over phosphorus pentoxide. Hydrochloric acid solutions were prepared from the C. P. concentrated reagent and standardized against standard 0.1 *N* sodium hydroxide, the primary standard being Bureau of Standards potassium acid phthalate. C. P. potassium chloride was used directly.

Heavy oxygen water, prepared by fractional distillation,[8] was refluxed with alkaline permanganate for one hour, fractionated, and distilled from chromic acid. Analysis by the method of Cohn and Urey[8] showed that this water was 0.515% H_2O^{18}. Heavy oxygen benzoic acid was prepared as follows. A solution of 1.7 g. of benzoic acid in 65 cc. of heavy oxygen water which was also 0.1 *N* in hydrochloric acid was allowed to stand in the thermostat at 80° for forty-eight hours. The heavy oxygen water and the hydrochloric acid were completely distilled away *in vacuo*, and the remaining solid was powdered and dried over phosphorus pentoxide. Conversion of a sample to carbon dioxide by the above procedure and analysis in the mass spectrometer showed that this benzoic acid contained 0.465% O^{18}. Ordinary benzoic acid was found to contain 0.204% O^{18}.

Kinetics.—Kinetic measurements were made in an oil thermostat set at 80.00 ± 0.03° with a Bureau of Standards platinum resistance thermometer. In general, 10 cc. of hydrochloric acid solution (ordinary H_2O or H_2O^{18}) was pipetted into a 20-cc. long-necked flask fitted with a ground-glass joint and stopper. After allowing the flask to stand in the thermostat for at least thirty minutes, a glass bucket containing about 120 mg. of benzoic acid (heavy) was lowered into it by means of a platinum wire. The flask was shaken vigorously and the time recorded; the benzoic acid was completely dissolved within one minute. In calculating velocity constants, concentrations were corrected for expansion of the solution from room temperature to 80°; evaporation error was found to be negligible.

At known intervals, approximately 1-cc. portions were withdrawn by means of a long medicine dropper and delivered into the benzoic acid sample tubes of the type mentioned above and shown in the upper left of Fig. 1. The tubes were chilled immediately to room temperature, causing most of the benzoic acid to crystallize and effectively stopping the reaction. Most of the solution was then drawn off by means of a fine capillary pipet, the benzoic acid crystals being large enough to remain behind. Before decarboxylation, the last traces of water were

(8) Huffman and Urey, *Ind. Eng. Chem.*, **29**, 531 (1937).

pumped away from each sample by inserting the tube into a larger tube fitted with a ground cap and connected to a Hyvac pump.

The efficiency of this drying process was tested by crystallizing ordinary benzoic acid from heavy oxygen water in the absence of hydrochloric acid catalyst, drawing off the water, and pumping for various lengths of time. The benzoic acid was then decarboxylated and the carbon dioxide analyzed in the mass spectrometer. It was found that four hours of pumping were necessary to remove the water completely within the precision of analysis. About one-fourth of the benzoic acid was also lost during the pumping process.

Mass Spectrometer Analysis.—The carbon dioxide samples from the benzoic acid decarboxylations were analyzed for the ratio of mass 44 to mass 46, corresponding to the species CO_2^{16} and $CO^{16}O^{18}$, respectively. The relation of the heavy oxygen content of the carbon dioxide to this ratio can be seen from the following. If α is the atom fraction of O^{18} in the carbon dioxide, the amounts of the three species CO_2^{18}, $CO^{16}O^{18}$ and CO_2^{16} will be in the ratio $\alpha^2 : 2\alpha(1-\alpha) : (1-\alpha)^2$, assuming the gas to be in statistical equilibrium. The ratio of mass 44 to mass 46 will then be

$$R = (1-\alpha)^2/2\alpha(1-\alpha)$$

Solving for α, we have

$$\alpha = 1/(2R+1)$$

as the formula for calculating the mole fraction of O^{18} from the experimentally determined ratio. Only small amounts of gas are necessary for a mass spectrometer determination; the precision of these analyses was in general better than 1%.

Kinetics of the Reaction

In the exchange of O^{18} between benzoic acid and water, the three species of benzoic acid and two species of water react as follows

$$C_6H_5CO_2{}^{18}H + H_2O^{16} \underset{k^{-1}}{\overset{k_1}{\rightleftharpoons}} C_6H_5CO^{16}O^{18}H + H_2O^{18}$$

$$C_6H_5CO^{16}O^{18}H + H_2O^{16} \underset{k^{-2}}{\overset{k_2}{\rightleftharpoons}} C_6H_5CO_2{}^{16}H + H_2O^{18}$$

Assuming that there are no specific differences in reactivity between O^{16} and O^{18} species of the same compound, and that both oxygens of benzoic acid exchange with equal ease, the relations of the various rate constants to each other may be determined by inspection. For example, at equal concentrations, reaction 1 will be twice as successful as reaction 2, since only half the reactions of $C_6H_5CO^{16}O^{18}H$ with H_2O^{16} will result in exchange; that is, $k_2 = k_1/2$. In like manner, it will be seen that $k_{-1} = k_1/2$ and that $k_{-2} = k_1$.

If the three forms of benzoic acid are statistically distributed, their concentrations may be represented

$$[C_6H_5CO_2{}^{18}H] = \alpha^2[C_6H_5CO_2H]$$
$$[C_6H_5CO^{16}OH^{18}] = 2\alpha(1-\alpha)\,[C_6H_5CO_2H]$$
$$[C_6H_5CO_2{}^{16}H] = (1-\alpha)^2\,[C_6H_5CO_2H]$$

where α is the atom fraction of O^{18} in the benzoic acid and $[C_6H_5CO_2H]$ is the (constant) total concentration of the benzoic acid in moles/liter. Similarly, we may write

$$[H_2O^{18}] = \beta[H_2O]$$
$$[H_2O^{16}] = (1-\beta)[H_2O]$$

where $[H_2O]$ is the total concentration of water and β is the atom fraction of O^{18} or the mole fraction of H_2O^{18} in the water.

Considering the initial condition in which the benzoic acid contains the excess of O^{18}, the rate of the reaction will be

$$\frac{-d}{dt}\{[O^{18}] \text{ in benzoic acid}\} = \frac{-d}{dt}\{[C_6H_5CO^{16}O^{18}H] + 2[C_6H_5CO_2{}^{18}H]\}$$
$$= k_1[C_6H_5CO_2{}^{18}H][H_2O^{16}] + k_2\,[C_6H_5CO^{16}O^{18}H][H_2O^{16}]$$
$$-k_{-1}[C_6H_5CO^{16}O^{18}H][H_2O^{18}] - k_{-2}[C_6H_5CO_2{}^{16}H][H_2O^{18}]$$

Substituting for the various rate constants their equivalents in terms of k_1 and for the concentrations of reactants the values given above, we obtain, after cancelling terms

$$-2[C_6H_5CO_2H]\frac{d\alpha}{dt} = k_1[C_6H_5CO_2H]\,[H_2O]\,(\alpha-\beta)$$

$$\frac{d\alpha}{dt} = k(\beta-\alpha), \text{ where } k = k_1[H_2O]/2.$$

Therefore the change of the O^{18} content of the benzoic acid with time should be independent of the concentration of benzoic acid and first order in the difference of O^{18} content of the reactants. Integrating, holding β constant[9]

$$k = \frac{2.303}{t}\log\frac{\alpha-\beta}{\alpha_0-\beta}$$

By an entirely similar derivation, it can be shown that when the water contains the excess of O^{18} initially

$$k = \frac{2.303}{t}\log\frac{\beta-\alpha_0}{\beta-\alpha}$$

(9) Under the conditions of these experiments, the water is in large excess over the benzoic acid so that the heavy oxygen content of the water does not change measurably. If the water were not in large excess, one would proceed by noting that the total O^{18} concentration is a constant, *i. e.*

$$[O^{18}] = 2\alpha[C_6H_5CO_2H] + \beta[H_2O] = \text{constant}$$

Substituting for β in the above rate expression

$$\frac{d\alpha}{dt} = \frac{k_1}{2}\{[O^{18}] - \alpha([H_2O] + 2[C_6H_5CO_2H])\}$$

an equation which is symmetrical in the water and the benzoic acid and which is easily integrated.

Results and Discussion

A typical set of data is shown in Table I and plotted in Fig. 2. The second column of Table I gives the amount of carbon dioxide at atmospheric pressure obtained from each benzoic acid sample; this was calculated from the volume of the apparatus and the pressure observed. The best straight line which is drawn through the points of Fig. 2, was calculated by the method of least squares. The length of the lines represents the probable error. Velocity constants were calculated from the slope of the least squares straight line, the time being in minutes.

TABLE I

KINETIC EXPERIMENT 4

$[HCl] = 0.478\ N$; $[C_6H_5CO_2H] = 0.0564\ M$; $\beta = 0.00200$; $\alpha_0 = 0.00465$

t, min.	Cc. CO_2 at atm. P	R	α	$-\text{Log}\ (\alpha - \beta)$
0	4.4	107.1	0.00465	2.5767
30	0.6	121.0	.00412	2.6737
45	.8	120.3	.00414	2.6696
60	.8	129.2	.00386	2.7305
75	.8	137.0	.00364	2.7852
90	1.0	150.8	.00330	2.8861
120	1.0	159.4	.00313	2.9469
150	0.8	172.9	.00288	3.0555
180	1.6	180.1	.00277	3.1135
210	0.5	189.4	.00263	3.2007

The results of the five experiments performed are shown in Table II. A comparison of Experiments 1 and 2 will show that the rate of the reaction is independent of which reactant contains the excess of O^{18} initially. In Experiment 3, the hydrochloric acid concentration was increased five-fold, causing a five-fold increase in the rate. Decreasing the concentration of benzoic acid by a factor of two in Expt. 4 had no effect on the reaction velocity, as predicted by our derivation above. Finally, addition of potassium chloride in Expt. 5 had no effect on the rate, demonstrating the absence of any salt effect. The variation of k_H is within the precision of about 4% for the determination of a rate constant.

[a] This reaction mixture was also 0.0937 N in potassium chloride. [b] k_H is the rate constant for 1 N hydrochloric acid. Mean $k_H = 0.0142 \pm 0.0004$.

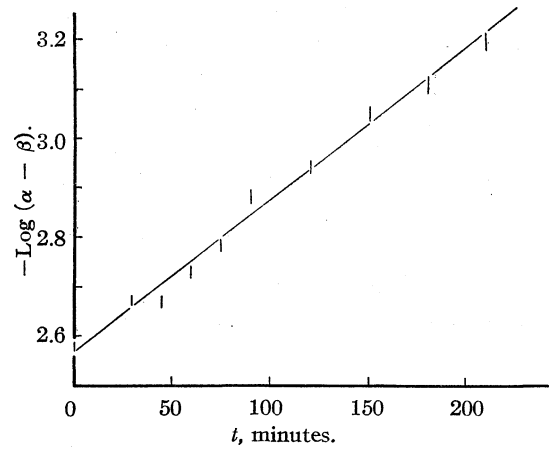

Fig. 2.—Expt. 4.

The fact that the exchange reaction is first order in hydrogen ion serves to further demonstrate the similarity of the nature of this reaction to the acid catalyzed esterification and ester hydrolysis reactions. The agreement of the rates of these three reactions with each other offers further evidence toward this conclusion. We already have demonstrated that in methyl alcohol as a medium the rates of esterification and exchange of benzoic acid are comparable.[10,11] In addition, the rate of hydrolysis of methyl benzoate at 80° is of the same order of magnitude as the rate of exchange determined in the present work,[12] the exchange being about ten times faster.[13] Discussion of the mechanisms of the three reactions on the basis of oxygen exchange work and the existing kinetic data is left for a succeeding paper.

From the point of view of reaction kinetics in general, further work on the exchange of oxygen between benzoic acid and water should include the temperature coefficient, the rate in H_2O–D_2O mixtures, and the effect of substituents in the benzene ring on the rate. It should be emphasized that oxygen exchange reactions proceed at convenient rates with no change in the medium and are of a simple first order dependence.

Summary

The rate of exchange of oxygen between benzoic

(10) Roberts and Urey, THIS JOURNAL, **60**, 2391 (1938).

(11) Herbert and Lander, *Trans. Faraday Soc.*, **34**, 1219 (1938); *Nature*, **142**, 954 (1938), have predicted this result on the basis of our previous experiments.[8]

(12) Bolin, *Z. anorg. Chem.*, **177**, 227 (1938).

(13) The observed k_H for the exchange was multiplied by 2 to obtain $k_1[H_2O] = 0.0284$ as compared to $k[H_2O] = 0.0028$ calculated from the data of Bolin for the hydrolysis. k_1 as defined in the derivation above is the constant which should be used for this comparison since it represents the rate constant for the exchange which is effective at every reaction.

acid and water has been measured at 80° in dilute aqueous solution using hydrochloric acid as a catalyst. The reaction was followed by decomposing into benzene and carbon dioxide samples of benzoic acid crystallized from the reaction mixture and analyzing the carbon dioxide in the mass spectrometer. The rate is first order in the difference of O^{18} content of the reactants, first order in hydrogen ion, independent of the concentration of benzoic acid, and free of salt effects.

The Mechanisms of Acid Catalyzed Ester Hydrolysis, Esterification and Oxygen Exchange of Carboxylic Acids

BY IRVING ROBERTS AND HAROLD C. UREY

In addition to the known kinetic data on the acid hydrolysis of esters and on the esterification of carboxylic acids, we now have available the results of heavy oxygen studies of both the esterification[1] and the exchange[2] of carboxylic acids. The purpose of this paper is to show that by combining these data it is possible to eliminate all but a few of the large number of mechanisms which may be proposed for all three reactions.

The three reactions show a number of striking similarities. Besides the structural similarity of reactants and products, the reactions are all catalyzed by acids. In addition, there seems to be little doubt that both the hydrolysis and esterification are general acid catalyzed. Dawson[3] has shown that the hydrolysis of ethyl acetate is catalyzed by acetic acid molecules, chloroacetic acid molecules and bisulfate ions. Hinshelwood[4] has demonstrated catalysis of the esterification by a number of fatty acid molecules and Goldschmidt[5] has done the same for such acids as trichlorobutyric acid. On the basis of this general acid catalysis the retardation of esterification in alcoholic media by the addition of water discovered by Goldschmidt[6] is explained by the fact that ROH_2^+ is a stronger acid than H_3O^+ in the Brönsted sense. The exchange of oxygen between benzoic acid and water is first order in hydrogen ion[2]; as yet there are no data to determine whether the reaction is general acid catalyzed.

A further correlation lies in the fact that the rates of the three reactions are of the same order of magnitude. The nearness of the rates of hydrolysis and esterification is well known; one of the problems in studying the kinetics of either reaction has been the elimination of the reverse one. Furthermore, in a methyl alcoholic medium containing about 5% water, the rate of esterification is about twice the rate of exchange of benzoic acid[1]; when these rates are corrected to the same concentrations of methanol and water, the latter is about four times as fast as the former. Finally, in water as a medium, the rate of exchange of benzoic acid is about ten times the rate of hydrolysis of methyl benzoate at the same temperature.[2]

A similarity in the linkages broken on esterification and exchange is also known. In the esterification of benzoic acid a carbon–oxygen bond of the benzoic acid is broken rather than that of the methyl alcohol.[1] The same must of course be true for the exchange of oxygen between benzoic acid and water. A recent heavy oxygen study of acid catalyzed ester hydrolysis has shown that the same linkage is broken in this reaction.[7]

Because of the above evidence, we are assuming that the mechanisms of all three reactions are entirely similar. This would presuppose a symmetrical mechanism for esterification and hydrolysis, since it is reasonable to assume that the reverse of one would be the mechanism of the other. The term "symmetrical mechanism" is used here in the sense that the reverse of such a mechanism for esterification will be a mechanism for hydrolysis which is structurally similar to it. A symmetrical mechanism must obviously be the case for the oxygen exchange reaction, where for example the mechanism of the reaction of $RCO^{16}O^{18}H$

with H_2O^{16}, would be similar to its reverse, the reaction of $RCO^{16}{}_2H$ with H_2O^{18}. Finally, as a further simplification, we are making the usual assumption that each mechanism will contain only one rate controlling step, *i. e.*, that there is only one activated complex whose disappearance controls the rate of the reaction.

An important consideration which does not seem to have been emphasized previously is that the esterification and hydrolysis reactions are very probably first order in alcohol and water, respectively. The existence of the relationship

$$\frac{\text{moles ester} \times \text{moles water}}{\text{moles alcohol} \times \text{moles acid}} = K$$

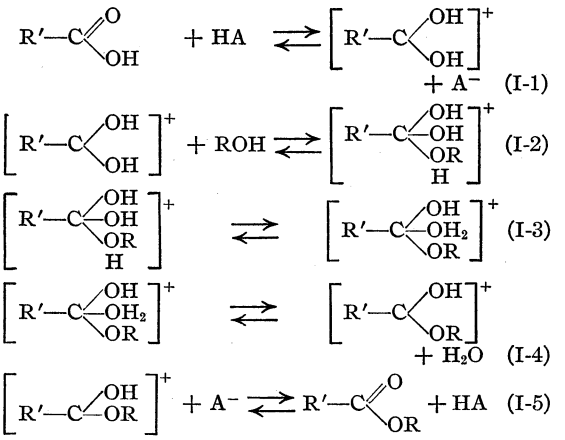
which is so universal as to be largely independent of medium as well as temperature,[8] would argue at least at equilibrium for a first order dependence of esterification rate on the alcohol concentration and of hydrolysis rate on the water concentration. While some reactions are known to change in mechanism while approaching equilibrium, this would not be expected to take place for these comparatively simple reactions. This is especially true for the exchange reaction, where the equilibrium constant is undoubtedly very close to unity. It is therefore difficult to see how the first order dependence on the alcohol and water concentration would apply to the condition of equilibrium and not to other conditions.

In addition, a first order dependence of the rate of esterification on the alcohol concentration is known in formic and acetic acid as media from the cryoscopic measurements of Kailan and co-workers,[9] who have also demonstrated different esterification rates for different alcohols.

The Reactive Complex

It is possible to eliminate immediately a large number of mechanisms by a consideration of the reactive complex for each of the three reactions under discussion. As Wynne-Jones and Eyring[10] have emphasized, kinetics of a reaction alone can only determine the compounds entering into the rate controlling step, *i. e.*, the composition of the reactive complex. Granting that the exchange, esterification, and hydrolysis reactions are general acid catalyzed and first order in alcohol or water, their reactive complexes must be, respectively, R'COOH·H_2O·HA, R'COOH·ROH·HA, and R'COOR·H_2O·HA. Of course, the last two are identical since the reactive complex must be the same for forward and reverse reactions.

Having determined the composition of the critical complex, we can state that all mechanisms which do not form this complex are incorrect. Under this classification falls a group of bimolecular mechanisms (*i. e.*, mechanisms consisting of a series of bimolecular steps) several of which have been widely supported. For example, the esterification mechanism of Watson,[11] although not given as a symmetrical one, may be written



The reverse of this mechanism will be seen to be a similar mechanism for ester hydrolysis.

None of these steps produces the critical complex required by the kinetic data for step (I-1) lacks a molecule of alcohol, steps (I-2), (I-3), and (I-4) lack an A^- ion, and step (I-5) lacks a water molecule. Or, from another point of view, one may state that step (I-1) cannot be rate controlling, since the reaction would then be independent of the alcohol concentration, and that step (I-2) cannot be rate controlling, for then the reaction would be specific hydrogen ion catalyzed. This last may be seen from the rate expressions

$$V = k_2[\text{ROH}]\left[\text{R}'\text{—C}(\text{OH})_2\right]^+ = k_2K_1\frac{[\text{ROH}][\text{RCOOH}][\text{HA}]}{[\text{A}^-]}$$

$$= \frac{k_2K_1}{K_a}[\text{ROH}][\text{RCOOH}][\text{H}^+]$$

where k_2 is the rate constant for step (I-2), K_1 is the equilibrium constant for step (I-1), and K_a is the dissociation constant of the acid HA.

(8) Berthelot and Pean de St. Gilles, *Ann. chim. phys.*, [3] **65**, 385 (1862); **66**, 5 (1862); **68**, 225 (1863); Schultz, THIS JOURNAL, **61**, 1443 (1939).

(9) Kailan and co-workers, *Monatsh.*, **51**, 334 (1929); **60**, 386 (1932); **61**, 116 (1932); **62**, 284 (1933); **63**, 52 (1933); **63**, 155 (1933).

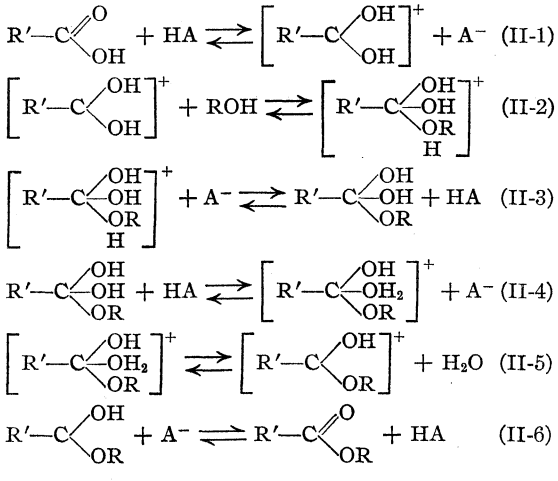
(10) Wynne-Jones and Eyring, *J. Chem. Phys.*, **3**, 492 (1935).

(11) Evans, Morgan, and Watson, *J. Chem. Soc.*, 1168 (1935); Watson, "Modern Theories of Organic Chemistry," Oxford University Press, 1937, pp. 130, 211.

Similar reasoning would apply to the other steps, but this is sufficient to demonstrate that the much simpler consideration of the critical complex involved would eliminate these steps as possibilities.

The mechanism proposed by Ingold[7,12] for ester hydrolysis involving the intermediate ion RCO^+ is eliminated similarly since none of its steps contains the correct reactive complex. In fact, on this basis we have eliminated eight other such bimolecular mechanisms, any of which are as reasonable as the two mentioned above.

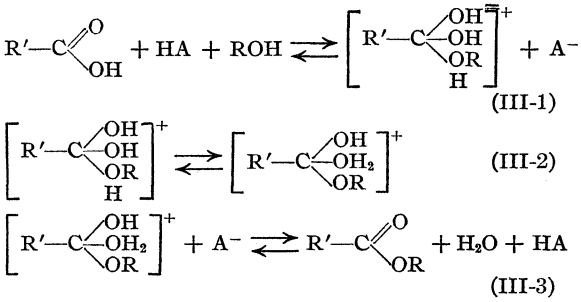
There are three possible mechanisms, however, which do lead to the reactive complex required by the kinetics. One of these is a bimolecular mechanism



Reaction (II-1) cannot be rate controlling since it does not contain the alcohol. If (II-2) or (II-5) were rate controlling the reaction would be specific hydrogen ion catalyzed. (II-6) cannot be rate controlling since it does not contain the water. Only (II-3) or (II-4) contain the required reactive complex and hence can be rate controlling. Modifications of this reaction mechanism may be made. Thus instead of (II-1) a reaction donating the proton to the OH group giving  is possible. This might be followed by the addition of the ROH to the double bond giving  . The remainder of the mechanism could then be written in a symmetrical way.

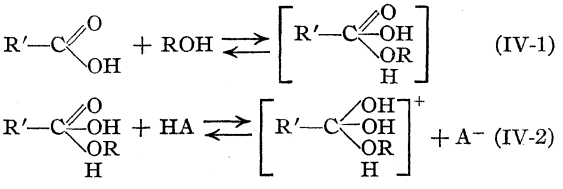
This mechanism II, or its modification discussed above, is in line with current mechanisms of similar reactions. From this point of view, the formation of an acid or ester ion by the addition of a proton seems probable. Only after the formation of such an ion or when HA is in the neighborhood of the acid or ester could water or alcohol take part in the reaction since otherwise the reaction would not be catalyzed. The addition and subtraction of protons represented by steps (II-3) and (II-4) are commonly assumed mechanisms.

Lowry[13] has proposed a termolecular mechanism for esterification of the following nature



where either step (III-1) or (III-3) may be rate controlling. This mechanism is entirely possible, since it would yield both general acid catalysis and a first order dependence on the alcohol concentration or on the water concentration in the case of the hydrolysis reaction.

An alternative mechanism would be obtained by separating step (III-1) into the equivalent reactions



in which step (IV-2) would be rate controlling. This differs from mechanism (III) merely in that it supposes a time interval between addition of alcohol and catalyst molecules, rather than a simultaneous addition of the two to the carboxylic acid. In the case of ester hydrolysis this mechanism is lent some support by cryoscopic studies which demonstrate the existence of ester–water compounds in aqueous solution.[14]

The complex formed in step (IV-1) cannot be of the type  since this reaction and its reverse would result in uncatalyzed esterification (if a water molecule were removed) as well as rapid uncatalyzed exchange of carboxylic

acids. Step (IV-3) could be divided into two steps in an entirely similar manner.

The reactive complex method also proves to be more than a method of simplification; it may, in addition, bring out mechanisms which might otherwise have been missed. For example, in the exchange of oxygen between acetone and water, not only is the bimolecular mechanism of Cohn and Urey[15] a possibility, but several other mechanisms, including a termolecular one, will yield the same reactive complex. At the present time there seems to be no method of distinguishing among these mechanisms for acetone exchange, and also of distinguishing among the mechanisms proposed for the three reactions discussed in this paper. However, the elimination process which we have presented above does lead to a criticism of current theory of the relative rates of acid catalyzed reactions in light and heavy water.

The criterion of pre-equilibrium proposed by Bonhoeffer and Reitz[16] is based on a two step mechanism similar to the first two steps of mechanism I. The criterion may be stated as follows. If the rate of an acid catalyzed reaction is increased on going from H_2O to D_2O, then a pre-equilibrium exists and the reaction is specific hydrogen ion catalyzed. If, however, the rate is decreased on going from H_2O to D_2O, the first step is not an equilibrium but is rate controlling, and the reaction is general acid catalyzed.

It has been demonstrated that the rate of ester hydrolysis is greater in D_2O than in H_2O for both methyl acetate[17] and ethyl acetate.[18] Thus, by the above criterion, we would expect the reaction to be specific hydrogen ion catalyzed. Actually, the data of Dawson quoted above show that ester hydrolysis is general acid catalyzed. A similar contradiction exists for the esterification reaction. Since the equilibrium constant for the equilibrium ester + water $\rightleftarrows$ alcohol + acid does not change on going from H_2O to D_2O,[19,20] and since the rate of hydrolysis is known to be greater in D_2O than in H_2O, the rate of esterification must also increase on going from H_2O to D_2O. Here again the data quoted above show general acid catalysis, whereas the Bonhoeffer criterion would predict a pre-equilibrium.

The source of these difficulties lies in the assumption of a simple two step mechanism, a mechanism which, as we have shown in the discussion given previously, is very improbable for ester hydrolysis and esterification since neither of these steps contains the correct reactive complex.

Summary

1. By combining recent heavy oxygen studies with the available kinetic data for acid catalyzed ester hydrolysis, esterification and oxygen exchange of carboxylic acids, it has been shown to be very probable that all three reactions are similar in mechanism.

2. On the basis that these reactions are general acid catalyzed and first order in alcohol or water, it is possible to write the composition of the reactive complexes whose disappearance will control the reaction rates.

3. Of the large number of mechanisms which have been proposed for these reactions, only three yield the critical complex required by the kinetics.

4. The Bonhoeffer criterion of pre-equilibrium in light and heavy water has been criticized on the ground that the mechanism assumed is incorrect for the reactions discussed here.

Adsorption Studies on Enamel, Dentine and Bone[1]

BY MARIAN LEFEVRE MANLY AND SYLVIA R. LEVY

The adsorption of radioactive phosphorus by calcified tissues is possible both during the preparation of samples using the glycol-extraction procedure[2] and during calcification of these tissues in the animal body.

In previous work from this Laboratory using rats fed radioactive phosphorus, tooth and bone samples were freed from organic material by extraction with a 3% potassium hydroxide–ethylene glycol solution. If adsorption occurred during the extraction procedure, phosphate from the organic portions would be added to the inorganic material, thereby giving high results. Adsorption might be expected for tooth and bone apatites if their behavior is analogous to that of precipitated hydroxyl-apatite. Hodge, LeFevre and Bale[3] postulated that "commercial tertiary calcium phosphates are probably hydroxyl-apatite with more or less adsorbed phosphate ions to give empirical formulas approaching the theoretical."

Adsorption may also have a role in calcification *in vivo*, since the mineral salts have an apatite structure[4] yet contain greater than the theoretical amounts of phosphorus. A demonstration that phosphate ions in contact with the mineral phase of tooth or bone substance yield solutions which are described by the Freundlich adsorption isotherm would constitute an important confirmation of the adsorption hypothesis.

Procedure

Radioactive sodium acid phosphate was prepared by dissolving radioactive red phosphorus in *aqua regia* and neutralizing with sodium carbonate to *p*H 6–7.

Samples.—The samples used were powdered, size-graded dentine, powdered enamel and bone, all of which had been extracted with 3% potassium hydroxide in ethylene glycol to remove the organic material.[5] The enamel and dentine had been separated according to the flotation method of Manly and Hodge.[6] Samples of approximately 100 mg. of the dried powders were placed in 50-cc. centrifuge tubes, 10 cc. of 3% potassium hydroxide in ethylene glycol added and amounts of the radioactive sodium acid phosphate (not greater than 1 cc. volume) added to give various concentrations of phosphate. The mixtures were boiled for one and one-half hours, centrifuged and the glycol decanted according to the procedure already published.[5] The powder was then washed in boiling distilled water, centrifuged, and the water decanted and the powder washed with hot water into a porcelain filter set in a suction flask. After a second washing with hot distilled water, the powder was dissolved in hydrochloric acid, the solution evaporated down to 2 cc. and the activity determined with a Geiger–Müller counter.[7]

Results

To ascertain the relation of the phosphate adsorbed to that remaining in the glycol, all the data have been plotted to test the agreement with the Freundlich adsorption equation.

$$\log_{10}\frac{x}{m} = \log_{10} k + \frac{1}{n}\log_{10} C$$

The curves for enamel, size-graded dentine and bone are found in Figs. 1 and 2. Regardless of the particle size or the amount of phosphate used for each tissue, when the logarithm of the amount of phosphate adsorbed per unit weight of adsorbent is plotted against the logarithm of the concentration remaining in the solution, a straight line is obtained.

Discussion

Appreciable adsorption of phosphate takes place *in vitro* on enamel, dentine and bone. However, significant amounts of phosphate would be adsorbed during the preparation of samples for analysis only if the concentration of phosphate in the extraction medium is high. The calcified part of tooth tissues contains much larger amounts of marked phosphorus than the associated soft tissues, for example, the average percentage of the dose in incisor pulps is 0.007%, while that in the incisors from the same animals is 0.38%.[8] Therefore, even with a 95% adsorption of the phosphate from the pulp, the error would not exceed 2%, which is less than the error of the radioactivity measurement.[7]

According to Freundlich, the constant k is the

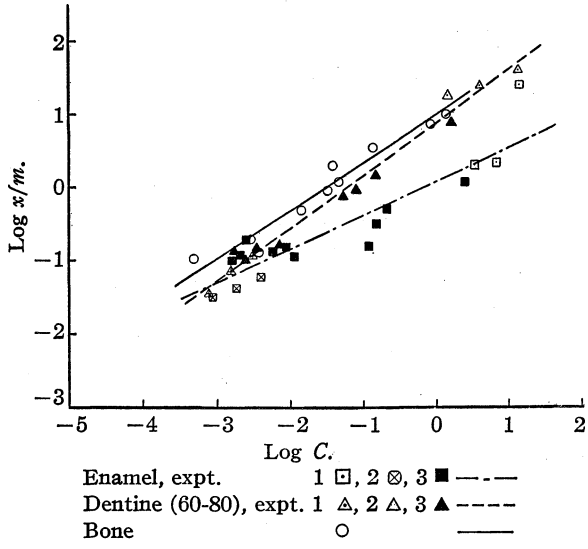

Fig. 1.—Showing the adsorption of radioactive phosphate by powdered enamel, dentine and bone. Note the adsorption in each case obeys the Freundlich equation.

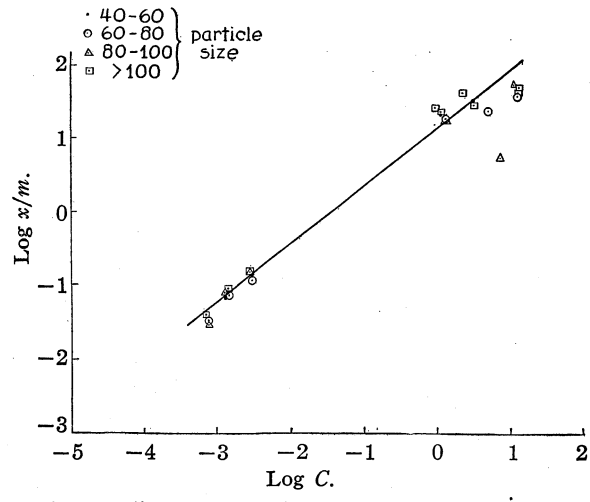

Fig. 2.—Showing the adsorption of radioactive phosphate by powdered size-graded dentine of different sizes. Note that there is no relation between adsorption and particle size.

adsorbent value; and, for any specified adsorbed substance, is characteristic of the adsorbent. The adsorption exponent $1/n$ at a given temperature and for adsorbents of identical chemical composition is characteristic of the adsorbed substance. Although the mineral phase of dentine is known to have slightly more magnesium and carbonate than that of enamel, the principal constituents (calcium and phosphorus) are present in equal amounts in the two tissues[9] and the principal molecular lattices apparently are identical.[10] Therefore, $1/n$ can be assumed to be independent of the adsorbent. From the curves for enamel, dentine and bone (Fig. 1) the calculated constants are as follows.

	Enamel	Dentine	Bone
Adsorption exponent (n)	2.3	1.4	1.6
Adsorbent value (k)	1.4	7.3	8.8

Since the adsorbed substance is the same for these experiments, the adsorption exponents should be the same. The values found for enamel, dentine and bone, 2.3, 1.4 and 1.6, respectively, are regarded as agreeing satisfactorily. However, the k values, which characterize the adsorbent, are not the same for the three tissues. Although the values for dentine and bone are nearly alike (7.3 and 8.8) the enamel value (1.4) is about one-sixth as large. This means a much greater adsorptive power for dentine and bone than for enamel. The greater adsorption is consistent with the fact that the ultimate crystals of dentine and of bone are smaller than those of enamel (of the order of 10^{-6}, 10^{-6} and 10^{-5}, respectively).[11] The effect must be attributed to the ultimate crystal size, for differences in particle size do not affect the amount of phosphate adsorbed (Fig. 2).

Furthermore, the concept of Hodge[12] that tooth and bone crystals are hydroxyl-apatite with varying amounts of adsorbed phosphate is supported by these findings.

One point should be emphasized: these studies demonstrate true adsorption and not the establishment of a chemical equilibrium between the tooth or bone powder and the phosphate in the surrounding medium. At the beginning of the experiment, there is a certain ratio of marked to total phosphorus in the extraction medium. If there were a chemical exchange of phosphorus, a constant ratio between marked phosphorus in the tissue and in the extraction medium would be observed and there would be no change in the total phosphorus in either phase. The data presented here show no such linear relationship; they satisfy exactly the criteria for adsorption according to Freundlich's adsorption isotherm.

Acknowledgments.—The authors acknowledge the assistance of Dr. Harold C. Hodge and Dr. Richard S. Manly in supplying some of the samples and for aid in preparing the manuscript.

Summary

Quantitative measurements on the adsorption of phosphate ion by powdered enamel, dentine and bone have been made. From varying concentrations of radioactive phosphorus as sodium acid phosphate in ethylene glycol, the tissues adsorb phosphate according to the Freundlich adsorption isotherm. The adsorptive power of dentine and bone are about the same and seven times greater than that of enamel.

A Redetermination of the Fluorine–Fluorine Distance in Potassium Bifluoride

BY L. HELMHOLZ AND M. T. ROGERS

Introduction

In an electron diffraction investigation of gaseous hydrogen fluoride, Bauer, Beach and Simons[1] obtained the value 2.55 ± 0.03 Å. for the F–H–F distance and confirmed the existence of polymers $(HF)_n$. The reported values for the F–H–F distance in crystals are:

NH_4HF_2 = 2.37 ± 0.1 Å.[2]
$NaHF_2$ = 2.50 ± 0.2 Å.[3]
KHF_2 = 2.25 ± 0.2 Å.[4]

The assumption that the mean value 2.25 Å. reported for potassium bifluoride is correct leads to the conclusion that the F–H–F bond is weakened and the distance correspondingly increased when additional hydrogen bonds are formed as in $(HF)_n$. Also the distance is not accurately enough known to judge whether the two additional hydrogen bonds from fluorine to nitrogen in ammonium bifluoride cause a lengthening of the F–H–F distance over that in alkali bifluorides. In view of the large limits of error ascribed to the F–H–F distance, a redetermination of the parameter in potassium bifluoride has been carried out in order to test this conclusion.

In this work the value 2.26 ± 0.01 Å. has been found for the F–H–F distance in close agreement with the mean value reported by Bozorth.[4]

Experimental

Potassium hydrogen fluoride crystallizes in the tetragonal system forming plates with {001} developed and sides parallel to {110}. The structure was determined by Bozorth,[4] who gives it the space group D_{4h}^{18}, four molecules in the unit cell, with the atoms in the following positions

4H in $0\frac{1}{2}0$; $\frac{1}{2}00$; $\frac{1}{2}0\frac{1}{2}$; $0\frac{1}{2}\frac{1}{2}$
4K in $00\frac{1}{4}$; $00\frac{3}{4}$; $\frac{1}{2}\frac{1}{2}\frac{1}{4}$; $\frac{1}{2}\frac{1}{2}\frac{3}{4}$
8F in $u,\frac{1}{2}+u,0$; $\bar{u},\frac{1}{2}-u,0$; $\frac{1}{2}-u,u,0$; $\frac{1}{2}+u,\bar{u},0$; $\frac{1}{2}+u,u,\frac{1}{2}$; $\frac{1}{2}-u,\bar{u},\frac{1}{2}$; $u,\frac{1}{2}-u,\frac{1}{2}$; $\bar{u},\frac{1}{2}+u,\frac{1}{2}$
a = 5.67 Å. c = 6.81 Å. u = 0.14 + 0.01 F–H–F = 2.25 ± 0.02 Å.

Symmetric and asymmetric Laue photographs were taken with the beam normal to (001). The parameter was narrowed down to a small range by the use of qualitative Laue data.

Theoretical curves for the dependence of intensity on the parameter u were calculated from the equation

$$I = C \left| S \right|^2 e^{-3.0(\sin\theta/\lambda)^2}$$

using f values from the Pauling–Sherman tables.

Comparing observed intensity ratios with the theoretical curves of Fig. 1, the upper and lower limits shown in Table I were placed on the value

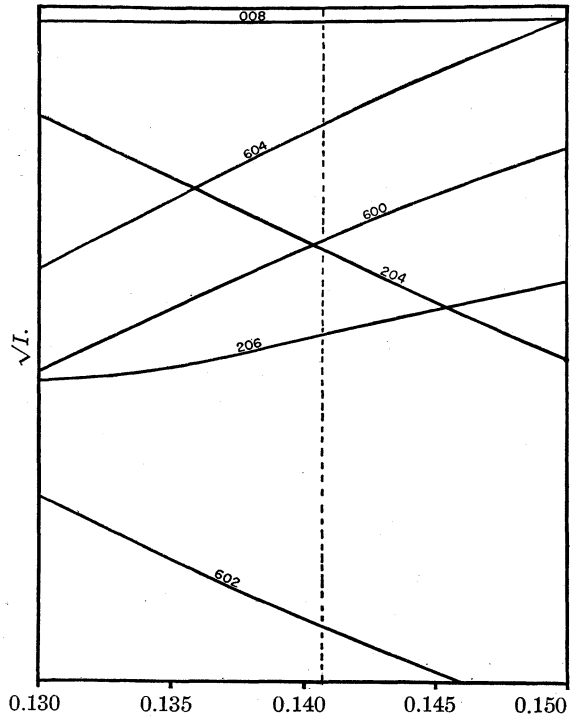

Fig. 2.

of u. This gives $0.1394 \leqq u \leqq 0.1413$ and $2.235 \leqq$ F–H–F distance $\leqq 2.265$ Å.

A more exact value of the parameter was then found by visually comparing intensities of reflections on oscillation photographs. Theoretical curves for the dependence of intensity on parameter were drawn (Fig. 2) using

$$I = \text{Const.}\ \frac{1 + \cos^2 2\theta}{\sin^2 2\theta} \left| S \right|^2 e^{-3.0(\sin\theta/\lambda)^2}$$

From a visual estimate of the ratio of the intensities of two reflections, estimates of the parameter value probably good to ±5% were made using the theoretical curves. Comparisons were made between reflections in the same layer line and not too widely separated values of sin θ. The mean value for the twenty-seven independent estimates made was weighted by multiplying each value by the angle between the intensity curves for the planes involved. The weighted mean for the parameter u is 0.1408, the average deviation is 0.0015 and the most probable deviation is $0.0015/27^{1/2}$ or 0.0003. The value $u = 0.1408 \pm 0.0003$ corresponds to the distance F–H–F = 2.258 ± 0.005 Å. This is in good agreement with the

26	(510) ($\bar{2}$15)	20	2	.1445
27	(413) (316)	23	0.22	.1422

Laue data, and, considering both, the value of the F–H–F distance may be given as 2.26 Å. with a probable error of not more than 0.01 Å.

Discussion

In going from the HF_2^- ion in crystalline potassium bifluoride to the $(HF)_n$ polymers in gaseous hydrogen fluoride there is a lengthening of 0.29 ± 0.06 Å. in the F–H–F distance. This shows that formation of additional hydrogen bonds lengthens the F–H–F distance. While the value 2.37 ± 0.1 Å. for the F–H–F distance in ammonium bifluoride leaves some doubt as to a lengthening, it is strongly indicated that the formation of two additional N–H . . . F bonds causes a weakening of the F–H–F bond and a probable lengthening of about 0.1 Å. The theoretical value calculated by Pauling[5] for this distance is 2.32 Å. with a symmetrical linear configuration for F–H–F.

Summary

A redetermination of the parameter in potassium bifluoride has been carried out using Laue and oscillation photographs. The value $u = 0.1408 \pm 0.003$ leads to the fluorine–fluorine distance 2.26 ± 0.01 Å. in $\{F\text{–}H\text{–}F\}^-$. A comparison is made with other reported values.

Silver and Mercurous Iodide Electrodes

BY WARREN C. VOSBURGH, PAUL F. DERR, GERALD R. COOPER AND ROGER G. BATES[1]

The silver and mercurous iodide electrodes have both been shown to be reproducible under favorable conditions,[2] and it seemed desirable to attempt a direct comparison of the two. This was found surprisingly difficult, and the result can be considered only approximate. Some of the observations made in the course of the study are of value, however.

Silver Iodide Electrode.—All of the silver iodide electrodes were prepared by the thermal method; some from silver oxide and iodate[2a] and some from oxide and iodide.[2b] In the preparation of some, the platinum wire was electroplated with silver before application of the paste, but this was found unnecessary and was omitted in the later electrodes.

Silver iodide electrodes agreed within 0.02 mv. when compared in the same vessel with oxygen-free potassium iodide solution (about 0.02 *m*) as the electrolyte. The agreement was better on the second day than on the first, and continued good indefinitely. The agreement was not as good when the electrolyte was saturated with lead iodide or when 0.01 *m* cadmium iodide was used as the electrolyte. When air was admitted to a cell consisting of two silver iodide electrodes in the same vessel, it caused disagreement of the electrodes.[3] A trace of mercurous iodide also caused disagreement.

Mercurous Iodide Electrodes.—While the mercurous iodide electrode is highly reproducible when the electrolyte is a saturated cadmium iodide solution,[2c,d] it was found much less reproducible when the electrolyte was a potassium iodide solution. Two mercurous iodide electrode systems in a single H-vessel prepared with nitrogen-vacuum technique gave a cell with an electromotive force anywhere from zero to well over a millivolt in spite of considerable care to avoid errors. When one electrode had a thick (1 to 2 cm.) layer of mercurous iodide paste covering the mercury and the other a thin (0.5 cm.) layer, the thick-layer electrode was always positive, and the electromotive force varied from 0.3 mv. to nearly 2 mv. in different cells and at different times. When both layers of mercurous iodide were thin, the electromotive force varied from zero to 0.3 mv. When the electrolyte was a 0.01 or 0.02 *m* cadmium iodide solution, the effect of thick and thin layers was not as pronounced. Solid lead iodide at both electrodes, with a potassium iodide electrolyte, reduced the effect of thick and thin layers, also.

(3) (a) Smith and Taylor, *Roczniki Chem.*, **18**, 762 (1938); (b) Taylor and Smith, *J. Research Natl. Bur. Standards*, **22**, 307 (1939).

The effect of thick and thin layers may possibly be explained on the basis of the reaction

$$Hg_2I_2 + 2I^- \rightleftarrows Hg + HgI_4^=$$

This reaction takes place when mercurous iodide and sufficient iodide ion come together, and therefore the iodide ion concentration at a mercurous iodide electrode is not the same as in the main body of the electrolyte. If the reaction is slow, diffusion would be able to keep the iodide ion concentration at the thin-layer electrode larger than at the thick-layer electrode. A larger iodide ion concentration means a smaller mercurous ion concentration and consequently a more negative electrode. Mercurous iodide electrodes are reproducible in saturated cadmium iodide solutions because the small iodide ion concentration[4] is held practically constant by the various equilibria in the solution. If this theory is correct, the value assigned to the normal potential of the mercurous iodide electrode[4] must be considered less certain than the precision of the measurements would indicate.

Cells.—A large number of cells were made, each with one silver iodide and one mercurous iodide electrode. When made in ordinary H-shaped vessels the constancy was not satisfactory. Diffusion of the mercurous iodide to the silver iodide electrode was probably responsible. A plug of glass wool to retard diffusion helped, but did not overcome the trouble, and the special cell vessel illustrated in Fig. 1 was designed. The electrode systems were placed in parts A and B, with the use of nitrogen-vacuum technique. The tube C was not filled with electrolyte until a measurement was to be made. It was then filled through tube D with air-free solution from a flask like that described by Brown and MacInnes.[5] After a measurement, the solution in C was expelled through F by nitrogen pressure. Some of the vessels used had interchangeable ground-glass joints at C. This allowed an interchange of electrodes between cells. A few vessels had two legs at A and two at B, allowing the preparation of duplicate electrodes of each kind. Cells made in the vessels having the joints at C were maintained at constant temperature in an air-bath and the others in an oil-bath.

Of a large number of cells made with 0.02 *m* potassium iodide solution as the electrolyte, 48 were selected as the most satisfactory. The electromotive forces of these on the first day varied between 0.1119 and 0.1141 v. at 30°, the silver iodide electrode being negative.

The highest cells decreased during the next few days and most of the lower ones increased. For 18 cells that varied less than 0.2 mv. during the first four days the range was 0.1127 to 0.1136 v. This is within the range of variability of mercurous iodide electrodes with different thicknesses of the mercurous iodide layer. Three of the cells were measured over a period of twenty-four to forty days. One of these started at 0.1141 v. and decreased to 0.1131 v. On shaking the mercurous iodide electrode, the value dropped to 0.1128 v. and remained constant thereafter for twenty-five days. Another cell started at 0.1130 v., decreased in four days to 0.1128 v. and remained constant for thirty-six days. Its electromotive force was not affected by shaking. The third was like the first, except that its initial electromotive force was not as high. All three cells gave the value 0.1128 v. after shaking.

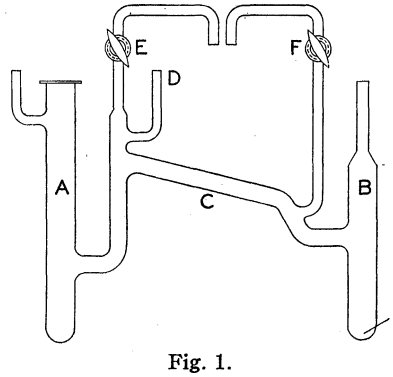

Fig. 1.

If the differences between cells is ascribed in part to differences in thickness (or denseness of packing) of the mercurous iodide layer, the lower electromotive forces should correspond to cells in which the layer is thin. The effect of shaking is probably to aid diffusion, and this lowers the electromotive force to the thin-layer value of 0.1128 v.

A group of cells made with 0.01 *m* potassium iodide solution was less satisfactory, but the best ten varied between 0.1124 and 0.1130 v. between the second and fourth days, with an average of 0.1127 v. A number of cells made with an electrolyte of 0.02 *m* potassium iodide solution saturated with lead iodide were variable and unsatisfactory, except for one cell that was constant at 0.1128 v. The use of a dilute cadmium iodide

(4) Bates and Vosburgh, THIS JOURNAL, **59**, 1189 (1937).
(5) Brown and MacInnes, *ibid.*, **57**, 1358 (1935).

solution as the electrolyte gave cells that were rather variable and lower than 0.1128 v. Saturated cadmium iodide gave cells that started very high and decreased continuously. The bad effect of cadmium iodide is undoubtedly on the silver iodide electrode.

In connection with a study of the thermodynamics of zinc iodide in aqueous solution by means of zinc–silver iodide cells,[2b] some cells with mercurous iodide electrodes were made from which the electromotive force of the silver–mercurous iodide cell could be calculated. The calculated values are given in Table I. The results are in

approximate agreement with those described above. They show that the electromotive force depends on the electrolyte concentration, which is in agreement with the theory proposed above for the variability of the mercurous iodide electrode. Table I and also some measurements of the previously described cells show that the temperature coefficient is about 0.00030 v. per degree; 0.1127 v. at 30° corresponds to 0.1112 v. at 25°.

Bates and Vosburgh[4] found for the normal potential of the mercurous iodide electrode the value 0.0405 v. at 25°. They used rather thin layers of mercurous iodide and a molality of potassium iodide of about 0.01 and their value can be combined with 0.1112 v. to give the approximate value 0.1517 v. at 25° for the normal potential of the silver iodide electrode. Owen[2a] found 0.1522 v. and Cann and Taylor[6] found 0.1510 v. In view of the uncertainty of the value 0.1517 v., it cannot be considered to be in serious disagreement with either of these. Some recent measurements by Gould and Vosburgh of the silver iodide electrode against a hydrogen electrode are in as good agreement with 0.1517 v. as could be expected.

Summary

The cell Ag/AgI, I^-/I^-, Hg_2I_2/Hg was found to be not as reproducible or constant as experience with the two electrode systems in other cells would lead one to expect, but the most probable value based on a large number of cells leads to an approximate value for the silver iodide electrode.

The trouble with the silver–mercurous iodide cell may be summarized by saying that while each of the electrode systems is highly reproducible under favorable conditions, no single electrolyte was found that did not affect one or the other of the electrodes unfavorably.

A Thermodynamic Study of the Lead–Antimony System

BY HARRY SELTZ AND BERNARD J. DEWITT

In the hope that the accumulation of data on the thermodynamic properties of binary liquid metal solutions may lead eventually to a better understanding of the nature of such systems, investigations along these lines are being continued in this Laboratory. In this paper the results of a study of the lead–antimony system are described. The electromotive force values of cells of the type

$$Pb(l)/PbCl_2 \text{ in } KCl\text{–}LiCl(l)/Pb\text{–}Sb(l)$$

were measured, using the purified metals and technique described in previous publications.[1,2]

(1) Strickler and Seltz, THIS JOURNAL, **58**, 2084 (1936).

(2) Seltz and DeWitt, *ibid.*, **60**, 1305 (1938).

In this work it was found possible to extend the e. m. f. readings in rather thick-walled Pyrex H-cells under vacuum up to 630° without collapse of the cells. This permitted measurements to a mole fraction of lead of 0.1 and eliminated any difficulty in the extrapolation of the activity and partial molal relative heat content curves.

Experimental Data

In Table I, the experimental results are tabulated, along with the calculated activities and relative heat contents for lead at the various mole fractions. (The subscript 1 will be used to designate values for the lead component.) At the

highest mole fraction of antimony the readings, due to separation of the solid phase, could be made over a range of only 30°; but, as in previous measurements with fused salt electrolytes, this permitted a sufficiently accurate determination of the slope of the curve to evaluate $\bar{L}_1$ within ±15 cal.

TABLE I

Average number of readings per run, 20; maximum deviations, ±0.04 mv.

Discussion of Results

The forms of the activity and $\bar{L}$ curves for this system are surprising when compared with those of the previously studied lead–bismuth solutions. Here, the negative deviations of the activities are comparatively slight, with the extrapolated Henry's law value for the activity coefficient, a_1/N_1, reaching a value of only 0.740, while for

the lead–bismuth system this value is 0.480. Furthermore, the lead–bismuth solution followed "regular" solution behavior closely, with a "b" value of -1200. A plot of log a_1/N_1 *vs.* N_2^2 for this system, Fig. 3, indicates clearly the deviations from such behavior, and this is demonstrated further by the forms of the $\overline{L}$ and ΔH curves, which are not compatible with the regular solution concepts. In fact, it would seem that two

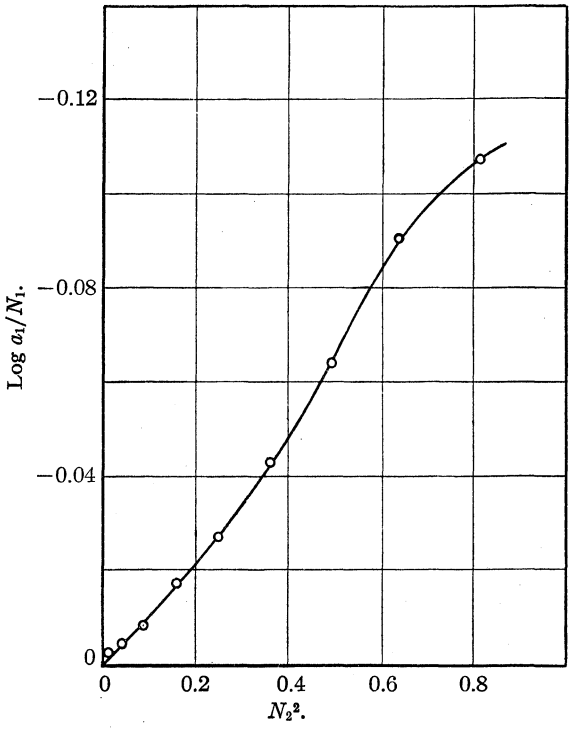

Fig. 3.—Deviations from "regular" behavior.

opposing factors contribute to the deviations from Raoult's law, one tending to produce positive and the other negative deviations. This is not apparent in the activity curves which show negative deviations over the entire range at this temperature. However, with positive values of $\overline{L}_1$ at higher mole fractions, the activity coefficients would tend to become greater than one at lower temperatures. At lower concentrations of lead, on the other hand, the negative $\overline{L}_1$ values would decrease the activity coefficients to yet smaller values. For the cadmium–antimony system,[2] in which intermetallic compounds separate in the solid state, these opposing influences are more pronounced; the activity curve for cadmium shows both positive and negative deviations at 753.1°K. Similar results, not yet published, have been obtained for the zinc–antimony system.

Calculation of Solid–Liquid Equilibria

Solid–liquid equilibria in the lead–antimony system have been studied by several investigators and the data have been reviewed critically by Hansen.[3] It has been established that the system shows a simple eutectic with α- and β-solid solutions of antimony in lead and lead in antimony respectively as the solid phases. The eutectic temperatures and compositions reported range between 245–252° and 12.1–13% antimony. From the activity data for the two components in the liquid state, it should be possible to calculate these conditions more accurately and also to establish the solid solubility limits of the α- and β-phases at the eutectic. For these calculations the free energies of fusion of the two components are needed, and the heats of fusion and the heat capacity data recommended by Kelley[4] lead to the equations:

$$\mathrm{Sb(s)} = \mathrm{Sb(l)};\quad \Delta F^\circ = 4015 - 1.64T \ln T + 0.89 \times 10^{-3}T^2 + 5.914\,T \quad (1)$$

$$\mathrm{Pb(s)} = \mathrm{Pb(l)};\quad \Delta F^\circ = 969 - 1.03\,T \ln T + 1.01 \times 10^{-3}T^2 + 4.371\,T \quad (2)$$

Hansen[3] has accepted 247° for the eutectic temperature and 13% antimony, corresponding to a mole fraction $N_2 = 0.2027$, for the composition of the eutectic liquid. From the experimental activity and $\overline{L}$ values, we calculate at this temperature and composition $a_2 = 0.1556$. From equation (1) the activity of pure solid antimony, a_2(s), relative to pure liquid as the standard state, is calculated to be 0.1451. At this temperature, it is obvious that a liquid containing 13% antimony cannot exist in equilibrium with even pure solid antimony. Taking the lower limit of the reported values of 12.1% ($N_2 = 0.1898$), we calculate $a_2 = 0.1457$, which likewise is greater than a_2(s) at this temperature. Since the β-solid solution has been shown to contain at least 4% of lead, it would seem that 247° is too low for the eutectic temperature. To confirm this conclusion, cooling curves were taken on 12 and 13% melts using the calibrated chromel–alumel couples employed in the e. m. f. studies. In both runs, complete solidification took place when the temperature reached 250°. At this temperature a_2(s) is calculated to be 0.1487 and a_2 for a 13% solution is 0.1557, which indicates that even at this temperature the eutectic must be richer in

(4) K. K. Kelley, Bureau of Mines Bulletins 383 (1935) and 393 (1936).

lead for equilibrium. Taking the lower limit of 12.1%, we calculate that $a_2 = 0.1458$, which is now less than the value $a_2(s) = 0.1487$. Assuming Raoult's law to be obeyed in the dilute β-solid solutions, as has been shown to be true for lead–bismuth solid solutions,[1] we calculate for the solid solubility of lead in antimony at the eutectic temperature, $N_\beta = 0.1458/0.1487 = 0.973$, which corresponds to a solubility of 4.51% of lead. In a similar manner, the composition of the α-solid solution at the eutectic can be determined. The activity of solid lead, relative to liquid, from equation (2) is 0.8694, and a_1 for the 12.1% solution is 0.8132, which gives for the solid solubility $N_\alpha = 0.936$, corresponding to a solubility of 3.86% of antimony.

Summary

1. The activities and relative heat contents of lead and antimony in their liquid alloys have been determined.

2. The eutectic temperature for the system has been shown to be 250° and the eutectic composition 12.1% antimony. The eutectic solids have been calculated to have the compositions 3.86% antimony for the α-phase and 4.51% lead for the β-phase.

Proof of the Steric Nature of the Ortho Effect in the Hydrogen Exchange Reactions of Aromatic Tertiary Amines

BY WELDON G. BROWN, ALEX H. WIDIGER AND NICHOLAS J. LETANG

It has been postulated previously[1] that the acid catalyzed hydrogen exchange reactions of dimethylaniline and its derivatives take place through a direct addition of deuterons at the ortho or para positions, giving rise to tautomeric forms of the amine salt with a quinoid type of structure. In view of the requirement in classical structural theory that the dialkylamino group should be coplanar with the quinonoid ring in these forms, it was possible to interpret the inhibiting effect of an ortho nitro group, which had been observed in a study of the exchange reactions of the nitrodimethylanilines in deuteroalcohol, as a steric effect having to do with the obstruction offered by the nitro group to the attainment of a coplanar configuration. Several further examples of inhibition of the hydrogen exchange reaction by ortho substituents have since been discovered and it is now obvious that the ortho effect is as characteristic for this reaction as it is for numerous other reactions of aromatic tertiary amines.[2]

In an effort to test experimentally the validity of this theory of the ortho effect in hydrogen exchange reactions, two independent lines of approach were explored. One obvious method of attack was to vary the size of the ortho substituent in the expectation that as the size of the group becomes small the inhibiting effect should diminish or eventually vanish. The series selected for this purpose was that of the bromo, chloro and fluoro derivatives of dimethylaniline (*cf.* Fig. 1). The second line of attack was based on the argument that if the amino nitrogen were to be linked to the ortho carbon atom in such a way as to form a five-membered ring, as in N-methylindoline (I), which would necessarily be coplanar with the benzene ring, there should be no ortho effect. A similar result was predicted for

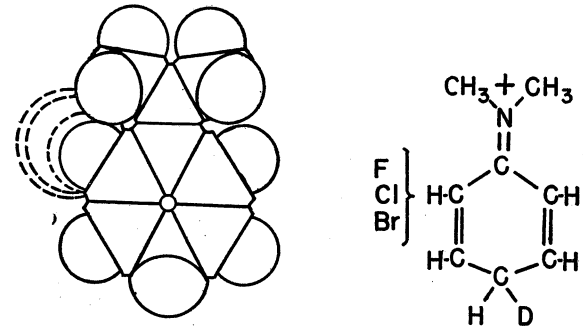

Fig. 1.—On the left, representation based on scale atomic models of the structures indicated on the right. The dotted lines show approximately the relative dimensions of F, Cl and Br.

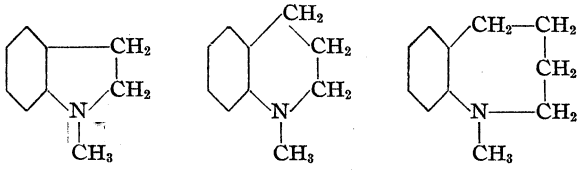
(1) Brown, Kharasch and Sprowls, *J. Org. Chem.*, in press.

(2) The literature on the subject of ortho effects in the reactions of aromatic tertiary amines, particularly with regard to the reactions with methyl iodide, nitrous acid, diazo compounds, and formaldehyde, is too extensive to be cited here in detail, but the very extensive work of the late Julius von Braun in this field deserves special mention. For a review on the subject of ortho effects in general, see Ludwig Anschütz, *Z. angew. Chem.*, **41**, 691 (1928).

an analogous compound with a six-membered ring, N-methyltetrahydroquinoline (II), though perhaps with less certainty because of the probable slight strain in the coplanar configuration. With a highly puckered seven-membered ring, on the other hand, as in N-methyl-*homo*-tetrahydroquinoline (III), the opportunity for a steric effect of the type under consideration definitely arises and this compound should exhibit the characteristic inhibition of the normal lability of the para and unsubstituted ortho hydrogen atoms.



(I) (II) (III)

The experimental results are entirely in accordance with the predictions. We find a pronounced ortho effect in the failure of *o*-bromodimethylaniline and of *o*-chlorodimethylaniline to undergo hydrogen exchange to any appreciable extent under experimental conditions such that the exchange reactions of the corresponding meta and para isomers are substantially complete. The effect is very much less conspicuous, although not entirely absent, in *o*-fluorodimethylaniline which undergoes hydrogen exchange at an intermediate rate. In the series of cyclic bases, it is observed that N-methylindoline and N-methyltetrahydroquinoline exhibit a very high degree of reactivity in the exchange reaction, the former being more reactive but both exceeding dimethylaniline, whereas N-methyl-*homo*-tetrahydroquinoline exchanges hydrogen at a relatively slow rate. These results provide rather convincing evidence that the key to the situation really lies in the ability of the dialkylamino group to come into the plane of the benzene ring.

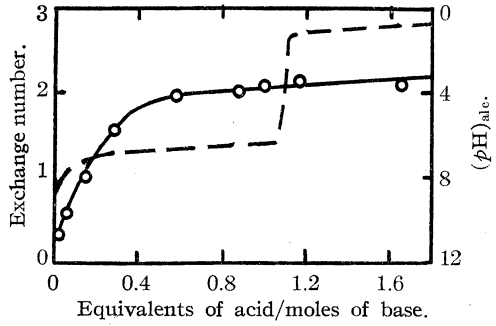


Fig. 2.—The rate of exchange of dimethylaniline in deuteroalcohol with varying amounts of sulfuric acid. The dotted line indicates the estimated $(p\mathrm{H})_{\mathrm{alc.}}$

In the meantime further evidence in support of the mechanism of direct deuteron addition at the site of the exchange (ortho and para carbon atoms) was forthcoming in a study of the effect of acid concentration on the rate of exchange of dimethylaniline in deuteroalcohol solution. As Ingold, Raisin, and Wilson[3] first pointed out, and verified experimentally with reference to the exchange of dimethylaniline in dilute hydrochloric acid, it is a consequence of this mechanism that on increasing the amount of acid the rate of exchange should reach a maximum value which would represent a compromise between the increasing concentration of acid catalyst and the decreasing concentration of free base. Our results on the sulfuric acid catalyzed exchange reaction of dimethylaniline in deuteroalcohol are similar to those obtained by Ingold, Raisin, and Wilson in showing that beyond a certain point the rate of exchange does indeed fail to keep pace with the increasing concentration of acid (*cf.* Fig. 2).

It is characteristic of the ortho effect in the reactions of aromatic tertiary amines that it does not always appear as a completely dominant effect. It is rather an effect of limited magnitude which may be partially or wholly obscured by opposing influences. In the hydrogen exchange reaction the effect is known to be of limited magnitude not only in the case of *o*-fluorodimethylaniline, in which the inhibition of reactivity is only slight, but also in the case of *o*-chlorodimethylaniline which does not exchange hydrogen readily at 110° but does so at 180°. It is therefore of interest in connection with the interpretation of the behavior of more complicated molecules to know the extent to which the ortho effect can be overcome by suitably oriented activating groups. An effect in this direction can be seen in the fact that dimethyl-*p*-xylidine exchanges hydrogen, albeit slowly, while under similar conditions N-dimethyl-*o*-toluidine and 2-dimethylamino-*m*-xylene exhibit no appreciable exchange. In this example the deactivating steric effect of an ortho methyl group is to some

(3) Ingold, Raisin, and Wilson, *J. Chem. Soc.*, 1639 (1936). The fundamental difference between the mechanism proposed by these authors and our mechanism is that they apparently believe the hydrogen exchange to be effected in a single step involving simultaneous proton and deuteron transfers and nothing is indicated with regard to a possible quinonoid structure for the intermediate complex. In our view the formation of a quinoid form of the cation by deuteron transfer is followed by a proton transfer in which the acceptor will not necessarily be the anion derived from the catalyzing acid.

TABLE I

EXCHANGE REACTIONS OF TERTIARY AROMATIC AMINES IN DEUTEROALCOHOL

In all experiments the amount of substance used was 0.0130 mole, the amount of alcohol 0.0850 mole.

N-Methyl-*homo*-tetrahydroquinoline	.01	44	60	2.79	2.78	0
N-Methyl-*homo*-tetrahydroquinoline	.02	70	120	2.77	2.57	0.85

extent alleviated by the normal activating effect of a meta methyl group. A similar case is provided by 5-dimethylaminotetralin, which undergoes hydrogen exchange slowly. These results provide a clue to the behavior of α-dimethylaminonaphthalene, which can be regarded, formally at least, as an ortho substituted amine but which shows a high degree of reactivity in the hydrogen exchange reaction. We suppose that the steric inhibition which might be expected is very nearly compensated by the activating effect of the benzo group. It is to be anticipated that the steric factor in such a molecule could be greatly increased by substituents in the 8-position and experiments are in progress to test this prediction.[4]

It will be obvious, in view of the parallel occurrence of ortho effects in the hydrogen exchange reaction and in coupling, nitrosation, and condensation reactions of aromatic amines, that the elucidation of the nature of the effect for one type of reaction has important implications with regard to the others. There appears to be no obstacle in the way of extending the principles and the experimental approach of the present work to these related reactions, and in fact much of the necessary data is already available in the literature. In subsequent papers an attempt will be made to show how this extension can be carried out.

(4) The α-dialkylaminoanthraquinones present a similar picture in so far as the steric relationships are concerned and it seems possible that this may be the origin of many of the anomalies to be encountered in the chemistry of these substances.

TABLE II

HYDROGEN EXCHANGE OF DIMETHYLANILINE WITH VARYING AMOUNTS OF ACID[a]

H_2SO_4, cc.	Acid/base	Initial % D_2O[b]	Final % D_2O	Exchange number
0	0	2.83	2.81	0

[a] The mixture of the ortho and para derivatives which was obtained on nitrating fluorobenzene, and which contained approximately 13% of the ortho compound, was separated without difficulty by fractional distillation at 50 mm. pressure using a 1-meter column packed with glass helices. [b] This compound was prepared by the method of Koizumi, Kowski, and Titani, *Bull. Jap. Chem. Soc.*, **13**, 645 (1938), and was reduced to N-methylindoline by the method of Wenzing, *Ann.*, **239**, 246 (1887). Other methods for the preparation of the latter which were first tried gave unsatisfactory results. [c] The compound assumes a bright red color when exposed to air and the rate of coloration is enormously accelerated by traces of acid. In the exchange experiments the samples were distilled into reaction tubes under high vacuum without subsequent exposure to air. Under these conditions no color developed in the control experiments and only a slight yellow color in the tubes containing acid. [d] The methylation of *homo*-tetrahydroquinoline was carried out by refluxing equal volumes of the amine, methyl iodide, and methyl alcohol for three hours, resulting in a 65% yield of the tertiary amine as compared with a 20% yield reported by v. Braun and Seemann.[9]

Kharasch, Brown, and McNab,[5] and later modified,[1,6] has been improved as a result of the discovery[7] that significant errors can arise from isotopic fractionation in the distillation of ethyl alcohol at reduced pressure. In order to minimize these errors the distillations are now carried out at atmospheric pressure and care is exercised in collecting the same fraction in each distillation. With these precautions a constant decrease, amounting to 0.8% of the concentration of deuterium, was obtained. Control experiments, in which no catalyst was added, were carried out with each compound and in no case did we find evidence of exchange in the absence of added acid.

Experimental Results.—The experimental results are given in tabular form in Tables I and II. The extent of hydrogen exchange is expressed in terms of the "exchange number," which is used here as a matter of convenience,[8] and which is derived from the data by means of the relation: $n = (a/s)(D_1 - D_2)/D_2$, where a/s is the molar ratio of alcohol to substance, and D_1 and D_2 are the initial and final concentrations of deuterium in the alcohol. Since the unit of deuterium concentration does not enter into the result, it is unnecessary to transform the analytical data from mole % D_2O in the water of combustion, in which form they are obtained and are given in the tables, to mole % C_2H_5OD in the alcohol.

Corrections were applied for the dilution of the deuterium by the normal hydrogen of the sulfuric acid added. In the series of experiments recorded in Table II, this correction becomes quite large with the higher concentrations of acid and there is some uncertainty as to how it should be applied.

Materials.—The tertiary amines required for this work have been described previously and were prepared by the methods given in the literature, the principal exception being the preparation of N-methyl-*homo*-tetrahydroquinoline which was carried out by a less laborious route than the original one of v. Braun and Seemann.[9] Extensive use was made of the acetic anhydride treatment as a method of purifying tertiary amines, and in connection with the possible occurrence of secondary amines as impurities in certain cases it may be mentioned that the amino hydrogen exchanges rapidly in the absence of added catalyst and thus the control experiments served also as a check on the purity of the substances.

The physical constants of the materials used in the exchange experiments, and also of some of the intermediates required in the preparations, are given in Table III.

(7) Widiger and Brown, THIS JOURNAL, **61**, 2453 (1939).

(8) Since equilibrium data are in most cases not yet available the true degree of completion of the reactions cannot be given. Experience indicates that the limiting value of the "exchange number" in reactions involving C–H hydrogens is less than the actual number of exchanging hydrogen atoms per molecule by 15–20%.

(9) Von Braun and Seemann, *Ber.*, **55**, 3824 (1922).

A careful examination of the problems involved in the synthesis of N-methyl-*homo*-tetrahydroquinoline by the method of v. Braun and Seemann[9] led to the discovery that γ-(*o*-aminophenyl)-butyric acid, one of the later intermediates, could be prepared more conveniently by the Beckmann rearrangement of the *p*-toluenesulfonic ester of α-tetraloneoxime.[10] This method was adopted and the subsequent steps were carried out essentially as described by v. Braun and Bartsch[11] and by v. Braun and Seemann.[9]

α-Tetralone.—The following method was used for the preparation at a reasonable cost of the relatively large quantities of α-tetralone needed for the above-mentioned synthesis. Air is blown gently for a period of one hundred hours through a suspension of finely powdered copper oxide in tetralin maintained at 90°. The suspension is then allowed to settle and the liquid decanted. Upon fractional distillation at reduced pressure 80% of the tetralin is recovered and there is obtained in 20% yield a mixture of α-tetralol and α-tetralone containing 50–75% of the latter. This product is dissolved in an equal volume of acetic acid and treated in the cold with an equal weight of chromic acid dissolved in a small quantity of water. After the addition of chromic acid is complete, the solution is allowed to warm to room temperature and is maintained at room temperature for six hours. The product is then isolated by the usual methods, yield 90% based on tetralin consumed, b. p. 134° (15 mm.).

α-Tetraloneoxime.—The oxime was prepared using a technical grade of neutral hydroxylamine sulfate, recrystallized from 50% alcohol using a little Norite; yield 90%, m. p. 102°.

Summary

Some further examples of the inhibition of the acid catalyzed hydrogen exchange reactions of dimethylaniline derivatives by ortho substituents are reported.

In support of the theory that the ortho effect is primarily a steric effect having to do with the tendency of an ortho substituent to block the formation of quinonoid structures, it is shown that the inhibition of hydrogen lability caused by an ortho fluorine atom is much less than that caused by an ortho chlorine atom. A more decisive test of the theory is provided by a study of the exchange reactions of the cyclic bases, N-methylindoline, N-methyltetrahydroquinoline, and N-methyl-*homo*-tetrahydroquinoline. The first two of these, having bicyclic structures which are coplanar or nearly so, were observed to exchange hydrogen readily, while the third, in which the heterocyclic ring must be highly puckered, exhibited the inhibition of reactivity which is characteristic of ortho substituted tertiary amines.

Inactivation of Tyrosinase in the Oxidation of Catechol

BY B. J. LUDWIG AND J. M. NELSON

When catechol is oxidized by means of an excess of the oxidase, tyrosinase, two atoms of oxygen are consumed per mole of the substrate. If, however, less than a sufficient amount of the enzyme is used, then the enzyme becomes inactivated before the catechol is completely oxidized (curves I and III, Fig. 1).

The inactivation of one unit of catecholase[1] has been found to involve a definite amount of oxygen uptake. In fact the amount of oxygen required for the inactivation may be used as a quantitative measure of the amount of catecholase present in a given preparation of the enzyme, provided the latter has been purified sufficiently. Crude tyrosinase preparations[2] are apt to contain from the plant, serving as the source, catechol or catechol derivatives and phenols which are aerobically oxidized by the enzyme, or tend to form with the latter inactive complexes. For this reason crude tyrosinase preparations often tend to lose activity on standing. These concomitant substances are usually lost when the purification has reached the stage, in the case of tyrosinase from the common mushroom, *Psalliota campestris*, when 1 mg. dry weight is equivalent to 80 or more catecholase units (for definition of units see legend Fig. 1). Sufficiently purified tyrosinase preparations from the last-mentioned source require for complete inactivation an uptake of 100 ± 5 cu. mm. of oxygen per catecholase unit (column 4, Table I).

It has been shown by Parkinson (unpublished) in these laboratories and also by others[3,4] that in

(1) Since tyrosinase catalyzes the oxidation of both catechol and *p*-cresol, the terms catecholase and cresolase have been used for the respective enzymic activities.

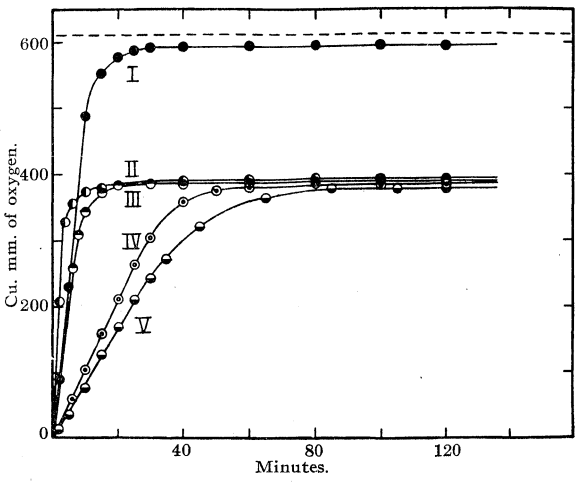

Fig. 1.—Showing oxygen uptake when catechol is oxidized aerobically in the presence of tyrosinase. Barcroft differential respirometer (ref. 5) used. Temp. 25°. Contents of control flasks differed from that in reaction flasks by substituting an equal volume of water in place of the enzyme solution. Curve I shows the complete oxidation (2 atoms of oxygen) of catechol when sufficient enzyme is used. Reaction mixture in reaction flask: 3 cc. 0.2 *M* phosphate buffer (*p*H of final reaction mixture 6.7), 1 cc. gelatin solution (5 mg.), 2 cc. tyrosinase solution (8.0 catecholase units) and sufficient water to make the final reaction mixture 8 cc.; 1 cc. catechol solution (3 mg.) was added from the side arm to the reaction mixture at zero time. Curve III shows inactivation of the tyrosinase when less enzyme (4 units) and more catechol (4 mg.) was used than in the experiment corresponding to curve I. Otherwise reaction mixture for experiment (curve III) same as that represented by curve I. After the expiration of ninety minutes 2 mg. more catechol was added to each of the two above reaction mixtures. In the case of the mixture corresponding to curve I, further oxidation took place, showing the enzyme to be still active, while in the case of the mixture (curve III) no further uptake of oxygen occurred, showing that the enzyme was no longer active. Curves II, IV and V are discussed in a later section of the text. They show that the amount of oxygen corresponding to complete inactivation is influenced neither by the length of time the enzyme is exposed to the reaction mixture nor by the rate at which the catechol is oxidized or by the concentration of the oxygen in the reaction mixture. The reaction mixtures used in these experiments were the same as that used in the experiment for curve III, but the composition of the gases in the reaction vessel differed: II 100% oxygen, III 21% O_2 (air), and IV 2% oxygen and 98% nitrogen. In the experiment corresponding to curve V, the air in the flask was replaced by nitrogen, the final traces of oxygen being removed by alternately evacuating and reflushing the flask with nitrogen. The catechol was then added to the main reaction flask and the latter shaken for forty minutes, after which time the nitrogen was replaced by a 2% oxygen–98% nitrogen mixture, and the oxygen uptake measured. 2% oxygen was used here, instead of air, in order to slow down the rate of the reaction and permit equilibrium conditions to be attained before appreciable oxygen consumption occurred. A comparison of the curves IV and V reveals that although a slightly different rate of oxygen consumption resulted, nevertheless, the total oxygen uptake, before inactivation of the enzyme was complete, was the same in the two experiments. The slower rate evidenced by curve V may be attributed to the initial lack of dissolved oxygen in the reaction mixture. The tyrosinase used in the above mentioned experiments was obtained from the common mushroom, *Psalliota campestris*, and contained about 320 catecholase units per γ of copper. For definition of catecholase units see paper by Adams and Nelson (ref. 6).

the case of reasonably purified preparations of tyrosinase the catecholase activity is proportional to the copper content. It therefore follows that the amount of oxygen required for the inactivation of catecholase is proportional to the copper content (3.3×10^4 cu. mm. of oxygen per γ of copper, column 6, Table I). The first three values in column 6 are low and indicate that an appreciable amount of copper, inactive toward catechol, is present in preparations C101A, B and D. This may be due to foreign copper proteins being present in these relatively impure preparations as has been suggested by Keilin and Mann or to the presence of inactivated enzyme, removable by further purification.

The cresolase activity, determined according to the Graubard and Nelson method as modified by Adams and Nelson, appears to bear no relation to the amount of oxygen consumed in the complete inactivation of the enzyme (column 7, Table I).

In Part B, Table I, data are presented for tyrosinase preparations from sources other than *Psalliota campestris*. These data indicate that the amount of oxygen consumed for the complete inactivation of these tyrosinases is different. In the case of the wild mushroom, *Lactarius piperatus*, an oxygen uptake of 400 ± 15 cu. mm. is required for the inactivation of one unit (catecholase). Since Dalton (unpublished) has shown that the catecholase activity of the tyrosinase from this source is also proportional to the copper content (42 units per γ of copper), it follows that the total oxygen required to inactivate the amount of enzyme equivalent to one γ of copper, in this case, is about 1.7×10^4 cu. mm. This value is approximately one-half of 3.3×10^4 cu. mm., the corresponding value for the enzyme from *Psalliota campestris*.

This inactivation of tyrosinase resulting when the enzyme catalyzes the oxidation of catechol has been ascribed by several workers[7,8] to the *o*-benzoquinone formed in the oxidation of the catechol. The fact that the inactivation persists when the reaction is allowed to take place in the presence of sodium benzenesulfinate is an argument against this view. Bordner and Nelson[9] have shown that sodium benzenesulfinate combines almost quantitatively with *o*-benzoquinone, thereby rendering the latter inactive.

Further evidence that *o*-benzoquinone does not

All the tyrosinase preparations mentioned in Part A were obtained from the common mushroom, *Psalliota campestris* The fresh mushrooms were ground in a meat grinder, and the ground pulp frozen. The frozen material was then placed in an equal volume of water and allowed to stand overnight to thaw out. The material was then filtered, the residue pressed dry in a hydraulic press and the pressed juice and filtrate combined. The latter was treated with an equal volume of cold acetone, the precipitate filtered off, dissolved in water and made 0.6 saturated with ammonium sulfate. The precipitate from the ammonium sulfate treatment was redissolved in water and made *p*H 4.8 by adding 2% trichloroacetic acid. The precipitate thus obtained was centrifuged off, discarded and the supernatant liquid remaining was brought to *p*H 7 by means of dilute ammonium hydroxide. The solution thus obtained was treated with just enough alumina to adsorb about 15% of the enzyme together with some of the accompanying impurities. After filtering off the alumina, the filtrate remaining was made 0.6 saturated with ammonium sulfate, the precipitate formed filtered off and redissolved in a small amount of water and dialyzed against glass-distilled water. The dialyzed solution contained preparation C101A. The greater portion of the solution containing preparation C101A was treated with enough alumina to adsorb the enzyme completely. The enzyme was eluted from the alumina by means of disodium phosphate, filtered and the solution concentrated by making it 0.6 saturated with ammonium sulfate, filtering off the precipitate, redissolving in a small amount of water and dialyzing against glass-distilled water. The solution thus prepared contained preparation C101B. The major portion of the latter solution was adjusted to *p*H 7.4 by 0.1 *M* ammonium hydroxide, treated with a small amount of recently prepared tricalcium phosphate and filtered. The filtrate, which contained most of the enzyme, was made 0.4 saturated with ammonium sulfate, the precipitate obtained dissolved in water and the *p*H adjusted to 6.5 by 0.1 *M* ammonium hydroxide. The enzyme in the latter solution was adsorbed to alumina, eluted with disodium phosphate and dialyzed. The solution thus obtained contained preparation C101C. The tyrosinase in a portion of the solution containing the preparation C101C was adsorbed to alumina, eluted with disodium phosphate and the solution obtained made 0.3 saturated with ammonium sulfate. The precipitate obtained was dissolved in water and dialyzed. This solution contained preparation C101D. The filtrate remaining after the treatment of the solution from which preparation C101D was obtained, with 0.3 saturated ammonium sulfate still contained considerable enzyme which was not precipitated under those conditions. This portion of the tyrosinase was precipitated by making the above mentioned filtrate 0.4 saturated with ammonium sulfate. The precipitate thus obtained was dissolved in water, dialyzed and the resulting solution contained preparation C101E. Preparations C95, C100, C102 and C106 were obtained from different lots of mushrooms (*Psalliota campestris*), and were purified by procedures similar to those described above. Preparations C94, C96 and C97 were also from *Psalliota campestris* but only partly purified.

exert a destructive effect on tyrosinase is shown by the data represented graphically in Fig. 2. In one of these experiments (curve II) the enzyme was allowed to react with only a fraction of the amount of catechol necessary to inactivate it completely. The active enzyme remaining after the oxidation of this initial addition of catechol was shaken in the Warburg apparatus for forty minutes in the presence of the *o*-benzoquinone previously formed, and then an excess of catechol was added to the reaction vessel, whereupon further consumption of oxygen occurred. The total oxygen uptake was found to be the same as in the case of the control (curve I) in which the enzyme was allowed to react on an excess of catechol at the start.

The inactivation of tyrosinase in the presence of an excess of catechol is not influenced by the rate at which the catechol is oxidized, hence the length of time at which the enzyme is exposed to the reaction mixture is without effect on its activity. This fact is brought out by comparing the oxygen uptakes necessary for inactivation when the oxidation took place rapidly in the pres-

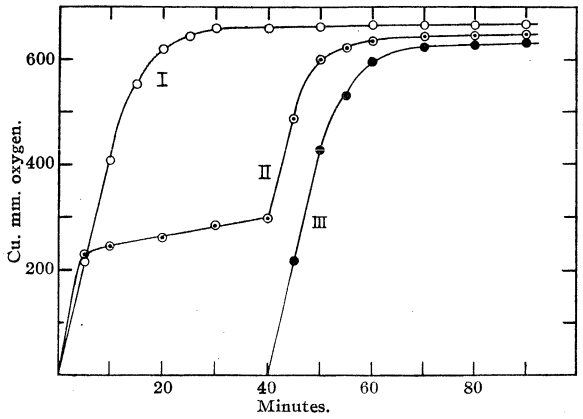

Fig. 2.—Showing that the products of the enzymatic oxidation of catechol are without destructive effect on the enzyme. Warburg respirometer, 25°. Reaction mixture: 2 cc. of tyrosinase solution (8 units), 3 cc. of 0.2 *M* phosphate buffer (final *p*H 4.3), 1 cc. of 0.5% gelatin (5 mg.) solution and 1.5 cc. of water. Final volume was 8 cc. The catechol (7.5 mg.) was added from a side-arm in experiment (curve I) at zero time; in experiment (curve III) the same amount of catechol was added after the rest of the reaction mixture had been shaken in the Warburg flask for forty minutes; in experiment (curve II) the catechol was added in two portions, one portion (2.25 mg.) was introduced at zero time by means of a "dangling tube" (Dixon[9]) and the remainder (5.25 mg.) from the side-arm after the expiration of forty minutes. At completion of the experiments further addition of catechol brought about no more oxygen uptake, showing the tyrosinase to be inactive. Tyrosinase from *Psalliota campestris* was used in the above experiment. A low *p*H was used because *o*-benzoquinone is less fugitive in acid solutions.[10]

ence of 100% oxygen and when the rate was slow in the presence of 2% oxygen and 98% nitrogen (curves II and IV, Fig. 1). Permitting the tyrosinase to remain in contact with the catechol and the other components of the reaction mixture, but in the absence of oxygen, had no inactivating effect on the enzyme. This fact is shown by Curve V, Fig. 1, which represents an experiment in which the enzyme was introduced into the reaction mixture in the absence of oxygen. After the expiration of forty minutes a mixture of 2% oxygen and 98% nitrogen was introduced and the oxygen uptake measured.

The data given in Table II show that using the amount of oxygen consumed in the inactivation of a given amount of enzyme as a measure, the inactivation is independent of the hydrogen-ion concentration between *p*H 5 and 7.5.

The temperature at which the inactivation is permitted to take place does, however, influence the amount of oxygen uptake required to bring about complete inactivation. At 25° the oxygen uptake, as already stated, is 100 ± 5 cu. mm. per unit for tyrosinase from *Psalliota campestris*. At 35° this value drops to about 80 cu. mm. of oxygen.

TABLE II

SHOWING THE INFLUENCE OF *p*H ON THE TOTAL OXYGEN CONSUMPTION PER UNIT OF CATECHOLASE (*Psalliota campestris*) INACTIVATED, WHEN THE LATTER WAS PERMITTED TO ACT ON AN EXCESS OF CATECHOL

Warburg respirometer; temp. 25°; reaction mixture: 1 cc. tyrosinase solution (4 units); 1 cc. gelatin solution (5 mg.); 3 cc. 0.2 *M* phosphate buffer solution (except for the first two in which phosphate–citrate was used); sufficient water to make final volume 8 cc.; 1 cc. catechol solution (4 mg.) added from the side-arm.

*p*H of reacn. mixt.	4.0	4.3	4.8	5.2	5.8
Cu. mm. O_2 per unit of enzyme inactivated	67	86	90	95	95
*p*H of reacn. mixt.	6.2	6.6	7.6	8.1	8.6
Cu. mm. O_2 per unit of enzyme inactivated	95	95	93	82	78

The oxidation of a definite amount of catechol is necessary for the complete inactivation of a given quantity of tyrosinase, irrespective of the concentration of the catechol in the reaction mixture. This was shown by oxidizing various amounts of catechol in the presence of an excess of a suitable reducing agent, such as ascorbic acid. Such a reducing agent converts the quinone as fast as it is formed to catechol, thereby maintaining a constant supply of catechol during the course of the reaction. Under these conditions it was found that although the rate of oxygen uptake was influenced by the amount of catechol present, the total oxygen consumed per unit of catecholase inactivated was independent of the concentration of catechol used, and was the same as when the enzyme was allowed to act in the presence of an excess of catechol (curves II and III, Fig. 3).

Tyrosinase from *Psalliota campestris* is incapable of catalyzing the oxidation of hydroquinone, but the latter like ascorbic acid reduces *o*-benzoquinone. Hence, through the medium of catechol, tyrosinase oxidizes ascorbic acid to dehydroascorbic acid and hydroquinone to *p*-benzoquinone. It is therefore possible to maintain a low concentration of catechol constant in the reaction mixture by means of hydroquinone, just as when ascorbic acid is used as the reductant. However, the presence of hydroquinone allows the reaction to continue for a longer time, and as a result, the total oxygen consumed before the enzyme is inactivated is much greater than that consumed when the enzyme is allowed to act in the presence of an excess of catechol (curves I and II, Fig. 3). This difference in behavior when these substances are used with catechol as the substrate makes it apparent that whereas both

function as reductants of *o*-benzoquinone and tend to keep the supply of catechol constant, hydroquinone, in addition, exerts a protective influence on the tyrosinase.

In order to gain further information concerning the nature of the protective action on the enzyme exhibited by hydroquinone under these conditions, a study was made of the effect of varying the ratio of hydroquinone to catechol on the rate of oxygen uptake and on the total amount of oxygen consumed during the inactivation of the enzyme. Using a constant concentration of catechol in the reaction mixture, it was found that the rate of oxygen uptake was practically independent of the amount of hydroquinone present. On the other hand, the total volume of oxygen consumed per unit of catecholase inactivated was found to increase with increasing amounts of hydroquinone.

Additional evidence has been obtained which suggests that the protective action shown by the hydroquinone might be due to a tendency of this substance to combine with the enzyme. It was found that benzoic acid, when added to the reaction mixture in concentrations equal approximately to that of the catechol used, produced a marked inhibitory effect on the rate of oxygen uptake. Yet the total oxygen uptake consumed per unit of catecholase inactivated was unchanged. This inhibition due to benzoic acid can be seen by comparing curves II and III with curves IV and V, respectively, in Fig. 3. Furthermore, upon adding to the reaction mixture a sufficient quantity of benzoic acid (*p*H adjusted to 7) to inhibit completely the enzymic action, and subsequently subjecting the reaction mixture to dialysis, it was found that the enzyme, dialyzed free of benzoic acid, had regained all of its original activity.

The behavior of the benzoic acid toward the tyrosinase–catechol reaction suggests that tyrosinase exerts its catalytic action by first combining with the substrate to form a complex, this combination being of such a nature that it is reactive toward molecular oxygen. In such a mechanism, benzoic acid acts as an inhibitor simply by competing with the substrate for the space available at the active enzyme center.

Only compounds of certain molecular configuration are capable of combining with the enzyme, the tendency being dependent on the molecular structure. Of those substances which can combine with the enzyme, only a few are capable of becoming activated sufficiently so that they are

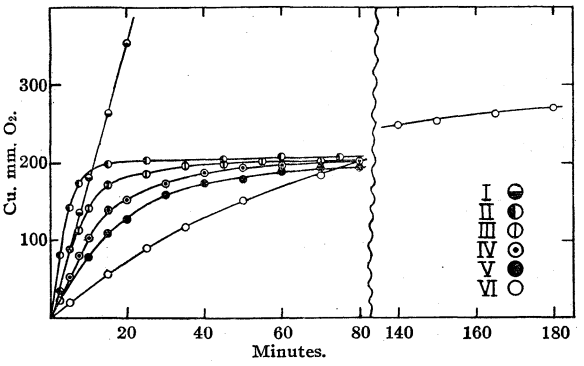

Fig. 3.—Showing the effects of ascorbic acid, hydroquinone, *p*-cresol and benzoic acid on the inactivation of tyrosinase. Tyrosinase prepared from *Psalliota campestris*. Temp. 25°, Barcroft respirometer (Dixon[3]). Curve II: inactivation of enzyme in the presence of an excess of catechol. Reaction mixture was 3 cc. of 0.2 *M* phosphate buffer (final *p*H 7.0), 1 cc. of gelatin (5 mg.), 1 cc. of tyrosinase solution (2 catecholase units), sufficient water to make final volume 8 cc. and 1 cc. of catechol solution (4 mg.) in side-arm. Curve III, showing that ascorbic acid only reduces the *o*-benzoquinone back to catechol without influencing the amount of oxygen uptake required for inactivation. Reaction mixture was same as for expt. II except a 1.5 cc. of solution containing 0.1 mg. of catechol and 5 mg. of ascorbic acid in side-arm. Curve I, showing the difference in effect on the reaction when hydroquinone is used in place of ascorbic acid as in expt. III. Reaction mixture same as for expt. III except 5 mg. of hydroquinone in place of the 5 mg. of ascorbic acid. Curve IV shows the inhibiting influence of benzoic acid on the oxidation of catechol by tyrosinase. Reaction mixture was same as for expt. II except that the reaction flask contained in addition 1 cc. of 0.1 *M* sodium benzoate. Curve V, showing the inhibiting influence of benzoic acid on the oxidation of catechol in the presence of ascorbic acid. Reaction mixture was the same as for expt. III except that reaction flask contained in addition 1 cc. of 0.002 *M* sodium benzoate. Curve VI, showing the protective action against the inactivation of the enzyme by *p*-cresol. Reaction mixture was same as for expt. II except 1 cc. of a solution containing 4 mg. *p*-cresol and 0.1 mg. catechol in side-arm. In all experiments the contents of the side arm were transferred to the main reaction vessel at zero time, when the mixture had attained the temperature of the thermostat. The control flasks in each experiment contained the same reaction mixture except that water replaced the enzyme solution.

oxidized by the oxygen which also takes part in the complex. On this basis the difference in effect manifested by ascorbic acid, *p*-cresol, benzoic acid and hydroquinone on the tyrosinase–catechol reaction becomes clear. Ascorbic acid does not have a suitable configuration to permit it to combine with the enzyme molecule; hence when it is added to the tyrosinase–catechol reaction mixture, it behaves simply as a reductant of the *o*-quinone. On the other hand, according to some observations of Gregg (unpublished) *p*-cresol combines more readily with tyrosinase (*Psalliota campestris*) than does catechol. When the latter is added to a reaction mixture containing the enzyme and an equal amount of the cresol, the course of the reaction is practically the same as if no catechol[11] had been added. Benzoic acid

(11) Except the trace necessary to remove the initial lag period occurring in the enzyme oxidation of the *p*-cresol.

seems to combine with the enzyme to about the same extent as catechol, but is not sufficiently activated by the enzyme to become oxidized. Hydroquinone also combines with tyrosinase and like benzoic acid is not activated sufficiently, when combined with the enzyme, to become oxidized. Unlike benzoic acid, however, it resembles ascorbic acid, as has been mentioned above, in that it acts as a reductant toward *o*-benzoquinone. The protective action of the hydroquinone on the activity of tyrosinase may also be due to its tendency to combine with the enzyme. *p*-Cresol also tends to protect tyrosinase, as is shown by curve VI in Fig. 3, and it, too, as has been pointed out, seems to have a strong tendency to combine with the enzyme. The inactivation of the enzyme takes place in the process of the reaction and is not due to the reactants nor to the reaction products present in the reaction.

One substance which might be suspected of inactivating the enzyme in the tyrosinase–catechol reaction is hydrogen peroxide. The latter is known to inactivate many enzymes. Dawson and Ludwig,[10] however, were unable to detect any formation of peroxide in this reaction, and reached the conclusion that if it is formed it must be used up in performing some intermediary function at a rate faster than its rate of formation. Therefore, if hydrogen peroxide, or some activated form of oxygen, is responsible for the inactivation, the inactivation must occur during the process of the oxidation of the catechol. As a matter of fact, in the light of our present knowledge, the cause of the inactivation of tyrosinase, when it catalyzes the oxidation of catechol, is still unknown.

Summary

It has been found when tyrosinase, from *Psalliota campestris*, is inactivated in the oxidation of catechol, that:

1. The inactivation, at 25°, involves a constant uptake of oxygen: 100 ± 5 cu. mm. per unit of enzyme, or 3.3×10^4 cu. mm. per γ of copper.

2. This amount of oxygen is independent of: (a) the rate of oxidation of the catechol; (b) the concentration of oxygen; (c) the hydrogen-ion concentration between *p*H 5 and 7.5; (d) the ratio of catecholase activity to cresolase activity; (e) but is dependent on temperature.

3. The inactivation is not due to any products, known to be formed, in the oxidation of the catechol, but occurs at the time the catechol is oxidized.

4. Tyrosinase from different sources consumes different amounts of oxygen per unit of catecholase inactivated. The total oxygen consumed in the inactivation of purified preparations from *Lactarius piperatus*, at 25°, is 400 ± 15 cu. mm. per unit or 1.7×10^4 cu. mm. per γ of copper.

5. Hydroquinone, when used in excess with low concentration of catechol, besides serving as a reductant of *o*-benzoquinone, exerts a protective influence against inactivation of the enzyme. Ascorbic acid, also a reductant toward *o*-benzoquinone, exerts no protective influence.

6. Benzoic acid exerts a retarding influence on the activity of the enzyme toward catechol, but has no protective action.

Oxidation of 1,2-Glycols or 1,2,3-Polyalcohols by Means of Lead Tetraacetate in Aqueous Solution

BY ERICH BAER, J. M. GROSHEINTZ AND HERMANN O. L. FISCHER

Criegee[1] found that lead tetraacetate oxidizes 1,2-glycols by breaking the bond between the hydroxyl-carrying carbon atoms, thereby forming aldehydes and ketones. This cleavage reaction takes place quantitatively at room temperature; its velocity depends greatly on the structure of the glycol and the *solvent* in which the reaction takes place. The method has found extensive application both in analytical and preparative procedures. The discoverer contended that non-aqueous solvents only can be used, *e. g.*, benzene, nitrobenzene, chloroform, di- and tetrachlorethane or glacial acetic acid. Considerable emphasis was placed on the drying of such solvents.

The same oxidative cleavage of glycols can be carried out in aqueous solution with periodic acid according to Malaprade.[2] This method is very suitable for the titration of glycols, and frequently has been used whenever it is desirable to work in water.

One of us (E. B.) observed that, contrary to prevailing views, the glycol cleavage with lead tetraacetate also may be carried out in moist organic solvents and even in aqueous solution, if the velocity of oxidation be higher than that of the hydrolysis of the oxidizing agent. Since the lead is easily removed quantitatively by dilute sulfuric acid, we believe that this modification will greatly extend the applicability of Criegee's method of oxidative glycol cleavage.

In preliminary qualitative experiments lead tetraacetate was added to aqueous solutions of glycerol, *d*-mannitol, *d*-glucose and *d*-mannose, either as a concentrated solution in glacial acetic acid or in a finely powdered form. In both cases the aqueous solution generally remained clear. Although slight brown turbidities sometimes occurred due to local excess of the reagent, these disappeared very rapidly. The end of the reaction is indicated by the immediate formation of a permanent brown precipitate of lead oxides. These compounds contained up to six adjacent hydroxyl groups and therefore a mixture of oxidation products, giving mixed precipitates with substituted hydrazines, resulted.

In order to make a quantitative study of the oxidation with lead tetraacetate in aqueous solution we investigated the cleavage of 1,2–5,6-diacetone-*d*-mannitol and of pinacol. We chose these compounds since they possess only a single pair of vicinal hydroxyl groups and further because the oxidation of these substances (in organic solvents) is unambiguous and was already familiar to us.[3] Further, the cleavage products are easily determined quantitatively. A concentrated solution of the equivalent amount of lead tetraacetate in acetic acid was added to an aqueous solution of 1,2–5,6-diacetone-*d*-mannitol. Oxidation took place immediately and the acetone-*d*-glyceraldehyde which was formed was hydrolyzed quickly to *d*-glyceraldehyde in the presence of the dilute acetic acid. The amount of aldehyde present was equal to 99% of the theoretical yield. By oxidation of *d*-glyceraldehyde with bromine, *d*-(−)-glyceric acid was obtained in a yield of 76%. This is a convenient way of preparing *d*-(−)-glyceric acid and its derivatives. The procedure for preparing *d*-(−)-glyceric acid has been included at the end of this paper. Its antipode may be prepared similarly from *l*-glyceraldehyde[3c] recently synthesized by us.

The pinacol was oxidized in the same manner as above described and the yield of acetone was 95% of the theoretical.

The results of our quantitative studies of the oxidation of *α-glycols* with lead tetraacetate in aqueous solutions indicate that these reactions follow the same course and go as thoroughly to completion in water as in non-aqueous solvents—a finding quite unexpected in view of Criegee's insistence on the necessity of drying all solvents.

From glycols containing two hydroxyl groups we turned our attention to compounds with three adjacent hydroxyl groups. Previous experiments[4] had already shown that compounds such as

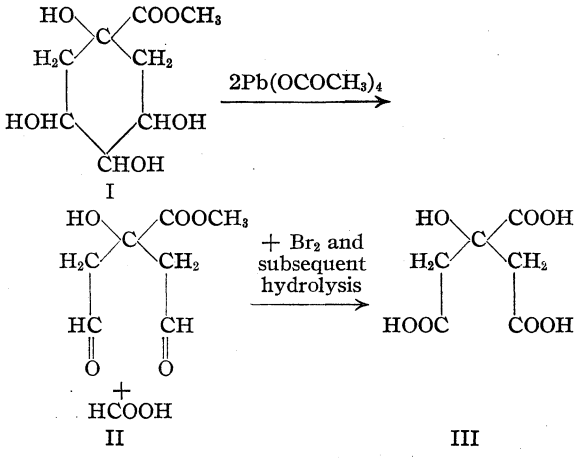
quinic acid (1 mole) and shikimic acid (1 mole) could be oxidized with periodic acid (2 moles) in aqueous solution. Dialdehydes were formed and the central carbon atom was split out as formic acid.

In order to test the usefulness of lead tetraacetate for this reaction, we studied the oxidation of the methyl ester of quinic acid and found, in agreement with our expectations, that one mole of quinic acid methyl ester (I) in aqueous solution formed one mole of dialdehyde (II) and one mole of formic acid, using up two moles of lead tetraacetate.[5]

The reaction takes place according to the equation



Titration according to the method of Willstätter and Schudel showed an amount of dialdehyde present in the aqueous solution equal to the theoretical. The dialdehyde was then oxidized by bromine to the stable citric acid (III) which was isolated in a yield of 86% of the theoretical.

Experimental

A. Glycol Cleavage

I. Lead Tetraacetate Oxidation of 1,2–5,6-Diacetone-*d*-mannitol.—A colorless solution of 4.43 g. of lead tetraacetate (0.01 mole) in 25 cc. of warm glacial acetic acid[6] was added rapidly with constant agitation to a solution of 2.63 g. of diacetone-*d*-mannitol (m. p. 121–122°)[3d] (p. 466) (0.01 mole) in 60 cc. of water. The oxidation took place instantaneously and the mixture remained perfectly clear. After a few minutes 20 cc. of 1 *N* sulfuric acid was added, and the precipitate of lead sulfate was separated by centrifuging. During this procedure the cleavage product, acetone-*d*-glyceraldehyde, hydrolyzed quickly to *d*-glyceraldehyde and acetone in the acid solution. Acetone was removed by evaporation *in vacuo* and the concentrate was made up to 50.00 cc. with distilled water (solution I). The product was not isolated at this stage. The precipitation of the 2,4-dinitrophenylhydrazone (m. p. 155–156°) and dimedone compound (m. p. 198°; $[\alpha]_D$ +198°) from the above solution confirmed our expectation that the product of the reaction would be the same (*i. e.*, *d*-glyceraldehyde) in water as in non-aqueous solvents. The yield was determined by the method of Willstätter and Schudel.[7] In three such titrations, 5.00 cc. of solution I required 39.2, 39.4 and 39.6 cc. of 0.1 *N* iodine solution, equivalent to 176, 177 and 178 mg. of aldehyde, respectively. The yield was therefore 98.8% of the theoretical.

Solution I was dextro-rotatory, $[\alpha]^{20}D$ +9.0°. We already have reported[8] the occurrence of solutions of glyceraldehyde with low specific rotation and have described a method for converting this material to a form with the characteristic maximal specific rotation of +14°.

II. Lead Tetraacetate Oxidation of Pinacol.—A colorless solution of 4.43 g. of lead tetraacetate (0.01 mole) in 30 cc. of warm glacial acetic acid was added gradually with gentle agitation to 1.18 g. of pinacol (0.01 mole) dissolved in 50 cc. of distilled water. After a few minutes[9] 5 cc. of 5 *N* sulfuric acid was added, and the precipitated lead sulfate was separated by centrifuging. A perfectly clear solution was obtained, containing only the cleavage product, acetone (0.02 mole). The solution was then made up to 100.0 cc. with distilled water and the acetone determined quantitatively by the method of Messinger.[10] Two 5.0-cc. portions of the solution required 56.8 and 57.3 cc. of 0.1 *N* iodine solution, respectively, which correspond to 55.0 and 55.4 mg. of acetone, respectively; yield, 95% of the theoretical.

B. Cleavage of 1,2,3-Polyalcohols

The oxidation of quinic acid methyl ester was carried out in two different ways with equally good results. (a) The lead tetraacetate dissolved in glacial acetic acid was added slowly to the aqueous solution of the substance to be oxidized, as described in the case of pinacol and diacetone-mannitol. (b) The aqueous solution of the substance to be oxidized was poured into a saturated solution of lead tetraacetate in glacial acetic acid. We shall describe the latter method only, since the inverted order of procedure is an interesting variation of the oxidation with lead tetraacetate in aqueous solution.

Lead Tetraacetate Oxidation of Quinic Acid Methyl Ester.—A solution of 6.18 g. of quinic acid methyl ester (0.03 mole) in 50 cc. of distilled water was poured into a mixture of 25 cc. of glacial acetic acid and 26.58 g. of lead tetraacetate (0.06 mole). The crystals of lead tetraacetate dissolved slowly as the oxidation proceeded. After ten minutes, 125 cc. of 1 *N* sulfuric acid was added, the solution was made up to 500.0 cc. and the precipitate

(5) Cases in which more lead tetraacetate is required will be described in a subsequent paper. (J. G.)

(6) The glacial acetic acid was warmed only for the purpose of dissolving the lead tetraacetate in a minimal quantity of solvent, thus keeping the ratio of water and acid as much as possible in favor of the water.

(7) Willstätter and Schudel, *Ber.*, **51**, 780 (1918).

(8) H. O. L. Fischer and E. Baer, *Helv. Chim. Acta*, **19**, 524 (1936); refs. 3b and 3c.

(9) The velocity of this reaction is much higher in aqueous solution than in organic solvents. Probably this will be the case for other compounds also.

(10) Messinger, *Ber.*, **21**, 3366 (1888).

of lead sulfate was removed by centrifuging. The dialdehyde formed was determined by titration according to Willstätter and Schudel; 25 cc. of the solution used up 61.0 cc. of 0.1 *N* iodine solution: dialdehyde calculated, 208.8 mg.; found, 211.0 mg.

For the oxidation of the dialdehyde the solution was freed from the excess of sulfuric acid by dropwise addition of barium acetate and diluted to 300 cc. with distilled water; 15 g. of bromine was added and the resulting mixture was placed in a tightly sealed bottle and allowed to stand for two days with occasional shaking. The excess bromine was removed by aeration, the hydrobromic acid formed was removed with silver acetate and the excess silver was precipitated with hydrogen sulfide. The mixture was then evaporated to dryness and the remaining citric acid monomethyl ester was saponified by boiling for half an hour with 60 cc. of 2 *N* sodium hydroxide. An amount of 1 *N* sulfuric acid (120 cc.) equivalent to the sodium hydroxide used was added and the solution evaporated to dryness under reduced pressure. The *citric acid* was separated from the sodium sulfate by extraction of the residue with ethyl acetate; 4.9 g. of crude citric acid was obtained (86% yield). Recrystallization from water yielded pure citric acid (m. p. 151°).

Preparation of *d*-(—)-glyceric acid.[11]—To an aqueous solution of *d*-glyceraldehyde prepared as described on page 2608, Col. 1, from 25 g. of diacetone-*d*-mannitol,[3d] 40 g. of bromine was added and the solution was shaken for two hours. After standing at room temperature for an additional fifteen hours, the excess bromine was removed by aeration and the bromide ions by shaking with silver carbonate or acetate. The silver ions were precipitated by hydrogen sulfide. The solution was then evaporated at 40° (10 mm.) to a dry sirup of constant weight; 15.4 g. (76% of the theoretical) of glyceric acid was obtained.

Preparation of *d*-Glyceric Acid Methyl Ester (Dextrorotatory).—Eleven grams of glyceric acid together with 250 cc. of dry methyl alcohol, containing 1.5% of hydrochloric acid (gas), was refluxed for twenty-four hours. After shaking the liquid for twelve hours with finely powdered silver carbonate, the silver salts were removed by centrifuging. The methyl alcohol was evaporated at reduced pressure and the residue was distilled *in vacuo:* yield, 11.5 g. (92% of the theoretical) of glyceric acid methyl ester; b. p. (8 mm.) 114–116°. Calculated for $C_4H_8O_4$ (120): C, 40.00; H, 6.70. Found: C, 39.96; H, 6.70. *Optical rotation* in homogeneous substance: $\alpha^{26}D$ +5.92 (1-dm. tube, d^{26}_4 1.279, $[\alpha]^{26}D$ +4.7).[12]

Preparation of the Calcium Salt of *d*-Glyceric Acid.—Eight grams of *d*-glyceric acid methyl ester was added to a solution of 2.47 g. of calcium hydroxide in 40 cc. of distilled water. After warming on the water-bath for one hour, the solution was neutralized with a few drops of 5 *N* hydrochloric acid and filtered, while still hot. Warm ethanol was then added until the clear and hot solution became turbid and the mixture was allowed to cool in the refrigerator; 8.0 g. of calcium salt was precipitated after six hours (84% yield). Calcd. for $(C_3H_5O_4)_2Ca\cdot 2H_2O$ (286): Ca, 13.99. Found: Ca, 13.95. *Optical rotation* of the calcium salt containing 2 moles of crystal water, in aqueous solution: 1-dm. tube, c = 5.19, $\alpha^{20}D$ +0.67°, $[\alpha]^{20}D$ +12.9°.[13]

Summary

It has been shown that oxidation with lead tetraacetate can be carried out quantitatively in *aqueous* solution and in water-containing solvents. This observation that the reaction does not always require dry organic solvents enlarges the field of its application. Lead tetraacetate yields the same oxidation products in water as in organic solvents, except in rare cases where secondary hydrolytic reactions may occur.

The Nitrogen Compounds in Petroleum Distillates. XV. Counter-Current Acid Extraction of Kero Bases. Isolation of 2,4-Dimethyl-8-*n*-propylquinoline

BY W. NELSON AXE[1] AND J. R. BAILEY

Introduction

It has been reported previously[2] that a satisfactory separation of 2,3-dimethyl-8-*n*-propyl- and 2,3,4,8-tetramethylquinoline from associated bases in the 300° boiling range of kero bases was accomplished by supplementing the conventional methods of processing petroleum bases with so-called fractional degassing of their acid sulfite solution under aeration.

In Jantzen's monograph,[3] the author reports the isolation of the following products from coal tar bases (b. p. 238–266°), through employment of counter-current extraction: quinoline, each of the seven monomethylquinolines, 2,8-dimethylquinoline,[4] isoquinoline, 1- and 3-methylisoquinoline, 1,3-dimethylisoquinoline, two $C_{10}H_9N$ bases (probably 6-methyl- and 5- or 7-methylisoquino-

line, respectively), and a C_7H_5NS compound (a thioisoquinoline?). Of these sixteen products, relatively few had been encountered by previous investigators in processing coal tar bases.

Lately, through employment of counter-current extraction,[5] 2,4-dimethyl-8-ethylquinoline was obtained from the kero base fraction of b. p. 292–293°.[6]

(6) W. N. Axe, THIS JOURNAL, **61**, 1017 (1939).

We find in separation of mixtures of aromatic petroleum bases that fractional degassing of their acid sulfites, because of the simplicity in operation, can be employed to advantage frequently in their partial separation, preliminary to the use of exhaustive counter-current extraction.

This paper deals with the isolation of a $C_{14}H_{17}N$ base[2] by the extraction method and its identification as 2,4-dimethyl-8-*n*-propylquinoline through degradation and synthesis. The formation of 2,4-dimethylquinoline-8-carboxylic acid in chromic acid oxidation was confirmed by the usual comparison with an authentic sample of this preparation.[6] This showed the original base to be an 8-*n*- or isopropyl homolog of 2,4-dimethylquinoline. The *n*-propyl derivative was synthesized from acetyl acetone and *o*-amino-*n*-propylbenzene[2] and was proved to be the $C_{14}H_{17}N$ kero base.

Experimental

The preliminary work carried out for assembling the 292–293° fraction of aromatic base, known to contain the $C_{14}H_{17}N$ quinoline homolog, has been published previously.[2]

Prior to counter-current extractions, the base mixture was processed through acid sulfites to yield 10% of 2,3-dimethyl-8-ethylquinoline.[7]

Figure 1 shows the construction of the unit employed in counter-current extraction. The bases are dissolved in petroleum ether in the volume ratio of 1:2. Enough 2 *N* hydrochloric acid is used for the partial neutralization of the bases and the acid is diluted to a volume equal to that of the petroleum ether solution of bases. The final concentration of the acid in all extractions was close to 1.5 *N*. The bases are fed in at the bottom of the column through F and the acid above the column through G, an approximately equal flow-rate of the two solutions being maintained through stopcock control of the proportioning ratio. The maximum throughput without reducing contact efficiency is around 80 cc. of bases per hour. Thorough interdispersion of the acid and base solutions is accomplished by operating the stirrer at the maximum speed allowable without producing emulsions. At the end of the extraction, the petroleum ether solution containing Base Fraction I is run off through H. From their hydrochlorides collected in D, the bases are recovered and carried through a second partial extraction to yield Base Fraction II. Table 1 summarizes the final results from a repetition of the above procedure so as to obtain a total of seven fractions.

To effect separation of the component bases, the separate fractions were processed as follows: (1) picration was carried out in hot acetone; (2) the acetone-insoluble picrates were recrystallized from glacial acetic acid; (3) the acetone-soluble picrates were recrystallized from alcohol, followed by liberation of the bases from the alcohol-insoluble salts; (4) the bases obtained from the

[a] In this paper, the abbreviations Me_2, Et, Pr and Q denote dimethyl, ethyl, propyl and quinoline, respectively. In this and subsequent tables, *yield* applies to the volume of base in each fraction.

picrates in (3) were dissolved in dilute hydrochloric acid and converted to zinc chloride salts, with subsequent recrystallization from a dilute zinc chloride–hydrochloric acid solution. Step 2 in several fractions yielded 2,3-dimethyl-8-ethyl- and 2,3-dimethyl-8-*n*-propylquinoline. 2,4-Dimethyl-8-*n*-propylquinoline was encountered in Step 4 in processing fractions 3 and 4.

Characterization and Proof of Structure of the $C_{14}H_{17}N$ Base as 2,4-Dimethyl-8-*n*-propylquinoline

Zinc Chloride Salt.—This salt crystallizes in lustrous oblique parallelograms melting at 225–226°.

Anal. Calcd. for $(C_{14}H_{17}N\cdot HCl)_2\cdot ZnCl_2$: C, 55.33; H, 5.96; Cl, 23.34. Found: C, 55.14; H, 6.08; Cl, 23.12.

Free Base.—Prepared from the zinc chloride salt, the base is a colorless, viscous liquid with the following constants: b. p. 298° (747 mm.); $n^{25}D$ 1.5748; d^{20}_4 0.9992.

Anal. Calcd. for $C_{14}H_{17}N$: C, 84.42; H, 8.54. Found: C, 84.71; H, 8.56.

Phthalone.—On heating the base and phthalic anhydride at 200° for four hours, an orange yellow phthalone is formed which, after recrystallization from alcohol, melts at 198–199°.

Anal. Calcd. for $C_{22}H_{19}O_2N$: C, 80.21; H, 5.81. Found: C, 80.15; H, 5.90.

2,4-Dimethylquinoline-8-carboxylic Acid.—To a boiling solution of 5 g. of base in 6 *N* sulfuric acid is added slowly 15 g. of potassium dichromate in 12 cc. of concentrated sulfuric acid diluted with 25 cc. of water. The oxidation is complete in one hour and the carboxylic acid melting at 241–242° can be isolated in a yield of 45%.[2] This product, like an authentic sample of 2,4-dimethylquinoline-8-carboxylic acid, crystallizes from alcohol in long, slender needles melting at 241–242°. A mixed melting point of the two preparations showed no depression. This degradation product established a 2,4-dimethyl-8-*n*- or isopropyl structure for the original base.

Anal. Calcd. for $C_{12}H_{11}O_2N$: C, 71.64; H, 5.47. Found: C, 71.38; H, 5.44.

2,4-Dimethylquinoline.—Soda-lime distillation of the above carboxylic acid gives a liquid base, the picrate of which crystallizes from alcohol in long needles, melting at 194°. This salt was recognized as the suspected 2,4-dimethylquinoline picrate by the exceptional property of a rapid color change from bright yellow to brown on exposure to sunlight. Further confirmation of structure was obtained by the usual mixed melting point method.

Anal. of picrate. Calcd. for $C_{17}H_{14}O_7N_4$: C, 52.85; H, 3.64. Found: C, 52.92; H, 3.75.

Synthesis of 2,4-Dimethyl-8-*n*-propylquinoline.—Synthesis of the base from ortho-*n*-propylaniline[2] and acetylacetone[8] was confirmed by the same melting point for the individual and mixed picrates of the synthetic base and the kero base.

As a comparative study of the effectiveness of countercurrent extraction and degassing of acid sulfites in separation of 2,3-dimethyl-8-*n*-propylquinoline and 2,3,4,8-tetramethylquinoline,[9] the data in Tables II and III are submitted.

Summary

This paper deals with the isolation through counter-current hydrochloric acid extraction of a new kero base, 2,4-dimethyl-8-*n*-propylquinoline, the structure of which was established by chromic acid oxidation to a $C_{11}H_{10}NCOOH$ acid, previously obtained in the Texas Laboratory by a similar oxidation of the kero base, 2,4,8-trimethylquinoline. This orientation was confirmed by synthesis, in which acetylacetone and *o*-*n*-propylaniline were the intermediates.

The Nitrogen Compounds in Petroleum Distillates. XVI. Use of Multiple Acid Extraction in Isolation of 2,3,4-Trimethyl-8-ethylquinoline

BY RICHARD A. GLENN AND J. R. BAILEY

Introduction

In a systematic investigation in the Texas Laboratory of kero quinoline homologs from crude bases furnished by the Union Oil Company of California, the 310° fraction was processed through cumulative extraction[1] in order to segregate the aromatic components in satisfactory concentration. In further refining, the latter material in the 305–315° range was processed through multiple acid-extraction.[2]

This method of separation yielded a $C_{14}H_{17}N$ base which degradation and synthesis revealed as 2,3,4-trimethyl-8-ethylquinoline. In chromic acid oxidation a $C_{12}H_{12}NCOOH$ acid was obtained which proved the replacement of an *ethyl* by *carboxyl*. The 8-position of the ethyl follows from the fact that the acid was identical with one previously obtained by chromic acid oxidation of 2,3,4,8-tetramethylquinoline.[3] Its structure was confirmed by synthesis from methylacetylacetone and *o*-aminoethylbenzene.[4]

Experimental

In carrying out multiple acid-extraction with 4000 cc. of aromatic bases in the 305–315° range, the procedure charted by Morton[5] was followed. By this method the bases were resolved into ten fractions of varying volume. Next, separate fractions were carried through one fractional distillation. The physical constants, including boiling point, density and refractivity, of each of the 95 distillation cuts were determined for comparative purposes.

In the present work only fractions IX 14, IX 15, X 12 and X 13, in the 314–319° range, were of interest, because lower boiling fractions had been investigated previously. From all of this material on picration in alcohol, crystalline salts, free of smears, separated. However, in further purification, the four fractions were combined and carried through counter current extraction using the equipment described in the preceding paper by Axe and Bailey.[6]

TABLE I

COUNTER CURRENT EXTRACTION DATA

Cut	Volume, cc.	$n^{25}D$	d^{25}_4
1	22	1.5841	1.0174
2	36	1.5878	1.0237
3	21	1.5888	1.0277
4	30	1.5920	1.0386

Isolation of 2,3,4-Trimethyl-8-ethylquinoline.—From Fractions 1, 2 and 3, this base[7] was separated as the picrate which after four recrystallizations from 60% acetic acid was obtained in lemon-colored, long rectangular microscopic plates, melting at 216° without decomposition. This salt is readily soluble in glacial acetic acid but only sparingly soluble in other common solvents.

Anal. Calcd. for $C_{20}H_{20}O_7N_4$: C, 56.07; H, 4.71; N, 13.08. Found: C, 56.00; H, 4.51; N, 13.11.

Free Base.—The base was liberated from the picrate and recrystallized from methyl alcohol in ill-defined microscopic plates. The following constants were determined: m. p. 52.5–53.0°; b. p. 320°; $n^{54}D$ 1.5798. Methyl alcohol has proved a selective solvent in recrystallization of 2,3,4-trimethyl kero quinolines alkylated at position 8.[3]

Anal. Calcd. for $C_{14}H_{17}N$: C, 84.42; H, 8.54; N, 7.03. Found: C, 84.23; H, 8.29; N, 7.19.

2,3,4-Trimethylquinoline-8-carboxylic Acid.—To a boiling solution of 1 g. of the base in 6 *N* sulfuric acid, a mixture of 2.5 g. of potassium dichromate, 3.8 g. of sulfuric acid and 4.2 g. of water is added slowly. The reaction is complete in twelve hours. The solution is cooled, made alkaline with ammonium hydroxide, acidified with acetic acid and extracted with chloroform. The acid crystallizes from alcohol in needles melting at 233.5–234.0°. A mixed

(7) None of the base was found in Fraction 4, but here 24 g. of the crude picrate of 2,3,4,8-tetramethylquinoline was encountered (Axe and Bailey, reference 3).

melting point determination with an authentic sample of 2,3,4-trimethylquinoline-8-carboxylic acid[3] showed no depression.

Anal. Calcd. for $C_{13}H_{13}O_2N$: C, 72.04; H, 6.11; N, 6.51. Found: C, 72.03; H, 5.87; N, 6.72.

Phthalone.—Molar amounts of phthalic anhydride and base are heated together for four hours at 190°. The melt is recrystallized from 70% acetic acid in yellow microscopic plates melting at 253°.

Anal. Calcd. for $C_{22}H_{19}O_2N$: C, 80.24; H, 5.77; N, 4.26. Found: C, 80.01; H, 5.48; N, 4.31.

Nitrate.—Concentrated nitric acid added to an alcohol or ether solution of the base precipitates the nitrate which recrystallizes from alcohol in tetragonal truncated pyramids, melting with decomposition at 159.5–160.0°.

Anal. Calcd. for $C_{14}H_{17}N\cdot HNO_3$: C, 64.10; H, 6.91; N, 10.69. Found: C, 64.33; H, 6.96; N, 10.51.

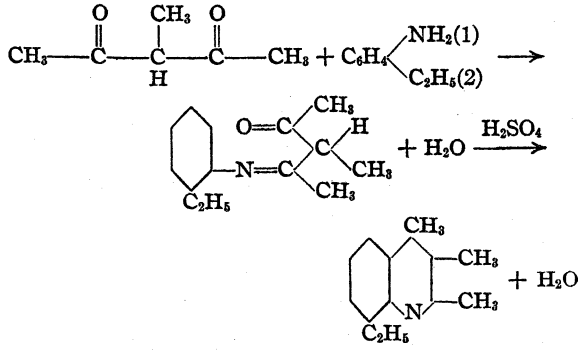
Acid Sulfate.—On addition of concentrated sulfuric acid to an alcohol or acetone solution of the free base, the acid sulfate precipitates and recrystallizes from water in microscopic fan-like needles melting without decomposition at 245–246°.

Anal. Calcd. for $C_{14}H_{17}N\cdot H_2SO_4$: SO_4, 32.32. Found: SO_4, 32.26.

Hydrochloride.—This salt is prepared by passing hydrogen chloride into an ether solution of the base. It crystallizes difficultly from acetone in fan-like microscopic needles, melting without decomposition at 203–204°.

Anal. Calcd. for $C_{14}H_{17}N\cdot HCl$: Cl, 15.05. Found: Cl, 15.25.

Synthesis of 2,3,4-Trimethyl-8-ethylquinoline.—As outlined below, methylacetylacetone[8] is condensed in two steps[9] with *o*-aminoethylbenzene.[10] A mixed melt of the purified synthetic base and the kero base gave no depression.



It is of interest to note that the spread in refractive index and in density obtained by multiple acid extraction compares favorably with that obtained by Axe[6] in counter-current extraction of a lower boiling base fraction. However, it may be emphasized that multiple acid extraction, unlike counter-current extraction, admits of a minimum of supervision and the processing of large quantities of bases in one operation.

Summary

This paper deals with multiple acid extraction in the isolation of a new $C_{14}H_{17}N$ kero base, 2,3,4-trimethyl-8-ethylquinoline. Its structure has been established by chromic acid oxidation to a $C_{12}H_{12}NCOOH$ acid, identical with the acid Axe and Bailey reported from a similar oxidation of 2,3,4,8-tetramethylquinoline. This structure was confirmed through synthesis of the base from methylacetylacetone and *o*-ethylaniline.

The Nitrogen Compounds in Petroleum Distillates. XVII. The Use of Multiple Acid Extraction in Isolation of 2,3,4-Trimethyl-8-*n*-propylquinoline

BY LESLIE M. SCHENCK AND J. R. BAILEY

Introduction

In multiple extraction of a pyrolysis distillate from transformer oil bases, furnished by the Union Oil Company of California, a new $C_{15}H_{19}N$ base, b. p. 330°, was isolated in the form of the picrate. To determine whether a *pyrolysis* or a *preformed* product was involved, a search was made for this particular base among the *aromatic* kero bases in the 320–330° range. Multiple extraction was also employed here, and the $C_{15}H_{19}N$ base was encountered in greatly increased yield, due probably to its presence in very small amount in high-boiling transformer oil bases.

The $C_{15}H_{19}N$ compound on chromic acid oxidation was converted to a $C_{12}H_{12}NCOOH$ acid which proved identical with the oxidation product of both 2,3,4,8-tetramethylquinoline[1] and 2,3,4-trimethyl-8-ethylquinoline.[2] In this way orientation of the base as a 2,3,4-trimethyl-8-propylquinoline was established. In determining the

(2) See preceding paper by Glenn and Bailey, THIS JOURNAL, **61**, 2612 (1939).

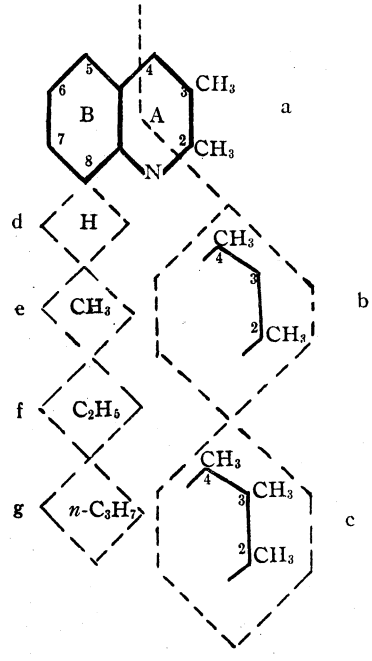
nature of the propyl group it was necessary to supplement degradation by synthesis. Accordingly, in anticipation of an *n*- and not an isopropyl, a Combes synthesis[3] with the intermediates methylacetylacetone and *o*-*n*-propylaniline was carried out. The product obtained proved identical with the kero base.

The subjoined diagram shows an interesting relationship between eleven of the twelve quinoline homologs so far isolated from California petroleum. The base not included is 2,8-dimethylquinoline. A futile search was made for 2,3,4-trimethylquinoline.[4,5] With this exception, the recent discovery of 2,3,4-trimethyl-8-ethylquinoline and 2,3,4-trimethyl-8-*n*-propylquinoline completes the series.

DIAGRAM I

TWELVE QUINOLINE HOMOLOGS OCCURRING IN STRAIGHT-RUN DISTILLATES OF CALIFORNIA PETROLEUM

A and B refer to the Py- and Bz-nuclei, respectively.
Aa, Ab and Ac show variation in methylation in the Py-nucleus.
Bd, Be, Bf and Bg show the substituent, if any, at position 8.
2,3,4-Trimethylquinoline (AcBd) has not been found.
2,8-Dimethylquinoline, a known kero base, is omitted.



Experimental

Our limited supply of pyrolyzed transformer oil bases (600 cc.) was carried through cumulative extraction,[6] followed by exhaustive fractional distillation. Fractions over a boiling range of 240–360° were obtained. Several multiple acid extractions[7] of each fraction yielded on picration small quantities of several known bases previously isolated in this Laboratory. After recombinations in the order of *n*-values of the extraction fractions in the 340° range, cumulative extraction and counter current extraction yielded in the first fraction (Table I) only 100 mg. of 2,3,4-trimethyl-8-*n*-propylquinoline.

TABLE I

BASE FRACTIONS FROM COUNTER CURRENT EXTRACTION

Fraction	$n^{25}D$	Vol., cc.
1	1.6143	4
2	1.6195	5
3	1.6154	8

Since the meager amount of the new base obtained above was insufficient for even a complete analysis, 13.5 liters of kero bases with $n^{20}D$ 1.5698 and b. p. 320–330° were cumulatively extracted and an aromatic fraction, 3.7 liters with $n^{20}D$ 1.5841, was obtained. Below are tabulated the results obtained in processing this material through multiple acid extraction.

TABLE II

FRACTIONAL ACID EXTRACTION

Fraction	B. p., °C.	Volume, cc.	$n^{20}D$
1	317	705	1.5760
2	319	715	1.5794
3	322	713	1.5829
4	323	711	1.5853
5	323	740	1.5890

Picrates were prepared in alcohol from 100 cc. of no. 5. Three 80-g. batches of crystalline salts were obtained. For purification, the picrates were converted to nitrates and acid sulfates with recrystallization at each stage, followed by reconversion to picrates. Since only 2,3,4-trimethyl-8-ethylquinoline[2] was encountered, the search for the 8-propyl homolog was shifted to Fraction 3, Table II. This material was further processed through a second multiple extraction, the tabulated results being given in Table III.

TABLE III

SECOND MULTIPLE EXTRACTION

Fraction	B. p., °C.	Volume	$n^{20}D$

trated nitric acid in slight excess, 28 g. of nitrate separated from which the base was liberated and converted to the picrate. The picrate after digestion with benzene was changed through the liberated base to the nitrate, a *selective* salt for this base. The nitrate crystallizes from acetone–ether in long slender needles melting with decomposition at 160.1°.

Anal. Calcd. for $C_{15}H_{19}N \cdot HNO_3$; C, 65.18; H, 7.23. Found: C, 64.99; H, 7.32.

Base.—This odorless base crystallizes from methyl alcohol in fine radiating needles and has the following constants: m. p. 69–70°; b. p. 330°; $n^{70}D$ 1.5618; $n^{44}D$ 1.5731.

Anal. Calcd. for $C_{15}H_{19}N$: C, 84.45; H, 8.98; N, 6.57. Found: C, 84.62; H, 9.12; N, 6.41.

Picrate.—This salt which, with the exception of glacial acetic acid, is difficultly soluble in ordinary solvents, crystallizes from 50% acetic acid in long lemon colored hexagonal needles melting undecomposed at 211–211.5°.

Anal. Calcd. for $C_{21}H_{22}O_7N_4$: C, 57.07; H, 5.01; N, 12.66. Found: C, 56.85; H, 5.08; N, 12.45.

Acid Sulfate.—On the addition of the calculated amount of concentrated sulfuric acid to the base in acetone, this salt precipitates. It crystallizes from *t*-butyl alcohol in small irregular platelets melting without decomposition at 230.5–231°.

Anal. Calcd. for $C_{15}H_{19}N \cdot H_2SO_4$: SO_4, 30.86. Found: SO_4, 30.91.

Hydrochloride.—This hygroscopic salt separates on passing dry hydrogen chloride into an ether solution of the base. No solvent was found for its recrystallization. It forms small lustrous ill-defined crystals melting undecomposed at 221–222°.

Anal. Calcd. for $C_{15}H_{19}N \cdot HCl$: Cl, 14.23. Found: Cl, 14.59.

2,3,4-Trimethylquinoline-8-carboxylic Acid.—The base (0.44 g.) is dissolved in a sufficient amount of 12 *N* sulfuric acid to redissolve the initially precipitated acid sulfate and to the boiling solution 2.25 g. of potassium dichromate in 3 g. of concentrated sulfuric acid and 15 cc. of water is added dropwise over a period of forty minutes. The reaction mixture is made alkaline with ammonium hydroxide and then acidified with acetic acid. The chloroform extracted acid crystallizes from ethyl alcohol in long slender needles melting sharply and undecomposed at 234°; yield 0.090 g. A mixed melt of this product with an authentic sample of 2,3,4-trimethylquinoline-8-carboxylic acid[1] showed no depression.

Anal. Calcd. for $C_{13}H_{13}O_2N$: C, 72.53; H, 6.07; N 6.51. Found: C, 72.23; H, 5.89; N, 6.48.

Synthesis of the Base.—In preparation of the intermediate, *o*-*n*-propylaniline from *n*-propylbenzene,[8] the procedure of Axe and Bailey[1] was followed. Molecular amounts of this base and methylacetylacetone are condensed in two steps,[5] with a yield of about 90%. The usual melting point comparison of the kero and synthetic bases established their identity.

Summary

This paper deals with multiple acid extraction in the isolation of a new $C_{15}H_{19}N$ kero base, 2,3,4-trimethyl-8-*n*-propylquinoline. Its structure has been established by chromic acid oxidation to a $C_{12}H_{12}NCOOH$ acid identical with the acid obtained by Axe and Bailey through a similar oxidation of 2,3,4,8-tetramethylquinoline. This structure was confirmed through synthesis of the base from methylacetylacetone and *o*-*n*-propylaniline.

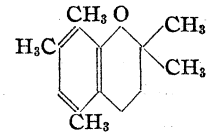
The Chemistry of Vitamin E. XVIII. Condensation of Phenols and Hydroquinones with Allylic Alcohols, Allylic Halides, and Conjugated Dienes[1]

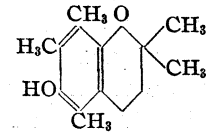
BY LEE IRVIN SMITH, HERBERT E. UNGNADE, J. R. STEVENS AND C. C. CHRISTMAN

In a previous paper[2] it was shown that isoprene could be condensed with 2,3,5-trimethylphenol to give the chroman I, and with trimethylhydroquinone to give the analogous chroman II. The same chroman, II, was obtained by condensing trimethylhydroquinone with γ,γ-dimethylallyl bromide.[3]

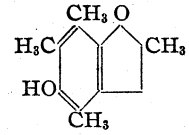
Several years ago Claisen[4] reported that allylic



I



II



III

carbinols as well as appropriate diols which gave dienes when catalytically dehydrated, would con-

dense with phenols to give chromans. This type of condensation has been modified for the preparation of α-tocopherol from trimethylhydroquinone and phytol by Bergel, Copping, Jacob, Todd and Work[5] and by us also.

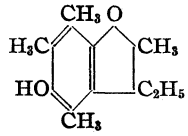
Claisen implied that when allylic carbinols and diols condensed with phenols, the first step in the reaction involved formation of the diene which then condensed with the phenol, and when it was found that phytadiene could be condensed with trimethylhydroquinone to produce α-tocopherol,[2] Claisen's mechanism appeared to offer a common explanation for the formation of tocopherols from hydroquinones and phytyl bromide, phytol or phytadiene. In harmony with this conception was the formation of the chromans I and II when either γ,γ-dimethylallyl bromide or isoprene was used.

This mechanism, however, offers some difficulties when considered in the light of known facts regarding the addition of phenols to double bonds. In the first place, allyl alcohol, bromide and chloride all condense with 2,3,5-trimethylhydroquinone to give coumaran III and it is obvious that the diene-allene- cannot be an intermediate in this case unless an unusual mode of addition of the hydroquinone is postulated. Second, in some of the reactions between conjugated dienes and phenols, hydroquinones and their derivatives, allylic phenols or their HX addition products are formed and these may be cyclized in a separate operation, giving rise to the same cyclic compound whether the reaction is carried out in one step or in two.[2,4,6] With a substituted diene such as isoprene, therefore, it is again difficult to interpret the reaction as a direct addition of the phenol to the diene without assuming an unusual mode of addition, since the intermediate is known to contain a γ,γ-dimethylallyl group.

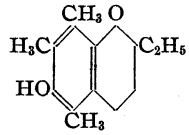
In order to reach a decision as to whether or not the diene is an intermediate, we have condensed ethylvinylcarbinol (IV) and pentadiene-1,3 (V) with trimethylhydroquinone under identical conditions. Since the diene to be expected

$CH_3CH_2CHOHCH{=}CH_2$ (IV)
$CH_3CH{=}{=}CHCH{=}CH_2$ (V)

by dehydration of IV is V, these two substances should give identical products when condensed with the hydroquinone, providing that the diene is an intermediate. Actually, however, the two products are different. Although the structures of these products have not been proved definitely, tentatively we regard the products from ethylvinylcarbinol and pentadiene as the coumaran VI and the chroman VII, respectively.

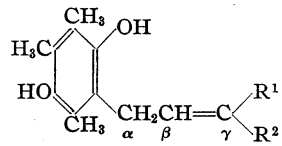


VI

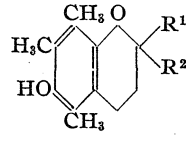


VII

Thus, the diene cannot be an intermediate in the formation of VI, and it is therefore necessary to devise some other mechanism which will account for the known products obtained in these condensations when dienes, allylic alcohols and halides are used. While such a mechanism cannot at present be stated with certainty, the following is at least in harmony with present knowledge.

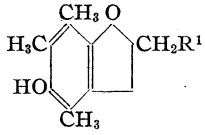


VIII

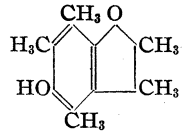


IX

(a) In the case of the halides and alcohols, the first step involves nuclear "allylation" without rearrangement. Thus a primary allylic alcohol (or halide), such as allyl alcohol or phytol (or their halides), would give the intermediate allylic phenol VIII. The second step, the cyclization, may be regarded as an addition of the phenolic hydroxyl group to the double bond, in accordance with Markownikoff's rule and hence, when R^1 and R^2 are alkyl groups, the product would be a chroman (IX); when R^1 and R^2 are hydrogen, the



X



XIII

product would be a coumaran (III); while when R^1 is alkyl and R^2 is hydrogen, the product might be either the chroman (IX) or the coumaran (X) although the former is produced in all cases which have so far been investigated.

(b) When the diene is used, the first intermediate is the 1,4-addition product of the acidic catalyst (proton), (whether the addition is really 1,4 or is 1,2 followed by rearrangement). This intermediate then "allylates" the phenol directly,

(5) Bergel, Copping, Jacob, Todd and Work, *J. Chem. Soc.*, 1382 (1938).

(6) Claisen, *Ann.*, **401**, 26 (1913); *ibid.*, **442**, 210 (1935); *Ber.*, **58**, 279 (1925).

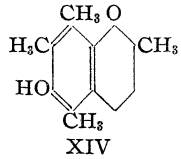
and the cyclization proceeds in a second step as outlined under (a).

Thus pentadiene-1,3 (V), isoprene, 2,3-dimethylbutadiene, phytadiene, and other similarly constituted dienes with terminal CH_2 groups (XI, R^1, R^2, R^3 = H or alkyl) all give the same products as would be obtained by using the halide or

$$R^1CH{=}C(R^2){-}C(R^3){=}CH_2 \quad (XI)$$
$$R^1CH_2C(R^2){=}C(R^3)CH_2X \quad (XII)$$

alcohol XII (R^1, R^2, R^3 = H or alkyl, X = OH or halogen). On the other hand, the secondary and probably also the tertiary allylic alcohols and halides give products different from those obtained from the related dienes and this regardless of whether the alcohols and halides are single substances or mixtures of allylic isomers, so long as one of the allylic isomers is not related to the diene as XII is to XI.

In accordance with this scheme, trimethylhydroquinone and methylvinylcarbinol give the coumaran XIII; crotyl bromide gives the chroman XIV, although the product is very difficult to purify and is probably contaminated with the isomeric coumaran (X, R = CH_3)[7] or with the coumaran XIII, derived from 3-chlorobutene-1, the allylic isomer of crotyl chloride.



XIV

In connection with this work, certain improvements in procedure have been discovered which make it possible to use the cheaper allylic chlorides instead of the bromides, and also an improved procedure for condensing the allylic alcohols with phenols and hydroquinones has been devised. The latter, applied to the condensation of trimethylhydroquinone and phytol, constitutes, we believe, the best procedure so far developed for the preparation of α-tocopherol. The yield is not only better, but the product is more readily purified than that obtained by any method so far known to us. These details are given in the experimental section.

Experimental Part

Condensations with Allylic Alcohols

2,4,6,7-Tetramethyl-5-hydroxycoumaran (II).—Trimethylhydroquinone (1 g.), allyl alcohol (1 cc.), zinc chloride (0.3 g.) and benzene (5 cc.) were sealed into a Carius tube and the mixture was heated for three and one-half hours at 200°. The product was dissolved in petroleum ether and the solution was washed with water. The organic layer was allowed to stand for a day, and then filtered. The filtrate was evaporated and the residue was steam distilled. The distillate deposited a solid (200 mg.) on cooling. After crystallization from petroleum ether, the substance melted at 127–128° and did not depress the melting point (129–130°) of a specimen made by another method.[3]

2,3,4,6,7-Pentamethyl-5-hydroxycoumaran (XIII).—Trimethylhydroquinone (1 g.), methylvinylcarbinol (1 cc.), zinc chloride (0.3 g.) and benzene (5 cc.) were heated in a Carius tube for three hours at 200°. The product was crystallized directly from petroleum ether; yield 70 mg. After repeated crystallization first from dilute ethanol and then from petroleum ether, the white substance melted at 119.5–120.5°.

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.73; H, 8.74. Found: C, 75.82; H, 8.68.

The coumaran is very soluble in 95% ethanol, somewhat soluble in aqueous ethanol, and soluble in ether and petroleum ether. It gives a positive phenol test (Folin), reduces alcoholic silver nitrate slowly, shows a positive Furter reaction, and gives a greenish-yellow color with cold concd. sulfuric acid. This color turns to orange-yellow when ferric chloride is added.

2,4,6,7-Tetramethyl-3-ethyl-5-hydroxycoumaran (VI).—Trimethylhydroquinone (2 g.), ethylvinylcarbinol (2 cc.), zinc chloride (0.6 g.) and benzene (5 cc.) were heated in a Carius tube for one hour at 150°, one hour at 150–200°, followed by one hour at 200°. The product was steam distilled and the solid in the distillate was crystallized first from petroleum ether and then from dilute methanol. The white solid melted at 88–89°; a mixture of VI and VII (m. p. 113–114°) melted at 77.5–81°.

Anal. Calcd. for $C_{14}H_{20}O_2$: C, 76.36; H, 9.09. Found: C, 76.54; H, 9.50.

The substance gives a positive phenol test (Folin) and a red color with nitric acid in absolute ethanol (Furter). It reduces alcoholic silver nitrate and gives a bright greenish-yellow color with cold concd. sulfuric acid.

2,5,7,8-Tetramethyl-2-isohexyl-6-hydroxy-chroman (?).—Trimethylhydroquinone (2 g.), geraniol (3 cc.), zinc chloride (0.6 g.) and benzene (5 cc.) were heated in a Carius tube for one hour at 150° and one hour at 200°. The product was diluted with ether and washed with water. The ether solution was filtered and the filtrate evaporated. The unsaturated chroman was extracted from the residue with petroleum ether; after removal of the petroleum ether, the chroman was taken up in methanol and reduced in the presence of a platinum oxide catalyst. The catalyst was filtered off, the solvent was evaporated, and the residue was distilled under high vacuum. The main fraction boiled at 110–115° (thermometer in the liquid) under 10^{-6} mm. Although the product was not obtained analytically pure, it showed the properties of a 6-hydroxychroman, *viz.*, positive Furter reaction, positive Folin test, yellow color with cold concd. sulfuric acid, and it reduced alcoholic silver nitrate.

2,4,6-Trimethyl-7-allyl-5-hydroxycoumaran and 2,4,6-Trimethyl-5-hydroxycoumaran.—*m*-Xylohydroquinone (5

(7) Karrer and Escher, *Helv. Chim. Acta*, **22**, 264 (1939).

g.), allyl alcohol (5 cc.), zinc chloride (1.5 g.) and benzene (10 cc.) were heated in a Carius tube at 150° for one hour and then at 200° for one hour. The product was steam distilled, but only traces of oil appeared in the distillate. The residue was an oil soluble in hot carbon tetrachloride. It brominated rapidly. It was considered to be mostly the trimethylallylcoumaran, although it was not obtained analytically pure.

α-Tocopherol.—Trimethylhydroquinone (200 g.) and fused zinc chloride (100 g.) were dissolved in acetic acid (800 cc.). The solution was refluxed gently (oil-bath temperature 125–130°) under an atmosphere of nitrogen, and with stirring phytol (400 g.) was added slowly (one hour). After refluxing for two hours longer, the mixture was poured over ice (several kilograms) and extracted with ether several times. The ether layer was washed with dilute potassium hydroxide several times, then with water, and dried over sodium sulfate. The ether was removed in an atmosphere of nitrogen, and the residue refluxed for an hour with a solution of potassium hydroxide (40 g.) in methanol (2000 cc.). The solution was poured over ice and worked up as before; then the treatment with alcoholic potassium hydroxide was repeated twice more. The concentrate (470 g.) finally was degassed and then distilled in a molecular still. A small amount (5–10%) of low boiling material came over first, followed by the tocopherol at 145–150°. The distillate was dissolved in petroleum ether (5 volumes) and stirred, in the presence of nitrogen, with an equal weight of aluminum oxide. The suspension was filtered and the filtrate distilled as before. The distillate had a pale yellow color and its absorption spectrum was identical with that of natural α-tocopherol.

Condensation with Dienes

2-Ethyl-5,7,8-trimethyl-6-hydroxychroman (VII).—Trimethylhydroquinone (2.74 g.), pentadiene-1,3 (1.23 g.), zinc chloride (0.3 g.) and sulfuric acid (1 drop) were refluxed in acetic acid (30 cc.) for an hour. The product was poured into water and the solid removed and crystallized several times from petroleum ether. It melted at 115–116°; mixed with VI, m. p. 77.5–81°.

Anal. Calcd. for $C_{14}H_{20}O_2$: C, 76.36; H, 9.1. Found: C, 76.06; H 9.11.

The substance gives a yellow color with cold concd. sulfuric acid, a positive Folin test, a positive Furter reaction, and reduces alcoholic silver nitrate.

Other examples of condensations between dienes and phenols or hydroquinones already have been reported.[2]

Condensations with Allylic Halides, Particularly Chlorides

Allyl chloride reacts with trimethylhydroquinone under the same condition as does the bromide, and the product in both cases is the known 2,4,6,7-tetramethyl-5-hydroxycoumaran. When crotyl chloride is used, the product is a mixture which consists predominantly of 2,3,4,6,7-pentamethyl-5-hydroxycoumaran (XIII), the same substance as is obtained when methylvinylcarbinol is used in the condensation. The crotyl chloride used in this experiment was obtained from the isomeric mixture of crotyl and methylvinylcarbinyl chloride by fractionation; the formation of XIII can be explained by an isomerization of the halide, which is known to occur at elevated temperatures and in the presence of acidic catalysts, particularly hydrochloric acid.

$$CH_3CH{=}CHCH_2Cl \rightleftharpoons CH_3CHClCH{=}CH_2$$

Crotyl chloride also will react with trimethylhydroquinone at atmospheric pressure, using benzene as a solvent, zinc chloride as the catalyst, and an inert atmosphere. The reaction with the chloride occurs as readily as it does with the bromide.

2,4,6,7-Tetramethyl-5-hydroxycoumaran (III).—Trimethylhydroquinone (1 g.), and allyl chloride (5 cc.) were heated in a tube at 150° for three hours. The product, isolated and purified as described above, weighed 600 mg. and had a melting point and mixed melting point of 130.6–131°.

2,3,4,6,7-Pentamethyl-5-hydroxycoumaran (XIII).—Trimethylhydroquinone (1 g.), and pure crotyl chloride (4 cc.) were heated in a tube at 150° for four hours. The product (400 mg.) was dissolved out with ether and crystallized from petroleum ether. After several crystallizations, the product melted at 117–117.5° and showed no depression in melting point when mixed with a specimen of XIII prepared from methylvinylcarbinol. It gave an acetate, melting point 70.5–71°. Using the procedure of Karrer, and substituting pure crotyl chloride for crotyl bromide, the product was the same. A repetition of Karrer's experiment,[3] using the isomeric mixture of crotyl bromide and methylvinylcarbinyl bromide, again gave predominantly this same substance, although the product was a mixture.

2,4,6-Trimethyl-7-allyl-5-hydroxycoumaran. — *m*-Xylohydroquinone (5 g.) and allyl bromide (10 cc.) were heated in a tube at 150° for three hours. The product was dissolved out with ether and steam distilled. Only traces of it came over into the distillate. The residue, when distilled under 10 mm. pressure from a sausage flask, gave a distillate consisting of a pale yellow, viscous oil, the properties of which corresponded with those of the product obtained from the hydroquinone and allyl alcohol (see above).

Summary

1. Allylic alcohols can be condensed directly with phenols and hydroquinones, thus avoiding the necessity of converting the alcohols into halides.

2. Although dienes also can be condensed with phenols and hydroquinones, the dienes are not always intermediates in the condensations when allylic alcohols and halides are used, for the products are not always the same.

3. A mechanism is proposed for these condensations, which, though not proved, correlates the facts well.

4. Allylic chlorides condense with phenols and hydroquinones as well as the bromides do.

5. An improved procedure is given for the preparation of α-tocopherol from trimethylhydroquinone and phytol.

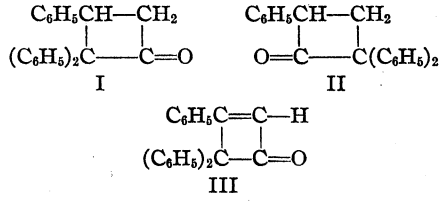
The Reaction between Diphenylketene and Phenylacetylene[1]

BY LEE IRVIN SMITH AND HARVEY H. HOEHN[2]

In a previous paper[3] it has been shown that the addition product obtained from diphenylketene and cyclopentadiene is a cyclobutanone derivative. Staudinger and Suter[4] added diphenylketene to styrene, and likewise regarded the product as a cyclobutanone derivative, I or II. At first these authors favored structure II with the more hindered carbonyl group, because the substance failed to form a phenylhydrazone or a benzal derivative but later,[5] when it was discovered that the product, on alkaline cleavage, gave α,α,β-triphenylbutyric acid, formula II was abandoned in favor of I. It has been shown recently[6] that formula I is really correct, although the cleavage product is actually β,γ,γ-triphenylbutyric acid, which Staudinger and Rheiner mistook for the α,α,β-acid.



I II

III

The facile formation of cyclobutanone derivatives is often observed in reactions between ketenes and unsaturated compounds, and in connection with earlier work[3] Agre[7] had sought to obtain further evidence that styrene and diphenylketene reacted to form a cyclobutanone derivative. His plan of attack involved addition of diphenylketene to phenylacetylene; assuming that styrene and phenylacetylene added to the ketene in the same way, then reduction of the adduct III from the acetylenic hydrocarbon should give the adduct II of the ethylenic hydrocarbon.

Contrary to the statement of Staudinger,[8] phenylacetylene and diphenylketene can be made to react with the production in excellent yield of a crystalline compound melting at 143–144°. Beyond showing that this product had the composition required by formula III and that its chemical properties were quite unusual for a compound of this structure, Agre did no further work upon it.

In the present communication, it is shown that this adduct is not a cyclobutanone derivative at all, but is 3,4-diphenyl-α-naphthol, IV, an isomer of III. Analysis and molecular weight determinations showed the composition to be $C_{22}H_{16}O$. The substance was readily soluble in (methyl) alcoholic potassium hydroxide; it gave a positive phenol reaction (Folin) and in the Grignard machine showed one active hydrogen atom and no addition of the reagent. It formed an acetate (IX) and a methyl ether (X), and it coupled with diazotized sulfanilic acid to give the azo compound XIII.

The adduct (IV) formed a monobromo derivative (V) which was still a phenol for it could be converted into an acetate (XI) or a methyl ether (XII). This bromophenol (V) was readily soluble in aqueous alkali, hence was more strongly acidic than the parent compound IV.

The adduct IV was extremely sensitive to oxidizing agents, even turning brown in air in a few days. It decolorized permanganate instantly, and depending upon the conditions and upon the oxidizing agent used, a variety of products was obtained. Using permanganate or chromic acid under mild conditions, the oxidation led to a product, insoluble in carbonate solution, whose structure has not yet been determined. Using potassium dichromate under vigorous conditions, the products were *o*-benzoylbenzoic and benzoic acids. The formation of these oxidation products eliminated the possibility that the adduct IV was 1,4-diphenyl-β-naphthol, since the latter compound would have produced *o*-dibenzoylbenzene on oxidation.

Oxidation of the bromo derivative V by chromic acid in acetic acid or oxidation of the phenol IV by lead tetraacetate produced a bright red solid (VI) having the properties of a 1,2-naphthoquinone. Reduction of VI by zinc and acetic acid or by sodium hydrosulfite gave colorless solutions, which in the air rapidly turned red and de-

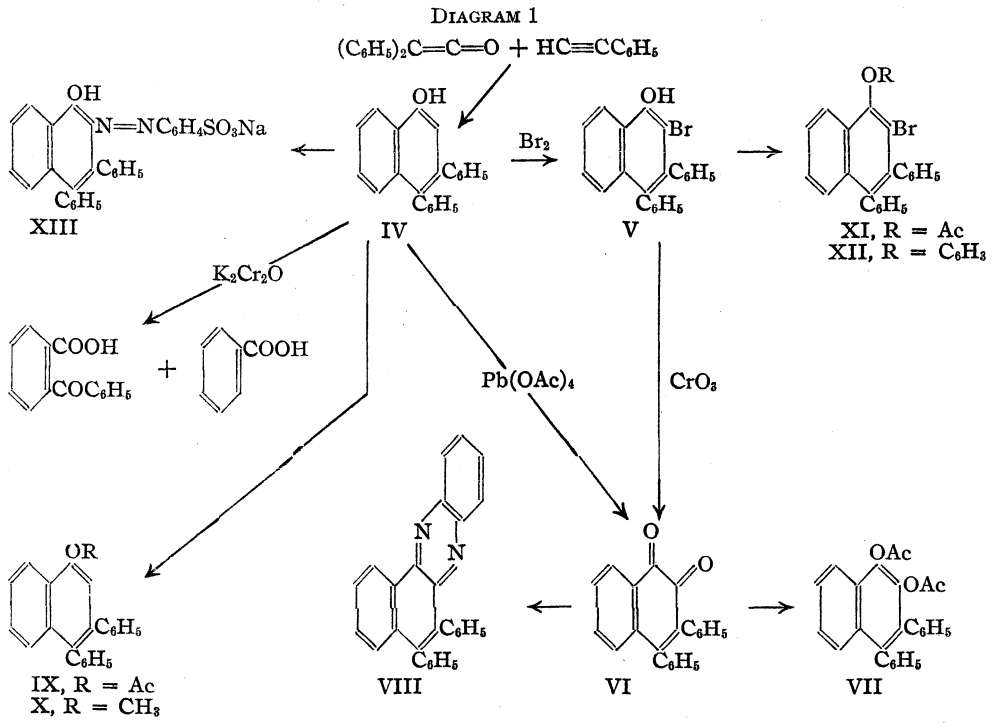
DIAGRAM 1

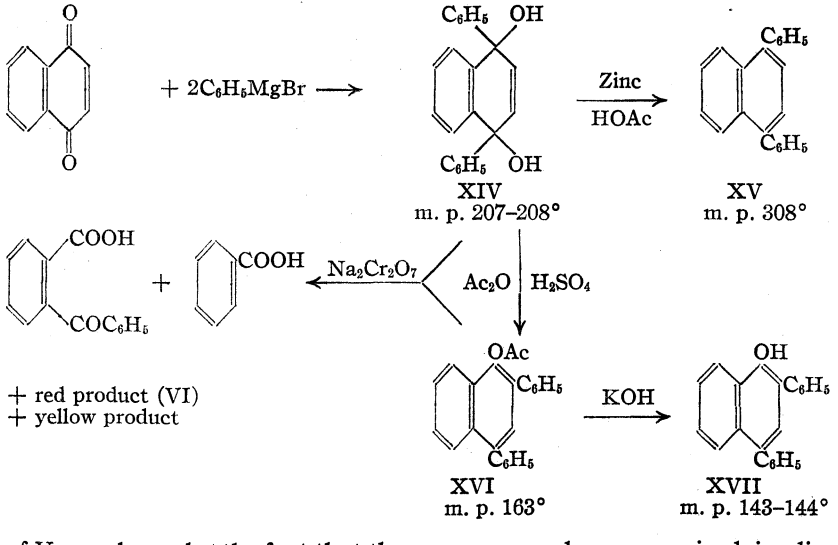


posited VI when the reducing agent was removed. Reductive acetylation of VI gave a colorless diacetate, VII. Finally, the *o*-quinone structure of VI was definitely settled by conversion of VI to a phenazine, VIII. That the azo group of XIII occupies the same position as the bromine atom of V was shown by the fact that the azo compound on reductive cleavage followed by oxidation of the intermediate amine (not isolated) also gave the red quinone VI.

These transformations, which are shown in diagram 1, are all explained adequately by structure IV, 3,4-diphenyl-α-naphthol, for the product of the reaction between diphenylketene and phenylacetylene.

Although the reactions shown in diagram 1 definitely prove that the adduct IV is a diphenyl naphthol with the two phenyl groups located in positions 3 and 4, these results do not definitely locate the hydroxyl group, for the reactions shown would be just as consistent with the β- as with the α-naphthol structure. In order to locate the hydroxyl group, an independent synthesis of IV was undertaken. Some years ago Franssen[9] studied the addition of phenylmagnesium bromide to 1,4-napthoquinone; his results, using the structures which he assigned, are summarized in diagram 2.

DIAGRAM 2

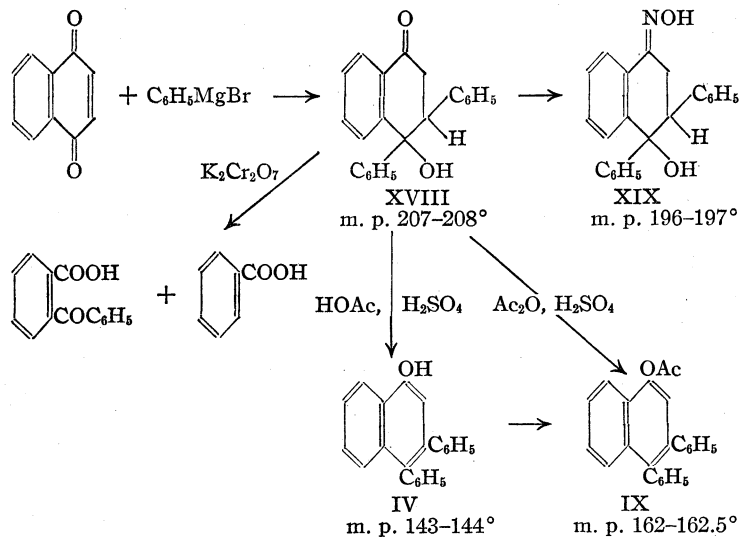


Franssen's work was of interest in connection with the present work, since the melting points of two of his products, XVI and XVII, coincided with

(9) Franssen, *Bull. soc. chim.*, [4] **37**, 902 (1925).

two obtained in this work, those of IX and IV, respectively. That is, Franssen reported a phenol and its acetate which had the same melting points as the phenol IV and its acetate obtained by an entirely different series of reactions. It followed almost certainly that Franssen's compounds and ours were identical, but this could not be the case if the structures assigned by Franssen were correct. Franssen's evidence for structure XIV rested primarily upon the conversion of XIV into 1,4-diphenylnaphthalene, XV. But this compound since has been synthesized by Weiss, Abeles and Knapp[10] and by Allen and Gilman,[11] who report that it melts at 135–137° and 134–136°, respectively, and not at 308° as does Franssen's compound XV. Another serious objection to Franssen's formulations is that the production of *o*-benzoylbenzoic and benzoic acids by oxidation of XIV and XVI, and the conversion of XIV into XVI, must both involve rearrangements. Crawford[12] showed that phenylmagnesium bromide added to 2,3-dimethyl-1,4-naphthoquinone to give a variety of products, the relative amounts of which depended largely upon the relative amounts of the quinone and Grignard reagent. She showed that when two moles of phenylmagnesium bromide was added to the quinone, the product formed in largest amount was the one resulting from a 1,4-addition to the conjugated system followed by a 1,2-addition to the other carbonyl group. Franssen's products could be reconciled with ours if this same type of reaction were assumed in the case of 1,4-naphthoquinone. To test this point, Franssen's work was repeated. The products which we obtained and their relationships are shown in diagram 3.

DIAGRAM 3



When 1,4-naphthoquinone was added to a large excess (5 moles) of phenylmagnesium bromide the addition product XVIII, identical with Franssen's XIV, resulted. That this substance possessed a carbonyl group was shown by the formation of an oxime (XIX). When XVIII was subjected to the action of acetic and sulfuric acids, or to the action of acetic anhydride, it was transformed into the naphthol IV and the acetate IX, respectively. These transformations can be understood readily on the basis of structure XVIII for the primary product, for the tertiary hydroxyl group in position 4 would be expected to be eliminated readily under the conditions used, giving the naphthol IV directly, or its acetate IX. Structure XVIII also serves to explain the observed oxidation products; Franssen's XIV should give, not the observed oxidation products, but *o*-dibenzoylbenzene, none of which was obtained by Franssen nor by us. It follows, therefore, that Franssen's formulation of the reaction, and the structure of his products, are incorrect. His XIV must be replaced by XVIII; and his XVI and XVII must be replaced by IX and IV, respectively. What Franssen's hydrocarbon XV can be, it is not possible as yet to say. We have observed similar high melting products when certain of our products are oxidized, but we have not, as yet, been able to establish the structure of any of these. Certainly, however, Franssen's XV is not 1,4-diphenylnaphthalene.

When the results of these two syntheses, and the degradation of the products, are considered and assembled, the proof appears quite definite that diphenylketene reacts with phenylacetylene to produce 3,4-diphenyl-α-naphthol, IV. The reaction between this as well as other ketenes and acetylenic compounds appears to be quite general, and the hydrogen atom in the acetylene is not apparently necessary, for diphenylketene and diphenylacetylene also give a crystalline addition product. Consideration of the limits of

this reaction and also of the mechanism will, however, be reserved for later communications.

Experimental Part[13]

Addition of Diphenylketene to Phenylacetylene: 3,4-Diphenyl-α-naphthol (IV).—Diphenylketene (1.94 g., 0.01 mole) and phenylacetylene (1.02 g., 0.01 mole) were mixed and allowed to stand at room temperature. After about ten hours, the mixture became very viscous and shortly thereafter a yellow solid separated. After standing for three days, the solid was washed with a little petroleum ether (b. p. 28–38°) and then was recrystallized from petroleum ether (b. p. 90–100°). The white needles weighed 2.4 g. and melted at 139–141°. After crystallization twice more, the product melted at 143–144°.

Anal. Calcd. for $C_{22}H_{16}O$: C, 89.19; H, 5.71; mol. wt., 296. Found: C, 89.23; H, 5.80; mol. wt., 296. Calcd. for structure IV: active H, 1.0; carbonyl, 0. Found: active H, 0.97; carbonyl, 0.

The magnesium compound resulting from this determination, on acidification, gave IV, m. p. 143–144°.

The naphthol IV also was produced when a solvent was used, but the reaction was much slower and the yield much less. This undoubtedly was the cause of Staudinger's report that no reaction occurred, for he operated with 0.1 molar solutions. Diphenylketene (17.4 g.), phenylacetylene (9.3 g.) and petroleum ether (18 g., b. p. 57–70°) were allowed to stand for one week in an atmosphere of carbon dioxide. The solid was removed and crystallized from a mixture of petroleum ether and benzene. It weighed 13 g. (50%) and melted at 143–144°.

Apparently the naphthol IV exists in two forms, one melting at 143–144°, and the other at 154°. In the early experiment it was observed frequently that the substance, after melting at 143–144°, would crystallize as the temperature was raised slowly, and then remelt at 154°. In the later stages of the work, however, this phenomenon, which was observed independently by C. L. Agre and one of us (H. H. H.) could not be duplicated.

3,4-Diphenyl-α-acetoxynaphthalene (IX).—The naphthol (5 g.) was dissolved in acetic anhydride (30 cc.) containing a drop of sulfuric acid and the solution was heated to the boiling point. The product, isolated by pouring the reaction mixture over ice, formed white cubes when recrystallized from ethanol. The yield was 5.5 g., and the melting point was 162–162.5°.

Anal. Calcd. for $C_{24}H_{18}O_2$: C, 85.17; H, 5.37. Found: C, 84.86; H, 5.22.

3,4-Diphenyl-α-methoxynaphthalene (X).—The naphthol (500 mg.) and dimethyl sulfate (1.5 cc.) were dissolved in methanol (5 cc.). The solution was heated and stirred, and to it was slowly added a solution of potassium hydroxide (1 g.) in methanol (10 cc.). After refluxing for thirty minutes, water (75 cc.) was added. The precipitate was washed with Claisen's alkali (10 cc.) and then with water. The substance (400 mg.) was then recrystallized, first from alcohol–acetone and then from alcohol. It formed white cubes melting at 203–203.5°.

Anal. Calcd. for $C_{23}H_{18}O$: C, 88.99; H, 5.85. Found: C, 88.74; H, 5.85.

(13) Microanalyses by J. W. Opie, C. O. Guss and H. H. Hoehn.

3,4-Diphenyl-1-methoxy-2-nitronaphthalene.—Although the naphthol IV could not be nitrated (see below), the methyl ether X (200 mg.) in acetic acid (2 cc.) was nitrated readily by addition of nitric acid (0.08 cc.). The mixture was heated to the boiling point and then cooled. The nitro compound (70 mg.) which separated was removed and crystallized from ethanol. It formed yellow needles which melted at 202°.

Anal. Calcd. for $C_{23}H_{17}O_3N$: C, 77.72; H, 4.83. Found: C, 77.99; H, 4.78.

Oxidation of the Naphthol IV. (a) By Lead Tetraacetate.—This is the best preparative method for **3,4-diphenyl-1,2-naphthoquinone, VI.** The naphthol IV (296 mg.) and lead tetraacetate (800 mg.) were refluxed in acetic acid (10 cc.) for five hours. The solution was poured onto ice (100 g.) and most of the acetic acid was neutralized by adding saturated aqueous sodium carbonate. The mixture, containing an orange red precipitate, was extracted with chloroform. The chloroform was removed and the red residue was taken up in hot ethanol and filtered while hot. On cooling, the filtrate deposited orange red needles (130 mg.) which softened at 245° and melted at 247–248°. The melting point was not depressed by addition of a specimen of VI made from the bromonaphthol V; this latter specimen was carefully purified (m. p. 249–250° and was analyzed (see below).

(b) **Oxidation by Nitric Acid.**—The naphthol IV could not be nitrated; all attempts to do so led only to oxidation, the chief product being the red quinone VI although the yield was poor. The naphthol (1 g.) was dropped into a well-stirred mixture of nitric acid (1 cc.), sulfuric acid (2 cc.) and chloroform (10 cc.). After stirring the mixture for thirty minutes at room temperature, water was added, the chloroform layer was removed and the aqueous layer extracted with chloroform. The combined chloroform solutions were washed with bicarbonate and then with water. Removal of the chloroform left a red residue, which when worked up as described above gave 70 mg. of the quinone VI, m. p. 246–247°. The only other products were uncrystallizable oils.

(c) **Oxidation by Dichromate.**—The naphthol IV (1 g.) and potassium dichromate (3 g.) were refluxed in acetic acid (30 cc.) for eight hours. The green solution was poured onto ice (100 g.) and some of the excess acetic acid was neutralized with saturated carbonate. The mixture was extracted with benzene; the benzene was then extracted with sodium hydroxide (10%) and the alkaline extract was acidified and steam distilled. From the distillate benzoic acid (100 mg.), m. p. and mixed m. p. 121°, was isolated. From the residue in the distillation flask *o*-benzoylbenzoic acid (440 mg.) was isolated. This substance was identified as the hydrate after crystallization from water; m. p. and mixed m. p. 95°. From the residual benzene solution there was isolated a small amount (80 mg.) of a yellow solid melting at 280–286° which was not investigated further.

Reduction of the Quinone VI.—The quinone (140 mg.) in acetic acid (10 cc.) and water (1 cc.) was heated with zinc (20 mesh) for an hour. The red color of the quinone disappeared within ten minutes. The mixture was diluted with water, decanted from the zinc, and extracted with ether. The ether solution rapidly turned red, and re-

moval of the ether left red crystals of VI. Practically all of the starting material was recovered. Essentially the same results were obtained when VI was reduced by sodium hydrosulfite.

Reductive Acetylation: 1,2-Diacetoxy-3,4-diphenylnaphthalene (VII).—The quinone (50 mg.) and fused sodium acetate (50 mg.) were dissolved in acetic anhydride (1 cc.), a little zinc dust was added, and the mixture was heated to boiling. The red color faded at once. The zinc was filtered off and the filtrate was diluted with water. The solid (64 mg.) was removed and crystallized from dilute ethanol. It formed white needles which melted at 166–167°.

Anal. Calcd. for $C_{26}H_{20}O_4$: C, 78.76; H, 5.09. Found: C, 78.48; H, 5.15.

Phenazine (VIII).—The quinone VI (95 mg.) and *o*-phenylenediamine (60 mg.) were heated in alcohol (20 cc.) for thirty minutes on the steam-bath. After about five minutes, yellow crystals of the phenazine began to separate. The solid (110 mg.) was removed from the cooled mixture and recrystallized from alcohol–benzene. It formed yellow needles which melted at 274–275°.

Anal. Calcd. for $C_{28}H_{18}N_2$: C, 87.93; H, 4.75. Found: C, 87.92; H, 4.71.

Coupling Reaction of IV. The Azo Compound XIII.—Sulfanilic acid dihydrate (1.6 g.) was dissolved in sodium carbonate solution (15 cc., 2.5%) and sodium nitrite (0.56 g.) was added. The solution was poured into a mixture of ice (8 g.) and hydrochloric acid (1.5 cc.). To this suspension of the diazonium compound was added a solution of the naphthol IV (2.2 g.) and sodium acetate (0.6 g.) in acetic acid (30 cc.). The mixture was allowed to stand at room temperature for four hours, with occasional shaking. The red solid (2.8 g.) was filtered off and dried. It was not analyzed.

Reductive Cleavage of the Azo Compound: The Quinone VI.—The red compound XIII (1 g.), sodium hydrosulfite (0.4 g.) and sodium hydroxide (0.2 g.) were dissolved in water (20 cc.) and the solution was boiled. More hydrosulfite (0.5 g.) and alkali (0.5 g.) were added. The red color disappeared, and a white solid (the amino naphthol) separated when the solution was cooled. This solid was filtered off as rapidly as possible; the filtrate turned black within a few minutes. The white solid was boiled with aqueous ferric chloride and the mixture was extracted with chloroform. Evaporation of the chloroform left a red residue which, recrystallized from ethanol–ether, melted at 246–247° and showed no depression in melting point when mixed with a specimen of VI made by oxidation of IV or V.

Attempts to purify the intermediate **2-amino-3,4-diphenyl-α-naphthol** by crystallization failed, for solutions of it oxidized in the air very rapidly and turned black.

2-Bromo-3,4-diphenyl-α-naphthol (V).—The naphthol IV (2 g.) in ether (10 cc.) was stirred and brominated by the slow addition of bromine (0.35 cc.) in ether (10 cc.). Stirring was continued for thirty minutes after all of the bromine was added. Water was added, the ether layer was separated, washed with bisulfite and the solvent was evaporated. The residue, when crystallized twice from methanol, formed white needles (2.05 g.) melting at 157–158°.

Anal. Calcd. for $C_{22}H_{15}OBr$: C, 70.39; H, 4.03. Found: C, 70.6; H, 3.82.

2-Bromo-3,4-diphenyl-α-acetoxynaphthalene (XI).—The bromonaphthol V (100 mg.) was acetylated by heating it in acetic anhydride (2 cc.) containing a drop of sulfuric acid. The product (120 mg.), isolated in the usual way and crystallized from ethanol, formed white needles melting at 199–200°.

Anal. Calcd. for $C_{24}H_{17}O_2Br$: C, 69.06; H, 4.11. Found: C, 69.03; H, 4.28.

2-Bromo-3,4-diphenyl-1-methoxynaphthalene (XII).—The bromonaphthol V (750 mg.) was dissolved in sodium methoxide solution (prepared from 60 mg. of sodium and 20 cc. of methanol), and dimethyl sulfate (3 cc.) was added slowly. After stirring the mixture for an hour, sodium hydroxide (4 cc., 40%) was added and the mixture was poured into water and extracted with ether. The ether was evaporated and the residue (500 mg.) was crystallized twice from alcohol. The product separated in fine white needles melting at 209–210°.

Anal. Calcd. for $C_{23}H_{17}OBr$: C, 70.95; H, 4.41. Found: C, 70.52; H, 4.45.

Oxidation of the Bromonaphthol: 3,4-Diphenyl-1,2-naphthoquinone (VI).—A solution of the bromonaphthol V (0.5 g.) in acetic acid (10 cc.) was heated on the steam-bath, and to it was added chromic acid (150 mg.). After heating for two hours, the mixture was poured into water. The product was removed and crystallized twice from ethanol. It weighed 150 mg. The m. p. was 249–250°; when mixed with a specimen of VI prepared from the naphthol IV, the substance melted at 247–248°.

Anal. Calcd. for $C_{22}H_{14}O_2$: C, 85.13; H, 4.54. Found: C, 85.24; H, 4.84.

4-Hydroxy-3,4-diphenyl-α-tetralone (XVIII).—1,4-Naphthoquinone (20 g.) suspended in ether (500 cc.) was added slowly (two hours) to a solution of phenylmagnesium bromide prepared in the usual way from magnesium (16 g.), bromobenzene (99 g.) and ether (500 cc.). The color became first wine red and then orange. After adding all of the quinone, the mixture was stirred and refluxed for five hours. The reaction mixture, which contained a brown, sticky precipitate, was poured into ice and hydrochloric acid (150 cc.). The ether layer was separated, and the tetralone suspended in it was filtered off. The aqueous layer was thoroughly extracted with ether, the ether solutions were combined and the solvent was distilled off. The tetralone, separated during removal of the ether, was removed from time to time. The solids were combined and digested with chloroform. Most of the sparingly soluble red impurity was removed by filtering the hot solution. The filtrate was decolorized with charcoal, and the chloroform solution was concentrated and alcohol was added. The cooled solution deposited white plates of the tetralone XVIII (8.1 g.) melting at 207°. This is the same substance reported by Franssen as having structure XIV.

Anal. Calcd. for $C_{22}H_{18}O_2$: C, 84.04; H, 5.78. Found: C, 83.93; H, 5.87.

Oxime XIX.—The tetralone XVIII (400 mg.), hydroxylamine hydrochloride (1 g.), sodium hydroxide (2 cc., 20%), water (6 cc.) and ethanol (20 cc.) were refluxed

for fifteen minutes, giving a clear solution. Most of the alcohol was distilled off and the residual solution, on cooling, deposited white plates of the oxime XIX (500 mg.) melting at 195–196°. Recrystallization from alcohol gave a product melting at 196–197°.

Anal. Calcd. for $C_{22}H_{19}O_2N$: C, 80.20; H, 5.82. Found: C, 80.09; H, 6.21.

Oxidation.—The tetralone XVIII (1 g.) and potassium dichromate (3 g.) were refluxed in acetic acid (30 cc.) for six hours. The green solution was poured into water (100 cc.) and most of the acetic acid was neutralized with sodium carbonate. Some sticky, orange material rose to the top of the solution; this was removed with a spatula. The aqueous solution was extracted with benzene, and the benzene solution then extracted with sodium hydroxide solution (10%). The alkaline extraction was acidified and steam distilled. From the distillate, benzoic acid (200 mg.), m. p. and mixed m. p. 121°, was isolated. The residue in the distilling flask was extracted with ether; from the ether extract, *o*-benzoylbenzoic acid (hydrate) (520 mg.), m. p. and mixed m. p. 88–90°, was isolated. From the sticky orange solid originally found in the oxidation, a very small amount of the red quinone VI, m. p. and mixed m. p. 245°, was isolated by repeated crystallization from alcohol.

Naphthol IV.—The tetralone XVIII (500 mg.), acetic acid (15 cc.) and sulfuric acid (5 drops) were boiled for thirty minutes and then poured into water. The pinkish solid was removed, dissolved in alcohol and the solution decolorized with charcoal. The alcohol was boiled off and replaced by petroleum ether (b. p. 90–100°). On cooling white needles of 3,4-diphenyl-α-naphthol IV (430 mg.) were deposited. These had a melting point and mixed melting point of 142–143° and showed the phenomenon of solidification after melting with remelting at 153–154° (see above under properties of IV). This is the same substance reported by Franssen as having structure XVII.

Acetate IX.—The tetralone XVIII (1 g.), acetic anhydride (7.5 cc.) and sulfuric acid (1 drop) were boiled for fifteen minutes. The cooled solution was poured onto ice and the pinkish solid (m. p. 160–162°) was removed. The solid was dissolved in chloroform and the solution was decolorized with charcoal. Most of the chloroform was removed, alcohol was added and the solution was cooled. White cubes of the acetate IX (950 mg.), m. p. and mixed m. p. 162–162.5°, were obtained. This is the same substance reported by Franssen as having structure XVI.

Summary

1. Diphenylketene and phenylacetylene react by addition to form, in good yield, 3,4-diphenyl-α-naphthol, IV.

2. The structure of the naphthol was proved by degradation and by an independent synthesis from 1,4-naphthoquinone and phenylmagnesium bromide.

3. The work of Franssen on the addition of phenylmagnesium bromide to 1,4-naphthoquinone has been repeated and his structures for the products have been shown to be incorrect. These have been supplanted by the correct structures.

4. The reaction between diphenylketene and acetylenes appears to be quite general, although no solvent, or quite concentrated solutions, must be used in order to bring about a reaction. As yet the mechanism of this reaction is not known, but observations to be reported later indicate that an acetylenic hydrogen atom is not involved because diphenylacetylene also reacts with the ketene.

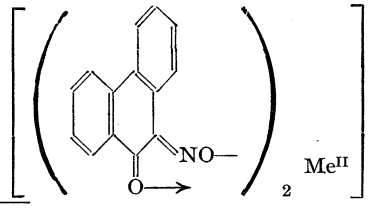
Ortho-quinone Monoxime Inner Complexes

BY HELMUT M. HAENDLER WITH GEORGE MCP. SMITH

Recently, Ciusa,[1] in work on phenanthrenequinone, observed that the monoxime behaved as do α-isonitroso ketones in reacting even in extremely dilute solutions with salts of cobalt, nickel, and iron. The divalent cobalt and nickel inner complexes obtained were of regular composition, having the structure



In general, cobalt, nickel, and copper form inner complexes more readily than do other metals. To determine, however, the extent to which other inner complexes of this group would form, various metals were tested with phenanthrenequinone monoxime and other oximes possessing the chelating group C, C–NOH, O.[2]

Inner complexes of cadmium, copper, lead, manganese, and uranyl with phenanthrenequinone monoxime were prepared, and complexes of copper, lead, manganese, nickel, and uranyl with chrysenequinone monoxime also were prepared. In all cases except that of the uranyl compounds

[a] Forms unstable greenish black addition compound with pyridine. [b] Ratio of $[UO_2 \rightleftarrows (Pqx)_2] : C_2H_5OH$ determined. Calcd. 1:2. Found 1:1.95, 1:2.10. [c] Made by heating the alcohol addition compound to 100°. [d] Ratio of $[UO_2 \rightleftarrows (Cx)_2] : C_2H_5OH$ determined. Calcd. 1:2. Found 1:1.96. [e] Made by heating the alcohol addition compound to 100°.

the simple inner complex formed. In the case of the uranyl complex, a compound containing two moles of ethyl alcohol, probably coördinated directly to the uranyl, first precipitated and then decomposed on heating to the normal inner complex.

In addition to the complexes described, tests[3] on these two oximes indicate that chromium, mercury (I), palladium, rhodium, and zinc also form complexes.

Retenequinone monoxime exhibits the same reactive tendencies as the two oximes used; the colors shown, however, are somewhat duller than those of the phenanthrenequinone monoxime complexes but not as dark as those of the chrysenequinone monoxime compounds. 2-Nitrophenanthrenequinone monoxime gives colors duller than the phenanthrenequinone monoxime complexes but also somewhat duller than those from the 4-nitro isomer. Whether these indications will be supported by observations on other types of complexes remains to be seen.

It originally was intended to measure the absorption spectra of these complexes, but due to their insolubility this plan was, of necessity, abandoned. We hope, however, to carry out this phase of the problem with certain complexes which seem to show greater promise from the standpoint of solubility.

The description of color is so vague that it was felt a more tangible reference would be useful. All the complexes prepared have been classified according to the color charts of Maerz and Paul,[4] by assigning them what we have termed the M. and P. No., being the actual color plate reference of the compound.

Experimental

Phenanthrenequinone Monoxime.—Phenanthrene, purified by the method of Bachmann,[5] was oxidized to the quinone as described by Jakubowitsch and Worobjowa,[6] purified by the method of Moore and Huntress,[7] and converted to the monoxime by Goldschmidt's procedure[8]; m. p. 158–159°.

Chrysenequinone Monoxime.—Purified chrysene[9] was oxidized and converted to the oxime according to Graebe and Hönigsberger[10]; m. p. 162–163°.

Inner Complexes.—The complexes of phenanthrenequinone monoxime ($C_{14}H_9NO_2$ = PqxH) and chrysenequinone monoxime ($C_{18}H_{11}NO_2$ = CxH) were prepared by treating a hot alcohol solution of a slight excess of the oxime with either an alcohol or water solution of the metallic salt and adjusting the *p*H of the mixture with ammonium hydroxide or acetic acid until coagulation of the precipitate occurred. The compounds, after filtration, were purified by extraction of the excess organic compound with alcohol. The complexes are extremely stable, insoluble in practically all organic solvents commonly available, soluble with decomposition in warm glacial acetic acid, and are only slightly attacked by mineral acids in most cases. For the sake of simplicity the preparational data are presented in tabular form.

Summary

1. Several new inner complexes of phenanthrenequinone monoxime and chrysenequinone monoxime have been prepared.

The Entropy of Hydrogen Cyanide. Heat Capacity, Heat of Vaporization and Vapor Pressure. Hydrogen Bond Polymerization of the Gas in Chains of Indefinite Length

BY W. F. GIAUQUE AND R. A. RUEHRWEIN

This paper reports the results of low temperature calorimetric measurements on solid and liquid hydrogen cyanide. The data have been used to calculate the entropy of hydrogen cyanide gas and the experimental result has been compared with the value calculated from available band spectrum data.

It has been shown by Sinosaki and Hara[1] and by Felsing and Drake[2] that hydrogen cyanide gas is partially polymerized, and it is therefore necessary to apply a correction in obtaining the entropy of HCN from the entropy of the actual gas.

The measurements were made in a calorimeter with the laboratory designation Gold Calorimeter III which has been described previously.[3] The standard thermocouple which had been compared with a helium gas thermometer[3] was compared with oxygen and hydrogen vapor pressures during the course of this work. Agreement was found to within 0.05° at all temperatures measured. The resistance thermometer was calibrated directly in terms of the vapor pressure of hydrogen for temperatures below 20°K.

Preparation and Purity of Hydrogen Cyanide.—Hydrogen cyanide was prepared by a method described by Perry and Porter.[4] 18 Normal sulfuric acid was dropped on sodium cyanide until enough gas had been generated to make 300 cc. of liquid hydrogen cyanide. The gas from the generator was passed through 2 tubes of anhydrous calcium chloride and 3 tubes of phosphorus pentoxide. All of the tubes were 30 cm. long and 3 cm. in diameter. A considerable amount of a dark brown product was left in the reaction vessel.

The collected liquid was distilled three times, a portion being discarded at the beginning and end of each distillation. A purified portion of 135 cc. remained. This was distilled in a vacuum-jacketed column, for a reason to be discussed later. The whole system could be subjected to a high vacuum and between each distillation the hydrogen cyanide was solidified by means of liquid air and pumped with a mercury diffusion pump.

The material was a clear colorless liquid and it remained so even after a portion had been allowed to stand at room temperature for about one year.

From the slight rise in heat capacity below the melting point, due to premelting, the liquid-soluble solid-insoluble impurity was estimated to be of the order of one mole in one hundred thousand moles of hydrogen cyanide.

An interesting phenomenon was observed when the solidified hydrogen cyanide was warmed from or cooled to liquid air temperatures in a glass bulb. Intense flashes of bluish-white light were emitted in the temperature range 100 to 200°K. both on warming or cooling. The static discharge probably was due to strains set up in the solid by an unequal rate of temperature change. The discharge was accompanied by a cracking sound characteristic of crystals breaking under strain. The temperature range of the effect was obtained roughly by sealing a well into the glass bulb so that a thermocouple could be introduced.

The above effect is an interesting demonstration of the necessity of providing glass bulbs with a protective sheath to prevent contact of such materials with liquid air in case of breakage. It appears that solid hydrogen cyanide cooling in contact with liquid air would be practically certain to explode although we did not try it. Electrostatic effects in some degree are to be expected when such materials are fractured.

The Melting Point and Vapor Pressure of Hydrogen Cyanide.—A summary of the melting point investigation is given in Table I.

The values of the vapor pressure are given in Table II. The measurements were made by means of a Société Génévoise cathetometer with a precision of 0.002 cm., used as a comparison instrument with a standard meter. The standard acceleration of gravity was taken as 980.665 cm. sec.$^{-2}$ and the acceleration at this location as 979.973 cm. sec.$^{-2}$. The meniscus height corrections were taken from the work of Cawood and Patterson[5] and the corrections to international

cm. of Hg were made by means of data given in the "I.C.T."[6]

Several vapor pressure observations were made on the solid but it became evident that the results were slightly high due to the presence of a small amount of solid in the line just above the calorimeter. For this reason these observations are omitted. In solidifying the substance for calorimetric measurements this was avoided by the sudden introduction of an atmosphere of helium with the material at the freezing point and practically all solid. Cooling was then accomplished before diffusion could take place. The possibility that helium might be entrapped in the solid with subsequent diffusion during the vapor pressure measurements caused us to forego this method of keeping the tube open in that case.

(6) "International Critical Tables," McGraw-Hill Book Co., Inc., New York, 1926, Vol. I.

The data in Table II have been represented by and compared with the equation

Liquid hydrogen cyanide, 259.86 to 298.8°K.

$$\log_{10}P \text{ (inter. cm. Hg)} = -\frac{1600.8}{T} - 0.0017835\,T + 7.77114 \qquad (1)$$

The temperatures are given to 0.001° only because of relative accuracy. The triple point value marked with an asterisk was given no weight because a slight superheating of the surface may have occurred when the solid was nearly all melted and that which remained was at the bottom of the container due to its greater density.

From Equation 1 the boiling point of hydrogen cyanide was determined to be 298.80°K.

The melting and boiling point temperatures obtained by various observers are given in Table III.

The Heat Capacity of Hydrogen Cyanide.—The heat capacity data are given in Table IV, and are shown graphically in Fig. 1. The amount was determined by condensing the substance in an evacuated bulb which was weighed. This was especially convenient since hydrogen cyanide boils a little above room temperature. The molecular weight was taken as 27.026 and 3.3721 moles were used for the measurements; 4.1832 international joules was taken as one calorie. The heat capacity observations were corrected for vaporization into the small volume of calorimeter and line at all temperatures where the effect was appreciable. This correction which involves no appreciable inaccuracy utilized the data of Sinosaki and Hara[1] on the density of liquid hydrogen cyanide and the density of the

150	10.11	300	16.97

A narrow region of high heat capacity occurred near 170°K. as is shown in Fig. 1. The points marked with asterisks in Table IV are not plotted in Fig. 1 because the temperature interval used was too large to allow them to be considered as values of differential heat capacity in this region of rapid variation. When the effect was first noted, during some preliminary observations, it was thought that it might be due to impurity, so the hydrogen cyanide was removed and fractionated in a vacuum-jacketed column. This produced no change in the effect.

Attainment of thermal equilibrium was a little less rapid in the region 140 to 170°K. and in order to determine whether the region of high heat capacity was due to some false equilibrium in the solid, the material was allowed to stand at approximately 165°K. for three days. No change in the effect was found.

In order to determine the entropy connected with the above effect, the total energy absorbed over a temperature of several degrees was measured. While the heat absorption was not sharp,

it was possible, without much arbitrariness, to subtract what may be considered the normal $\int C_p dT$ over the interval and thus assign a value to the heat effect accompanying the phenomenon. These values are given in Table VI. The first three values given correspond to the measurements made before the material was removed for fractionation in the column. The differences between the several values are somewhat greater than might be expected but we do not feel that any significance is to be attached to the variations.

The effect was also studied by means of cooling rate observations in this region. The temperature of the heavy metal cylinder which surrounded the calorimeter was set a little below that of the calorimeter, which thus cooled very slowly. The rate of cooling in the region of normal heat capacity was 0.0103° per minute while at the maximum of the heat capacity curve the rate decreased to 0.0044° per minute. The cooling rates give the best available information as to the character of the curve. The maximum heat capacity of 31 cal. deg.$^{-1}$ mole^{-1} occurred at 170.37°K. The cooling curve data, which are shown in Fig. 2, were also used to calculate a value for the total heat effect. This value is included in Table VI. The agreement of the results obtained by heating and cooling shows that no appreciable irreversibility is involved.

TABLE VI

MOLAL ENERGY ABSORPTION OF HYDROGEN CYANIDE NEAR 170°K.

Amounts given are in calories per mole above the heat corresponding to the "normal" heat capacity. Maximum heat capacity at 170.37°K.

No. of energy increments	Temp. interval	Heat input cal. mole^{-1}	$\int C_p dT$	ΔH cal. mole^{-1}
	Before fractionation			
1	167.166–173.499	99.34	94.80	4.5
	A few % melted, stood 10 hrs. resolidified			
2	169.231–173.320	64.93	61.15	3.8
3	168.198–173.759	87.48	83.15	4.3
	Material removed from calorimeter and fractionated			
0	From graphical integration of cooling rate			3.2
2	168.224–171.969	59.36	55.26	4.1
10	167.690–171.749	63.43	59.89	3.5
1	168.574–172.490	61.30	58.22	3.1
			Mean value	3.8

The entropy change corresponding to the 3.8 cal. mole^{-1} is only 0.022 cal. deg.$^{-1}$ mole^{-1}. The physical process which results in such a small change in entropy must be one involving the actions of large groups of hydrogen cyanide molecular units.

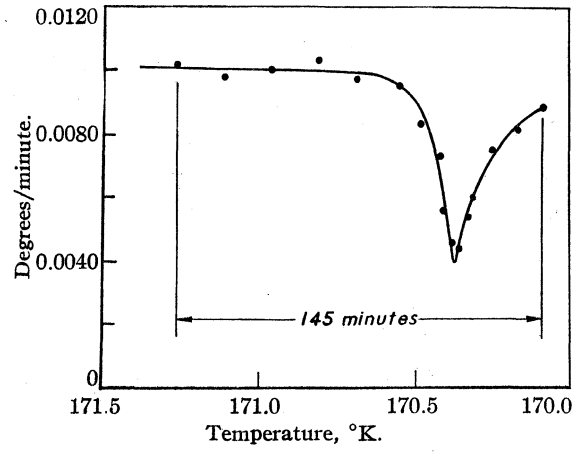

Fig. 2.—Cooling rate curve for hydrogen cyanide near 170°K.

As has been pointed out by Smyth and McNeight,[13] the low dielectric constant of the solid precludes any possibility of appreciable molecular rotation in the crystalline state and the hydrogen bond polymerization to be discussed later in this paper should be effective in preventing rotation.

The Heat of Fusion of Hydrogen Cyanide.—The determinations were made in the usual manner, each measurement was started somewhat below the melting point and ended somewhat above. Corrections for the $\int C_p dT$ were made. The results are given in Table VII.

TABLE VII

MOLAL HEAT OF FUSION OF HYDROGEN CYANIDE

Melting point 259.86°K. 0°C. = 273.10°K. Molecular weight, 27.026.

Temp. interval	Heat added per mole	$\int C_p dT$	ΔH, cal. mole^{-1}
257.400–263.844	2142.5	132.8	2010
257.388–263.975	2144.7	135.8	2009
257.030–264.166	2155.3	147.0	2008
		Average value	2009

The Heat of Vaporization of Hydrogen Cyanide.—The heat of vaporization was measured at constant pressure, the gas being absorbed in a bulb containing 150 cc. of 4 *M* sodium hydroxide and arranged with a mercury trap at the bottom. Only the lower half of the calorimeter heater was used to supply energy and hydrogen cyanide was evaporated only from the upper part of the calorimeter. The data are given in Table VIII, which also lists a value obtained from the vapor pressure observations represented by Equation 1. In using the equation

$$\Delta H \text{ vaporization} = \frac{dP}{dT} T \Delta V$$

(13) Smyth and McNeight, THIS JOURNAL, **58**, 1723 (1936).

we have made use of the liquid and gas density data of Sinosaki and Hara[1] which are discussed later in this paper. $(PV/RT) = 0.9239$ at 1 atmosphere and 298.80°K., which leads to a gas volume of 22,655 cc. per mole of HCN at the boiling point. The molal volume of the liquid is 40 cc. at this temperature.

TABLE VIII

HEAT OF VAPORIZATION OF HYDROGEN CYANIDE

Boiling point 298.80°K. 0°C. = 273.10°K. Molecular weight, 27.026.

Moles evap.	Time, min.	ΔH cal., deg.$^{-1}$ mole^{-1}
0.21455	45	6007
.22473	45	6031
.22549	45	6033
.22656	45	6035
	Average value	6027
Calcd. from vapor pressure Equation 1		6083

The value of the heat of vaporization obtained from the vapor pressure data is given no weight in comparison with the calorimetric value.

The Entropy of Hydrogen Cyanide from Calorimetric Data.—A summary of the entropy calculation for the equilibrium mixture of hydrogen cyanide and its associated forms at the boiling point is given in Table IX.

	47.18
Gas imperfection correction	0.03
Entropy of 27.026 g. of gas at 298.80°K.	47.21

The correction for gas imperfection was made by assuming Berthelot's equation of state and the critical constants for hydrogen chloride

$$T_c = 324.5°\text{K.},^{14}\ P_c = 83\ \text{atm.}^{14}$$
$$\Delta S = S_{\text{ideal}} - S_{\text{actual}} = 27\ RT_c^3P/32\ T^3P_c$$
$$= 0.03\ \text{cal. deg.}^{-1}\ \text{mole}^{-1}$$

Although Berthelot's equation does not hold for an associated gas, the above estimate should be fairly accurate since the gas consists largely of the monomer.

(14) Pickering, *J. Phys. Chem.*, **28**, 97 (1924).

The Polymerization of Hydrogen Cyanide Gas.—In order to calculate the entropy of monomeric hydrogen cyanide gas from the above results, it is necessary to consider the association of the substance. Sinosaki and Hara[1] have made a very extensive investigation of the gas density of hydrogen cyanide as a function of temperature and pressure and more recently Felsing and Drake[2] have reported single observations at each of three temperatures which show that association exists.

The results in this paper are based on the work of Sinosaki and Hara and we have not used their observations at pressures below 0.3 atmosphere because the accuracy limitations of gas density measurements make them unsuitable for the accurate determination of the extent of association. In making corrections for gas imperfection the equation $PV = RT(1 + \lambda P)$ was used and λ was taken as -0.0056 at the boiling point of hydrogen cyanide, this being the value for hydrogen chloride considered to be a Berthelot gas. Similarly values of λ were obtained at other temperatures. The value of λ for associated forms is undoubtedly larger but it may be shown readily that it is unimportant to consider the difference. The critical data of hydrogen cyanide were not used to calculate λ because it may be shown that a considerable amount of the polymer is present at the critical point. The effect of variation of λ will be discussed later.

The first calculations were based on the assumption that

$$2\text{HCN} = (\text{HCN})_2$$

represented the polymerization with

$$K = \frac{\alpha/2(1 - \alpha/2)}{(1 - \alpha)^2P}$$

where α represents the fraction of the material in the dimeric form and

$$1 - \alpha/2 = \frac{(PV)_{\text{observed}}}{RT(1 + \lambda P)}$$

$(PV)_{\text{observed}}$ was taken as the volume of one mole on a monomeric basis. The values of K calculated showed a very considerable decrease with decreasing pressure at the several temperatures and even impossibly large values of λ could not appreciably alter the trend. Calculations based on the presence of some hydrogen isocyanide assumed to be out of equilibrium with hydrogen cyanide and the formation of dimers in the various possible combinations did not satisfy the data.

The assumption of specific formation of a trimer

gave impossible results and indicated that the average polymer was intermediate between a dimer and trimer and thus the presence of both.

It is evident that if the equilibrium constants calculated on the assumption of dimer formation are plotted, the true constant for the formation of $(HCN)_2$ will be obtained by extrapolating the values to zero pressure. Values so obtained are shown in Table X, together with the false values corresponding to one atmosphere to show the trend.

TABLE X

EQUILIBRIUM CONSTANTS FOR THE REACTION 2HCN = $(HCN)_2$

T, °K.	$K(p=0) \times 10^2$ True	$K(p=1) \times 10^2$ False
273.1	9.5	...
303.0	5.6	8.6
333.1	3.4	4.2
373.1	2.0	2.3
462.3	1.0	1.0

The logarithms of the values of the constants given in the second column of Table X fall nearly on a straight line when plotted against the reciprocal of the absolute temperature and may be represented by the equation

$$\log_{10}K_D = (717/T) - 3.616 \qquad (2)$$

where K_D is the equilibrium constant for dimer formation.

K_T for the reaction

$$3HCN = (HCN)_3$$

was then calculated at the several temperatures.

$$K_T = \frac{\beta/3(1-\alpha/2-2\beta/3)^2}{(1-\alpha-\beta)^3P^2} \qquad (3)$$

where α and β are the fractions associated to dimer and trimer, respectively, and

$$(1 - \alpha/2 - 2\beta/3) = \frac{(PV)_{\text{observed}}}{RT(1 + \lambda P)} \qquad (4)$$

Values of K_T obtained by means of the above equations decreased somewhat with decreasing pressure. Again extrapolating to zero pressure, the values 0.055, 0.0087, 0.0030 and 0.0013 atm.$^{-2}$ are found for K_T at the temperatures 273.1, 303.0, 333.1 and 373.1°K., respectively. These results can be represented by the equation

$$\log_{10}K_T = (1905/T) - 8.320 \qquad (5)$$

If hydrogen cyanide forms both a dimer and trimer, one might reasonably ask whether higher polymers are not present also and there are good reasons for believing this to be the case. The trend in K_T with pressure is in the right direction to indicate higher polymers but this places too great a strain on the gas density to be considered as more than a suggestion. However, Kumler[15] has explained the phenomenally high dielectric constants of such liquids as hydrogen cyanide and hydrogen fluoride by assuming chains due to hydrogen bond formation and it is difficult to see any other explanation for the high electric moment.

There is no evident limit to the length of the hydrogen cyanide chains possible by such a mechanism except that the longer groupings are less stable thermodynamically. Equations 2 and 5 may be used as a basis for estimating the fractions of higher polymers.

Bauer, Beach and Simons[16] recently have presented electron diffraction evidence which indicates that hydrogen fluoride gas consists principally of zig-zag chains due to hydrogen bonds.

There are two simple tests which may be applied to Equations 2 and 5 to judge their reasonableness. First: the entropy change in the formation of the dimer should roughly approximate the Trouton value for the reduction by one of the number of moles of gas by a condensation process and the change for trimer formation should be about twice that for the above quantity. Second: the heat of formation for the trimer from the monomer should be of the order of twice the value for the dimer. The following values are found

$$\Delta S^\circ_D = -16.5 \text{ cal. deg.}^{-1} \text{ mole}^{-1}$$
$$\Delta S^\circ_T = -38 \text{ cal. deg.}^{-1} \text{ mole}^{-1}$$
$$\Delta H^\circ_D = -3{,}280 \text{ cal. mole}^{-1}$$
$$\Delta H^\circ_T = -8{,}720 \text{ cal. mole}^{-1}$$

Taking the increments between the dimer and trimer values as more representative of further additions, a general equation may be written as

$$\Delta F^\circ = -RT \ln K_n = \Delta H^\circ - T\Delta S^\circ \qquad (6)$$
$$= 7600 - 5440n - T(26.5 - 21.5n) \qquad (7)$$

where n is the number of molecules combined in the polymer.

From Equation 7 and equations similar to Equation 3, the fractions associated in the various polymers have been calculated and are given in Table XI.

Since deuterium bonds would be expected to be stronger than those of hydrogen gas density measurements on deuterium cyanide should show a larger, more easily studied, polymerization.

(15) Kumler, THIS JOURNAL, **57**, 600 (1935).
(16) Bauer, Beach and Simons, *ibid.*, **61**, 19 (1939).

TABLE XI

FRACTIONS OF HYDROGEN CYANIDE GAS IN THE STRAIGHT CHAIN SERIES OF POLYMERS

T = boiling point = 298.80°K., P = 1 atmosphere.

Polymer	Fraction
Dimer	0.0988
Trimer	.0268
Tetramer	.0064
Pentamer	.0015
Hexamer	.0003
Heptamer	.00004

The question also arises as to whether hydrogen bond polymerization does not occur to a small extent in gaseous water and we believe that it can be answered in the affirmative in the following way. From the gas density data as summarized by Keenan and Keyes,[17] $\lambda = -0.016$ atm.$^{-1}$ for saturated vapor at the boiling point. If the specific effects due to hydrogen bonds could be eliminated, the λ for hydrogen sulfide should be larger than that for water at the same temperature. Berthelot's equation of state represents the gas density of hydrogen sulfide quite accurately at ordinary temperatures and it seems safe to assume that it does so at the boiling point of water. λ is found to be -0.004 and from this we conclude that hydrogen bond association exists to the extent of about 3% in gaseous water at one atmosphere and 373.1°K. A larger effect would be anticipated in the case of deuterium oxide gas.

The Entropy of Monomeric Hydrogen Cyanide.—The entropy of the equilibrium mixture in hydrogen cyanide gas is given by the expression

$$S^\circ_{\text{mixture}} = (1 - \alpha - \beta - \ldots)\, S^\circ_{\text{HCN}} + \alpha/2\, S^\circ_{\text{D}} + \beta/3\, S^\circ_{\text{T}} + \ldots - R(1 - \alpha/2 - 2\beta/3 - \ldots) [N_{\text{M}} \ln N_{\text{M}} + N_{\text{D}} \ln N_{\text{D}} + N_{\text{T}} \ln N_{\text{T}} + \ldots] \quad (8)$$

$$= S^\circ_{\text{HCN}} + \alpha/2\, \Delta S^\circ_{\text{D}} + 2\beta/3\, \Delta S^\circ_{\text{T}} + \ldots + R\,(1 - \alpha/2 - 2\beta/3 - \ldots)\, \Sigma\, N \ln N \quad (9)$$

$$S^\circ_{\text{HCN}} = S^\circ_{\text{mixture}} - \alpha/2\, \Delta S^\circ_{\text{D}} - \beta/3\, \Delta S^\circ_{\text{T}} - \ldots + R \left[(1 - \alpha - \beta - \ldots) \ln \frac{(1 - \alpha - \beta - \ldots)}{(1 - \alpha/2 - 2/3\beta - \ldots)} + \alpha/2 \ln \frac{\alpha/2}{(1 - \alpha/2 - 2/3\beta - \ldots)} + \beta/3 \ln \frac{\beta/3}{(1 - \alpha/2 - 2/3\beta - \ldots)} + \ldots \right] \quad (10)$$

The total entropy correction to be added to the value for the entropy of the equilibrium mixture on account of polymerization is 0.73 cal. deg.$^{-1}$ mole^{-1}, of which only 0.05 cal. deg.$^{-1}$ mole^{-1} is due to all polymers higher than the trimer.

(17) "Thermodynamic Properties of Steam," Keenan and Keyes, John Wiley and Sons, Inc., New York, 1936.

To test the importance of the particular choice of λ, the calculations were repeated with $\lambda = -0.025$ atm.$^{-1}$. With the larger λ the 0.03 cal. deg.$^{-1}$ mole^{-1} correction for ordinary gas imperfection, given in Table IX, is increased to 0.12 cal. deg.$^{-1}$ mole^{-1}. It is sufficient to include only polymers up to and including the trimer in making the comparison. The following result was obtained

$\lambda = -0.025$: correction = 0.12 + 0.57 = 0.69 cal. deg.$^{-1}$ mole^{-1}

$\lambda = -0.0056$: correction = 0.03 + 0.68 = 0.71 cal. deg.$^{-1}$ mole^{-1}

The difference of 0.02 cal. deg.$^{-1}$ mole^{-1} for such a large variation of λ makes it evident that the final result does not depend appreciably on the particular value selected as the best estimate.

Comparison of the Entropy Values from Calorimetric and Spectroscopic Data.—The necessary molecular data for calculating the entropy were taken from the band spectrum observations of Bartunek and Barker,[18] who give a summary of previous observers. The moment of inertia, I, is 18.72×10^{-40} g. cm.^{2} and the observed vibrational quanta for excitation to the first level of each type are 2089.0, 712.1 and 3312.9 cm.$^{-1}$ respectively. The 712.1 cm.$^{-1}$ corresponds to the bending motion and has a weight of 2.

$$S_{\text{Translation}} = 3/2\, R \ln M + 5/2\, R \ln T - R \ln P - 2.300$$

$$S_{\text{Rotation}} = R \ln IT + 177.676$$

The vibrational entropy was calculated by means of the Einstein formula. The nuclear spins of H, C and N are $1/2$, 0 and 1, respectively; thus the spin contribution is $R \ln (2 \times 1/2 + 1)(2 \times 1 + 1) = R \ln 6 = 3.560$ cal. deg.$^{-1}$ mole^{-1}. A comparison of the entropy values at the boiling point 298.80°K. and at 298.10°K. is given in Table XII. The value 48.23 cal. deg.$^{-1}$ mole^{-1} for 298.10°K. is identical with the result of a similar calculation made by Gordon,[19] who also considered

TABLE XII

COMPARISON OF CALORIMETRIC AND SPECTROSCOPIC VALUES FOR THE ENTROPY OF HYDROGEN CYANIDE

Temperature, °K.	298.80	298.10
Equilibrium gas, actual	47.18±0.1	...
Equilibrium gas, ideal	47.21	...
Correction for polymerization	0.73	...
HCN ideal, experimental	47.94	47.92
HCN spectroscopic less nuclear spin contribution	48.25	48.23
Correction for nuclear spin	3.56	3.56
Absolute entropy, cal. deg.$^{-1}$ mole^{-1}	51.81	51.79

(18) Bartunek and Barker, *Phys. Rev.*, **48**, 516 (1935)

(19) Gordon, *J. Chem. Phys.*, **5**, 30 (1937).

the effect of polymerization. However, Gordon was unaware of the experiments of Sinosaki and Hara[1] and thus was led to assume that only a dimer was formed.

The experimental value is 0.31 cal. deg.$^{-1}$ mole^{-1} lower than the one obtained from molecular data. We believe that not more than 0.1 cal. deg.$^{-1}$ mole^{-1} of this can be attributed to calorimetric error. The weakest point in the calculation appears to be the strain placed on the gas density observations in obtaining the temperature coefficients of the association constants. The density measurements of Sinosaki and Hara[1] have been made with great care but the amounts of polymeric forms decrease so rapidly with increasing temperature that high accuracy is not to be expected when the data are used to calculate association constants. Here, as in so many other cases of equilibrium measurements, the onset of error is gradual and the straight line obtained with a log K *vs.* $1/T$ plot must not be taken too seriously.

The net correction for the presence of polymers is only 0.73 cal. deg.$^{-1}$ mole^{-1}; the entropy terms in Equation 10 which are based on the temperature coefficient of gas density amount to 1.28 cal. deg.$^{-1}$ mole^{-1}. Thus we conclude that the entropy obtained from the third law of thermodynamics is in agreement with the value obtained from molecular data.

The entropy value 48.23 cal. deg.$^{-1}$ mole^{-1}, which does not include the nuclear spin effect, is the one which should be used in ordinary thermodynamic calculations for monomeric hydrogen cyanide. The entropy of liquid hydrogen cyanide at 298.1 is 26.97 cal. deg.$^{-1}$ mole^{-1}.

We thank Dr. T. M. Powell for assistance with the measurements.

Summary

The heat capacity of solid and liquid hydrogen cyanide has been measured from 14 to 300°K.

The melting and boiling points were found to be 259.86 and 298.80°K., respectively (0°C. = 273.10°K.).

The heat of fusion is 2009 cal. mole^{-1}.

An energy absorption of 3.8 cal. mole^{-1} occurred over a small temperature range with a maximum at 170.37°K.

The heat of vaporization at the boiling point was determined calorimetrically to be 6027 cal. mole^{-1}.

The vapor pressure of liquid hydrogen cyanide has been measured and the data have been represented by the equation liquid, 259.86 to 298.9°K.

$$\log_{10}P \text{ (inter. cm. Hg)} = -(1600.8/T) - 0.0017835\,T + 7.77114$$

The triple point pressure is 14.040 inter. cm. Hg.

The available gas density data on hydrogen cyanide have been used to show that multiple polymerization exists. The data are taken to indicate indefinite straight chain hydrogen bond polymerization in the gas, as suggested by Kumler for the liquid, in explanation of its abnormally high dielectric constant. The fraction of the gas in the various polymeric forms up to the heptamer has been calculated.

It has been estimated that hydrogen bond polymerization occurs in saturated water vapor to the extent of 3% at the boiling point.

The data and the third law of thermodynamics have been used to calculate the entropy of monomeric hydrogen cyanide gas at 298.10°K. and 1 atm. The experimental value 47.92 cal. deg.$^{-1}$ mole^{-1}, which contains a small possible error on account of uncertainty in the temperature coefficients of the polymerization reactions, is in agreement with the value 48.23 cal. deg.$^{-1}$ mole^{-1}, calculated from the band spectrum data.

The entropy of liquid hydrogen cyanide at 298.1°K. is 26.97 ± 0.05 cal. deg.$^{-1}$ mole^{-1}.

The Influence of Ionic Strength on the Quenching of Fluorescence in Aqueous Solutions

BY R. W. STOUGHTON AND G. K. ROLLEFSON

The quenching of fluorescence in solution has usually been discussed as a deactivation of the photoactivated molecule by a collision with the quenching ion in which some energy is transferred to the quencher. Such a process is analogous to the type assumed in the discussion of gaseous systems. A more specific picture to adopt for the mechanism of quenching would be to say that the activated molecule and the quencher react to form an intermediate, such as is assumed in the discussion of rates of reaction, and that when this intermediate decomposes into the original molecules, neither is in a state which can radiate. At first it may seem that there is no essential difference between the two views but there is a definite difference to be expected for the effect of ionic strength on the efficiency of a quencher. In this paper we shall show that the quenching process behaves exactly as a second order reaction.

According to the interionic attraction theory, the limiting law for the effect of ionic strength on the activity coefficient of an ion in water at 25° is

$$\log \gamma = -0.5\, z^2\mu^{1/2} \qquad (1)$$

in which γ is the activity coefficient, z the charge on the ion and μ the ionic strength. This shows that the activity of an ion at a given concentration will decrease as the ionic strength is increased. If the quenching action of ions in solution on fluorescence is considered as simply a collision of the second kind and it is assumed that the number of effective collisions is determined by the activities of the colliding molecules, it follows that raising the ionic strength will decrease the quenching efficiency of a given ion. On the other hand, if the quenching process is analogous to the rate of a bimolecular reaction involving ions in solution, the effect which will be observed will depend on the nature of the molecules involved. Thus it has been found that the logarithm of the rate constant for an ionic reaction is given by

$$\log k = \log k_0 + 0.5\ \Delta z^2\mu^{1/2}$$

or

$$(2/\Delta z^2) \log k/k_0 = \mu^{1/2} \qquad (2)$$

in which k is the rate constant at ionic strength μ, k_0 is the constant at $\mu = 0$, and Δz^2 is the difference between the square of the charge of the intermediate complex formed from the reactants and the sum of the squares of the charges of the reactant molecules. On the basis of this equation raising the ionic strength may increase, decrease, or have no effect on the quenching action depending on the sign of Δz^2. The three possibilities may be illustrated by writing the equations

$$M^{-*} + X^- \rightleftarrows MX^{--} \longrightarrow M^- + X^- \quad \Delta z^2 = 2 \quad (3)$$

$$M^* + X^- \rightleftarrows MX^- \longrightarrow M + X^- \quad \Delta z^2 = 0 \quad (4)$$

$$M^{+*} + X^- \rightleftarrows MX \longrightarrow M^+ + X^- \quad \Delta z^2 = -2 \quad (5)$$

The first step is written as reversible in accordance with the assumption usually made in deriving equation (2). It must be stressed, however, that the validity of that equation as a limiting law rests on an experimental basis and is independent of any assumptions which may be made in justifying it on theoretical grounds. Furthermore, the application of the equation to the quenching of fluorescence is independent of the nature of the products in (3), (4) and (5) except that the molecules of the fluorescent substance must be regenerated.

In the following paragraphs we present data on twelve systems in all of which the quenching changes in the way predicted for a bimolecular ionic reaction. The limiting law is not strictly valid at the concentrations used but the deviations observed are within the same range as found for electrolytes such as the alkali halides and halogen acids.

Materials.—The KNO_3, $NaClO_4$, KCl, KBr, KI, KCNS, $AgNO_3$, quinine sulfate and acridone used in these experiments were C. P. grade. The fluorescein was reprecipitated by dissolving it in an alkaline solution and acidifying. The anthracenesulfonic acid was prepared by a method outlined in the literature.[1] The acridone sulfonic acid was prepared by heating acridone and fuming sulfuric acid in the presence of glacial acetic acid to 100°, diluting, removing the excess sulfuric acid with barium hydroxide and evaporating to dryness.

Apparatus.—The apparatus is shown in Fig. 1. Light from the Heraeus type mercury arc S passed through the lens L and the filter F and excited the fluorescent solution in the cell C, which was placed in the water thermostat B. F was a no. 586 Corning filter and transmitted only the group of mercury lines around 3660 Å. The fluorescent light from C passed through the filter F′, which absorbed

(1) *Chem. Zentr.*, **83**, II, 1413 (1912).

all ultraviolet light, and onto the photocell P_1. In order to compensate for fluctuations in the arc, light from the same source was allowed to pass through the same type of filter F and illuminate a second photocell P_2. The currents of the two photocells were balanced with a potentiometer. With this arrangement the potentiometer readings were proportional to the intensity of light falling on P_1 when adjustment was made so that no current flowed through the galvanometer G. The linearity of the potentiometer readings as the light intensity was varied was verified by placing calibrated screens between F' and P_1.

Method.—All the solutions used in these experiments were kept in a thermostat at 25°, and mixing was done immediately before the measurements were taken to prevent the possibility of photoöxidation on standing. The thermostat in which the cell was placed was also kept at 25°.

The potentiometer reading obtained when the cell C was filled with a dye solution at a definite hydrogen ion concentration and at a definite ionic strength was recorded as I_0. Similar readings were taken at various concentrations of the quenching salt and recorded under the heading I. From these data values of the quenching constant k were calculated using the equation

$$I/I_0 = 1/(1 + kC_q)$$

where C_q is the concentration of the quenching ion.

In order to test the validity of the present explanation for the quenching of fluorescence, the charge on the fluorescent substance in solution had to be known. It was possible to fix the molecular species present by using the proper hydrogen ion concentration. Two different sets of data were recorded in the case of fluorescein: one in 0.001 M perchloric acid ensuring the presence of only the un-ionized molecules and one in 0.001 M potassium hydroxide to ensure having only the divalent negative ion in solution. All the measurements with quinine sulfate were taken in 0.01 M nitric acid, so that the substance would be in the form of the divalent positive ion. No acid or base was added in the case of acridone, anthracenesulfonic acid or acridonesulfonic acid since acridone exists only as the neutral molecule and the other two are strong acids.

The values of k at a given ionic strength were determined for various concentrations of the quenching salts in the cases of fluorescein with potassium iodide in both acid and basic solutions and quinine sulfate with potassium chloride and bromide and silver nitrate. It was found that k depended only slightly on the concentration of the quencher. The variations that were observed showed a slight increase with increasing concentration with the negative ions but with Ag^+ there was a decrease. In order to separate the effect of ionic strength from any variations of this type, values of k were determined in which the concentration of the quenching salt was kept constant and the ionic strength varied by adding sodium perchlorate in the case of fluorescein and potassium nitrate in all other cases. Small corrections were made for the quenching of quinine sulfate by potassium nitrate. No measurable quenching was observed by either potassium nitrate or sodium perchlorate with the other dyes. The results are given in the tables.

Discussion

From the data in Tables I to V, values of $(2/\Delta z^2) \log k$ were determined and plotted against $\mu^{1/2}$. The values of Δz^2 were obtained by subtracting the sum of the squares of the charges of the reacting ions from the square of the charge of the intermediate complex formed. The quenching ions in these reactions were the negative ions of the potassium halides and potassium thiocyanate used, and the silver ion in the case of silver nitrate. The charges on the dye ions were discussed before. Thus the Δz^2 values for the reactions of the quenching of fluorescence of quinine sulfate by potassium iodide and silver nitrate would be as follows

$$Q^{++*} + I^- \rightleftharpoons QI^+ \longrightarrow Q^{++} + I^- + \text{energy} \qquad \Delta z^2 = -4$$

$$Q^{++*} + Ag^+ \rightleftharpoons QAg^{+++} \longrightarrow Q^{++} + Ag^+ + \text{energy} \qquad \Delta z^2 = +4$$

Q^{++*} and Q^{++} representing the activated and unactivated quinine ions, respectively.

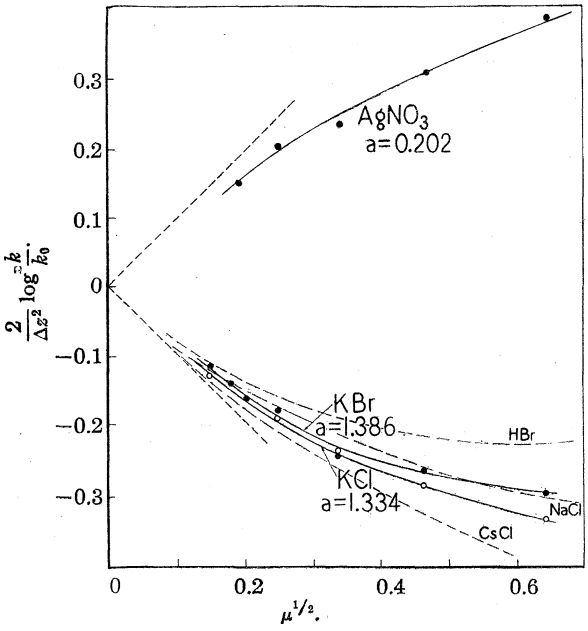

Fig. 2.—Quenching of fluorescence of quinine sulfate by $AgNO_3$, KBr and KCl.

In order properly to compare the $(2/\Delta z^2)\log k$ *vs.* $\mu^{1/2}$ curves obtained with known activity coefficient curves, it was necessary to determine the value of $\log k_0$. This determination was accomplished by drawing in the limiting curve of slope ± 1 in the position which seemed most appropriate and extending it to the ordinate. The value of the ordinate at this intersection was taken as $(2/\Delta z^2)\log k_0$, and the entire curve was shifted by this amount toward the origin by moving it parallel to the $(2/\Delta z^2)\log k$ axis. This method was equivalent to plotting $(2/\Delta z^2)\log k/k_0$ *vs.* $\mu^{1/2}$ and it brought all the curves into the same region for comparison. The results are shown in Figs. 2, 3, 4, 5 and 6.

The values of a here represent $(2/\Delta z^2)\log k_0$. The dotted lines of slope $+1$ and -1 represent the limiting slope predicted by the Debye–Hückel theory. The activity coefficient curves for hydrobromic acid, sodium chloride, and cesium chloride are shown dotted in Fig. 2 for comparison.

The possibility of explaining the quenching of fluorescence as due to the tying up of part of the dye ions by complex formation with the quenching ions before activation of the dye was considered. Absorption measurements were made on solutions of quinine sulfate, fluorescein and acridone sulfonic acid in the presence and absence of the quenching ions used in each case. These measurements were taken with such concentrations of the dyes that about 50% of the incident light was absorbed. A negligible decrease in absorption in the presence of the quenching salts was noted in all cases except those involving Ag^+, where a small increase (less than 1%) was observed. Since it is very improbable that the complexes in all cases would have the same absorption coefficients as the dye molecules

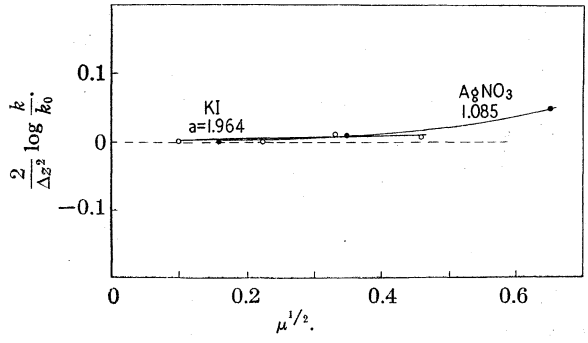

Fig. 4.—Quenching of fluorescence of acridone by silver nitrate and potassium iodide.

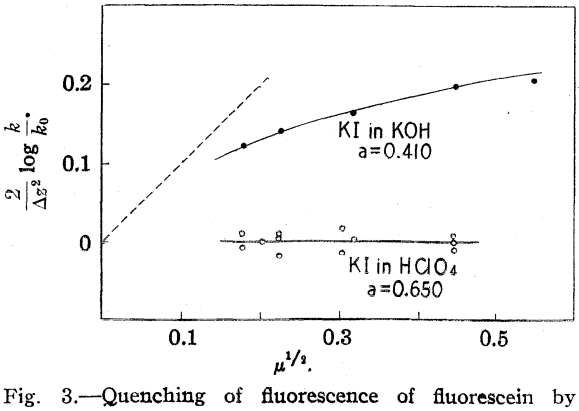

Fig. 3.—Quenching of fluorescence of fluorescein by potassium iodide in acid and basic solutions.

themselves, these results may be interpreted as eliminating the possibility of explaining the quenching by complex formation before activation of the dye.

It may be well to emphasize here the importance of fixing the molecular species in solution of those dyes which are weak electrolytes. For our purpose the charge on the ions had to be known, and it was pointed out by Desha, Sherrill and Harrison[2] and later by Eisenbrand[3] that the form of the molecules due to the value of *p*H has an enormous effect on the intensity of fluorescent

light in the region of hydrogen ion where dissociation takes place. This ensuring of a single definite molecular species in solution has been overlooked by many investigators of fluorescence quenching.

From the data presented it can be seen that the variations of values of $(2/\Delta z^2) \log k/k_0$ with varying ionic strength are of the same type and magnitude as those known to occur in ordinary bimolecular reactions. In every case the curves are of the required form and in every case the increase or decrease of the values of the quenching constants at low values of μ is in accordance with the sign of Δz^2. In view of these results and the considerations of the previous paragraphs, it follows that the quenching is due to an ordinary bimolecular reaction between the activated dye molecules and the quenching ions.

It must be pointed out here that in the present paper no attempt is made to attribute the decrease in fluorescence intensity with increasing dye concentration to the ionic strength effect on the quencher. Only the quenching due to known non-fluorescing quenching ions was explained in this way.

From the results of the present work the study of the quenching of fluorescence seems to offer a very convenient means for studying a simple bimolecular reaction. The first step of such a process may be determined directly without having to consider the products formed as is usually the case. A perhaps even more useful possibility is to reverse the process used here, that is, assume the reaction to be of the ordinary bimolecular type and then determine the molecular species involved by a study of the variations of log k with varying ionic strength. Such an application should be of considerable importance in determining the form of the ions present in non-aqueous solutions.

Summary

The quenching constants at various values of ionic strength were determined for the quenching of fluorescence of quinine sulfate by potassium chloride and bromide and silver nitrate; of fluorescein by potassium iodide in acid and basic solutions; of acridone by potassium iodide and silver nitrate; of anthracene sulfonic acid by potassium iodide and silver nitrate and of acridone sulfonic acid by potassium iodide, potassium thiocyanate and silver nitrate.

The values of $(2/\Delta z^2) \log k$ were plotted against $\mu^{1/2}$ and in every case the curves obtained were of the same type as those expected for an ordinary bimolecular reaction.

Absorption measurements were made with the dye solutions in the presence and absence of the quenching ions. Only a negligible change of absorption was observed, thus eliminating the possibility of explaining the quenching as due to complex formation of the dye with the quencher before excitation of the former.

The quenching in all cases appeared to be due to an ordinary bimolecular reaction between the quenching ion and the activated dye molecule.

Studies on Hydrazine: The Heat of Formation of Hydrazine and of Hydrazine Hydrate*

BY ALBERT M. HUGHES, R. J. CORRUCCINI AND E. C. GILBERT

In order to extend previous results from this Laboratory on the thermochemistry of hydrazine and its compounds in aqueous solution,[1] attention has been turned to heats of combustion. For this a new calorimeter has been constructed, in which, however, the adiabatic principle of the earlier work has been retained.[1a]

Apparatus and Method

In the construction of the calorimeter the general principles and restrictions laid down by White[2] were followed closely. Certain details, however, are pertinent. Automatic temperature control by means of a 17-junction thermel, high sensitivity galvanometer and Weston Photronic cell, and electrolytic heating is the same as in the earlier apparatus.[1a] For the combustion a Parr double valve Illium bomb of 360 cc. capacity was used. The 3-mm. pegs with which it was originally provided were replaced by pegs 12 mm. high which allowed more effective circulation of water around it. The bomb was held in an oval calorimeter of approximately 2000 cc. capacity. This in turn was contained in a submarine jacket with a 12-mm. air gap between the two. The water was stirred by means of a chain driven stirrer and synchronous motor. The heat of stirring was of the order of 0.0001° per minute. The stirrer shaft contained a bakelite insert to minimize heat transfer. The ignition leads were led through copper tubing immersed in the outer bath for the same reason.

A temperature difference of 0.0002° between the calorimeter and the outer bath could be detected by the thermel galvanometer. During the runs the divergence never amounted to more than 0.0006°, and that only for brief intervals during the combustion. The automatic heating was augmented during the rapid temperature rise by the manual addition of hot water. There was a lag of approximately four seconds in the temperature equalization between the calorimeter and the outer bath.

The temperature was measured by means of a Leeds and Northrup platinum resistance thermometer, a "Mueller-type" thermometer bridge, and a Leeds and Northrup galvanometer (2285-b). Resistance could be read under the optimum conditions accurately to 0.00001 ohm. The bridge was newly calibrated in terms of the international ohm.[3] The bomb was provided with special crucible supports constructed by the Parr Instrument Co., having screw binding posts. Heavy platinum wires led from these to a point near the charge to be burned. The charge was ignited by heating an exactly measured (2–3 cm.) piece of iron wire (no. 36) electrically using a 14-volt transformer. The energy introduced by the heating and combustion of this wire was determined by a series of blank runs, the mean result being 0.00019 ohm (0.0019°) for 3 cm.

The same mass of water was used in the calorimeter each time within 0.1 g. The mass of the charge was determined to 0.00001 g. The crucible for holding the charge was of very thin platinum, a factor which seemed to minimize carbon formation.

The bomb was washed out several times with oxygen at 4–5 atm. to remove residual air. Nitric acid formed in the combustions was determined by titration of the bomb washings with standard base, using brom cresol green as indicator. For the heat of formation of nitric acid at 25° and constant volume the value of 13,960 cal. mole^{-1} was used.[4] This correction was of considerable importance in the compounds burned for this investigation.

The same pressure of commercial oxygen, 30 atm. absolute, was used in every run, and 1 g. of water was added to the bomb.

The results are referred to the standard temperature of 25°, by using in each instance an initial temperature of 25 ± 0.1°, and calculations involving the heat capacity of the products of the reaction. This procedure was adopted because of uncertainty regarding the heat capacity of the reactants.

Calibration of the Calorimeter

The energy equivalent of the calorimeter was determined by the combustion of benzoic acid (Standard Sample 39e) supplied by the Bureau of Standards. The isothermal heat of combustion of this sample at 25° is given as 26,419 int. joules per gram true mass when burned under standard conditions.[5] The ratio of mass of acid and water to volume of the bomb being not quite "standard" a small correction ensues[5] (p. 491), which gives a value of 26,418 int. joules developed by the combustion of one gram of benzoic acid under the bomb conditions of this calorimeter. For convenience in making heat capacity calculations and in interpreting results, the results of this paper are largely expressed in conventional calories derived from the international joule by dividing by the factor 4.1833.[6]

Independent determinations were made by two operators (A. M. H. and R. J. C.) and the results are shown in Table I.

Heat of Combustion of Hydrazine Hydrate

Purification.—Purification of this compound is difficult on account of its instability and ease of oxidation, factors which also complicate the problem of securing uncon-

taminated samples in the glass ampoules, a necessary step in the process. The freezing point curve for the system hydrazine–water has been established recently by Semishin.[7] From this it appears that upon freezing, any solution of hydrazine and water containing between 30 and 60% hydrazine should yield crystals of the hydrate (m. p. −46.8°). This was attempted with the apparatus used for anhydrous hydrazine and described below, but the product obtained after two recrystallizations contained hydrazine in nearly 5% excess over the amount needed to make the hydrate. Combustions were run on this material and are reported with the other results. Since the heat of solution of anhydrous hydrazine in the hydrate is not known, no worthwhile conclusions may be drawn from these values except as they indicate the reproducibility of the combustion process, with a given sample. A number of samples of Kahlbaum hydrazine hydrate "pro analysi" (99.8–100.5%) were available and the procedure finally adapted was the same as that used in the earlier work,[1d] which was to take the distilled Kahlbaum preparation, determine the hydrazine content by the iodic acid method[8] (which in our experience is the most accurate available) and add the proper amount of water to give the exact composition of the hydrate (64.03% N_2H_4) (all weights reduced to vacuum). This material was then used for filling the ampoules for combustion. The air in the ampoules was replaced by hydrogen, and hydrate introduced by evacuation in a hydrogen-filled desiccator. They were filled completely, sealed off and used for combustion runs within a few hours. The results are shown in Table II.

The precision of the analysis rather than of the combustion is presumably the limiting factor. Combustions conducted on samples of hydrate from widely different batches over a year apart and by different individuals gave quantitative agreement, however.[9] The only impurity to be obvious would be ammonia, but tests for this substance were negative. Since the heat of combustion of ammonia is higher than that of hydrazine, its presence would give high results.

			Mean $-\Delta U_B/m$	= 2,935.2	±0.6 cal. g.$^{-1}$

$-\Delta U_B$ = 146,936 ± 30 cal. mole^{-1}

[a] The samples checked by analysis to contain 0.0539% by wt. N_2H_4 and 0.9461% $N_2H_4 \cdot H_2O$, hence were not used in further calculations. [b] Corrected for heat of stirring, evaporation, etc., and for the ignition energy.

Purity of the Reaction.—A question also of considerable importance is that of the purity of the reaction and the absence of side reactions. The following products that might conceivably occur were tested for in the bomb washings: nitrites,[10] ammonia[10] (p. 468), hydrazoic acid, and excess hydrazine hydrate. None was found, except in a few bad runs there was some unburned hydrate, apparently from splashing. Flattening the sides of the ampoules and filling them fuller seemed to obviate this difficulty.

Calculation of Results.—Due to the fact that hydrazine hydrate contains only nitrogen, hydrogen and oxygen, it was necessary to depart from the classical equations of Washburn[11] for the heat capacity of the products. The pure reaction for the combustion is

$$N_2H_4 \cdot H_2O(liq) + O_2(g) \longrightarrow N_2(g) + 3H_2O(liq)$$

from which it may be seen that the only pressure change will be due to oxygen used in the forma-

(10) Mahin, "Quantitative Analysis," 4th ed., McGraw-Hill Book Co., Inc., N. Y., 1932, p. 473.

(11) Washburn, *Bur. Standards J. Research*, **10**, 525 (1933).

tion of the small amount of nitric acid and ferric oxide. Also the appearance of nitrogen, mole for mole, for the oxygen consumed otherwise further simplifies the problem, since their thermodynamic properties may be considered equal. Due however to the large amount of water formed, a significant correction is introduced. From the figures of Washburn[11] (p. 556) and making due allowance for the water present as vapor at 25°, the mass of liquid water after the combustion will be

$$(m_w + 54.06m_h/50.06 - 0.0068)$$

where m_w = mass of water initially placed in the bomb and m_h = mass of hydrate burned.

Any correction for the heat of dilution of nitric acid is disregarded since Becker and Roth[4a] have shown that this may be done safely. Allowance was made, however, for the fact that the specific heat of the resultant nitric acid solution is significantly less than that of pure water. The final expression developed for the heat capacity of the products for an average charge of hydrate is

$$S_F = 5.01(n_{O_2} - \phi_{HNO_3} - \phi_{Fe}) + 0.965\ (m_w + 54.06\ m_h/50.06 - 0.0068) + 0.7\ V + 0.158\ m_{Fe} + 0.0024\ \text{cal.}_{15}\ \text{deg.}^{-1}$$

using the notation of Washburn. All other calculations followed the usual procedure and need not be described.

Heat of Combustion of Anhydrous Hydrazine

Purification.—Kahlbaum hydrazine hydrate was dehydrated with sodium hydroxide in an all-glass apparatus with a fractionating column by the method of Raschig[12] and the product which analyzed variously 99–100% pure was subjected to fractional crystallization in the apparatus shown in Fig. 1, in an atmosphere of dry hydrogen. In this apparatus the hydrazine could be crystallized repeatedly and melted with no exposure to moisture, oxygen or ground-glass surfaces. Since the f. p. is in the neighborhood of 2.0°, the manipulation and temperature control is much simpler than for the hydrate, which perhaps accounts for the lack of success with the latter. The material froze in the arm A to give beautiful, long, loose crystals of the anhydrous hydrazine. When about two-thirds was frozen the apparatus was turned so the residual liquid could be forced out through the platinum filter plate F and side tube B by hydrogen pressure. The solid was then melted and the process repeated. The material thus obtained analyzed to be 99.90% anhydrous hydrazine. Two samples were prepared by freezing and one was prepared by dehydration of the hydrate by barium oxide followed by fractional distillation. The procedure for filling the ampoules was the same as for the hydrate. The results of the combustion are shown in Table III. In calculating the heat capacity of the products the same

(12) Raschig, *Ber.*, **43**, 1927 (1910).

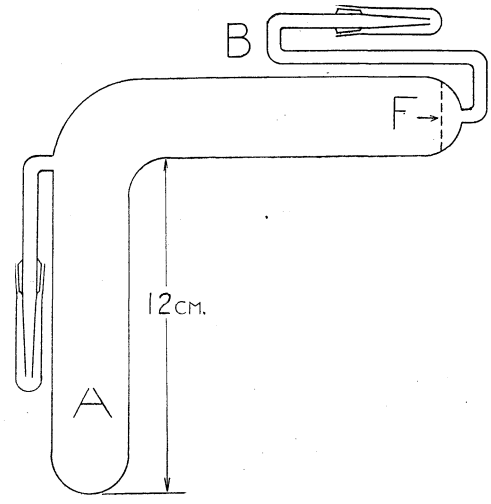

Fig. 1.—Device for fractional crystallization of hydrazine in an inert atmosphere.

equation was used as for the hydrate, due allowance being made for the different amount of water produced.

TABLE III

THE ISOTHERMAL HEAT OF COMBUSTION OF HYDRAZINE AT 25°

Sample	True mass, g.	Total heat[a] evolved at 25°, cal.	Heat from HNO_3 cal.	$-\Delta U_B/m$, cal. g.$^{-1}$	Deviation from mean
2(b)	1.28528	5,979.8	25.4	4,633.2	+0.3
2(c)	1.13373	5,274.6	24.9	4,630.7	−2.2
3(b)	1.49549	6,955.7	26.5	4,633.4	+0.5
3(d)	1.09253	5,087.4	24.1	4,634.2	+1.3
(X)				4,630.7	

Mean $-\Delta U_B/m$ for 99.90% N_2H_4 = 4,632.9 ±1.1 cal. g.$^{-1}$

Calcd. mean $-\Delta U_B/m$ for 100% N_2H_4 = 4,637.6 cal. g.$^{-1}$

Calcd. $-\Delta U_B$ = 148,635 ± 30 cal. mol^{-1}

[a] Corrected for heat of stirring, evaporation, etc., and for ignition energy.

(X) This value was obtained by A. L. H. (Thesis, ref. 9) with a different calorimeter, on hydrazine prepared by fractional distillation of the hydrate from barium oxide, but not analyzed.

Discussion of Results

The heat quantity obtained, $-\Delta U_B$, is the heat of the reaction under bomb conditions and to be useful should be converted to $-\Delta U_R$, the heat evolved by the reaction in the reference state of 1 atm. and 25°. Following the system of Washburn as closely as the difference in types of reaction permitted, this correction proved to amount to 0.003% and was disregarded, $-\Delta U_B$ and $-\Delta U_R$ being taken as equal. From the stoichiometric reaction also it may be seen that $-\Delta U_R = -\Delta H_R$ the heat of the isothermal reaction at constant pressure.

On this basis the results permit some interesting calculations.

(1) $-\Delta H^{\circ}_{298.1}$, the heat of formation of the compounds may be obtained from $-\Delta H_R$ with the use of $-68{,}318.1$ cal.[13] as the heat of formation of liquid water at 25°. For the hydrate is thus obtained

(a) $N_2(g) + 2H_2(g) + H_2O(liq) \longrightarrow N_2H_4 \cdot H_2O(liq)$ $\Delta H^{\circ}_{298.1} = 10{,}300$ cal.

and for anhydrous hydrazine, from the combustion data

(b) $N_2(g) + 2H_2(g) \longrightarrow N_2H_4(liq)$ $\Delta H^{\circ}_{298.1} = 12{,}000$ cal.

Incorporating with (a) the following quantity previously found in this Laboratory by direct measurement[1d]

$N_2H_4(liq) + H_2O(liq) \longrightarrow N_2H_4 \cdot H_2O(liq)$ $\Delta H^{\circ}_{298.1} = -1800$ cal.

a slightly different figure is obtained for (b), *i. e.*

$$\Delta H^{\circ}_{298.1} = 12{,}100 \text{ cal.}$$

(2) In converse manner, the difference between the molal heat of combustion of the hydrate and anhydrous hydrazine should give the heat of hydration. Thus is found

$N_2H_4(liq) + H_2O(liq) \longrightarrow N_2H_4 \cdot H_2O(liq)$ $\Delta H_{298.1} = -1700$ cal. (± 45)

in comparison with the value -1800 cal. found by dilution measurements.[1d] Both of these quantities are obtained by differences and errors are magnified.

(3) From (1) and (2) may be obtained, by using a mean value $\Delta H^{\circ}_{298.1} = 12{,}050$ cal. for hydrazine, and the following quantity[1d]

$N_2H_4(liq) + Aq. \longrightarrow N_2H_4 \cdot Aq$ $\Delta H_{298.1} = -3890$ cal.

a value for the heat of formation in dilute solution;

$N_2(g) + 2H_2(g) + Aq \longrightarrow N_2H_4 \cdot Aq$ $\Delta H_{298.1} = 8160$ cal.

(13) Rossini, *Bur. Standards J. Research*, **22**, 407 (1939).

From earlier thermochemical work, by indirect calculation, Bichowsky and Rossini[14] give three estimates for this quantity, *viz.*, +3500, +4500, and +5800 with apparent preference for the middle value. From the lack of agreement among themselves it would seem that little dependence may be placed on these earlier values.

(4) From $\Delta H^{\circ}_{298.1}$ for anhydrous hydrazine and its heat of vaporization ($\Delta H_v = +10{,}200$ cal. at 25°) reported recently by Hieber and Woerner,[15] $-\Delta H^{\circ}_{298.1}$ for the formation of hydrazine gas may be found. Our figures yield a value for this quantity $\Delta H^{\circ}_{298.1}$ (gas) = 22,250 cal., which compares interestingly with a value calculated from theoretical reasoning by Pauling,[16] of 22,100 cal. (0.96 e. v. mole^{-1}).

Grateful acknowledgment is due the National Research Council and the General Research Council of this College for financial assistance which made this work possible.

Summary

1. An adiabatic calorimeter for precise determinations of heats of combustion has been described briefly, along with its calibration.

2. Heats of combustion for hydrazine and hydrazine hydrate have been determined.

3. The standard heat of formation of hydrazine, liquid and gas; hydrazine hydrate, liquid and aqueous; and the heat of hydration of anhydrous hydrazine have been calculated.

The Electron Diffraction Investigation of the Molecular Structures of Ethyl Chloride, Ethyl Bromide, Isopropyl Chloride, Isopropyl Bromide, Methyl Chloroform and Isocrotyl Chloride[1]

BY J. Y. BEACH AND D. P. STEVENSON[2]

In a previous paper[3] we determined by the electron diffraction method the bond angles and bond distances in *t*-butyl chloride and *t*-butyl bromide. The bond distances in methyl chloride[4] and methyl bromide[5] also have been studied previously. In this paper we shall report an electron diffraction investigation of the molecular structures of ethyl chloride, ethyl bromide, isopropyl chloride and isopropyl bromide. This completes the investigation of the compounds derived from methyl chloride or methyl bromide by replacing zero, one, two or three hydrogen atoms by methyl groups. It is found in all cases that the distortion of the bond angles from the tetrahedral value is less than about 3°. However, we observe a trend in the bond angles which is probably real in going from the simpler molecules to the more complicated molecules. The interatomic distances are found to agree with those predicted by the table of covalent radii.

Methyl chloroform was studied for a comparison with *t*-butyl chloride. Methyl chloroform can be considered to be derived from *t*-butyl chloride by replacing the methyl groups by chlorine atoms and the chlorine atom by a methyl group.

In an electron diffraction investigation of phosgene and the chloroethylenes[6] it was found that the interatomic distance for a carbon–chlorine bond adjacent to a double bond is less than the carbon–chlorine bond distance in saturated compounds. The present study of isocrotyl chloride constitutes an extension of that investigation.

The electron diffraction apparatus used in this investigation is similar to the one described by Brockway.[7] The electron wave length, λ, was 0.0590 Å. The photographs were interpreted by the visual method[8] and by the modified radial distribution method. The theoretical scattering formula used in the visual method is $I = \Sigma_i \Sigma_j Z_i Z_j \sin sr_{ij}/sr_{ij}$. Z_i is the atomic number of the i^{th} atom, r_{ij} is the distance between the i^{th} and j^{th} atoms and $s = (4\pi \sin \theta/2)/\lambda$ where θ is the angle of scattering. Both sums are taken over all the atoms in the scattering molecule. The radial distribution method[9] has recently been improved[10] to give more detailed and reliable results. The coefficients in the radial distribution function were obtained from the visually estimated intensities by multiplying them by $s^2e^{-as^2}$ where $se^{-as^2} = 0.1$ for the largest ring. We have used this modification of the radial distribution method throughout this paper.

Ethyl Chloride.—Kahlbaum ethyl chloride was used without further purification. The photographs showed eight measurable maxima. The

(10) Ch. Degard, *Bull. Soc. Sci. Liège*, February, 1938; V. F. H. Schomaker, paper presented to the American Chemical Society at Baltimore, April, 1939. The modification of the radial distribution method used in this paper is not identical with the modification proposed by Schomaker.

observed values of $s(s_0)$ for the maxima and minima and the visually estimated intensities of the maxima are given in Table I. The fourth maximum is close to the third and is difficult to measure. The eight-term radial distribution function is shown in Fig. 1, curve A. The two principal peaks at 1.76 and 2.74 Å. represent the two carbon–chlorine distances in the molecule.

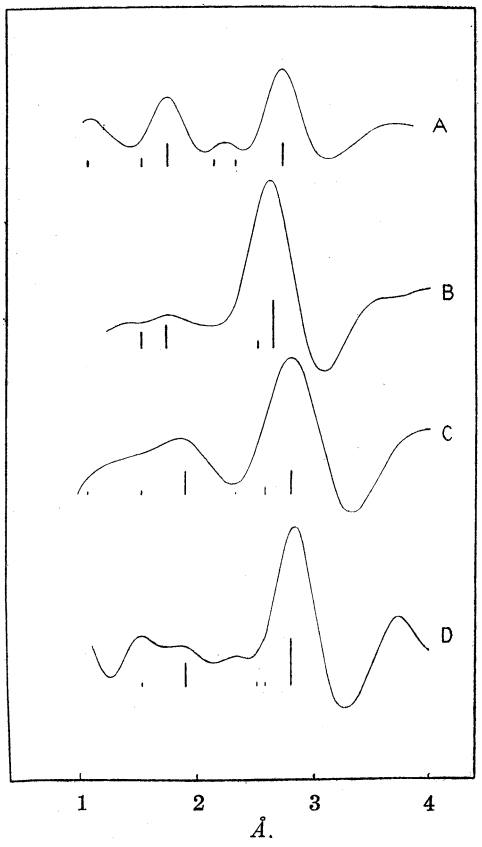

Fig. 1.—Modified radial distribution function for: A, ethyl chloride; B, isopropyl chloride; C, ethyl bromide; D, isopropyl bromide. The vertical lines indicate the final values for the interatomic distances and their importance.

The smaller peaks represent, less reliably, the less important distances in the molecule. In calculating the theoretical intensity curves the ratio of the carbon–chlorine distance to the carbon–carbon distance was taken to be 1.76/1.54. This was the only ratio tried as it gave a final value for the carbon–carbon distance of 1.54 Å., the value we assume to be correct. Other ratios lead to different carbon–carbon distances. No attempt was made to determine the motion of the methyl groups as their orientation has a negligible effect on the theoretical scattering curve.

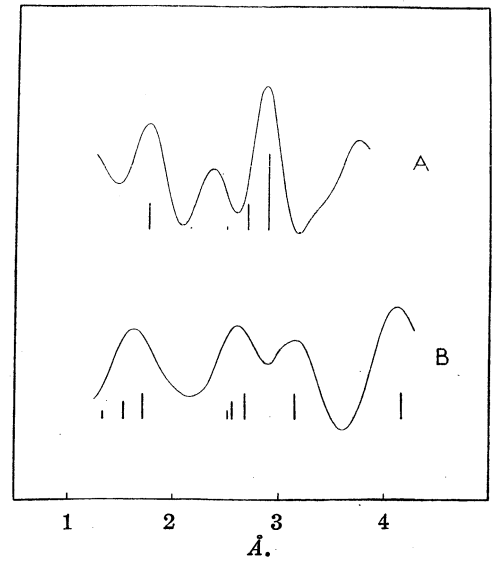

Fig. 2.—Modified radial distribution function for: A, methyl chloroform and B, isocrotyl chloride. The vertical lines indicate the final values for the interatomic distances and their importance.

For the purpose of calculating curves we assumed them to be oriented so that the hydrogen atoms avoided as much as possible the atoms on the other end of the molecule. Theoretical intensity curves were calculated for values of the C–C–Cl angle of 109° 28′ (tetrahedral), 112° and 114° 30′. These curves are shown in Fig. 3. The 112° curve agrees best with the photographs.

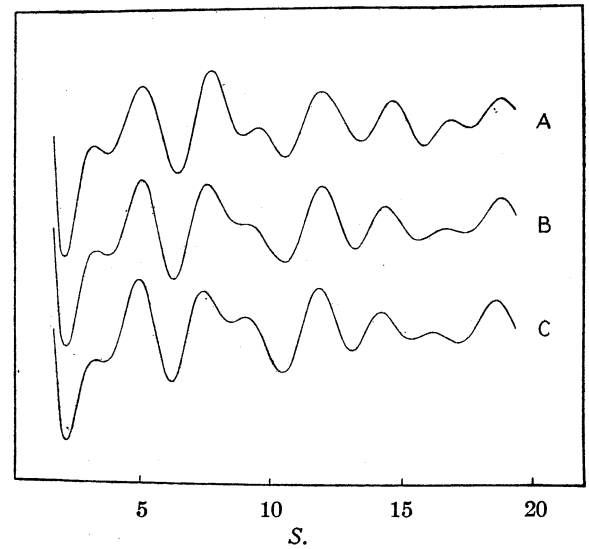

Fig. 3.—Theoretical intensity curves for ethyl chloride. The C–C–Cl angle is: curve A, 109° 28′; curve B, 112°; curve C, 114° 30′. The ratio of carbon–chlorine distance to carbon–carbon distance is 1.76/1.54.

The seventh maximum on the 109° 28′ curve is higher than on the photographs. The 114° 30′ curve is unsatisfactory because the fourth maximum, or shelf, is too high. Quantitative comparison of the photographs with the 112° curve is made in Table I.

The final results are: carbon–chlorine bond distance, 1.76 ± 0.02 Å.; long carbon–chlorine distance, 2.74 ± 0.02 Å.; C–C–Cl angle, 111° 30′ ± 2°. The carbon–carbon and carbon–hydrogen distances were assumed to be 1.54 and 1.09 Å., respectively.

Ethyl Bromide.—Eastman Kodak Co. ethyl bromide was purified by fractional distillation. The electron diffraction photographs showed six measurable maxima. The values of s_0 for the maxima and minima and the visually estimated intensities of the maxima are tabulated in Table II. The six-term radial distribution function is shown in Fig. 1, curve C. The two peaks at 1.87 and 2.81 Å. represent the two carbon–bromine distances in the molecule. In calculating the theoretical intensity curves the methyl group was assumed to possess a static configuration in which the hydrogen atoms avoid as much as possible the atoms on the other end of the molecule. The carbon–hydrogen distance was assumed to be 1.09 Å. and all bond angles except the C–C–Br angle were assumed to be tetrahedral. Curves were calculated for models in which the ratio of the carbon–bromine distance to the carbon–carbon distance was 1.91/1.54, the C–C–Br angle ranging from 107° 30′ to 113° 30′. These curves are shown in Fig. 4. When the C–C–Br angle is greater than the tetrahedral angle the fourth maximum on the calculated curves is much too low. A curve intermediate between curves A and B resembles the photographs most closely. Quantitative comparison of the photographs with both curves A and B is made in Table II. Theoretical intensity curves were also calculated for models in which the ratio of the carbon–bromine distance to the carbon–carbon distance were given values of 1.87/1.54 and 1.95/1.54. Decreasing the carbon–bromine distance has the same effect on the calculated curves as increasing the C–C–Br angle and therefore is impossible. Increasing the carbon–bromine distance is unsatisfactory because the fourth and fifth maxima merge into one.

TABLE II

ETHYL BROMIDE

				Average	0.998		1.010
				C–Br = 1.91 Å.		C–Br = 1.93 Å.	
				long C–Br = 2.81 Å.		long C–Br = 2.81 Å.	

[a] Calculated for a model having a ratio of carbon–bromine to carbon–carbon distance of 1.91/1.54 and a C–C–Br angle of 109° 28′. [b] Calculated for a model having a ratio of carbon–bromine to carbon–carbon distance of 1.91/1.54 and a C–C–Br angle of 107° 30′.

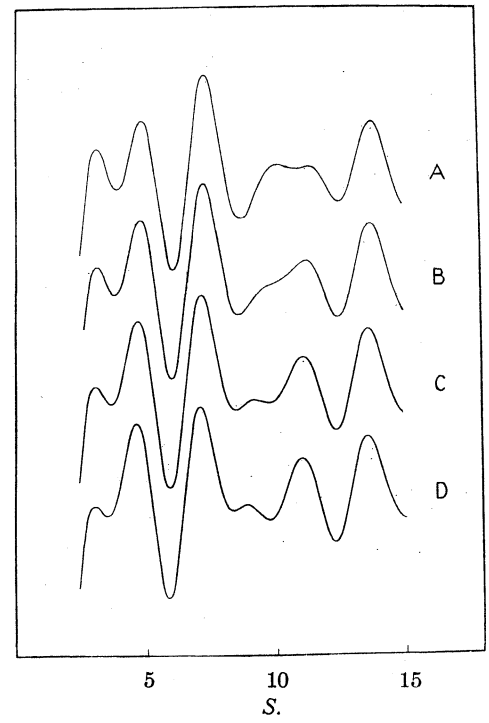

Fig. 4.—Theoretical intensity curves for ethyl bromide. The C–C–Br angle is: curve A, 107° 30′; curve B, 109° 28′; curve C, 111° 30′; curve D, 113° 30′. The ratio of the carbon–bromine distance to the carbon–carbon distance is 1.91/1.54.

Taking the results of the quantitative comparisons together with the radial distribution function we arrive at the final results: carbon–bromine bond distance, 1.91 ± 0.02 Å.; long carbon–bromine distance, 2.81 ± 0.02 Å.; C–C–Br angle, 109 ± 2°.

Isopropyl Chloride.—Eastman Kodak Co. isopropyl chloride was purified by fractionation in a

thirty-inch (76-cm.) column. The photographs show six measurable maxima. The fifth is better defined than the fourth. The values of s_0 for the maxima and minima and the intensities of the maxima are listed in Table III. The radial distribution function is shown in Fig. 1, curve B. The principal peak at 2.64 Å. is an unresolved combination of the long carbon–carbon distance and the two equal long carbon–chlorine distances. If the carbon–carbon distance is 2.52 Å., the value which would obtain if the carbon–carbon bond distance were 1.54 Å. and the C–C–C angle were 109° 28′, then the long carbon–chlorine distance would be 2.66 Å. To make this calculation it is assumed that the observed position of the radial distribution peak is a weighted mean of the two contributing distances, the weighting factors being the importance of the interatomic distance in the scattering function. If all the bond angles in the molecule are tetrahedral and the carbon–chlorine and carbon–carbon distances are 1.76 and 1.54 Å., respectively, then the long carbon–chlorine distance would be 2.70 Å. The value 2.66 Å. obtained from the radial distribution function indicates that the C–C–Cl angle is somewhat less than the tetrahedral value or that the bond distances just assumed are too great. We shall assume that the carbon–carbon distance has the value 1.54 Å., and show that the carbon–chlorine distance is not appreciably less than 1.76 Å., but that the C–C–Cl angle is slightly less than the tetrahedral value.

TABLE III

6		1	14.83	14.41	0.972	14.68	0.990
				Average	0.985		1.000
				C–Cl = 1.73		C–Cl = 1.76	
				long C–Cl = 2.66		long C–Cl = 2.66	

[a] Calculated for a model having a C–C–C angle of 109° 28′, a C–C–Cl angle of 109° 28′ and a ratio of carbon–chlorine to carbon–carbon distance of 1.76/1.54. [b] Calculated for a model having a C–C–C angle of 111° 30′, a C–C–Cl angle of 107° 30′ and a ratio of carbon–chlorine to carbon–carbon distance of 1.76/1.54.

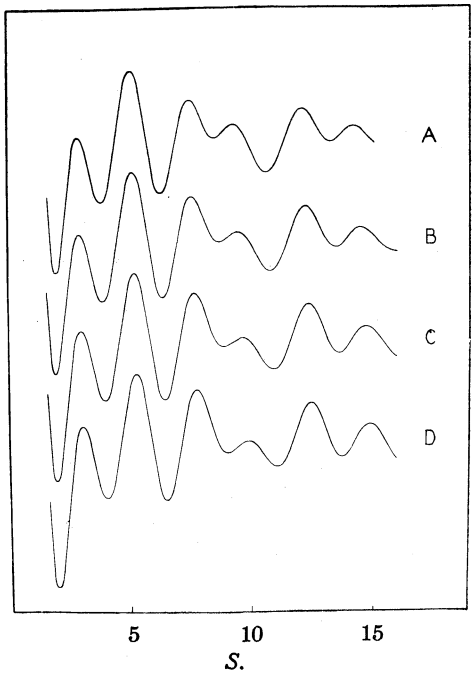

Fig. 5.—Theoretical intensity curves for isopropyl chloride. The C–C–C angle and the C–C–Cl angle, respectively, are: curve A, 107° 30′ and 111° 30′; curve B, 109° 28′ and 109° 28′; curve C, 111° 30′ and 107° 30′; curve D, 113° 30′ and 106°. The ratio of the carbon–chlorine distance to the carbon–carbon distance is 1.76/1.54 for all four curves.

A theoretical intensity curve was first calculated for the model having all tetrahedral angles and a ratio of carbon–chlorine distance to carbon–carbon distance of 1.76/1.54. This curve is in satisfactory qualitative agreement with the photographs and is shown in Fig. 5, curve B. Quantitative comparison of the photographs with this curve is made in Table III. This comparison leads to a carbon–carbon distance of 1.52 Å., 0.02 Å. less than the value we assume to be correct. Quantitative comparison with curves for models having a larger C–C–Cl angle lead to still smaller values for the carbon–carbon distance so these models are discarded. Curve C, Fig. 5, calculated for a model having a C–C–Cl angle of 107° 30′, is in satisfactory qualitative agreement with the photographs. Quantitative comparison is made in Table III. Curve D, Fig. 5, calculated for a model in which the C–C–Cl angle is 106°, is unsatisfactory because the fourth maximum is too low. Models having a ratio of carbon–chlorine distance to carbon–carbon distance much different from 1.76/1.54 are not in satisfactory qualitative agreement with the photographs or lead to values for the carbon–carbon distance different from 1.54.

The results in Table III and the radial distribution function lead to the final results: carbon–chlorine distance, 1.75 ± 0.02 Å.; long carbon–chlorine distance, 2.66 ± 0.03 Å.; C–C–Cl angle 109 ± 3°; C–C–C angle 110 ± 3°.

Isopropyl Bromide.—Eastman Kodak Co. isopropyl bromide was purified by fractional distillation. The photographs possess eight measurable maxima, the seventh being the most difficult to measure. The values of s_0 for the maxima and minima and the intensities of the maxima are given in Table IV. The radial distribution function is shown in Fig. 1, curve D. The large peak at 2.84 Å. represents the long carbon–bromine distance. This peak is not shifted appreciably by the long carbon–carbon distance because the long carbon–bromine distance is of much greater importance in the scattering function. The value calculated for this distance from a tetrahedral bond angle and 1.91 and 1.54 Å. for the carbon–bromine and carbon–carbon bond distances, respectively, is 2.82 Å. The two small peaks at 1.53 and 1.86 Å. represent less reliably the carbon–carbon and carbon–bromine bond distances.

7		1	15.77	16.50	(1.047)	16.60	(1.052)
8		1	18.04	18.11	1.004	18.21	1.010
				Average	0.996		1.008
				C–Br = 1.90 Å.		C–Br = 1.93 Å.	
				long C–Br = 2.81 Å.		long C–Br = 2.81 Å.	

[a] Calculated for a model in which the C–C–C angle and the C–C–Br angle are both equal to 109° 28′ and the ratio of the carbon–bromine distance to the carbon–carbon distance is 1.91/1.54. [b] Calculated for a model in which the C–C–C angle and the C–C–Br angle are equal to 111° 30′ and 107° 30′, respectively, and the ratio of the carbon–bromine distance to the carbon–carbon distance is 1.91/1.54.

Theoretical intensity curves were calculated for models in which the C–C–C angle ranged from 107° 30′ to 113° 30′, the C–C–Br angle ranged from 106° to 111° 30′ and the ratio of the carbon–bromine distance to the carbon–carbon distance varied from 1.87/1.54 to 1.95/1.54. Curve A, Fig. 6, is calculated for a model having tetrahedral angles and a ratio of carbon–bromine distance to carbon–carbon distance of 1.91/1.54. This curve is in good qualitative agreement with the photographs and quantitative comparison is made in Table IV. When the C–C–Br angle is decreased below 107° 30′, the seventh maximum becomes too prominent (see curve C, Fig. 6). When this angle is made larger than 111° 30′ the seventh maximum is too low. When the photographs are compared quantitatively with curves for models in which the ratio of the carbon–bromine distance to the carbon–carbon distance is different from 1.91/1.54, a carbon–carbon distance is obtained which differs from the value 1.54. These models are therefore eliminated.

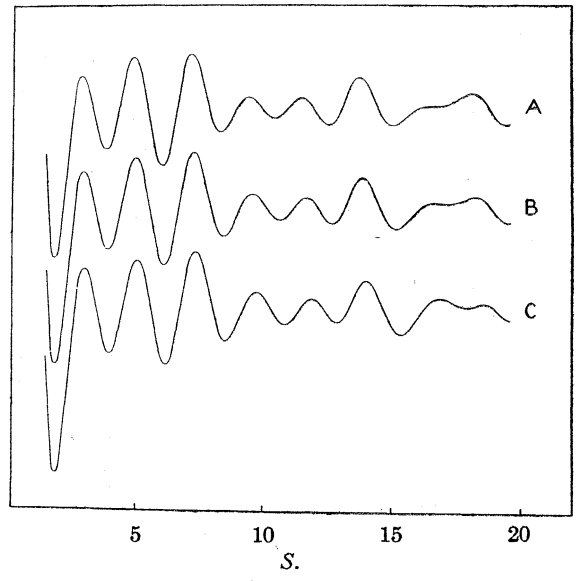

Fig. 6.—Theoretical intensity curves for isopropyl bromide. The C–C–C angle and the C–C–Br angle, respectively, are: curve A, 109° 28′ and 109° 28′; curve B, 111° 30′ and 107° 30′; curve C, 113° 30′ and 106°. The ratio of the carbon–bromine distance to the carbon–carbon distance is 1.91/1.54 for all three curves.

The quantitative comparisons in Table IV and the radial distribution function lead to the final results: carbon–bromine bond distance, 1.91 ± 0.03 Å.; long carbon–bromine distance 2.81 ± 0.03 Å., C–C–C angle, 109° 28′ ± 3°; C–C–Br angle 109° 28′ ± 3°.

Methyl Chloroform.—Eastman Kodak Co. methyl chloroform was purified by fractional distillation. The photographs show eight measurable maxima. The values of s_0 for the maxima and minima and the intensities of the maxima

C–Cl = 1.76 Å.
Cl–Cl = 2.88 Å.

[a] Calculated for a model having tetrahedral bond angles and a ratio of carbon–chlorine distance to carbon–carbon distance of 1.76/1.54.

are given in Table V. The radial distribution function, shown in Fig. 2, curve A, possesses two large peaks at 1.75 and 2.87 Å. The first peak represents the carbon–chlorine bond distance. The second is due principally to the chlorine–chlorine distance. It is shifted slightly by the long carbon–chlorine distance. If this distance is taken to be 2.70 Å. calculated from a tetrahedral bond angle, a carbon–chlorine distance of 1.76 Å. and a carbon–carbon distance of 1.54, the chlorine–chlorine distance must be about 2.92 Å. This value indicates that the Cl–C–Cl angle is slightly greater than the tetrahedral value. Theoretical intensity curves were calculated for models having a Cl–C–Cl angle of from 109° 28′ to 114° 30′. The ratio of carbon–chlorine distance to carbon–carbon distance was taken to be 1.76/1.54. No attempt was made to determine the movement of the methyl group. The calculated curves are shown in Fig. 7. The 109° 28′ curve is in satisfactory qualitative agreement with the photographs. Quantitative comparison is made in Table V. Curve B is unsatisfactory because the sixth maximum is too low. Curve C is unsatisfactory because it leads to a carbon–carbon distance less than 1.54 Å. The final results for methylchloroform are: carbon–chlorine distance, 1.76 ± 0.02 Å.; chlorine–chlorine distance, 2.89 ± 0.03 Å.; Cl–C–Cl angle, 110 ± 2°.

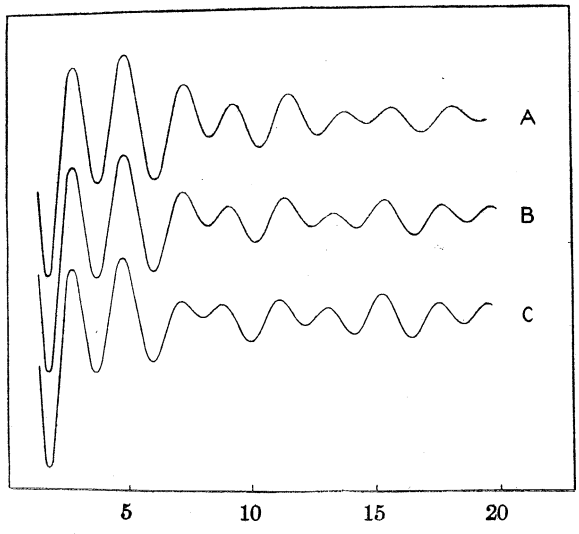

Fig. 7.—Theoretical intensity curves for methyl chloroform. The C–C–Cl angle is: curve A, 109° 28′; curve B, 112°; curve C, 114° 30′. The ratio of the carbon–chlorine distance to the carbon–carbon distance is 1.76/1.54.

Isocrotyl Chloride.—The isocrotyl chloride, $(CH_3)_2CCHCl$, used in this investigation was an Eastman Kodak Co. product which was carefully fractionated in a thirty-inch (76-cm.) distilling column. The photographs show seven maxima, the third being close to the second and difficult to read. An eighth maximum is visible but no reliable measurements could be made on it. The radial distribution function is shown in Fig. 2, curve B. The peak at 1.63 Å. is composed of the carbon–carbon single bond distance and the carbon–chlorine bond distance. If the carbon–carbon single bond distance is assumed to be 1.54 Å. and the observed position of the peak is a weighted mean, then the carbon–chlorine distance is 1.70 Å. The peak at 2.61 Å. consists of the next longer carbon–chlorine distance and the distance between methyl carbon atoms. If the carbon–carbon distance is 2.52 Å. (calculated from a tetrahedral bond angle and a bond distance of 1.54 Å.) the carbon–chlorine distance is 2.64 Å. The peaks at 3.15 and 4.12 Å. represent the two longest carbon–chlorine distances.

In calculating theoretical intensity curves only models were considered which were planar (except for hydrogen atoms) and which had a carbon–carbon single bond distance of 1.54 Å. The methyl groups were assumed to be stationary. Curves were calculated for ten models. The C–C–C angle was varied from 109° 28′ to 112°, the C–C–Cl angle was varied from 125° 16′ to 122° and the ratio of the carbon–chlorine dis-

tance to the carbon–carbon double bond distance was varied from 1.76/1.34 to 1.72/1.34. Some of the calculated curves are shown in Fig. 6. The difficultly measurable third maximum appears, at most, as a shelf, so while it can be included in the radial distribution function it cannot be used in the quantitative comparisons between curves and photographs. Curves A and B are both for models in which the C–C–C angle and the C–C–Cl angle are tetrahedral and the C–C–Cl angle is 125° 16′. The ratio of the carbon–chlorine distance to the carbon–carbon double bond distance is 1.76/1.54 for curve A and 1.72/1.54 for curve B. Both curves are unsatisfactory because the fifth maximum is not sufficiently prominent. Curve C differs from curve B in that the C–C–Cl angle has been decreased to 122°. This curve is in satisfactory qualitative agreement with the photographs. Quantitative comparison is made in Table VI. If the C–C–C angle is increased much above the tetrahedral value, the fifth maximum again becomes too small.

The final results, obtained from Table VI and from the radial distribution function, are: carbon–chlorine bond distance, 1.72 ± 0.02 Å.; C–C–Cl angle, 123 ± 2°; C–C–C angle 111 ± 3°.

C–Cl 1.73 Å.

[a] Calculated for a model having a C–C–C angle of 109° 28′, a C–C–Cl angle of 122° and a ratio of carbon–chlorine distance to carbon–carbon double bond distance of 1.72/1.34.

Discussion

In studying the structure of molecules as complicated as the molecules discussed in this paper it is not possible to determine all of the structure parameters from the electron diffraction data alone. In the case of these molecules we have not attempted to rule out, on the basis of the electron diffraction data, all of the structures bearing no geometrical relation to the conventional chemical structural formula. The number of conceivable (not chemically conceivable) arrangements of, say, ten atoms is tremendous and we have made no attempt to ascertain which non-chemical arrangements, if any, are compatible with the data. In all cases we have assumed that the structure of the molecule was essentially determined by the chemical structural formula, and then proceeded to determine the bond distances and bond angles. We have not attempted to determine the carbon–hydrogen bond distance for in all cases the hydrogen atoms contribute so little to the total electron scattering of the molecule that their positions can be assumed without fear of affecting the other results even though the assumptions are not accurate. We assumed throughout that the carbon–hydrogen bond distance is 1.09 Å., the value found for methane.[11] No attempt was made to determine the orientation of the methyl groups about the carbon–carbon bonds, and in calculating the theoretical intensity curves it was assumed that the hydrogen atoms avoid other atoms and each other as much as possible. Also, we have assumed the value 1.54 Å. for the carbon–carbon single bond distance. This distance is known with certainty from the X-ray study of

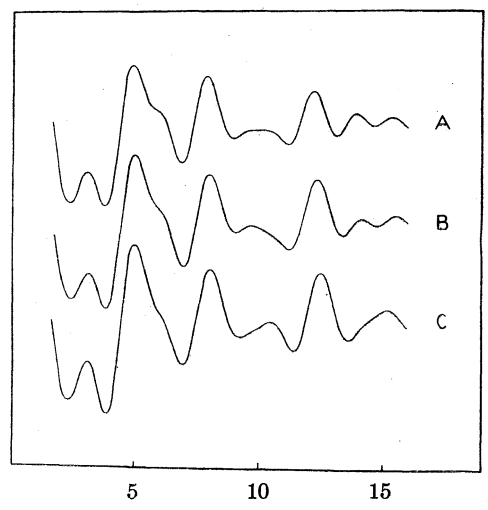

Fig. 8.—Theoretical intensity curves for isocrotyl chloride. The C–C–C angle is 109° 28′ in all three curves. The C–C–Cl angle is 125° 16′ in curves A and B, and 122° in curve C. The ratio of the carbon–chlorine distance to the carbon–carbon double-bond distance is 1.76/1.34 in curve A, and 1.72/1.34 in curves B and C.

(11) Ginsburg and Barker, *J. Chem. Phys.*, **3**, 668 (1935).

diamond[12] and the electron diffraction studies of a large number of saturated hydrocarbons.[13]

The C–C–Cl bond angles in ethyl chloride, isopropyl chloride and *t*-butyl chloride[3] are 111° 30′ ± 2°, 109 ± 3° and 107 ± 2°, respectively. These three values are equal to the tetrahedral angle within the experimental error. However, we believe the trend in angles to be real.

The fact that the C–C–Cl angle in *t*-butyl chloride is less than the tetrahedral value shows that the exchange repulsions and electrostatic repulsions between the methyl groups together with the electrostatic attraction of the chlorine atom for the hydrogen atoms is greater than the steric repulsion between the chlorine atom and the methyl groups. The C–C–Cl angle in methyl chloroform is 109 ± 2°. This molecule is similar to *t*-butyl chloride, the groups attached to the central carbon atom merely being interchanged. Here again the bond angle between unlike groups is less than the tetrahedral value. In both compounds the electrostatic repulsion of like groups and attraction of unlike groups determines the direction of the distortion of the bond angles from the tetrahedral values. The steric repulsions between attached groups in these two molecules must be roughly equal.

The C–C–Br angles in ethyl bromide, isopropyl bromide and *t*-butyl bromide are 109 ± 2°, 109° 28′ ± 3° and 107° 30′ ± 2°. The trend, observed in the case of the chlorides, while present is not pronounced.

The carbon chlorine single bond distance given by the table of covalent radii[13,14] is 1.76 Å. The carbon–chlorine distance observed in methyl chloride[4] is 1.77 ± 0.02 Å. The carbon–chlorine distances observed in ethyl chloride, isopropyl chloride and *t*-butyl chloride[3] are 1.76 ± 0.02 Å., 1.75 ± 0.03 Å. and 1.78 ± 0.03 Å., respectively. In methylchloroform the carbon–chlorine distance is 1.76 ± 0.03 Å. The carbon–chlorine distance in methyl chloride in which zero, one, two or three hydrogen atoms are replaced by methyl groups is found to be in agreement with the value given by the table of covalent radii.

The carbon–bromine distances in methyl bromide,[5] ethyl bromide, isopropyl bromide and *t*-butyl bromide are 1.91 ± 0.06 Å., 1.91 ± 0.02 Å., 1.91 ± 0.03 Å. and 1.92 ± 0.03 Å. The value given by the table of covalent radii for this distance is 1.91 Å. Here, as in the case of the chlorides, complete agreement is found.

In isocrotyl chloride, $(CH_3)_2CCHCl$, we have assumed the carbon–carbon single bond distance to be 1.54 Å., the value given by the table of covalent radii,[13,14] and found to obtain in isobutene.[13] The carbon–carbon double bond distance was assumed to be 1.34 Å., the value given by the table of covalent radii and found in ethylene[13] and allene.[13] The carbon–hydrogen bond distance was assumed to be 1.09 Å., the methane[11] value. The carbon–chlorine distance was found to be 1.72 ± 0.02 Å. The difference of 0.04 Å. between this value and the value found for the compounds discussed above is very probably real and is in fact not surprising. The effect of an adjacent double bond on a carbon–chlorine bond distance already has been observed. It was found in the case of the chloroethylenes[6] that the carbon–chlorine bond distance is less than the normal value; the shortening is greatest in the case of vinyl chloride and decreases as the number of chlorine atoms is increased. The shortening in isocrotyl chloride, 0.04 Å., is not so great as in vinyl chloride, 0.08 Å. As both compounds have one atom adjacent to the double bond this is at first surprising. The shortening in isocrotyl chloride is about the same as the shortening in trichloroethylene. The presence of two methyl groups decreases the shortening approximately as much as two chlorine atoms. This shows that there is some conjugation of the carbon–carbon single bonds with the double bond, decreasing the shortening in isocrotyl chloride to about the same extent that the additional chlorine atoms decrease the shortening in trichloroethylene. This conjugation will have some effect on the carbon–carbon single bond distance which we assumed to be 1.54 Å. The shortening of a single bond adjacent to a triple bond has been observed in methylacetylene[15,16] to be 0.08 Å. The shortening of a carbon–carbon single bond adjacent to a benzene ring is negligible. The carbon–carbon single bond distance in hexamethylbenzene is 1.53 Å.[17] We would, therefore, estimate the carbon–carbon single bond distance in isocrotyl chloride to be between 1.51 and 1.53 Å.

This will not affect materially the carbon–chlorine distance of 1.72 Å. we obtained assuming 1.54 Å.

Of the compounds discussed in this paper only ethyl chloride and ethyl bromide have been studied previously by the electron diffraction method.[18] The results were: 1.81 ± 0.1 Å. for the carbon–chlorine distance in ethyl chloride and 2.07 ± 0.07 Å. for the carbon–bromine distance in ethyl bromide. Both of these values are somewhat higher than the values reported by us. We believe our values to be more reliable because of the advances which have been made in electron diffraction technique since the other work was done.

Summary

Electron diffraction has been used to determine the molecular structures of ethyl chloride, ethyl bromide, isopropyl chloride, isopropyl bromide, methyl chloroform and isocrotyl chloride. The results are given in Table VII.

TABLE VII

Compound	C–Cl distance, Å.	C–C–Cl angle
Ethyl chloride	1.76 ± 0.02	111° 30′ ± 2°
Isopropyl chloride	1.75 ± 0.03	109 ± 3°
	C–Br	C–C–Br
Ethyl bromide	1.91 ± 0.02	109 ± 2°
Isopropyl bromide	1.91 ± 0.03	109° 28′ ± 3°
	C–Cl	C–C–Cl
Methylchloroform	1.76 ± 0.02	109 ± 2°
Isocrotyl chloride	1.72 ± 0.02	123 ± 2°

The Constitution of Natural Tannins. VI.[1] Coloring Matters Derived from 2,5-Dihydroxyacetophenone

BY ALFRED RUSSELL AND SAMUEL FRIEND CLARK[2]

The material already reported includes a description of polyhydroxychalcones derived from various 2-hydroxy ketones (notably resacetophenone, phloracetophenone, and gallacetophenone) and hydroxyaldehydes (notably protocatechualdehyde, vanillin, *m*-hydroxybenzaldehyde, and *p*-hydroxybenzaldehyde). By reduction of these 2′-hydroxychalcones with zinc dust and dilute alcoholic acids are obtained light colored amorphous products; when these amorphous products are water-soluble (those derived from protocatechualdehyde only), they are qualitatively indistinguishable from natural phlobatannins. On various grounds it is probable that the amorphous products are flavopinacols hydroxylated on the patterns of the parent chalcones; for the sake of simplicity they are formulated as of the *bis* type, although their structure may be more complicated.

To continue the series so far described, polyhydroxychalcones derived from the various hydroxyaldehydes with three other hydroxy ketones should be examined; these ketones are the dihydroxyacetophenones, 2,3-, 2,6- and 2,5-. The reason for selecting 2,3-dihydroxyacetophenone is the frequent occurrence of catechol as a fission product of natural materials, it not being at all certain that this always comes from a benzopyran compound hydroxylated in the 3′,4′-positions (I)—an hydroxyl group may in some cases be located in the 8-position (II) (the second one ortho to the first appearing after fission). 2,6-Dihydroxyacetophenone must be included because of the frequent occurrence of resorcinol, not necessarily resulting from a compound hydroxylated in the 7-position (III) but possibly from a compound hydroxylated in the 5-position (IV). 2,5-Dihydroxyacetophenone is selected because of the occasional occurrence of quinol as a decomposition product of natural materials, suggesting a benzopyran compound hydroxylated in the 6-position (V). In particular, the monomethyl ether of quinacetophenone has been isolated as a decomposition product of a yellow coloring matter from a European variety of stemless primrose.[3] Moreover, Nierenstein[4] has reported finding quinol amongst the decomposition products of quebracho tannin.

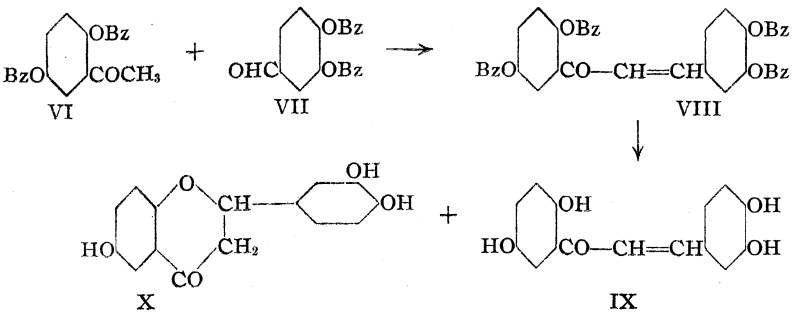
I II III IV V

There are now described syntheses of polyhydroxychalcones,[5] flavanones, and anthocyanidins derived from 2,5-dihydroxyacetophenone (quinacetophenone) and various hydroxyaldehydes. The anthocyanidins are of the luteolinidin type,

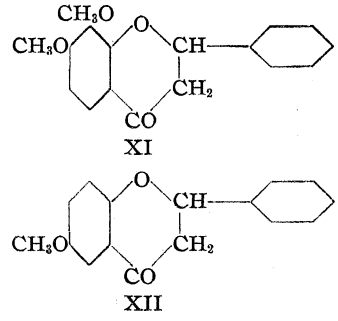


VI VII VIII IX X

containing no hydroxyl group in the 3-position. There is also included a qualitative comparison of the amorphous reduction product of 3,4,2′,5′-tetrahydroxychalcone—*bis*-(6,3′,4′-trihydroxy)-flavopinacol—with natural hemlock and mimosa tannins in aqueous solution.

The synthesis of a typical stable polyhydroxychalcone may be outlined first. Quinacetophenone dibenzoate (VI) was condensed with protocatechualdehyde dibenzoate (VII) in solution of dry ethyl acetate using anhydrous hydrogen chloride to give 3,4,2′,5′-tetrabenzoyloxychalcone (VIII). This, by debenzoylation with alcoholic potassium hydroxide, gave 3,4,2′,5′-tetrahydroxychalcone (IX) and 6,3′,4′-trihydroxyflavanone (X). The chalcone is stable in the sense of remaining unchanged by ordinary laboratory treatment of the dry solid. However, an easy equilibrium exists between the flavanone and chalcone in dilute alcoholic solution, the formation of the flavanone being favored at higher temperatures. This made the task of isolating a pure sample of the chalcone extremely difficult.

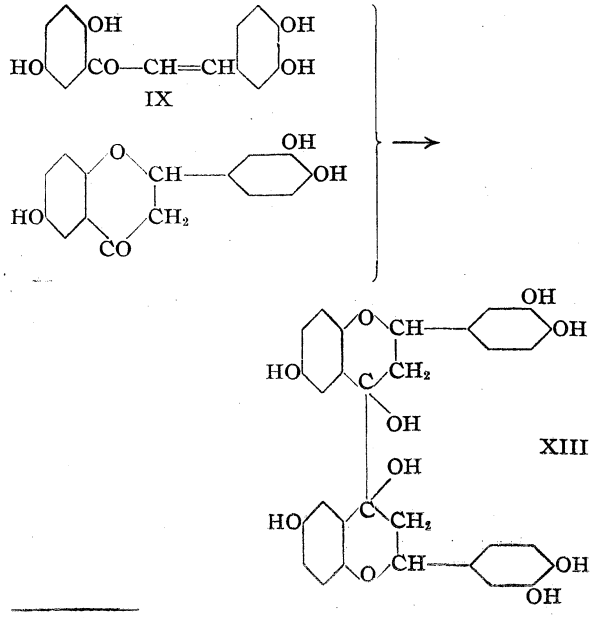
The ready formation of flavanone has been noted by v. Kostanecki,[6] who has isolated flavanone to the exclusion of chalcone in two cases (XI and XII). Further, it is in concordance with



XI XII

the suggestion of Wheeler[7] that this process of making polyhydroxychalcones might, in some instances, give rise to some quantity of flavanone.

Reduction of pure 6,3′,4′-trihydroxyflavanone (X), or of a mixture of flavanone and 3,4,2′,5′-tetrahydroxychalcone (IX) consisting mostly of the latter, with zinc dust and alcoholic hydrochloric acid, gave an amorphous light red material—*bis*-(6,3′,4′-trihydroxy)-flavopinacol (XIII).



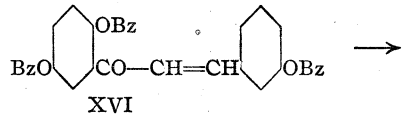
IX XIII

(5) The numbering system used for the hydroxychalcones is that of *Chemical Abstracts*, following the original system of v. Kostanecki. The benzene ring nearer the carbonyl group bears the prime numbers. It is to be noted that this is contrary to the English system of the *British Chemical Abstracts* and the *Journal of the Chemical Society*.

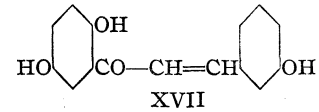
(6) Woker, v. Kostanecki and Tambor, *Ber.*, **36**, 4235 (1903); v. Kostanecki and Lampe, *ibid.*, **37**, 773 (1904).

(7) Nadkarni and Wheeler, *J. Chem. Soc.*, 1320 (1938).

Similarly to the above-described synthesis of a polybenzoyloxychalcone, the preparation of seven other polybenzoyloxychalcones was accomplished. These were 4,2′,5′-tribenzoyloxychalcone (XIV) from *p*-hydroxybenzaldehyde, 3,2′,5′-tribenzoyloxychalcone (XVI) from *m*-hydroxybenzaldehyde, 4,2′,5′-tribenzoyl-oxy-3-methoxychalcone (XIX), vanillin, 2,2′,5′-tribenzoyloxychalcone (XXI) from salicylaldehyde, 2,4,2′,5′ - tetrabenzoyloxychalcone (XXV) from resorcylaldehyde, 2,4,2′,5′-tetrabenzoyloxy-6-methylchalcone (XXVIII) from orcylaldehyde, and 2,4,6,2′,5′-pentabenzoyloxychalcone (XXXI) from phloroglucinaldehyde. With the exception of the last one, which is an oil, the polybenzoyloxychalcones are pale yellow, difficultly crystalline and without sharp melting points.

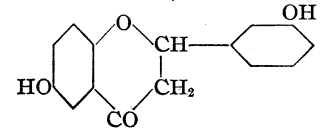


XVI



XVII

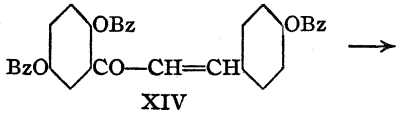
+



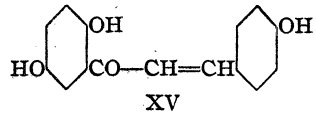
XVIII

Considerable difficulty was experienced in effecting debenzoylation of the polybenzoyloxychalcones without causing fission of the products to initial materials. Even under the mild conditions of saponification finally adopted, the product required was always accompanied by some quantity of quinacetophenone (the hydroxyaldehydes are more soluble and do not appear). This is evidenced by the fact that, although the yield of polybenzoyloxychalcone was upward of 70% of the theoretical, the actual yield of polyhydroxychalcone and other products by hydrolysis in many cases was below 40% of the theoretical. It is clear that the polyhydroxychalcones hydroxylated on the 2′,5′-pattern are particularly sensitive to alkaline fission. Thus, the results were so varied as to necessitate separate description.

The synthesis of 4,2′,5′-trihydroxychalcone (XV) proceeded comparatively smoothly with some accompanying quinacetophenone, but no flavanone.



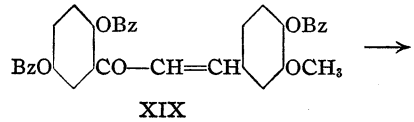
XIV



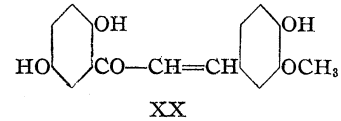
XV

The synthesis of 3,2′,5′-trihydroxychalcone (XVII) furnished some difficulty, because the chalcone was accompanied by quinacetophenone and almost an equal quantity of 6,3′-dihydroxyflavanone (XVIII). The equilibrium between chalcone and flavanone was more evenly balanced in this instance than in that first described (IX and X); consequently, the separation of the two substances by fractional crystallization from dilute alcohol was comparatively easy.

4,2′,5′-Trihydroxy-3-methoxychalcone (XX) was prepared with some accompanying decomposition. In this case the benzoyloxychalcone more stubbornly resisted the action of alkali and was recovered in part. No flavanone could be found, although it appears probable that repetition of the synthesis here or in the case of 4,2′,5′-trihydroxychalcone might yield some quantity of flavanone.



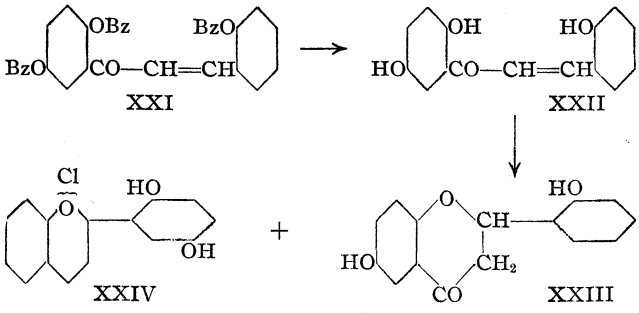
XIX



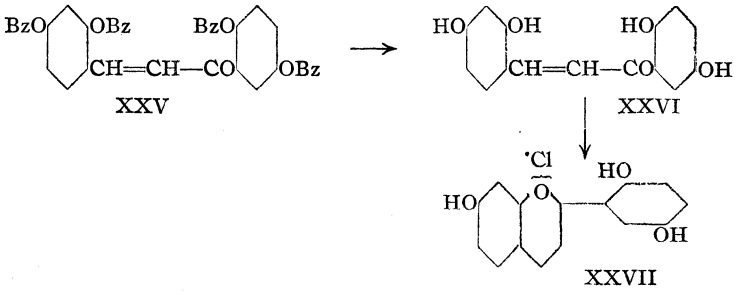
XX

In those cases where the liberated hydroxychalcone had an hydroxyl group in the 2-position, acidification of the alkaline solution after debenzoylation caused cyclization to the anthocyanidin. Thus, 2,2′,5′-trihydroxychalcone (XXII) gave 2′,5′-dihydroxy-2-phenylbenzopyrylium chloride (XXIV) on boiling with 10% hydrochloric acid. The accompanying production of 6,2′-dihydroxyflavanone (XXIII) in considerable quantity was noted. It is believed to be a rare occurrence for a flavanone to be formed in competition with an anthocyanidin.

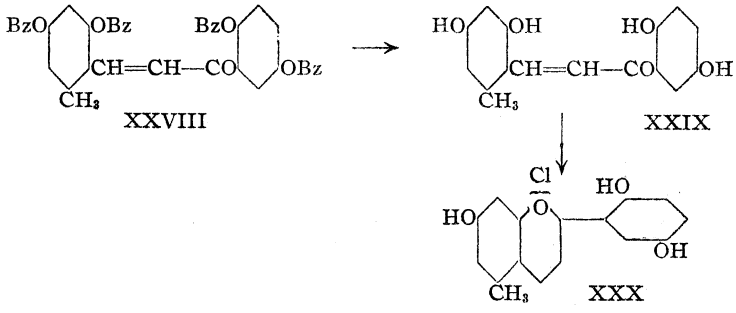
The benzoyloxychalcone (XXV) from resorcylaldehyde was converted to the anthocyanidin—7,2′,5′-trihydroxy-2-phenylbenzopyrylium chlo-



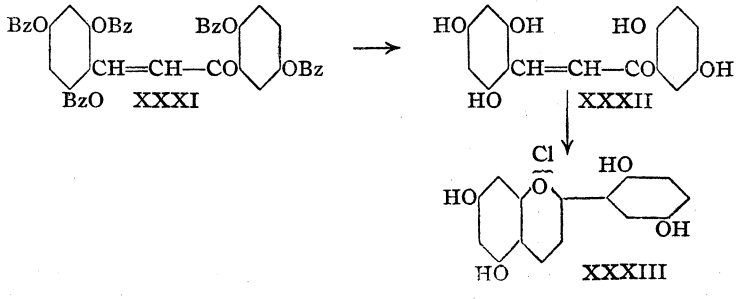
ride (XXVII)—through the intermediate hydroxychalcone (XXVI).



Similarly, the benzoyloxychalcone (XXVIII) from orcylaldehyde was converted to 7,2′,5′-trihydroxy-5-methyl-2-phenylbenzopyrylium chloride (XXX).



Finally, the synthesis of 5,7,2′,5′-tetrahydroxy-2-phenylbenzopyrylium chloride (XXXIII) was accomplished from the benzoyloxychalcone (XXXI). Some difficulty was experienced in isolating this substance due to the usual decomposition and its appreciable water solubility.



The polyhydroxychalcones are various shades of orange, the color deepening as the number of hydroxyl groups increases, and are definitely crystalline with sharp melting points. The anthocyanidins are red in color and are associated with water of crystallization, as R. Robinson[8] previously has noted in other instances. The flavanones are white crystalline substances with a faint yellowish tinge. The flavopinacol is a light red amorphous powder that is difficult to dry and retains traces of solvents with great obstinacy—its analysis was not attempted.

In view of the relationship between chalcone and flavanone exhibited in the present work, it may be that such a relationship exists in other series. For example, Kurth[9] has reported the synthesis of yellow 3,4,2′,3′,4′ - pentahydroxychalcone, m. p. 249°, by the action of cold alkali on gallacetophenone and protocatechualdehyde, followed by acidification and crystallization from dilute alcohol. This substance was previously reported by Russell[2] as a deep orange material, m. p. 233°. Since the color of polyhydroxychalcones deepens (yellow-deep orange) as the number of hydroxyl groups increases, it is possible that Kurth's product is the corresponding flavanone. Moreover, the fact that it gave a pentabenzoate is not relevant evidence that it is a pentahydroxychalcone, as many instances are on record[10] where acylation of hydroxyflavanones produced the fully acylated chalcones corresponding.

The table below gives a qualitative comparison, by means of various reagents, of *bis*-(6,3′,4′-trihydroxy)-flavopinacol with natural hemlock and mimosa tannins, using approximately 1% aqueous solutions. It will be seen that the resemblance is very close.

Experimental

Quinacetophenone.—This ketone was prepared more than twenty times. A typi-

cal run is cited. Quinol (100 g.) was dissolved in boiling glacial acetic acid (200 cc.). Freshly fused zinc chloride (400 g.) was added, and the mixture refluxed for an hour. The temperature rose to 150–165°, and the solution became dark red. At the end of the reflux period the solution was poured into ice water. The precipitated crude quinacetophenone was recrystallized from dilute alcohol with several charcoal treatments. Quinacetophenone crystallized in greenish-yellow plates, m. p. 200–201°. The yield averaged 20–25%, being rather low due to the necessity of heavy charcoaling to free the ketone from colored material.

Preparation of Aldehydes.—Protocatechualdehyde was prepared by the method of Pauly[11] from piperonal. Resorcylaldehyde, orcylaldehyde, and phloroglucinaldehyde were prepared by the Adams modification[12] of the Gattermann reaction, using the corresponding phenol, zinc cyanide, and dry hydrogen chloride in ice-cold ether solution. Vanillin, salicylaldehyde, *p*-hydroxybenzaldehyde, and *m*-hydroxybenzaldehyde were the best Eastman Kodak Co. grade.

Preparation of Benzoates.—The same method was employed for all benzoates. The ketone or aldehyde (0.3 mole) was dissolved in pyridine (150 cc.) and benzoyl chloride in 10–15% excess of that required to benzoylate all hydroxy groups was added with shaking over a period of ten minutes. The mixture was warmed on the steam-bath for twenty to thirty minutes and then set aside overnight at room temperature. The mixture was poured into cold water (1500 cc.) and stirred until the benzoate solidified. It was usually tan to light brown in color. The crude material was washed thoroughly with water and finally with dilute hydrochloric acid. It was then recrystallized from alcohol (charcoal) and dried in the air. The yields were in the range 65–90%, depending on the purity of the initial material. The benzoates were all colorless, although quinacetophenone dibenzoate was difficult to obtain free from yellow coloration.

TABLE II

Benzoate	M. p., °C.	% yield
Quinacetophenone	113	88
p-Hydroxybenzaldehyde	89	81
m-Hydroxybenzaldehyde	37–38	65
o-Hydroxybenzaldehyde	B. p. 208 (15 mm.)	60
Vanillin	97	73
Protocatechualdehyde	75	78
Resorcylaldehyde	98	85
Orcylaldehyde	134–135	82
Phloroglucinaldehyde	130	46

***m*-Benzoyloxybenzaldehyde.**—This benzoate apparently has not been reported before. It melted at a rather low temperature, which necessitated dissolving it in alcohol at room temperature and immersing the solution in a freezing mixture of salt and ice to induce crystallization. It crystallized in colorless prismatic needles, m. p. 37–38°.

Anal. Calcd. for $C_{14}H_{10}O_3$: C, 74.3; H, 4.5. Found: C, 74.2; H, 4.5.

Resorcylaldehyde Dibenzoate.—This benzoate has not been reported previously. It crystallized from alcohol in clusters of colorless prismatic needles, m. p. 98°. *Anal.* Calcd. for $C_{21}H_{14}O_5$: C, 72.8; H, 4.1. Found: C, 72.5; H, 4.1.

Orcylaldehyde Dibenzoate.—This benzoate has not been reported previously. It crystallized from alcohol as a mass of white felted needles, m. p. 134–135°. *Anal.* Calcd. for $C_{22}H_{16}O_5$: C, 73.3; H, 4.5. Found: C, 73.1; H, 4.5.

General Method for Benzoyloxychalcones.—Quinacetophenone dibenzoate (0.07 mole) and the aldehyde benzoate (0.07 mole) were dissolved in anhydrous ethyl acetate (350–400 cc.) (dried over calcium chloride, distilled, and stored over sodium sulfate). Dry hydrogen chloride was passed in for two to five days at ice temperatures. The

(12) Adams and Levine, THIS JOURNAL, **45**, 2373 (1923).

solution turned in color from a pale yellow to a clear dark red. When the solution had been thoroughly saturated for at least a day, it was evaporated on the steam-bath to a thick red sirup. On triturating with cold alcohol, the material usually hardened after ten minutes. It was boiled with alcohol (100 cc.) to remove initial materials, cooled to room temperature, and the alcohol decanted. The material was considered sufficiently pure for conversion to the free hydroxychalcone. For analysis a sample of the benzoyloxychalcone was recrystallized from alcohol, in which it was difficultly soluble.

It had been found previously[1] that benzoyloxychalcones retained alcohol rather tenaciously, which tended to disturb the analytical results. The benzoyloxychalcones were dried in a vacuum desiccator over sodium hydroxide for several days at room temperature. The analytical results were in rather good agreement with the calculated values, considering the nature of the substances.

General Method for Hydroxychalcones.—The preparation of the free hydroxychalcones from the benzoyloxychalcones constituted an unexpected and stubborn problem. The debenzoylation of benzoyloxychalcones derived from resacetophenone and phloracetophenone proceeded smoothly under the conditions previously described.[1] Repetition of this work in the case of 4,2′,4′-trihydroxychalcone and 4,2′,4′-trihydroxy-3-methoxychalcone gave the expected results without difficulty. The method of debenzoylation involved solution of the benzoyloxychalcone in acetone, replacement of acetone by alcohol, slow addition under nitrogen of an aqueous solution of twice the theoretical quantity of potassium hydroxide, distillation of the alcohol over a period of three to four hours, cooling, and finally acidification of the solution to precipitate the hydroxychalcone.

When this method was applied to representative benzoyloxychalcones in the quinacetophenone series, hydrolytic fission of the molecule occurred at the double bond, and quinacetophenone appeared on acidification. The aldehydes were soluble and did not appear. Numerous modifications of the procedure were tried with the view to decreasing the extent of fission at the double bond. It was thought that the excess of potassium hydroxide together with the extended heating period were responsible for the decomposition. (The heating period was quite long due to the large amount of alcohol required to dissolve the benzoyloxychalcones, which seem more insoluble than those of other series.) Accordingly, the following scheme finally was worked out.

The benzoyloxychalcone from the above preparation was introduced into a 3-necked, 1-liter flask, so placed in a steam-bath that most of the surface could be heated directly by the live steam. The small necks of the flask were fitted with a dropping funnel and a tube bent downward for distillation. The large neck bore a mercury-seal stirrer and a gas inlet tube. Alcohol (500–600 cc.) was added and brought to boiling with mechanical stirring under an atmosphere of nitrogen. No attempt was made to dissolve the benzoyloxychalcone completely. An aqueous solution of potassium hydroxide (1 g. excess over requisite theoretical quantity in 200 cc. of water) was added over a period of forty to sixty minutes to the boiling solution. The color turned from a pale yellow to a dark red, and all suspended matter disappeared. Distillation of the alcohol was continued for an hour longer until the original volume was collected.

The solution was then chilled in an ice-bath and acidified with dilute sulfuric acid (20 cc. of concd. acid in 50 cc. of water). The precipitated chalcone and benzoic acid were filtered off and washed with cold water. Separation of the benzoic acid was effected either with cold sodium bicarbonate solution or with hot benzene in a Soxhlet. The specific method employed is described in each case below. The resulting hydroxychalcone contained quinacetophenone and in certain instances flavanone. These were separated by fractional crystallization from dilute alcoholic solutions, the quinacetophenone being more soluble than the hydroxychalcone and the flavanone less soluble. Due to the apparently unavoidable decomposition and to the tedious separation required, the yields (calculated on the basis of quinacetophenone dibenzoate) were much lower than those previously reported.[2]

4,2′,5′-Tribenzoyloxychalcone.—Quinacetophenone dibenzoate (0.07 mole) and *p*-benzoyloxybenzaldehyde (0.07 mole) were converted to the benzoyloxychalcone, a pale yellow semi-crystalline solid, m. p. 134–136°. The yield was 31 g. (78%). *Anal.* Calcd. for $C_{36}H_{24}O_7$: C, 76.0; H, 4.3. Found: C, 75.3; H, 4.5.

4,2′,5′-Trihydroxychalcone.—The benzoyloxychalcone (31 g.) was debenzoylated as described above. The hydroxychalcone was separated from benzoic acid by extraction of the latter with cold dilute sodium bicarbonate solution (12 g. sodium carbonate in 200 cc. of water saturated with carbon dioxide). The chalcone was filtered, washed with cold water, and recrystallized from 35% alcohol (600 cc.). The yield was 10 g. (56%). The crystals were orange-yellow prismatic needles, m. p. 222–224°. *Anal.* Calcd. for $C_{15}H_{12}O_4$: C, 70.3; H, 4.7. Found: C, 70.3; H, 4.8. No trace of flavanone could be found.

3,2′,5′ - Tribenzoyloxychalcone.—Quinacetophenone dibenzoate (0.07 mole) and *m*-benzoyloxybenzaldehyde (0.07 mole) were converted to the benzoyloxychalcone, a light yellow semi-crystalline solid, m. p. 174–175°. The yield was 27 g. (67%). *Anal.* Calcd. for $C_{36}H_{24}O_7$: C, 76.0; H, 4.3. Found: C, 75.6; H, 4.4.

3,2′,5′-Trihydroxychalcone.—The benzoyloxychalcone (27 g.) was debenzoylated as described above. The hydroxychalcone was separated from benzoic acid by extraction of the latter with cold dilute sodium bicarbonate solution (12 g. sodium carbonate in 250 cc. of water saturated with carbon dioxide). The chalcone was filtered and washed with cold water. The product proved to be a mixture, containing quinacetophenone, chalcone, and flavanone. The chalcone was finally separated by fractional crystallization from 20% alcohol as orange needles, m. p. 204–206°. The yield was 3.5 g. (20%). *Anal.* Calcd. for $C_{15}H_{12}O_4$: C, 70.3; H, 4.7. Found: C, 70.2; H, 4.8.

6,3′-Dihydroxyflavanone.—The flavanone was separated from the corresponding chalcone by fractional crystallization. It was finally crystallized in colorless needles, having faint yellow coloration, m. p. 234–236°, from 70% alcohol (charcoal). The yield was 2.0 g. (12%). *Anal.* Calcd. for $C_{15}H_{12}O_4$: C, 70.3; H, 4.7. Found: C, 70.4; H, 4.9.

4,2',5' - Tribenzoyloxy - 3 - methoxychalcone.—Quinacetophenone dibenzoate (0.07 mole) and vanillin benzoate (0.07 mole) were converted to the benzoyloxychalcone, a pale yellow semi-crystalline solid, m. p. 145–147°. The yield was 37 g. (88%).

Anal. Calcd. for $C_{38}H_{26}O_8$: C, 74.2; H, 4.4. Found: C, 74.1; H, 4.5.

4,2',5'-Trihydroxy-3-methoxychalcone.—The benzoyloxychalcone was debenzoylated as described above. The hydroxychalcone was separated from benzoic acid by extraction of the latter with cold dilute sodium bicarbonate solution (12 g. sodium carbonate in 250 cc. of water saturated with carbon dioxide). The chalcone was dissolved in dilute alcohol and filtered. The residue was unconverted benzoyloxychalcone (10 g.). The hydroxychalcone crystallized in dark orange needles, m. p. 172–173°. The yield was 5 g. (46%). *Anal.* Calcd. for $C_{16}H_{14}O_5$: C, 67.1; H, 4.9. Found: C, 67.1; H, 5.0. No trace of flavanone could be found.

3,4,2',5' - Tetrabenzoyloxychalcone.—Quinacetophenone dibenzoate (0.14 mole) and protocatechualdehyde dibenzoate (0.14 mole) were converted to the benzoyloxychalcone, a pale yellow semi-crystalline solid, m. p. 182–184°. The yield was 75 g. (78%). *Anal.* Calcd. for $C_{43}H_{28}O_9$: C, 75.0; H, 4.1. Found: C, 74.7; H, 4.2.

3,4,2',5'-Tetrahydroxychalcone.—The benzoyloxychalcone was debenzoylated as described above. The chalcone was separated from benzoic acid by extraction of the latter with hot benzene in a Soxhlet. (The 3,4-dihydroxy grouping increases the water solubility of the chalcone to the point where the sodium bicarbonate solution would dissolve an appreciable amount. Since the benzene solubility is at the same time decreased, this method of separation was used successfully.) The crude material was recrystallized from dilute alcohol (1 liter). The recrystallized product obtained weighed 25 g. (66%). However, it was found to be a mixture of chalcone and flavanone. Attempted fractional crystallization from dilute alcohol seemed to establish the equilibrium between chalcone and flavanone in favor of the latter. Consequently, only a small amount of pure chalcone (less than a gram) was obtained. It crystallized in dark orange micro-crystals, m. p. 225–227°. *Anal.* Calcd. for $C_{15}H_{12}O_5$: C, 66.1; H, 4.5. Found: C, 65.8; H, 4.6.

6,3',4'-Trihydroxyflavanone.—The flavanone was separated from the chalcone by fractional crystallization and finally by the action of charcoal. It crystallized in a mass of white felted needles with a slight yellowish tinge, m. p. 218–220° (dec.). *Anal.* Calcd. for $C_{15}H_{12}O_5$: C, 66.1; H, 4.5. Found: C, 66.1; H, 4.5.

2,2',5'-Tribenzoyloxychalcone.—Quinacetophenone dibenzoate (0.07 mole) and salicylaldehyde benzoate (0.07 mole) were converted to the benzoyloxychalcone, a bright yellow semi-crystalline solid, m. p. 137–139°. The yield was 32.5 g. (82%). *Anal.* Calcd. for $C_{36}H_{24}O_7$: C, 76.0; H, 4.3. Found: C, 75.6; H, 4.3.

2',5'-Dihydroxy-2-phenylbenzopyrylium Chloride.—The benzoyloxychalcone (27.5 g.) was debenzoylated as described above. The free hydroxychalcone was precipitated with hydrochloric acid and separated from benzoic acid by extraction of the latter with cold dilute sodium bicarbonate solution (11 g. of sodium carbonate in 150 cc. water saturated with carbon dioxide). The resulting material was recrystallized from 10% alcoholic hydrochloric acid, separation from a considerable quantity of quinacetophenone being effected. The recrystallized product (3.5 g.) proved to consist of chalcone, flavanone, and a very small quantity of anthocyanidin. The anthocyanidin was separated from the chalcone and flavanone by extraction of the latter two substances with ether in which the salt was not soluble. The anthocyanidin (less than 1 g.) formed a reddish micro-crystalline powder, m. p. 175° (dec.). *Anal.* Calcd. for $C_{15}H_{11}O_3Cl \cdot {}^1/_2H_2O$: Cl, 12.5. Found: Cl, 12.6. It gave a red solution in acid and a blue solution in sodium carbonate.

6,2'-Dihydroxyflavanone.—This substance, separated from the colored material as described above, was recrystallized from dilute alcohol. It apparently is formed in preference to the anthocyanidin. It crystallized in very pale yellow prismatic needles, m. p. 178–180° (dec.). *Anal.* Calcd. for $C_{15}H_{12}O_4 \cdot H_2O$: C, 65.8; H, 5.1. Found: C, 66.2; H, 5.1. No attempt was made to isolate the chalcone of which only a trace was present.

2,4,2',5'-Tetrabenzoyloxychalcone.—Quinacetophenone dibenzoate (0.07 mole) and resorcylaldehyde dibenzoate (0.07 mole) were converted to the benzoyloxychalcone, a yellow crystalline solid, m. p. 137–139°. The yield was 39 g. (81%). *Anal.* Calcd. for $C_{43}H_{28}O_9$: C, 75.0; H, 4.1. Found: C, 74.7; H, 4.2.

7,2',5'-Trihydroxy-2-phenylbenzopyrylium Chloride.—The benzoyloxychalcone (34 g.) was debenzoylated as described above. The hydroxychalcone was precipitated by the addition of hydrochloric acid and was separated from benzoic acid by extraction of the latter with cold dilute sodium bicarbonate solution (12 g. sodium carbonate in 200 cc. of water saturated with carbon dioxide). The product was crystallized from dilute alcoholic 10% hydrochloric acid. The yield of anthocyanidin was 7 g. (39%). A portion was recrystallized for analysis. It separated as a dark red microcrystalline powder, m. p. 190° (dec.). Its solution in acid was red and in sodium carbonate blue. *Anal.* Calcd. for $C_{15}H_{11}O_4Cl \cdot 5^1/_2H_2O$: Cl, 9.1. Found: Cl, 9.1.

2,4,2',5' - Tetrabenzoyloxy - 6 - methylchalcone.—Quinacetophenone dibenzoate (0.07 mole) and orcylaldehyde dibenzoate were converted to the benzoyloxychalcone, a pale yellow semi-crystalline solid, m. p. 125–127°. The yield was 42 g. (86%).

Anal. Calcd. for $C_{44}H_{30}O_9$: C, 75.2; H, 4.3. Found: C, 74.7; H, 4.5.

7,2',5' - Trihydroxy - 5 - methyl - 2 - phenylbenzopyrylium Chloride.—The benzoyloxychalcone (37 g.) was debenzoylated as described above. The hydroxychalcone was precipitated with hydrochloric acid and separated from the benzoic acid by extraction of the latter with hot benzene in a Soxhlet. The brown residue was crystallized from dilute alcoholic 10% hydrochloric acid as dark, red, iridescent plates, m. p. 285–287° (dec.). Its solution in acid was red and in sodium carbonate blue. *Anal.* Calcd. for $C_{16}H_{13}O_4Cl \cdot H_2O$: Cl, 11.0. Found: Cl, 11.1.

2,4,6,2',5' - Pentabenzoyloxychalcone.—Quinacetophenone dibenzoate (7 g.) and phloroglucinaldehyde tribenzoate (9 g.) were converted to the benzoyloxychalcone, a

yellow oil, which was not analyzed but transformed into the anthocyanidin.

5,7,2′,5′-Tetrahydroxy-2-phenylbenzopyrylium Chloride.—The benzoylchalcone was debenzoylated as described above. The hydroxychalcone was precipitated with hydrochloric acid and was separated from benzoic acid by extraction of the latter with cold dilute sodium bicarbonate solution. The residue was crystallized from 10% hydrochloric acid in which it was very soluble. The dark red crystal mass was extracted with ether, leaving less than a gram of anthocyanidin. It was a brownish-red crystalline powder, m. p. above 300°. *Anal.* Calcd. for $C_{15}H_{11}O_6Cl.2H_2O$: Cl, 10.4. Found: Cl, 10.3. It gave a red solution in acid and blue in sodium carbonate.

bis-**(6,3,′4′-Trihydroxy)-flavopinacol.**—This flavopinacol, possessing the possible phlobatannin structure, was prepared by reduction of pure 6,3′,4′-trihydroxyflavanone (1 g.) and also by reduction of a mixture (1 g.) of flavanone and 3,4,2′,5′-tetrahydroxychalcone, consisting mostly of the latter. The flavanone (or mixture of chalcone and flavanone) was dissolved in alcohol (40 cc.) and zinc dust (5 g.) and concd. hydrochloric acid (12 cc.) were added. The solution was boiled for five minutes, during which time the color changed from dark orange (in the case of the mixture) to a pale yellow. The solution was filtered from unreacted zinc and nearly neutralized with sodium bicarbonate, a tan precipitate separating. The solution was saturated with sodium chloride and extracted without filtering with two portions (75 cc. each) of ethyl acetate. The ethyl acetate was dried over sodium sulfate overnight and evaporated on the steam-bath. Most of the remaining solvent was removed in a vacuum desiccator over sodium hydroxide. The final product was a light red friable solid, retaining traces of solvent with great tenacity. It was readily soluble in acetone, alcohol, and ethyl acetate and partially soluble in water. The water-soluble portion was qualitatively indistinguishable from natural phlobatannins such as mimosa and hemlock tannins, as indicated in the table above. No analysis was attempted.

Summary

1. The production of a new flavopinacol from quinacetophenone and protocatechualdehyde is reported. This substance is qualitatively indistinguishable from such natural phlobatannins as hemlock and mimosa tannins.

2. New benzoyloxychalcones, hydroxychalcones, flavanones, and anthocyanidins derived from quinacetophenone are reported.

3. The peculiar sensitivity of 2′,5′-hydroxychalcones to alkali is noted.

Alkanolamines. VII. Condensation Products of Monoethanolamine and the Isomeric Dichloronitrobenzenes

BY CHESTER B. KREMER AND AARON BENDICH

The activation of a halogeno or nitro group on the benzene nucleus by the presence of other substituted groups is well known. The reactions among such molecules and the amino alcohols were originally investigated in these laboratories. This present paper records our findings with the isomeric dichloronitrobenzenes.

Quite recently, Waldkötter[1] has extended our findings dealing with the condensing ability of monoethanolamine. In general, however, he has dealt with benzene molecules which are quite heavily substituted in the nucleus and contain, usually, at least two nitro groups on the ring. Under such conditions, it is frequently an active nitro group that is split out on condensing with the amino alcohol rather than a halogeno group. Work carried out in our laboratories checks exactly with these results. Our investigations, however, have not been limited to reactions with the ethanolamines and we expect to publish these data in our next article.

The preparation of all six dichloronitrobenzenes is not an easy task. The 2,5- and 3,4-isomers are readily available, but the others are usually prepared through a number of intermediate syntheses. The fundamental researches dealing with the preparation of most of the isomers were carried out by Beilstein and Kurbatow[2] and improved and extended by Holleman and Reiding[3] and Holleman and De Mooy.[4] In preparing the 3,5- and the 2,6-dichloronitrobenzenes we followed their procedures with slight modifications. 2,4-Dichloronitrobenzene usually is prepared by the nitration of *m*-dichlorobenzene. We synthesized this material from a by-product formed in the synthesis of 2,6-dichloronitrobenzene. An outline of the complete synthesis of these three dichloronitrobenzenes is given in Chart I.

Theoretically, it should be possible to obtain

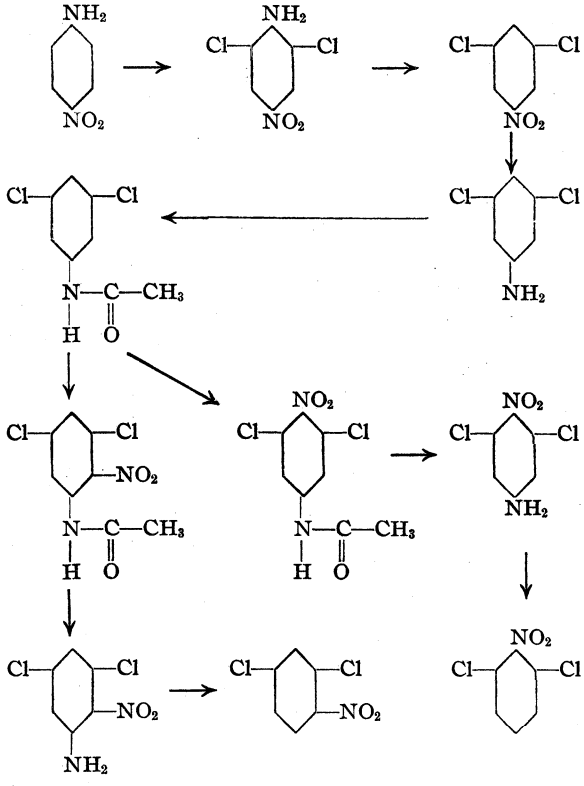
(1) Waldkötter, *Rec. trav. chim.*, **57**, 1294 (1938).

(2) Beilstein and Kurbatow, *Ann.*, **196**, 228 (1879).

(3) Holleman and Reiding, *Rec. trav. chim.*, **23**, 357–379 (1904).

(4) Holleman and De Mooy, *ibid.*, **35**, 1–66 (1916).

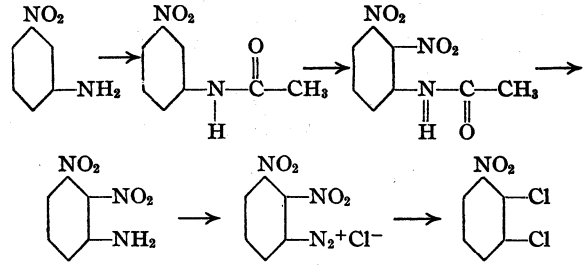
CHART I



2,4- and 2,6-dichloronitrobenzenes by nitration in a suitable medium, followed by diazotization, of 2,4-dichloroaniline. Our preliminary results with this nitration were uniformly unsuccessful; but recently we have been able to obtain some very small yields of the desired products. We hope to be able to develop further this line of work.

2,3-Dichloronitrobenzene can be prepared by chlorinating *o*-chloronitrobenzene in the presence of antimony chloride. Holleman and Reiding[3] used this method but it is not conducive to the preparation of large amounts of material. With this in mind, Holleman and De Mooy[4] devised a synthesis of the compound by taking advantage of the fact that when 2,3-dinitroaniline is involved in a Sandmeyer reaction to replace the amine group with halogen, not only is the amine group replaced but also the ortho nitro group. In their synthesis of 2,3-dinitroaniline, they nitrated *m*-nitroacetanilide according to the procedure of Wender.[5] It is claimed that a mixture of three isomers, with the desired product constituting about 50% of the whole, is obtained. We tried this nitration several times and found that it gave most unsatisfactory results. We therefore devised a different method of nitration. By treating *m*-nitroacetanilide with fuming nitric acid (sp. gr. 1.50) at room temperature we were able to obtain a product which after one recrystallization from ethanol gave a melting point of 185–186°. With this method, 30 g. of the *m*-nitroacetanilide yielded 25 g. of the desired product and there could be recovered 6 g. of low-melting isomers. The steps involved in the synthesis of 2,3-dichloronitrobenzene are given in Chart II.

CHART II



The condensations between the amino alcohol and the dichloronitrobenzenes were carried out in the usual reflux apparatus, using propyl or butyl alcohol as solvent and magnesium oxide as an acid binding agent.

All of the nitro condensation products were highly colored solids varying from yellow to red with the exception of 2-(6-chloro-2-nitroanilino)-ethanol which was a red liquid. The reduced products were white solids with the exception of 2-(6-chloro-4-aminoanilino)-ethanol, which apparently is a liquid.

Experimental

Preparation of the Dichloronitrobenzenes.—The 2,5- and 3,4-dichloronitrobenzenes were obtained from the Eastman Kodak Co.

3,5-Dichloronitrobenzene.—One hundred and thirty-eight grams of *p*-nitroaniline is mixed with 2 liters of concentrated hydrochloric acid and 60 g. of potassium chlorate added slowly, care being taken to keep the temperature around 70°. When the reaction is complete, the whole is poured into 2 liters of water, the crude 2,6-dichloro-4-nitroaniline removed by filtration and washed free of acid. Varying amounts of 4-nitro-2-chloroaniline are usually found mixed with the desired dichlorinated product. The two can be separated by treatment with hot alcohol.

The 2,6-dichloro-4-nitroaniline is air dried and 105 g. is then added to a mixture of 375 cc. of ethanol and 100 g. of concentrated sulfuric acid in a flask equipped with reflux condenser and automatic stirrer. Thirty-six grams of sodium nitrite is added and the mixture heated on the water-bath for about one hour. This is followed by steam

(5) Wender, *Jahresber.*, **42**, 775 (1889).

distillation. Seventy grams of the 3,5-dichloronitrobenzene distil over, is filtered and recrystallized from ethanol; m. p. 65°.

2,6-Dichloronitrobenzene.—Ninety-six grams of 3,5-dichloronitrobenzene is added to 350 cc. of hydrochloric acid (sp. gr. 1.19) in 150 cc. of water and 180 g. of finely divided tin is added gradually until the reduction is complete. Two hundred grams of sodium hydroxide is then added and the whole steam distilled. About 70 g. of 3,5-dichloroaniline melting at 51° is obtained. The product is recrystallized from dilute ethanol.

The dichloroaniline is dissolved in 50 cc. of glacial acetic acid and 100 cc. of 45% acetic anhydride in glacial acetic acid is added. The acetanilide separates out instantly and forms a compact mass. After standing for four hours, it is diluted with water, filtered and air dried. The yield is quantitative and the product melts at 186°.

Fifty grams of the acetanilide is treated with 250 g. of fuming nitric acid (sp. gr. 1.51) until nitration is complete. The mixture is poured into water, whereupon a mixture of two isomers, 3,5-dichloro-4-nitroacetanilide and 3,5-dichloro-2-nitroacetanilide, precipitates out. These are separated by treatment with hot benzene, the former compound being quite insoluble in the hot solvent. The product is washed several times with hot benzene and finally recrystallized from dilute ethanol; m. p. 222°.

Ten grams of the 3,5-dichloro-4-nitroacetanilide is dissolved in 40 g. of concentrated sulfuric acid and warmed for a half hour around 110°. This solution is then poured into 150 cc. of ethanol; 3 g. of sodium nitrite is added and the mixture refluxed on the water-bath until evolution of nitrogen ceases. This is followed by steam distillation. There is obtained 6.5 g. of the 2,6-dichloronitrobenzene. This is recrystallized from ethanol and then vacuum distilled; b. p. 100–101°, 4–5 mm. pressure. Whereas the literature reports this compound as yellow, our product was pure white and melted at 70.5°.

2,4 - Dichloronitrobenzene.—3,5 - Dichloro - 2 - nitroacetanilide is prepared as described above. After separation from the 3,5-dichloro-4-nitroacetanilide, which is also produced at the same time, by means of hot benzene, the desired isomer is quite pure and melts at 138°. This compound is treated identically as described above for the other isomer and results in the same yield. A light yellow solid is obtained which melts at 34° and can be purified further by vacuum distillation; b. p. 105–107° at a pressure of 3–4 mm. and 132–133° at a pressure of 13–14 mm.

2,3-Dichloronitrobenzene.—One hundred and thirty-eight grams of *m*-nitroaniline was acetylated according to Kaufmann[6] by mixing a concentrated solution of the aniline in benzene with 105 g. of acetic anhydride and refluxing for one hour. The mixture is cooled, the acetanilide filtered and air dried. It melts at 154–155°.

The acetanilide was nitrated as follows: 30 g. was treated with 60 cc. of fuming nitric acid (sp. gr. 1.50) at 20° for one hour. The resulting mixture was poured onto crushed ice and the resulting yellow product filtered and washed free of acid. Recrystallization from a relatively large volume of ethanol yielded 25 g. of a near white solid melting at 186–187°. Evaporation of the mother liquor yielded 6–8 g. of isomers melting at 100°.

The dinitroacetanilide was treated with four times its volume of concentrated sulfuric acid and heated at 110° for half an hour. The mixture was poured onto crushed ice, the resulting orange solid filtered off and the 2,3-dinitroaniline recrystallized from a small volume of ethanol; m. p. 127°.

One hundred and eleven grams of the 2,3-dinitroaniline was treated with 128 cc. of concentrated hydrochloric acid and the mixture poured into an ice-cold concentrated solution containing 38 g. of sodium nitrite. To this solution was added dropwise a solution of cuprous chloride in hydrochloric acid prepared according to van der Linden.[7] The mixture was stirred at room temperature for ten minutes and then refluxed over a free flame for half an hour. It was then cooled with ice and filtered. The filtered solid was steam distilled and the material coming over in the steam distillate recrystallized from ethanol. The 2,3-dichloronitrobenzene is white and melts at 61°. It can be purified further by vacuum distillation.

Condensation Reactions

These were run in a solvent, usually normal butyl alcohol, and in some cases magnesium oxide was employed as an acid binder.

Reactions Using Magnesium Oxide.—One-tenth of a mole of the dichloronitrobenzene was dissolved in 50 cc. of warm butanol and 0.1 mole of magnesium oxide was suspended in the solution. A reflux apparatus with mechanical stirrer and dropping funnel was employed. The suspension was heated until the alcohol refluxed gently and then slightly more than 0.1 mole of monoethanolamine was added dropwise and the mixture refluxed for several hours. The whole was filtered clear of any excess magnesium oxide and then steam distilled. On cooling the residue in the distillation flask, the condensed product separated out as a solid (with one exception) and was filtered off. It was then recrystallized from the appropriate solvent. The products obtained with the various dichloronitrobenzenes along with other data are given in Table I.

A somewhat modified procedure was followed in several cases with excellent results. Instead of butanol, propanol was employed as solvent in these runs. After refluxing the reaction mixture as described above and filtering off the magnesium oxide, the alcohol solution was cooled in ice, whereupon a goodly portion of the condensed product separated out. This was filtered off and the over-all yield materially increased by throwing the filtrate into water, whereupon further precipitation of the desired product occurred. This method obviates the use of steam distillation but requires a longer reaction period due to the lower boiling point of the propanol.

Reactions without Magnesium Oxide.—These were run practically the same as described above with the exception that the molar ratio of the monoethanolamine was two or three times that of the dichloronitrobenzene. When propanol was used as the solvent, the steam distillation was omitted as described above.

Reaction between 3,4-Dinitrochlorobenzene and Monoethanolamine.—This reaction was run to assist in proving the structure of the condensation product obtained

with 2,4-dichloronitrobenzene. The procedure was the same as just described. The product obtained is identical with that formed in condensing 2,4-dichloronitrobenzene with the amino alcohol.

Reductions

All reductions of the nitro compounds were carried out using sodium hydrosulfite in a weakly alkaline medium. Yields were practically quantitative in most cases. The properties of these reduced products are included in Table I.

Discussion

In certain of the dichloronitrobenzenes, two chloro groups are capable of replacement. This is the case with the 2,4- and the 2,6-isomers. In all of the other isomers only one chloro group is capable of replacement as the other is in the meta position to the activating nitro group and, as proved by work in these laboratories with amino alcohols, and in analogous work with ammonia, sodium methoxide and potassium sulfide as recorded in the literature,[4,8] such a chloro group is inactive. In the case of 3,5-dichloronitrobenzene both of the chloro groups are in the meta position and no condensation whatsoever occurs here.

That only one of the two chlorine atoms is removed in condensing either 2,4- or 2,6-dichloronitrobenzene with monoethanolamine is shown by both quantitative and qualitative analyses. In the case of the 2,6-isomer it makes no difference which chlorine is removed; the resulting compound would be the same. It then only becomes a question of determining which of the two chlorine atoms in the 2,4-isomer reacts. It is definitely established that the one ortho to the nitro group is mobile. This is proved by condensing 3,4-dinitrochlorobenzene in the same manner as described for the dichloronitrobenzenes. The product obtained is identical with that obtained in condensing 2,4-dichloronitrobenzene.

It is interesting to compare the ability of the dichloronitrobenzenes to condense with monoethanolamine, with those condensations involving ammonia, substituted amines and sodium methoxide. Much of this latter work has been carried out by Holleman and his co-workers.[3,4] They find the most reactive isomer to be the 2,4. The remaining order is 3,4, 2,5, 2,3 and 2,6. Our results check fairly well with those presented in the literature. There can be no doubt that 2,6-dichloronitrobenzene is the least reactive, the yields seldom exceeding 15% even after long periods of refluxing. We find, however, that 2,5-dichloronitrobenzene appears to react more readily with monoethanolamine than the 3,4-compound, which is at variance with the findings of Holleman; but in general our order of reactivity follows closely his order of "speed of reaction."

Summary

1. A study of the preparation of the isomeric dichloronitrobenzenes has been made.

2. The reaction between the dichloronitrobenzenes and monoethanolamine in a neutral solvent has been studied.

3. A report is made upon the preparation and properties of several new chloronitroanilino and chloroaminoanilino ethanols.

Synthesis of Iodinated Benzoylbenzoic Acids and Anthraquinones[1]

BY ROBERT W. HIGGINS AND C. M. SUTER

Although many halogenated anthraquinones have been prepared, the known iodine derivatives are limited in number. The 1- and 2-iodoanthraquinones have been obtained from the amines[2] and 1,5-diiodoanthraquinone has been prepared from the diamine.[3] The action of iodine and sodium nitrite in fuming sulfuric acid upon anthracene yields a mixture of mono- and diiodoanthraquinones of unknown structure[4] whose physical properties were not recorded. It has been reported[5] that the action of iodine on anthraquinone in 70% oleum at 180° yields a complex mixture of products of which a tri-, a tetra- and a penta-iodoanthraquinone were isolated. The tetra compound was characterized by its high melting point (500°). The only attempt so far made to prepare an iodinated anthraquinone by a nuclear synthesis was that of Eckert and Klinger.[5] They found that the benzoyltetraiodobenzoic acid obtained from tetraiodophthalic anhydride and benzene when heated with concentrated sulfuric acid at 190–200° lost iodine but nevertheless there resulted a 20% yield of a tetraiodoanthraquinone, m. p. 476° (dec.), which they believed was not the 1,2,3,4-compound. Attempts to bring about ring closure by the use of aluminum chloride resulted in evolution of iodine and hydrogen chloride with formation of a diiodoanthraquinone (m. p. 290–292°) of unknown structure.

Lawrance[6] found that tetraiodophthalic anhydride condensed readily with toluene but ring closure was not attempted. The conversion of benzoyltetrabromobenzoic acid to the anthraquinone[7] has been brought about by heating with 13% oleum and a variety of substituted anthraquinones has been prepared from the benzoylbenzoic acids resulting from the action of tetrachlorophthalic anhydride upon benzene derivatives.[8]

Since Pratt and Perkins[9] have shown that the di- and triiodophthalic anhydrides obtained by partial iodination of phthalic anhydride in oleum can be separated it was decided to investigate the condensation of these with representative aromatic compounds under various conditions. The condensation of the 3,4-, 4,5- and 3,6-di-, and the 3,4,6-triiodophthalic anhydrides with benzene occurs readily in the presence of two molecular equivalents of aluminum chloride. The products from the 3,4- and 4,5-diiodo anhydrides are purified readily by crystallizing their potassium salts from hot water. On the other hand, the potassium salts of the acids obtained from the 3,4,6-triiodo- and tetraiodophthalic anhydrides do not separate from water readily. No effort has so far been made to determine which of the two possible acids results from the 3,4-diiodo anhydride and benzene but the ease of ring closure indicates that it is 2-benzoyl-3,4-diiodobenzoic acid. The 3,4,6-triiodo anhydride yields a mixture in practically equal amounts of the two possible isomeric acids.

Ring closure of the three benzoyldiiodobenzoic acids was effected readily with 100% sulfuric acid. With a lower concentration iodine elimination occurred. The 2,3-diiodoanthraquinone corresponds in melting point to the diiodoanthraquinone obtained by Eckert and Klinger[5] through the action of aluminum chloride upon benzoyltetraiodobenzoic acid. The identity of these acids is reasonable as the iodine atoms in the 1,4-positions are eliminated easily. Attempts to condense phthalic anhydride with *m*-diiodobenzene under a variety of conditions were unsuccessful. It was thought that from the benzoylbenzoic acid so obtained it might be possible to prepare the unknown 1,3-diiodoanthraquinone.

Conversion of the two isomeric benzoyltriiodobenzoic acids into 1,2,4-triiodoanthraquinone occurred under narrowly defined conditions in yields of about 25%. In view of these results various attempts were made to induce a similar reaction with benzoyltetraiodobenzoic acid under conditions where iodine was not eliminated but without success, confirming previous reports.[5]

The results of some preliminary experiments designed to prepare iodinated hydroxyanthraqui-

nones may be mentioned. Although phthalic anhydride condenses with veratrole and with 4-chloroveratrole without undue difficulty, so far it has not been possible to bring about reaction of either of these ethers with 4,5-diiodophthalic anhydride or the tetraiodo compound. On the other hand, anisole and the methyl ethers of *o*- and *m*-cresol react readily with both anhydrides. Further work on this aspect of the investigation is in progress.

Considerable difficulty was encountered in the analysis of iodinated anthraquinones for iodine. The usual procedure with the Parr bomb gave only partial decomposition of the compounds. The Stepanow method using sodium and alcohol gave erratic results which were high until it was found that digestion of the silver iodide precipitate for several hours with dilute nitric acid gave consistent results on both known compounds and the iodinated anthraquinones. The intermediate benzoylbenzoic acids were titrated in aqueous alcohol solution with standard alkali using thymol blue as the indicator.

Experimental

Iodophthalic Acids.—Iodination of phthalic anhydride was conducted according to the procedures of Pratt and Perkins.[9] The low temperature iodination gave the more satisfactory results. In the original directions where separation of the 4,5-diiodophthalic acid is effected by precipitation with a definite volume of "acetic acid," the volume given refers to 6 *N* acid; the use of 100% acetic acid gave a mixture of iodinated acids. In the precipitation of the 3,4,6-triiodo acid 18 cc. of 6 *N* acetic acid gave better results than the 10 cc. specified in the original. The volumes of concentrated hydrochloric acid found necessary in the later stages of the separation checked those specified by Pratt and Perkins. The precipitates obtained by this separation procedure required considerable purification before the products gave satisfactory melting points and the yields of iodophthalic anhydrides isolated were distinctly lower than the amounts of nearly pure acids obtained in the original preparation would suggest. From 780 g. of phthalic anhydride, 1270 g. of iodine, and 2500 g. of 50% oleum after heating for six days at 70–80° were obtained 100 g. of 4,5-diiodophthalic anhydride, m. p. 215–216°, 147 g. of the 3,4,6-triiodo anhydride, m. p. 220–223° (further crystallization raised this to 226–227°); 325 g. of the 3,4-diiodo anhydride, m. p. 194–196° and 395 g. of 3,6-diiodo anhydride, m. p. 228–231°. In addition, smaller amounts of the compounds having somewhat lower melting points were isolated.

2-Benzoyl-4,5-diiodobenzoic Acid.—A mixture of 5 g. of diiodophthalic anhydride, 3.65 g. (10% excess over two molecular equivalents) of aluminum chloride and 40 ml. of benzene was refluxed for twenty-four hours, poured into cold water and the benzene steam distilled out. The water-insoluble residue was filtered and then treated with hot potassium carbonate solution which left only a trace of undissolved material. The solution upon cooling deposited the potassium benzoylbenzoate which was redissolved in hot water and the solution acidified. Crystallizing the precipitate from dilute alcohol gave 4.8 g. of product melting[10] at 244–245°. This corresponds to an 80% yield.

Anal. Calcd. for $C_{14}H_8O_3I_2$: neut. equiv., 478. Found: neut. equiv., 481, 481.

2-Benzoyl-3,4-(?)-diiodobenzoic Acid.—By a procedure exactly analogous to that used in the preceding section, there was obtained a 65% yield of the benzoylbenzoic acid from the 3,4-anhydride. The m. p. was 223–224°. Only one product was isolated. When the time of heating was shortened to nine hours the yield was about the same.

Anal. Calcd. for $C_{14}H_8O_3I_2$: neut. equiv., 478. Found: neut. equiv., 476, 478, 481.

2-Benzoyl-3,6-diiodobenzoic Acid.—The potassium salt of the benzoylbenzoic acid from the 3,6-anhydride did not crystallize readily from aqueous solution. Acidification of the solution and crystallization of the precipitate from dilute alcohol gave a 60% yield of acid of m. p. 218–220°.

Anal. Calcd. for $C_{14}H_8O_3I_2$: neut. equiv., 478. Found: neut. equiv., 482, 482, 476.

2-Benzoyl-3,4,6- and 3,5,6-triiodobenzoic Acids.—From 32.6 g. (0.061 mole) of 3,4,6-triiodophthalic anhydride, 18.1 g. (0.136 mole) of aluminum chloride and 200 ml. of benzene after twenty-one hours of refluxing was obtained 37 g. of product soluble in potassium carbonate solution. Heating the product in concentrated hydrochloric acid did not produce a yellow color, indicating that no appreciable amount of anhydride was unreacted. Refluxing the product with 400 ml. of 95% alcohol for forty-five minutes left an insoluble residue amounting to 20 g. which melted at 252–262°. This residue was extracted with hot dioxane, leaving a small amount (2.4 g.) of inorganic material. Concentrating and cooling the dioxane solution gave 13.5 g. of acid melting at 257–258° and a second crop of 2.8 g. melting at 254–257°.

Cooling the alcohol solution gave 10.7 g. of the low melting isomer, m. p. 224–227°, and then further smaller fractions which were practically pure. A total of 16.3 g. of the high melting and 14.4 g. of the low-melting isomer were obtained. The purest samples of these melted at 257–258° and 225–227°, respectively.

Anal. Calcd. for $C_{14}H_7O_3I_3$ (m. p. 257–258°): neut. equiv., 604. Found: neut. equiv., 607, 602.

Anal. Calcd. for $C_{14}H_7O_3I_3$ (m. p. 225–227°): neut. equiv., 604. Found: neut. equiv., 600, 613.

2,3-Diiodoanthraquinone.—To 40 g. of 100% sulfuric acid at 140° was added gradually over thirty minutes with stirring 2 g. of 2-benzoyl-4,5-diiodobenzoic acid. The mixture was then cooled to 70–80° and diluted slowly by adding small pieces of ice. The mixture was filtered and the precipitate warmed with aqueous potassium carbonate to remove any unreacted acid. The insoluble portion was crystallized from benzene and acetic acid and then melted at 291–292°. The yield was 1.6 g. or 80% of the theoretical amount.

(10) All melting points are corrected.

Anal. Calcd. for $C_{14}H_6O_2I_2$: I, 55.21. Found: I, 55.0, 55.3.

1,2-Diiodoanthraquinone.—This was prepared in a manner similar to that used with the 2,3-isomer. It crystallized in orange-red plates from a benzene–toluene mixture and melted at 236–237°.

Anal. Calcd. for $C_{14}H_6O_2I_2$: I, 55.21. Found: I, 55.6, 55.6.

1,4-Diiodoanthraquinone.—From heating 2 g. of 2-benzoyl-3,6-diiodobenzoic acid with 75 g. of 100% sulfuric acid at 100° for two hours, was obtained 1.1 g. (60%) of the anthraquinone. After crystallizing from alcohol it melted at 218–219°.

Anal. Calcd. for $C_{14}H_6O_2I_2$: I, 55.21. Found: I, 55.4, 55.3, 55.7.

1,2,4-Triiodoanthraquinone.—A. Two grams of the high-melting benzoyltriiodobenzoic acid was added to 60 g. of 100% sulfuric acid kept at 105° over a thirty-minute period with stirring and the mixture heated and stirred for thirty minutes longer. It was then cooled and poured on ice and the resulting colloidal suspension coagulated by heating on the steam-bath. The precipitate was then treated with dilute sodium hydroxide. The red residue upon crystallization from acetic acid yielded 0.5 g. of product melting at 202–204°. This is about 25% of the theoretical amount. Alterations in these conditions did not improve the yield.

B. From treatment of the low-melting benzoyltriiodobenzoic acid as in A was obtained 0.4 g. of the anthraquinone. After two crystallizations from acetic acid the m. p. was 202–203.5°.

Anal. Calcd. for $C_{14}H_6O_2I_2$: I, 64.84. Found: I, 64.9, 65.0.

Summary

1. The condensation of di- and triiodophthalic anhydrides with benzene and aluminum chloride gives good yields of the benzoylbenzoic acids.

2. Ring closure of benzoyldiiodobenzoic acids is readily effected by treatment with 100% sulfuric acid. The triiodo compounds give smaller yields of the triiodoanthraquinones.

3. Veratrole and 4-chloroveratrole do not condense readily with iodinated phthalic anhydrides. Work upon the synthesis of iodinated hydroxyanthraquinones is being continued.

EVANSTON, ILLINOIS RECEIVED JULY 7, 1939

[CONTRIBUTION FROM THE RESEARCH LABORATORY OF EX-LAX, INC.]

3,3′-Dimethyl-4,4′-dihydroxybenzophenone

BY MAX H. HUBACHER

During the progress of some work being carried out recently, it became necessary to prepare a quantity of 3,3′-dimethyl-4,4′-dihydroxybenzophenone. This was done by a caustic potash fusion of *o*-cresolphthalein.[1]

Since the properties of the compound prepared from *o*-cresolphthalein did not agree with those recorded by Doebner and Schroeder,[2] an investigation of this discrepancy was made in order to determine the true properties of this material. These chemists obtained a compound which they designated as dioxydimethylbenzophenone, melting at 138°, by caustic potash fusion of *o*-cresolbenzein. For an analysis they report, calculated for $C_{15}H_{14}O_3$: C, 78.51; found, 78.19. Evidently, an error was made in calculation as the value for carbon is 74.36.

A caustic potash fusion of *o*-cresolbenzein produced no trace of a compound melting at 138°. Instead, a product melting at 247° was obtained which was identical with that from *o*-cresolphthalein. That the compound of melting point 247° was the expected 3,3′-dimethyl-4,4′-dihydroxybenzophenone was confirmed by analysis and the preparation of the diacetyl derivative and the mono and dimethyl ethers. On prolonged fusion with caustic potash, the benzophenone was converted into *o*-cresol and 3-methyl-4-hydroxybenzoic acid.

Experimental[3]

3,3′-Dimethyl-4,4′-dihydroxybenzophenone (I).—Seventy grams of potassium hydroxide was heated in a nickel crucible to 260–265° (oil-bath temperature) and 10 g. of *o*-cresolphthalein of m. p. 224–225° was stirred in. After ten minutes, the melt was poured into 1.5 liters of water and acidified with hydrochloric acid. The 6.60 g. of crude was crystallized from 75 cc. of glacial acetic acid; 4.85 g. (69.3%) of (I), melting at 246–247° was obtained. A second crystallization or a sublimation *in vacuo*[4] at 180° gave a pure product, melting point 247.0–247.8°. It formed colorless needles from 20% ethanol and rectangular plates from acetic acid. It dissolved in both sodium hydroxide or concd. sulfuric acid with yellow color.

(2) O. Doebner and G. Schroeder, *Ann.*, **257**, 74 (1890).

(3) All melting points are corrected.

(4) All the sublimations were done in a vacuum produced by a CenCO-HyvAC pump guaranteed to produce a vacuum of 0.3 micron.

Anal. Calcd. for $C_{15}H_{14}O_3$: C, 74.36; H, 5.82; mol. wt., 242. Found: C, 74.42; H, 5.95; mol. wt. (Rast, in camphor), 237, 241.

The aqueous mother liquor from the crude (I) yielded 1.09 g. of benzoic acid.

3,3′-Dimethyl-4,4′-diacetoxybenzophenone was prepared by refluxing 2.42 g. of (I), 3.1 g. of acetic anhydride, 10 cc. of acetic acid and one drop of concd. sulfuric acid; 3.11 g. (95%) was obtained. The pure compound formed thin plates from ethanol and melted at 106.8–107.2°.

Anal. Calcd. for $C_{19}H_{18}O_5$: C, 69.91; H, 5.56. Found: C, 70.21; H, 5.53.

3,3′-Dimethyl-4,4′-dimethoxybenzophenone (II).—To 2.42 g. of (I) in 60 cc. of normal sodium methylate was added 5.0 g. of dimethyl sulfate and the mixture refluxed for one hour. After the evaporation of the methanol and taking up in water, the alkali insoluble portion weighed 0.85 g. After sublimation *in vacuo* at 100°[4] and crystallization from 50% ethanol, the dimethyl ether (II) melted at 113.7–114.2° (silky needles).

Anal. Calcd. for $C_{17}H_{18}O_3$: C, 75.52; H, 6.71. Found: C, 75.71; H, 6.83.

3,3′-Dimethyl-4,4′-dimethoxybenzophenoneoxime.—1.35 g. of (II) and 0.70 g. of hydroxylamine hydrochloride in 4 cc. of pyridine were heated for three hours to 90°. The oxime (1.41 g.) melted at 160.9–161.2° after crystallizations from ethanol.

Anal. Calcd. for $C_{17}H_{19}O_3N$: N, 4.91. Found: N, 5.14.

3,3′-Dimethyl-4-methoxy-4′-hydroxybenzophenone.—The alkali soluble portion from the methylation of (I) above weighed 1.61 g. After sublimation *in vacuo* at 180°,[4] followed by several crystallizations from ethanol, the pure monomethyl ether melted at 203.7–204.2°.

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 74.96; H, 6.29; OCH_3, 12.11. Found: C, 74.77, 75.57; H, 5.91, 6.55; OCH_3, 11.97.

Fusion of *o*-Cresolbenzein with Potassium Hydroxide.—Five grams of *o*-cresolbenzein[2] and 30 g. of potassium hydroxide were heated for ten minutes at 260–265° (oil-bath temperature). The crude, after one crystallization from glacial acetic acid, weighed 2.31 g. (61%) and melted at 246.0–247.3°. Neither a mixture of this material with (I) nor a mixture of the diacetyl derivatives showed a depression of the melting points.

Fusion of (I) with Potassium Hydroxide.—Ten grams of (I) prepared from *o*-cresolphthalein and 50 g. of potassium hydroxide were heated for one hundred and ten minutes at 280°. The fusion was poured into water and saturated with carbon dioxide. The ether extract was distilled, the fraction boiling at 186–190°, weighing 3.77 g. The 2,4-dinitrophenyl ether prepared from this fraction melted at 88.4–88.8° and showed no depression when mixed with a known sample of 2,4-dinitrophenyl *o*-cresyl ether of m. p. 88.7–90.0°.

The aqueous solution was acidified and the precipitate purified by sublimation at 160° *in vacuo* (5.41 g.), a crystallization from water, followed by a second sublimation. The 3-methyl-4-hydroxybenzoic acid melted at 173.9–175.0°.[5] Neutralization equiv. calcd. 152, found 151.3. The methyl ether melted at 195.9–196.2°[6] and the ethyl ester at 95.0–96.6°.[7]

Summary

3,3′-Dimethyl-4,4′-dihydroxybenzophenone was made by caustic potash fusion of *o*-cresolphthalein and of *o*-cresolbenzein. Its diacetyl derivative and the mono and dimethyl ethers were prepared. The structure was shown by its conversion into *o*-cresol and 3-methyl-4-hydroxybenzoic acid.

The 3,3′-dimethyl-4,4′-dihydroxybenzophenone reported by Doebner and Schroeder as melting at 138° is incorrect.

BROOKLYN, N. Y. RECEIVED JUNE 3, 1939

(5) F. Tiemann and C. Schotten, *Ber.*, **11**, 777 (1878), gave a m. p. of 172–175° for 3-methyl-4-hydroxybenzoic acid.

(6) C. Schall, *ibid.*, **12**, 825 (1879), reported a m. p. of 192–193° for the 3-methyl-4-methoxybenzoic acid.

(7) K. Auwers, *ibid.*, **39**, 3174 (1906), gave a m. p. of 98–99° for the ethyl ester of 3-methyl-4-hydroxybenzoic acid.

The Use of Triiodophenyl Ethers for the Identification of Alkyl Halides

BY ROBERT D. DREW AND JULIAN M. STURTEVANT

In a recent paper proposing the use of sodium saccharin as a reagent for the preparation of derivatives of alkyl halides, Merritt, Levey and Cutter[1] have pointed out that the types of derivatives for these compounds previously investigated are relatively difficult to prepare. Another convenient type of derivative is suggested by the work of Brenans[2] and Daniels and Lyons,[3] who found certain ethers of 2,4,6-triiodophenol to be nicely crystalline substances. In the present work a convenient standardized method of preparation has been devised using the sodium salt of triiodophenol and the alkyl halide dissolved in absolute alcohol, and several new ethers have been prepared. As found by Merritt, Levey and Cutter[1] in the case of sodium saccharin, most alkyl chlorides react very slowly with sodium triiodophenolate.

Experimental

Five grams of 2,4,6-triiodophenol and an equivalent amount of the alkyl halide are added to 22 cc. of a solution of sodium ethylate (12.3 g. of sodium dissolved in 1 liter of absolute ethyl alcohol), and the solution is refluxed for thirty minutes, or until a precipitate of sodium halide has formed. After filtering, the solution is cooled and diluted with water, the precipitate filtered and recrystallized from alcohol or dilute alcohol. About 1 g. of product is obtained after three or four successive recrystallizations. Some of the lower melting ethers separate from the cooled reaction mixture as liquids. In these cases the mixture is allowed to settle, the supernatant liquid decanted, and the product recrystallized from alcohol. One such recrystallization is usually sufficient to produce a solid product. A slightly longer period of reflux is found to give better results in these cases.

TABLE I

2,4,6-TRIIODOPHENYL ETHERS

Halide used	M. p., °C. (corr.)	Empirical formula	% iodine Calcd.	% iodine Found	
Methyl iodide[a]	98.5	$C_7H_5I_3O$	...	...	...
Ethyl bromide[a]	83.5	$C_8H_7I_3O$	76.16	76.49	76.12

Ethyl bromoacetate[b]	124.0	$C_{10}H_9I_3O_3$	68.25	67.94	67.92
Ethyl α-bromopropionate	80.5	$C_{11}H_{11}I_3O_3$	66.58	66.65	66.30

[a] Ethers previously prepared by Brenans.[2] Brenans also prepared the allyl ether, melting at 113–114°, from allyl iodide. [b] Previously prepared by Daniels and Lyons,[3] who found the melting point to be 128.5°.

In Table I are listed the corrected melting points and the analyses (by the Parr bomb method) of the various ethers prepared by this method. It was found in all cases where the melting points are close together that a mixed melting point shows a large depression.

Summary

The use of 2,4,6-triiodophenol as a reagent for the identification of alkyl halides has been found to be satisfactory. Several new alkyl triiodophenyl ethers have been prepared, and their melting points determined.

The Reaction of Tetrahydrofuran and 2,5-Dimethyltetrahydrofuran with Acyl Halides[1]

BY JOHN B. CLOKE AND FREDERICK J. PILGRIM

The need for certain δ-halogenobutyl and similar esters led us to study the action of acyl halides on tetrahydrofuran. In the case of acetyl chloride, the reaction gave not only δ-chlorobutyl acetate (I), as was anticipated, but also at least two other products whose properties correspond to the acetate of ditetramethylene glycol chlorohydrin, *i. e.*, δ-(δ-chlorobutoxy)-butyl acetate (II) and to the related compound (III)

$$CH_3COCl + \underbrace{CH_2CH_2CH_2CH_2O} \longrightarrow$$

$$\underset{(I)}{CH_3CO_2(CH_2)_4Cl} + \underset{(II)}{CH_3CO_2(CH_2)_4O(CH_2)_4Cl} + \underset{(III)}{CH_3CO_2(CH_2)_4O(CH_2)_4O(CH_2)_4Cl}$$

Since the yield of δ-chlorobutyl acetate by the foregoing process was but 42% in one run and somewhat better than 50% in another, zinc chloride was added to the reaction mixture in view of its well-known action in the fission of ethers. In one run we employed an amount of anhydrous zinc chloride corresponding to that used by Underwood[2] for the preparation of esters from ordinary ethers, but this led to the formation of much sludge and only 10% of the desired ester. However, it was found eventually that by decreasing the amount of zinc chloride to a few milligrams, a 76% yield of (I) and some of the higher boiling products (II and III) could be obtained. Similar results were obtained in the preparation of analogous δ-chloro esters from both tetrahydrofuran and 2,5-dimethyltetrahydrofuran. However, acetyl bromide gave bromoacetates which could not be separated easily from the accompanying dibromide. Likewise, in our work thus far on the action of acetyl fluoride on tetrahydrofuran we have not yet separated in a state of purity the several products formed.

The δ-chlorobutyl acetate can be methyl alcoholized to give tetramethylene chlorohydrin. It also will give tetramethylene chlorobromide, although the optimum conditions for this reaction have not yet been ascertained.

(1) The data reported herein have been taken from a thesis presented to the Rensselaer Polytechnic Institute in 1939 by Frederick John Pilgrim in partial fulfilment of the requirements for the degree of Bachelor of Science in Chemistry.

Experimental Part

Furan.—The major part of the required furan was prepared in batches by the decarboxylation of 500 g. of furoic acid in the presence of 500 cc. of refined quinoline and 3 g. of cupric oxide[3] contained in a 2-liter flask, which was heated in an oil-bath to 225°. The furan and carbon dioxide mixture was passed through a soda-lime tower, which was immersed in water at 75°, when the furan was liquefied by the use of a spiral condenser cooled by circulating ice water. The crude furan, obtained in yields of about 150 cc. per hour, was dried and distilled, giving approximately 85% yields.

Tetrahydrofuran.—The furan was hydrogenated in 200-g. lots in the presence of 20 g. of Raney nickel[4] at initial pressures ranging from 800–1500 pounds per sq. in. (55–100 atm.) in an American Instrument Co. high pressure hydrogenator. Yields of about 97% of tetrahydrofuran were obtained.

δ-Chlorobutyl Acetate (1) Reaction of Acetyl Chloride with Tetrahydrofuran without a Catalyst.—In the first run on the preparation of δ-chlorobutyl acetate, 185 g. (2.57 moles) of tetrahydrofuran[5] was boiled with 435 g. (5.55 moles) of redistilled acetyl chloride for twelve hours in an all-glass apparatus. The acetyl chloride and most of the unchanged tetrahydrofuran (A) were then distilled in the water-bath, leaving 242 g. of crude residue (B). The recovered acetyl chloride–tetrahydrofuran mixture (A) was then boiled again for twelve hours, whereby 60 g. of crude product (C) and another distillate (D) were obtained. The repetition of the process on the distillate (D) gave a further 14 g. yield of crude product (E), where the process was discontinued.

Two distillations of the combined residues (B), (C), and (E) gave 164 g. of δ-chlorobutyl acetate of b. p. 90–92° at 21 mm., 91 g. of product (F) of b. p. 157–165° at 20 mm. and a third product (G) of boiling point 165 to 200° at 23 mm. with intermediate fractions. The redistillation of (F) gave 74 g. of product of b. p. 165–167° at 24 mm., whereas (G) gave a product of b. p. 175–178° at 10 mm. (°C., uncorr.).

The foregoing process gave a 42.5% yield of δ-chlorobutyl acetate.[6] Various preparations boiled as follows: 78–79° at 15 mm., 90–91° at 20 mm., and 92–93° at 22 mm. Our material possessed a density d^{20}_4 of 1.0805 and a refractive index $n^{20}D$ of 1.43439, which correspond to a molecular refractivity, M_D of 36.29 as compared with the calculated value of 36.43.

Anal. Calcd. for $C_6H_{11}O_2Cl$: Cl, 23.56. Found: Cl, 23.47, 23.47.

(5) We are indebted to H. Tennent and C. Wear for this material.

(6) Bennett and Heathcoat, *J. Chem. Soc.*, 268 (1929).

The redistilled product (F) of b. p. 165–167° at 24 mm. possessed a density, d^{20}_4, of 1.0471 and a refractive index, $n^{20}D$, of 1.44474, which correspond to a molecular refractivity, M_D, of 56.85. The molecular refractivity calculated for the compound $CH_3COOCH_2CH_2CH_2CH_2OCH_2CH_2CH_2CH_2Cl$ is 56.54.

Anal. Calcd. for $C_{10}H_{19}O_3Cl$: Cl, 15.94. Found: Cl, 16.05, 16.09, 16.27.

The redistilled product (G) of b. p. 175–178° at 10 mm., of which only a few grams were obtained, possessed a chlorine content corresponding to the formula $CH_3COO(CH_2)_4O(CH_2)_4O(CH_2)_4Cl$.

Anal. Calcd. for $C_{14}H_{27}O_4Cl$: Cl, 12.01. Found: Cl, 12.61, 12.58, 12.54.

δ-Chlorobutyl Acetate. (2) Reaction of Acetyl Chloride with Tetrahydrofuran in the Presence of Zinc Chloride.—In view of the long period of heating required to bring about the interaction of acetyl chloride and tetrahydrofuran, anhydrous zinc chloride was added with the expectation that it would increase the yield. In the first run, 261 g. (3.32 moles) of acetyl chloride was added gradually to 111 g. (1.54 moles) of tetrahydrofuran and 53.2 g. (0.39 mole) of anhydrous zinc chloride in an all-glass apparatus, which was protected from the entrance of atmospheric moisture. Much heat was evolved at first and the reaction mixture turned dark. At the end of twelve hours of refluxing a considerable amount of sludge was found to have been formed in the flask. The mixture was extracted with ether, the ethereal solution was washed with water, dried over calcium chloride and distilled, giving only a 10% yield of δ-chlorobutyl acetate and a small amount of fraction boiling from 96–160° at 25 mm.

Subsequent runs, summarized in Table I, led to the use of a 10–20 mg. portion of zinc chloride, a period of refluxing of about an hour and the direct distillation of the mixture without the hydrolysis procedure mentioned above. Run 10, made in this way, gave 72 g., a 76% yield, of δ-chlorobutyl acetate and 9 g. of the higher boiling products, which account for most of the tetrahydrofuran.

TABLE I

Run	CH_3COCl	Tetrahydrofuran	$ZnCl_2$	Yield, G.	%	Time reflux, hr.	Remarks
1	261 g.	111 g.	53.2 g.	20	10	12	Heavy sludge
2	135	66	10	30	20	1.5	Heavy sludge
3	212	90	2	36	14	2	Light sludge
4	94	48	7.3	30	27	No	Heavy sludge
5	94	48	0.5	40	38	1	Light sludge
6	94	48	0.3	54	52	1	Light sludge
7	94	48	0.1	54	52	2.5	Light sludge
8	94	48	10 mg.	71	70	0.5	No sludge, no discoloring
9	65	50	10 mg.	72	71	0.5	No discoloring
10	65	50	10 mg.	79	76	1.5	Direct distn.

(3) Reaction of Acetyl Chloride with Tetrahydrofuran in the Presence of Anhydrous Aluminum Chloride.—A weight of 48 g. (0.67 mole) of tetrahydrofuran and 94 g. (1.12 moles) of acetyl chloride was allowed to react in the presence of 1 g. of anhydrous aluminum chloride. The reaction, which was very violent, gave much sludge and a poor yield of δ-chlorobutyl acetate. No attempts were made to find the optimum amount of catalyst.

δ-Chlorobutyl Propionate.—When 93 g. (1.01 moles) of propionyl chloride, 70 g. (0.98 mole) of tetrahydrofuran and 15 mg. of zinc chloride were allowed to react for one hour, hydrolyzed and distilled, δ-chlorobutyl propionate was obtained in a 73% yield together with some higher boiling products. The propionate had a b. p. of 93.5–94.5° at 15 mm. and 101.5–102.5° at 20 mm.; d^{20}_4 1.0537; $n^{20}D$ 1.43640; M_D (calcd.) 40.99; M_D (found), 40.84.

Anal. Calcd. for $C_7H_{13}O_2Cl$: Cl, 21.56. Found: Cl, 21.38, 21.63.

δ-Chlorobutyl *n*-Butyrate.—A one and one-half hour period of heating 50 g. (0.69 mole) of tetrahydrofuran, 90 g. (0.85 mole) of *n*-butyryl chloride and 10 mg. of zinc chloride gave a 62% yield of the chlorobutyl butyrate and a small amount of higher fractions. It is probable that a longer period of refluxing would improve the yield. The ester had a b. p. of 105.5–106.5° at 15 mm., and 112.5–113.5° at 20 mm.; d^{20}_4 1.0302; $n^{20}D$ 1.43791; M_D (calcd.), 45.61; M_D (found), 45.54.

Anal. Calcd. for $C_8H_{15}O_4Cl$: Cl, 19.87. Found: Cl, 20.21, 20.08.

δ-Chlorobutyl Benzoate.—A mixture of 110 g. (0.52 mole) of benzoyl chloride, 50 g. (0.69 mole) of tetrahydrofuran and 10 mg. of zinc chloride, when refluxed for an hour, gave a 54.5% yield of δ-chlorobutyl benzoate and considerable higher boiling material. In this case the tetrahydrofuran was used in excess in order to see what effect this would have on the yield of chlorobutyl benzoate, which in this single run was less than in the case of the aliphatic esters. The product was an oily liquid of b. p. 140–142.5° at 4 mm.; d^{20}_4 1.1429; $n^{20}D$ 1.52028; M_D (calcd.), 55.92; M_D(found), 56.54.

Anal. Calcd. for $C_{11}H_{13}O_2Cl$: Cl, 16.69. Found: Cl, 16.61, 16.58.

δ-Bromobutyl Acetate.[7]—The reaction of 50 g. (0.69 mole) of tetrahydrofuran and 90 g. (0.73 mole) of acetyl bromide in the presence of 5 mg. of zinc chloride took place with the evolution of much heat. At the end of one hour of refluxing, 109 g. of a fraction of b. p. 87–93° at 15 mm. was obtained. The redistillation of this gave a product of b. p. 89.5–92° at 15 mm., which, however, gave consistently high values for bromine. The same discrepancy was also noted after five further distillations. The values for the density (d^{20}_4 1.4921) and refractive index ($n^{20}D$ 1.46799), likewise, gave a molecular refractivity (M_D 37.91) which did not correspond with that computed for the ester (M_D 39.33) from the atomic refractivities of Auwers and Eisenlohr, assuming molecular weights. The impurity responsible for these discrepancies is doubtless tetramethylene dibromide.

Anal. Calcd. for $C_6H_{11}O_2Br$: Br, 41.00. Found: Br 46.63.

δ-Bromobutyl Benzoate.[8]—A mixture of 100 g. (0.54 mole) of benzoyl bromide and 35 g. (0.49 mole) of tetrahydrofuran was allowed to react in the presence of 10 mg. of zinc chloride. After the vigor of the reaction had subsided, the mixture was refluxed for one-half hour and then distilled at 9 mm., giving 94 g. of δ-bromobutyl benzoate

(7) Grishkevich-Trokhimovskii, *J. Russ. Phys.-Chem. Soc.*, **48**, 901 (1916); *C. A.*, **11**, 785 (1917).

(8) V. Braun, *Ber.*, **46**, 1782 (1913).

(76%) of b. p. 155–157°; d^{20}_4 1.3539, and $n^{20}D$ of 1.53694, together with some high boiling fractions; M_D (calcd.), 58.92; M_D (found), 59.26.

Anal. Calcd. for $C_{11}H_{18}O_2Br$: Br, 31.11. Found: Br, 31.16, 31.25, 31.09.

2,5 - Dimethyltetrahydrofuran.—Redistilled Eastman Kodak Co. 2,5-dimethylfuran of b. p. 91–94° (10 parts) was reduced in the presence of Raney nickel (1 part) in a high pressure hydrogenator as in the case of the furan itself. However, high temperatures must be avoided during the hydrogenation. The reduced product boiled from 89–91° (uncorr.), which is somewhat less than the boiling points reported for the compound prepared by other methods.

α-Methyl-δ-chloroamyl Acetate.—A mixture of 106 g. (1.06 mole) of 2,5-dimethyltetrahydrofuran and 204 g. (2.83 mole) of acetyl chloride was allowed to react in the presence of 10 mg. of zinc chloride. The mixture was then refluxed for one-half hour, carefully hydrolyzed and then worked up in the usual way, giving 145 g. of the chloro ester, a yield of 77%. The product had a b. p. of 85.5–87° at 15 mm. or 94–95° at 20 mm.; d^{20}_4 1.0132; $n^{20}D$ 1.43288; M_D (calcd.), 45.74; M_D (found), 45.67.

Anal. Calcd. for $C_8H_{15}O_2Cl$: Cl, 19.87. Found: Cl, 20.16, 20.30.

α-Methyl-δ-bromoamyl Acetate.—The reaction of 50 g. (0.5 mole) of 2,5-dimethyltetrahydrofuran, 70 g. (0.57 (mole of acetyl bromide and 5 mg. of zinc chloride took place with considerable violence. From the mixture 75 g. of product of b. p. 105–107° at 20 mm. was obtained. Although several redistillations were made, no ester could be obtained whose analysis corresponded to pure α-methyl-δ-bromoamyl acetate, as in the case of the δ-bromobutyl acetate, probably on account of the presence of dibromide.

Anal. Calcd. for $C_8H_{15}O_2Br$: Br, 35.85. Found: Br, 38.44, 38.37, 38.60.

Tetramethylene Chlorohydrin.—A mixture of 60 g. of δ-chlorobutyl acetate, 120 cc. of methanol and 0.7 cc. of concd. hydrochloric acid was warmed at 40° for three and a half days. At the end of this period most of the methyl acetate and methanol was removed by distillation under diminished pressure, being careful not to overheat the residue, since the tetramethylene chlorohydrin gives hydrogen chloride and tetrahydrofuran when heated.[9] A further quantity of 60 cc. of methanol was then added to the residue, and this mixture was again heated at 50° for six hours and then at 30° for seventeen, when the mixture was distilled, giving 36.5 g. of the δ-chlorobutanol of b. p. 64–65° at 3 mm., an 80% yield.

Summary

Acetyl chloride will react with tetrahydrofuran to give δ-chlorobutyl acetate with certain other products. The yield of δ-chloro ester is improved by the addition of a trace of zinc chloride. Other acyl halides react similarly both with the tetrahydrofuran and 2,5-dimethyltetrahydrofuran.

The work is being continued and extended.

Studies in the Ketone Sugar Series. IX. The Validity of Hudson's Rules of Isorotation in the *l*-Sorbose Series. β-Ethylsorboside and its Tetraacetate

BY EUGENE PACSU

By the discovery[1] of the true α-pentaacetylfructose <2,6> and by the subsequent[2] interconversion of this substance and the β-pentaacetate, there has become known for the first time in the ketose group an α,β-pair, the mutual relationship of the members of which has been definitely proved. According to Hudson's rules of isorotation, the different a_x constants that may be calculated from this true α,β-pair and the β-derivatives of *d*-fructose should be of general applicability for all the ketoses and their derivatives. These a_x constants, with the exception of a_{OH} for chloroform solution, have been found to be throughout larger than the corresponding A_x constants in the aldose series. Difference between the values of a_x and A_x is, of course, to be expected, since the constants represent, in the latter series, the molecular rotations of carbon atom 1, H–C–X, whereas in the ketose series they express the rotational values of carbon atom 2, ROH_2C–C–X, where R designates a hydrogen atom in the free ketoses and their glycosides, and an acetyl group in the acetylated products. According to the rules of isorotation, the difference in structure or configuration of the basal chain, b_x, of the ketoses should not alter to any large extent the values of the a_x constants. If large deviations be found, it would not necessarily follow that the principle of optical superposition as applied by Hudson is of no general validity, because it is possible that the deviating "constants" have been calculated from the molecular rotations of com-

[a] The rotations of the acetates refer to chloroform solutions and those of the other substances to aqueous solutions.

pounds which are not true α,β-stereoisomeric pairs. The history of the application of Hudson's rules in sugar chemistry shows that such errors frequently have been made in the past. Only a few years ago it was discovered[3] that neither "α"-pentaacetylfructose nor "α"-chloroacetylfructose possesses any ring structure in its molecule. Yet, the rotations of these compounds had been used together with those of the true β-compounds for calculations at a time when the correctness of the assigned structural formulas of these "α"-compounds had not been questioned. Also in the aldose series it recently has been shown[4] that the α-ethyl- and α-benzylthioglucosides are furanosides and not the diastereoisomers of the pyranoid β-compounds as earlier workers had believed.

In view of all these recent cases, where the apparent invalidity of Hudson's rules has been traced back to erroneous assumptions regarding the chemical structures of the "α,β-pairs," it appears to be necessary to ascertain the stereochemical relationship of the constituents of a reference pair, before using their rotational data for computations. This seems to be of special importance in instances where the results of the calculations indicate a failure of the principle of optical superposition. Such a failure of Hudson's rules has been recorded by Schlubach and Graefe[5] in their paper dealing with the preparation of new *l*-sorbose derivatives and with the numerical relationship of rotations in the *l*-sorbose series.

From the known α-tetraacetate of *l*-sorbose the authors have prepared the α-pentaacetate and the α-acetochloro compound. From the latter, by the replacement of the chlorine atom with an acetoxyl or methoxyl group, the β-pentaacetate and the β-methylsorboside tetraacetate have been obtained. Deacetylation of the glycoside has yielded the β-methylsorboside. Since the publication of Schlubach's work, Whistler and Hixon[6] have prepared the α-ethylsorboside and its tetraacetate, and in the Experimental Part of this paper the corresponding β-isomers are described. In the preparation of the latter compounds it has been found that the reaction between α-acetochlorosorbose and ethyl alcohol, just as in the fructose series, does not give rise exclusively to the true β-ethylsorboside tetraacetate. This sorboside is only the product of a side reaction, the main reaction being the formation of a new ethylsorboside tetraacetate possessing ortho ester structure. On account of its sirupy nature, the latter compound has not been investigated closely. Table I contains the data of all the *l*-sorbose derivatives which have been used for calculations in the present publication.

In carrying out their computations, Schlubach and Graefe have assumed that the two methylsorbosides and their acetates constitute true α,β-stereoisomeric pairs. From the molecular rotations of these pairs they have obtained $b_{\text{sorb.}} = -4800$[7] and $b_{\text{sorb. ac.}} = 4900$. Using these values, Schlubach and Graefe have calculated from the molecular rotations of the α-derivatives the different a_x constants; these values were found to be 4400 to 9250 units smaller than those

of the corresponding constants determined by Pacsu and Cramer[1] from the rotations of the whole group of the fructose derivatives (Table II).

TABLE II

COMPARISON OF THE a_x VALUES OF SCHLUBACH AND GRAEFE[5] AND THE CORRESPONDING a_x VALUES DETERMINED FOR THE KETOSES BY PACSU AND CRAMER[1]

	a_x values (S. and G.) (for acetylated sorbose derivatives in chloroform)	a_x values (P. and C.) (for acetylated fructose derivatives in chloroform)	Difference
a_{OH}	12,300	17,750	−5,450
a_{OMe}	24,000	30,850	−6,850
a_{OEt}	25,400[a]	33,650	−8,250
a_{OAc}	26,900	32,850	−5,950
a_{Cl}	35,500	44,750	−9,250
	For deacetylated sorbose derivatives in water	For deacetylated ketose derivatives in water	
a_{OMe}	12,400	21,200	−8,800
a_{OEt}	15,700[a]	20,100	−4,400
a_{OH}	3,050[a]	11,800[a,b]	−8,750

[a] Addition of the present author. [b] Calculated from the rotation of the basal chain in the two methylfructosides <2,6>, $b_{fruct.} = -12,200$, and the initial rotation of β-fructose (−24,000).

Furthermore, it has been pointed out by Schlubach and Graefe that if the calculations be based on the molecular rotations of the two sorbose pentaacetates instead of the acetylated methylsorbosides, the value of $b_{sorb.\ ac.}$ becomes only 3500 instead of 4900, and all the a_x values will be 1400 units smaller. This fact could be regarded as an indication that there might be a difference in the structure of the α- and β-derivatives, since the substitution of an acetoxyl group for a methoxyl group should not influence the rotation of the basal chain to such a large extent. The other fact that the a_x values in the sorbose series deviate so greatly (4400–9250 or more) from the a_x values for the fructose derivatives could be construed as confirmatory evidence that once again incorrect "α,β-pairs" have been used for calculations. However, application of the periodic acid oxidation method of Jackson and Hudson[8] gave results which indicate that both the α- and β-sorbosides possess pyranoid ring structures. Such a structure already has been established by Whistler and Hixon[9] for the α-alkylsorbosides. Therefore, the results of the above calculations would appear to indicate a complete failure of Hudson's rules in the ketose series (column 6, Table I). However, it will be shown in the following calculations that *the isorotation rules hold closely in the sorbose series provided that the a_x constants for the fructose derivatives are applied separately to the α- and β-sorbose derivatives.*

From the molecular rotation of α-methylsorboside tetraacetate (−19,100) and the a_{OMe} constant for the fructose series, the value of the basal chain is calculated to be $b_{\alpha\text{-sorb. ac.}}$[10] = 11,750, from the equation: $-19,100 = -30,850 + b_{\alpha\text{-sorb. ac.}}$ Combination of $b_{\alpha\text{-sorb. ac.}}$ with the different a_x constants for the fructose derivatives gives the calculated specific rotations of *all the α-sorbose derivatives.* The values obtained agree satisfactorily with those found by experiment (column 7, Table I). From the molecular rotation of β-methylsorboside tetraacetate a new value for the basal chain, $b_{\beta\text{-sorb. ac.}} = -1950$, is obtained from the equation: $28,900 = 30,850 + b_{\beta\text{-sorb. ac.}}$ Combination of this new value with the a_x constants for the fructose series gives the specific rotations of *all the β-sorbose derivatives.* Again, the agreement between calculated and observed values is quite satisfactory (column 7, Table I). Similar results are obtained if calculations be carried out by the use of the molecular rotations of the two methylsorbosides. From the [M] value of α-methylsorboside (−17,200) and $a_{OMe} = 21,200$, which is the constant for the fructose derivatives, the value of the basal chain is calculated to be $b_{\alpha\text{-sorb.}} = 4000$ from the equation: $-17,200 = -21,200 + b_{\alpha\text{-sorb.}}$ From the molecular rotation of the β-methylsorboside (7600) a new value for the basal chain is calculated to be $b_{\beta\text{-sorb.}} = -13,600$, from the equation: $7600 = 21,200 + b_{\beta\text{-sorb.}}$. Combination of the respective basal chain values with the a_x constants for the fructose series gives the rotations of the α- and β-sorbose derivatives, the agreement between calculated and found values being satisfactory (column 7, Table I).

The principle that underlies these calculations is Hudson's glycoside-sugar corollary[11] from his rules of optical isorotation. He showed that the difference between the molecular rotation of a given glycoside and that of its parent sugar, $A_{OMe} - A_{OH}$, has the same numerical value (10,000) and the proper sign throughout the sugar group. He found it "a very noteworthy fact that the normal value of the difference holds for

(10) The symbols b_α, b_β and $b_{\alpha,\beta}$ indicate that their values were obtained from the α-form, or β-form, or the α,β-pair of the sugar derivatives.

(11) Hudson, THIS JOURNAL, **47**, 268 (1925).

mannose and rhamnose," although "these sugars . . . exhibit a considerable and similar deviation from the principle of optical superposition when the rotations of their respective α and β forms are compared." He also suggested that "the known α forms of mannose ($[\alpha]_D$ + 30) and methyl mannoside (+79), rhamnose (−7.7) and methyl rhamnoside (−62.5) . . . possess ring structures common to the respective members of each pair" and "that the β forms of these sugars, the rotations of which have been shown to differ from those of the respective α forms by a much smaller amount than is required by the principle, possess rings that are different from those of the α forms." At present, it is recognized that "rings that are different" cannot in these cases be rings that differ in the *number* of their members (pyranoid and furanoid rings), since the α- and β-derivatives of these sugars and also those of *l*-sorbose and *d*-fructose possess six-membered rings throughout. It seems probable that the difference may be ascribed to a new type of isomerism that is not apparent in the customary α,β-stereoisomeric formulas, an isomerism which very well can be accounted for by the existence of any or all of the two possible *trans* and six *cis* ring conformations[12] constituted on the Sachse principle. The numerical value of this new factor (F) can be obtained easily from either equation

$$[M]_\alpha = + A_x + (B_{\alpha,\beta} + F) \text{ and}$$
$$[M]_\beta = - A_x + (B_{\alpha,\beta} - F)$$

where A_x represents the "normal" values valid for *all* the aldoses. Until the exact physical significance of F is fully understood and it becomes definitely known for which particular sugars this additional optical factor must be considered, it is only a matter of convenience to assume that F = 0 in the arabinose–glucose series, where the majority of the most common aldoses belong. Consequently, the A_x values obtained from the α,β-stereoisomeric pairs of these sugars and derivatives will represent the "normal" values valid for *all* the aldoses. From α-methylmannopyranoside ($[M]_\alpha$ = 15,250) and β-methylmannopyranoside ($[M]_\beta$ = −13,200), the value of the basal chain is calculated to be $B_{\alpha,\beta\text{-man.}}$ = 1025. These two substances do not obey Hudson's rules, since the half of the difference of their rotations gives A'_{OMe} = 14,225, instead of the "normal" value of A_{OMe} = 18,700, obtained from the members of the arabinose–glucose series. From either modified equation: $[M]_\alpha = A_{OMe} + (B_{\alpha,\beta\text{-man.}} + F)$ and $[M]_\beta = -A_{OMe} + (B_{\alpha,\beta\text{-man.}} - F)$ the value of F is calculated to be −4475. This represents the numerical value of the contribution of the new optical factor (ring conformation) to the total rotation of the molecule. According to the above arbitrary assumption, this factor does not occur, or it cancels out, in the glucose type of sugars. By the aid of F the rotation of α-mannose is calculated to be $[M]_\alpha = A_{OH} + (B_{\alpha,\beta\text{-man.}} + F)$, that is: 8450 + 1025 − 4475 = 5000, where A_{OH} = 8450 represents the "normal" value obtained from the members of the glucose type of aldoses for *all* the aldehyde sugars. Similarly, the molecular rotation of β-mannose is calculated from the equation: $[M]_\beta = -A_{OH} + (B_{\alpha,\beta\text{-man.}} - F)$ to be −2950. Then the specific rotation of α-mannose becomes 5000/180 = 28° and that of β-mannose, −2950/180 = −16.4°, which values agree excellently with the observed respective values of +29.9 and −16.3°.

In the ketose group the values of $a_{OMe} - a_{OH}$ for α-*l*-sorbose and β-*d*-fructose and their corresponding methyl glycosides are constant (9500) and practically identical with those for the aldoses (10,000).[13] However, the a_x values from the sorbose derivatives are entirely at variance with the a_x constants calculated from the fructose derivatives (Table II). Here again, just as in the aldose group, at present, it is only a matter of convenience to decide which values should be chosen as the "normal" values valid for *all* the ketoses, that is, which one of the two ketoses possesses *strictly* comparable b parts in its α- and β-forms. It is suggested that until no contradictory evidence is discovered, the a_x values derived from the fructose derivatives should be used as the "normal" values for all the ketoses. Then in the calculation of the rotations of those ketoses and their derivatives which do not obey Hudson's rules, *e. g.*, *l*-sorbose, a factor F must be added to the value of $b_{\alpha,\beta}$ for all the α-forms and subtracted from $b_{\alpha,\beta}$ for all the β-isomers. From α-methylsorbopyranoside ($[M]_\alpha$ = −17,200) and β-methylsorbopyranoside ($[M]_\beta$ = 7600) the constant $b_{\alpha,\beta}$ = −4800 is obtained. From either equation: $[M]_\alpha = -a_{OMe} + (b_{\alpha,\beta\text{-sorb.}} + F)$ and $[M]_\beta = a_{OMe} + (b_{\alpha,\beta\text{-sorb.}} - F)$, where a_{OMe} = 21,200 represents the "normal" value obtained

(12) Haworth, "The Constitution of Sugars," Edward Arnold and Co., London, 1929, p. 91.

(13) Since all the A_x constants for the aldoses are different from the a_x constants for the ketoses, the agreement is probably fortuitous.

from the two methylfructopyranosides, the value of F is calculated to be 8800. Addition of $F = 8800$ to $b_{\alpha,\beta\text{-sorb.}} = -4800$ gives $b_{\alpha\text{-sorb,}} = 4000$ for all the α-sorbose derivatives and subtraction of $F = 8800$ from $b_{\alpha,\beta\text{-sorb.}} = -4800$ gives $b_{\beta\text{-sorb.}} = -13{,}600$ for all the corresponding β-isomers. Similarly, from the acetylated α- and β-methylsorbopyranosides $F = 6850$ is obtained, which when added to, or subtracted from, $b_{\alpha,\beta\text{-sorb. ac.}} = 4900$, gives $b_{\alpha\text{-sorb. ac.}} = 11{,}750$ for all the acetylated α-sorbose derivatives and $b_{\beta\text{-sorb. ac.}} = -1950$ for all the corresponding β-forms. The very satisfactory agreement between the values calculated on this basis and the actually observed values of all the *l*-sorbose derivatives (column 7, Table I) leads to the conclusion that Hudson's rules of isorotation hold closely in the *l*-sorbose series and that measurements of the factor F for various sugars may furnish evidence concerning ring conformations.

Addendum.—The possibilities of the construction of two *trans*- and six *cis*-models of sugars on the Sachse principle have been discussed and explored by Haworth.[12] However, our attempts to build up these different forms by using the latest atom models[14] based on the true atomic dimensions resulted in the surprising discovery that only one *trans*- and one *cis*-conformation of a hexopyranose could be constructed. The skeleton models of these two conformations are shown in the sketches Figs. 1 and 2.

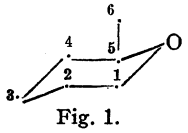

Fig. 1.

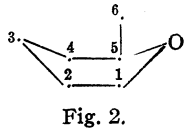

Fig. 2.

In any other conformation more or less obstruction occurs between certain atoms or atomic groups such as the terminal —CH_2OH group, the hydrogen atom and the hydroxyl group of one or more ring carbon atoms, thus making the construction of the molecule impossible. Since theoretical considerations[15] indicate that the *cis*-forms would seem to be unstable due to large repulsion both in the ring and among the subsidiary groups, there remains only one *trans*-form (Fig. 1) from which all the hexopyranoses and their derivatives must be derived. Under such circumstances the physical significance of F appears to be the disturbing effect of the different orientation of the hydroxyl groups in the α and β-isomers of certain sugars. The occurrence of such disturbances at present cannot be predicted beyond some empirical rules, neither can the effect be measured by any chemical or physical methods. In many instances the optical effect of the orientation appears to be negligible (glucose–arabinose series) but for various sugars (mannose, sorbose, etc.) it must be eliminated from the calculations by the introduction of factor F, a characteristic constant for each of these sugars. If this conclusion regarding the nature of F be correct, then the numerical value of this factor must remain the same not only for one particular sugar and its glycosidic derivatives but for any other similarly constructed sugar and its corresponding derivatives. The structure of rhamnose is very similar to that of mannose, consequently the orientation of the hydroxyl groups should not differ to any great extent in the two sugars. Indeed, the numerical value of the factor for *d*-mannose ($F = -4475$) is practically equal and opposite to that for rhamnose ($F = 4650$, obtained from α- and β-methyl-*l*-rhamnopyranoside) which belongs to the *l*-series. By the use of this factor the initial rotations of α- and β-*l*-rhamnose are calculated to be $-5.3°$ and $41.0°$, respectively. Jacobi[16] observed $-5°$ and Hudson[17] measured $-7.7°$ for the α-form, and Fischer[18] gave $31.5°$ for the β-form of a sample which probably was not quite pure.

Experimental Part

Preparation of β-Ethylsorboside Tetraacetate.—Twelve grams of α-sorbose tetraacetate was dissolved in 150 cc. of absolute ether and the solution saturated with dry hydrogen chloride at $-70°$ in a pressure bottle. After having been warmed up to 0° for twelve hours, the solution was cooled and the bottle opened. The solution was evaporated four times with ether to a sirup, rotating $-67°$ in chloroform. Attempts at crystallization of the acetochloro compound from the sirupy product failed. In order to convert it into the glycoside, the crude acetochlorosorbose was shaken with absolute ethyl alcohol and silver carbonate for several hours, then the reaction mixture was filtered and the filtrate treated with hydrogen sulfide to remove traces of silver salts. After filtration with activated carbon, the solution was evaporated to a sirup, which was stirred vigorously for ten minutes in 100 cc. of boiling water containing one drop of 0.1 N hydrochloric acid. The latter operation was necessary in order to decompose the large quantity of ortho ester formed from the

acetochloro compound, which ortho ester prevented the crystallization of the true glycoside. The resulting solution containing sorbose tetraacetate, which is the decomposition product of the ortho ester, and oily drops of the partially soluble β-ethylsorboside tetraacetate, was cooled and extracted with 200 cc. of benzene in several portions. The latter solution was then extracted repeatedly with water until the aqueous extract no longer reduced Fehling's solution. The benzene solution was dried over anhydrous sodium sulfate, then evaporated to a sirup, whose 15-cc. ether solution, on addition of 30 cc. of petroleum ether, deposited 2.5 g. of crystalline β-ethylsorboside tetraacetate. After repeated recrystallization from the same solvents, the substance melted at 86° and showed $[\alpha]^{20}D$ 82.7, $[\alpha]^{20}C$ 66.0 and $[\alpha]^{20}Hg_I$ 98.0 in chloroform solution (0.200 g. of substance, 10 cc. of solution, 2-dm. semimicro tube; rotations 3.31, 2.64 and 3.92° to the right, respectively). In an acetyl estimation, 0.3762 g. of the substance required 40.3 cc. of decinormal alkali; calcd. for four acetyls, 40.0 cc.

The same compound was obtained from the acetochlorosorbose, which was prepared according to Schlubach and Graefe from the reaction of sorbose tetraacetate and liquid hydrogen chloride in an autoclave at 0°. Also in this case a large quantity of ortho ester accompanied the formation of the glycoside. The crystalline β-methylsorboside tetraacetate of Schlubach and Graefe was obtained readily by either method after the ortho ester, the main product of the reaction, had been decomposed by very dilute acid.

β-Ethylsorboside.—A solution of 0.05 g. of metallic sodium in 5 cc. of absolute methyl alcohol was added to 4 g. of β-ethylsorboside tetraacetate dissolved in 5 cc. of the same solvent.[19] After two days the solution was evaporated to leave a colorless sirup, which was extracted with cold absolute ethyl alcohol. The substance, a colorless product, has not yet been obtained in crystalline form. Its specific rotation was 31.0° in water solution (0.4324 g. in 25 cc. rotated 1.07° to the right; 2-dm. tube). Reacetylation gave back the crystalline β-ethylsorboside tetraacetate.

Oxidation of α-Methylsorboside and β-Ethylsorboside by Periodic Acid.—Jackson and Hudson[8] showed that the cleavage type of oxidation by periodic acid of the glycosides provides a new method for the determination of ring structure. Differentiation between the pyranosides and furanosides of the pentoses and hexoses is based on the fact that, on treatment by periodic acid, the pyranosides give rise to one mole of formic acid whereas the furanosides yield no formic acid under similar experimental conditions. Application of this method to the α- and β-sorbosides resulted in the formation of nearly one equivalent of formic acid which was obtained by distillation under diminished pressure of the reaction mixture. This result is regarded as a definite proof of the pyranoid ring structure present in both alkyl sorbosides.

(19) Zemplén and Pacsu, *Ber.*, **62**, 1613 (1929).

Twenty cc. of a 0.1 molar solution of crystalline periodic acid was added to 10 cc. of a 0.1 molar aqueous solution of the glycoside. After sixteen hours of standing at room temperature, the solution was mixed with 20 cc. of decinormal sodium hydroxide solution, then transferred into a 250-cc. distilling flask and evaporated to dryness under diminished pressure at a bath temperature of 45 to 50°. The receiver flask containing 10 cc. of the same standard alkali solution was cooled by running water during the distillation. The residue was then dissolved in 10 cc. of distilled water and the solution was evaporated *in vacuo*, the distillate being collected in the same receiver. Titration of the content of the receiver by decinormal acid solution showed that 9 cc. and 8.6 cc. of 0.1 molar formic acid was obtained from α-methylsorboside and β-ethylsorboside, respectively, instead of the theoretical yield of 10 cc.

Acknowledgment is made to Dr. C. S. Hudson for the *l*-sorbose used in this investigation. The author also wishes to thank Dr. J. W. Green for his helpful assistance in the experimental work.

Summary

It has been shown that Hudson's rules of isorotation hold closely in the *l*-sorbose series provided that the a_x constants for the ketoses are applied separately to the α- and β-derivatives.

The rotations of the α- and β-isomers can be calculated by introduction of factor F in the equations: $[M]_\alpha = -a_x + (b_{\alpha,\beta} + F)$ and $[M]_\beta = a_x + (b_{\alpha,\beta} - F)$. The numerical value of F has been determined to be 6850 for the acetylated and 8800 for the deacetylated products. Similarly, by introduction of a factor (F) in the equations, the rotation of α- and β-mannose can be calculated from the "normal" A_{OH} value for the aldoses. It is suggested that F represents the numerical value of the contribution of a new optical factor (ring conformations) to the total rotation of the molecule.

It has been found that the reaction between α-acetochlorosorbose and methyl or ethyl alcohol gives rise to the ortho esters, as the main products and only to a small quantity of the true β-alkylsorboside tetraacetates. Crystalline β-ethylsorboside tetraacetate has been obtained and the pyranoid ring structure of α-methyl- and β-ethylsorboside has been proved by the periodic acid oxidation method of Jackson and Hudson.

Studies in the Ketone Sugar Series. X. The Synthesis of a New Disaccharide, 1-β-Glucosidofructose, and the Structure of Turanose and Melezitose[1]

BY EUGENE PACSU, E. JUSTIN WILSON, JR., AND LADISLAS GRAF

In 1926 Zemplén and Braun[2] prepared hendecamethylmelezitose which on controlled hydrolysis gave 2,3,4,6-tetramethylglucose and heptamethylturanose. On further hydrolysis the latter substance gave rise to the same tetramethylglucose and a sirupy trimethylfructose with $[\alpha]_D$ 30° in water and 25° in alcohol solution. Using the method of elimination for structure determination, Zemplén and Braun concluded that their product was the 1,3,4-trimethylfructose. On this basis and on the assumption that melezitose was a derivative of sucrose which at that time was believed to possess a 2,6-ring in its fructose constituent, Zemplén and Braun also concluded that melezitose contained a glucosidic group at the fifth carbon atom of the fructose portion of the molecule and that turanose was a 5-glucosidofructose. After Haworth and Hirst[3] had shown that the fructose constituent of sucrose did not belong to the pyranoid type but contained a 2,5-ring, Zemplén[4] pointed out that in such case turanose was a 6-glucosidofructose and melezitose was the corresponding 6-glucosido derivative of sucrose. Zemplén's results and conclusions were later confirmed by Miss Leitch[5] with the exception that she reported the rotation 55.5° in alcohol solution for the sirupy trimethylfructose. In 1931 Pacsu[6] found that on treatment with triphenylmethyl chloride and subsequent acetylation turanose gave rise to a triphenylmethyl derivative and its pentaacetate. He considered this fact as evidence of the presence of three primary hydroxyl groups in turanose. This discovery together with the results of the methylation experiments of Zemplén and of Leitch led him to the conclusion that the formulas of turanose and melezitose originally suggested by Zemplén and Braun were the more probable. In a series of investigations Pacsu[7] subsequently prepared and studied the properties of the acetohalogeno derivatives, the methylglycosides and the acetates of turanose. For reasons discussed in Part VII[7e] several of these derivatives were described as ortho esters. Especially the existence of five octaacetates made it necessary that other than normal structures should be assigned to some of them in order to avoid conflict with the accepted structure of turanose. During the later phase of these investigations, however, it became increasingly difficult, if not impossible, to reconcile the new experimental facts with either the 5- or the 6-glucosidofructose formula of turanose. Striking difference between the properties of the true, crystalline 1,3,4-trimethylfructose[8] (m. p. 75°; $[\alpha]^{18}D$ −52° in water solution) and those of the similarly named sirupy product of Zemplén and of Leitch also indicated that error must have been made in the structure determination of this important key substance and, consequently, the structures assigned to both turanose and melezitose were incorrect. If positions 5 and 6 in the fructose portion of turanose are thus eliminated from the possibilities where the disaccharide linkage might occur, there remain only carbon atoms 1, 3 and 4 for such union. If the glucosidic group were combined with carbon atom 4, the osazone of turanose[9] would be identical with maltosazone. This, however, is not the case.[10] Hence the glucosidic group must be attached on either carbon atom 1 or carbon atom 3. The fact that turanose gives an osazone does not *a priori* eliminate carbon atom 1 as a possible place for the disaccharide linkage. It is entirely conceivable that the ketone group and the adjacent secondary alcoholic group of a 1-glucosidofructose might react with phenylhydrazine to give a 2,3-osazone. Similarly constructed osazones have been reported[11] in the literature.

(1) This work was begun in the first semester of the academic year 1937-38 in the II. Chemical Institute of the Royal Hungarian University at Budapest, where the senior author spent his sabbatical leave. The experiments carried out in that Institute with Dr. Ladislas Graf, University Assistant, were later repeated and concluded in this Laboratory with Mr. E. Justin Wilson, Jr., Research Assistant on Special Funds from the Rockefeller Foundation.

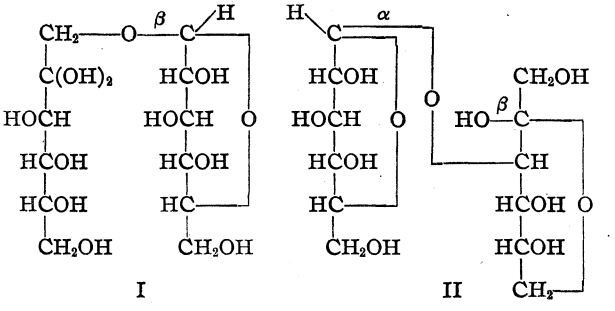
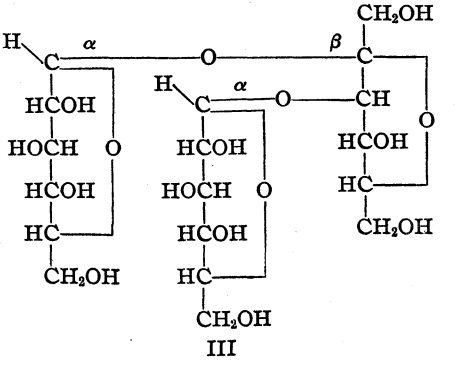
For the investigation of this problem with all its implications regarding the structure of turanose and melezitose, 1-β-glucosidofructose was prepared in the following way. The starting material, 2,3-4,5-diacetone-β-fructopyranose[12] was condensed with tetraacetyl-1-bromoglucose by means of the Königs–Knorr reaction as modified by Reynolds and Evans.[13] The product of the reaction was 1-tetraacetyl-β-glucosido-2,3-4,5-diacetone-β-fructopyranose with m. p. 162–163° and $[\alpha]^{20}D$ −32.9° in chloroform solution. Deacetylation of this compound resulted in the formation of 1-β-glucosido - 2,3 - 4,5-diacetone - β - fructopyranose with m. p. 174–175° and $[\alpha]^{20}D$ −45.6° in water solution. On removal of the two acetone residues by controlled acid hydrolysis, this substance gave rise to the desired disaccharide, 1-β-glucosidofructose with m. p. 132–135° and $[\alpha]^{20}D$ −59.2° in water solution. The new sugar crystallized from its aqueous solution with two molecules of water, of which one was probably chemically bound. It reduced Fehling's solution but unlike turanose it was not fermented by yeast and no mutarotation could be observed in its aqueous solution. The latter fact lent support to the view that the substance represented a derivative of the open-chain fructose hydrate (I). Although the new disaccharide was obviously different from turanose there remained the possibility that the difference was caused by an α,β-isomerism similar to that in the cellobiose–maltose pair. The α-glucosidic linkage in turanose has been proved[14] by Bridel and Aagaard and the presence of a β-glucosidic linkage in the new disaccharide follows from the fact that the sugar was prepared from acetylbromoglucose. It was, therefore, of great interest to investigate whether or not the 1-β-glucosidofructose will give an osazone as readily as turanose. It was found that under normal experimental conditions no osazone was formed from the new sugar. However, in the presence of an excess of acetic acid or if the heating with phenylhydrazine was extended to thirty minutes, a slight precipitation occurred and the isolated substance was identified as glucosazone.[15]

From the results of these experiments it became evident that turanose and 1-β-glucosidofructose were two entirely different sugars. Consequently the α-glucosidic group in turanose must be attached on carbon atom 3 of the fructose constituent as the only possible position left for the disaccharide linkage. Since Isbell and Pigman[10] have shown that crystalline turanose exhibits a pyranose–furanose mutarotation, the structure of this sugar has now become definitely established as 3-α-glucosido-β-fructopyranose represented by formula II.



As to the structure of melezitose, the identity of the potential disaccharide fructose< >glycopyranose presents an interesting problem. Unlike turanose this disaccharide cannot be isolated in a free state and it may be sucrose with a 2,5-ring in the fructose part or a ring isomer of sucrose with a fructopyranose constituent. This problem is now under investigation in this Laboratory and the results so far obtained indicate that in all probability the structure of melezitose corresponds to formula III.



With the recognition of the true structure of turanose as 3-α-glucosidofructose, it became necessary to revise the chemical formulas assigned to all the

On deacetylation of this acetate the authors obtained a small quantity of an amorphous product which was found to give glucosazone in a very small yield when treated with phenylhydrazine "in the customary manner."

TABLE I

DESIGNATION OF THE INCORRECT AND THE TRUE STRUCTURAL FORMULAS OF TURANOSE DERIVATIVES AND THE M. P. AND SPECIFIC ROTATION OF THE SUBSTANCES

Present incorrect designation	M. p., °C.	$[\alpha]^{20}D$ in chloroform solution	Designation of the correct structural formula
"First octaacetylturanose"[a] (Hexaacetyl-β-turanose<2,6>-2,3-*l*-semiorthoacetic anhydride)	216–217	20.5°	Octaacetyl-3-α-glucosido-β-fructopyranose
"Fourth octaacetylturanose"[a] (Hexaacetyl-β-turanose<2,6>-2,3-*d*-semiorthoacetic anhydride)	194–195	103.2°	Octaacetyl-3-α-glucosido-α-fructopyranose
"Fifth octaacetylturanose"[b] (β-Octaacetylturanose)	Sirup	67.4°	Octaacetyl-3-α-glucosido-β-fructofuranose
"Second octaacetylturanose"[a] (α-Octaacetylturanose)	158	107.0°	Octaacetyl-3-α-glucosido-α-fructofuranose
"Third octaacetylturanose"[a,c] (Octaacetyl-*keto*-turanose)	96	126.2°	Octaacetyl-3-α-glucosido-*keto*-fructose
"Stable chloroacetylturanose"[a] (Hexaacetyl-β-turanose<2,6>-2,3-*l*-orthoacetyl chloride)	165	− 0.4°	Heptaacetyl-2-chloro-3-α-glucosido-β-fructopyranose
"Stable bromo-acetylturanose"[a] (Hexaacetyl-β-turanose<2,6>-2,3-*l*-orthoacetyl bromide)	133–134	−30.5°	Heptaacetyl-2-bromo-3-α-glucosido-β-fructopyranose
"Stable iodo-acetylturanose"[a] (Hexaacetyl-β-turanose<2,6>-2,3-*l*-orthoacetyl iodide)	105–106	−54.2°	Heptaacetyl-2-iodo-3-α-glucosido-β-fructopyranose
Heptaacetylturanose[d] (ortho ester structure with *l*-configuration)	140–141	37.0°	Heptaacetyl-3-α-glucosido-β-fructopyranose
"Normal" β-methylturanoside heptaacetate[d]	188–189	27.5°	Heptaacetyl-3-α-glucosido-β-methylfructopyranoside
"Normal" β-methylturanoside[d,e]	173–174	3.6°[f]	3-α-Glucosido-β-methylfructopyranoside
Heptaacetyl-β-methylturanoside with ortho ester structure[d]	162–164	80.0°	Hexaacetyl-1,2-[methoxyl-ethylidene]-3-α-glucosido-β(?)-fructopyranose
"γ"-(3)-Monoacetyl-β-methylturanoside[d]	137	114.6°[f]	1,2-[Methoxyl-ethylidene]-3-α-glucosido-β(?)-fructopyranose

[a] Note (7a). [b] Note (7d). [c] Note (7c). [d] Note (7b). [e] This substance was originally described as a sirup. Later it was obtained in long needles from alcohol solution and showed the indicated constants. [f] In water solution.

derivatives which were previously prepared from this sugar. In this revisionary work it was found that all the experimental facts accumulated during the past investigations could be interpreted excellently on the basis of the new formula. In Table I a list is given of the more important turanose derivatives with their incorrect designations as they now appear in the literature. The last column contains the names of the correct chemical formulas which are based on experimental facts and on the true structure of turanose. Since it is impractical to designate turanose derivatives possessing the furanoid or pyranoid fructose constituent by retaining the word "turanose," the scientific name of 3-α-glucosidofructose has been used throughout because this permits the precise designation of any structural difference.

The acetohalogeno derivatives, the methylglycosides and the acetates of 1-β-glucosidofructose are now being investigated in this Laboratory.

Experimental Part

2,3–4,5-Diacetone-β-fructopyranose.—This substance was prepared by a slightly modified procedure of Ohle and Koller.[12b] Forty cc. of concentrated sulfuric acid was added drop by drop with mechanical stirring to one liter of acetone in an ice–salt mixture. The solution was then shaken on the machine at room temperature with 50 g. of fructose. After three hours of shaking the solution became clear and it was made alkaline with concentrated ammonia solution; the ammonium sulfate was filtered off and the clear filtrate was evaporated *in vacuo* yielding a solid residue or a sirup. This was dissolved in hot water containing about 25% ethyl alcohol and the hot solution was filtered with activated carbon. The resulting clear, orange-colored solution was treated with water until a slight cloudiness developed; then it was warmed up again and allowed to cool and crystallize. Large prismatic crystals of pure β-diacetonefructose were obtained. On concentration *in vacuo* the mother liquor yielded additional crystals. After one recrystallization from dilute alcohol, the substance had m. p. 96–97° and $[\alpha]^{20}D$ −33.0° in water solution. These values are in good agreement with those recorded[12a,b] in the literature; total yield, 47 g.

1-Tetraacetyl-β-glucosido-2,3–4,5-diacetone-β-fructopyranose.—The condensation of β-diacetonefructose with acetylbromoglucose was carried out according to the procedure of Reynolds and Evans[13] for the preparation of gentiobiose. Twenty-six g. of β-diacetonefructose, 25 g. of silver oxide prepared according to Helferich and Klein,[16] 100 g. of Drierite and 100 g. of absolute chloroform were placed in a 500-cc. three-necked flask equipped with a mercury-sealed stirrer, calcium chloride tube and a separatory funnel. The mixture was stirred for one hour to ensure the absence of moisture, then 5 g. of iodine was added after the manner of Helferich and co-workers.[17] A solution of 42 g. of acetylbromoglucose in 150 cc. of absolute chloroform was then added in one hour to the reaction mixture under vigorous stirring at room temperature. After twenty-four hours of continuous stirring the apparatus was fitted with a condenser and the stirring was continued at 55–60° for one hour. The reaction mixture was filtered through a layer of activated carbon, the filtrate was concentrated *in vacuo* and the crystalline residue was dissolved in 200 cc. of hot ethyl alcohol. Upon cooling the disaccharide derivative separated in colorless needles which were recrystallized from alcohol; yield, 30

(17) Helferich, Bohn and Winkler, *Ber.*, **63**, 990 (1930).

to 35 g.; m. p. 162–163°; $[\alpha]^{20}D$ −32.9° in chloroform solution (*c*, 2.374). The substance was insoluble in cold water, slightly soluble in hot water and petroleum ether, soluble in cold ether. In an acetyl estimation 0.4666 g. of the substance was dissolved in 22 cc. of pure acetone. This solution required 31.75 cc. of decinormal alkali, whereas the value calculated for tetraacetyl-1-glucosido-β-diacetonefructose is 31.63 cc.

Anal. Calcd. for $C_{26}H_{38}O_{16}$: C, 52.85; H, 6.48. Found: C, 53.14; H, 6.47.

1 - β - Glucosido - 2,3 - 4,5 - diacetone - β - fructopyranose.—The deacetylation of the tetraacetate was carried out by a small quantity of sodium methoxide according to the method of Zemplén and Pacsu.[18] Sixty grams of the acetate in 300 cc. of methyl alcohol was heated on the water-bath for thirty minutes with 15 cc. of a 0.2 *N* methyl alcoholic sodium methoxide solution. After treatment with activated carbon the solution was concentrated *in vacuo* and the solid residue was crystallized from hot absolute alcohol. From the mother liquor, after treatment with activated carbon, additional crystals were obtained; yield, 42 g.; m. p. 174–175°; $[\alpha]^{20}D$ −45.6° in water solution (*c*, 0.986).

Anal. Calcd. for $C_{18}H_{30}O_{11}$: C, 51.15; H, 7.16. Found: C, 51.27; H, 7.22.

1-β-Glucosidofructose.—The conditions for the removal of the two acetone residues without simultaneously hydrolyzing the disaccharide linkage were established by quantitative estimation of the increase during hydrolysis of the reducing power of the acid solution. A 0.5179-g. sample of the diacetone derivative was dissolved in 50 cc. of 5% acetic acid, then the solution was transferred to a flask for heating in the water-bath. For reduction determination by the Bertrand method, 4-cc. samples were withdrawn at certain intervals of time and diluted to 20 cc. The permanganate solution used was standardized against a solution containing 0.3010 g. of pure glucose in 100 cc. of water. Twenty cc. of this solution required 18.22 cc. of the potassium permanganate solution, so that 1 cc. of the latter was equivalent to 6.2 mg. of copper. The results are summarized in Table II.

TABLE II

HYDROLYSIS AT 100° OF THE ACETONE GROUPS IN 0.5179 G. OF 1-β-GLUCOSIDO-β-DIACETONEFRUCTOSE DISSOLVED IN 50 CC. OF 5% ACETIC ACID. OPTICAL ROTATIONS AND COPPER REDUCING POWER

Hours	Observed rotation	$[\alpha]^{20}D$	Cc. of permanganate soln. for 4-cc. samples	Mg. of Cu	Mg. of sugar (calcd. as glucose)
0.16	−0.45°	−43.4°	..	..	..
0.42	− .38	..	..	..	..
1.50	− .38	..	2.35	14.6	7.0
3.5	− .48	..	4.0	24.8	12.0
5.5	− .50	−59.8 (calcd. as free sugar)	4.40	27.3	13.5
17.7	− .38	....	4.45	27.6	13.8
23.0	− .30	....	4.85	30.1	15.0
41.5	− .24	....	5.00	31.0	15.4

It is seen from the table that in the presence of 5% acetic acid about six hours of heating is sufficient to remove the acetone residues. At that time a 4-cc. sample of the solution, as used for the reduction determination, should contain 33.4 mg. of the new sugar. From the figure (13.5 mg.) obtained it follows that the reducing power of the disaccharide is only 40% of that of glucose. For the conversion of 40 g. of the diacetone derivative into the free sugar, eight 5-g. samples were dissolved each in 500 cc. of 5% acetic acid and the solutions were heated on the water-bath at 100° for six hours. After this time the batches were united and the solution was concentrated *in vacuo* at 45° to a crystalline mass. This was treated repeatedly with water, each time the solvent being evaporated *in vacuo* to ensure the removal of the acetic acid. Finally the hot aqueous solution of the residue was allowed to stand at 0° and crystallize. Colorless, fine needles of pure 1-β-glucosidofructose dihydrate were obtained. On concentration *in vacuo* the mother liquor yielded additional crystals: total yield, 30.5 g. After one recrystallization from water the substance had m. p. 132–135° and $[\alpha]^{20}D$ −59.2° in water solution (*c*, 1.3328; first reading, eight minutes after addition of solvent). The rotation remained constant during an observation period of one day. The new sugar is difficultly soluble in cold water, hot methyl alcohol and hot dioxane, and practically insoluble in ethyl alcohol. It is regarded as an open-chain derivative of fructose hydrate (I).

Experiments carried out in fermentation saccharimeters showed that while yeast was capable of fermenting turanose very readily in distilled water to give carbon dioxide, it was without any effect on the new disaccharide.

On account of the difficult solubility of the sugar in suitable solvents the usual methods of molecular weight determination could not be employed. Finally by the aid of Menzies' differential thermometer[19] the molecular weight of the sugar in methyl alcohol was determined in a special ebullioscopic apparatus[20] as being 381 instead of the calculated value of 378. For analysis the substance was dried at room temperature over concd. sulfuric acid in a vacuum desiccator to constant weight.

Anal. Calcd. for $C_{12}H_{22}O_{11}\cdot 2H_2O$: C, 38.07; H, 6.93. Found: C, 37.76; H, 6.73.

Osazone Test on 1-β-Glucosidofructose.—When 0.5 g. of the sugar in 5 cc. of hot water was heated on the water-bath with a filtered solution of 0.5 g. of phenylhydrazine (3 moles) and 0.3 g. of glacial acetic acid (3 moles) in 5 cc. of water, the solution remained almost colorless for ten minutes. On continued heating the solution became yellow and after thirty minutes a very small precipitation of osazone took place. After filtration the solution was heated with 1 cc. of glacial acetic acid for thirty minutes, during which time a somewhat larger quantity of osazone separated. In another experiment 0.2 g. of the sugar was heated in 10 cc. of water with 0.4 g. of phenylhydrazine (6 moles) and the same amount of glacial acetic acid (10 moles). In twelve minutes a brown colored osazone separated which was filtered off. After additional heating for twenty minutes, the solution again deposited a brown colored substance. The combined solids were purified with moist ethyl acetate; yield, 70 mg. of light yellow crystals; m. p. 204–206°; $[\alpha]^{20}D$ −65.5°, in a mixture of

six parts of absolute alcohol and four parts of pyridine (c, 0.58). After one day the rotation became constant at $-34.5°$. On the basis of these data the substance was identified as pure glucosazone.

Summary

The present structures of turanose and melezitose are based on the supposed 1,3,4-trimethylfructose, a sirupy product obtained by Zemplén and by Leitch from the fully methylated melezitose. The existence of the true, crystalline 1,3,4-trimethylfructose and the number and properties of the octaacetates and other derivatives of turanose indicate that neither carbon atom 5 nor carbon atom 6 of the fructose part of turanose can carry the glucosidic linkage. Carbon atom 4 is also eliminated because turanosazone is not identical with maltosazone. If carbon atom 1 were the position of the linkage, 1-β-glucosidofructose would be the β-glycosidic isomer of turanose. This new disaccharide has been synthesized by condensation of acetylbromoglucose with β-diacetonefructose and subsequent hydrolysis of the acetyl and isopropylidene groups. The synthetic sugar is entirely different from turanose and unlike the latter it does not give an osazone except for a small quantity of glucosazone. Turanose, therefore, must be 3-α-glucosidofructose and melezitose the corresponding sucrose derivative. Based on the true formula of turanose the correct structures of the more important turanose derivatives are given.

Infrared Absorption Studies of Some Glycols and Ethoxyalcohols

BY F. T. WALL AND W. F. CLAUSSEN

It has been recognized for some time that hydroxy compounds such as the alcohols and acids can undergo association through the formation of hydrogen bonds.[1,2] This association can lead to the formation of well-defined dimers in certain cases, or to the formation of polymers of indefinite size. Thus the monocarboxylic acids form definite dimers,[3] whereas water and the alcohols can associate to form aggregates of varying sizes.[4]

It has been observed further that certain hydroxy compounds such as water not only can associate with themselves,[5] but also can bond to other molecules such as the ethers.[6] Ethyl ether has no active hydrogens, and so cannot form hydrogen bonds by itself, but its oxygen readily can take part in the formation of a hydrogen bond by serving as an acceptor for an active hydrogen atom from another molecule.

In addition to molecules bonding to others of the same kind or to suitable molecules of a different kind, it also has been found that internal bonding, giving rise to ring formation, can occur in certain cases. This type of bonding known as "intramolecular" bonding (to be distinguished from "intermolecular" bonding) occurs, for example, in o-nitrophenol,[7] and salicyl aldehyde,[8] in which cases a stable six-membered ring containing a hydrogen bond is formed.

Evidence for the above-described effects has been provided in numerous ways, but one of the most convenient methods is through the study of infrared absorption. Infrared studies show that, whereas a certain absorption frequency to be associated with an OH group is generally present in hydroxy compounds, that frequency is shifted by an appreciable amount when hydrogen bonding occurs.[1,8] The shifted or hydrogen bond frequency occurs at wave lengths higher than is found for the fundamental OH, and the magnitude of the shift is usually sufficiently large so as to leave no doubt that a change in the nature of the hydroxyl group has taken place.

The effects discussed above were first observed for the simple hydroxy compounds, by themselves or in combination with simple ethers. It was accordingly felt desirable to investigate by means of infrared absorption studies the association of the glycols and ethoxyalcohols. It is clear from their structures that these molecules offer the possibility of not only associating with one another,

but that they might also undergo intramolecular bonding when the chain length is suitable. It was the purpose of these studies to find out which effect or to what extent both effects take place when these compounds are introduced into an inert solvent like carbon tetrachloride.

Substances Used.—The glycols studied were ethylene, propylene, butylene, pentamethylene, hexamethylene, decamethylene and octadecamethylene glycols. Of these, ethylene and propylene glycols have been investigated previously,[9] but under different conditions, so that it was felt desirable to repeat them here. Most of these compounds were obtained from the preparation stock rooms of our organic chemistry division. However, the pentamethylene glycol was specially prepared by the hydrolysis of pentamethylene dibromide in an alkaline water–alcohol solution. Octadecamethylene glycol was prepared under the direction of Professor C. S. Marvel by the reduction of the corresponding ester of the dibasic acid with sodium and alcohol. All of these compounds were carefully distilled or recrystallized, the physical constants being recorded in Table I.

With the exception of 2-ethoxyethanol-1 ("cellosolve"), which is commercially available, all of the ethoxyalcohols used in these studies were prepared in this Laboratory. 3-Ethoxypropanol-1 was synthesized from propylene chlorohydrin and sodium ethylate. 4-Ethoxybutanol-1 was prepared from the monosodium derivative of tetramethylene glycol and ethyl bromide. 5-Ethoxypentanol-1 was made by hydrolyzing the product from the reaction of equimolar quantities of pentamethylene dibromide and sodium ethylate. These ethoxy alcohols were carefully fractionally distilled, and the resulting boiling points are recorded in Table II.

Experimental

The technique employed for the absorption studies has been described previously.[2] The spectroscope used was of the prism type, the rock salt prism being on a Littrow–Wadsworth mounting. The source of radiation was a Nernst glower, and the intensity of the beam was measured

by means of a thermocouple–galvanometer arrangement. In some cases a Moll amplifier[10] was used to increase the deflections.

The glycols were not very soluble in carbon tetrachloride, so approximately saturated solutions which were about 0.002 molar were used for the most part. In some cases more dilute solutions were investigated in order to study the effect of concentration. The solutions were placed in absorption cells of length 10.18 cm.

The ethoxyalcohols were more soluble than the glycols so they were studied for a concentration range from 0.004 to 0.256 molar. In the case of the ethoxyalcohols, the length of the cell times the concentration of the solute was kept constant for the different runs, so that the radiation passed the same amount of material in each case.

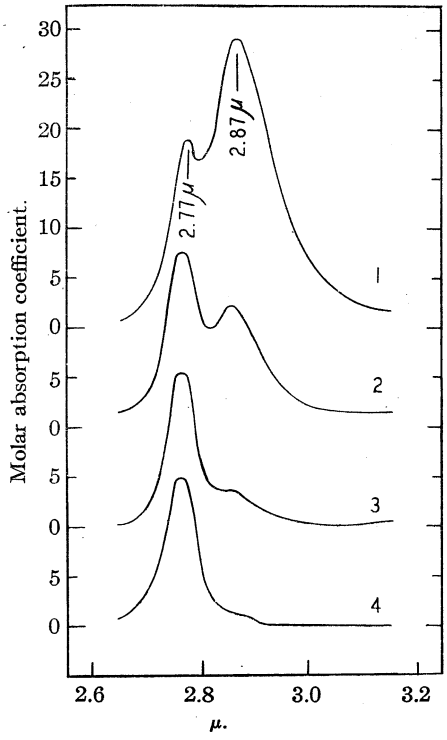

Fig. 3.—2-Ethoxyethanol-1 (1) 0.256 *M* in 0.162-cm. cell, (2) 0.064 *M* in 0.640-cm. cell, (3) 0.016 *M* in 2.53-cm. cell, (4) 0.004 *M* in 10.18-cm. cell.

The results of the experimental investigation are shown in Figs. 1 to 6. For the glycols the values of log I_0/I are plotted against wave length where I_0/I is the ratio of the intensities of light transmitted by pure solvent to that transmitted by the same length of solution. For the ethoxyalcohols, there are plotted the molar extinction coefficients defined as

$$K = \frac{1}{cd} \log \frac{I_0}{I}$$

where c is the concentration in moles per liter and d is the length of the cell in centimeters. The published curves show the absorption only in the 2.8 μ region. It should be added that all the molecules show absorption in the neighborhood of 3.35 μ and beyond, which is due to carbon–hydrogen absorption. Since we are concerned here only with hydrogen bonding possibilities, the carbon–hydrogen absorption is not included in the curves.

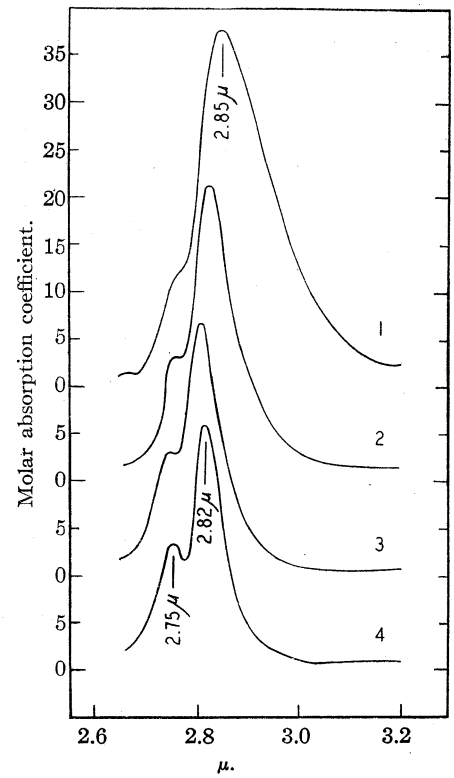

Fig. 4.—3-Ethoxypropanol-1 (1) 0.256 *M* in 0.162-cm. cell, (2) 0.064 *M* in 0.640-cm. cell, (3) 0.016 *M* in 2.53-cm. cell, (4) 0.004 *M* in 10.18-cm. cell.

Discussion of Results

The results for the glycols are somewhat difficult to interpret because their limited solubility in carbon tetrachloride prevented their study over a wide concentration range. Ethylene glycol gives no evidence for a bonded peak, but does show the fundamental OH at 2.76 μ. The failure to bond might well be due to the low concentration.

A saturated solution of propylene glycol shows a peak at 2.80 μ with a shoulder on the short wave length side. Upon dilution, using the same length cell, however, this shoulder can be resolved into an absorption maximum at 2.76 μ. Upon further dilution the 2.80 μ peak becomes relatively less im-

(10) Moll and Burger, *Phil. Mag.*, **50**, 724 (1925).

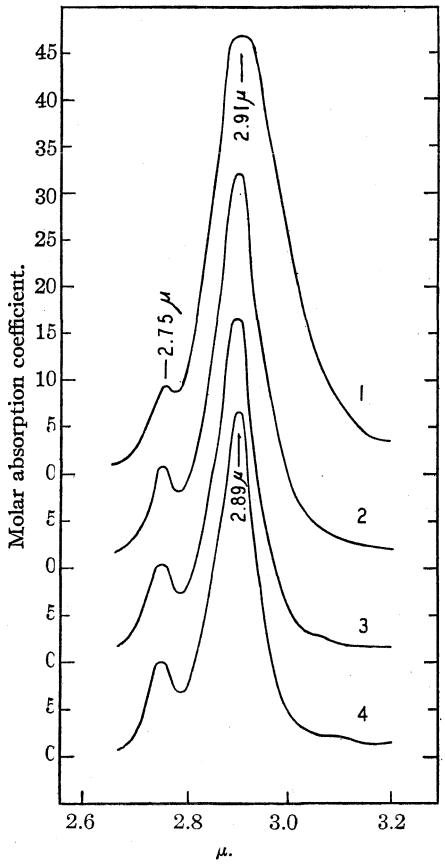

Fig. 5.—4-Ethoxybutanol-1 (1) 0.256 *M* in 0.162-cm. cell, (2) 0.064 *M* in 0.640-cm. cell, (3) 0.016 *M* in 2.53-cm. cell, (4) 0.004 *M* in 10.18-cm. cell.

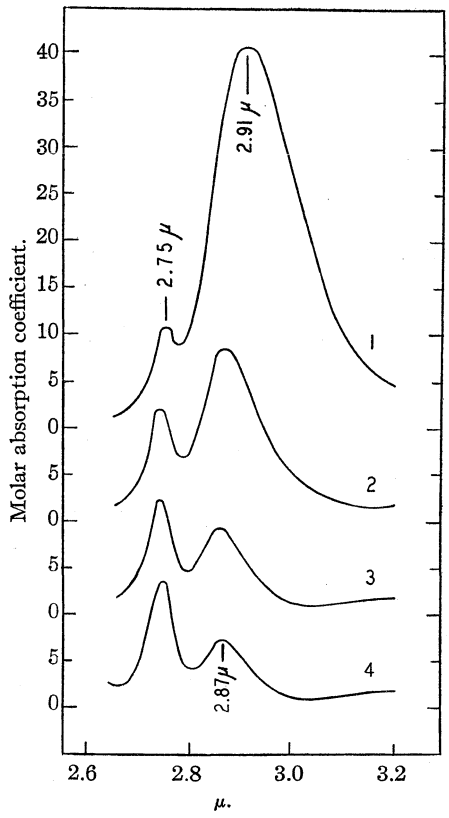

Fig. 6.—5-Ethoxypentanol-1 (1) 0.256 *M* in 0.162-cm. cell, (2) 0.064 *M* in 0.640-cm. cell, (3) 0.016 *M* in 2.53-cm. cell, (4) 0.004 *M* in 10.18-cm. cell.

portant suggesting that it is due partly to association. In the light of the results obtained for the ethoxyalcohols, the association peak for propylene glycol very likely is due to intramolecular bonding. It is possible that two non-linear hydrogen bonds are formed when the ends of propylene glycol are joined together. Such non-linear bonds would show a much smaller shift in frequency from the fundamental OH than would a regular hydrogen bond, which is in agreement with the observation.

Butylene glycol shows two well-defined peaks at 2.89 μ and 2.76 μ. Upon dilution the 2.89 μ absorption maximum goes down considerably suggesting that it is largely due to association. However, some ring formation is to be expected. The 2.76 μ absorption is due of course to the fundamental OH vibration.

The penta-, hexa-, and decamethylene glycols all show two maxima, a strong fundamental OH and a weaker bonded peak. In the case of these molecules ring formation is not probable. Octadecamethylene glycol gave evidence only for the fundamental OH frequency.

The ethoxyalcohols provide a much more interesting set of data because of their greater solubility. Each of these compounds shows two peaks, one due to the fundamental OH and the other due to the hydrogen bonded OH. Since the absorption results for these molecules were obtained by keeping $c \times d$ constant, the relative heights of the peaks have a quantitative significance capable of immediate interpretation. For each compound, the bonded or higher wave length peak decreased in height as the concentration was lowered. However, the decrease was not the same in each instance. By plotting the height of the bonded peak against concentration (Fig. 7), an idea as to what is taking place can be obtained. By extrapolating those curves to zero concentration, one can determine the molar hydrogen bond absorption at infinite dilution.

At infinite dilution, any hydrogen bonding must be of the intramolecular (ring form) type. This

follows from equilibrium considerations. The extrapolation in Fig. 7 shows that there is no bonding whatsoever for the ethoxyethanol at infinite dilution. This means that any bonding which the molecule undergoes in actual solutions must be of the intermolecular type. On the other hand, the substituted propanol and butanol show considerable bonding even at infinite dilution. This is to be attributed to ring formation. Moreover, ethoxypentanol shows only small hydrogen bonding at zero concentration. This can be associated with the fact that the pentanol would form a ring too long for stability.

It appears from these results that the most stable rings involving hydrogen bonds contain 6 or 7 atoms, including the hydrogen. These numbers are greater by one than those usually given for rings involving only the ordinary electron pair type of bond. No explanation seems immediately forthcoming as to why a five-membered hydrogen bond ring should be unstable, yet there seems to be no doubt as to the absence of ring formation in 2-ethoxyethanol-1.

Conclusion

The infrared absorption spectra of carbon tetrachloride solutions of various glycols and ethoxyalcohols have been studied in the neighborhood of 2.8 μ. The results show that the ethoxyalcohols can associate through the formation of intermolecular hydrogen bonds. Also the substituted propanol and butanol can form stable rings, whereas ethoxyethanol shows no evidence of ring formation. The glycols likewise demonstrate hydrogen bonding, but the evidence for their precise behavior is not conclusive because of their limited solubility.

On the Degassing of Hydrogen-Charged Palladium

BY F. D. BENNETT[1]

For a long time experimenters have recognized that palladium sorbs very great quantities of hydrogen gas. Metals such as iron and nickel are known to sorb hydrogen and other gases in varying quantities, portions of which are held tenaciously even when the metals are heated to the melting point in vacuum. While there is considerable indirect evidence suggesting that palladium releases its sorbed gas quickly at comparatively low temperatures, apparently no direct measurements have been made of the degassing of palladium in vacuum.

In a recent investigation of the palladium–hydrogen equilibrium by Gillespie and Galstaun,[2] a series of pressure–composition isotherms over the range 80–313° is presented and several palladium hydrides postulated to explain the existence of certain discontinuities in the isotherms.

In the preparation of the palladium black with which these experiments were carried out, Gillespie and Galstaun reduced palladosammine chloride in hydrogen. The black was degassed of hydrogen at 500° in a stream of carbon dioxide and then cooled. It was further degassed in an evacuated Pyrex bulb by heating with a hand torch until the glass began to soften. The black was then transferred to the reaction bulb and hydrogen admitted in order to clean up adsorbed oxygen.

(1) Graduate Assistant in Physics at The Pennsylvania State College.

(2) Gillespie and Galstaun, THIS JOURNAL, 58, 2565 (1936).

Further degassing was carried out at the experimental temperatures[3] (200–313°).

Question has been raised[4] as to whether the procedure used by Gillespie and Galstaun was sufficient to remove all significant amounts of hydrogen from the palladium sample before the measurements were taken. The possibility of a small amount remaining in the palladium even under very strenuous degassing was suggested. Such a residual amount might cause serious error in the concentration values used by Gillespie and Galstaun and correction of the error would necessitate assumption of different hydrides from those mentioned.

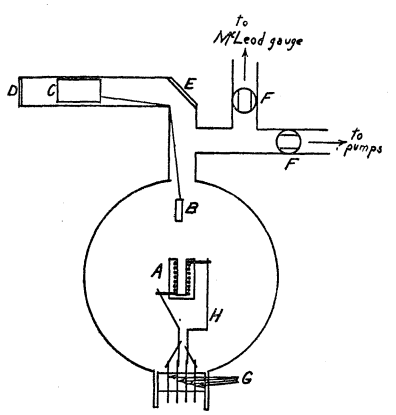

Fig. 1.

The work of Gutbier[5] and Kemmerer[6] on the determination of the atomic weight of palladium is open to similar objection, *viz.*, that neither of these investigators made certain that the palladium samples used were free of hydrogen. Kemmerer's technique differs from that of Gutbier in that Kemmerer allowed the hydrogen-treated sample to cool from 955° to room temperature in an atmosphere of nitrogen while the highest temperature at which degassing might have taken place in Gutbier's treatment was about 500°.

The purpose of this investigation is to make some quantitative determination of the degassing of hydrogen-charged palladium at various temperatures up to the melting point of palladium and to determine whether a considerable amount of hydrogen is retained at low temperatures (200–600°).

The experimental work is divided into two sections, the first of which deals with the degassing of palladium over the temperature range 650–1553°; the second covers the degassing experiments at temperatures 180–440°.

Experimental. I

Apparatus.—Figure 1 shows a schematic representation of the degassing apparatus which consists essentially of a small high-temperature furnace in a closed system with auxiliary mechanism for evacuation of system, introduction of the palladium sample and measurement of pressure changes. A refers to the crucible, B to the metallic palladium sample suspended by a thin tungsten wire from a soft-iron cylindrical shell C. The shell may be moved by magnets outside the system and the palladium lowered into the furnace at will. D is a plane piece of Pyrex sealed onto the tube; E is an aluminized mirror sealed in and inclined so that the interior of the crucible may be seen by viewing through D. F and F are mercury seal stopcocks. G indicates four 60 mil tungsten leads sealed into the bulb. H shows the 40 mil nickel wires used to support the crucible and conduct current to the tungsten furnace winding. All interior connections are spot-welded. 110 v. d. c. through a suitable system of control rheostats was used to heat the furnace. A current of 9.5 amp. was sufficient to attain the highest temperatures used—about 1600°.

The furnace itself consists of a 20 mil tungsten winding embedded in zirconium oxide shaped in crucible form. Crucible dimensions do not exceed 2 cm. each way. Zirconium chloride added to the oxide paste served as a binder until the whole had been fired by a hand torch.

Samples and Charging.—In these experiments metallic palladium rod was used instead of palladium black. The electrolytic charging method was found to be the only efficient method of charging the solid samples.

Dilute sulfuric acid (5% by weight) was used as the electrolyte in the charging cell. The sample of palladium was made the cathode of the cell and held by a platinum electrode sealed through glass under an inverted 50-cc. buret filled with the electrolyte. The hydrogen given off at the cathode either entered the palladium sample or came off in gaseous form and was collected in the buret. By passing a known charge through the cell and observing the amount of gas collected, the amount of hydrogen sorbed by the palladium could be deduced. In reducing the amount of gas collected to N. T. P. correction was made for the vapor pressure of the solution which was assumed sufficiently dilute to be considered the same as pure water. No correction was made for the amounts of hydrogen in solution in the electrolyte; these were so small as to be negligible (0.00016 g. of hydrogen dissolves in 100 g. of water at 20° and 1 atm. hydrogen pressure).

The palladium sample was charged past equilibrium by this electrolytic method, but on standing lost gas until approximate equilibrium was reached. After several chargings a nearly constant H/Pd ratio was obtained and at this ratio the sample was considered completely charged.

(3) This use of hydrogen to clean up adsorbed oxygen was not mentioned specifically in Gillespie and Galstaun's paper, but Dr. Gillespie in written communication with Dr. W. R. Ham (of The Pennsylvania State College) stated that the clean-up technique was used and has been described by him in a previous paper: Gillespie and Hall, THIS JOURNAL, **48**, 1207 (1926).

(4) Dr. W. R. Ham raised this question in the unpublished correspondence with Dr. Gillespie.

(5) Gutbier, *J. prakt. Chem.*, N. F., **79**, 235 (1909).

(6) Kemmerer, THIS JOURNAL, **30**, 1701 (1908).

Degassing.—For degassing, the charged sample was cut in half and one part left under the buret while the other was sealed into the degassing chamber. In this way a check was had on the amount of gas given up by the sample in the sealed chamber during the time prior to actual degassing.

The general technique of degassing was as follows. The furnace was heated to the highest temperature to be used in the degassing process and the system thoroughly degassed. Then the furnace was cooled to approximately 650°, system closed off and palladium introduced to furnace. Large amounts of hydrogen were liberated, but pressure change was not measured until furnace and gas had been cooled down to room temperature. The system was then evacuated thoroughly, closed off and furnace and sample again degassed at 650° to determine the amount of hydrogen sorbed when furnace and sample were cooled in the atmosphere of liberated hydrogen. This correction proved to be slightly more than 1%.

After evacuation at 650° the system was again closed off and temperature raised to 1550° in order to melt the palladium. Pressure change over the range was recorded.

Experimental. II

Apparatus.—Figure 2 shows a schematic diagram of the degassing apparatus used for the low temperature measurements. A refers to a heavy nickel tube about 14″ (35.5 cm.) long with inside diameter $^3/_8$″ (1 cm.) and outside diameter $^{13}/_{16}$″ (2.1 cm.) situated in the nichrome wound electric furnace D. B refers to water coolers brazed onto the ends of the nickel tube to cool the de Khotinsky joints E where the nickel tube is sealed to the glass tubing which makes up the remainder of the system. C is the chromel-alumel thermocouple used to measure furnace temperatures. Its leads pass out through de Khotinsky plugs F. I represents the charged sample of palladium which is attached by a stiff nichrome wire to a small piece of soft iron which may be moved by means of magnets from the outside. G and H indicate mercury seal stopcocks and K denotes the mercury manometer on which pressure changes may be read. For this series of experiments stopcock G was closed and manometer alone was used.

Samples and Charging.—A thin palladium tube about 3 mm. in diameter and 3 cm. long was used. The tube was charged by the electrolytic method exactly as described in the first section except that no particular effort was made to reach the final equilibrium charge each time. After several electrolyses the sample would spontaneously degas to a certain extent and when this occurred the tube was considered sufficiently charged.

Degassing.—The charged sample was attached to the nichrome wire and sealed into the system. The furnace was heated to the experimental temperature desired and system allowed to degas for several hours at this temperature. Then stopcock H was closed and the palladium sample introduced to the furnace. At this point time and manometer readings were recorded. Usually the degassing of the sample started within one minute from the time of introduction into the furnace and continued for a considerable period of time, especially at the lower temperatures. When the manometer reading remained constant for several minutes the degassing was taken to be complete; the sample was withdrawn and the furnace shut off so that the system could come to room temperature. When the system was cool, manometer, temperature and barometric pressure readings were taken. These together with the volume of the system allowed calculation of the amount of gas liberated by the palladium.

It was thought for a time that the low-temperature degassing might not be complete or that the furnace and palladium might re-sorb considerable quantities of hydrogen and to detect these the system was evacuated cold, closed off and heated several hundred degrees higher than the experimental temperature, whereupon the sample was readmitted and degassed further. It was found that the hydrogen given off during this process was about 3% of the total at the lowest temperature and negligible at the three higher ones.

Discussion

Table I gives the charging data and calculations. From Table I we see that the first electrolysis was sufficient to bring the ratio of hydrogen to palladium atoms to 0.577. This charge was evidently well below equilibrium because no hydrogen was lost on standing. Further electrolysis succeeded in raising the charge as high as 0.800, but on standing hydrogen was lost spontaneously until the ratio fell to about 0.700. This loss of hydrogen was easy to follow visually, for on breaking the current bubbles of hydrogen continued to come from the sample until the equilibrium charge was reached.

Row V shows the amount of hydrogen lost over a two-day period after the fourth electrolysis, and 0.698 represents the stable charge ratio of the sample at room temperature. Observations on the control sample show no further loss of hydrogen during the remainder of the time prior to actual degassing.

This final, stable charge is in good agreement with results of von Samson-Himmelstern[7] who found, on electrolytically charging palladium at 20°, stable charge values from 0.70 to 0.80. Of his seven determinations, four lie between 0.70 and 0.72.

The 30° isotherm of Gillespie and Hall[8] shows that at an external hydrogen pressure of 500 mm. about 72.5 cc. of hydrogen is sorbed by each gram of palladium. This amount is equivalent to an atomic ratio of about 0.69. From the curvature of the isotherm it seems likely that a moderate increase in external pressure would have brought the equilibrium charge up to 0.70.

Table II shows the degassing data and calculated results. At 650° an initial large change in pressure is recorded. The succeeding pressure changes represent the amount of gas taken up by the furnace and sample upon cooling in the liberated hydrogen.

The apparent concentration of hydrogen in palladium as shown by the 650° degassing is 0.709. This value is in close agreement with that of the known initial charge, 0.698. The variation here is about 1.6%, which is within the experimental error.

The degassing at 1553°, the melting point of palladium, gave rise to a very small pressure change and indicated that a negligible amount of hydrogen was given off.

Table III shows the results of degassing a charged sample at four temperatures lower than 650°. Of these four trials the first at 181° was the only one in which any appreciable amount of hydrogen came off during the second degassing. The 0.619 apparent H/Pd came off over a period of fourteen hours at 181° and the 0.017 correction came off in less than a minute at about 300°. Thus the total charge indicated for this trial was about 0.636 H/Pd.

The variations between the H/Pd ratio as shown by degassing and the H/Pd ratio calculated from electrolytic charging data are from 1 to 4%. These variations are erratic and are due to experimental error.

Within the uncertainty of the experiment these data show that massive hydrogen-charged palladium degasses completely and rapidly in vacuum at temperatures as low as 300°. Below this temperature degassing occurs, but takes place over much greater lengths of time and at temperatures below 200° is probably not complete.

While these data apply strictly to massive palladium, similar results obtain without doubt for palladium black. Massive palladium is notoriously more difficult to use in equilibrium experiments because of the slowness with which it takes up or gives off hydrogen. One would expect the degassing of palladium black to be somewhat more rapid than that of massive palladium, but otherwise essentially the same.

Summary

A stable charge of hydrogen in palladium is obtained by the electrolytic method such that the ratio H/Pd is equal to 0.698. This value agrees well with the existing experimental data on the subject.

It is shown within the limits of experimental error that all of the important amounts of hydrogen in a charged sample of massive palladium are driven off by degassing in vacuum at temperatures as low as 300°. Below this temperature degassing occurs but at much slower rates and with less probability of completion.

Further degassing up to the melting point shows negligible liberation of hydrogen.

No correction for unremoved hydrogen in the atomic weight of palladium as determined by Gutbier[5] and Kemmerer[6] is indicated. The assumption of Gillespie and Galstaun[2] that their samples of palladium black were sufficiently well degassed by treatment at 650° and over the range 200–300° is correct.

Saturated Standard Cells with Small Temperature Coefficients. IV. The Addition of Various Sulfates to the Electrolyte of the Weston Cell

BY W. C. VOSBURGH, PAUL F. DERR, GERALD R. COOPER AND BARBARA PETTENGILL

Modification of the saturated Weston cell by the addition of bismuth to the amalgam and the double salt of sodium and cadmium sulfates to the electrolyte in excess gives a saturated cell of smaller temperature coefficient than that of the normal Weston cell.[1] Some cells made by the addition of other sulfates and double sulfates to the electrolyte of the Weston cell have now been studied.

The details of the preparation and measurement of the cells were essentially as described previously.[1a] The amalgam was a 10% cadmium amalgam, except as otherwise noted. The added salt was sometimes added merely in the form of the specially purified simple salt, with the expectation that any double salt formation necessary for stable equilibrium would take place within the cell. Care was taken to provide an excess of hydrated cadmium sulfate, except as mentioned below. In some of the cells the proper double salt was added, along with cadmium sulfate. Enough sulfuric or acetic acid was added to the electrolytes to make them either 0.01 molar with respect to sulfuric acid or about 0.07 molar with respect to acetic acid.

The cells in Table I all contained hydrated cadmium sulfate as one solid phase, and contained a second solid salt which was either the salt in the first column, or a hydrate of this, or a double salt formed from this salt and cadmium sulfate. The cells were kept at 25° until the electromotive forces were constant and then measured at other temperatures. The temperatures were probably correct within 0.05°. For comparison, data for sodium sulfate from a previous paper[1a] and for the Weston cell (no added salt), and for the amalgam cell,[1] Cd(Bi,Hg)/Cd^{++}/Cd(Hg) have been added. The last was included because it was found that the cells of lowest temperature coefficient could be made by the use of a cadmium–bismuth amalgam instead of cadmium amalgam. The electromotive force of such a cell can be calculated by combination of the data for a Weston-type cell (made with cadmium amalgam) with that for the amalgam cell as if the two were connected in series. The temperature coefficient of the combination cell is the algebraic sum of the coefficients of the amalgam cell and the Weston-type cell.

[a] Ref. 1. [b] Ref. 1a. [c] The two cells differed by 0.1 mv. [d] The two cells differed by 0.2 to 0.25 mv.

From the data in Table I it can be seen that the cell containing lithium sulfate when combined with the amalgam cell should give a cell of lower temperature coefficient than the sodium sulfate cell.

A number of cells were made in which the electrolyte was saturated with cadmium and lithium sulfates[2] and the amalgam was cadmium–bismuth. These cells were made in four different groups and at different times. All were more or less disturbed by temperature changes, and sometimes they assumed new electromotive forces that seemed constant after changes in temperature. This could not be ascribed to impurities, because one pair of these cells which behaved abnormally was made at the same time and so far as possible with the same materials as three of the potassium sulfate cells of Table I, and the latter behaved normally.

The lithium sulfate cells shown in Table II have two objections as standards in comparison with the sodium sulfate cells,[1a] they are more variable and they have an electromotive force somewhat different from saturated and unsaturated Weston cells. The temperature coefficient has the low value predicted. The disagreement

(2) Parks, Patterson and Vosburgh, THIS JOURNAL, **59**, 2141 (1937).

of Cells 817–822 in temperature coefficient may be the result of temperature hysteresis, which was somewhat pronounced in these cells.

TABLE II

MODIFIED WESTON CELLS CONTAINING LITHIUM SULFATE AND CADMIUM–BISMUTH AMALGAM

Cells	E_{25}, v.	$E_t - E_{25}$, v. × 10^5 15°	20°	30°	35°
(Calcd.)	1.01581	−3	−4	5	12
817–22	1.01593	+4	+5	0	..
831–34	1.01591	−6	−5	4	13
837, 839–40[a]	1.01587	...	−4	7	13
841–42	1.01597	...	+1	6	5

[a] These cells had an electromotive force of 1.01581 v. at 25° which was constant for several weeks when first prepared.

A few cells were made in which the electrolytes were saturated with a double salt of cadmium sulfate and potassium or ammonium sulfate together with an excess of potassium or ammonium sulfate. These cells had cadmium amalgams. In one group of these cells the electrolyte was saturated with both the double salt[3] $K_2SO_4 \cdot CdSO_4 \cdot 1^1/_2H_2O$ and potassium sulfate, and in another the electrolyte was saturated with the double salt[4] $(NH_4)_2SO_4 \cdot CdSO_4 \cdot 6H_2O$ and ammonium sulfate. Both cells had electromotive forces larger than that of the Weston cell, and much larger temperature coefficients. The results are shown in Table III.

TABLE III

CELLS CONTAINING A DOUBLE SALT OF CADMIUM SULFATE BUT NO CADMIUM SULFATE SOLID PHASE

No. of cells	Solid phases	E_{25}, v.	$Et - E_{25}$, v. × 10^5 20°	30°
2	$K_2SO_4 \cdot CdSO_4 \cdot 1 \cdot 5H_2O$; K_2SO_4	1.04780	79	− 75
3	$(NH_4)_2SO_4 \cdot CdSO_4 \cdot 6H_2O$; $(NH_4)_2SO_4$	1.05975	378	−401

In the previous paper on the sodium sulfate cells[1a] the most important data were for cells between one and two months old. The same cells, nos. 749–758, have now been observed for a much longer time, and some others of the same kind have been made. A new group, Cells 761–764, was made by Dr. Roger G. Bates. They were like Cells 754–758, the electrolyte having been made by the saturation of 0.1 *M* acetic acid solution with cadmium sulfate and the double salt. The amalgam for all these cells was cadmium–bismuth. Three of the newer group of cells when newly prepared agreed within 0.01 mv. with Cells 749–758. The fourth was 0.02 to 0.04 mv. lower.

Cells 749–758 eight months after they were prepared agreed almost exactly with the values reported previously. At that time, Cells 750, 752 and 754 were withdrawn from the group for a test at room temperature. From Cells 761–764, Cell 764 was taken for test at room temperature and Cell 763 was accidentally broken. The remaining nine cells of the two groups were observed from time to time at constant temperature, and their record is given in Table IV. While these cells have shown no change in two years larger than the error of measurement, a group of unsaturated Weston cells could be expected to decrease in electromotive force by something of the order of magnitude of 0.1 mv.[5] during that time.

TABLE IV

ELECTROMOTIVE FORCES OF MODIFIED WESTON CELLS CONTAINING SODIUM SULFATE AT VARIOUS AGES

Cells	E_{25} − 101,800, volts × 10^5 3 mo.	8	13	17–23	24–29
749, 751, 753	41	41	41	41	40
755–758	39	38	38	38	38
761–762	37	37	..	37	36

Four of the sodium sulfate modified cells were measured occasionally for a period of more than eight months at room temperature. The cells were mounted in wooden boxes to ensure uniformity of temperature.[6] The temperature as measured inside one of the boxes varied from 20 to 28.7°, while the average electromotive force of the four varied from 1.01835 to 1.01845 when no correction for temperature was applied. A correction for temperature would reduce the variation considerably.

It may be concluded that the sodium sulfate cell is more nearly constant in electromotive force at constant temperature than the unsaturated Weston cell, for periods of over two years at least. Its variation under ordinary room-temperature conditions is not large enough to cause serious error for many purposes if it should be used as a standard.

Summary

Modified Weston cells were prepared in which the electrolytes were saturated with two sulfate salt phases, one phase being either hydrated cad-

mium sulfate or a double salt of cadmium sulfate. These cells were measured at different temperatures.

The temperature coefficient of the cell containing lithium sulfate was such that if made with cadmium–bismuth amalgam it would have a temperature coefficient less than that of the sodium sulfate cell previously reported.

A number of the lithium sulfate cells with ternary amalgams were not as constant or reproducible as the sodium sulfate cell.

Further observations on the constancy and reproducibility of the sodium sulfate cell are reported.

The System Li_2SO_4–$Al_2(SO_4)_3$–H_2O at 0°

BY HAROLD A. HORAN AND JOHN A. SKARULIS

Systematic studies of the ternary system Li_2SO_4–$Al_2(SO_4)_3$–H_2O have been carried out at 30°[1] and at 0°[2] and in both cases it was concluded that the only solid phases in equilibrium were $Li_2SO_4 \cdot H_2O$ and $Al_2(SO_4)_3 \cdot 18H_2O$. In the study at 0°, the solubility of pure lithium sulfate was found to be 25.43%, while for aluminum sulfate the value found was 27.02%. The former value differs considerably from that found by Friend,[3] namely, 26.51%, which was determined using carefully prepared and purified lithium sulfate and employing an analytical method which was direct and not subject to appreciable error. The aluminum sulfate value given above is considerably higher than the values found by Poggiale[4] and by Kremann and Hüttinger[5] and definitely lower than a recently found value[6] of 27.97%. The large differences in the values for both salts undoubtedly are due to differences in the purity of materials used, methods of obtaining equilibrium and the analytical methods employed.

Rather recently the existence and properties of a lithium alum have been reported.[7] The alum is supposedly formed at temperatures in the neighborhood of 0° although no definite temperature is mentioned.

In view of these claims as well as the disagreements in solubilities mentioned above, it was thought advisable to reinvestigate the ternary system at 0°, taking special care as to the materials used, methods of obtaining equilibrium and methods of analysis.

Purification of Materials

Lithium Sulfate.—Reagent grade (Merck) lithium carbonate was recrystallized from hot water according to the method of Kraus and Burgess.[8] After drying, this salt was used to neutralize 6 *N* sulfuric acid. This solution was heated to boiling and slowly evaporated. The lithium sulfate which crystallized out was separated from the solution, drained and washed with 95% alcohol and then dried at 130°. It was then heated in platinum to expel traces of sulfuric acid.

Aluminum Sulfate.—The problem of obtaining hydrated aluminum sulfate of known composition for use in making up complexes offered some difficulties. Hill and Kaplan[9] attempted to prepare the octadecahydrate by allowing the recrystallized salt to come to constant composition in desiccators over some partially dehydrated aluminum sulfate, which consisted of a mixture with the next lower hydrate, the supposed $16H_2O$. This procedure was not wholly successful in that the salt thus produced usually contained more than the required amount of water (as revealed by aluminum determinations on the material). This also has been the experience of Smith.[10] It is questionable whether occluded water is removed by this method of drying. It is believed that the slow crystallization of aluminum sulfate is favorable to the occlusion of considerable amounts of water.

The material used in this investigation was prepared in the following manner. Reagent grade (Merck) aluminum sulfate was dissolved in water at 60° to make a solution of sp. gr. 1.33. The filtered solution was cooled slowly to room temperature. The crystals were filtered off and sucked as dry as possible. After washing with 95% alcohol, the crystals were again sucked as dry as possible. In order to free the crystals of occluded water, they were effloresced in vacuum desiccators over sulfuric acid. The desiccators were evacuated repeatedly to remove the alcohol. The salt, in a finely divided condition, was placed in small amounts (5–10 g.) on petri dishes in desiccators over a saturated solution of sodium bromide dihydrate. Analysis of the salt for aluminum by the quinolate method[11]

[a] n is not definitely decided in this study. It may be between 15 and 18 H_2O.

revealed progressive hydration. After a month's time, during which the salt was stirred thoroughly each day, aluminum determinations revealed little if any further change in composition. At this time the aluminum value was 8.34%, considerably higher than that required at $Al_2(SO_4)_3 \cdot 18H_2O$, *i. e.*, 8.09%. In the belief that the vapor pressure within the desiccators was insufficient fully to hydrate the salt, it was transferred to desiccators over a saturated solution of sodium chloride.[12] Little change was observed in three weeks time. Aluminum determinations at this time were 8.30%. The salt was definitely homogeneous and there was no evidence of further change. This aluminum value corresponds closely to that required by $Al_2(SO_4)_3 \cdot 17H_2O$, namely, 8.32%. The salt was kept in the desiccators until needed for making up complexes. In making these the salt was weighed, by difference, from a glass-stoppered container into the solubility tubes. The percentage anhydrous aluminum sulfate in the complexes was calculated from the aluminum (quinolate) value obtained on a representative sample taken while the former were being made up.

Experimental

In several cases complexes containing accurately known amounts of anhydrous lithium sulfate, hydrated aluminum sulfate and water were prepared. In other cases the compositions of the original complexes were not known accurately. The mixtures, contained in 60-ml. glass-stoppered tubes, were rotated for two weeks in a well insulated bath maintained at 0 ± 0.05°. Samples were removed at the end of ten days and again at the end of two weeks and aluminum determinations on both showed that equilibrium had been reached. These samples were removed with a previously cooled pipet fitted with a filter. In the cases where the compositions of the original complexes were not known accurately, samples of the residues were collected on a filter kept near the temperature of the bath, and the excess mother liquid quickly removed. These wet residues were transferred as quickly as possible to weighing bottles.

(12) Kolthoff and Sandell, "Textbook of Quantitative Inorganic Analysis," The Macmillan Co., New York, N. Y., 1936, p. 123.

For analysis, aluminum was determined as the quinolate.[11] The combined filtrate and washings from this precipitation were evaporated to approximately 25 ml. At this point a mixture of concentrated hydrochloric acid and nitric acid (10 ml. to 5 ml.) was introduced along with sufficient sulfuric acid to convert the lithium to sulfate. The solution was then evaporated to fumes of sulfur trioxide. The residue was washed into a large platinum crucible. After the introduction of a drop or so of sulfuric acid, the solution was evaporated to incipient dryness in a radiator. The excess of sulfuric acid was expelled and the residue gently ignited. The lithium was then weighed as the sulfate. Several blank determinations on solutions containing no lithium revealed a constant blank of 1.5 mg. In the analyses this amount was deducted from the weight of the residues. The amounts of lithium sulfate weighed in most cases were greater than 0.15 g. The entire procedure was tested successfully many times on solutions containing known amounts of lithium sulfate and aluminum sulfate, the ratio of the two being varied considerably.

The data are given in Table I and the results are represented graphically in Fig. 1.

Discussion of Results

The solubility of pure aluminum sulfate at 0° has been found to be 27.50%.[13] This is considerably different from previously accepted values.[2,4,5,6] It is close to the values obtained for the same salt 25° by Hill and Kaplan[9] and Smith,[10] *viz.*, 27.39 and 27.89%, respectively. In the light of this it is questioned whether the solid phase in equilibrium at 25° is the same as that at 0°.

The solubility found for pure lithium sulfate at 0° agrees well with that of Friend[3] and is definitely higher than that of Sanders and Dobbins.[2]

(13) The solubility of unrecrystallized Merck reagent grade aluminum sulfate, which according to the label had as main impurities alkali sulfates 0.15%, free acid 0.12%, was determined in the same manner and found to be 27.70%.

No lithium alum has been found at 0°. Its formation at lower temperatures is still a possibility. In this study only two solid phases were found to exist. One is definitely lithium sulfate monohydrate. On the aluminum sulfate side, in addition to being too few in number, the extrapolations are too scattered due to slight variations in the composition of the aluminum sulfate used in making up the complexes as well as accidental errors in the analyses to be significant in the designation of the formula of the hydrate in equilibrium with the saturated solutions. Similar scattering in the extrapolations was found by Hill and Kaplan[9] when working with aluminum sulfate.

In previous ternary investigations involving aluminum sulfate as one of the phases, the octadecahydrate has been assumed to be the solid phases over a considerable range of temperatures although in the few cases where the tie lines were extrapolated, large deviations from the theoretical values were evident.

Additional work is being carried out in this Laboratory in an attempt to decide the hydration of aluminum sulfate at 0° as well as at other temperatures. The results of this work will be reported later.

The isothermally invariant point for this system has been found to be 16.83% aluminum sulfate and 14.45% lithium sulfate. This is considerably different than the previously reported value[2] at this temperature.

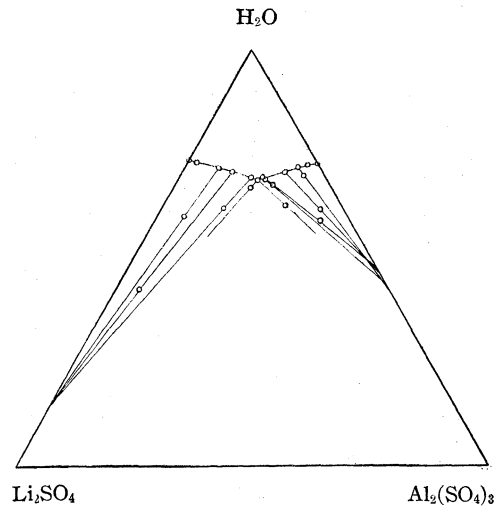

Fig. 1.—0° Isotherm: Li_2SO_4–$Al_2(SO_4)_3$–H_2O.

Summary

Solubility measurements are given for the system Li_2SO_4–$Al_2(SO_4)_3$–H_2O at 0°. There is no evidence of double salt formation or solid solution.

A new value for the solubility of aluminum sulfate at 0° is given.

The degree of hydration of aluminum sulfate in contact with a saturated solution at 0° has not been determined with certainty. The previous assumptions of the existence of the octadecahydrate at this temperature have been questioned.

Binary Liquid Systems. I. Vapor–Liquid Equilibria in the System Carbon Tetrachloride–Ethyl Acetate

BY PHILIP W. SCHUTZ

In a survey of the behavior and properties of homogeneous binary liquid systems it became of interest to investigate the system carbon tetrachloride–ethyl acetate. A careful search of the literature showed that the only vapor–liquid equilibria data available, covering the complete range of composition for this system, were those due to Tyrer.[1] These data have been quoted in the "International Critical Tables" and other similar compilations. Unfortunately, a careful scrutiny of these data shows that they are most probably in error. When the vapor and liquid compositions given are plotted against the boiling temperature (at 745 mm. in this case) as the concentration of carbon tetrachloride increases from zero mole per cent., both curves show the normal behavior for a system which exhibits a minimum boiling mixture. The behavior continues normal until the composition of the azeotropic mixture is reached (about 51 mole per cent.) at which point the vapor and liquid curves *cross* instead of becoming *tangent*. The vapor curve then continues to lie below the liquid curve through the rest of the concentration range. This behavior leads to the theoretically impossible situation of a system ex-

(1) Tyrer, *J. Chem. Soc.*, **101**, 81 (1912).

hibiting a minimum boiling point and at the same time giving at all concentrations, except that of the azeotropic mixture, a vapor which is richer in one component, carbon tetrachloride in this case, than the liquid in equilibrium with it. Because of these facts, it was deemed advisable to repeat the equilibrium measurements on this system.

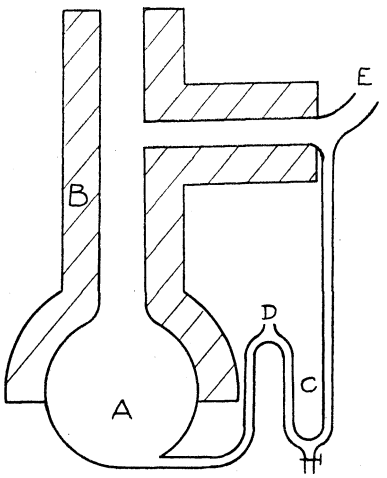

Fig. 1.—Cross section of apparatus: A, boiling flask; B, asbestos lagging; C, condensate receiver and return to boiling flask; D, pressure equalizing vent, kept loosely covered during operation; E, condenser attached here. Thermometer and internal electrical heater not shown.

Experimental

Carbon Tetrachloride.—Merck technical carbon tetrachloride was treated with a mixture of 50% potassium hydroxide solution and ethyl alcohol and subsequently with concentrated sulfuric acid as suggested by Fieser.[2] After removing the dissolved acid by washing with water, the material was dried for several hours over calcium chloride and finally for twenty-four hours over phosphorus pentoxide. The dried material was distilled through a twenty-inch (51-cm.) packed column under heavy reflux, and a fraction boiling at 73.50° under 687.0 mm. collected for use. The boiling range was not detectable on a thermometer graduated in 0.1°. The refractive index of this product ($n^{20}D$) was 1.46023.

Ethyl Acetate.—Merck technical ethyl acetate was washed with saturated sodium carbonate and then with saturated calcium chloride. After drying for twenty hours over calcium chloride, it was distilled in the column mentioned above. A fraction boiling between 73.9 and 74.2° at 685 mm. was then dried over phosphorus pentoxide for several weeks and refractionated. Material taken as product from this fractionation boiled at 74.10 ± 0.05° under 685.0 mm. and had a refractive index ($n^{20}D$) of 1.37239.

Apparatus and Method.—The apparatus used consisted of a 250-cc. round-bottomed distilling flask on which the usual side-arm was replaced by a piece of 12 mm. i. d. glass tubing. It was so arranged that the condensed vapor was returned continuously to the distilling flask. The detail of this arrangement is shown in Fig. 1. The entire vapor space, up to the point at which the condensate return line was attached, was enclosed in three-quarters of an inch (2 cm.) of asbestos paper in order to minimize fractionation in this section. That this was accomplished is indicated by the fact that the results obtained were not affected by a two-fold change in the rate of distillation. Had there been an appreciable amount of fractionation, this would not have been true. The condensate trap had a volume of about 2 cc. In order to avoid the possibility of error due to condensate from the beginning of a run being trapped in the short length of tubing (volume about 0.25 cc.), leading to the ungreased stopcock, a small volume of condensate was drawn off slowly about the middle of the run and discarded. In no case did this amount to more than 0.5 cc. In making a run the flask was charged with 100–125 cc. of mixture and heating begun with the internal electrical heater. After distillation had attained its maximum rate, it was continued for forty-five minutes, when the heating was stopped and the condensate sample withdrawn into a small tightly stoppered vial. The boiling liquid sample was removed by tilting the whole apparatus and filling the condensate trap. This was done three or four times, and the material drawn off was discarded in order to rinse the trap. The next filling was then withdrawn as a sample. Both samples were put into a thermostat at 20.00 ± 0.02° and analyzed by means of a Pulfrich refractometer whose temperature was controlled by a stream of water from the same thermostat. All of the concentrations are judged to be accurate to at least ±0.1 mole per cent. Temperatures were measured with a mercury-glass thermometer which was checked against a Bureau of Standards calibrated thermometer. The recorded temperatures are accurate to ±0.03°. No effort was made to control the pressure, all runs being made at the normal barometric pressure here. During the period of these runs, it did not vary by more than 1 mm. from 685 mm. (corrected to 0°).

Discussion of Results

TABLE I

VAPOR–LIQUID EQUILIBRIA AT 685 MM.

T, °C.	Mole % CCl_4 in vapor	Mole % CCl_4 in liquid	$n^{20}D$ of liquid
73.40	100	100	1.46023
72.57	87.1	89.4	1.45044
72.12	76.5	79.2	1.44122

74.01	0.8	0.5	1.37280
74.10	0.0	0.0	1.37239

(2) Fieser, "Experiments in Organic Chemistry," D. C. Heath and Company, 1935, p. 308.

The data are presented in Table I. Because of the difficulty of reproducing on a small scale a plot of temperature *vs.* composition when the liquid and vapor are so nearly alike, this plot has been omitted. On a large-scale plot all of the points fall on smooth curves with no deviations as large as those given above. It is evident from these data that this system behaves in the normal manner for systems exhibiting a minimum boiling mixture. The azeotropic mixture contains 58.2 mole per cent. carbon tetrachloride and boils at 71.56° under 685 mm. pressure.

In Table II are given the various data available on the azeotropic constants for this system at different pressures. The values attributed to Tyrer were obtained after a careful consideration of his data and do not agree with those given in the International Critical Tables.[3]

Inspection of Table II shows that the rate of change of composition of the azeotrope with pressure is decreasing as the pressure decreases. This behavior is just the reverse of that found in numerous other systems which have been investigated over a range of pressures.[4] Because of this apparent difference in behavior, this system is being investigated over a wide pressure range in order to verify this difference with a single set of data.

TABLE II

AZEOTROPIC DATA AT DIFFERENT PRESSURES

P, mm.	B. p., °C.	Mole % CCl_4	Observer
760	74.75	43	Young,[5] Lecat[6]
745	74.04	51.0 ± 0.5	Tyrer[1]
685.0	71.56	58.2	This paper
318.8	49.99	67.4	Zawidzki[7]

The refractive index–composition curve falls just slightly below the straight line joining the indices of the two pure components. The maximum deviation comes at 50 mole per cent., and the curve appears to be symmetrical about this point.

Summary

The system carbon tetrachloride–ethyl acetate has been investigated at 685 mm. and found to behave as expected for a system having a minimum boiling mixture, contrary to indications from other data.

The Peroxide Effect in the Addition of Reagents to Unsaturated Substances. XXII. The Addition of Hydrogen Bromide to Trimethylethylene, Styrene, Crotonic Acid, and Ethyl Crotonate

BY CHEVES WALLING,[1] M. S. KHARASCH AND F. R. MAYO

Recently we described an abnormal addition of hydrogen bromide to 2-bromo-2-butene under peroxidic conditions in dilute pentane solution, and commented upon the efficacy of this method of obtaining the abnormal addition of this reagent.[2] Further interesting results, with the aid of this technique, now have been obtained with several more olefins.

Addition of Hydrogen Bromide to Trimethylethylene.—In 1904 Ipatieff and Dechanov[3] observed that, while treatment of trimethylethylene with hydrogen iodide or aqueous hydrobromic acid yielded exclusively the tertiary halide, addition of hydrogen bromide in 60% acetic acid gave 10–25% of *s*-isoamyl bromide (2-methyl-3-bromobutane). A similar result was reported by Michael and Zeidler.[4] Recently, however, Smith[5] has indicated that *t*-amyl bromide is the sole product of the addition of hydrogen bromide to this olefin and that peroxides are without effect upon the course of the reaction, but unfortunately he does not describe the experimental conditions employed. The latter conclusion is contradicted by the results of this investigation, as shown in Table I. In the absence of a solvent and air and in the presence of an inhibitor, a

(5) Smith, *Chemistry and Industry*, **57**, 561 (1938).

product containing 95% of the normal addition product, *t*-amyl bromide (I), results. Addition in pentane solution containing lauroyl peroxide yields as much as 64% of the abnormal addition product, 2-methyl-3-bromobutane (II). When the peroxide is replaced by diphenylamine, the product is chiefly normal, indicating that reversal is not due to the solvent itself.

$$(CH_3)_2C{=}CHCH_3 \xrightarrow{HBr} (CH_3)_2CBrCH_2{-}CH_3 \quad (I)$$

$$(CH_3)_2C{=}CHCH_3 \xrightarrow[HBr]{Peroxides} (CH_3)_2CH{-}CHBr{-}CH \quad (II)$$

Experiments in the presence of peroxides in ethyl bromide[6] and nitrobenzene gave 60 and 100% of normal product, respectively. A similar if less pronounced difficulty in detecting abnormal addition in nitrobenzene solution has been observed in the addition of hydrogen bromide to isobutylene.[7]

[a] In moles per mole of ethylene derivative. [b] Vacuum technique employed.[2] [c] Reaction mixture illuminated with 500-watt incandescent lamp during addition.

A possible explanation of the failure of Smith to obtain evidence of abnormal addition to trimethylethylene lies in the ease with which the abnormal product undergoes isomerization. Thus, treatment of methylisopropylcarbinol or isopropylethylene with hydrogen bromide yields, respectively, 79[4] (p. 284) and 48%[8] of the tertiary halide. In order to avoid this complication in the work reported here, any prolonged contact of the addition products with hydrogen bromide was avoided, and all distillations were carried out at reduced pressure.

Addition of Hydrogen Bromide to Styrene.—Although it is generally considered that the product obtained by adding hydrogen bromide to styrene is α-phenylethyl bromide, it has been observed that thiophenol,[9,10] thioglycolic acid,[11] and bisulfite[12] all add abnormally to this olefin to yield β-phenylethyl derivatives. Also, a method has been described in the patent literature[13] for treating styrene with hydrogen bromide at 95° in ethylbenzene solution in the presence of benzoyl peroxide. Under these conditions, it is claimed that the product contains 92% β-phenylethyl bromide.

TABLE II

THE ADDITION OF HYDROGEN BROMIDE TO STYRENE

Expt.	Substance added	Moles[a]	Yield, %	Product α-Phenylethyl bromide, %
V	Diphenylamine[b]	0.02	65	100
VII	Diphenylamine[b]	0.02	70	100
II	....	...	70	95
VIII	....	...	85	100

	Pentane	10.00		
X	Lauroyl peroxide[c]	0.02	75	20
	Pentane	6.0		

[a,b] Have the same significance as in Table I. [c] Hydrogen bromide passed in during several hours.

Accordingly, it was of especial interest to investigate this problem. It has now been found that in absence of solvent styrene adds hydrogen bromide almost instantaneously to form α-phenylethyl bromide (III), and that even the presence of added peroxide does not lead to the formation of over 7% of the abnormal product (Table II).

(6) The result recorded in Table I was obtained with ethyl bromide purified by washing thoroughly with sulfuric acid, followed by fractionation. Two experiments with ordinary commercial ethyl bromide (which apparently contained alcohol or ether, as it darkened sulfuric acid) gave only the normal product, a result which seems reasonable in view of the ability of alcohol to inhibit reactions involving bromine atoms.

However, when the normal reaction is retarded by working in dilute pentane solution and peroxides are added, products may be isolated which contain as much as 80% of β-phenylethyl bromide (IV). There seems to be no reason to doubt that greater dilution and the slower addition of the halogen acid would result in an even greater percentage of this product.

$$C_6H_5CH{=}CH_2 \xrightarrow{HBr} C_6H_5CHBrCH_3 \quad (III)$$

$$C_6H_5CH{=}CH_2 \xrightarrow[HBr]{Peroxides} C_6H_5CH_2CH_2Br \quad (IV)$$

Addition of Hydrogen Bromide to Crotonic Acid and Ethyl Crotonate.—Preliminary investigation in this Laboratory has found only one product (the usual β-bromo derivative) in the addition of hydrogen bromide to acrylic, crotonic and bromocrotonic acids[14] in both the presence and absence of oxygen and peroxides. Furthermore, no reversal of addition has been obtained with bromomaleic,[15] bromofumaric,[15] and tetrolic acid,[16] although in the latter case there is evidence that the products obtained in the presence of peroxides are stereoisomeric with those obtained in the absence of these materials.

We can now report that even in the presence of a peroxide, illumination, and dilution with a solvent such as pentane, the only products of the addition of hydrogen bromide to crotonic acid and ethyl crotonate are the β-bromo derivatives.

Discussion

It is well established and is further shown in this paper that the normal addition of hydrogen bromide to olefins in which the double bond is not at the end of a hydrocarbon chain or is conjugated with a benzenoid nucleus proceeds with great rapidity. The present work shows that when these addition reactions are carried out in dilute pentane solution the normal reaction is retarded, and considerable abnormal addition of hydrogen bromide is observed. The previous paper in this series reached a similar conclusion in the case of 2-bromo-2-butene.

However, even though these conditions markedly retard the addition of hydrogen bromide to crotonic acid and its ethyl ester, no reversal of the direction of addition could be observed under even the most favorable conditions; neither do peroxides markedly accelerate the addition of hydrogen bromide to these substances in dilute pentane solution as they do in the case of other olefins.[17] This fact may indicate that the chain mechanism postulated for abnormal addition[18] is inoperative in the case of ethylenic bonds conjugated with a carboxyl or similar group. However, the alternative explanation cannot be excluded, that the mechanisms of both normal and abnormal addition lead, in the case of these compounds, to the formation of the same product. Indeed this explanation is to some extent supported by the reaction of tetrolic acids cited previously.

Experimental

Trimethylethylene and Hydrogen Bromide.—**Trimethylethylene** was prepared from Eastman *t*-amyl alcohol. Four hundred grams was placed in a distilling flask equipped with an efficient condenser and a "cold finger" in the neck of the flask to minimize the distillation of alcohol. Thirty cubic centimeters of concentrated sulfuric acid was added, and the flask heated on a steam-bath. Distillation of the product (together with a little alcohol and water) began almost at once, and the reaction was practically complete in two hours. The distillate was washed with sodium carbonate solution, dried over calcium chloride, and distilled through a 1.5-meter packed column. Two fractionations yielded 114 g. (36%) of trimethylethylene, b. p. 37.6–38.0° (744 mm.).

Addition of hydrogen bromide was carried out as indicated in Table I. Seven grams (0.1 mole) of trimethylethylene was used in all experiments. The pentane employed was a 30–35° fraction free from unsaturated material obtained from the Skelly Oil Company, Tulsa, Oklahoma. Hydrogen bromide was passed in (at room temperature except in vacuum experiments) and seemed to react as rapidly as it was added. After the removal of solvent the products were distilled at 100 mm. through a Podbielniak column. The yield recorded in the table is the amount of distillate collected at 47–52°. In the experiment in nitrobenzene the addition products were quickly distilled from the reaction mixture at reduced pressure and then fractionated.

Preliminary experiments on a redistilled sample of Kahlbaum *t*-amyl bromide, $n^{20}D$ 1.4420, indicated that it was hydrolyzed to the extent of 95% in fifteen minutes at 100° in 80% aqueous acetone, and that under the conditions of the experiment this amount presumably represented an equilibrium, as longer heating produced no fur-

(14) Kharasch and McNab, unpublished work.

(16) Grigorieff, Ph.D. Dissertation, University of Chicago, 1939.

(17) As an example, 0.1 mole of crotonic acid in 1.2 moles of pentane kept saturated with hydrogen bromide at about 20° reacted only to the extent of 40% in six hours, despite strong illumination and the presence of 0.0025 mole of lauroyl peroxide. In absence of solvent, crotonic acid, if warmed to start the reaction, will absorb the theoretical amount of hydrogen bromide in a few minutes. Propylene, by way of contrast, is subject to abnormal addition, and, while it undergoes the normal reaction in absence of solvent at a rate roughly comparable with crotonic acid, it reacts completely with hydrogen bromide in a few minutes in dilute pentane solution in the presence of only traces of peroxides (Mayo and Savoyias, kinetic investigation now in progress in this Laboratory).

(18) Kharasch, Engelmann and Mayo, *J. Org. Chem.*, **2**, 288 (1937).

ther hydrolysis. Similarly, when the products of experiments I, II, and V were combined and carefully fractionated into four portions, the third and fourth fractions (which presumably contained the greatest proportion of 2-methyl-3-bromobutane) were hydrolyzed by this procedure to the extent of 17.9 and 5.7%, respectively. As it seemed likely that even the highest boiling fraction contained some *t*-amyl bromide, it was assumed for purposes of calculation that 2-methyl-3-bromobutane was not measurably hydrolyzed under these conditions. Accordingly, 0.3 g. of the addition products was weighed out into Pyrex tubes of about 10 cc. capacity, and 5 cc. of 80% aqueous acetone added. The tubes were then sealed and placed in boiling water for fifteen minutes. After cooling and opening, the liberated acid was titrated with standard base.

As an additional check, the indices of refraction of all products were determined, and the percentage of normal and abnormal product calculated. Although results by both methods are included in Table I, we consider those obtained by hydrolysis to be the more accurate. The index of refraction of 2-methyl-3-bromobutane was found to be $n^{20}D$ 1.4453 by extrapolation.

Styrene and Hydrogen Bromide.—Styrene used in this investigation was obtained from the Bakelite Corporation, Bloomfield, New Jersey. As it contained hydroquinone to prevent polymerization, it was distilled *in vacuo* shortly before use. Experiments were performed as indicated in Table II. In all experiments, 10.4 g. of styrene was used; 9 g. of hydrogen bromide was passed in (at room temperature in all except vacuum experiments) and in no case did addition appear to require more than a few minutes. The products were worked up by distillation through a Podbielniak column at a pressure of 9 mm. of mercury. The yield recorded in Table II is based upon the weight of the fraction collected. In cases of addition in pentane, the solvent was removed before distillation by evaporation at atmospheric pressure.

For analysis, 0.2 g. of the product was weighed out into a Pyrex tube of about 10 cc. capacity, and 5 cc. of 80% aqueous acetone added. After sealing and heating for two hours in boiling water, the liberated acid was titrated with standard base. Experiments with samples of known composition indicated that, under these conditions, hydrolysis proceeded to the extent of 95% with α-phenylethyl bromide as compared with less than 2% with β-phenylethyl bromide.

As a further check, the addition product of experiment I (Table II) were treated with alcoholic potassium hydrosulfide,[19] and the potassium salts of the resulting mercaptans allowed to react with 2,4-dinitrochlorobenzene according to the procedure of Bost, Turner, and Norton.[20] From the reaction mixture, β-phenylethyl 2,4-dinitrophenyl sulfide was obtained in yellow pearly plates (m. p. after crystallization from alcohol 87–88°). Similar treatment of the product from experiment II yielded α-phenylethyl 2,4-dinitrophenyl sulfide (orange crystals, m. p. after crystallization from alcohol 108–109°).

Addition to Crotonic Acid and Ethyl Crotonate.—Two sets of conditions were chosen as favoring the abnormal reaction. (a) One-tenth mole of crotonic acid or ethyl crotonate, 0.0025 mole of lauroyl peroxide, and 1.0 to 1.2 moles of pentane were placed in a Pyrex bomb tube and cooled to −80°. One-eighth mole of hydrogen bromide was passed in, the tube sealed, and allowed to warm to room temperature. After standing overnight, the tubes were opened, the solvent evaporated off, and the products distilled under reduced pressure. (b) Hydrogen bromide (0.14–0.16 mole) was condensed in a Pyrex tube cooled to −80°. By carefully raising the tube from the cooling-bath, a very slow stream of hydrogen bromide could be obtained. This was bubbled very slowly through another Pyrex vessel containing 0.1 mole of the unsaturated material and 0.0025 mole of lauroyl peroxide in 1.2 moles of pentane. During the addition the vessel was illuminated by a 500-watt incandescent lamp at a distance of 15 cm. and cooled to about 20° by a stream of water. After three to six hours the product was worked up as described under (a). Under these conditions, crotonic acid added hydrogen bromide to the extent of 40% in six hours, while in the case of ethyl crotonate the reaction was virtually complete in three hours.

Fifteen-hundredths gram of the crotonic acid addition product was weighed into a flask, and 2.00 ml. of 1.942 *N* potassium hydroxide solution added. After standing for one hour at room temperature the mixture was diluted with water and titrated with standard acid. Under these conditions hydrogen bromide was liberated from known α- and β-bromobutyric acids to the extent of 3 and 98%, respectively. By this method all samples obtained by the addition of hydrogen bromide to crotonic acid contained over 95% of the β-bromo acid. A different method of analysis was used for the ester addition products on account of the partial hydrolysis of the esters. Three-tenths gram of the addition product was weighed out and 2.0 cc. of 1.8 *N* alcoholic potassium hydroxide added. After one minute the mixture was diluted with water and acidified with nitric acid. After addition of an excess of standard silver nitrate solution, the mixture was back titrated with ammonium thiocyanate solution. Under these conditions the α- and β-bromo esters liberated 1.3 and 99.3%, respectively, of the theoretical bromide ion. By this method, all samples obtained by addition of hydrogen bromide to ethyl crotonate contained 97% or more of ethyl β-bromobutyrate.

Summary

1. Trimethylethylene adds hydrogen bromide in the absence of oxygen and peroxides to give *t*-amyl bromide. Under conditions of peroxide catalysis the product contains as much as 64% of the abnormal product, 2-methyl-3-bromobutane.

2. Styrene adds hydrogen bromide in the absence of oxygen and peroxides to give α-phenylethyl bromide. Under conditions of peroxide catalysis and in the presence of solvent the product contains as much as 80% β-phenylethyl bromide.

3. In presence or absence of peroxides, crotonic acid and ethyl crotonate yield only β-bromobutyric acid and ethyl β-bromobutyrate, respectively.

The Composition of the Seeds of Sapindus Drummondii[1,2]

BY O. C. DERMER AND L. T. CREWS

The tree *Sapindus drummondii* H. and A., commonly known as Western Soapberry or Wild Chinaberry, is widely distributed in the southwestern part of the United States. Its clusters of yellow translucent fruits or "berries" ripen in the fall and remain on the tree during the winter. Each drupe-like fruit contains a round, black, hard-shelled seed which averages 0.4 g. in weight as compared to 1 g. for the whole fruit. The reputedly toxic pericarp is rich in a saponin which has been employed as a soap substitute, while the polished seeds have been used as primitive ornaments.

The only published chemical data on this fruit[3] show that whole fruits from Oklahoma contain 8%, and their seed kernels 43%, of a non-drying oil.

Experimental

The fruits used in this work were gathered in December and January from trees in the Cimarron River valley near Coyle, Oklahoma. After several months the slightly sticky outer pulp was removed by hand and preserved for an intended investigation of the saponin present. Nearly all the seeds were ground whole, for kernels could be separated from shells only by tedious hand sorting.

Since it is well known that different methods of extraction of an oil remove different kinds and proportions of other substances, some of the meal (1–2 kg.) was percolated with ether, some with petroleum ether, and some was warmed and pressed hydraulically to remove the oil. The oils thus obtained, after the removal of any solvent and filtration, gave substantially the same constants. The seed kernels were found to contain 42.7% of ether-soluble materials,[4] whereas the whole seeds contained 23–24%.

The oil was greenish-brown to yellow-brown in color and had the characteristic but not unpleasant odor and taste of the seed kernels. It did not become rancid readily. The usual physical properties and chemical constants were determined by standard methods[5] unless otherwise specified. The results, in Table I, show the limits of variation of characteristics of the oils extracted by different methods.

TABLE I

CHEMICAL AND PHYSICAL CHARACTERISTICS OF THE OIL

Specific gravity, 25°/25°	0.903–0.917
Refractive index, $n^{25}D$	1.4704–1.4722
Acid value	0.3–0.9
Saponification value	213–219
Iodine no. (Hanus)	81.5–83.5
Thiocyanogen no.	63.9–67.2
Unsaponifiable matter, %	1.2
Reichert–Meissl no.	0.0
Polenske no.	0.0
Acetyl value	14.5
Unsaturated acids, %	74–77,[a] 82[b]
Saturated acids, %	17–20,[a] 13[b]

[a] Calculated from iodine number and thiocyanogen number. [b] Observed by separation and weighing, and corrected for impurities.

The air-dry exhausted meal was analyzed with the following results: protein 21.3%; crude fiber 18.0;[6] ash 3.70%; moisture 8.40%. It contained starch (iodine test) but no reducing sugars.

Fatty Acids.—Saturated acids were best separated from unsaturated acids by low-temperature crystallization of the free acids from acetone.[7] The unsaturated fraction gave a negative hexabromide test for linolenic acid. The presence of oleic acid was confirmed by its conversion to elaidic acid, but bromination of the unsaturated fraction in petroleum ether at −10° gave no precipitate of linoleic acid tetrabromide, probably owing to the solvent action of the large amount of oleic acid dibromide present. From the iodine number and the thiocyanogen number of the original oil it can be estimated that there were present about 60–65% of oleic acid and 15% of linoleic acid.

Fractional crystallization of portions of the mixed saturated acids (iodine numbers 5.0–28) led to the isolation of palmitic acid, m. p. 61.5–62.5°, and stearic acid, m. p. 68.5–69.5°, identified by melting points and mixture melting points. No others could be found, although average molecular weights obtained by either direct titration or saponification of the saturated fraction from different runs indicated the presence of an acid higher than stearic acid in the series.

When a portion of the saturated acids derived from the oil extracted with petroleum ether was distilled at 1 mm., a few crystals of alkali-insoluble material were isolated from the highest-boiling fraction and about an equal amount from the residue in the still. After recrystallization from alcohol, these waxy crystals melted at 63–64° and about 130° (indefinite), respectively. They were proved to be alkanes by their insolubility in even hot concentrated sulfuric acid. The known occurrence of

saturated hydrocarbons in seed coats and the ability of seeds of *Sapindus drummondii* to take a high polish suggest that these alkanes came from the unremoved seed coats rather than from the kernels. Such complications in fat chemistry have been remarked before.[8]

The seed oils of the following relatives of *Sapindus drummondii* have been studied: *Schlichera trijuga*,[5] *Naphelium lappaceum*,[5] *Nephelium mutabile*,[5] *Sapindus trifoliatus*,[5] *Ungnadia speciosa*,[5] *Sapindus mukurossi*,[9] and *Sapindus marginatus*.[10] The iodine number of the seed oil of *Sapindus drummondii* is higher than that of any of the others except *S. marginatus;* this is in agreement with the observation that, among related plants, growth in a cooler climate connotes greater unsaturation of the oil. The principal difference between the oil of *S. drummondii* and that of any of its relatives, however, appears to be its lack of *n*-eicosanic (arachidic?) acid.

Studies on Lignin and Related Compounds. XLVI. The Action of Ozone on Isolated Lignins[1]

BY RODGER M. DORLAND, W. LINCOLN HAWKINS AND HAROLD HIBBERT

The action of ozone on lignin preparations has been studied by a number of workers but the identifiable fragments split off by this treatment have been too small to be of any real value in the elucidation of the structure of lignin. Thus Phillips and Goss[2] isolated anisic acid in small yield by the action of ozone on methylated alkali lignin obtained from corn cobs. Bell, Hawkins, Wright and Hibbert[3] have noted the formation of acetone in the ozonization of birch formic acid lignin. In general it may be said that, when a lignin is subjected to the action of ozone, there results, after treating the resulting product with water, a water-insoluble lignin and an aqueous solution. This latter solution contains mainly a water-soluble, lignin-like material and oxalic acid. The more prolonged the treatment with ozone, the smaller is the resulting water-insoluble and the greater the water-soluble fraction. This action is accompanied by a decrease in the methoxyl content of the ozonized lignin.

In connection with studies being carried out in these Laboratories on the mechanism of the solubilization of lignins by means of aqueous bisulfite solution, it was observed that formic[4a] and acetic acid[4b] lignins are insoluble in aqueous bisulfites but that after a carefully controlled ozonization in formic acid solution they become completely soluble.

The increase in the solubility in sulfite "cooking liquor" and the decrease in the methoxyl content of the lignin with increasing degree of ozonization were studied by carrying out a series of ozonizations on identical samples of birch formic acid lignin using increasing amounts of ozone. The resulting ozonized samples were then analyzed for methoxyl and the quantitative solubility in sulfite "cooking liquor" was determined (Table I).

TABLE I

THE ACTION OF OZONE ON BIRCH FORMIC ACID LIGNIN

G. of O_3 reacting per 2 g. of lignin	Water-insoluble fraction % yield	Water-insoluble fraction % OCH_3	Original minus final OCH_3	% solubility in sulfite liquor of ozonized lignin
0.167	95	15.9	2.7	36
.290	88	13.9	4.7	61
.368	68	11.7	6.9	88
.404	72	12.5	6.1	78
.396	73	12.6	6.0	73
.405	65	11.5	7.1	82
.463	60	11.8	6.8	80
.544	53	10.9	7.7	93

These results expressed graphically (Fig. 1) show that both the loss in methoxyl and the increased solubility in sulfite liquor vary directly with the amount of ozone employed. From these data it was possible to calculate the approximate amount

(1) From a thesis submitted to the Faculty of Graduate Studies and Research, McGill University, by Rodger M. Dorland in partial fulfilment of the requirements for the Degree of Doctor of Philosophy, May, 1939. Paper XLV, THIS JOURNAL, **61**, 2204 (1939).

of ozone necessary to give a completely bisulfite soluble lignin. Accordingly, birch formic acid[4a] and birch acetic acid[4b] lignins were treated with ozone to the required degree and the sulfonic acids prepared by the customary "sulfite cook."

The lignin sulfonic acid prepared by cooking yellow birch wood meal with acid sodium sulfite yields, on alkaline cleavage, 2.7% vanillin and 2.8% syringaldehyde based on the weight of lignin.[5] Acetosyringone, but not acetovanillone, also has been isolated from the same waste sulfite liquor although the yield was much smaller, being of the order of 0.8%.[6] Accompanying this was a small quantity of pyrogallol 1,3-dimethyl ether amounting to 0.2%.[7] In view of these results it was of interest to determine the action of alkali on the sulfonated, ozonized birch lignins. The sulfonated, ozonized, birch formic acid lignin yields, on alkaline cleavage, only guaiacyl derivatives, namely, vanillin and acetovanillone, and in approximately equal amounts (1%). The same results have been observed in the case of the corresponding ozonized acetic acid lignin, the yields being of the order of 2.7% also based on the weight of lignin. Presumably this is the first time that acetovanillone has been obtained from a hard wood waste sulfite liquor since Leger and Hibbert[6] found only acetosyringone.

There are two possible explanations as to why no syringyl analogs were found in the present investigation. In the first place the formic and acetic acid lignins which were used had been subjected previously to a solvent fractionation and in both cases the vanillin and acetovanillone were obtained from fractions of the crude lignin having the lowest methoxyl content. It is also to be noted that the formic and acetic acid lignins, previous to sulfonation, were subjected to the action of ozone and there is thus the possibility that, if syringyl groups did exist, they might have been split off as part of the water-soluble fraction. This latter possibility is at present under investigation.

Experimental

The Loss in Methoxyl and the Increase in Solubility in Sulfite Liquor of Birch Formic Acid Lignin with Respect to the Degree of Ozonization.—A 2.0-g. sample of formic acid lignin[4a] (18.6% OCH_3) was dissolved in 50 cc. of formic acid (95%) and at 0° ozone was passed into this solution for varying lengths of time. The amount of ozone delivered by the machine was determined at intervals by passing the gas through a neutral potassium iodide solution for a definite period of time and titrating with standardized thiosulfate the iodine liberated on acidification. The gas passing out of the lignin solution was also treated in a similar manner in order to determine the amount of ozone not absorbed by the solution. When the ozonization was complete the formic acid was removed by distillation under reduced pressure, 300 cc. of water added to the residue and the solution refluxed for thirty minutes. On cooling, the water-insoluble lignin was filtered off, washed with water, dried at 60° (20 mm.) and then weighed.

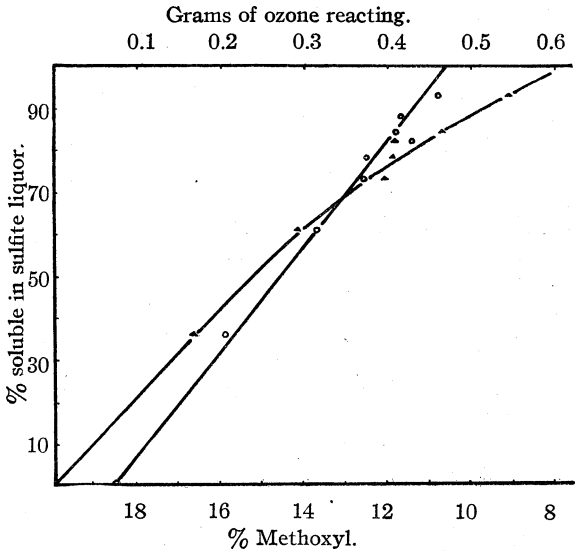

Fig. 1.—The action of ozone on birch formic acid lignin: ▲, increase in solubility of birch formic acid lignin in sulfite liquor with increasing ozonization; O, increase in solubility of birch formic acid lignin in sulfite liquor with loss in methoxyl.

The ozonized lignin was analyzed for methoxyl and the solubility in sulfite liquor determined in the following manner. Exactly 0.100 g. of the lignin was sealed in a small glass bomb with 6 cc. of sodium bisulfite "cooking liquor" (6.0% total and 1.15% combined sulfur dioxide) and the bomb placed in a toluene vapor bath (110°) for twelve hours. On completion of the cook the bomb was cooled to 0°, opened, and the contents washed into a small, tared, centrifuge cup. The insoluble lignin was centrifuged off, washed with water, and dried overnight at 60° (20 mm.). The per cent. soluble in the sulfite liquor was then calculated by difference. These results have been summarized in Table I.

The Isolation of Vanillin and Acetovanillone from Ozonized Birch Formic Acid Lignin.—Ten grams of birch formic acid lignin (15.5% OCH_3)[4a] was dissolved in 400 cc. of formic acid (95%) and at 0° this solution was treated with 2.56 g. of ozone over a period of eight hours, during which time 2.34 g. of ozone was absorbed by the solution. The solvent was then removed under reduced pressure and the residue refluxed for one hour with one liter of water. Upon cooling, the water-insoluble fraction was filtered off, washed with water and dried. This product

(5) Hawkins, Wright and Hibbert, THIS JOURNAL, **59**, 2447 (1937).
(6) Leger and Hibbert, *ibid.*, **60**, 565 (1938).
(7) Leger and Hibbert, *Can. J. Research*, **16B**, 151 (1938).

was ground to a fine powder and again refluxed with one liter of water for forty-five minutes. The lignin was then filtered, washed and dried: yield 6.9 g.; 8.3% OCH_3; 95% soluble in bisulfite "cooking liquor" after heating at 110° for twelve hours.

Sodium bisulfite liquor (200 cc. containing 6.0% total and 1.15% combined SO_2) and 6.8 g. of the ozonized lignin were heated in a stainless steel bomb to 110° over a period of one and one-half hours. The bath was held at 110° for four hours and then raised to 130° for an additional eight hours. Upon cooling, the contents of the bomb were filtered and the volume of the filtrate made up to 500 cc. with water. The insoluble material after drying weighed 0.8 g.

A portion of the filtrate (100 cc.) was freed from inorganic material by dialysis against running distilled water for seven days. On evaporating the solution to dryness a relatively pure sample of the sulfonated lignin product was obtained; analysis, 3.3% OCH_3, 6.6% sulfur.

The alkaline cleavage of the sulfonated product was carried out by adding 70 g. of sodium hydroxide to 290 cc. of the crude liquor and heating this at 135° for twelve hours under an atmosphere of oxygen-free nitrogen. The solution was cooled, just acidified with 50% sulfuric acid and extracted continuously with benzene for forty-eight hours. The benzene extract was shaken out ten times with 15-cc. portions of 5% sodium bisulfite; this latter solution was acidified and the sulfur dioxide removed under reduced pressure. The solution was then filtered and the volume made up to 200 cc. The total aldehydes present were determined by adding 10 cc. of an aqueous solution of 2,4-dinitrophenylhydrazine hydrochloride to a 20-cc. aliquot of the solution. After standing for six hours the precipitate was filtered on to a tared sintered glass funnel, washed and dried at 105°; weight, 0.1005 g. or 1.3%, calculated as vanillin based on the lignin in the liquor.

The remaining 180 cc. of solution was extracted continuously with ether. The residue after the removal of the ether was sublimed at 61° (2 mm.) yielding 0.040 g. of a crystalline product. Recrystallization from petroleum ether (80–90°) gave white, feathery crystals, m. p. 81–82°. A mixed m. p. with an authentic sample of vanillin showed no depression. The yield of the vanillin based on the lignin was 1.1%.

The benzene extract of the acidified alkaline cleavage product, left after the extraction with bisulfite, was evaporated to dryness under reduced pressure. The residue was sublimed at 150° (2 mm.). Resublimation of this product at 90° (2 mm.) yielded 0.055 g. of crystalline material. Recrystallization from petroleum ether (80–90°) gave white crystals, m. p. 111–112°. A mixed melting point with an authentic sample of acetovanillone showed no depression. The yield of acetovanillone based on the lignin was 1.2%.

The Isolation of Vanillin and Acetovanillone from Ozonized Birch Acetic Acid Lignin.—Twelve grams of birch acetic acid lignin (18.8% OCH_3)[4b] was dissolved in 300 cc. of formic acid and at 0° the solution then treated with 2.16 g. of ozone over a period of five and one-half hours, during which time 1.84 g. of ozone was absorbed by the solution. The solvent was removed under reduced pressure and the residue refluxed with one liter of water for forty-five minutes. Upon cooling, the water-insoluble fraction was filtered off, washed with water and dried. This product was ground to a fine powder and again refluxed with one liter of water for forty-five minutes. The ozonized lignin was then filtered, washed and dried; yield 5.4 g.; 13.3% OCH_3; 95% soluble in sulfite liquor at 110° for twelve hours.

Five grams of the ozonized lignin and 200 cc. of the above sodium bisulfite "cooking liquor" were heated in a stainless steel bomb to 110° over a period of one and one-half hours and the bath then maintained at that temperature for twelve hours. The bomb was cooled, the contents filtered and the volume of the filtrate made up to 250 cc. with water. The insoluble material after drying weighed 0.02 g.

A portion of the filtrate (50 cc.) was purified by dialysis against running distilled water for seven days. The sulfonated product was obtained by evaporating the solution to dryness; 6.4% OCH_3; 6.15% sulfur.

The alkaline cleavage of this sulfonated product was carried out by adding 33.6 g. of sodium hydroxide to 140 cc. of the crude, filtered liquor and heating the mixture at 135° for twelve hours under an atmosphere of oxygen-free nitrogen. The cooled reaction product was just acidified with 50% sulfuric acid and extracted continuously with benzene for forty-eight hours. This benzene extract was then shaken out with bisulfite solution, as previously described, the bisulfite solution acidified, the sulfur dioxide removed, solution filtered and made up to a volume of 250 cc. The total aldehydes present were determined as the 2,4-dinitrophenylhydrazones on a 20-cc. aliquot of this solution; yield 0.0208 g. or 4% calculated as vanillin based on the lignin in the liquor.

The subsequent ether extract of the remaining acidified bisulfite solution was worked up in the same manner as described previously. The residue on sublimation and recrystallization yielded 0.075 g. of white crystals, m. p. 82–83°. The mixed m. p. with an authentic sample of vanillin showed no depression. The yield of vanillin based on the lignin was 2.7%.

The benzene extract of the acidified alkaline cleavage solution, after extraction with the bisulfite, was worked up in a similar manner and yielded 0.075 g. of crystalline material, m. p. 112–113°. The mixed m. p. with an authentic sample of acetovanillone showed no depression. The yield of acetovanillone based on the lignin was 2.7%.

Acknowledgments.—The authors wish to thank the Canadian National Research Council for the grant of a Bursary to one of them (R. M. D.).

Summary

Isolated lignins, obtained by extraction with formic and acetic acids, and which are normally insoluble in aqueous bisulfite solution, have been shown to yield soluble sulfonic acids after a prior treatment of the lignin with ozone.

Sulfonic acids obtained in this manner from birch formic and acetic acid lignins have been shown to yield vanillin and acetovanillone on alkaline cleavage. Presumably this is the first

time that acetovanillone has been obtained from a lignin sulfonic acid prepared from a hard wood.

An increase in solubility in aqueous bisulfite solution and a decrease in methoxyl content of formic acid lignin with increasing ozonization have been shown to take place.

Enzymic Preparation of *d*-Galacturonic Acid[2]

BY H. H. MOTTERN AND H. L. COLE

d-Galacturonic acid has been available only in limited quantities. Three methods have been used for its preparation: synthesis from galactose,[3] acid hydrolysis of pectic substances,[4] and enzymic hydrolysis of pectic substances.[4b,5] Although materials such as pectin with a galacturonic acid content of approximately 70%, are readily available, because of the lack of definite knowledge concerning the nature of the starting materials, complicated procedures, and low yields, *d*-galacturonic acid has remained a rare chemical.

Because of recent interest in the possible biological significance[6] of *d*-galacturonic acid, it is desirable to have a method whereby *d*-galacturonic acid can be prepared free from contamination with heavy metals and in quantity at nominal cost. A method which is the subject of this report has now been developed which for the first time makes it possible to prepare readily large or small quantities of the pure acid. A commercial pectinase preparation converts commercially available polygalacturonic acid[7] into galacturonic acid in good yields. This method is not subject to interference by side reactions such as decarboxylation to the acid and the formation of furan derivatives, which interfere with crystallization.[8] Disadvantages of Ehrlich's methods[4b,5] were that they employed the use of a little known "pectolsaure," and an enzyme from a special mold described as "*Penicillium Ehrlicii*."

Experimental Part

Preparation of Polygalacturonic Acid.—One hundred grams of powdered apple or citrus pectin[9] was suspended in 250 cc. of 50% ethanol in a mixing bowl of 2 liters capacity which was provided with an egg-beater type stirrer. Since adequate stirring could not be accomplished with a common motor-driven laboratory stirrer it was necessary to use the egg-beater type. When the pectin had been thoroughly wetted by the ethanol and was uniformly dispersed, 10 g. of calcium chloride[10] dissolved in 250 cc. of water was added. The mixture was stirred until the pectin had taken up the aqueous solution and then 250 cc. of 3 *N* sodium hydroxide solution measured ready for use was added promptly. Stirring was continued until the mixture formed a smooth pasty mass. It was permitted to stand for fifteen minutes, after which any clear supernatant liquor was decanted. The mixture was neutralized with hydrochloric acid and sufficient excess added to give a concentration of about 1.5%, and boiled for ten minutes while being vigorously stirred. The polygalacturonic acid was filtered with suction and washed with water containing 10 cc. of concentrated hydrochloric acid per liter. The hydrochloric acid was removed by washing with 50% ethanol. The product was dried by washing several times with ethanol and then with ethyl ether. Yields of 75–80 g. were obtained. Polygalacturonic acid in the moist state may be used directly for the preparation of galacturonic acid.

Enzymic Hydrolysis of Polygalacturonic Acid to Galacturonic Acid.—Seventy-five grams of dry polygalacturonic acid (or the equivalent of the moist preparation obtained as described above) was suspended in 750 cc. of water, which had been warmed to 40°, in a mixing bowl which was provided with an egg-beater type stirrer and while stirring 75 cc. of 3 *N* sodium hydroxide solution was added. The mixture formed a smooth viscous mass. After dispersion the *p*H was adjusted to between 3.7 and 4.0 by the addition of measured amounts of 3 *N* sodium hydroxide or 3 *N* sulfuric acid solutions. To the mixture was then added 3.75 g. of "Pectinol 100D."[11] The mixture was

(9) Ordinary commercial fast-setting powdered pectin was satisfactory without purification.

(10) The calcium salt was used to control the degree of swelling of the pectic acid particles so that a grainy precipitate was obtained which could be satisfactorily filtered and washed.

(11) This preparation is "Pectinase 46 AP" standardized by the addition of diatomaceous earth. It was obtained from Röhm and Haas Co., Bristol, Penna.

next placed in a bottle and sufficient toluene was added to prevent mold growth. The bottle, stoppered with cork, was kept at a temperature of 35–40° for ten days.

At the end of the hydrolysis period[12] (usually less than ten days) the calculated amount of dilute sulfuric acid was added to set free the galacturonic acid from its sodium salt. The hydrolyzate was clarified by filtration using infusorial earth as a filter aid and was concentrated to a thick sirup under vacuum. The sirup was purified by the addition of five volumes of 95% ethanol and three volumes of ethyl ether, which precipitated sodium sulfate, ethanol insoluble fractions of the enzyme preparation, and any unhydrolyzed polygalacturonic acid. After standing for twelve hours the ethanol–ether solution of galacturonic acid was decanted from the residue and evaporated to a thick sirup under vacuum. Crystallization,[13] which required approximately twenty-four hours for completion, was hastened by adding small amounts of 95% ethanol and seeding with a few crystals of galacturonic acid. The acid was triturated with cold 90% ethanol, filtered, and washed with ethanol. It was purified further by dissolving in 50% ethanol, treating with charcoal, filtering, and recrystallizing after the addition of sufficient ethanol to make the ethanol concentration 75%. The yield from 75 g. of polygalacturonic acid was 20 g. of the purified product. The m. p. was 113–115° (uncorr.).[14]

(12) Indicated by treating a test portion with fresh enzyme for twenty-four hours and showing no increased reduction of Fehling's solution over previous samples.

(13) Direct crystallization of α-*d*-galacturonic acid from the purified hydrolyzate depends upon the use of starting materials which will not yield substances such as sugars interfering with crystallization.

Acknowledgment.—The writers are indebted to the California Fruit Growers Exchange, Research Department, Ontario, California for citrus pectin, to General Foods Corporation, New York City, for apple pectin, and to Röhm and Haas Co., Bristol, Penna., for pectinase preparations. Acknowledgment is also made to Dr. I. A. Manville, University of Oregon School of Medicine, for helpful suggestions and criticisms.

Summary

A method has been developed for the quantity preparation of *d*-galacturonic acid by the action of a pectinase enzyme on polygalacturonic acid.

Iodo Derivatives of Phenyl Ether. II. Studies in Orientation

BY R. Q. BREWSTER AND H. S. CHOGUILL

Substances containing two or more benzene rings offer numerous problems in orientation. A given substituent may enter one of the nuclei at a certain position while another substituent may take an entirely different location. The experiments here reported were undertaken in order to obtain more information on these orientation effects in the phenyl ether series. Such knowledge was desirable in the continuation of a study of the iodinated derivatives of phenyl ether[1] which has been conducted in this Laboratory. Much work upon this subject has been done by several other investigators[2] using particularly those phenyl ether derivatives containing substituents of halogens, acetamino, nitro and to some extent methoxy groups. The present work is concerned primarily with the derivatives of 2-methoxy- and 4-methoxyphenyl ether. Since the methoxy radical is one of the more strongly directing groups, it would be expected that 4-methoxyphenyl ether would undergo substitution at position 3 and so it does upon nitration, 3-nitro-4-methoxyphenyl ether being the sole product.[2c] We find that halogenation however introduces the halogen atom at position 4′. If that position should be occupied, the halogen attaches itself to the carbon atom at 3 unless the substituent at 4′ is a group such as hydroxy or amino which exceeds the methoxy group in orienting power. Likewise the methoxy group is the controlling factor in the nitration of 2-methoxyphenyl ether as the product obtained is 5-nitro-2-methoxyphenyl ether, yet halogens substitute at position 4′ and take position 5 only if 4′ is occupied. In the halogenation of 4-nitrophenyl ether or 2-nitrophenyl ether, McCombie, Macmillan and Scarborough[2b] showed that a halogen enters at 4′, *i. e.*, para to the ether oxygen and always in the non-nitrated nucleus. The strong preference of a halogen for a position para to the ether oxygen is shown in the iodination of 4-methoxy-2′-nitrophenyl ether where the iodine takes position 4′ (Compound XIII) in spite of the presence of a nitro group in the same ring. However, in the iodination of 2-methoxy-4-nitro-

phenyl ether the iodine atom is directed to position 5 even though position 4 is unoccupied, *i. e.*, the methoxy group exceeds the 4-nitrophenoxy radical in power of orientation.

Experimental

The laboratory procedures used in these experiments are of standard types and are referred to in the table by letters as follows: A, preparation of phenyl ethers by the Ullmann reaction[3]; B, the modified Ullmann reaction using nitrofluorobenzene[4] in place of nitrochlorobenzene; C, iodination by heating on the steam-bath with iodine monochloride in acetic acid solution for one or two hours; D, bromination in acetic acid solution; E, nitration with nitric acid (d. 1.42) in acetic acid solution; F, reduction of nitro compounds free from halogen substituents with hydrogen and the Adams platinum catalyst; G, reduction of nitro compounds containing halogen with iron powder in

(3) *Org. Syntheses*, **14**, 66 (1934).

(4) Rarick, Brewster and Dains, THIS JOURNAL, **55**, 1289 (1933).

(5) Potassium phenate and 4-bromoanisole according to the procedure of Oesterlin[2d] gave a 70% yield of 4-methoxyphenyl ether while bromobenzene and hydroquinone monomethyl ether gave only a 20% yield. Iodination of 4-methoxyphenyl ether gave I which was also obtained from 4-methoxy-4′-aminophenyl ether by the Sandmeyer reaction. The samples made by both methods were identical by a mixed melting point test.

(6) 4-Methoxyphenyl ether (100 g.) was heated with anhydrous aluminum chloride (65 g.) for one hour in an oil-bath at 130°. Fifteen grams of additional aluminum chloride was then added and the temperature raised to 140–150° for another hour after which the mass was cooled and poured into water; yield of 4-hydroxyphenyl ether, 75 g., m. p. 84°. It forms the benzoyl derivative readily upon shaking with benzoyl chloride and alkali.

(7) Thirty grams of III was hydrolyzed to IV by boiling with 100 cc. of ethyl alcohol and 50 cc. of 20% sodium hydroxide solution for one hour; yield 20 g.

(8) Nitration of 4-methoxyphenol ether in acetic acid solution[2c] gave a 70% yield of 4-methoxy-3-nitrophenyl ether which gave practically a quantitative yield of V upon reduction.

(9) For diazotization 22.5 g. (0.1 mole) of V was dissolved in 300 cc. of water and 50 cc. of concentrated sulfuric acid and cooled in ice. Crystals of the sulfate separated but redissolved readily upon diazotization with 7.5 g. of sodium nitrite which was added all at once. After ten minutes 5 g. of urea was added, the solution filtered and poured into 25 g. of potassium iodide in 100 cc. of water.

(10) Distils at 182–187°, ten mm.

(11) Compound VIII was obtained both by the bromination of I and the iodination of VII. The two samples were purified from ethyl alcohol and from ligroin and showed no lowering of the melting point on mixing.

(12) Produced by iodination of either I or VI and through the diazo reaction from XI.

(13) No. X was also obtained by iodination of 4-methoxy-3-nitrophenyl ether. Both specimens were shown to be identical by a mixed melting point.

(14) The Sandmeyer reaction with XI gave IX.

(15) Obtained in 70% yield from *o*-nitrochlorobenzene and hydroquinone monomethyl ether.

(16) Deamination of XIV gave I showing that the iodination of XII occurred at 4′.

(17) Compound XV, produced by the nitration of XII, most probably has the composition here assigned as it was not identical with XVI made from 2,4-dinitrochlorobenzene and hydroquinone monomethyl ether.

(18) For conversion to a solid derivative, XVII was nitrated in acetic acid solution giving XVIII. The location of the iodine atom at position 4′ in XVII was established by its synthesis from 2-methoxy-4′-aminophenyl ether through the Sandmeyer reaction. This sample also gave XVIII upon nitration. The fact that the nitro group in XVIII was at position 5 was shown by the preparation of an identical sample by iodination of XX.

(19) In the iodination of 2-methoxy-4′-nitrophenyl ether the iodine enters at 5, producing compound XIX, identical by mixed melting point with a sample prepared from 4-nitrofluorobenzene and the potassium salt of 2-methoxy-5-iodophenol (4-iodoguaiacol).

(20) Lea and Robinson[2c] obtained compound XX by the nitration of 2-methoxyphenyl ether but considered that the nitro group most probably took position 6. We proved that its location was at 5 by synthesis of 2-methoxy-5-nitrophenyl ether, identical with XX by a mixed melting point, from potassium phenate and 2-methoxy-5-nitrobromobenzene.

acetic acid solution; and H, replacement of an amino group by halogen through the Sandmeyer reaction. Other explanatory comments are given in the footnotes.

Summary

The study of the orienting effect of the methoxy group in phenyl ether derivatives has been extended. In determining this orientation a group of new compounds has been prepared and the structure of each proved.

Derivatives of Piperazine. XVIII. Synthesis of Substituted Piperazines and the Hydrolysis of Amines

BY J. P. BAIN[1] AND C. B. POLLARD

It has been shown that N-phenylpiperazine[2] may be prepared readily by heating a mixture of aniline and diethanolamine hydrochlorides. We have found that this method cannot be extended conveniently to the preparation of C-substituted piperazines from arylamines and diisopropanolamine. We have shown that piperazines may be prepared from amino alcohols[3] using the catalytic alkylation methods of Paden and Adkins[4] and Hill and Adkins.[5] This paper reports an extension of the synthesis of piperazines by this method and the formation of alcohols by hydrolysis of amines under catalytic alkylation conditions. This interesting side reaction does not appear to have been reported by other investigators.

Experimental

N-Cyclohexylamines were prepared by passing ethylene oxide into a methanol solution of cyclohexylamine. After removal of the solvent at atmospheric pressure the amino alcohols were distilled at 10 mm. pressure. N-Cyclohexylethanolamine distilled at 118° and N-cyclohexyldiethanolamine at 175°. The neutral equivalents of these compounds were determined using methyl red as the indicator: N-cyclohexylethanolamine, neut. equiv. calcd. 143.2, found 143.0; $n^{25}D$ 1.4842; N-cyclohexyldiethanolamine, neut. equiv. calcd. 187.3, found 187.2; $n^{25}D$ 1.4927.

N-Phenyldiisopropanolamine was prepared by heating one mole of aniline with two moles of propylene oxide in 300 cc. of dioxane to 170° in a bomb for several hours. The product was a viscous straw-colored liquid boiling at 184–185° at 10 mm.; N calcd. 6.69, found 6.60.

N-*p*-Tolyldiisopropanolamine was prepared similarly. After removal of solvent the product solidified and was recrystallized several times from hexane and from diisopropyl ether as slightly pink needles, m. p. 112°; N calcd. 6.27, found 6.20.

1,4-Dicyclohexylpiperazine was prepared by two methods. (a) Six hundred ml. of dioxane containing 1 mole each of cyclohexylamine and N-cyclohexyldiethanolamine was heated to 250–270° and shaken for three to four hours in hydrogen at a pressure of 34 atmospheres with 25 g. of copper–chromium oxide catalyst. After filtration from the catalyst and removal of the dioxane, the reaction mixture was distilled at 10 mm. pressure. The first fraction of 20 g., boiling at 60–61°, was identified as cyclohexanol by conversion to the phenylurethan, m. p. 82.5°. The second fraction, 19 g., boiling at 109–110°, was not identified. The third fraction, distilling between 170° at 10 mm. and 200° at 5 mm. partly solidified on cooling. Recrystallized first from pentane and then from aqueous methanol it yielded the piperazine in 20% yield, m. p. 118°. For analysis it was converted to the sparingly soluble dihydrobromide: Br calcd. 38.77, found (gravimetric) 38.76, neut. equiv. calcd. 206, found (by titration with phenolphthalein in the presence of benzene to remove the free amine as formed). (b) Cyclohexylethanolamine treated under the same conditions gave the piperazine in the same yield as well as the two low boiling fractions.

1-Cyclohexyl-2,6-dimethyl-4-phenylpiperazine, b. p. 205–210° at 2 mm., was prepared in 20% yield from cyclohexylamine and N-phenyldiisopropanolamine. The dihydrobromide was used for analysis: N calcd. 6.45, found 6.41; Br calcd. 36.81, found 36.83.

1-Cyclohexyl-2,6-dimethyl-4-*p*-tolylpiperazine, prepared from cyclohexylamine and N-*p*-tolyldiisopropanolamine, boiling at 175–230° at 5 mm., 15% yield, was converted to the hydrobromide and recrystallized from water; for the monohydrobromide, Br calcd. 21.72, found 21.67.

Cyclohexanol from Cyclohexylamine.—Sixty grams of cyclohexylamine, 300 ml. of dioxane, 20 ml. of water and 20 g. of copper–chromium oxide catalyst were placed in a bomb under 500 lb./sq. in. (34 atm.) hydrogen pressure and heated at 260–270° for four hours with shaking. After removal of low boiling material the product was fractionated at 10 mm. The fraction boiling at 55–65° was acidified and the neutral material extracted with ether. The neutral material distilled at 60–61° at 10 mm. and was identified as cyclohexanol by conversion to the phenylurethan, m. p. 82.5°. The yield of the pure alcohol was 20%.

(1) This paper is abstracted from a portion of a dissertation submitted by J. P. Bain to the Graduate Council of the University of Florida in partial fulfilment of the requirements for the degree of Doctor of Philosophy, May, 1939.

(2) Pollard and MacDowell, THIS JOURNAL, **56**, 2199 (1934).

(3) Bain and Pollard, *ibid.*, **61**, 532 (1939).

(4) Paden and Adkins, *ibid.*, **58**, 2487 (1936).

(5) Hill and Adkins, *ibid.*, **60**, 1033 (1938).

Diethylcyclohexylamine was prepared from cyclohexylamine and diethyl sulfate. Primary and secondary amines were removed with benzenesulfonyl chloride. The product boiled at 68.5–69 at 10 mm.; neut. equiv. calcd. 155.3, found 156.1.

Cyclohexanol was prepared from diethylcyclohexylamine in 33% yield under the conditions used for the hydrolysis of cyclohexylamine. Seventy-eight grams of diethylcyclohexylamine was treated with 300 ml. of 50% aqueous dioxane and 23 g. of copper–chromium oxide catalyst at 270–280° without hydrogen pressure. The product boiling at 50–68° at 10 mm. was acidified and extracted with ether. Only about 1 g. of neutral material was obtained. The amine hydrochlorides were treated with alkali and the free amines fractionated at 10 mm. The fraction boiling at 53.5–56° weighed 12 g. and gave a neutral equivalent of 133.0 (calculated for mono- and diethylcyclohexylamines, 127.2 and 155.3, respectively). This product on treatment with sodium nitrite and hydrochloric acid yielded 5 g. of a pale yellow oil, b. p. 127–128° at 12.5 mm. The literature[6] gives 130° at 12 mm. as the boiling point of N-nitrosoethylcyclohexylamine.

Summary

1. A number of new piperazine derivatives have been prepared from amino alcohols by catalytic alkylation.

2. The formation of alcohols from amines under catalytic alkylation conditions has been reported. This side reaction may account in part for the poor yields obtained in certain alkylations.

3. The generality and applicability of this reaction is being studied.

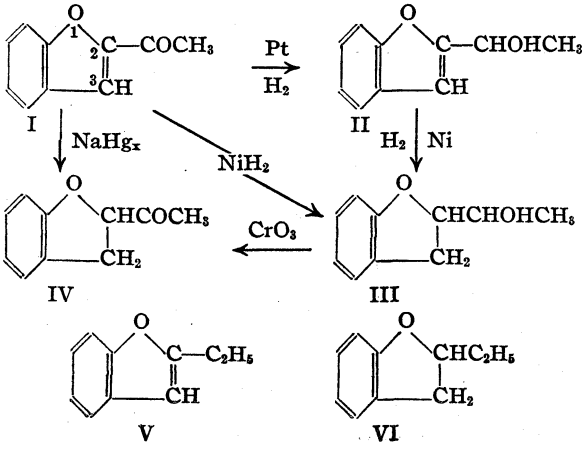
Derivatives of Coumaran. VI. Reduction of 2-Acetobenzofuran and its Derivatives

BY R. L. SHRINER AND JOHN ANDERSON

In an investigation concerned with the preparation of 2-substituted coumarans, the catalytic hydrogenation of 2-acetobenzofuran and some of its derivatives was studied.

It has been found possible to obtain the two alcohol reduction products of 2-acetobenzofuran (I) by catalytic hydrogenation provided the appropriate catalyst is employed. Hydrogenation with a platinum catalyst results in the formation of 2-(1-hydroxyethyl)-benzofuran (II) while a Raney nickel catalyst leads to the formation of 2-(1-hydroxyethyl)-coumaran (III). The coumaran (III) also can be obtained from the benzofuran (II) by hydrogenation in the presence of Raney nickel.



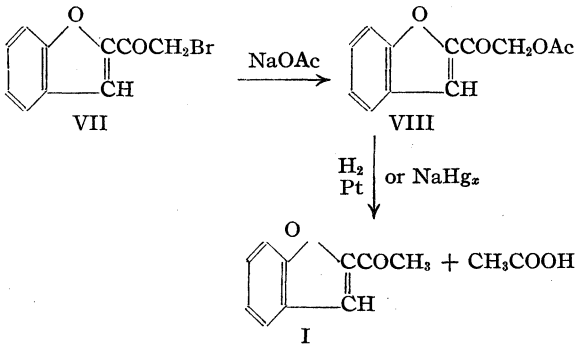
Hydrogenation in the presence of colloidal platinum resulted in a mixture of II, III, 2-ethylbenzofuran (V) and 2-ethylcoumaran (VI). No 2-acetocoumaran (IV) was found among the products of catalytic reduction. A sample of this ketone was made by oxidation of the alcohol (III) and by a sodium amalgam reduction of 2-acetobenzofuran. It was characterized by its semicarbazone.

The catalytic reduction of 2-acetobenzofuran thus follows a course different from that of the closely related benzalacetone, which is smoothly reduced to benzylacetone[1] first and then undergoes further reduction to 4-phenyl-2-butanol. The results constitute further evidence that catalytic hydrogenation of α,β-unsaturated ketones occurs by 1,2-addition[1] and not by 1,4-addition[2] as is the case in reduction by chemical means.[3] In this particular case the double bond in the 2,3-position probably is stabilized to some extent by resonance in the benzofuran nucleus.

ω-Acetoxy-2-acetobenzofuran (VIII) was prepared by bromination of 2-acetobenzofuran, followed by treatment of the resulting ω-bromo-2-acetobenzofuran (VII) with sodium acetate.

An unusual reaction took place when ω-acetoxy-2-acetobenzofuran (VIII) was subjected to

(1) Kern, Shriner and Adams, THIS JOURNAL, 47, 1147 (1925).
(2) Straus and Grindel, *Ann.*, 439, 276 (1924).
(3) Conant and Cutter, *J. Phys. Chem.*, 28, 1105 (1924).



catalytic hydrogenation. It was found that the major portion of the reacting material underwent cleavage to acetic acid and 2-acetobenzofuran (I). In the reductions when only one mole of hydrogen was absorbed, 2-acetobenzofuran was obtained as the cleavage product while mixtures of reduction products of 2-acetobenzofuran were obtained when more than one mole of hydrogen was absorbed. Sodium amalgam reduction of ω-acetoxy-2-acetobenzofuran in acetic acid solution resulted in a similar cleavage producing a mixture of the reduction products of 2-acetobenzofuran.

It seemed possible that this cleavage reaction might be general for phenacyl esters but catalytic reduction of phenacyl acetate in the presence of platinum oxide gave a good yield of 1-phenyl-2-acetoxyethanol and only a very small amount of methylphenylcarbinol and acetic acid.

Experimental

2-Acetobenzofuran.—This substance was prepared from salicylaldehyde and chloroacetone according to the method of Stoermer, Chydenius and Schinn.[4] A 60% yield of colorless crystals melting at 74–75° was obtained.

ω-Bromo-2-acetobenzofuran.—The method for the preparation of this compound was indicated by Calov and Stoermer[5] but these authors gave neither detailed directions for the preparation nor analysis of the product. A solution of 25.0 g. of bromine in 200 cc. of carbon disulfide was added dropwise, with stirring, into a solution of 25.0 g. of 2-acetobenzofuran in 200 cc. of the same solvent. The bromine was added during a period of two hours and at the end of this time the carbon disulfide was removed by evaporation to leave a yellow solid residue. The pure product, which exists in the form of white needles with a melting point of 90–91°, was obtained in a yield of 34 g. by recrystallizing the residue twice from ethanol. The yield was 91% of the theoretical.

Anal. Calcd. for $C_{10}H_7BrO_2$: C, 50.24; H, 2.95; Br, 33.42. Found: C, 50.52; H, 3.16; Br, 33.25.

ω-Acetoxy-2-acetobenzofuran.—A solution of 50 g. of sodium acetate trihydrate, 25.0 g. of ω-bromo-2-acetobenzofuran and 5 cc. of 6 *N* hydrochloric acid in 500 cc. of 50% ethanol was refluxed for one and a half hours. The mixture was poured into 500 cc. of ice water and the crude product was removed by filtration. The product was purified by recrystallization from ethyl acetate to give 17 g. (74%) of yellow needles which had a melting point of 86–87°.

Anal. Calcd. for $C_{12}H_{10}O_4$: C, 66.05; H, 4.62. Found: C, 66.29; H, 4.72.

2-(1-Hydroxyethyl)-benzofuran.—A mixture of 16.0 g. of acetobenzofuran in 100 cc. of absolute ethanol and 0.1 g. of platinum oxide was shaken in an atmosphere of hydrogen at a pressure of 2 to 3 atmospheres for six hours. At the end of this time one mole of hydrogen had been absorbed and the absorption had ceased. The catalyst was removed by filtration and the ethanol was removed by distillation from an oil-bath at 150°. The residue solidified to give the product, which had a melting point of 41°, in a quantitative yield. Recrystallization of the product by dissolving it in a small amount of ether at room temperature and cooling in a dry ice–acetone bath did not raise the melting point. The product boiled at 147° under a pressure of 19 mm. but purification by distillation did not raise the melting point.

Anal. Calcd. for $C_{10}H_{10}O_2$: C, 74.05; H, 6.22. Found: C, 74.25; H, 6.33.

The phenylurethan of the product was prepared by heating equimolecular quantities of the alcohol and phenyl isocyanate on a steam-bath for five hours. The mixture was taken up in carbon tetrachloride and filtered. Evaporation of the carbon tetrachloride at room temperature caused precipitation of the phenylurethan in crystalline form. It was recrystallized from a mixture of one part of benzene and two parts of low-boiling petroleum ether to give white needles with a melting point of 102–103°.

Anal. Calcd. for $C_{17}H_{15}NO_3$: N, 4.98. Found: N, 5.11.

Previous investigators[6] described 2-(1-hydroxyethyl)-benzofuran and its phenylurethan but the alcohol was reported to have a melting point of 37° and the phenylurethan to have a melting point of 126°.

2-(1-Hydroxyethyl)-coumaran from 2-(1-Hydroxyethyl)-benzofuran.—To a solution of 8 g. of 2-(1-hydroxyethyl)-benzofuran in 100 cc. of absolute ethanol there was added 2 g. of Raney nickel. The mixture was shaken in an atmosphere of hydrogen at a pressure of two to three atmospheres. One mole of hydrogen was absorbed in fourteen hours and the absorption ceased. The ethanol was removed by distillation and the residue subjected to vacuum distillation. The entire residue distilled at 145° under a pressure of 20 mm. to yield 6.5 g. (81%) of the product as a colorless, viscous liquid with the following constants: d^{25}_{25} 1.1138; $n^{25}D$ 1.5470; M_D found 46.7, M_D calcd. 45.9.

Anal. Calcd. for $C_{10}H_{12}O_2$: C, 73.14; H, 7.37. Found: C, 72.94; H, 7.38.

This compound was reported by former investigators[6] to have a density of 1.506 at 18°.

The phenylurethan of the above compound was prepared by heating equimolecular quantities of the compound

(4) Stoermer, Chydenius and Schinn, *Ber.*, **57**, 75 (1924).
(5) Calov and Stoermer, *Ann.*, **312**, 322 (1900).
(6) Stoermer and Shaffer, *Ber.*, **36**, 2869, 2871 (1903).

and phenyl isocyanate on a steam-bath for eight hours. The reaction mixture was taken up in glacial acetic acid and poured into ice water to cause separation of the crude phenylurethan. It was recrystallized from a mixture of one part of benzene and two parts of low-boiling petroleum ether to give white needles which melted at 115–116°.

Anal. Calcd. for $C_{17}H_{17}NO_3$: N, 4.95. Found: N, 5.16.

The phenylurethan of 2-(1-hydroxyethyl)-coumaran was formerly reported[6] to have a melting point of 73° but it seems probable that this was a mixture of the phenylurethans of 2-(1-hydroxyethyl)-coumaran and 2-(1-hydroxyethyl)-benzofuran.

2-(1-Hydroxyethyl)-coumaran from 2-Acetobenzofuran.—To a solution of 25 g. of acetobenzofuran in 120 cc. of absolute ethanol there was added 8 g. of Raney nickel and the mixture was shaken in an atmosphere of hydrogen at a pressure of two to three atmospheres. Two moles of hydrogen was absorbed in thirty-six hours and the absorption ceased. The solution was filtered, the ethanol removed by distillation, and the residue fractionally distilled to yield 22.5 g. of 2-(1-hydroxyethyl)-coumaran which was identical in all its properties with that prepared by hydrogenation of 2-(1-hydroxyethyl)-benzofuran. The yield by this method of preparation was 90% of the theoretical.

Hydrogenation of 2-Acetobenzofuran in the Presence of Colloidal Platinum.—To a solution of 24 g. of 2-acetobenzofuran in 100 cc. of absolute ethanol there was added 1.0 g. of Norite, 0.1 g. of chloroplatinic acid and 0.05 g. of platinum oxide. The mixture was shaken in an atmosphere of hydrogen at a pressure of two to three atmospheres and one mole of hydrogen was absorbed in nine minutes. The catalyst was removed by filtration and the ethanol by distillation. The only pure compound which could be isolated from the residue was unchanged acetobenzofuran.

A second reduction was carried out in which two moles of hydrogen were absorbed. The product was isolated as above and consisted of two definite fractions. The lower-boiling fraction weighed 5.5 g., distilled at 99–100° under a pressure of 19 mm. and had the following constants: d^{20}_{20} 1.0196; $n^{20}D$ 1.5475.

Anal. Calcd. for $C_{10}H_{10}O$: C, 82.16; H, 6.89. Calcd. for $C_{10}H_{20}O$: C, 81.04; H, 8.16. Found: C, 81.92; H, 7.56.

This product was evidently a mixture of 2-ethylbenzofuran and 2-ethylcoumaran. The higher-boiling fraction weighed 7.5 g. and distilled at 144–145° under a pressure of 19 mm. It was a mixture of 2-(1-hydroxyethyl)-coumaran and 2-(1-hydroxyethyl)-benzofuran.

Chromic Anhydride Oxidation of 2-(1-Hydroxyethyl)-coumaran.—To a solution of 14.5 g. of 2-(1-hydroxyethyl)-coumaran in 40 cc. of glacial acetic acid there was added, with stirring, 58.0 g. of a 10% solution of chromic anhydride in glacial acetic acid. The oxidizing solution was added in portions over a period of forty-four hours and the mixture was stirred for twelve hours longer at room temperature and seven hours at 80°. The reaction mixture was poured into 700 cc. of water and the resulting solution was treated with sodium bicarbonate until all of the acetic acid was neutralized. The neutral solution was extracted with 400 cc. of ether in four portions, the ether extract was dried over calcium chloride and the ether removed by evaporation. The methyl ketone portion of the concentrate was then isolated by shaking in saturated sodium bisulfite solution and removing the bisulfite addition compound by filtration. The bisulfite addition product weighed 7 g., which is 29% of the theoretical yield. The bisulfite addition compound was decomposed by shaking it in 2% sulfuric acid, the free ketone was extracted with ether and the ether solution dried over calcium chloride. After the calcium chloride was removed by filtration and the ether by evaporation, the crude ketone was treated with semicarbazide hydrochloride and sodium acetate in ethanol solution in the usual manner and the semicarbazone which formed was recrystallized five times from 50% ethanol to give white needles with a melting point of 168–169°.

Anal. Calcd. for $C_{11}H_{13}N_3O_2$: N, 19.17. Found: N, 19.20.

Since 2-acetocoumaran semicarbazone has been reported[4] to have a melting point of 192°, it was thought advisable to determine the melting point of a mixture of the product described above and 2-acetobenzofuran semicarbazone which would be the impurity most likely to be present in the compound previously described because the investigators had obtained their 2-acetocoumaran from sodium amalgam reduction of 2-acetobenzofuran. It was found that the addition of small quantities of 2-acetobenzofuran semicarbazone (m. p. 217°) to the semicarbazone obtained above raised the melting point to the neighborhood of 190°.

A sodium amalgam reduction of 2-acetobenzofuran, using a much larger excess of sodium amalgam than that given in the directions of Stoermer, Chydenius and Schinn,[4] resulted in the formation of a ketone the semicarbazone of which melted at 168–169° and which proved to be identical with the semicarbazone obtained above.

Hydrogenation of ω-Acetoxy-2-acetobenzofuran. (a) **With Platinum Oxide.**—A solution of 7.5 g. of ω-acetoxy-2-acetobenzofuran in 60 cc. of absolute ethanol and 1.5 g. of platinum oxide was shaken with hydrogen at 3 atmospheres pressure. One mole equivalent of hydrogen was absorbed in ten minutes and the reaction was stopped at this point. The catalyst was removed by filtration, the solvent distilled and the residue fractionated.

The forerun was treated on a watch glass with piperazine hexahydrate and the piperazonium salt which formed was recrystallized from *n*-butanol. It melted at 208–209° and comparison with an authentic sample of piperazinium diacetate[7] showed that they were identical and proved the presence of acetic acid in the reduction mixture. The main fraction boiled at 147–148° at 20 mm. and solidified on standing. Recrystallization from alcohol yielded 4.2 g. of colorless crystals melting at 74–75° and which were identical with 2-acetobenzofuran.

A second reduction was carried out using only 0.2 g. of catalyst. At the end of forty-eight hours 1.8 mole equivalents had been absorbed.

Fractionation of the products yielded 6.0 g. of a liquid which boiled at 146–148° at 18 mm. and 2.4 g. which boiled at 180–200° at 18 mm. The lower boiling fraction was redistilled and a middle fraction taken for analysis.

(7) Pollard, Adelson and Bain, THIS JOURNAL, 56, 1759 (1934).

Anal. Calcd. for $C_{10}H_8O_2$: C, 74.99; H, 5.03. Calcd. for $C_{10}H_{10}O_2$: C, 74.05; H, 6.22. Calcd. for $C_{10}H_{12}O_2$: C, 73.14; H, 7.37. Found: C, 74.97; H, 6.64.

The analyses indicate that this material is probably a mixture of acetobenzofuran and its reduction products. Had the acetoxy group not been cleaved, the carbon and hydrogen analyses would both have yielded much lower values.

A third reduction was carried out in which a solution of 10.0 g. of acetoxyacetobenzofuran in 150 cc. of cyclohexane was shaken with hydrogen at 2 to 3 atmospheres pressure in the presence of 5.0 g. of Raney nickel. No hydrogen was absorbed in three hours and 0.1 g. of platinum oxide was added to the reaction mixture. One mole of hydrogen was then absorbed in twenty-four hours and absorption ceased at this point. The catalyst was removed by filtration and the solvent by distillation to leave a residue which solidified. Recrystallization of the residue yielded 4.3 g. of 2-acetobenzofuran.

(b) **With Raney Nickel in Ethanol.**—Hydrogenation with Raney nickel in ethanol at 2 to 3 atmospheres pressure took place slowly. Acetic acid was identified as one product but the remainder consisted of a mixture which could not be separated readily.

Sodium Amalgam Reduction of ω-Acetoxy-2-acetobenzofuran.—To a solution of 10.0 g. of ω-acetoxy-2-acetobenzofuran in 300 cc. of 60% acetic acid there was added in small portions, over a period of twenty-four hours, 600 g. of 3% sodium amalgam. The solution which had been stirred and kept at room temperature throughout the time of addition was then diluted with an equal volume of water, neutralized with the calculated quantity of 5% sodium hydroxide solution and extracted with ether. The ether extract was dried over calcium chloride and the ether was removed by distillation to leave a liquid residue. Fractional distillation of the residue gave a product which weighed 6.2 g. and boiled at 115–130° at 6 mm. Refractionation of this product gave 4.5 g. of material boiling at 115–120° and 1.2 g. boiling at 120–130°. The lower boiling material was again fractionated and the middle portion taken for analysis.

Anal. Calcd. for $C_{10}H_8O_2$: C, 74.99; H, 5.03. Calcd. for $C_{10}H_{10}O_2$: C, 74.05; H, 6.22. Found: C, 74.16; H, 6.09.

All portions of the product were treated with semicarbazide hydrochloride and sodium acetate in ethanol solution to yield a semicarbazone which melted at 200–201°. This semicarbazone gave the following analytical data.

Anal. Calcd. for $C_{13}H_{15}N_3O_4$: N, 15.16; C, 56.30; H, 5.42. Calcd. for $C_{11}H_{11}N_3O_2$: N, 19.35; C, 60.81; H, 5.11. Calcd. for $C_{11}H_{13}N_3O_2$: N, 19.17; C, 60.26; H, 5.98. Found: N, 19.38; C, 60.52; H, 5.66.

This semicarbazone is evidently a mixture of the semicarbazones of 2-acetobenzofuran and 2-acetocoumaran. The analyses show that under these conditions the acetoxy group is cleaved in a manner similar to the cleavage in the catalytic hydrogenations and that the ketone portion of the product is a mixture of 2-acetobenzofuran and 2-acetocoumaran.

Hydrogenation of Phenacyl Acetate.—A solution of 25.0 g. of phenacyl acetate in 200 cc. of absolute ethanol was shaken with hydrogen at two to three atmospheres pressure in the presence of 0.2 g. of platinum oxide. One mole of hydrogen was absorbed in three and one-half hours and the reduction was stopped at this point. The catalyst was removed by filtration and the ethanol by distillation. The residue was distilled and 1 cc. of distillate collected. This was treated with piperazine hydrate and the salt which resulted recrystallized from *n*-butanol. It melted at 208–209°, corresponding to piperazinium diacetate. The remainder was fractionally distilled to yield 1.8 g. of material boiling at 90–140° under a pressure of 25 mm. and 19.5 g. of material boiling at 163–168° under a pressure of 25 mm. The main fraction was redistilled and it boiled almost entirely at 136–137° under a pressure of 6 mm. and a middle fraction showed the following constants: d^{20}_{20} 1.1438; $n^{20}D$ 1.5260; M_D calcd. for 1-phenyl-2-acetoxyethanol, 48.0; M_D found, 48.4.

Anal. Calcd. for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71. Found: C, 66.80; H, 6.65.

The lower boiling fraction was redistilled and the fraction which boiled at 190–205° was treated with α-naphthyl isocyanate at room temperature for ten hours to give a reaction mixture which was extracted with 250 cc. of petroleum ether. The petroleum ether extract was evaporated at room temperature to give a crude α-naphthyl urethan which was recrystallized from petroleum ether to give white needles with a melting point of 94–96°. Since this substance was not obtained in sufficient quantities to allow further purification by recrystallization, it was subjected to analysis.

Anal. Calcd. for $C_{19}H_{17}NO_2$: N, 4.81. Found: N, 4.96.

Evidently this lower boiling fraction contained a small amount of phenylmethylcarbinol which formed the above urethan.

Summary

Catalytic reduction of 2-acetobenzofuran with platinum and hydrogen produced 2-(1-hydroxyethyl)-benzofuran. With hydrogen and nickel 2-(1-hydroxyethyl)-coumaran was formed. 2-Acetocoumaran was obtained by a sodium amalgam reduction of 2-acetobenzofuran and by oxidation of 2-(1-hydroxyethyl)-coumaran.

ω-Acetoxy-2-acetobenzofuran was cleaved by reducing agents to 2-acetobenzofuran and acetic acid.

Vinyl Chloride Polysulfone[1]

BY C. S. MARVEL AND L. H. DUNLAP

Vinyl chloride is unique among the olefins which have been found to combine with sulfur dioxide to give polysulfones since it yields a polymer having two olefin units to one sulfur dioxide unit.[2] In the work previously reported no evidence for the exact structure of the polymer was obtained. Hence a further study of this problem has been made.

When vinyl chloride polysulfone is hydrolyzed with 20% sodium hydroxide and volatile products are removed rapidly from the reaction flask in a current of steam, an aldehyde is produced.[2] This aldehyde has now been identified definitely as acetaldehyde. During the hydrolysis not only is the aldehyde formed but at the same time all of the chlorine is removed from the organic molecule as sodium chloride and practically all of the sulfur remains in organic combination. These facts make it possible to assign a definite structure (I) to vinyl chloride polysulfone.

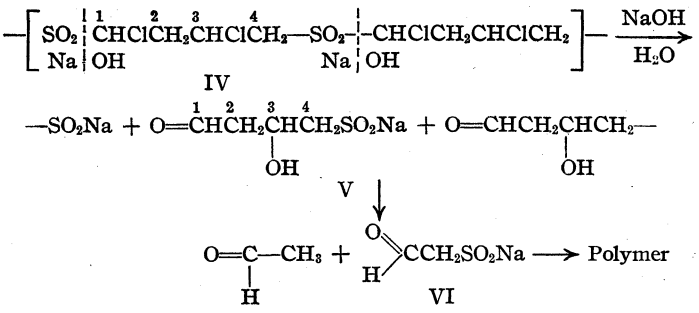
$$-[SO_2CHClCH_2CHClCH_2]_n-$$
I

$$-[SO_2CHClCH_2CH_2CHCl]_n-$$
II

$$-[SO_2CH_2CHClCHClCH_2]_n-$$
III

The three most probable structures for the polymer are those represented by formulas I, II and III in which there are four carbon atoms between the sulfone groups. It is conceivable that vinyl chloride could dimerize to a butylene derivative which then would form a polysulfone. But all of the polysulfones which are derived from olefins are degraded by liquid ammonia and by dilute alkalies to yield cyclic disulfones.[3] Vinyl chloride polysulfone does not show this behavior.

Only structure I can account for the hydrolysis of the polymer to yield acetaldehyde and a sulfur-containing organic residue, according to the following scheme.



The α-halogen sulfone linkage should break readily to yield the aldehyde on carbon 1 (IV and V). The hydrolysis of the chlorine atom on carbon 3 then gives a β-hydroxy aldehyde, which by a retrograde aldol reaction would give acetaldehyde and an aldehydo sulfinic acid (VI) which would be expected to polymerize in the alkaline reaction medium.

A polymer of structure II would be expected to yield succindialdehyde which would polymerize in the alkaline medium and no acetaldehyde could form. A polymer of structure III might hydrolyze to a glycol but the primary sulfone linkage would not break readily under the conditions used in our experiments.

Further experiments on the pyrolysis of vinyl chloride polysulfone in dioxane solution have shown that the reaction is very complex and both hydrogen chloride and sulfur dioxide are lost. No definite polymeric residue seems to be formed. Liquid ammonia removes the chlorine from the polymer forming ammonium chloride and considerable sulfur dioxide is also removed from the polymer. The reaction is not clean cut and definite polymeric products could not be isolated from the reaction mixture.

Experimental

Alkaline Hydrolysis of Vinyl Chloride Polysulfone.—In a 1-liter distilling flask were placed 4.8 g. of powdered vinyl chloride polysulfone and 100 cc. of 20% aqueous sodium hydroxide. A current of steam was passed through this mixture, the distillate was cooled in a long condenser and collected below the surface of a solution containing 1 g. of 2,4-dinitrophenylhydrazine, 10 cc. of concentrated sulfuric acid and 75 cc. of ethanol. After about one hour of steam distillation the distillate was worked up to yield the aldehyde 2,4-dinitrophenylhydrazone. The yield was 0.35 g. (6.2% of the theoretical amount). In another run

(1) This is the tenth communication on polysulfones. For the ninth see, THIS JOURNAL, **60**, 1603 (1938).

(2) Marvel and Glavis, *ibid.*, **60**, 2622 (1938).

(3) Staudinger and Ritzenthaler, *Ber.*, **68**, 455 (1935); Hunt and Marvel, THIS JOURNAL, **57**, 1691 (1935); Glavis, Ryden and Marvel, *ibid.*, **59**, 707 (1937).

2.8 g. of polymer gave 0.2 g. (6.1%) of the 2,4-dinitrophenylhydrazone derivative. The derivative was carefully recrystallized from alcohol and then melted at 160°. Acetaldehyde 2,4-dinitrophenylhydrazone melts at 164.5°[4] and a mixture of an authentic specimen with the derivative isolated from the above hydrolysis melted at 162°.

Anal. Calcd. for $C_8H_8N_4O_4$: C, 42.8; H, 3.57. Found: C, 43.05; H, 3.68.

An authentic specimen of propionaldehyde 2,4-dinitrophenylhydrazone, m. p. 151° (lit. 155°[5]), was mixed with the derivative obtained in the above hydrolysis and the mixture melted at 140–144°.

The alkaline residue remaining in the distilling flask after the steam distillation was filtered to remove aldehyde resin and other insoluble material and analyzed for chloride, sulfite and sulfate. No sulfites were found. Precipitation of the sulfate with barium chloride showed that 3.72–4.22% out of the 16.9% of the sulfur originally present in the polymer had been converted to sulfate. Of the 37.6% of chlorine originally present in the polysulfone, 35.5% was present in this filtrate as chloride ion.

Action of Liquid Ammonia on Vinyl Chloride Polysulfone.—Many experiments were tried adding liquid ammonia to the polymer and vice versa. The liquid ammonia was then allowed to evaporate and the residue treated with water and filtered. Extensive analyses of the water solution and the insoluble part showed that the chlorine was entirely removed from the polymer as ammonium chloride. Considerable sulfur was removed as ammonium sulfite. The remaining polymeric products were not uniform in character and varied over a considerable range in their sulfur content.

Pyrolysis in Dioxane.—When small quantities of vinyl chloride polysulfone were suspended in dioxane and the mixture heated to boiling under a reflux condenser, gas was evolved. This gas consisted of a mixture of hydrogen chloride and sulfur dioxide. No vinyl chloride could be detected among the volatile products. In fact no organic material except dioxane was carried over through the reflux condenser. Analysis of the residual polymeric materials showed that they varied widely in sulfur content.

(4) Strain, THIS JOURNAL, **57**, 758 (1935).
(5) Allen, *ibid.*, **52**, 2955 (1930).

Summary

1. Alkaline hydrolysis of vinyl chloride polysulfone produces acetaldehyde which is evidence that the polymeric unit in this material is —$CHClCH_2CHClCH_2SO_2$—.

2. The polymer does not give a clean-cut reaction with liquid ammonia and pyrolysis causes loss of both hydrogen chloride and sulfur dioxide.

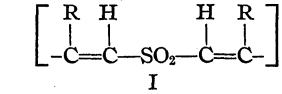
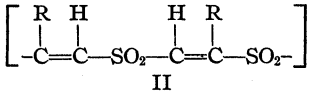
Acetylene Polysulfones. XI.[1] The Compound $C_{10}H_{16}SO_2$ from 1-Pentynepolysulfone and Some Experiments on Other Acetylenepolysulfones

BY C. S. MARVEL AND W. W. WILLIAMS

When acetylenes of the type RC≡CH combine with sulfur dioxide, the polysulfone formed has one remaining double union for each acetylene unit.[2] The arrangement of these units in the polymer may be either that shown in formula I or



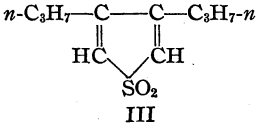
I



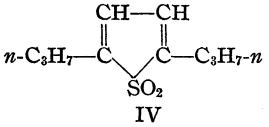
II

that in formula II or the polymer may consist of a random mixture of these units. The present work was undertaken in order to add to our knowledge concerning these compounds.

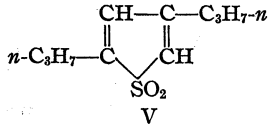
It was found[2] that heating a solution of 1-pentynepolysulfone $(C_5H_8SO_2)_n$ gave a crystalline solid of the composition $C_{10}H_{16}SO_2$ which tentatively was considered to be a di-*n*-propylthiophene sulfone (III, IV or V). This product must



III



IV



V

be formed by the loss of sulfur dioxide from two units of polymer and hence knowledge of its structure would make it possible to assign a definite formula for the polymer.

A more detailed study of the pyrolysis of 1-pentynepolysulfone in dioxane has been made. The reaction proceeds to some equilibrium stage. Isolation of the unchanged polymer and repetition of the pyrolysis in fresh dioxane gives more of the decomposition product. By using this stepwise

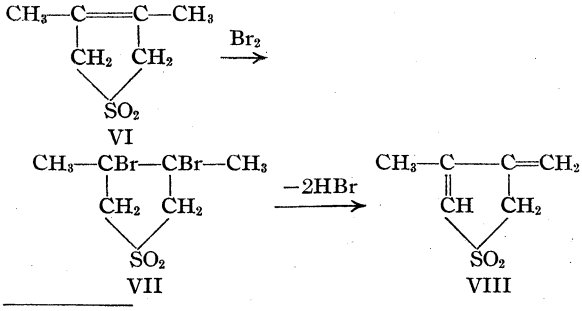
(1) For the tenth communication on polysulfones, see THIS JOURNAL, **61**, 2709 (1939).
(2) Ryden and Marvel, *ibid.*, **58**, 2047 (1936).

procedure it has been possible to increase the yield of the crystalline sulfone to 22% on the basis of the polysulfone which is used up in the process. It has not been possible to obtain other crystalline products from 1-pentynepolysulfone. Neither has it been possible to pyrolyze other acetylene-polysulfones to give a product similar to the $C_{10}H_{16}SO_2$ compound.

Evidence that this crystalline degradation product has an α,β-unsaturated sulfone linkage has been obtained by a study of its addition reactions. Sodiomalonic ester adds readily to give a product of the expected composition.[3] Reduction of the cyclic sulfone with zinc and acetic acid yields a dihydro compound. This reaction must proceed by a 1,4-addition of hydrogen with a resulting shift of the double union to the 3,4-position in the ring (III, IV or V) as otherwise this reduction would be expected to give a tetrahydro compound.

Catalytic reduction of the cyclic sulfone using hydrogen at three atmospheres and a platinum oxide–platinum black catalyst[4] gave another dihydro compound. The catalyst was poisoned rather quickly during this reaction. Since this dihydro compound is isomeric with the one formed by a 1,4-addition of hydrogen, it must be the 1,2-addition product. However, if it is the result of 1,2-addition of hydrogen to one of the structures III, IV or V, the resulting molecule would still be an α,β-unsaturated compound and would be expected to reduce with zinc and acetic acid. This could not be accomplished.

One or the other of these reduction products may be derived from a rearranged form of the cyclic sulfone. Backer and Strating[5] have shown that the cyclic sulfone (VIII) obtained by the addition of sulfur dioxide to 2,3-dimethylbutadiene



followed by bromination and removal of two molecules of hydrogen bromide has only one double bond in the ring.

The sulfone (III, IV or V) obtained by the pyrolysis of 1-pentynepolysulfone might have a similar structure but the fact that Backer and Strating's compound (VIII) adds bromine, whereas our compound does not, seems to cast doubt on this possibility.

The polysulfones derived from acetylenes have an α,β-unsaturated sulfone linkage[6] (I or II) and therefore would be expected to show the characteristics of simpler molecules containing this system.[3] Attempts to add sodiomalonic ester, the Grignard reagent and hydrogen from zinc and acetic acid all resulted in degradation of the polymers without the formation of products which could be characterized.

X-Ray diffraction patterns of the polysulfones from 1-pentyne, 1-hexyne, 1-heptyne, 1-nonyne and 1-pentadecyne have been furnished us by Dr. S. T. Gross. Fibered samples obtained by extruding the hot sample through a conical orifice were used. The patterns were prepared at 5 cm. using radiation from a copper target Phillips metallix diffraction X-ray tube. A nickel filter furnishing approximately monochromatic K-radiation was used. An analysis of the patterns will be reported later by Dr. Gross. It is of interest to note that the patterns are much better defined than any which have been obtained with olefin polysulfones. It is possible that the many asymmet-

ric centers in the latter are responsible for their less sharp patterns.

Attempts to prepare a polysulfone from acetylene itself proved futile.

Experimental

Heat Degradation of 1-Pentynepolysulfone.—In general the polymer was decomposed by boiling its dioxane solution as previously described.[2] The yields have been improved and the details of a typical experiment follow.

A solution of 10 g. of 1-pentynepolysulfone in 500 cc. of dioxane was heated under reflux condenser for about fifty hours. The evolution of sulfur dioxide had nearly stopped at this time. The dioxane was removed by boiling under reduced pressure and ether was added to the brownish residue. The ether solution was filtered and the residue again extracted with ether. The ether extracts were combined, washed with 5% sodium hydroxide solution and then with water. The alkaline extract turned orange-red during the extraction. The ether layer was dried over anhydrous sodium sulfate, filtered and most of the ether removed by distillation on a steam cone. The last of the ether was removed in a desiccator under reduced pressure. The brownish residue containing some crystals was allowed to stand for about a day in the refrigerator to permit as much crystallization as would occur. This residue, which resembled apple butter, was spread on a clay plate and allowed to stand about a day. The residual material was scraped off and crystallized from dilute alcohol. Norite was used to remove the color. The material thus obtained amounted to 0.3 to 0.4 g. (3.5–5.3%) of product melting at 88°.

In one run 10 g. of polysulfone in 400 cc. of purified

dioxane was heated under a reflux condenser in a current of nitrogen for about one hundred twenty-five hours. The evolved sulfur dioxide was led into standard alkali and titration showed that 8.5% of the total sulfur dioxide in the polymer came off in this time. Evaporation of the dioxane and extraction of the residue with ether left 6.6 g. of polymer which sulfur analysis showed to be essentially unchanged. The yield of crystalline monosulfone in this run was 0.3 g. (3.48% on total polymer or 11.5% on polymer destroyed).

In another set of experiments 30-g. samples of the polymer in 500 cc. of dioxane were heated for about twenty-four hours, then the unchanged polymer was isolated, put in fresh dioxane and heated again for twenty-four hours. This was repeated until practically no unchanged polymer was left. Only one such experiment is recorded for illustration.

	Heating				
	First	Second	Third	Fourth	Fifth
G. polymer	30	24	18.3	14.0	10.7
Cc. dioxane	500	300	250	200	200
Hours refluxing	24	25	26	25	35
G. polymer lost	6	5.7	4.3	3.3	2.7
G. crystalline $C_{10}H_{16}SO_2$	0.88	0.8	0.71	0.43	0.28
% yield based on polymer used	19.4	18.5	21.8	17.1	13.7

Careful fractional distillation of the dioxane from one of the decomposition experiments showed a low boiling fraction which contained a small amount of 1-pentyne. This was identified as the mercury derivative by means of Johnson and McEwen's reagent.[7] Known 1-pentyne gave a derivative melting at 117–118°, the alkyne from the pyrolysis gave a derivative melting at 116–119°; the mixture of the two melted at 116–119°.

An acidic substance was always present in the dioxane after the heating period but no definite acidic product could be separated.

Reactions of $C_{10}H_{16}SO_2$.—As noted previously[2] the sulfone would not add bromine but did decolorize alkaline potassium permanganate solution.

The addition of sodiomalonic ester was accomplished by treating 0.7 g. of ethyl malonate in about 5 cc. of benzene with sodium until the salt was formed. The excess sodium was removed and 60 cc. of benzene added. To the suspension thus obtained was added 0.44 g. of the sulfone. The reaction mixture was heated for three hours on a steam-bath, cooled, washed with water until the washings were neutral, and the benzene removed. The excess malonic ester was removed by distillation under reduced pressure. When the residue was cooled and dried on a clay plate, 0.56 g. of white crystals remained. Crystallization from alcohol gave a product melting at 104.5–105°.

Anal. Calcd. for $C_{17}H_{28}O_6S$: S, 8.9. Found: S, 8.6.

Attempts to add a second mole of malonic ester to this product were ineffective and the starting material was recovered.

Reduction with zinc and acetic acid was carried out by dissolving 0.41 g. of the sulfone in 50 cc. of glacial acetic acid and boiling the mixture for seven hours with 10 g. of zinc. The hot mixture was then filtered from undissolved zinc, the zinc washed with hot acetic acid, and then the combined acetic acid solutions diluted with water. The solution turned cloudy but no crystals separated. The solvent was then removed through a Widmer column and the residue was dissolved in ether. After removal of the ether the residue was finally induced to crystallize from low-boiling petroleum ether. The product thus obtained melted at 49–50° on a hot-stage microscope. Analysis showed it to be a dihydro derivative of the sulfone.

Anal. Calcd. for $C_{10}H_{18}SO_2$: C, 59.35; H, 8.97. Calcd. for $C_{10}H_{20}SO_2$: C, 58.76; H, 9.87. Found: C, 59.43; H, 9.06.

Catalytic reduction of 2.86 g. of the sulfone in 50 cc. of absolute alcohol with hydrogen in the presence of 0.1 g. of platinum oxide–platinum black[4] in a low pressure reduction apparatus[8] for twenty hours gave a solution with a faint odor of hydrogen sulfide. The platinum catalyst was removed by filtration. The solution was cooled in a dry ice–acetone bath and the solid collected in a filter. The solid thus obtained was twice recrystallized from ether by cooling the solution in a dry ice–acetone bath. This product melted at 56.5–57° on a hot-stage microscope.

Anal. Calcd. for $C_{10}H_{18}SO_2$: C, 59.35; H, 8.97. Found: C, 59.55, 59.43; H, 8.88, 8.90.

A mixture of this compound with the dihydro derivative which melted at 49–50° melted below 44°. This dihydro compound could not be further reduced with zinc and acetic acid.

Attempts to Add Reagents to the Acetylene Polysulfones.—When 5 g. of 1-pentynepolysulfone in 225 cc. of glacial acetic acid was boiled under a reflux condenser with 15 g. of powdered zinc for thirteen hours, some hydrogen sulfide was liberated. After isolating the polymer it was found to have the melting point (200–208°) characteristic of the original 1-pentynepolysulfone.[2] Attempts to reduce 1-nonynepolysulfone with zinc and acetic acid were also unsuccessful. Similarly attempts to reduce dioxane solutions of 1-nonynepolysulfone, propynepolysulfone and 1-pentynepolysulfone with hydrogen in the presence of platinum oxide–platinum black[4,8] were unsuccessful.

The carefully dried polysulfones from 1-pentyne, 1-hexyne, 1-heptyne, 1-nonyne and phenylacetylene dissolved in an ether solution of ethylmagnesium bromide with the evolution of gas and the formation of amber to red colored solutions. Attempts to follow the gas liberation quantitatively gave unreproducible results. Recovery of the polymers from the solution showed that considerable degradation had taken place in this reaction. No evidence for a simple addition was obtained.

Sodiomalonic ester in dry benzene did not add to 1-pentynepolysulfone in the cold and when the mixture was warmed the polymer was degraded.

Attempts to Obtain Acetylene Polysulfone.—Various attempts to bring about the combination of acetylene and sulfur dioxide at atmospheric pressure and under the pressure of a solution of acetylene in acetone and sulfur dioxide were made. Ascaridole was used as a catalyst. Ethyl alcohol was also added to some of the mixtures. In the experiments at atmospheric pressure acetylene was bubbled through the cold reaction mixture. No evidence of polymer formation was ever obtained.

Summary

1. The pyrolysis of 1-pentynepolysulfone to yield a crystalline sulfone, $C_{10}H_{16}SO_2$, has been studied further and evidence that the new sulfone has a cyclic unsaturated sulfone structure has been described. No similar products have been obtained from other acetylenepolysulfones by pyrolysis.

2. Attempts to add reagents to the α,β-unsaturated sulfone systems present in the acetylene polysulfones resulted in degradation of the polymers.

3. Some X-ray diffraction patterns of typical acetylenic polysulfones have been recorded.

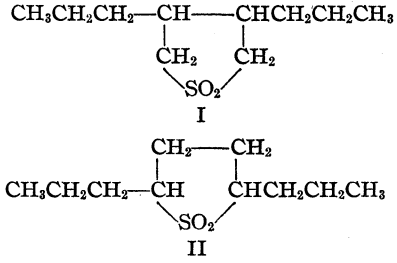
Polysulfones. XII.[1] The Synthesis of 3,4- and 2,5-Di-*n*-propyltetrahydrothiophene-1,1-dioxides

BY C. S. MARVEL AND W. W. WILLIAMS

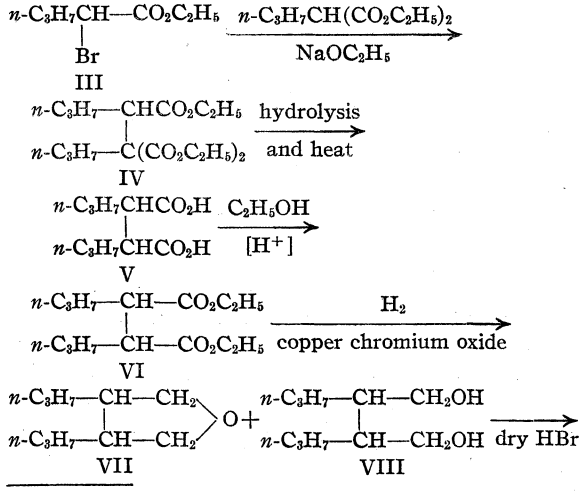
The pyrolysis of 1-pentynepolysulfone in dioxane has yielded a cyclic unsaturated sulfone which is probably a di-*n*-propylthiophene oxide.[2] The positions of the alkyl groups are uncertain as they may be 3,4, 2,5 or 2,4. In order to have available related compounds of known structure, we have now synthesized the 3,4- and the 2,5-di-*n*-propyltetrahydrothiophene-1,1-dioxides (I and II).



I

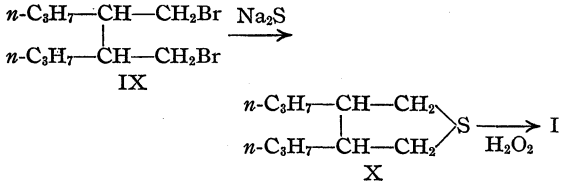
II

The synthesis of the 3,4-di-*n*-propyl derivative (I) has been accomplished by the following reactions.



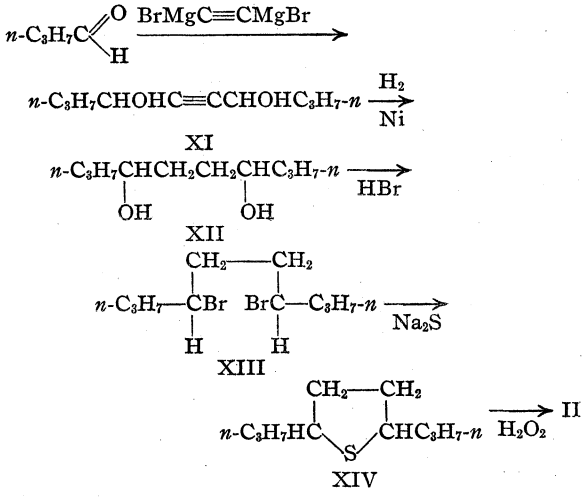
(1) For the eleventh communication on polysulfones, see THIS JOURNAL, **61**, 2710 (1939).

(2) Ryden and Marvel, *ibid.*, **58**, 2047 (1936); see also ref. 1.



The di-*n*-propylsuccinic acid has been prepared previously by Bone and Sprankling[3] from cyanoacetic ester but the procedure described in the experimental part of this communication worked more smoothly for us.

The synthesis of the 2,5-di-*n*-propyl derivative has been accomplished by the following reactions.



4,7-Decanediol has been prepared previously by Bogert and Slocum[4] but the details of their process were not available to us at the time the above synthesis was performed.

2,5-Di-*n*-propyltetrahydrothiophene-1,1-diox-

(3) Bone and Sprankling, *J. Chem. Soc.*, **77**, 654 (1900).

(4) Bogert and Slocum, *Am. Perfumer*, **18**, 621 (1924); *C. A.*, **18**, 1271 (1924).

ide (II) is a liquid. By use of its refractive index and density it is possible to assign a refractive constant of 8.7 to the sulfone group.

Experimental

4,4,5-Tricarboethoxyoctane (IV).—A regular malonic ester synthesis using 469 g. of ethyl *n*-propylmalonate, 500 cc. of dry xylene, 53.4 g. of sodium and 490 g. of ethyl α-bromovalerate and heating for fifteen hours gave 454.4 g. (59%) of a product boiling at 182–183° (1 mm.); d^{20}_{20} 1.0170; $n^{20}D$ 1.4393.

Anal. Calcd. for $C_{17}H_{30}O_6$: C, 61.78; H, 9.16. Found: C, 61.91; H, 8.95.

α,α′-Di-*n*-propylsuccinic Acid (V).—A solution of 405 g. of the above ester in 1250 g. of aqueous 40% potassium hydroxide was refluxed overnight. About 300 cc. of water was distilled from the flask and heating was continued for two days, after which time the solution became nearly homogeneous. A few drops of unsaponified material was removed by ether extraction and then the solution was cooled to 0° and hydrochloric acid was added until the solution was distinctly acid to congo paper. When the solution warmed up to room temperature carbon dioxide was evolved rapidly. The organic acid was extracted with ether and the ether evaporated. There remained a nearly quantitative yield of the mixture of diastereoisomers of the desired acid. Recrystallization of a sample from benzene gave the *cis*-form[3] melting at 115–117°. The *trans*-form never was isolated in an entirely pure form.

Ethyl α,α′-Di-*n*-propylsuccinate (VI).—The mixed isomers of the acid were esterified with ethyl alcohol in the presence of sulfuric acid. The ester was obtained in about 87% yield based on the acid not recovered; b. p. 86–87° (less than 1 mm.); d^{20}_{20} 0.9568; $n^{20}D$ 1.4302.

Anal. Calcd. for $C_{14}H_{26}O_4$: C, 66.58; H, 10.38. Found: C, 65.53; H, 10.22.

Catalytic Reduction of Ethyl α,α′-Di-*n*-propylsuccinate.—The ester was reduced by the general method for ester reduction described by Adkins.[5]

A solution of 70.7 g. of ester in 125 cc. of dioxane was refluxed with a few grams of Raney nickel catalyst for two hours to remove catalyst poisons. The nickel catalyst was removed by filtration and 7.1 g. of copper–chromium oxide catalyst was added. The reaction mixture was placed in a steel bomb under a hydrogen pressure of over 4400 lb. per square inch (300 atm.) at a temperature of 260°. The pressure drop noted in about twenty hours indicated the reduction was complete. The catalyst was removed by filtration and the reaction mixture was fractionally distilled through a Widmer column. The first fraction boiling at 55–63° (1–2 mm.) weighed 23.2 g. (54.2%) and was identified as 3,4-di-*n*-propyltetrahydrofuran (VII). Redistillation gave a product, b. p. 40–42° (less than 1 mm.); d^{20}_{20} 0.8683; $n^{20}D$ 1.4369.

Anal. Calcd. for $C_{10}H_{20}O$: C, 76.84; H, 12.91. Found: C, 76.82; H, 12.92.

After removal of the furan a second fraction boiling at 63–83° (1 mm.) amounting to 26 g. was obtained and a residue weighing 2 g. remained. Redistillation of the residue gave a liquid boiling at 103° (less than 1 mm.); d^{20}_{20} 0.9378; $n^{20}D$ 1.4563. Analysis showed this fraction to be the expected 2,3-di-*n*-propyl-1,4-butanediol (VIII).

Anal. Calcd. for $C_{10}H_{22}O_2$: C, 68.89; H, 12.74. Found: C, 68.76; H, 12.71.

1,4-Dibromo-2,3-di-*n*-propylbutane (IX).—No very satisfactory procedure for obtaining the dibromide was worked out in detail. The furan (44.1 g.) and the glycol (6 g.) obtained as above were heated to 125° for about ten hours with dry hydrogen bromide in glacial acetic acid and the samples of impure bromide were obtained. These crude products were mixed and again heated to 125° for fifteen hours with hydrogen bromide in glacial acetic acid but analysis of the best fractions indicated there was incomplete reaction. Finally the crude material from this treatment was heated to 128–154° for about fifty hours with dry hydrogen bromide slowly bubbling through the mixture. This product was washed with sodium carbonate solution, then water and dried. Redistillation gave 34.2 g. of product boiling at 81–94° (about 1 mm.). The best fraction boiling at 94° (about 1 mm.) had the following properties: d^{20}_{20} 1.3834; $n^{20}D$ 1.4971.

Anal. Calcd. for $C_{10}H_{20}Br_2$: C, 40.00; H, 6.72. Found: C, 40.68; H, 6.88.

3,4-Di-*n*-propyltetrahydrothiophene (X).—In a 200-cc. three-necked flask equipped with a dropping funnel, stirrer, and reflux condenser was placed 125 cc. of an alcoholic solution of sodium sulfide.[6] The alcohol was heated to boiling and the stirrer started. Then 14.7 g. of 1,4-dibromo-2,3-di-*n*-propylbutane in 15 cc. of absolute alcohol was added from the dropping funnel over a period of one hour. Boiling was continued about ten hours and then the cooled reaction mixture was poured into 265 cc. of 25% sodium chloride solution. The organic sulfide was extracted with petroleum ether (b. p. 35–38°), the extract was dried and then distilled. A second run using 15.5 g. of the bromide and other equivalent reagents was made and mixed with the above. From the two runs 13.4 g. (77.5%) of 3,4-di-*n*-propyltetrahydrothiophene was obtained, b. p. 65–66° (1 mm.); d^{20}_{20} 0.9129; $n^{20}D$ 1.4830.

Anal. Calcd. for $C_{10}H_{20}S$: C, 69.68; H, 11.70. Found: C, 69.76; H, 11.73.

3,4-Di-*n*-propyltetrahydrothiophene-1,1-dioxide (I).—To a solution of 11.5 g. of the above tetrahydrothiophene derivative in 25 cc. of glacial acetic acid was added cautiously 35 cc. of 100 volume hydrogen peroxide. The heat developed caused the reaction mixture to boil. The mixture was then heated on a steam-bath for about two hours. Cooling the reaction mixture in the icebox caused some crystals to separate. These were collected on a filter, washed with water and dried at 1 mm. pressure. The yield was 8.75 g. The filtrate and washings were extracted several times with ether and the ether extract dried and concentrated. There remained 3.53 g. of oil which was apparently also cyclic sulfone as no odor of the sulfide remained.

The above solid was examined on a hot-stage microscope and found to consist of irregular scales mixed with

(5) Adkins, "Reactions of Hydrogen with Organic Compounds over Copper–Chromium Oxide and Nickel Catalysts," The University of Wisconsin Press, Madison, Wis., 1937.

(6) Bost and Conn, *Org. Syntheses*, **15**, 72 (1935), John Wiley and Sons, Inc., New York, N. Y., 1935, p. 72.

oily droplets. At 58° it was completely liquid. The solid was purified by dissolving in a little ether and cooling in a dry ice–acetone bath. The glistening white, scale material thus formed melted at 57–59.5° on the hot-stage microscope.

Anal. Calcd. for $C_{10}H_{20}SO_2$: C, 58.77; H, 9.87. Found: C, 58.87; H, 9.80.

5-Decyne-4,7-diol (XI).—To a solution of 1.54 moles of acetylenedimagnesium bromide in ether prepared in the usual manner[7] was added 216.2 g. of *n*-butyraldehyde over a period of one and one-half hours. The mixture was stirred for nearly a day and then poured onto cracked ice, acidified with hydrochloric acid. The ether layer was worked up in the usual manner and 213 g. (41.8%) of a viscous golden oil of b. p. 113–114° (1 mm.) was obtained; d^{20}_4 0.9462; $n^{20}D$ 1.4678.

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.55; H, 10.66. Found: C, 70.58; H, 10.90.

4,7-Decanediol (XII).—The above acetylenic glycol was divided into two parts for reduction with hydrogen over Raney nickel.[8] In one run 102 g. of glycol, 35 cc. of alcohol and about 5 g. of Raney nickel were placed in the bomb at 25° and 2400 lb. (160 atm.) pressure. The bomb was warmed up to 85° during the reduction. At the end of the reaction the pressure had dropped to 800 lb. (53 atm.). In the other run 111 g. of glycol, 30 cc. of alcohol and about 5 g. of Raney nickel were placed in the bomb at 25° and 4430 lb. (298 atm.) pressure. This run was not heated but the reaction mixture warmed to 75° from the heat of reaction. At the end of the reduction the pressure had dropped to 750 lb. (30 atm.). The two reduction mixtures were united, filtered to remove catalyst and distilled. The portions boiling at 110–112° (1 mm.) solidified in the receiver. The yield was 164 g. (71%). The glycol was recrystallized from petroleum ether (b. p. 65–110°) and then melted at 79–80° on a hot-stage microscope.

Anal. Calcd. for $C_{10}H_{22}O_2$: C, 68.89; H, 12.74. Found: C, 68.94; H, 12.75.

(8) Covert and Adkins, *ibid.*, **54**, 4116 (1932).

4,7-Dibromodecane (XIII).—Dry hydrogen bromide was passed through the glycol for four hours at 45–60° and then for eighteen hours at 105–115°. The bromide was then distilled. From 112.6 g. of glycol there was obtained 165 g. (85.3%) of bromide, b. p. 106–109° (1 mm.); d^{20}_4 1.3354; $n^{20}D$ 1.4920.

Anal. Calcd. for $C_{10}H_{20}Br_2$: C, 40.00; H, 6.72; Br, 53.28. Found: C, 40.44; H, 6.77; Br, 52.90.

2,5-Di-*n*-propyltetrahydrothiophene (XIV).—Using the same procedure described for the previous cyclic sulfide, 120 g. of 4,7-dibromodecane gave 52.8 g. (77%) of the desired 2,5-di-*n*-propyltetrahydrothiophene, b. p. 74–75° (1 mm.); d^{20}_4 0.8958; $n^{20}D$ 1.4795.

Anal. Calcd. for $C_{10}H_{20}S$: C, 69.68; H, 11.70. Found: C, 69.61; H, 11.65.

2,5-Di-*n*-propyltetrahydrothiophene-1,1-dioxide (II).—The sulfide was oxidized in the same manner described for its isomer. The yield from 33 g. of sulfide was 38 g. of sulfone, b. p. 123–125° (1 mm.); d^{20}_4 1.0408; $n^{20}D$ 1.4719.

Anal. Calcd. for $C_{10}H_{20}SO_2$: C, 58.77; H, 9.87. Found: C, 58.90; H, 9.95.

Using the Eisenlohr values[9] 2.42 for each carbon atom and 1.1 for each hydrogen atom the refractive constant for the $—SO_2—$ group in the above sulfone is calculated as 8.7.

Summary

1. 3,4-Di-*n*-propyltetrahydrothiophene-1,1-dioxide and 2,5-di-*n*-propyltetrahydrothiophene-1,1-dioxide have been synthesized and many intermediates in these syntheses have been characterized.

2. Since 2,5-di-*n*-propyltetrahydrothiophene-1,1-dioxide is a liquid it has been possible to calculate a refractive constant of 8.7 for the sulfone group in this compound.

Saponins and Sapogenins. XIII. The Precipitability of Steroid Sapogenins by Digitonin

BY C. R. NOLLER

Marker and Rohrmann[1] have reported that chlorogenin is precipitated by digitonin, a finding contrary to our previously published experience.[2] They added to a boiling solution of 100 mg. of chlorogenin in 10 cc. of 95% alcohol, a hot solution of 600 mg. of digitonin in 20 cc. of 90% alcohol. We have repeated their experiment and have found that about half of the chlorogenin is indeed precipitated. However, assuming the addition complex to be a 1:1 molecular compound and digitonin to have the formula $C_{56}H_{92}O_{29}$, a 110% excess of digitonin was used and the concentrations were such that the solubility of digitonin at room temperature was exceeded greatly. Thus if 600 mg. of digitonin is dissolved in a hot solution of 10 cc. of 95% alcohol and 20 cc. of 90% alcohol and the solution cooled and inoculated with a trace of digitonin, 455 mg. will crystallize out on standing at room temperature. It is conceivable that this heavy precipitation would bring down a considerable quantity of chlorogenin along with it. In the usual procedure for the preparation of digitonides, one adds a solution of the compound being tested to an equal volume of a 1% solution of digitonin (1 g. in 100 cc. of 90% alcohol) so that there is no danger of digitonin crystallizing since the solubility of digitonin at room temperature is approximately 0.5 g. per 100 cc. of 90% alcohol. Under these conditions chlorogenin does not precipitate.

In view of the extensive use of the test it seemed desirable to attempt to establish a more definite criterion of compound formation with digitonin. The relative solubility of the compound and its components is the only property that can be used conveniently in this series and it would seem that to show compound formation it is necessary to show that the solubility of the digitonide is less than that of either of its components. If a solution of cholesterol or of β-cholestanol in 90% alcohol, saturated at room temperature, is mixed with an equal volume of a saturated solution of digitonin in the same solvent, a precipitate forms almost immediately. Under the same conditions tigogenin yields a precipitate after about twenty minutes, gitogenin after fifteen hours, while sarsasapogenin, chlorogenin, *epi*-coprosterol and *epi*-dihydrocholesterol give no precipitate after standing for five days. If, however, the solutions of the last four compounds are concentrated to half volume to bring the concentration of the compound and of digitonin to that of saturated solutions, all except *epi*-coprosterol give some precipitate after standing for five hours. It is seen therefore that neither condition gives a satisfactory test since before concentration sarsasapogenin, which is known to give a less soluble digitonide than its epimer,[3] did not precipitate whereas after concentration *epi*-dihydrocholesterol, which has the α-configuration, also was precipitated.

One obvious inaccuracy in the use of saturated solutions of the compounds for qualitative tests is that the solubility, and hence the concentration, is different for each compound. A semi-quantitative approach to the problem was made as follows. Five cubic centimeters of a saturated solution of the compound was evaporated to dryness and the residue weighed. This residue was then dissolved by warming with 5 cc. of a saturated solution of digitonin, tightly stoppered and allowed to stand overnight. The precipitate that had formed was filtered the next morning by suction through tared funnels, dried at 80° and weighed. If no precipitate had formed, which was the case with *epi*-dihydrocholesterol, sarsasapogenin and chlorogenin the solutions were inoculated with traces of precipitates that had been formed previously in more concentrated solutions, and allowed to stand for another twenty-four hours and the precipitates filtered. The filtrates were returned to the flasks and allowed to stand an additional three days to be certain that no more precipitate formed. In the case of those compounds that precipitated on mixing 5 cc. of a saturated solution with 5 cc. of digitonin solution, these precipitates after standing overnight were filtered and weighed. Assuming a molecular ratio of 1:1 and a molecular weight for digitonin

[a] For the pure samples of β-cholestanol, m. p. 143–145°, *epi*-dihydrocholesterol, m. p. 185–186°, and *epi*-coprosterol, m. p. 111°, all of which had been purified by means of digitonin, we are indebted to Dr. R. Schoenheimer, for sarsasapogenin, m. p. 192–194°, to Dr. L. F. Fieser, and for gitogenin, m. p. 270–274°, to Dr. W. A. Jacobs. The tigogenin, m. p. 202–207°, and chlorogenin, m. p. 273–276°, were isolated from *Chlorogalum pomeridianum*. [b] For the first three compounds the temperature of the solubility determinations was 23 ± 0.5° and the volume of the mixed solutions 10 cc. For the last five compounds the solubility determinations were made at 25 ± 0.5° and the volume of the mixed solutions was 5 cc.

of 1228, the weight of compound and of digitonin precipitated could be calculated and these values subtracted from the weights originally present gave the amounts of compound and of digitonin remaining in solution. From these data approximate solubility products for the digitonides could be calculated. The results are given in the table.

The solubility products are approximate only since they have been calculated from a single pair of concentrations in each case and no attempt was made to make the determinations more than roughly quantitative. The precipitates were not washed because of their known high solubility; hence they include the material dissolved in the adherent mother liquors. This may be partly compensated by the difficulty of quantitative transfer of the precipitates to the funnels. Where a second filtration was necessary, as in the case of chlorogenin, the weight of precipitate may be too high because of evaporation of the solvent during the first suction filtration, although such evaporation was held to a minimum. It is believed from several duplicate determinations that the error may be of the order of 5 to 10%. That the values are fairly accurate is indicated by the last column of the table which gives the products of the concentrations on mixing equal volumes of saturated solutions of the compounds and of digitonin. In the case of tigogenin and gitogenin these products exceed the solubility product and it is known that these compounds give precipitates under these conditions, whereas the concentration products are less than the solubility products in the case of *epi*-dihydrocholesterol, sarsasapogenin and chlorogenin.

The table shows clearly that tigogenin forms a stable digitonide as previously reported[4] although its precipitation can hardly be called "almost quantitative." Gitogenin, which has been reported as being not precipitated by digitonin,[4] forms a less soluble digitonide than sarsasapogenin whose epimer gives a more soluble digitonide.[3] Hence until the epimers of gitogenin have been prepared and their properties studied, gitogenin should be considered as being precipitable by digitonin. Chlorogenin digitonide on the other hand is considerably more soluble than sarsasapogenin digitonide, and hence tentatively should be considered as belonging to the group not precipitated by digitonin. The necessity of comparing pairs of epimers is shown clearly by the case of *epi*-dihydrocholesterol, which gives a digitonide having a solubility product the same as that of sarsasapogenin, yet they must be considered as belonging to two different stereochemical groups.

Precipitability by digitonin long has been considered to be specific for steroids having an hydroxyl group at C-3 with the same stereochemical configuration as that present in cholesterol.[5] In recent years it has been shown that not only are some compounds which lack this hydroxyl group precipitated by digitonin,[6] but that others con-

taining a C-3 hydroxyl group of the proper configuration are not precipitated by digitonin.[4,7] It thus may even be questionable whether precipitation by digitonin has the same significance for the steroid sapogenins as for the sterols.

Summary

1. The solubility of the digitonides of steroid sapogenins varies considerably and is much greater than that of the digitonides of cholesterol and β-cholestanol. Thus the solubility product of the digitonide of sarsasapogenin, which is known to be the less soluble of two epimeric forms, is practically the same as that of the digitonide of *epi*-dihydrocholesterol, which ordinarily is considered as not precipitable by digitonin.

2. Gitogenin digitonide has a smaller solubility product than sarsasapogenin digitonide and hence gitogenin provisionally must be considered as being the epimer that is precipitated by digitonin.

3. The digitonide of chlorogenin has a much larger solubility product than that of sarsasapogenin and until its epimer is prepared and shown to give a more soluble digitonide, chlorogenin must be considered as the isomer not precipitable by digitonin.

4. It has been shown that the solubility products of steroid digitonides vary so widely that qualitative tests for precipitation are without meaning unless the behavior of both isomers can be compared.

Sterols. LXXI. Urane Derivatives

BY RUSSELL E. MARKER AND EWALD ROHRMANN

In papers XXIX[1] and XXXVII[2] of this series the isolation from mares' pregnancy urine of uranetriol and uranediol was described. These substances were shown to possess hydroxyl groups at C-11 and both compounds were converted to the same parent hydrocarbon, urane (I), which is believed to differ from pregnane in the configuration at C-9.

In spite of the close relationship[1,2,3] existing between uranetriol and uranediol, they nevertheless show some unusual and striking differences. We have pointed out previously the fact that on the basis of precipitability with digitonin uranetriol is a 3-α while uranediol is a 3-β compound. There is also a pronounced difference in the reaction of bromouranetrione and bromouranedione with pyridine, the former yielding urenetrione directly while the latter gives largely pyridinium salt which yields urenedione upon destructive distillation. The fact that on the debromination of bromouranedione only one product was obtained suggests that the bromine occupied the C-4 position. Although it appears that the double bond in urenetrione and urenedione may be in the 4,5-position, no definite proof of this point has as yet been obtained.

In the catalytic hydrogenation of uranedione-3,11 (V) the carbonyl group at C-3 is much more easily reduced than that at C-11 and consequently the preparation of uraneol-3(β)-one-11 (VIII) is possible. There was no noticeable *epi* fraction obtained in this reduction. The same product was formed by the reduction of uranedione with aluminum isopropylate. Oxidation of the product with an excess of chromic anhydride gave uranedione.

Uranediol on partial oxidation with chromic anhydride yielded some uraneol-3(β)-one-11 (VIII) in addition to uranedione. No uraneol-11-one-3 was isolated from the oxidation. In the oxidation of uranediol with aluminum isopropylate, however, the oxidation proceeds readily at C-3 and the only ketonic product obtained was uraneol-11-one-3 (IX). This product formed a monoacetate and a monosemicarbazone.

By the Clemmensen reduction of uranedione-3,11 with unamalgamated zinc in ethanol solution, an almost quantitative yield of uraneone-11 (IV) was obtained. This product formed no semicarbazone, but on catalytic hydrogenation yielded uraneol-11 (VII) which formed a monoace-

tate. When the Clemmensen reduction was carried out with amalgamated zinc, the main product of the reaction was the hydrocarbon, urane (I).

The Clemmensen reduction of uranetrione (II) with unamalgamated zinc in ethanol solution yielded a diketone which is undoubtedly uranedione-11,20 (III).

This investigation was supported by a grant from the Committee for Research in Problems of Sex, National Research Council. We wish to thank Parke, Davis and Company for the mares pregnancy urine extracts from which the uranediol and uranetriol were isolated.

Experimental Part

Bromouranedione-3,11.—To a solution of 2 g. of uranedione in 40 cc. of acetic acid acidified with 3 drops of 48% hydrobromic acid was added 6.3 cc. of 1.05 *M* bromine in acetic acid. White crystals separated toward the end of the reaction. The reaction mixture was diluted carefully with water and the crystalline solid collected, washed and crystallized from ether to give compact white crystals, m. p. 202–203° dec.

Anal. Calcd. for $C_{21}H_{31}O_2Br$: C, 63.8; H, 7.9. Found: C, 63.4; H, 7.8.

Reaction of Bromouranedione-3,11 with Pyridine.—A mixture of 1.7 g. of bromouranedione-3,11 and 45 cc. of dry pyridine was refluxed for three and one-half hours. Small white plates separated shortly after refluxing was started. These were collected, washed with pyridine and ethanol and dried. The product did not melt below 300°; yield 1.5 g.

Anal. Calcd. for $C_{26}H_{36}O_2$: C, 65.8; H, 7.65. Found: C, 66.1; H, 7.7.

Decomposition of Pyridinium Salt of Bromouranedione-3,11.—The pyridinium salt (1.4 g.) was placed in a glass retort and heated at 5–10 mm. pressure until no more material distilled over. The reaction product was sub-

limed in high vacuum at 90–110°. The sublimate was taken up in ether and the pyridine salts removed by washing with dilute hydrochloric acid and water. The ether was evaporated and the product crystallized from aqueous acetone as white needles, m. p. 168–170°.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.2; H, 9.6. Found: C, 80.5; H, 9.6.

Uraneol-3(β)-one-11 from Uranedione-3,11. (a) **By Aluminum Isopropylate Reduction.**—A mixture of 700 mg. of uranedione, 1.5 g. of aluminum isopropylate (aged, powder) and 50 cc. of isopropyl alcohol was refluxed for fifteen hours. The solvent was distilled off over a period of one hour. The residue was shaken with dilute hydrochloric acid and extracted with ether. The ether was evaporated and the residue dissolved in 20 cc. of hot 95% ethanol and precipitated with a solution of 1 g. of digitonin and 60 cc. of 85% ethanol. A white precipitate separated at once. After standing for two hours this was collected, washed with ethanol, dried and decomposed with pyridine. The product was crystallized from acetone as compact white crystals, m. p. 205–207°. The product gave a 25° depression with uranediol-3(β),11.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.8. Found: C, 79.5; H, 11.0.

When refluxed for twenty minutes with acetic anhydride, the product gave an **acetate** which crystallized from aqueous acetone as white needles, m. p. 170.5–172°.

Anal. Calcd. for $C_{23}H_{36}O_3$: C, 76.6; H, 10.1. Found: C, 76.8; H, 10.3.

The *epi* fraction could not be separated readily from unchanged uranedione.

(b) **By Catalytic Hydrogenation.**—A mixture of 400 mg. of uranedione, 300 mg. of Adams catalyst and 120 cc. of absolute ethanol was shaken with hydrogen at 25° and 3 atmospheres pressure for two hours. The mixture was filtered and the filtrate evaporated to a volume of 75 cc. To this hot solution a solution of 1 g. of digitonin in 50 cc. of 95% ethanol was added and the mixture allowed to stand for twelve hours. The digitonide was filtered, washed, dried and decomposed with pyridine. The ether soluble material was crystallized from methanol as white crystals, m. p. 205–208°. This gave no depression with the product obtained by the aluminum isopropylate reduction of uranedione.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.8. Found: C, 79.2; H, 10.9.

Oxidation of the diol with chromic anhydride in acetic acid at 25° for one hour yielded a product which crystallized from aqueous acetone as white plates, m. p. 174–177°. This gave no depression with a sample of uranedione, m. p. 175–177°.

The *epi* fraction from the hydrogenation was negligible and was not investigated further.

Uraneol-3-one-11 by Oxidation of Uranediol.—About 5 g. of impure uranediol-3(β),11 obtained from mares pregnancy urine was oxidized in acetic acid at room temperature with 1.5 g. of chromic anhydride. The oxidation mixture which would not crystallize readily was adsorbed in a tower of alumina from benzene–ligroin solution and eluted with benzene. The product was crystallized from ethyl acetate and acetone to give compact white crystals, m. p. 207–209°. This gave no depression with previously prepared samples.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.8. Found: C, 79.4, 79.2; H, 10.9, 10.7.

The product was recovered unchanged upon treatment with semicarbazide acetate under the usual conditions.

On refluxing with acetic anhydride the product gave an **acetate** which crystallized from aqueous acetone as white crystals, m. p. 170°. This gave no depression with the acetate of uraneol-3(β)-one-11.

Anal. Calcd. for $C_{23}H_{36}O_3$: C, 76.6; H, 10.1. Found: C, 76.6; H, 10.1.

Uraneol-11-one-3.—A mixture of 1 g. of uranediol, 2 g. of aluminum isopropylate, 15 cc. of cyclohexanone and 50 cc. of dry toluene was refluxed for ten hours. The mixture was cooled, diluted with ether, washed with water and the solvent distilled with steam. The residual oil was treated with 2 g. of Girard's reagent to give approximately 250 mg. of crude ketones. The product was crystallized from ether–pentane as fine white needles, m. p. 169.5–171°.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.8. Found: C, 79.1; H, 10.9.

When refluxed for thirty minutes with an excess of acetic anhydride the product gave an **acetate** which crystallized from aqueous acetone as small white plates, m. p. 195–197°.

Anal. Calcd. for $C_{23}H_{36}O_3$: C, 76.6; H, 10.1. Found: C, 76.8; H, 10.1.

When treated with semicarbazide acetate in boiling 80% ethanol for one hour the product yielded a **semicarbazone** which crystallized from dilute ethanol as small white crystals, m. p. 251–253° dec.

Anal. Calcd. for $C_{22}H_{37}O_2N_3$: C, 70.3; H, 9.9. Found: C, 70.5; H, 10.0.

Uraneone-11.—To a boiling mixture of 600 mg. of uranedione-3,11, 60 cc. of 95% ethanol and 10 g. of 20-mesh zinc was added 8 cc. of concentrated hydrochloric acid over a period of three hours. The solution was decanted into water and the mixture extracted with ether. Evaporation of the ether gave a product which crystallized from acetone as white needles, m. p. 135–136.5°, yield 500 mg.

Anal. Calcd. for $C_{21}H_{34}O$: C, 83.4; H, 11.3. Found: C, 83.5; H, 11.5.

The product was recovered unchanged after treatment with semicarbazide acetate for one hour.

Hydrogenation of Uraneone-11.—A mixture of 275 mg. of uraneone-11, 120 cc. of acetic acid and 500 mg. of Adams catalyst was shaken with hydrogen at 3 atmospheres pressure, at 25° for seven hours. The mixture was filtered and the reduction product sublimed in high vacuum at 80–100°. The sublimate was crystallized repeatedly from methanol to give white crystals which melted poorly at 110°.

Anal. Calcd. for $C_{21}H_{36}O$: C, 82.8; H, 11.9. Found: C, 82.5; H, 12.0.

With boiling acetic anhydride the product yielded an **acetate** which crystallized from aqueous acetone as fine white needles, m. p. 140–142°.

Anal. Calcd. for $C_{23}H_{38}O$: C, 79.7; H, 11.1. Found: C, 80.0; H, 11.1.

Uranedione-11,20.—Uranetrione (600 mg.) was reduced by the Clemmensen method as described for uranedione-3,11. After sublimation in high vacuum, the product was crystallized from ether–pentane as white needles, m. p. 199–201°.

Anal. Calcd. for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2. Found: C, 80.0; H, 10.2.

Summary

The following reactions of urane derivatives have been observed:

1. Uranedione on partial oxidation with chromic anhydride yielded uraneol-3(β)-one-11. Uranediol on oxidation with aluminum isopropylate gave uraneol-11-one-3.

2. Mild catalytic hydrogenation of uranedione-3,11 gave uraneol-3(β)-one-11. Similar results were obtained on mild reduction with aluminum isopropylate.

3. Mild Clemmensen reduction of uranedione-3,11 gave uranone-11. Vigorous reduction gave urane. Mild Clemmensen reduction of uranetrione gave uranedione-11,20.

4. Urenedione has been prepared from bromouranedione.

STATE COLLEGE, PENNA. RECEIVED JULY 5, 1939

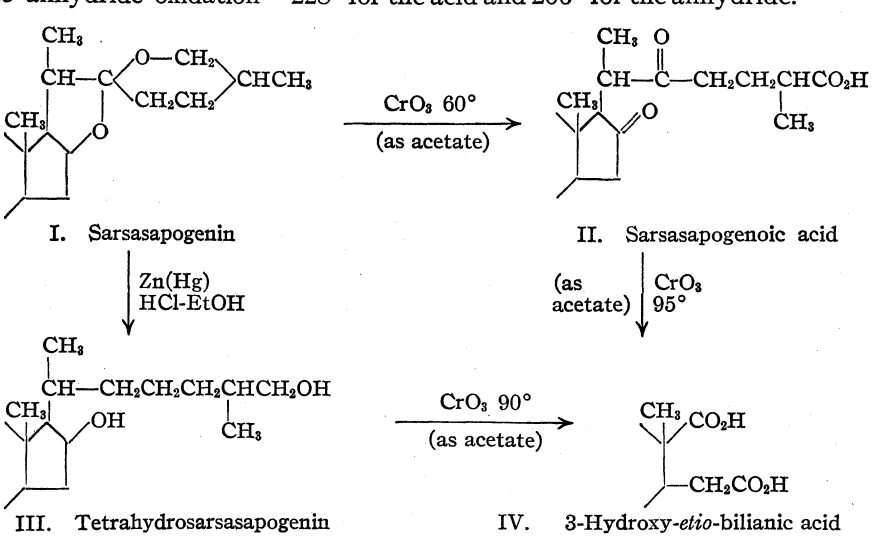
Sterols. LXXII. Oxidation Products of Sarsasapogenin. C_{19} Dibasic Acid

BY RUSSELL E. MARKER AND EWALD ROHRMANN

The fact that sarsasapogenin contains a substituent at C-16 and has by indirect methods been degraded to *etio*-bilianic acid[1] suggests that 3-hydroxy-*etio*-bilianic acid might be expected among the acidic products obtained by the direct oxidation of sarsasapogenin acetate with chromic anhydride.

In extending our investigation of the acidic products from the chromic anhydride oxidation of sarsasapogenin acetate (conducted at 85°), we have isolated from the hydrolyzed acidic fraction in addition to the C_{22} keto acid previously reported[2] a dibasic hydroxy acid of the composition $C_{19}H_{30}O_5$. The acid gives a dimethyl ester with diazomethane. The resulting dimethyl ester was characterized further by the formation of an acetate. Treatment of the acid with acetic anhydride either by refluxing or by the pyridine method resulted in the formation of an acetate anhydride of the composition $C_{21}H_{30}O_5$ which upon alkaline hydrolysis yielded the original acid.

Mild oxidation of the acid followed by Clemmensen reduction yielded a desoxy acid of the composition $C_{19}H_{30}O_4$, m. p. 232°. With acetic anhydride the desoxy acid yielded an anhydride, m. p. 207°. Although no direct comparison was made, the desoxy acid is very probably identical with *etio*-bilianic acid first reported by Wieland[3] and co-workers, who reported a melting point of 228° for the acid and 206° for the anhydride.



I. Sarsasapogenin

II. Sarsasapogenoic acid

III. Tetrahydrosarsasapogenin

IV. 3-Hydroxy-*etio*-bilianic acid

The same hydroxy dibasic acid was obtained in almost 12% yield by the oxidation of sarsasapogenoic acid acetate at 90–95° with chromic anhydride. A similar oxidation of the product ob-

(1) Farmer and Kon, *J. Chem. Soc.*, 414 (1937).

(2) Marker and Rohrmann, THIS JOURNAL, **61**, 1285 (1939).

(3) Wieland, Schlichting and Jacobi, *Z. physiol. Chem.*, **161**, 80 (1926).

tained by the acetylation of tetrahydrosarsasapogenin in pyridine in the cold gave only a poor yield of the dibasic acid. This is in accordance with our recently suggested structure for the tetrahydro compound[4] (III). Such a substance would not be expected to yield readily an easily oxidizable intermediate β-diketone or β-keto acid such as would be formed from our suggested formulation of sarsasapogenoic acid[5] (II).

The fact that sarsasapogenoic acid is oxidized easily to the dibasic acid suggests that it is an intermediate in the oxidation of sarsasapogenin to the bilianic acid.

The recent work of Litvan and Robinson[6] on the conversion of estric acid the dibasic acid from estrone analogous to *etio*-bilianic acid, to estrone suggests a very interesting possible method of converting 3-hydroxy-*etio*-bilianic acid to testosterone.

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part

C_{19} Dibasic Acid. (a) **From Sarsasapogenin Acetate.**—The hydrolyzed acidic fraction obtained from the oxidation of sarsasapogenin acetate with twice its weight of chromic anhydride at 85° was taken up in ether and allowed to stand for several days. The C_{22} keto acid which separated was collected and the filtrate evaporated to a sirup. Upon dilution of the sirup with chloroform, white crystals separated. These were collected, washed with chloroform and crystallized from acetone–chloroform to give a product, m. p. 220–222°.

Anal. Calcd. for $C_{19}H_{30}O_5$: C, 67.4; H, 8.9; neut. equiv., 169. Found: C, 67.2; H, 9.0; neut. equiv., 175.

(b) **From Sarsasapogenoic Acid Acetate.**—The acidic fraction obtained by the chromic anhydride oxidation of sarsasapogenoic acid acetate (3.3 g.) at 90–95° after being freed from most of the C_{22} keto acid was crystallized from chloroform to give 300 mg. of compact white crystals, m. p. 219–222°. This gave no depression with the above sample.

Anal. Calcd. for $C_{19}H_{30}O_5$: C, 67.4; H, 8.9. Found: C, 67.4; H, 9.1.

(c) **From Tetrahydrosarsasapogenin.**—Tetrahydrosarsasapogenin (3 g.) was acetylated with acetic anhydride in pyridine for twenty hours at room temperature. The sirupy product was dissolved in 100 cc. of acetic acid and to this solution heated at 90–95° was added 8 g. of chromic anhydride in 60 cc. of 80% acetic acid over a period of one hour. The mixture was heated for an additional two hours at 95° and the products separated into neutral and acidic fractions in the usual manner. Only a very small amount of neutral material was obtained and this was not investigated further.

The alkaline extract was heated and hydrolyzed by heating for twenty minutes on the steam-bath. The acids obtained would not crystallize. The acid fraction was acetylated with hot acetic anhydride and sublimed in high vacuum, the fraction distilling at 160–180° being collected, hydrolyzed with ethanolic potassium hydroxide and the acid crystallized from chloroform to give 40 mg. of white crystals, m. p. 219–222°. This gave no depression with samples obtained previously.

Anal. Calcd. for $C_{19}H_{30}O_5$: C, 67.4; H, 8.9. Found: C, 67.0; H, 8.9.

Acetate Anhydride of C_{19} Dibasic Acid.—A mixture of 200 mg. of the dibasic acid and 4 cc. of acetic anhydride was refluxed for thirty minutes. The excess acetic anhydride was destroyed with water and the white solid collected and crystallized from aqueous acetone to give small flat white needles, m. p. 203–204°.

Anal. Calcd. for $C_{21}H_{30}O_5$: C, 69.6; H, 8.3. Found: C, 69.6; H, 8.4.

The same product was obtained by allowing the acid (50 mg.) to stand at room temperature for twenty hours with 10 cc. of pyridine and 0.3 cc. of acetic anhydride.

Hydrolysis of the acetate anhydride with ethanolic potassium hydroxide yielded the original dibasic acid.

Dimethyl Ester of Dibasic Acid.—A solution of 200 mg. of the acid in 15 cc. of ether and 2 cc. of methanol was treated with an excess of diazomethane in ether. The solvent was evaporated and the residual sirup crystallized from ether–pentane to give white needles, m. p. 121–122°.

Anal. Calcd. for $C_{21}H_{34}O_5$: C, 68.8; H, 9.3. Found: C, 68.9; H, 9.3.

A mixture of 50 mg. of the dimethyl ester and 3 cc. of acetic anhydride was refluxed for twenty minutes. The excess acetic anhydride was destroyed with water and the oily product crystallized from ether–pentane to give compact white crystals of a **dimethyl ester acetate,** m. p. 103–104°.

Anal. Calcd. for $C_{23}H_{36}O_6$: C, 67.6; H, 8.9. Found: C, 67.6; H, 8.8.

Desoxy Dibasic Acid.—To a solution of 500 mg. of the C_{19} dibasic acid in 20 cc. of acetic acid was added a solution of 300 mg. of chromic anhydride in 8 cc. of 80% acetic acid. After standing at room temperature for one hour the mixture was diluted with water and the precipitated solid taken up in ether. Evaporation of the ether gave a non-crystalline residue. This product was dissolved in 40 cc. of acetic acid and to this solution was added 6 g. of amalgamated zinc (20-mesh) and 20 cc. of concentrated hydrochloric acid. The resulting mixture was refluxed for six hours, diluted with water and extracted with ether. The residue remaining upon evaporation of the ether was refluxed with an excess of ethanolic potassium hydroxide for thirty minutes. Acidification with hydrochloric acid yielded a product which was crystallized from ether–pentane as small white crystals, m. p. 230–232°.

Anal. Calcd. for $C_{19}H_{30}O_4$: C, 70.8; H, 9.4. Found: C, 70.7; H, 9.6.

(4) Marker and Rohrmann, THIS JOURNAL, **61**, 846 (1939).
(5) Marker and Rohrmann, *ibid.*, **61**, 2072 (1939).
(6) Litvan and Robinson, *J. Chem. Soc.*, 1997 (1938).

This gave no depression with a sample, m. p. 228–231°, prepared by oxidizing desoxysarsasapogenin with chromic anhydride at 90–95°.

The desoxy acid (75 mg.), m. p. 230–232°, was refluxed for thirty minutes with acetic anhydride and the reaction product was sublimed in high vacuum at 120–140°. The sublimate was crystallized from ether–pentane to give white needles of the **desoxy anhydride**, m. p. 205.5–207°.

Anal. Calcd. for $C_{19}H_{28}O_3$: C, 75.0; H, 9.3. Found: C, 75.0; H, 9.4.

Treatment of the desoxy anhydride with hot ethanolic potassium hydroxide gave the desoxy acid, m. p. 230–232°.

Summary

The acetates of sarsasapogenin, tetrahydrosarsasapogenin, and sarsasapogenoic acid upon oxidation with chromic anhydride yield a C_{19} dibasic acid, probably 3-hydroxy-*etio*-bilianic acid.

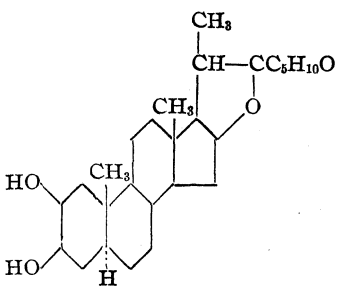
Sterols. LXXIII. Reactions of Digitogenin and Gitogenin

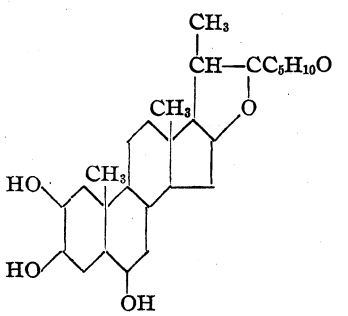
BY RUSSELL E. MARKER AND EWALD ROHRMANN

Although digitogenin (II) and gitogenin (I) were the first steroidal sapogenins to be studied,[1] the chemistry of the substances appears to be still in a somewhat confused state, particularly in regard to the nature of various oxidative degradation products. Unfortunately in all of the oxidation studies which have been reported on these substances no attempt was made to protect the reactive hydroxyl groups and therefore conclusions derived from such studies concerning the nature of the two less reactive oxygens must be regarded as of doubtful value.

The fact that tigogenin has been oxidized to gitogenic acid,[2,3] identical with that obtained by the chromic anhydride oxidation of gitogenin, shows conclusively that gitogenin is of the *allo*-configuration at C-5 and also offers strong support to the work of Tschesche and Hagedorn,[4] concerning the position of the nuclear hydroxyl groups. The evidence concerning the configuration of digitogenin at C-5 is not certain in spite of the fact that it has been degraded to gitogenic acid by the Wolff–Kishner reduction of digitogenic acid, inasmuch as inversion at C-5 may have occurred under the influence of alkali.



I. Gitogenin



II. Digitogenin

The fact that both α-methylglutaric acid and methylsuccinic acids have been reported from the chromic anhydride oxidation of digitogenic acid[2,4] is in accordance with our recently proposed structure of the sapogenin side chain III.[5] It is no longer necessary to regard the formation of α-methylglutaric acid as arising from the oxidation of the nucleus of the sapogenin as was necessitated by structure IV of Tschesche and Hagedorn.[4,6]

Contrary to Tschesche and Hagedorn,[7] we have found that both digitogenin and gitogenin yield insoluble digitonides, a characteristic which evidently is shown by all of the known steroidal sapogenins.

Digitogenin and gitogenin both readily yield dihydro compounds[5] upon catalytic hydrogenation in acidic medium. These dihydro compounds have not been investigated further. The acetates of digitogenin and gitogenin yield with

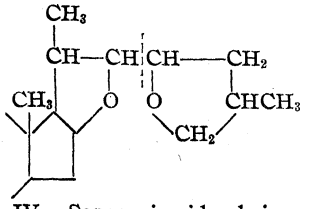
III. Sapogenin side chain



IV. Sapogenin side chain (Tschesche and Hagedorn[7])

bromine characteristic monobromo derivatives. Gitogenin and digitogenin also react with selenium dioxide.

That these two sapogenins are related more closely to tigogenin[8] than to sarsasapogenin is shown further by the fact that they appear to be relatively inert to treatment with alcoholic hydrochloric acid. Attempts to reduce the substances by the Clemmensen method[3] were unsuccessful.

The acetates of the C_{22} lactones of digitogenin and gitogenin were prepared by oxidizing digitogenin triacetate and gitogenin diacetate with chromic anhydride at 90–95°, the yields being comparable to those obtained by similar oxidations of sarsasapogenin and tigogenin acetates. Hydrolysis of the acetate lactones gave the corresponding hydroxy lactones.

We wish to thank Parke, Davis and Company for their generous support and assistance in the various phases of this work. We also wish to thank Mr. Paul H. Williams and Drs. Elmer J. Lawson and H. C. Benedict for their assistance in obtaining the bulbs of *Chlorogalum pomeridianum*.

Experimental Part

Isolation of Gitogenin from Chlorogalum Pomeridianum.—The filtrate remaining after removal of the chlorogenin and tigogenin from *Chlorogalum pomeridianum* was evaporated to dryness and the crystalline residue acetylated by boiling for thirty minutes with a large excess of acetic anhydride. The acetic anhydride was evaporated *in vacuo* and the residue crystallized from acetone to give white needles, m. p. 241–243°. This gave no depression with a sample of gitogenin diacetate prepared from gitogenin isolated from *Digitalis purpurea*.

Anal. Calcd. for $C_{31}H_{48}O_6$: C, 72.1; H, 9.4. Found: C, 72.4; H, 9.5.

Hydrolysis of the acetate with ethanolic potassium hydroxide yielded a product which crystallized from 95% ethanol as fine white needles, m. p. 266–268°. This gave a 25° depression when mixed with chlorogenin. This gave no depression with a sample of gitogenin isolated from *Digitalis purpurea*.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 74.9; H, 10.2. Found: C, 74.6; H, 10.2.

When heated with an acetic acid solution of selenium dioxide the substance readily yielded a red precipitate.

Gitogenin was recovered unchanged after treatment with amalgamated zinc and hydrochloric acid in alcohol solution for six hours.

Digitogenin from Recovered Digitonin.—To a hot solution of 50 g. of recovered digitonin in 400 cc. of absolute methanol was added a mixture of 100 cc. of concentrated hydrochloric acid, 100 cc. of water and 100 cc. of methanol. The resulting mixture was refluxed for eight hours. The material showed a considerable tendency to froth during the first two hours of refluxing. The mixture was then diluted with water and the white precipitate collected, washed with water and dried. The dried material was treated with Norite in 95% ethanol. Concentration of the alcoholic solution yielded white crystals which were recrystallized from dry benzene to give fine white needles, m. p. 278°.

Anal. Calcd. for $C_{27}H_{44}O_5$: C, 72.3; H, 9.9. Found: C, 72.6; H, 9.8.

The product reacted readily with a hot solution of selenium dioxide in acetic acid. Digitogenin was recovered essentially unchanged after treatment with amalgamated zinc and hydrochloric acid in ethanol solution for five hours.

Dihydrogitogenin.—A mixture of 2 g. of gitogenin diacetate, 1 g. of Adams catalyst and 100 cc. of glacial acetic acid was shaken with hydrogen (3 atmospheres) at 70° for twelve hours. The mixture was filtered and the acetic acid evaporated *in vacuo*. The residual sirup was hydrolyzed for twenty minutes in alcoholic potassium hydroxide. The resulting solution was diluted with water and the mixture extracted with ether and the product crystallized from ethyl acetate to give fine white needles, m. p. 195–197°. The substance gave a precipitate with digitonin. The substance showed no tendency to react with selenium dioxide.

Anal. Calcd. for $C_{27}H_{46}O_4$: C, 74.6; H, 10.7. Found: C, 74.1; H, 10.7.

Tri-*p*-nitrobenzoate of Dihydrogitogenin.—A solution of 100 mg. of dihydrogitogenin and 400 mg. of *p*-nitrobenzoyl chloride in 10 cc. of pyridine was heated on the steam-bath for six hours. After dilution with water the neutral material was crystallized from ether–acetone as pale yellow crystals, m. p. 189–191°.

Anal. Calcd. for $C_{48}H_{55}O_{18}N_3$: C, 65.35; H, 6.3. Found: C, 65.0; H, 6.3.

Dihydrodigitogenin.—This was prepared as described for dihydrogitogenin. The product was crystallized from acetone as white needles, m. p. 184–186°.

Anal. Calcd. for $C_{27}H_{46}O_5$: C, 71.9; H, 10.3; mol. wt.,

(8) Marker and Rohrmann, THIS JOURNAL, **61**, 1516 (1939).

450. Found: C, 71.6, 71.9, H, 10.5, 10.3, mol. wt. (Rast), 434.

Bromogitogenin Diacetate.—To a solution of 300 mg. of gitogenin diacetate in 30 cc. of acetic acid acidified with 2 drops of 48% hydrobromic acid was added 0.6 cc. of 1.05 *M* bromine in acetic acid. The solution was diluted with water and the precipitate collected, washed with water and dried. The product was crystallized from acetone–methanol as white needles, m. p. 219–220° dec.

Anal. Calcd. for $C_{31}H_{47}O_6Br$: C, 62.5; H, 8.0. Found: C, 62.3; H, 8.0.

When reduced with sodium and absolute ethanol the bromo compound yielded gitogenin, m. p. 265–267°.

The bromo compound showed no evidence of reaction when heated with an acetic acid solution of selenium dioxide.

Bromodigitogenin Triacetate.—This was prepared as described for bromogitogenin diacetate. The product was crystallized from aqueous methanol as white crystals, m. p. 142° dec.

Anal. Calcd. for $C_{33}H_{49}O_8Br$: C, 60.6; H, 7.6. Found: C, 60.8; H, 7.6.

Its behavior toward selenium dioxide and sodium and ethanol was analogous to that of the gitogenin compound.

Digitogenin Lactone Triacetate.—To a solution of 3 g. of digitogenin triacetate in 100 cc. of glacial acetic acid heated at 95° was added a solution of 5 g. of chromic anhydride in 60 cc. of 80% acetic acid over a period of one hour. The resulting mixture was heated for an additional ninety minutes. The mixture was evaporated *in vacuo* to a volume of about 50 cc. The residual solution, after dilution with water, was extracted with ether and the ethereal extract washed with 3% sodium hydroxide solution to remove acidic products. The ether was evaporated and the residue crystallized from acetone as compact white crystals, m. p. 281–283°.

Anal. Calcd. for $C_{28}H_{40}O_8$: C, 66.6; H, 8.0. Found: C, 66.7; H, 8.1.

Hydrolysis of the lactone acetate with an excess of ethanolic potassium hydroxide gave the **trihydroxy lactone** which crystallized from acetone as small white crystals, m. p. 279–282°.

Anal. Calcd. for $C_{22}H_{34}O_5$: C, 69.8; H, 9.0; neut. equiv., 378. Found: C, 69.4; H, 9.0; neut. equiv., 379.5.

Gitogenin Lactone Diacetate.—This was prepared from gitogenin diacetate as described for digitogenin lactone triacetate. The material was crystallized from acetone–pentane as compact white crystals, m. p. 248–251°.

Anal. Calcd. for $C_{26}H_{38}O_6$: C, 69.9; H, 8.7. Found: C, 69.7; H, 8.6.

Hydrolysis of the resulting diacetate with ethanolic potassium hydroxide yielded the **gitogenin lactone** which crystallized from ether–acetone as white needles, m. p. 276–278°.

Anal. Calcd. for $C_{22}H_{34}O_4$: C, 72.9; H, 9.5. Found: C, 72.6; H, 9.4.

Treatment of the dihydroxy lactone with benzoyl chloride in pyridine at room temperature for two days gave a **dibenzoate lactone** which, after treatment with Norite, crystallized from aqueous acetone as white needles, m. p. 275–278°.

Anal. Calcd. for $C_{36}H_{42}O_6$: C, 75.75; H, 7.4. Found: C, 76.0; H, 7.5.

Digitonides of Digitogenin and Gitogenin.—To a hot solution of 250 mg. of digitogenin in 35 cc. of 95% ethanol was added a boiling solution of 1.1 g. of digitonin in 35 cc. of 80% ethanol. A precipitate started to separate after thirty minutes and after standing overnight at room temperature the precipitate was collected, washed with 95% ethanol and dried: yield of digitonide, 800 mg. This was dissolved in 10 cc. of pyridine and the resulting solution heated on the steam-bath for twenty-five minutes. The solution was then poured into a mixture of 200 cc. of ether and 15 cc. of methanol. The white precipitate was collected and washed with ether. The filtrate after shaking with dilute hydrochloric acid was evaporated and the residue crystallized from acetone–benzene to give 180 mg. of fine white needles, m. p. 276–279°. This gave no depression with a sample of digitogenin.

Similar results were obtained with gitogenin.

Summary

Gitogenin and digitogenin resemble sarsasapogenin and tigogenin in their behavior toward catalytic hydrogenation, bromination and oxidation with selenium dioxide. They are relatively inactive toward isomerization with hydrochloric acid and Clemmensen reduction.

The C_{22} lactones of digitogenin and gitogenin have been prepared.

The Acetylation of Lactic Esters by Ketene

BY H. V. CLABORN AND LEE T. SMITH

The acetylation of lactic esters was accomplished first by Wislicenus[1] who acetylated ethyl lactate by means of acetyl chloride. He did not, however, report the yield obtained. More recently Burns and his co-workers[2] have used acetic anhydride for the acetylation of methyl, ethyl, butyl, and benzyl lactates. They reported yields of 81, 91, 92, and 70%, respectively. The authors have duplicated these results and in the case of methyl lactate have increased the yield to 92% of the theoretical. The improvement was due to: (1) the fact that the sulfuric acid used to catalyze the reaction was neutralized with calcium carbonate before the fractional distillation and (2) the use of a 24-inch (61-cm.) Widmer fractionating column, which proved very efficient in removing the acetic acid. This method also has been used with good results for acetylating other lactic esters.

Ketene has been used for the acetylation of alcohols,[3] primary amines,[3] amino acids,[4] ethyl mercaptan,[5] carbohydrates,[6] and phenols.[7] Hurd and Williams[5] have found that α-hydroxy acids such as benzilic and mandelic react with two moles of ketene to form acetylbenzilic acetic anhydride and acetylmandelic acetic anhydride, respectively. In order to obtain the corresponding acetoxy acids, it is necessary to decompose these anhydrides. However, the use of ketene for the acetylation of the esters of α-hydroxy acids has not been recorded.

The authors have found that when a trace, one drop per mole, of sulfuric acid[8] is present to catalyze the reaction, ketene reacts very smoothly with the lactic esters, and the yield of the corresponding α-acetoxypropionate obtained is practically the theoretical.

$$\underset{\text{OH}}{\overset{|}{\text{CH}_3\text{CHCOOR}}} + \text{CH}_2{=}\text{CO} \longrightarrow \underset{\text{CH}_3\text{COO}}{\overset{|}{\text{CH}_3\text{CHCOOR}}}$$

Since the lactic esters and the acetylated esters are both liquids, no solvent is necessary. This also makes possible the use of higher temperatures and, consequently, faster rates of reaction. The ketene may be introduced directly into the ester containing the sulfuric acid catalyst. Since the ketene reacts so readily with these esters, it is necessary to use only a slight excess to complete the reaction. This method is simplified further by the fact that the ketene produced by the pyrolysis of acetone may be used without purification. The reaction product requires only an ordinary type distillation for purification and not a fractional distillation as is required to remove the acetic acid when acetic anhydride is used.

In addition to the preparation of methyl, ethyl, butyl, and benzyl α-acetoxypropionates the physical properties of which already have been recorded,[2] *n*-propyl, isopropyl, isobutyl, *n*-amyl, and isoamyl α-acetoxypropionates were prepared both with ketene and with acetic anhydride. Glycol monolactate reacts with two moles of ketene and glycol monolactate diacetate is formed.

$$\underset{\text{OH}}{\overset{|}{\text{CH}_3\text{CHCOOCH}_2\text{CH}_2}}\underset{\text{OH}}{\overset{|}{}} + 2\text{CH}_2{=}\text{CO} \longrightarrow \underset{\text{CH}_3\text{COO}}{\overset{|}{\text{CH}_3\text{CHCOOCH}_2\text{CH}_2}}\underset{\text{CH}_3\text{COO}}{\overset{|}{}}$$

Some of the physical properties of these new compounds are recorded.

Experimental

The ketene used was prepared by the pyrolysis of acetone by the method of Hurd and Williams[5] modified by Williams.[9] The ketene was used directly as it was produced without purification. A typical example is given.

Methyl α-Acetoxypropionate.—Six moles (624 g.) of methyl lactate containing two drops of sulfuric acid was treated with ketene at the rate of 0.28 mole per hour for twenty-two hours (6.16 moles). The exothermic reaction caused the reaction flask to become quite warm after a few minutes, and it was immersed in an ice water-bath until the reaction was complete. No color change took place in the reaction flask until the end of the experiment. Then a yellow color developed which changed to a dark brown on standing overnight. This color change is an indication that the reaction is complete, for apparently it

* Glycol monolactate diacetate.

is the result of polymerization of the excess ketene. If the reaction mixture is not allowed to stand for a few hours before distillation, this yellow color may later develop in the final distilled product. The reaction product distilled at 68–73° at 14 mm.; yield, 844 g. or 96.4%.

Methyl, isobutyl, *n*-propyl, isopropyl, *n*-amyl and isoamyl lactate were acetylated with acetic anhydride by the method of Burns.[2] Calcium carbonate was added to neutralize only the sulfuric acid used for catalyst, and the reaction product was fractionated in vacuum with a 24-inch (61-cm.) Widmer fractionating column.

Benzyl lactate was prepared from benzyl chloride and sodium lactate.[10]

Acknowledgment.—The authors are grateful to Dr. J. W. Williams for his helpful suggestions and kind permission to copy the ketene lamp designed by him and now in use in his laboratory at the University of Maryland.

(10) M. Gomberg and C. C. Buchler, THIS JOURNAL, **42**, 2064 (1920).

Summary

The methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl, isobutyl, *n*-amyl, isoamyl and benzyl lactates and glycol monolactate were acetylated with ketene in the presence of a trace of sulfuric acid as catalyst. The yields were greater than those obtained when acetic anhydride was used, being practically quantitative. Six new compounds were prepared: namely, *n*-propyl, isopropyl, isobutyl, *n*-amyl, and isoamyl α-acetoxypropionates and glycol monolactate diacetate. Some of the physical properties of these compounds are given.

Synthesis of *t*-Butyl- and *t*-Amylcyclopentane and of their Intermediate Products[1]

BY HERMAN PINES AND V. N. IPATIEFF

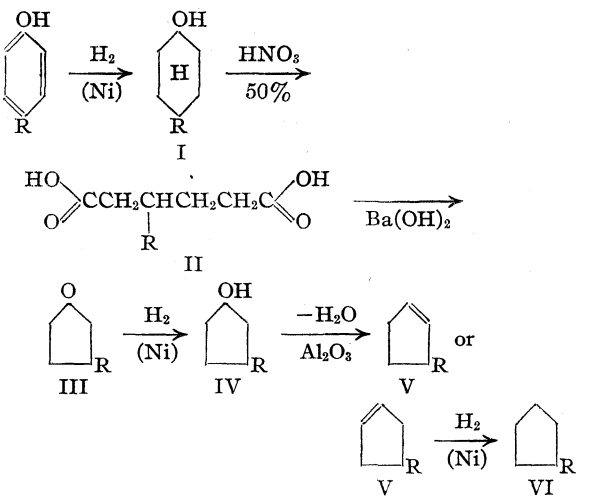
The preparation of *t*-alkylcyclopentanes has not been reported hitherto in the literature. Although the reaction of cyclopentanone with alkylmagnesium halide has been used successfully by others and also in our laboratory[2] for the preparation of several of the alkylcyclopentanes, the use of *t*-butylmagnesium halide did not yield the expected *t*-butylcyclopentanol, which would be an intermediate in the preparation of *t*-butylcyclopentane. Similarly, *t*-butylmagnesium bromide on reacting with cyclopentyl bromide gave only small yields of *t*-butylcyclopentane.

The method described in this paper for the preparation of *t*-alkylcyclopentane consists in cyclicizing alkyladipic acid to alkylcyclopentanone, a method which had been employed for the preparation of methylcyclopentanone. The starting products for the preparation of *t*-butyl- and *t*-amylcyclopentane were, respectively, *p*-*t*-butyl- and *p*-*t*-amylphenol, compounds which are now commercially available. The phenols were converted by catalytic hydrogenation to the corresponding *t*-alkylcyclohexanol; the latter on oxidation with nitric acid solution yielded β-*t*-butyl- and β-*t*-amyladipic acid. The β-*t*-alkyladipic

(1) Presented before the Division of Organic Chemistry at the American Chemical Society Meeting, Baltimore, Md., April 3–6, 1939.

(2) Chavanne and Becker, *Bull. soc. chim. Belg.*, **36**, 591 (1927); Pines and Ipatieff, THIS JOURNAL, **61**, 1076 (1939).

acids were converted into the 3-*t*-alkylcyclopentanones which were characterized by their solid semicarbazones and 2,4-dinitrophenylhydrazones. The yield of the 3-*t*-alkylcyclopentanone obtained based on the 4-*t*-butyl- and 4-*t*-amylcyclohexanol used was of the order of 60–75%. The alkyl cyclopentanone was hydrogenated catalytically to 3-*t*-butyl- and 3-*t*-amylcylopentanol, characterized by the α-naphthylurethans they yield with α-naphthyl isocyanate. The carbinols were dehydrated by the use of aluminum oxide to the olefins and the latter hydrogenated to *t*-butyl- and *t*-amylcyclopentane. The position of the double bond in the *t*-alkylcyclopentane is being investigated. The yields obtained on hydrogenation and dehydrogenation are almost quantitative. The methods of preparation may be illustrated as follows



(R = *t*-Butyl or *t*-Amyl)

Experimental

1. 4-*t*-Alkylcyclohexanol.—The compounds were prepared by hydrogenation in an Ipatieff type electrically heated rotating autoclave of 10 parts of the *p*-*t*-butyl- and *p*-*t*-amylphenols in the presence of 1 part of nickel catalyst with 100 atmospheres of hydrogen at 125°. The hydrogenated product did not contain any unreacted alkylphenol, since it gave a negative test with ferric chloride.

4-*t*-Butylcyclohexanol, m. p. 82° (crystallized from *n*-heptane).

4-*t*-Amylcyclohexanol, m. p. 24–25°, b. p. 154–155° at 40 mm., d^{20}_4 (vac.) 0.9034. *Anal.* Calcd. for $C_{11}H_{22}O$: C, 77.56; H, 13.03. Found: C, 77.50; H, 12.95.

α-Naphthylurethan crystallized twice from heptane, m. p. 113°. *Anal.* Calcd. for $C_{22}H_{29}O_2N$: C, 77.95; H, 8.91. Found: C, 77.79; H, 8.48.

II. β-*t*-Alkyladipic Acids.—These were prepared by the procedure described by Niederl and Smith.[3] Several portions consisting of 1 mole of *t*-alkylcyclohexanol and 560 cc. of 50% nitric acid were heated in the presence of 0.5 g. of ammonium vanadate.

β-*t*-Butyladipic acid (yield 87%) crystallized twice from hot water, m. p. 117° (uncorr.). *Anal.* Calcd. for $C_{10}H_{18}O_4$: C, 59.36; H, 9.44. Found: C, 59.12; H, 9.25.

β-*t*-Amyladipic acid (yield 95%) crystallized twice from hot water, m. p. 77–78°. *Anal.* Calcd. for $C_{11}H_{20}O_4$: C, 61.06; H, 9.31. Found: C, 61.09; H, 9.35.

III. 3-*t*-Alkylcyclopentanone.—One hundred and eighty grams of β-alkyladipic acid was heated in a short-necked distilling flask with 18 g. of barium hydroxide at 280°. Water and alkylcyclopentanone generated during heating were collected in a receiver; at the end of one and one-half to two hours of heating the content of the flask was composed of a solid mass and no more liquid distilled over. The alkylcyclopentanone was separated from the water layer, washed with sodium bicarbonate solution and then dried over anhydrous sodium sulfate.

3-*t*-Butylcyclopentanone (yield 64–70%), boiling point 200–201° at 759 mm., $d^{20}_{vac.}$ 0.9031; n^{20}_D 1.4505. *Anal.* Calcd. for $C_9H_{16}O$: C, 77.07; H, 11.50. Found: C, 76.83; H, 11.43.

Semicarbazone crystallized from 50% ethanol; m. p. 194–194.5° (uncorr.) decomposes. *Anal.* Calcd. for $C_{10}H_{19}N_3O$: N, 21.32. Found: N, 21.26.

2,4-Dinitrophenylhydrazone.—Crystallized from 95% ethanol, m. p. 139° (uncorr.). *Anal.* Calcd. for $C_{15}H_{20}O_4N_4$: N, 17.50. Found: N, 17.53.

3-*t*-Amylcyclopentanone, yield 75–80%, b. p. 120° at 27 mm., $d^{20}_{vac.}$ 0.9159; $n^{20}D$ 1.4601. *Anal.* Calcd. for $C_{10}H_{18}O$: C, 77.85; H, 11.77. Found: C, 78.06; H, 11.72.

Semicarbazone.—Crystallized from 50% ethanol, m. p. 189° (uncorr.). *Anal.* Calcd. for $C_{11}H_{21}N_3O$: N, 19.88. Found: N, 19.66.

2,4-Dinitrophenylhydrazone.—Crystallized from 95% ethanol, m. p. 174.5° (uncorr.). *Anal.* Calcd. for $C_{16}H_{22}O_4N_4$: N, 16.75. Found: N, 16.72.

IV. 3-*t*-Alkylcyclopentanol.—The alcohol was prepared by hydrogenating 10 parts of *t*-alkylcyclopentanone in the presence of 1 part of nickel catalyst at 80° and 100 atmospheres initial hydrogen pressure. When the pressure during hydrogenation decreased to 60 atmospheres, the bomb was recharged to 100 atmospheres. The hydrogenation was considered completed when there was no decrease in hydrogen pressure for a period of two hours.

3-*t*-Butylcyclopentanol.—B. p. 196–198° at 744 mm., $d^{20}_{vac.}$ 0.9006; $n^{20}D$ 1.4574. *Anal.* Calcd. for $C_9H_{18}O$: C, 75.98; H, 12.77. Found: C, 76.11; H, 12.74.

α-Naphthylurethan.—Crystallized from heptane, m. p. 95°. *Anal.* Calcd. for $C_{20}H_{25}O_2N$: C, 77.12; H, 8.09; N, 4.50. Found: C, 76.94; H, 7.60; N, 5.00.

3-*t*-Amylcyclopentanol.—B. p. 217° at 738 mm., $d^{20}_{vac.}$ 0.9114, $n^{20}D$ 1.4656. *Anal.* Calcd. for $C_{10}H_{20}O$: C, 76.84; H, 12.91. Found: C, 77.07; H, 12.76.

α-Naphthylurethan crystallized from heptane, m. p. 82°. *Anal.* Calcd. for $C_{21}H_{27}O_2N$: C, 77.48; H, 8.37; N, 4.30. Found: C, 77.18; H, 8.15; N, 4.57.

V. *t*-Alkylcyclopentenes.—The olefins were prepared by dehydrating *t*-alkylcyclopentanols by passing the carbinols over 40 g. of activated alumina with a rate of 40

(3) Niederl and Smith, THIS JOURNAL, **59**, 717 (1937).

cc. per hour and at a temperature of 345°. The dehydration was quantitative. The olefins were separated from the water, dried over sodium sulfate and distilled over metallic sodium. The position of the double bond in the dehydrated *t*-alkylcyclopentanol is being studied.

***t*-Butylcyclopentene.**—Boiling point by Cottrell[4] method, 139.6° at 760 mm., dT/dP (770 to 730 mm.) = 0.048°/mm., $d^{20}_{vac.}$ 0.8021; $d^{40}_{vac.}$ 0.7861; $n^{20}D$ 1.4421; $n^{20}H_\beta$ 1.4486; $n^{20}H_\alpha$ 1.4397; Δ^{20} (dispersion) 88.8; δ^{20} (specific dispersion) 110.7. *Anal.* Calcd. for C_9H_{16}: C, 87.08; H, 12.92. Found: C, 87.35; H, 12.90.

***t*-Amylcyclopentene.**—B. p. 163–165° at 743 mm., $d^{20}_{vac.}$ 0.8256; $n^{20}D$ 1.4554; $n^{20}H_\beta$ 1.4618; $n^{20}H_\alpha$ 1.4527; Δ^{20} 90.8; δ^{20} 110.0. *Anal.* Calcd. for $C_{10}H_{18}$: C, 86.86; H, 13.14. Found: C, 86.72; H, 13.27.

VI. *t*-Alkylcyclopentane.—This hydrocarbon was prepared by hydrogenating at 60° *t*-alkylcyclopentene in the presence of 10% by weight of nickel catalyst and 100 atmospheres of hydrogen. The hydrogenation proceeded to completion, for the final product was stable toward a nitrating mixture composed of 2 volumes of concentrated sulfuric acid and 1 volume of concentrated nitric acid.

***t*-Butylcyclopentane,** m. p. −96 ± 0.2°, boiling point by Cottrell method 145.2° at 760 mm., dT/dP (770–730 mm.) = 0.052°/mm., $d^{20}_{vac.}$ 0.7911; $d^{40}_{vac.}$ 0.7753; $n^{20}D$ 1.4341; $n^{20}H_\beta$ 1.4396; $n^{20}H_\alpha$ 1.4320; Δ^{20} 76.4; δ^{20} 96.6. *Anal.* Calcd. for C_9H_{18}: C, 85.63; H, 14.37. Found: C, 85.75; H, 14.49.

***t*-Amylcyclopentane.**—Boiling point by Cottrell method 173.9° at 760 mm., dT/dP (770–730 mm.) = 0.054°/mm., $d^{20}_{vac.}$ 0.8071; $d^{40}_{vac.}$ 0.7923; $n^{20}D$ 1.4457; $n^{20}H_\beta$ 1.4511; $n^{20}H_\alpha$ 1.4433; Δ^{20} 78.0; δ^{20} 96.6. *Anal.* Calcd. for $C_{10}H_{20}$: C, 85.63; H, 14.37. Found: C, 85.63; H, 14.25.

Acknowledgment.—The authors wish to express their thanks to Mr. M. Savoyias for the assistance he rendered, to Mr. R. W. Moehl for the analyses and to Mr. R. C. Wackler for the refractometric measurements.

Summary

Synthesis of *t*-butyl- and *t*-amylcyclopentane from *p*-*t*-butyl- and *p*-*t*-amylphenols is described.

The following compounds and their derivatives were synthesized for the first time: 4-*t*-amylcyclohexanol, β-*t*-butyl- and β-*t*-amyladipic acid, 3-*t*-butyl- and 3-*t*-amylcyclopentanone, 3-*t*-butyl- and 3-*t*-amylcyclopentanol, *t*-butyl- and *t*-amylcyclopentene, *t*-butyl- and *t*-amylcyclopentane.

Utilization of Alkoxy Ketones in the Synthesis of Quinolines by the Pfitzinger Reaction

BY LOY B. CROSS[1,2] WITH HENRY R. HENZE

Although the utilization of simple aldehydes and ketones in the synthesis of quinoline acids has received considerable attention, but little effort has been made to use bifunctional carbonyl compounds in this manner. Indeed, Henze[3] has reported the initial investigation in which keto ethers were employed in the Pfitzinger reaction, namely, the preparation of four 3-aryloxy-4-quinaldinecarboxylic acids from the appropriate aryloxyacetones.

Our study of the utilization of keto ethers in the Pfitzinger reaction has been extended to include alkoxy ketones and the condensation of ethoxyacetone and ethoxymethyl ethyl ketone with isatin to produce the corresponding 2-alkyl-3-ethoxycinchoninic acids. However, no evidence has been obtained of the formation of any of the isomeric 2-ethoxyalkylcinchoninic acids.[4] The substituted cinchoninic acids are readily decarboxylated by heating at the temperature of their melting points to form 2-alkyl-3-ethoxyquinolines. Also, these 3-alkoxycinchoninic acids are cleaved at the ether linkage by heating with concentrated hydrochloric acid under pressure. The cinchoninic acids and the 2-alkyl-3-ethoxyquinolines are both extremely resistant to reduction by means of hydriodic acid and red phosphorus and no hydrogenation of the pyridine nucleus was observed. However, 2-ethyl-3-hydroxyquinoline was converted, by means of the reducing action of tin and hydrochloric acid, into 2-ethyl-1,2,3,4-tetrahydroquinoline. An attempt was made to form the phthalone of 3-ethoxyquinaldinic acid by heating with phthalic anhydride. Although the temperature employed was approxi-

(4) Methyl ethyl ketone reacts with isatin in alkaline solution to form both 2,3-dimethylcinchoninic acid [Pfitzinger, *J. prakt. Chem.*, **56**, 283 (1897)] and 2-ethylcinchoninic acid [von Braun, Gmelin and Schultheiss, *Ber.*, **56**, 1344 (1923)].

mately fifty degrees below that of the melting point of the quinoline acid, the product of the reaction proved to be the phthalone of 3-hydroxyquinaldine. The latter was obtained also by phthalonation of 3-hydroxyquinaldine.

Experimental

Preparation of Alkoxy Ketones.—**Ethoxyacetone** was prepared in 65% yield by interaction of 0.9 mole of ethoxyacetonitrile (76.5 g.) and the Grignard reagent produced from one gram atom of magnesium and 1.1 moles of methyl iodide; b. p. 34–36° (corr.) (28 mm.); $n^{20}D$ 1.4000; d^{20}_4 0.9117; *MR* calcd., 26.94; *MR* found, 27.16.

Ethoxymethyl ethyl ketone was prepared in the same manner in 51% yield; b. p. 53–54° (corr.) (24–25 mm.); $n^{20}D$ 1.4065; d^{20}_4 0.9064; *MR* calcd., 31.56; *MR* found, 31.52.

Preparation of 3-Ethoxycinchoninic Acids.—Forty-six grams of isatin (0.313 mole) was dissolved in 200 g. of 33% potassium hydroxide solution, 32 g. of ethoxyacetone (0.314 mole) was added and the mixture was heated under a reflux condenser for twenty-four hours on a steam-bath. The mixture was diluted with water to about 750 cc., decolorized with Norite, cooled with ice, and acidified with a slight excess of acetic acid. The solid which separated was filtered, washed and dried; weight 32 g. (44% yield). After recrystallization from hot water, **3-ethoxy-4-quinaldinecarboxylic acid** melts at 243° (corr.) with decomposition.

Anal. Calcd. for $C_{13}H_{13}NO_3$: C, 67.50; H, 5.67; N, 6.05; neut. equiv., 231.2. Found: C, 67.35; H, 5.67; N, 6.24; neut. equiv., 227.9.

From 60.0 g. of isatin (0.408 mole), dissolved in 300 g. of 33% potassium hydroxide solution, and 52 g. of ethoxymethyl ethyl ketone under the same conditions was obtained 93 g. (92% yield) of crude **2-ethyl-3-ethoxycinchoninic acid** melting at 168–177°. After recrystallization from hot water, colorless needles were obtained melting at 199–201° (corr.) with decomposition.

Anal. Calcd. for $C_{14}H_{15}NO_3$: C, 68.5; H, 6.17; N, 5.71; neut. equiv., 245.3. Found: C, 68.22; H, 6.32; N, 5.69; neut. equiv., 244.8.

In preparing **2-ethyl-3-ethoxy-6-methylcinchoninic acid,** 15 g. of 33% potassium hydroxide solution was used to dissolve 3.28 g. of 5-methylisatin (0.0223 mole) and, after adding 2.6 g. of ethoxymethyl ethyl ketone, the mixture was heated for ten hours under reflux on a steam-bath. The yield of crude product was 3.25 g. (56% of the theoretical). Purification was achieved by solution in 0.3 *N* sodium hydroxide, decolorization with Norite and reprecipitation with 0.3 *N* hydrochloric acid. Thus was obtained 2.25 g. (39% yield) of acid melting at 222° (corr.) with decomposition.

Anal. Calcd. for $C_{15}H_{17}NO_3$: C, 69.47; H, 6.55; N, 5.40; neut. equiv., 259.3. Found: C, 69.26; H, 6.55; N, 5.41; neut. equiv., 258.7.

Decarboxylation of 3-Ethoxy-2-alkylcinchoninic Acids.—Thirty grams of 3-ethoxy-4-quinaldinecarboxylic acid (0.13 mole) was heated in a 125-cc. Claisen distilling flask at 250°. The solid melted and then carbon dioxide was evolved. After heating for thirty minutes, the residual liquid was distilled at 140–141° (corr.) (2–3 mm.); the colorless material, weighing 14.5 g. (59% yield), solidified in the receiver. This product, **3-ethoxyquinaldine,**[5] melts at 68–69° (corr.).

Anal. Calcd. for $C_{12}H_{13}NO$: C, 76.97; H, 7.00; N, 7.49. Found: C, 76.62; H, 6.94; N, 7.21.

In a similar manner, **2-ethyl-3-ethoxyquinoline** was obtained by heating 7 g. of 2-ethyl-3-ethoxycinchoninic acid (0.0286 mole) at 210° which gave a colorless liquid, distilling at 138–140° (corr.) (3–4 mm.) and solidifying in the receiver. The yield of solid melting at 58.5° (corr.) was 2.7 g., corresponding to 47% of the theoretical.

Anal. Calcd. for $C_{13}H_{15}NO$: C, 77.61; H, 7.51; N, 6.97. Found: C, 77.74; H, 7.60; N, 6.98.

Cleavage of 3-Ethoxy-4-quinaldinecarboxylic Acid with Concd. Hydrochloric Acid.—Two grams of 3-ethoxy-4-quinaldinecarboxylic acid was heated with concd. hydrochloric acid in a sealed tube for two hours at 150°. The cooled reaction mixture was neutralized with sodium hydroxide, producing a chrome-yellow precipitate which was purified by solution in alkali and reprecipitation with acid, producing 1.25 g. of material melting at 242–244° (corr.) with decomposition. The product was shown to be **3-hydroxy-4-quinaldinecarboxylic acid.**[6]

Anal. Calcd. for $C_{11}H_9NO_3$: C, 65.03; H, 4.52; N, 6.89. Found: C, 65.75; H, 4.67; N, 6.82.

Cleavage of 2-Alkyl-3-ethoxyquinolines with Concd. Hydrochloric Acid.—Eleven and one-half grams of 3-ethoxyquinaldine and 50 cc. of concd. hydrochloric acid were heated together in a sealed tube for three hours at 180°. The reaction mixture was diluted with a little water and the acid was neutralized with sodium hydroxide. The white solid which separated was filtered, dissolved in dilute alkali and reprecipitated with acid; after drying at 110° the product weighed 8 g. (81.5% yield). When heated, **3-hydroxyquinaldine** darkens at about 250° and melts at 260° (corr.).[7]

Anal. Calcd. for $C_{10}H_9NO$: C, 75.49; H, 5.66; N, 8.80. Found: C, 75.50; H, 5.73; N, 8.68.

In a similar manner, 1 g. of 2-ethyl-3-ethoxyquinoline was heated with 10 cc. of concd. hydrochloric acid in a sealed tube for five hours at 200°. Upon dilution of the reaction mixture with a little water a white crystalline solid separated. The latter was dissolved in alkali and reprecipitated by addition of acetic acid. The yield of **2-ethyl-3-hydroxyquinoline,** of melting point 206–208° (corr.) with decomposition, thus obtained was 0.8 g. (93% of the theoretical).

Anal. Calcd. for $C_{11}H_{11}NO$: C, 76.26; H, 6.41; N, 8.09. Found: C, 75.57; H, 6.57; N, 8.22.

(5) Koenigs and Stockhausen, *Ber.*, **35**, 2556 (1902), report its preparation by the interaction of ethyl iodide and an alcoholic potassium hydroxide solution of 3-hydroxyquinaldine and its m. p. 69–70° (corr.).

(6) The synthesis of this compound, from isatic acid and halogenated acetone, has been reported recently [French patent 784,365, July 22, 1935, through *C. A.*, **30**, 111 (1936)] but no data concerning physical properties were recorded.

(7) Koenigs and Stockhausen, ref. 5, report that 3-hydroxyquinaldine, prepared by condensation of *o*-aminobenzaldehyde and chloroacetone in dilute aqueous sodium hydroxide solution, darkens at 240° (corr.) and melts at 260° (corr.).

Action of Hydriodic Acid and Red Phosphorus on 3-Ethoxyquinolines.—Two grams of 3-ethoxyquinaldine, 1.7 g. of red phosphorus and 20 cc. of hydriodic acid (sp. gr. 1.7) were heated together under reflux for seven days at 150°. The phosphorus was removed from the hot mixture by filtration through asbestos and the filtrate subjected to steam distillation to remove most of the hydrogen iodide. The residual solution was made basic with sodium hydroxide, cooled, extracted with ether, and the ether extract dried over sodium sulfate. The aqueous layer was acidified with acetic acid, causing a white solid to separate. The precipitate was filtered, washed with water and dried yielding material melting at 251–256°. The melting point of a mixture with an authentic sample of 3-hydroxyquinaldine was 253–257°.

Anal. Calcd. for $C_{10}H_9NO$: N, 8.80. Found: N, 8.68.

The ether extract was concentrated on a steam-bath, diluted with alcohol and treated with an alcoholic solution of picric acid. The solution was warmed, diluted with water to faint turbidity and cooled in ice. The bright yellow, crystalline precipitate was recrystallized from dilute alcohol; m. p. 192–194° (corr.).[8]

Anal. Calcd. for $C_{16}H_{12}N_4O_7$: N, 15.05. Found: N, 14.92.

In a similar manner, 6.6 g. of 2-ethyl-3-ethoxyquinoline, 5 g. of red phosphorus and 50 cc. of hydriodic acid (sp. gr. 1.7) were heated together under reflux, but for only twenty-four hours at 140–150°. After removal of the unreacted phosphorus, there separated 3 g. of a cream colored solid which contained iodine and melted at 193–198° (corr.). The melting point of a mixture with an authentic sample of the **hydroiodide of 2-ethyl-3-ethoxyquinoline** was 190–197° (corr.).

The filtrate from the hydroiodide yielded 1 g. of a white solid melting at 206–208° (corr.). Mixed with known 2-ethyl-3-hydroxyquinoline the melting point was 206–208° (corr.).

Attempted Reduction of 2-Ethyl-3-ethoxycinchoninic Acid with Hydriodic Acid and Red Phosphorus.—A mixture of 8.1 g. of 2-ethyl-3-ethoxycinchoninic acid, 5 g. of red phosphorus and 50 cc. of hydriodic acid (sp. gr. 1.7) was heated under reflux at 125° for twenty-four hours. The hot reaction mixture was filtered from phosphorus and cooled, when 2 g. of a chrome-yellow solid separated. After solution in alkali and reprecipitation with acid the product melted at 208–209° (corr.) with decomposition. Additional material was obtained from the filtrate, giving a total yield of 4.5 g., corresponding to 63.5% of the theoretical, of **2-ethyl-3-hydroxycinchoninic acid.**

Anal. Calcd. for $C_{12}H_{11}NO_3$: C, 66.33; H, 5.11; N, 6.45; neut. equiv., 217.2. Found: C, 66.26; H, 5.28; N, 6.67; neut. equiv., 207.6.

In a second attempt at reduction the mixture was refluxed at 140–150° for forty-eight hours with additions of hydriodic acid from time to time until a total volume of 50 cc. of acid had been added. A small amount of the **hydroiodide of 2-ethyl-3-ethoxyquinoline,** m. p. 190–197°, was obtained, but the chief product of the reaction was the bright yellow, crystalline 2-ethyl-3-hydroxycinchoninic acid.

Anal. Calcd. for $C_{13}H_{15}NO \cdot HI$: I, 38.57. Found: I, 39.09.

Phthalonation of Quinaldine Derivatives.—An intimate mixture of 1 g. of 3-hydroxyquinaldine and 1 g. of phthalic anhydride was heated for three hours at 200°. The cooled reaction mixture was dissolved in concd. sulfuric acid and the solution poured over ice. The brown solid which formed was purified by crystallization from glacial acetic acid. The **phthalone of 3-hydroxyquinaldine** is a dark orange colored solid melting at 264–266° (corr.) with decomposition.

Likewise, an intimate mixture of 23 g. of 3-ethoxy-4-quinaldinecarboxylic acid (0.1 mole) and 15 g. of phthalic anhydride (0.1 mole) was heated for five hours at 200°. After recrystallization from glacial acetic acid, the reaction product melted at 264.5–265.5° (corr.) with decomposition. A mixture of this material with the phthalone of 3-hydroxyquinaldine melted at 264–265° (corr.) with decomposition. The yield of phthalone from the carboxylic acid was 10 g., or 34%.

Anal. Calcd. for $C_{18}H_{11}NO_3$: C, 74.73; H, 3.83; N, 4.84; mol. wt., 289.3. Found: C, 74.88; H, 4.30; N, 5.00; mol. wt. (Rast), 298.6.

Reduction of 2-Ethyl-3-hydroxyquinoline.—The reduction of this compound was accomplished in the same manner as that utilized by Reher[9] for the reduction of 2-ethylquinoline. After 23 g. of 2-ethyl-3-ethoxyquinoline (0.15 mole) had been heated with 125 cc. of concd. hydrochloric acid in a sealed tube for five hours at 175°, the solution was diluted with 150 cc. of concd. acid and treated with 77 g. of granulated tin (0.65 gram atom); the mixture was warmed intermittently on a steam-bath until all of the tin had dissolved. Then the solution was saturated with hydrogen sulfide, made basic with sodium hydroxide and subjected to steam distillation. A colorless oil in the distillate was extracted with ether, dried over sodium sulfate and the extract distilled *in vacuo*. The product, **2-ethyl-1,2,3,4-tetrahydroquinoline,**[10] a colorless liquid boiling at 125–127° (corr.) (7 mm.), weighed 5 g. (21% yield); $n^{20}D$ 1.5652; d^{20}_4 1.0178; *MR* calcd., 51.89; *MR* found, 51.54.

Anal. Calcd. for $C_{11}H_{15}N$: C, 81.94; H, 9.38; N, 8.69. Found: C, 81.22; H, 9.33; N, 8.70.

A picrate was formed by the interaction of 2.5 g. of the reduction product and 3.5 g. of picric acid dissolved in 150 cc. of 75% alcohol. Five grams of bright yellow picrate was obtained (83% yield). After recrystallization from 95% alcohol, there was recovered 3.5 g. of the purified **picrate of 2-ethyl-1,2,3,4-tetrahydroquinoline** melting at 143–145° (corr.).

Anal. Calcd. for $C_{17}H_{18}N_4O_7$: N, 14.35. Found: N, 14.34.

Summary

1. Pfitzinger's method has been extended to include the utilization of alkoxy ketones in the initial synthesis of three examples of a new type of substituted cinchoninic acid. The structure of

(8) Pictet and Bunzl, *Ber.*, **22**, 1847 (1889), record that the picrate of quinaldine melts at 191° (corr.).

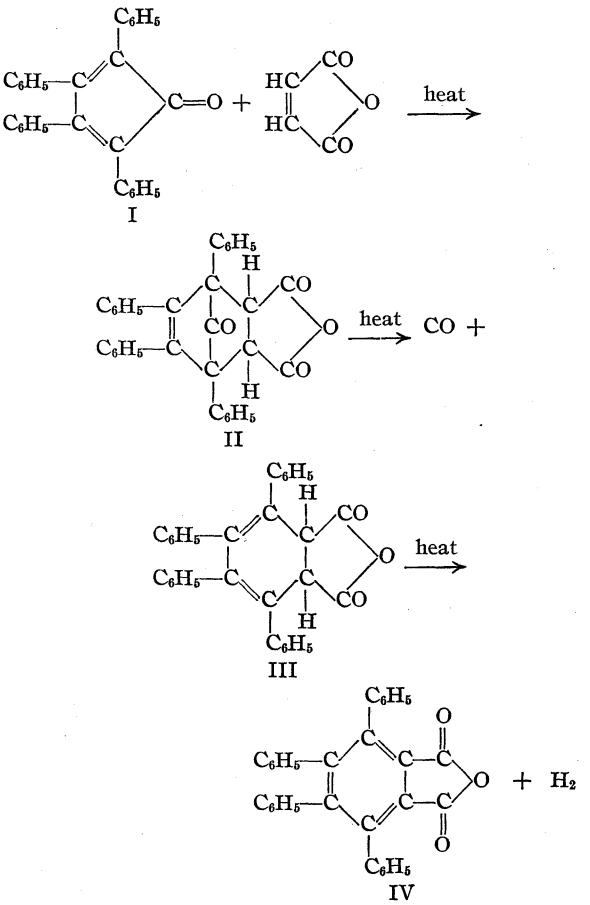
The Reaction of a Thiophene Derivative with Maleic Anhydride

BY DANIEL B. CLAPP[1]

It has been shown by Dilthey and his collaborators[2] that diene syntheses may be carried out readily between various highly arylated cyclopentadienones and maleic anhydride or other ethylenic or acetylenic derivatives. A typical example is the reaction of 2,3,4,5-tetraphenylcyclopentadienone (tetracyclone) (I) with maleic anhydride.[2a] The initial product of this reaction is 3,6-endocarbonyl-3,4,5,6-tetraphenyl-1,2-dihydrophthalic anhydride (II) which on heating successively loses carbon monoxide and hydrogen yielding tetraphenylphthalic anhydride (IV).

In the hope that the same product might be obtained in starting with the sulfur analog of tetracyclone, an attempt was made to bring about a reaction between tetraphenylthiophene (thionessal) and maleic anhydride. By analogy, if an adduct were formed, it might be expected to lose hydrogen sulfide. However, several attempts to carry out this reaction gave completely negative results.

Since it is well known that furan and many of its derivatives will take part readily in diene syntheses, undoubtedly attempts have been made to carry out such syntheses with corresponding thiophene derivatives. However, in a recent review of the Diels–Alder reaction[3] it is stated that no case of a thiophene derivative undergoing this reaction has been recorded. It is evident that the 1,4-conjugate system in thiophene compounds is less active than that present in furan derivatives, the former class being more aromatic in character and resembling benzene derivatives, none of which have been shown to undergo a Diels–Alder reaction. It may be noted that



Schomaker and Pauling[4] recently have shown that electron diffraction results, resonance energies, and other considerations indicate a greater degree of resonance stabilization for thiophene than for furan.

It is possible that the introduction of certain substituents into the thiophene nucleus might so activate the 1,4-system that a diene synthesis could occur. In the case of hydrindene, fixation

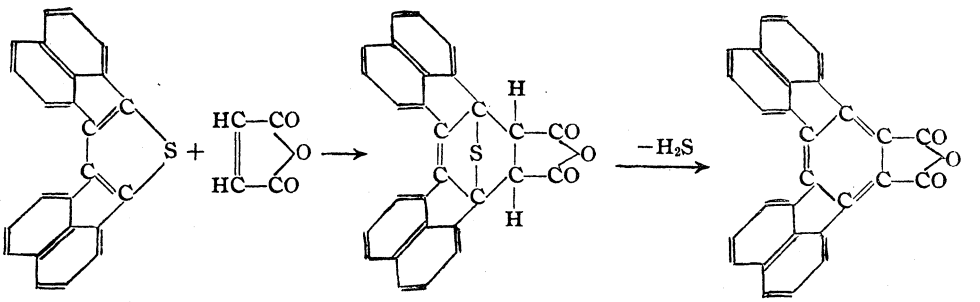
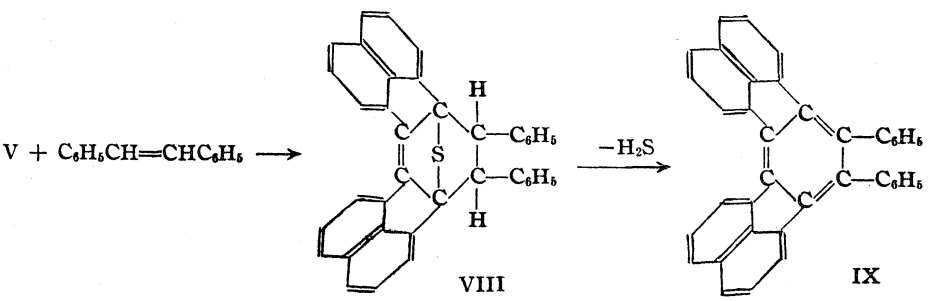
of the double bonds in the benzene ring, so as to leave a single bond common to the two rings, has been suggested.[5-7] Hence, it might be supposed that the presence of fused five-membered rings in the 2,3- and 4,5-positions of thiophene would increase the activity of the conjugate system, on account of the strain in such a molecule.

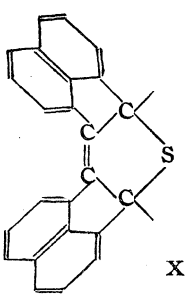
Since the resonance energy in hydrindene has been shown to be practically the same as in benzene,[8] the idea of the fixation of double bonds, at least in hydrindene, is untenable. It has been pointed out[9] that great differences in chemical reactivity may arise from quite small differences in electron distribution. However, the fixation hypothesis is certainly useful for the prediction of reactions and "reaction-structures," even though such structures do not represent completely the molecule in the physical sense.





For the application of this hypothesis to thiophene derivatives, a molecule of the desired type is found in 2,3,4,5-di-(1,8-naphthylene)-thiophene (V). The structure of this substance is indicated by its formation by the sulfur fusion of acenaphthene,[10,11] somewhat analogous to the formation of thionessal by the sulfur fusion of stilbene, and its oxidation to naphthalic anhydride.[10]

In benzene, the internal angle is 120°, which requires a reduction of 5.25° below the corresponding angle in open-chain structures; this necessitates increases in each of the two external angles.[5] Since the internal angles involved in thiophene, if the values calculated by Schomaker and Pauling[4] are assumed, are about 112°, in this case the external angles are increased still more. If it is assumed that these angles are increased proportionally, there will be a greater difference between the β-angle and the α-angle than in the case of benzene. In hydrindene, that structure in which the two greater angles, the β-angles, are included in the 5-ring, will be under the greater strain, since the normal internal angle of this 5-ring (108°) is more nearly equal to the α-angle. In dinaphthylenethiophene, an even greater distortion of the β-angles is required, particularly if the involved internal angles of the 5-ring are assumed to be those in acenaphthene; these latter, according to Banerjee and Sinha,[12] are 97°.



It has been found that dinaphthylenethiophene reacts smoothly with maleic anhydride. If a mixture of these two substances is heated at about 225°, evolution of hydrogen sulfide occurs, and the reaction product, which is obtained in good yield, is undoubtedly 3,4,5,6-di-(1,8-naphthylene)-phthalic anhydride (VII). Confirmation

of its structure is desirable, and this problem is being attempted. It may be noted that the substance resembles in its appearance and properties certain of the highly arylated phthalic anhydrides prepared by Dilthey.[2] In spite of numerous essays, isolation of the intermediate addition product (VI) has not been accomplished, but this is not surprising in view of the temperature necessary to initiate the reaction.

By the reaction of V with stilbene, 1,2-diphenyl-3,4,5,6-di-(1,8-naphthylene)-benzene (IX) is obtained. A similar reaction appears to take place with cinnamic acid, hydrogen sulfide being evolved steadily, but as yet no pure substance has been isolated from the reaction product.

The reactivity and unsaturated character of dinaphthylenethiophene is indicated by preliminary experiments on the formation of dissociable addition products with chlorine and bromine, details of which will be reported later. These experiments together with the intense red color of dinaphthylenethiophene are, in some degree, suggestive of a diradical structure (X) for the substance.

The work is being extended, and the reactions of other thiophene derivatives with various ethylenic and acetylenic compounds are being studied.

Experimental

2,3,4,5-Di-(1,8-naphthylene)-thiophene.—This substance was obtained by fusion of acenaphthene and sulfur according to the directions of Dziewonski[10] and Rehlander.[11] It was purified by vacuum sublimation at 2.5 mm. and a bath temperature of 260°, followed by recrystallization from xylene; red needles, m. p. 285.5–286° (corr.).

3,4,5,6-Di-(1,8-naphthylene)-phthalic Anhydride.—An intimate mixture of dinaphthylenethiophene (0.12 g.) and maleic anhydride (0.4 g.) was introduced into a test-tube fitted with a long air-condenser. The mixture was heated in a bath, maintained at 225°, for fifteen minutes. The reaction mixture was cooled, broken up, and heated with water; the undissolved solid was then filtered off, dried, finely ground, and boiled with 10 cc. of potassium hydroxide solution (5%). The phthalic anhydride, which was largely unattacked by this treatment, was filtered off, dried, and twice recrystallized from phenyl ether; yield 0.08 g. (60%); yellow needles, decomposing without melting about 385°; almost insoluble in common solvents and aqueous alkali; slightly soluble in alcoholic alkali.

Anal. Calcd. for $C_{28}H_{12}O_3$: C, 84.83; H, 3.06. Found: C, 84.45, 84.72; H, 3.00, 2.97.

1,2-Diphenyl-3,4,5,6-di-(1,8-naphthylene)-benzene.—Dinaphthylenethiophene (0.5 g.) and maleic anhydride (0.5 g.) were heated at a bath temperature of 310–320° for nine hours, at the end of which time evolution of hydrogen sulfide was complete. The reaction mixture was dissolved in benzene, and a crude product was precipitated by the addition of methyl alcohol. On sublimation at 3 mm. and a bath temperature of 255–260°, 0.25 g. of yellow material was obtained, which was recrystallized three times from benzene–methyl alcohol; yield 0.11 g. (14%); greenish yellow crystals, with pronounced yellow-green fluorescence in ultraviolet light; m. p. 290–291° (corr.).

Anal. Calcd. for $C_{38}H_{22}$: C, 95.36; H, 4.64; mol. wt., 478.5. Found: C, 95.21; H, 4.72; mol. wt. (Rast), 473.

Summary

3,4,5,6-Di-(1,8-naphthylene)-phthalic anhydride and 1,2-diphenyl-3,4,5,6-(1,8-naphthylene)-benzene have been obtained from 2,3,4,5-di-(1,8-naphthylene)-thiophene by reaction with maleic anhydride and stilbene, respectively.

Substituted Dialuric and Hydurilic Acids[1]

BY C. M. MARBERG AND D. W. STANGER

In the study of the ideational background underlying certain psychoses in which there is a barrier to communication, there is need for a drug which will permit the physician to establish contact with the patient. Intravenously, sodium-5,5-isoamylethylbarbituric acid has this property[2] to a limited extent. It has the disadvantage that the interview is terminated after a few minutes by the hypnotic effect of the drug. As part of a program to investigate some barbituric acid derivatives from this point of view, we decided to prepare and study the bibarbituric acids, 5,5′-diethylhydurilic and 5,5′-diisoamylhydurilic acid. As by-products in one method of preparation of these compounds, we also obtained the 5-hydroxy barbituric acids, ethyldialuric and isoamyldialuric acids.

Upon intraperitoneal injection of aqueous solutions of the sodium salts of these barbituric acid derivatives into rats, the following results were obtained. Sodium diethylhydurilate, in a dose of 500 mg. per kg. caused no depression. Sodium diisoamylhydurilate, up to 200 mg. per kg., caused no depression, but caused death by circulatory failure in a dose of 500 mg. per kg. Sodium ethyldialurate and sodium isoamyldialurate caused no depression in doses as high as 2 g. per kg. The results of further pharmacological tests will be published in detail elsewhere.

It was first planned to prepare the 5,5′-disubstituted bibarbituric acids from a tetraethyl ester prepared by the reaction of a monobromo-monoalkyl-substituted malonic diethyl ester and the sodium salt of a monoalkyl-substituted malonic diethyl ester. This should permit the ultimate synthesis of unsymmetrical as well as symmetrical dialkyl bibarbituric acids. Two difficulties were encountered. First, the yield of the bimalonic tetraethyl ester was poor, 21 to 24% in the case of the symmetrical diethyltetracarbethoxyethane. This is in agreement with the work of Bischoff,[3] who obtained only a 17% yield of the same ester. Second, attempts to prepare diethylbibarbituric acid, 5,5′-diethylhydurilic acid, from the symmetrical diethyltetracarbethoxyethane by condensation with urea in the usual manner with sodium ethylate were unsuccessful; unchanged ester was recovered. Conrad and Bischoff[4] failed to condense symmetrical tetracarbethoxyethane with urea in the presence of phosphorus oxychloride or phosphorus pentachloride.

The oxidation of the 5-monosubstituted barbituric acids to form 5,5′-disubstituted hydurilic acids, reported by Aspelund,[5] appeared to offer the best method. The preparation of the 5-ethyldialuric and 5,5′-diethylhydurilic acids was repeated and two new compounds, 5-isoamyldialuric and 5,5′-diisoamylhydurilic acids were prepared. For characterization, a benzoyl derivative of the 5-isoamyldialuric acid was prepared and the acid was also hydrolyzed to the isoamyltartronic acid.

Experimental Part

5-Ethylbarbituric Acid.—This acid was prepared according to the method of Fischer and Dilthey as described by v. Merkatz.[6] Our product melted at 196–196.5°.[7]

5-Ethyldialuric Acid.—This acid was prepared according to the method of Aspelund[5] and melted at 224.5–225°.

5,5′-Diethylhydurilic Acid.—This acid was prepared according to the directions of Aspelund[5] and melted with decomposition at 328°. Aspelund reports that it melts above 310° with previous darkening and evolution of gas.

5-Isoamylbarbituric Acid.—This acid was prepared by the Fischer–Dilthey synthesis following Volwiler's[8] directions, and melted at 246–246.5°.

5-Isoamyldialuric Acid.—The preparation of this acid was carried out according to the method of Aspelund[5] with slight modifications. A mixture of 2.1 g. of monoisoamylbarbituric acid and 25 cc. of 3% hydrogen peroxide was refluxed for an hour. The crystals obtained on cooling weighed 1.57 g. when dry and melted at 179.5–180°. Concentration of the mother liquor to 5 cc. increased the yield by 0.46 g., m. p. 176.5°.

Twelve and seven-tenths grams of isoamylbarbituric acid was ground to a fine paste with a small amount of water and transferred to a 1-liter Erlenmeyer flask with 100 cc. of water. After adding 1.5 cc. of concentrated sulfuric acid, the barbituric acid was oxidized by the slow addition of 0.2 *N* potassium permanganate solution from a dropping funnel. The flask was well shaken during the addition

and heated from time to time to decolorize the permanganate. When 400 cc. had been used and the suspension in the flask was at the boiling point, the further addition was continued until the brown color no longer could be discharged by boiling. This required an additional 200 cc. together with 1 cc. of concentrated sulfuric acid. When the suspension was cool, the brown solid was collected on a Büchner funnel, well washed with water and dried; yield 8.4 g. The filtrate and washings were combined and concentrated to 50 cc. On cooling, crystals of crude isoamyldialuric acid were obtained; yield 4.4 g. The acid was purified by boiling an aqueous solution with norite, filtration and crystallization: yield 3.4 g., m. p. 179.5°. The melting point of a mixture of the isoamyldialuric acid obtained by this procedure with that obtained by the peroxide oxidation showed no depression.

Anal. Calcd. for $C_9H_{14}O_4N_2 \cdot 2H_2O$: H_2O, 14.40. Fonud: H_2O, 14.12. Calcd. for $C_9H_{14}O_4N_2$: C, 50.46; H, 6.59; N, 13.08. Found: C, 50.56; H, 6.36; N, 12.86.

Hydrolysis of 5-Isoamyldialuric Acid.—One-half gram of the acid was added to a solution of 2 g. of sodium hydroxide in 4 cc. of water. Foaming and vigorous evolution of ammonia resulted, and the flask was placed in a steam oven overnight. The residue was dissolved in water, the solution made acid to congo red paper with hydrochloric acid and extracted with ether. The ether extract was concentrated to a small volume, a few cc. of benzene added, and the solution boiled to remove the ether. On cooling, 0.22 g. of isoamyltartronic acid was obtained, which melted with evolution of gas at 134.5°. The melting point of a mixture of this acid and isoamyltartronic acid prepared by the hydrolysis of bromo-isoamylmalonic diethyl ester, method of Braun and Nelles,[9] showed no depression.

5-Benzoyl-5-isoamyldialuric Acid.—One-half gram of 5-isoamyldialuric acid was added to 5 cc. of benzoyl chloride and the mixture was heated slowly to 200–210° in an oil-bath. Solution was almost immediate, followed by gradual evolution of hydrogen chloride. On cooling, crystals were obtained by scratching the walls of the flask with a stirring-rod. The reaction mixture was transferred to a centrifuge tube with ligroin and the crystals were washed several times with this solvent. The slightly brown crystals were dissolved in alcohol, boiled with norite, filtered, and the filtrate diluted with water. After standing for several days the crystals which formed were collected; yield 0.5 g. and m. p. 210.5–216°.

Anal. Calcd. for $C_{16}H_{18}O_6N_2$: N, 8.80. Found: N, 8.88.

5,5′-Diisoamylhydurilic Acid.—This acid which was present in the insoluble residue from the preparation of 5-isoamyldialuric acid by the permanganate method was dissolved in acetone and filtered from the manganese oxide. The acetone was diluted with water and the crystals which formed on standing were collected and air-dried; yield 5.3 g. The acid darkened and melted with decomposition at 290°.

Anal. Calcd. for $C_{18}H_{26}O_6N_4 \cdot 2H_2O$: H_2O, 8.37. Found: H_2O, 8.34. Calcd. for $C_{18}H_{26}O_6N_4$: C, 54.81; H, 6.65; N, 14.21. Found: C, 54.82; H, 6.52; N, 14.06.

We wish to thank Dr. Carl Pfeiffer for the pharmacological testing of our compounds, and Dr. H. A. Shonle, of Eli Lilly and Company, for the gift of certain chemicals which were used in the course of this work.

Summary

A new bibarbituric acid derivative, 5,5′-diisoamylhydurilic acid, and a new 5-hydroxybarbituric acid, isoamyldialuric acid, have been prepared. Solutions of the sodium salts of these compounds and of the corresponding ethyl compounds have no appreciable effect when injected into rats.

Vapor Pressures and Accommodation Coefficients of Four Non-Volatile Compounds. The Vapor Pressure of Tri-*m*-cresyl Phosphate over Polyvinyl Chloride Plastics

BY FRANK H. VERHOEK AND A. L. MARSHALL

The vapor pressures and accommodation coefficients of the non-volatile organic compounds useful as plasticizers are data of fundamental importance in interpreting the losses of plasticizers which occur from plastics under certain conditions. Such data are given below for pure samples of di-*n*-butyl phthalate, tri-*m*-cresyl phosphate, tri-*p*-cresyl phosphate, and dibenzyl sebacate. The experimental methods employed were: measurements of the rate of effusion of saturated vapor through various tubes and through a small hole in a thin plate; measurements of the rate of evaporation from a free surface; measurements of the vapor pressure by a static method similar to that of Hickman, Hecker and Embree.[1] The vapor pressures of tri-*m*-cresyl phosphate over polyvinyl chloride plastics in which it served as plasticizer were determined by the static method.

(1) Hickman, Hecker and Embree, *Ind. Eng. Chem., Anal. Ed.*, **9**, 264 (1937).

Experimental Details

Method I. (Figs. 1 and 1a.)—The saturated vapor effused through the Fernico tube T (length 2.00 cm., diameter 0.498 cm.). The apparatus was immersed up to the vacuum side-arm in a constant-temperature bath.

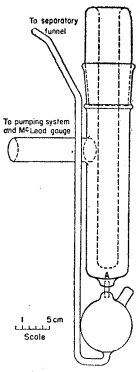

Fig. 1.

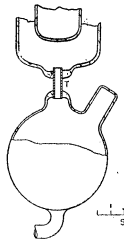

Fig. 1a.

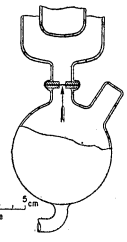

Fig. 2.

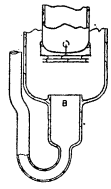

Fig. 3.

After the bath had been heated to a temperature in the region where measurements were to be made, the apparatus was evacuated, liquid air was placed in the condensing tube and the liquid (whose flow was controlled by the stopcock of a separatory funnel) was run slowly into the 300-cc. reservoir bulb. When the bulb was one-third full, giving an evaporating surface about 30 sq. cm. in area, the separatory funnel was sealed off below the stopcock. After further evacuation to remove any residual air that may have remained in the liquid, the vacuum was broken behind the liquid air trap and the liquid air sucked out of the condensing tube. When the latter had come to room temperature it was removed, washed with ether and replaced. The apparatus was then quickly exhausted; when the pressure had fallen below 10 microns, the condensing tube was refilled with liquid air, the time of this filling being taken as zero time for the experiment. When effusion had proceeded long enough for a suitable quantity of vapor—usually about 30 mg.—to condense on the liquid air tube, the experiment was stopped by breaking the vacuum. The condensate was then washed into a weighed platinum dish with 15–20 cc. of ether, which subsequently was evaporated so that the weight of condensate could be determined. Three or more experiments were made at each temperature and the average taken in calculating the vapor pressure; individual experiments agreed with each other to within 2 or 3%. The temperatures of the individual experiments conformed to no sequence; the last experiment on each substance was always carried out at the temperature of the first; these measures were taken to detect any change in the nature of the material under investigation. No evidence of any such change was observed with the four compounds in question. In certain cases, the reproducibility of the method was tested by making duplicate runs on separate charges of material; these results, which are in satisfactory agreement, are given under Method I, in Columns A and B of the tables below. The refractive index of the distillate was the same as that of the liquid being studied and in the case of tri-*m*-cresyl phosphate the distillate gave the correct percentage of phosphorus by analysis.

Method I'.—In the hope of measuring the rate of evaporation from a free surface, the Fernico tube and reservoir bulb in the above apparatus were replaced by a glass tube, 2.24 cm. in diameter, joined at A in Fig. 1. The smaller tube was filled to within a few centimeters of its top, and measurements were carried out as in Method I. Metal disks attached to the condensing tube (*cf.* Fig. 3) were used to minimize radiation losses from the surface of the liquid. (An attempt to reduce these losses by replacing the liquid air with 15° water had to be abandoned because of incomplete condensation.) Identical experimental results were obtained with the following systems of baffles, connected so as to make heat flow as difficult as possible: 7 nickel disks, 0.013 cm. thick; 3 such disks; and 3 disks with a nickel oxide or a silver surface facing the liquid.

The rates of evaporation measured in this apparatus increased as the level of the material approached A (Fig. 1), indicating that the 2.24-cm. tube was narrow enough to reduce the rate of evaporation to a value below that for a free surface.

A new apparatus (Fig. 3) was then constructed in which the position of the liquid meniscus could be accurately measured with a cathetometer in order to establish the length of narrow tube through which the vapor was effusing. The tube B (diameter 2.133 cm.) extends about 1 cm. into the larger tube, has its top carefully ground level, was sealed in without being distorted, and bears a reference mark to facilitate the cathetometer measurements. The baffle system consists of 3 nickel disks, 0.013 cm. thick.

Method II. (Fig. 3.)—The rate of evaporation from a free surface was measured directly by raising the level of the liquid to the top of B.

Method III. (Fig. 2.)—The rate of effusion of saturated vapor through a circular hole (diameter 0.1078 cm.) in a nickel disk 0.013 cm. thick held in a Fernico seal was measured. The diameter of the hole was measured after the seal had been made by projecting the image of the hole and a millimeter scale on a large screen.

Method IV. (Fig. 4.)—A static method can yield reliable vapor pressure results for substances (*e. g.*, plastics) for which dynamic methods may involve undesired changes in composition during the measurements. The apparatus of Hickman, Hecker and Embree[1] was modified by the addition of the condensing tube C (filled with liquid air) intended to eliminate possible back pressure on the disk D, and by the addition of a platinum resistance heater at 0. One or two watts output by the heater for a few minutes drove any material condensed near 0 back into the boiler; the presence of the condensate did not affect the experimental results, but it did introduce the hazard of having D held to the glass by the surface tension of the liquid. The vapor pressure is measured by turning the entire apparatus through an angle θ that will just suffice to close the orifice. To measure θ, the turning motion was carried through a worm gear to a disk 15.0 cm. in diameter divided on its circumference into 216 divisions, each of which corresponded to a deflection of one minute of arc. Consecutive readings at a given temperature could easily be reproduced to within one minute of arc. The pendulum consists of a duralumin disk D, 0.013 cm. thick, suspended by means of duralumin wire, 0.05 cm. in diame-

ter, from a shaft riding in jeweled bearings. The circular corrugation (dd′, Fig. 4) in the disk serves to stiffen and hold it perfectly flat. The effective weight of the assembled pendulum, carefully determined on an analytical balance, was 0.787 g. The vapor pressure is obviously given by

$$P \text{ (microns)} = \frac{0.787 \sin\theta}{0.00136(1.567)^2\pi} \qquad (1)$$

where the factor 0.00136 converts the pressure from grams per square centimeter into microns, and 1.567 cm. is the radius of the orifice at 0. The results of duplicate measurements on the same materials are given under Method IV, Columns A, B and C in the tables.

Materials.—A colorless sample of tri-*m*-cresyl phosphate was obtained from the Celluloid Corporation, and a slightly yellowish one from the Eastman Kodak Company. Neither sample was treated further.

The tri-*p*-cresyl phosphate was a Celluloid Corporation product melting at 76.4–76.7° (stem correction included). Five recrystallizations from a five-to-one mixture of absolute ethanol and water did not change this melting point, and made only a slight difference in the shape of the cooling curve.

The dibutyl phthalate was purified by vacuum distillation through a 1.25-meter column. The middle fraction, which was used, was colorless, neutral, with the theoretical saponification value, and $n^{20}D$ equal to 1.4933. Further distillation did not change the refractive index.

The dibenzyl sebacate was prepared and carefully purified in this Laboratory by Burnett and Russell.[1a]

The plastics were prepared by weighing out the required quantities of polyvinyl chloride and the Celluloid Corporation tri-*m*-cresyl phosphate, mixing by milling at 100°, and pressing into a thin sheet at 500 lb./sq. in. (33 atm.) for five minutes at 140°. Loss in the milling and pressing operations amounted to 0.2–0.4%. The pressed sheets were cut into strips weighing from 7 to 10 g., on which the measurements were made.

Calculations for the Dynamic Methods.—The number of molecules per second, Z, colliding with (hence entering) a uniform circular tube of radius a is

$$Z = a^2 p N \sqrt{\pi/2RTM} \qquad (2)$$

where p is the pressure; N, R and T have their usual meanings; M is the molecular weight; and c. g. s. units are employed. The experimental results give the rates of effusion, Q, in grams/sec., through tubes of varying length, when the pressure is equal to the vapor pressure of the liquid at one end and virtually zero at the other. To obtain the rate at which matter will leave such a tube, Z must be multiplied by the weight of a molecule and by the probability, W, that a molecule entering the tube will leave it; or

$$Q = WZM/N = Wa^2P\sqrt{M\pi/2RT} \qquad (3)$$

For a hole in an infinitely thin sheet, W is equal

(1a) Burnett and Russell, THIS JOURNAL, **61**, 2246 (1939).

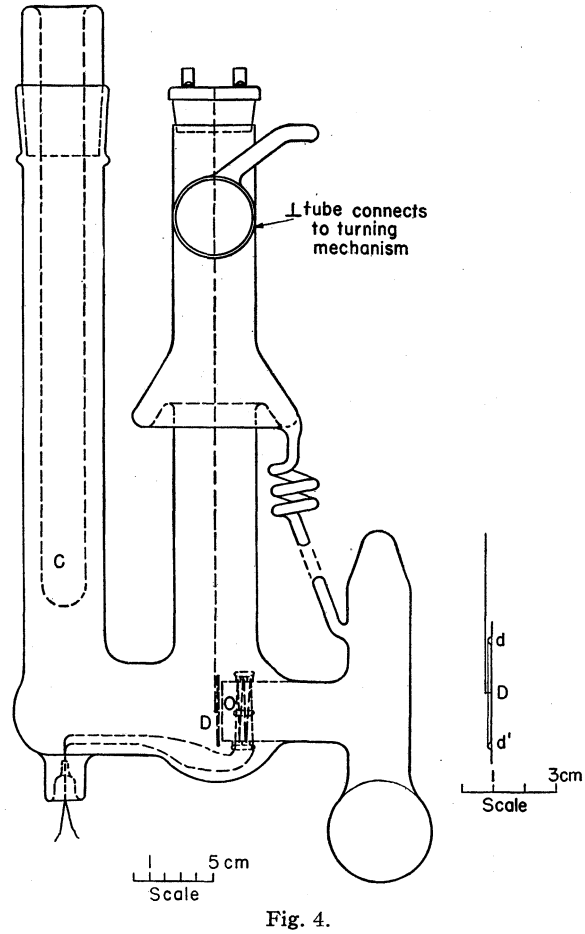

Fig. 4.

to unity; for a cylindrical tube with perfectly diffusing walls of length l such that $l \gg a$, at pressures such that the mean free path is much larger than the diameter of the tube, W equals $8a/3l$. For cylindrical tubes of intermediate length, Clausing[2] gives a table of values of W for various values of l/a, which represent close approximations that he made because he was unsuccessful in deriving an accurate expression for W in terms of known functions. The values of W used in calculating our values were obtained when necessary by interpolating in this table; for example, when $l/a = 8.025$ (Method I), $W = 0.2310$ so that

$$p = \frac{Q}{0.2310\, a^2}\sqrt{\frac{2RT}{\pi M}} \qquad (4)$$

In the actual calculations, $R = 83.15(10^6)$ ergs/degree was used, and the right-hand side of Eq. 4 was multiplied by 0.75 to give the pressures in microns.

For Method I′, W was obtained as for Method I. For Method II, W is obviously unity, and the

pressures were calculated on the assumption that the area of the liquid surface was equal to the cross-sectional area of B (Fig. 3). For Method III, W is unity and a is the area of the hole in the nickel disk.

In all these calculations, an accommodation coefficient of unity is assumed.

Results and Discussion

The Pure Substances.—The detailed results for the pure substances are given in Tables I–IV and in Fig. 5, in which the values of Hickman, Hecker and Embree[1] for dibutyl phthalate have also been plotted. The constants derived from these detailed results are given in Table V. With a single exception, there is no systematic departure from the straight lines in Fig. 5 for any one method of measurement on any one sample. The exception, tri-*p*-cresyl phosphate, shows results by method IV that are definitely larger than those by method I; a slight decomposition of the material to give volatile products is one reasonable explanation of this discrepancy. Our failure to check the measurements of Hickman, Hecker and Embree exactly is not surprising in view of the differences which we found in the vapor pressures of the tri-*m*-cresyl phosphates from two different sources.

$$\log p \text{ (microns)} = -(A/T) + B \quad L = 4.575\,A.$$

That the *accommodation coefficients* for all four substances are unity is shown by the agreement of the Method I′ results with the others. If a vapor pressure is calculated from a rate of evaporation into a vacuum (Method I′) on the assumption that the accommodation coefficient is unity, this calculated pressure will be less than the true pressure (as measured, for example, by Method III or IV) if a fractional accommodation coefficient exists.[3] Our results indicate that the accommodation coefficients will always be unity for substances of the type studied here.

Although it is true that the vapor pressure calculated from the rate of evaporation from a free surface (Method II) is somewhat lower than the others, this small discrepancy probably does not indicate the existence of a fractional accommodation coefficient. A difference of 1.1° between the temperature of the bath and the temperature of the liquid at the surface of Tube B, Fig. 3, is sufficient to account for the lower vapor pressure obtained by Method II. Since the apparatus is so constructed that the heat lost from the surface by evaporation is not readily replaced, such a temperature difference may well have existed.

The Plastics.—The static vapor pressures obtained by Method IV on three different polyvinyl chloride–tri-*m*-cresyl phosphate plastics are summarized in Table VI and plotted in Fig. 5. The values of θ could not be determined as accurately here as for the pure substances because the disk closing the orifice continued to vibrate. This vibration, which could not be eliminated by prolonged evacuation at the temperatures of the

(3) *Cf.* Langmuir, *Phys. Rev.*, **11**, 329 (1913), or Knudsen, *Ann. Physik*, **47**, 697 (1915).

measurements, might have been caused either by a continued liberation of air occluded in the sample or by the steady production of a volatile decomposition product in small amount (that a slight decomposition did occur was indicated by a gradual darkening of the sample). This explanation gains in plausibility from the fact that the measured vapor pressures for two of the plastics exceed somewhat the vapor pressure of the pure plasticizer.

TABLE VI

VAPOR PRESSURES OF POLYVINYL CHLORIDE–TRI-*m*-CRESYL PHOSPHATE PLASTICS

% polyviny chloride.....	0[a]	40	40	70	85
T, °C.					
114	1.44	1.38	1.68	1.37	1.79
119	2.29				3.17
124	3.59		4.19		4.17
129	5.57		6.02	4.97	7.02

[a] Calculated values (*cf.* Table V).

It seems reasonable to conclude that the vapor pressure of the plasticizer in these plastics is independent of concentration over the range 15–100% plasticizer. More results will be needed with other plasticizers to confirm this conclusion. It is possible that the quantity being measured in these experiments is the vapor pressure of a film of plasticizer on the surface of the plastics. Since the slope of the vapor pressure curve and also its absolute position is the same for the plastics and the pure plasticizer, it may be concluded from this type of experimentation that the heat involved on mixing polyvinyl chloride and tricresyl phosphate is practically zero. To confirm this conclusion it would be desirable to carry out calorimetric experiments on the heat of wetting at elevated temperatures of polyvinyl chloride by several plasticizers.

Summary

The vapor pressures of tri-*m*-cresyl phosphate, tri-*p*-cresyl phosphate, dibutyl phthalate and dibenzyl sebacate in the neighborhood of 100° have been measured by a static and by dynamic methods.

The accommodation coefficients for these liquids are unity.

The vapor pressure of the plasticizer in a polyvinyl chloride–tri-*m*-cresyl phosphate plastic containing at least 15% of the latter appears to be equal to the vapor pressure of the pure plasticizer and is independent of the composition of the plastic.

Pied des Monts Uraninite

BY O. B. MUENCH

A fine specimen of uraninite was collected from the Lac Pied des Monts district in Quebec and given to Mr. H. S. Spence,[1] who sent it by way of Dr. A. C. Lane[2] to the writer for an age determination by the lead–uranium method and for the extraction and preservation of the lead for an isotopic determination to be made later by A. O. Nier at Harvard University. This material is of interest since considerable work has been done by Ellsworth[3] on samples from this district. He gives a description of the geological occurrence of minerals in this district, accompanied by a complete chemical analysis and age determination. Another interesting account of the location, with references, is given in *Le Naturaliste Canadien*.[4] Material from this location has been called cleveite[5] by some, but Ellsworth,[3] Berman,[6] and others prefer the term uraninite for this mineral.

The surface of the mineral did not show any indication or sign of secondary uranium minerals. Before beginning the analysis, several autoradiographs were made of various pieces of the specimen on different smoothly ground surfaces. Some sections were cut through the middle and autoradiographs made of these. The prints seem to in-

(6) Dr. Berman of the Harvard Department of Mineralogy in a private communication to Professor A. C. Lane.

dicate a fairly uniform distribution of radioactive material and no visible evidence of leaching.

Analysis

The sample was broken into smaller pieces in a clean iron mortar and then finely powdered in a clean agate mortar to pass a 100-mesh sieve. The precautions necessary to this type of analysis were observed carefully to avoid contamination. Special precautions were taken in this respect with the lead. Pure analytical reagents were used, and these were purified further where the accuracy of the analysis depended upon it.

The sample was decomposed in nitric acid and the silica removed in the usual way. The lead, after separation and purification, was weighed as the sulfate. Recoveries for lead were made on all filtrates and from the silica.

The uranium was determined as the pyrophosphate,[7] which method is described in detail in previous papers.

Four five-gram samples were run for thorium by the iodate method, which also is described in previous papers.[7,8] The very small, hardly weighable residue carried some of the rare earths in the form of oxides as indicated by the pale yellow color.

TABLE I

RESULTS

Lead

Sample, g.	$PbSO_4$, g.	Lead, %
1.0005	0.0975	6.655
1.0024	.0979	6.675
1.0016	.0981	6.689
1.0020	.0978	6.666
1.0000	.0976	6.666
	Average	6.670

Uranium

Sample, g.	$(UO_2)_2P_2O_7$, g.	Uranium, %
0.2025	0.1495	49.22
.2016	.1488	49.23
.2027	.1498	49.29
.2013	.1487	49.27
	Average	49.25

Thorium

Four separate five gram samples quantitatively gave only a slight indication of thorium. Rare earths were present. 0.0% Thorium.

Loss on ignition	12.07%
Loss at 100° for four hours	0.41%

The lead-uranium ratio is 6.67/49.25 = 0.135.

The age of this mineral, calculated from the above figures, and using the logarithmic formula of Holmes,[9] is

$$\frac{\log (U + 0.36Th + 1.155Pb) - \log (U + 0.36Th)}{6.6 \times 10^{-5}} \text{ million years} = 956 \text{ million years.}$$

The lead sulfate from the lead determination was saved and sent to Alfred O. Nier at Harvard University for the isotopic determination. His analysis[10] has direct reference to this paper, and is of special interest in this age determination since it gives the figures for the isotopic composition of the lead which was used in this determination. The following is from his paper, with 206 taken as 100 in the proportion of isotopes

Pb	204	206	207	208
	0.047 ± 5%	100	7.60	1.92 ± 2%

Mass number	Physical atomic weight
206.103 ±0.002	206.078

Ac D/Ra G %	Pb/U	Ra G/U^{238}
6.88	0.1354	0.1233

Age, accordingly in million years: 903 by Ac D/Ra G
882 by Ra G/U^{238}

Calculation from the lead–uranium ratio without taking into consideration the isotopic composition of the lead yields an age of 956 million years.

The results of Nier's isotopic analysis of the lead from this sample indicate that about 4% of the lead is common lead. Correcting the lead percentage for this amount of common lead, changes the lead figure from 6.67 to 6.40%. This correction alters the lead–uranium ratio to 0.130. The corresponding age calculated by the logarithmic formula is 920 million years, which is nearer to Nier's ages determined by different methods.

Nier in his paper[10] has pointed out the fact that uranium rather than lead is usually lost whenever alteration takes place in a uranium mineral, thus making the lead–uranium ratio too high, whereas the age computed from Pb^{207}/Pb^{206} ratio hardly differs from the true age of the mineral.

Acknowledgments.—The author is indebted to the Geological Society of America for financial assistance in part, for this work; to Professor A. C. Lane for his constant inspiration and encouragement; to Mr. H. S. Spence for the mineral; and to the late Dr. Herman Schlundt and the University of Missouri for the generous use of laboratories, chemicals, and other facilities.

(10) A. O. Nier, *Phys. Rev.*, **55**, 158–159 (1939).

Summary

The lead–uranium ratio of a uraninite from Lac Pied des Monts, Quebec, was determined as 0.135. The analytical results show 6.67% lead, 49.25% uranium, and a trace of thorium.

An isotopic determination on the lead obtained from this analysis was made by A. O. Nier at Harvard University. With these results available, the age of the Lac Pied des Monts uraninite can now be given with greater assurance and accuracy. Corrections for common lead made from Nier's determination change the percentage to 6.40 and the lead–uranium ratio to 0.130. The age of the mineral, calculated with these corrected figures, is 920 million years and compares favorably with the results calculated from the isotopic determination of the lead from this sample.

Two independent age determinations made by entirely different methods on the same specimen yield results in fairly good agreement.

The Solubility of Mercuric Halides in Solutions of Potassium Halides. The Character of the Mercuric Halide Complex Ions. Evidence for Polymerization of Mercuric Chloride

BY A. B. GARRETT

The purpose of this paper is to present measurements of the solubility of mercuric halides in halide solutions and to calculate the equilibrium constants for the reactions involved in the formation of the complex mercuric halide ions; the values of these constants should indicate the character of the complex ions of mercury in the solutions studied.

The moderately low solubility of mercuric bromide and mercuric iodide makes possible a fairly direct determination of the character of the complex ions of these mercuric halides by means of solubility measurements. Additional information essential to this determination are these facts: (1) earlier work[1-6] has shown that the mercury halides are only slightly dissociated and (2) their solubility in halide solutions is predominantly specific to the concentration of the halide ion and not to the ionic strength. These facts make it possible to attribute the solubility of mercuric halides in halide solutions mainly to several or to all of the following reactions (using the bromide as an example)[7]

$$HgBr_2(\text{solid}) = HgBr_2(\text{solution}) \quad (1)$$

$$HgBr_2 + Br^- = HgBr_3^- \quad (2)$$

$$HgBr_2 + 2Br^- = HgBr_4^= \quad (3)$$

The data necessary are those in low concentrations where one might reliably expect the limiting law to be applicable. Only a meager amount of such data is available from early work.[1-6]

Early work is at variance with respect to definite conclusions concerning the character of these halide ions. A number of workers[3,8-10] have claimed the formation $HgCl_3^-$, $HgBr_3^-$ or HgI_3^- whereas others[11-13] submit evidence for the $HgI_4^=$ ion. Job[11] claims the presence of $KHgCl_3$, K_2HgBr_4 and K_2HgI_4 in their respective solutions. Sherrill[4] even gives data on the ionization constants for all of these salts, *i. e.*, $KHgI_3$, K_2HgI_4, $KHgBr_3$, K_2HgBr_4, etc. Tananaev and Pilipenko[13] assumed the near 2 to 1 ratio of added potassium iodide to mercuric iodide indicated the formation of $HgI_4^=$ predominantly.

Procedure.—Baker C. P. quality and Mallinckrodt Analytical Reagent mercuric bromide and mercuric iodide were used. For a number of preparations the mercuric bromide was recrystallized from hydrobromic acid solution and heated at 115° for four hours to assure complete removal of any hydrogen bromide. The same procedure was followed with the mercuric iodide but the recrystallization was omitted.

Baker Analytical Reagent potassium bromide and potassium iodide were used.

All work was done in conductivity water which was boiled free of oxygen, in an atmosphere of nitrogen, and at 25 ± 0.02°. Equilibrium was approached from undersaturation (u) and supersaturation (s). An equilibrium period of three days was established by the close approach of the (u) and (s) values. The data given are averages of these two values.

The samples were analyzed by precipitating the mercury as the sulfide. The halide content was determined by preparing the samples in standard halide solutions.

The *p*H of a number of the samples was measured with a glass electrode.

The Data

The data are given in Tables I to III. All values are expressed in moles per 1000 g. of water.

The water solubility was reinvestigated for the bromide since it is a critical value in the later treatment of the data. During this investigation it was revealed that repeated, careful washing was not enough to remove the impurity of hydrobromic acid. It seems only to be removed by oven drying and heating. The comparison of the data in Table I shows the consistent results obtained by such treatment and agree with values in the literature. Samples not receiving such treatment varied from 1.84×10^{-2} to 2.01×10^{-2} mole per 1000 g. of water.

the solubility of the mercuric halide can be accounted for by equations (1) and (2) only. Column 5 of Tables IV and V gives the ratio Hg complex/halide ion or in other words the equilibrium constant for equation (2) calculated on the assumption that equations (1) and (2) represent the only reactions taking place. The near constancy of the value of K_2 for the bromide suggests that the $HgBr_3^-$ ion is the main ion formed with the possibility of only a very small amount of the $HgBr_4^=$ ion. However, the value of K_2 for the iodide varies considerably, thus indicating that an additional reaction probably is present, namely, that represented by equation 3.

The calculation of K_2 is made quite accurately from the relationship

$$K_2 = \frac{m_{\text{Hg complex}^-}\gamma_{\text{Hg complex}^-}}{m_{\text{Br}^-}\gamma_{\text{Br}^-}}$$

and upon the reasonable assumption that the ratio $\gamma_{\text{Hg complex}^-}/\gamma_{\text{Br}^-}$ is unity throughout this range of concentrations.

The small variation in the value of K_2 (1.85 to 1.91) for mercuric bromide from 0.002 to 1 molal hardly justifies the calculation of the value of K_3 for reaction (equation(3)). Choosing the value of 1.85 as the most reliable value for K_2 as determined from low concentration measurements the value of ΔF_{298} is -365 cal. for equation (2).[14]

The variation in the value of K_2 for the iodide and the less than 2 to 1 ratio of potassium iodide–mercuric iodide complex indicate the necessity of including equation (3), together with equations (1) and (2), to explain the solubility of mercuric iodide in iodide solutions. The method of Garrett and Howell[15] for the calculation of the dissociation constants for mercuric hydroxide gives the values $K_2 = 0.48$, $\Delta F^\circ_{298} = +430$ cal., $K_3 = 35$ $\Delta F^\circ_{298} = -2100$ cal. for the iodides. This value of K_2 is in agreement with the extrapolation of the values of K_2 given in column 5 of Table V. These values of K_2 and K_3 indicate an appreciable amount of $HgI_4^=$ in solution.

The Mercuric Chloride–Chloride System

WITH ERNEST HOGGE

The mercuric chloride–chloride ion equilibrium has been investigated by Thomas.[1]

It is not easily possible to treat the data of these chlorides exactly due to the high molalities; however, this interesting observation is evident, namely, the concentration of the complex ion stands in almost a 1:1 ratio with the concentration of added chloride ion for reasonable concentrations of hydrochloric acid (to 1 molal) and for all concentrations of other salts (see Table VI). This suggests that equation (2) is sufficient to account for the increased solubility of mercuric chloride and that the most common complex chloride ion of mercuric chloride in all probability has the formula $HgCl_3^-$. The higher ratio of $m_{\text{HgCl}_2\text{ complex}}/m_{\text{added chloride}}$ at high solute concentrations suggests the possibility of the formation of a small amount of $HgCl_4^=$, but, on the other hand, this higher ratio may also be due to changing activity coefficients, which is expected at these high concentrations. It is virtually impossible to treat quantitatively any type of solution at such high concentrations; however, it may be concluded that the data in all the solutes used indicate the formation of $HgCl_3^-$ predominantly.

If it is true that the predominating ion is $HgCl_3^-$, then a quantitative treatment of the data becomes more possible due to the unit or near unit ratio of $\gamma_{HgCl_3^-}/\gamma_{Cl^-}$ in the equilibrium constant of K_2, for equation (2) over a wide range of concentrations. This should make possible a fairly reliable calculation of the value of K_2 from data even at 1 molal of added chloride ion (see Table VI, column 5). It is of interest to point out here the relatively large values of K_2 are indicative of a high ratio of $HgCl_3^-$ ion to free Cl^- ion; they also indicate that any other ion existing in the solution must be of relatively low concentration.

TABLE VI

[Thomas (ref. 1) revised]

m_{Cl}	s_{HgCl_2} in HCl	m_{HgCl_2} complex in HCl	m_{HgCl_2} complex in LiCl	Ratio $HgCl_2$ complex to free chloride ions = K_2	m_{HgCl_2} complex in $CaCl_2$	m_{HgCl_2} complex in $AlCl_3$

(14) This calculation and that for the iodides do not take into consideration a possibility of polymerization of mercuric bromide or mercuric iodide (see latter section of this paper for a discussion of this possible effect with mercuric chloride). No evidence of this effect in the bromide or iodide has come to our attention.

(15) Garrett and Howell, THIS JOURNAL, **61**, 1730 (1939).

An apparent anomaly still exists in these data at low concentrations of added chloride ion, namely, the data in Table VI show higher (about 5%) mercuric complex concentrations than can be accounted for on the basis of the 1:1 ratio of $HgCl_2:Cl^-$. This is outside the limit of experimental error and is consistent for all the salts used.

A very probable explanation of this apparent anomaly is the fact that a polymerization equilibrium may exist in mercuric chloride solutions. Such an equilibrium would make necessary the consideration of the following additional reactions in interpreting these data

$$xHgCl_2 \rightleftharpoons (HgCl_2)_x \qquad (4)$$

and

$$(HgCl_2)_x + Cl^- \rightleftharpoons (HgCl_2)_xCl^- \qquad (5)$$

That a polymerization equilibrium does exist is supported by other independent evidence, namely, (1) measurements of rise of the boiling point of mercuric chloride solutions[16-19] and (2) freezing point lowering.[20,21] Such evidence is somewhat uncertain as individual cases but all of the evidence taken as a whole points strongly to the validity of this assumption of the existence of at least a small per cent. of polymerized mercuric chloride molecules in solution.

An additional observation that seems to lend further support to this assumption is the fact that the values of K_2 calculated from Thomas'[1] data go through a minimum (see column 5, Table VI) whereas the values of K_2 for similar data for the bromide and iodide vary in the direction that one might reasonably expect if there are no secondary equilibria such as polymerization.

It is obvious that more careful work is necessary on vapor pressure lowering, freezing point lowering, distribution ratios, etc., to verify this assumption of polymerization. However, it would be reasonable to conclude that from the data now at hand the amount of polymerized mercuric chloride molecules need only be in the order of 10% to account for the apparent anomalous behavior of mercuric chloride. This also leads one to the conclusion that the complex ion of mercuric chloride that one expects to predominate is the $HgCl_3^-$ ion but it does not exclude the possibility of smaller amounts of other ions such as $(HgCl_2)_xCl^-$, $HHgCl_4^-$ and $HgCl_4^=$.

It may also be observed that a near 1 to 1 ratio of mercuric chloride to added chloride ion would indicate only a small amount of free chloride ions in solution and thus suggest a highly stable complex ion. Other work pointing to the high stability of these complex ions is the work of LeBlanc and Noyes[21] on the effect of mercuric chloride on the rate of catalysis of methyl acetate with hydrochloric acid and the work of Richards and Archibald[22] on the effect of mercuric chloride on the conductivity of hydrochloric acid. These papers also indicate that the new compounds formed are strong electrolytes. Again one is led to the conclusion that the predominating ion is the $HgCl_3^-$ ion; otherwise one would expect the catalytic activity and the conductivity of the hydrochloric acid to be considerably altered due to the removal of hydrogen ions to form the $HHgCl_4^-$ ion which would be only slightly dissociated in such concentrated solutions.

This conclusion is further supported by the data on these other halides which suggest an appreciable amount of $HgI_4^=$, and only a very small amount (if any) of $HgBr_4^=$. A reasonable prediction would suggest a still smaller amount of $HgCl_4^=$. If this conclusion be justified, then one obtains an approximate value of $K_2 = 20$ from Thomas' data, and a value of $\Delta F^\circ_{298} = -1700$ cal. if one assumes no polymerization at this value of chloride ion concentration. This value indicates a fairly stable complex chloride ion, which is in agreement with other evidence.

Evidence of hydrolysis was obtained in the mercuric bromide–bromide system when it was found that the *p*H of the samples varied from 4.1 for water solubility to 4.8 for the salt samples from $m_{KBr} = 0.01$ to 1.0 molal.

Acknowledgments.—The author is indebted to Mr. James Lemley and Dr. Claude Acker for aid in the experimental part of this paper.

Summary

The solubilities of mercuric bromide and mercuric iodide have been determined in potassium

bromide and potassium iodide solutions. The water solubility of mercuric bromide has been redetermined.

The equilibrium constants for the formation of the complex ions of mercuric halides have been evaluated. These calculations indicate that $HgBr_3^-$, HgI_3^- and $HgI_4^=$ are formed. Earlier work indicated the formation of $HgCl_3^-$ with small amounts of $(HgCl_2)_x$ and $(HgCl_2)_xCl^-$.

The anomalous solubility of mercuric chloride in low concentrations of chloride solutions is accounted for on the basis of polymerization of mercuric chloride. Other evidence is cited to indicate the existence of polymerized mercuric chloride molecules.

A number of different independent arguments are presented to indicate that the chief ion formed in the chloride solutions is the $HgCl_3^-$ ion.

The equilibrium constants and ΔF°_{298} of several of these ions have been evaluated. They have been shown to be in agreement among themselves and with other known data.

The free energy of formation of the various halide ions from mercuric halide and the halide ions is $HgCl_3^-$, $\Delta F^\circ_{298} = -1700$ cal.; $HgBr_3^-$, $\Delta F^\circ_{298} = -365$ cal.; HgI_3^-, $\Delta F^\circ_{298} = +430$ cal.; $HgI_4^=$, $\Delta F^\circ_{298} = -2100$ cal.

The Redistribution Reaction. I. The Random Intermolecular Exchange of Organic Radicals

BY GEORGE CALINGAERT AND HAROLD A. BEATTY

This is the first of a series of papers describing a hitherto unrecognized type of intermolecular exchange of organic radicals. The systematic study of this reaction has yielded simple laws governing its course, and supplies a ready interpretation of the small amount of related data scattered through the literature. The results obtained offer interesting suggestions regarding the behavior of the covalent bond as well as possibilities for new methods of probing into this field. The reaction also constitutes a new tool for the synthesis of several types of organic compounds. This first paper defines the nature of the reaction, using illustrations from the field of organo-metallic compounds, and constitutes a general introduction to subsequent papers which will cover specific phases of the subject.

Introduction.—A wide variety of reactions is known in which atoms or radicals linked by covalent bonds are transferred from one molecule to another through exchange with an atom or radical of another kind. For example, in the Jacobsen reaction, bromobenzene under the influence of aluminum chloride yields a mixture containing benzene and *p*-dibromobenzene, as well as other products. Likewise, under the influence of the same catalyst, toluene is converted into a mixture containing, in addition to toluene itself, benzene and several polymethylated benzenes. Reactions of this type are also known in the field of organo-metallic compounds. Dialkylzinc compounds have long been prepared by heating alkylzinc halides, which are converted into a mixture of the dialkyl compound and the zinc halide, the former being removed as formed, by distillation. A few cases also have been reported where the radicals exchanged were similar instead of dissimilar: for example, the interchange of methyl and ethyl radicals in organo-silicon compounds,[1] of phenyl and tolyl radicals in triarylbismuth compounds[2] and of halogen atoms in ethylene chlorobromide.[3]

Except in the last case, little or no indication has been given of the existence of an equilibrium, and in most cases a considerable amount of side reaction takes place. Also, the conditions used, namely, elevated temperatures or the presence of a powerful catalyst or both, suggest that the reactions are closely related to the irreversible decompositions of the compounds involved.

In the studies which will be reported in the present series of papers, it has been found that by a judicious choice of operating conditions and catalyst, it is possible to bring about an extensive

interchange of similar radicals, and of certain similar atoms, between molecules of the same chemical class. In contrast to most of the cases reported above, the present reaction takes place smoothly, without noticeable evolution of energy, and the resultant product is free from the secondary or decomposition products usually found in reactions involving the liberation of functional groups or atoms without substitution. While this reaction has been found to take place quite generally, and with several different classes of compounds, including alkyl halides, esters of organic acids, and organo-metallic compounds, the present general exposition will be based on the last-named compounds, which have proved to be particularly suitable for quantitative study.

The Exchange of Radicals in Organo-Metallic Halides.—As will be shown later, the present reaction is closely related to the interchange between radicals and halogen atoms in organo-metallic halides, and for that reason this type of reaction will be considered first. It is well known that several metallic halides react with organo-metallic compounds in accordance with the general equation

$$R_nM + M'X_{n'} \longrightarrow R_{n-m}MX_m + R_mM'X_{n'-m}$$

the extent to which the reaction takes place depending upon the nature of the metals (or metal), the R group and the halogen involved.[4] In some cases which have been studied more extensively, notably that of the system $R_2Mg + MgX_2$, the existence of a state of equilibrium has been established definitely.[4b]

In a previous report from this Laboratory,[5] it was shown that in the case of ethyllead halides, such a transformation did take place in both directions, between any of the possible stable components of the system, as indicated schematically below

$$R_4Pb \rightleftharpoons R_3PbX \rightleftharpoons R_2PbX_2 \rightleftharpoons [RPbX_3]$$
$$\downarrow \qquad\qquad \downarrow$$
$$R_2 + PbX_2 \qquad RX + PbX_2$$

The study of equilibrium in such a system as this is rendered difficult, if not impossible, by the instability of some of the compounds involved, as indicated above by the vertical arrows; nevertheless the formation of all these compounds in the system has been established with certainty.

It may be inferred from the above that the interchange of organic radicals and halogen atoms in organo-metallic compounds is quite general, and this suggests the use of this reaction to effect the interchange of organic radicals themselves between different molecules.

The first step in the broadening of our knowledge of the reactions in this field consisted in testing the possibility of the occurrence of this interchange between a fully alkylated metal atom and its corresponding monohalide, a case in which the reaction conceivably might not take place, as it does not lead to the formation of any new compound. This interchange was tested with triethyllead chloride and tetraethyllead, the latter compound containing the radioactive isotope of lead, Radium D, as an indicator. It was found that, even at room temperature and without a catalyst or solvent, radioactivity was detected after a short time in the triethyllead chloride, and after one day the lead obtained from both the tetraethyllead and triethyllead chloride showed the same intensity of radioactivity, and continued to do so. This demonstrates the rapid interchange of the chlorine atoms and ethyl radicals in accordance with the equation

$$Et_4Pb^* + Et_3PbCl \rightleftharpoons Et_3Pb^*Cl + Et_4Pb$$

The same reaction was then studied in the case where the alkyl groups present in the tetraalkyllead compounds are different from those present in the chloride: the pair, tetramethyllead plus triethyllead chloride, was used. Here again the reaction took place readily, but a complex mixture was obtained. Careful fractional distillation of the tetraalkyllead portion of the product showed the presence of all the five possible compounds containing either or both methyl and ethyl groups, that is, tetramethyllead, trimethylethyllead, dimethyldiethyllead, methyltriethyllead, and tetraethyllead. The alkyllead halide portion of the product was analyzed separately, and it was likewise shown conclusively that all the four possible trialkyllead chlorides were present. These results are represented by the equation

$$\left.\begin{matrix} Me_4Pb + \\ Et_3PbCl \end{matrix}\right\} \longrightarrow \left\{\begin{matrix} Me_4Pb + Me_3EtPb + Me_2Et_2Pb + \\ \qquad\qquad MeEt_3Pb + Et_4Pb \\ + Me_3PbCl + Me_2EtPbCl + \\ \qquad\qquad MeEt_2PbCl + Et_3PbCl \end{matrix}\right.$$

Equilibrium Interchange of Radicals in Metal Alkyls.—In the next step of this investigation,

(4) For a discussion of this subject, see (a) Challenger, Pritchard and Jinks, *J. Chem. Soc.*, **125**, 864 (1924); (b) Gilman, "Organic Chemistry," John Wiley and Sons, Inc., New York, N. Y., 1938, Vol. I, Chapter 4.

(5) Communication to the Mid-West Regional Meeting of the American Chemical Society, Columbus, Ohio, November, 1937; to be published.

the amount of alkyllead salt was decreased to catalytic quantities, and two different tetraalkyllead compounds were used. Again, extensive interchange of the alkyl groups took place at low temperature, and the product contained all the possible tetraalkyl compounds. Yet in the absence of the catalyst, there was no detectable reaction, even after prolonged heating. This indicated that the presence of the alkyllead salt caused the alkyl groups in tetraalkyllead compounds to become mobile to the extent of migrating from one molecule to another, as represented by the equation

$$R_4Pb + R'_4Pb \longrightarrow R_4Pb + R_3R'Pb + R_2R'_2Pb + RR'_3Pb + R'_4Pb$$

An investigation was then made to determine how general the reaction was for different R radicals and whether it would take place as well with other metals, and by means of other catalysts. It was found, indeed, to be quite general. Numerous tests were made, using two or more different radicals, including methyl, ethyl, *n*-propyl, isopropyl, *s*-butyl, *t*-butyl, phenyl, and *p*-tolyl, bound to one or more metals, including lead, tin, silicon, and mercury. In all cases, interchange took place freely, and ample evidence was found of the formation of all the possible compounds between the R groups and M atoms present. Whenever compounds of two different metals reacted under similar conditions, as a rule they also reacted with one another, again yielding all the possible compounds of both metals. Thus, the equation which expresses the products obtained from two different R groups bound to two different M atoms of different valences, and which illustrates the type of result obtained from all these transformations in general, is

$$R_nM + R'_{n'}M' \xrightarrow{\text{Catalyst}} R_nM + R_{n-1}R'M + R_{n-2}R'_2M + \ldots + RR'_{n-1}M + R'_nM + R_{n'}M' + R_{n'-1}R'M' + R_{n'-2}R'_2M' + \ldots + RR'_{n'-1}M' + R'_{n'}M'$$

Numerous catalysts also were found, most of which consisted, either directly or through secondary reaction, of halides or organic halides of elements susceptible of forming organo-metallic compounds. The activities of the various catalysts differed, and compounds of different metals reacted at different rates, depending on the temperature and on the kind and amount of catalyst. Usually, the reaction time was limited to five hours or less, and the reaction velocity was increased by elevating the temperature to 60–80° or, for some of the heavier R groups or less active catalysts, to 100–180°. To obtain these temperatures, and at the same time to provide stirring and to exclude air, it was convenient to add an inert solvent such as hexane or decalin, and to reflux the mixture. There was no evidence that these solvents participated in any way in the reaction. Experimental information and data on these topics will be presented in detail in a subsequent paper; illustrations of some of the systems tested, including different compounds and catalysts, are given in Tables I and II.

TABLE I

EXAMPLES OF METALS AND RADICALS WHICH DISPLAY INTERCHANGE

Reaction conditions, in general: a total of 0.3 mole organo-metallic compound, 1 g. $AlCl_3$, and 50 ml. hexane, heated to the boiling point, 60–80°, for 5–7 hours.

Metals	Radicals	Halides[a]
$Me_4Pb + Et_4Pb$	$Me_4Pb + Et_4Pb$	$Me_3PbCl + Et_3PbCl$[b]
$Me_4Sn + Et_4Sn$	$Me_3EtPb + MeEt_3Pb$[c]	$Me_2EtPbCl$[b]
$Me_2Hg + Et_2Hg$[c]	Me_2Et_2Pb	$Me_4Pb + Et_3PbBr$
$Et_4Si + Pr_4Si$[d]	Me_3-*i*-$PrPb$	$Me_4Pb + Et_3PbCl$
$Me_4Sn + Et_4Pb$	$Et_4Pb + Pr_4Pb$	$Et_4Pb + Me_3PbBr$
$Et_2Hg + Me_4Pb$	Et_2-*n*-Pr_2Pb	
	Me_2-*i*-Bu_2Pb	
	$Me_4Pb + Ph_4Pb$	
	$Ph_4Pb + (p\text{-tolyl})_4Pb$[e]	
	Me_3-*t*-$BuPb$[f]	

[a] No $AlCl_3$ used. [b] Acetone used as solvent. [c] No solvent used. [d] Temperature 180°. [e] Temperature 100°. [f] Temperature 130°; some decomposition occurred, probably as a result of the instability of the poly-*t*-butyllead compounds.

TABLE II

EXAMPLES OF CATALYSTS

Reaction tested, except as noted, with 0.3 mole mixed $Me_4Pb + Et_4Pb$, 50 ml. hexane or decalin, 1–2 g. catalyst, heated to 80° for five to six hours.

$ZnCl_2$[a,b,c]	Me_2AlCl	Me_3PbI[d,e]

$AlCl_3$	Et_3SnBr[d]	$FeCl_3$[a]
$AlBr_3$[d]	Et_3PbCl[e]	$PtCl_4$[h]

[a] Temperature 160–175°. [b] Some decomposition occurred. [c] Time 24 hours. [d] Reaction not complete in time allowed. [e] Catalyst 13 g. [f] Catalyst 5 g. [g] Reacted vigorously, forming lead chloride. [h] Temperature 100°.

Characteristics of the Reaction.—In most organic reactions involving the intermolecular transfer or metathetical substitution of radicals, functional groups, or atoms, yields of 80 to 90% of a single product are usually considered excellent, and it is generally accepted that a substan-

tial fraction of the compounds entering the reaction is diverted through competitive side reactions, including decompositions, polymerization, etc. In contrast, the type of reaction described in the present paper shows as one of its distinctive characteristics the essential absence of decomposition or other side reactions. In general, this was evidenced by the fact that there was no observable evolution of gas, or precipitation of metal, or heat of reaction, and that the recovery of the reactants was complete except for normal handling losses. The few exceptions, such as those noted in Tables I and II, could be ascribed to the use of high temperatures and the thermal instability at these temperatures of some of the compounds formed, or to the occurrence of irreversible reactions between the compounds and the catalyst when the latter was present in substantial amount. Quantitative evidence for the absence of side reactions in a typical normal case is given in the third paper of this series.[6]

Moreover, it was found that—after a period of time which depends on the temperature, the catalyst, and the compounds used—the system reached a constant composition which was not changed by further prolonged contact with the catalyst. This final composition is an equilibrium, since it can be reached from any direction, that is, starting with any initial mixture (or mixed-radical compound) which contains altogether the same proportions of each different kind of atom and radical involved. For example, an equimolecular mixture of tetramethyllead and tetraethyllead, or of trimethylethyllead and methyltriethyllead, or the single compound, dimethyldiethyllead, each gives the same final product. Also, these equilibria are entirely unaffected by the usual factors such as solvent, catalyst, or even temperature, and the equilibrium composition is a function only of the mole fraction of the various R and M components present in the system.

In view of this, it seemed logical to make the simplest possible hypothesis as to the nature of the process: to wit, that the interchange occurs *at random.* This was found to be the case: the final composition of any system agrees with that calculated from the laws of probability alone. The distinctive characteristics of this reaction and of the resulting equilibrium—the freedom from side reactions, and the absence of chemical or energy factors affecting this random equilibrium—seem to justify identifying them by new names, and it is proposed to call the reaction the "Redistribution Reaction," and its product a "Random Equilibrium Mixture."

Random Distribution: The Application of the Laws of Probability.—To illustrate the application of the laws of probability to this random distribution of the interchanged radicals or atoms, consider the simple case of a single metal, M, and two organic radicals, A and B, the mole fractions of which are a and b, respectively, where $a + b = 1$. Imagine that all the radicals have been removed from the M atoms, and are to be returned thereto at random. Then the probability that the first valence of M will be satisfied by A is a, and by B, is b; so that the concentrations will be

$$a\mathrm{MA} \quad \text{and} \quad b\mathrm{MB}$$

For the second valence, the same holds, and applies independently to MA and MB, giving, respectively

$$a^2\mathrm{MA_2} + ab\mathrm{MAB} \quad \text{and} \quad ab\mathrm{MAB} + b^2\mathrm{MB_2}$$

or

$$a^2\mathrm{MA_2} + 2ab\mathrm{MAB} + b^2\mathrm{MB_2}$$

Applying the same method of deduction to the more general case of one kind of central atom (or group) M, of valence n, and s different kinds of substituent radicals (or atoms), $\mathrm{R_1}$, $\mathrm{R_2}$, . . ., $\mathrm{R_s}$, whose mole fractions are $r_1, r_2, \ldots, r_s$, respectively, gives as a result that the concentration of any one of the possible compounds, $\mathrm{M(R_1)}_a\mathrm{(R_2)}_b \ldots \mathrm{(R_s)}_j$ (where $a + b + \ldots + j = n$) is equal to

$$\frac{n!\,(r_1)^a(r_2)^b \ldots (r_s)^j}{a!\,b! \ldots j!}$$

and the total number of different $\mathrm{R}_n\mathrm{M}$ compounds is equal to

$$\frac{(n + s - 1)\,!}{n!\,(s - 1)\,!}$$

When more than one kind of central atom or group, M, is present, these two general formulas apply independently to each kind of M taken in conjunction with the R groups attached to it.

The above formulas reduce to rather simple forms in the case of systems containing few constituents. Thus, when there is only one central group M of valence n and two different kinds of radicals ($s = 2$), the number of different compounds is equal to $(n + 1)$, and the concentration of each is given by the corresponding term of the binomial expansion of $(r_1 + r_2)^n$. Denoting

TABLE III

NUMBER, CONCENTRATIONS, AND EXAMPLES OF R_nM COMPOUNDS

Valence of M = n	No. of compds. R_nM	Concentration of R_nM, $R_{n-1}R'M$, ..., R'_nM					Examples of types of compds.
1	2	r	$(1-r)$				$CH_3CO\text{-}OR$; Et-X; R-Na; R-HgCl
2	3	r^2	$2r(1-r)$	$(1-r)^2$			R_2-Hg; R_2-$PbCl_2$; X_2-C_2H_4; 3	4	r^3	$3r^2(1-r)$	$3r(1-r)^2$	$(1-r)^3$		R_3-Bi; R_3-PbBr
4	5	r^4	$4r^3(1-r)$	$6r^2(1-r)^2$	$4r(1-r)^3$	$(1-r)^4$	R_4-Sn

r_1 by r, and r_2 by $(1-r)$, the corresponding values for valences of M from 1 to 4 are given in Table III, which includes examples of corresponding types of compounds.

From a knowledge of the composition of the original mixture, or from the over-all analysis of the product, the values of the r's are determined, and the expected concentrations in the final mixture can be calculated. As an illustration, the calculated concentrations of all five constituents in the system R_4M containing two kinds of groups, R and R', is shown in Fig. 1, for the whole range from $r = 0$ to $r = 1$.

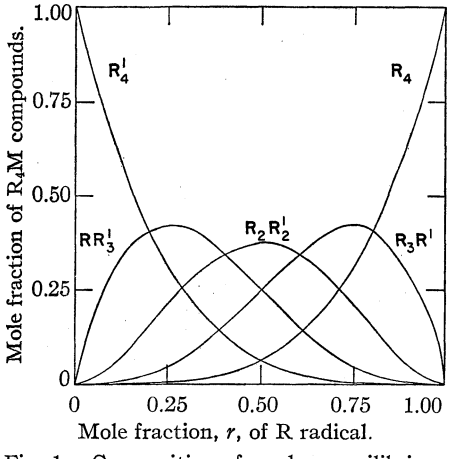

Fig. 1.—Composition of random equilibrium mixtures of the type $(R_nR'_{4-n})M$.

Experimental Confirmation of Random Equilibrium Mixtures.—The experimental data covering many of the systems which underwent the redistribution reaction were tested in this manner, with convincing results. In general, the analytical procedure consisted in washing or extracting the final reaction mixture to remove the catalyst, together with organo-metallic halides if present; the volatile metal alkyls (or other volatile compounds) were then separated by fractional distillation[7]; the less volatile metal aryls were analyzed by freezing-point determinations, and the halides, if any, were identified by methods (which will be described elsewhere) based on solubility and alkylation.

Since these studies in general were regarded as being exploratory in a new field, and it was desired to extend their scope as far as was expedient within the time available, it was advantageous in some cases to carry out the analyses only partially, or semi-quantitatively, to an extent sufficient to show that the redistribution reaction had occurred and that the composition of the product was at least roughly in accord with that estimated for a random equilibrium mixture.

The typical results obtained in most cases are illustrated, for six representative mixtures, by Figs. 2–5. These give the experimental distillation data plotted on a volume percentage basis, in comparison with the ideal distillation curves which were calculated for random equilibrium mixtures of the over-all compositions indicated by the experimental data. It is clear that these typical results show a very satisfactory agreement with the predicted values. The identity in composition shown in Fig. 2 for the prod-

(7) The procedure followed and results obtained are described in the second paper of this series, by Calingaert, Beatty and Neal, THIS JOURNAL, **61**, 2755 (1939).

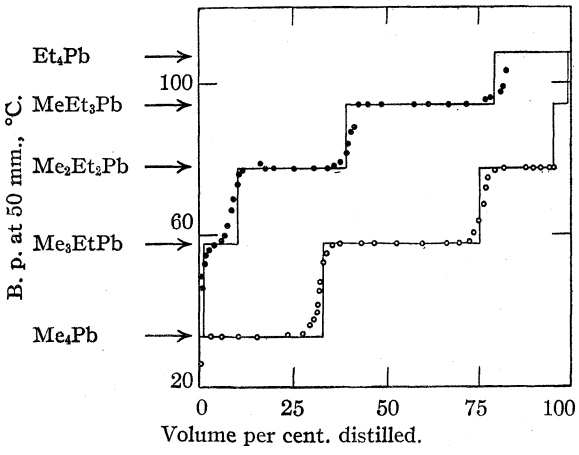

Fig. 3.—Distillation of the reaction product from $Me_4Pb + Et_4Pb$. Solid line calculated for random equilibrium mixture having ○ [Me] = 0.776; ● [Me] = 0.345.

ucts from two entirely different mixtures of the same over-all composition, and the marked difference between this product and those from two similar mixtures of somewhat different over-all composition (shown in Fig. 3) is noteworthy. The distillation shown in Fig. 4, although not

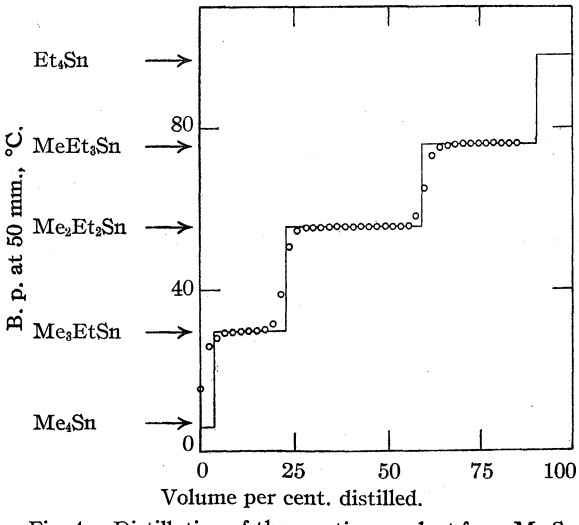

Fig. 4.—Distillation of the reaction product from $Me_4Sn + Et_4Sn$. Solid line calculated for random equilibrium mixture having [Me] = 0.46.

completed, is ample evidence for the agreement with theory in this case. In the particular experiment with two metals illustrated by Fig. 5, the separation and analysis of the various fractions was not rigorous, and as a result the over-all composition was not known with certainty. Hence, the ideal distillation curve is not given, but the results are considered adequate to indicate the presence of all ten possible compounds. As the care and accuracy of the analyses increase the agreement with theory becomes more exact, and is within the experimental error of less than 1%.[7]

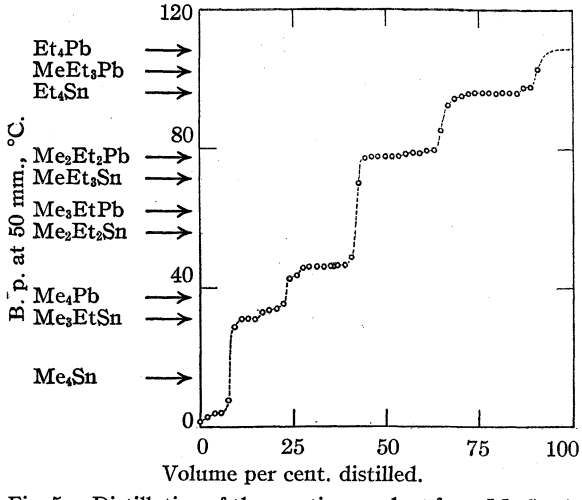

Fig. 5.—Distillation of the reaction product from $Me_4Sn + Et_4Pb$ (experimental curve only).

Discussion.—It is worthy of emphasis that, although organo-metallic compounds have been used for illustration here, the redistribution reaction is not limited to this field. The content of the present paper is designed to serve only as a general presentation of the subject, and subsequent contributions will cover, individually, specific points of interest in both organo-metallic compounds and other fields. Although we are not prepared to consider the scope of this reaction and its implications at this time, a few salient points may be mentioned here.

While the mechanism of the reaction clearly involves atoms and radicals, it is evident, from common knowledge of the conditions under which free atoms or radicals exist, that these are not present as such. Free radicals, of the kinds to be expected here, if liberated in a liquid phase would result in the formation of a variety of secondary products which are totally absent in the present reaction. Dissociation into ionized radicals also appears improbable, especially for the halogen-free alkyls; in accord with this, solvents are not required and, if added, do not appear to influence the reaction proper.

Accordingly, a mechanism involving the formation of molecular complexes or coördination compounds with the catalyst is indicated. The catalysts used are such as can be converted, in the reaction mixture, into the form of organic or

organo-metallic compounds which contain the radicals to be interchanged. Then the possibility is evident for the interchange to occur when the reactants and the catalyst are united together in a complex.

While the molecular activation required to form such complexes might be anticipated as the result of the action of powerful catalysts such as aluminum chloride, it would hardly have been expected with catalysts such as trialkyllead halides. Moreover, in some of the metal aryls at higher temperatures there is a spontaneous interchange of radicals without the presence of any catalyst, suggesting that the catalyst merely accelerates a process, the possible occurrence of which is inherent in the reactants themselves. This argues for a considerably greater flexibility of the covalent bonds in the metal alkyls and aryls than would commonly be assigned to compounds of their structure and chemical stability, and it is not evident how this can be ascribed to the existence of mesomeric or electromeric forms or to a state of resonance.

Information as to the relative mobilities or reactivities of the radicals, and as to the preferential association between different central atoms and radicals, can be obtained in one and the same system, when more than two different radicals or more than one central atom are present. Even when only one central group and two kinds of radicals are employed, the formation of random equilibrium mixtures implies that the energy of formation of the different compounds in each system is a linear function of the molecular weight, and (surprisingly) is not affected by the symmetry (or asymmetry) of the molecules. For example, the energy of formation of one mole each of tetramethyllead and tetraethyllead is equal to that of one mole each of trimethylethyllead and methyltriethyllead.

For studies of reaction kinetics in the liquid phase, catalyzed reactions such as described here, which reach an equilibrium in a measurable time and are free from side reactions and specific solvent effects, are particularly suitable. Also, the occurrence of two or more simultaneous reactions in such systems as R_4M or R_3M permits an internal check on the relative rates of the different reactions, regardless of the absolute rates, and this in turn provides a distinctive method of approach to the determination of the reaction mechanism.

In addition to opening up avenues of theoretical investigation, the redistribution reaction is adaptable as a new method of organic synthesis. As one illustration, metathesis can now be induced directly between similar compounds which are usually inert to one another, such as esters; more broadly, mixed compounds, such as mixed esters of polybasic acids, mixed polyhalides, and mixed organic compounds of polyvalent metals, can be prepared by direct metathetical reactions which may afford a considerable saving of time and material over the classical step-wise methods. A few examples of this type are

$$Me_4Pb + Et_4Pb \longrightarrow 2Me_2Et_2Pb$$
$$MeCOOEt + PrCOOMe \longrightarrow MeCOOMe + PrCOOEt$$
$$2EtCl + C_2H_4Br_2 \longrightarrow 2EtBr + C_2H_4Cl_2$$

Here the arrows indicate a suitable combination of reaction, separation, and re-cycle processes.

Summary

A hitherto unrecognized type of reaction is described, in which all the radicals or atoms of one kind, present in a mixture in which they are linked to one or more central groups or atoms of another kind, are interchanged between all the central groups present. This process, which is termed the "Redistribution Reaction," takes place smoothly at low temperatures in the liquid phase under the influence of a catalyst. The yield is quantitative, and the composition of the resultant mixture can be calculated from that of the reactants on the basis of a random distribution of the interchanged radicals or atoms: this reaction product is therefore termed a "Random Equilibrium Mixture." The reaction presents interesting possibilities for theoretical investigation into the nature and behavior of covalent bonds and the mechanism and kinetics of their reactions; also, the reaction provides novel methods of preparation of various organic compounds.

The Redistribution Reaction. II. The Analysis of Metal Alkyl Mixtures and the Confirmation of Random Distribution

BY GEORGE CALINGAERT, HAROLD A. BEATTY AND HERBERT R. NEAL

In the previous paper of this series[1] it was stated that the analysis of mixtures of organo-metallic compounds which had undergone the redistribution reaction showed that the composition of the product obtained corresponded to a random distribution of the interchanged radicals. The present paper describes the analytical method used for the volatile metal alkyls, including a test of its accuracy, and gives a quantitative demonstration of this random distribution. The corresponding analytical methods and results obtained for organo-metallic halide mixtures will be given in a subsequent paper.

The Accuracy of Analysis.—From an estimation of the precision of the various analytical observations and of other sources of error, it was concluded that the absolute accuracy obtainable for a mixture of volatile metal alkyls should be close to 1% for each constituent. This conclusion was tested as follows. Two different mixtures of the five methyl and ethyl tetraalkyllead compounds were prepared—one containing about equal amounts of each compound, the other having about the composition of a random equilibrium mixture containing equal proportions of methyl and ethyl radicals. These mixtures were made up by one experimenter, by volume, from the pure individual compounds, and the volumetric summation was checked by comparison of the total net weight with that calculated from the densities of the compounds. The entire mixtures were each analyzed by another experimenter, using the procedure described below. The results, given in Table I, confirm the predicted accuracy, and indicate that the errors are independent of the volatility or concentration of the constituent; the standard deviation between the taken and observed values for the entire group of ten values was 0.6%, and the maximum deviation was 0.7%.

Confirmation of Random Distribution.—Most of the data suitable for comparison with the compositions predicted for random distribution were obtained for mixtures of the methyl and ethyl tetraalkyllead compounds. The data in Table II were selected as the best of a large number of analyses of these mixtures, the basis of the selection being solely the appearance of the plotted distillation curve together with freedom from known unusual sources of error or other complications. Of this group so selected, one analysis was discarded as being statistically out of line with the remainder.

TABLE I

ANALYSIS OF KNOWN MIXTURES

Compound	Volume, ml. Taken	Volume, ml. Found	Volume, % Taken	Volume, % Found	Error
		Test no. 1			
Me_4Pb	13.00	12.3	20.60	19.9	−0.7
Me_3EtPb	12.49	12.7	19.79	20.5	.7

$MeEt_3Pb$	12.30	12.0	19.49	19.4	− .1
Et_4Pb	13.32	12.7	21.11	20.5	− .6
Total	63.11	61.8			
Weight, g., calcd., 114.04; found, 114.01					
		Test no. 2			
Me_4Pb	2.90	2.5	4.77	4.15	−0.6
Me_3EtPb	14.51	14.8	23.86	24.6	.7
Me_2Et_2Pb	23.80	23.4	39.14	38.85	− .3
$MeEt_3Pb$	15.00	14.5	24.67	24.1	− .6
Et_4Pb	4.60	5.0	7.56	8.3	.7
Total	60.81	60.2			
Weight, g., calcd., 108.96; found, 108.98.					

The mole fraction of methyl and ethyl radicals in the mixture is denoted, respectively, by r and $(1 - r)$. The value of r was, in many cases, not known in advance; accordingly, it was calculated in each case from the result of the analysis by means of the equation

$$r = [Me_4Pb] + 0.75[Me_3EtPb] + 0.5[Me_2Et_2Pb] + 0.25[MeEt_3]Pb$$

where the brackets denote the concentration in mole fraction. The predicted mole fractions of the five tetraalkyllead compounds are

Me_4Pb	Me_3EtPb	Me_2Et_2Pb	$MeEt_3Pb$	Et_4Pb
r^4	$4r^3(1-r)$	$6r^2(1-r)^2$	$4r(1-r)^3$	$(1-r)^4$

Inspection of the differences shown in Table II indicates that, like those in Table I, they are scattered at random and do not appear to be a function of the compounds or of their concentrations or of r, the mole fraction of methyl radicals. Moreover, there is no statistically

significant difference between the results given in Tables I and II. It appears, therefore, that the differences in Table II can be ascribed solely to experimental error. In contrast to these small differences are the large effects resulting from a change in the relative proportions of methyl and ethyl radicals, as can be seen by comparing the calculated compositions for different values of r in Table II, or by referring to Fig. 1 in the preceding paper.[1] The confirmation of the randomness of the redistribution, for this system of lead compounds at least, is evident.

TABLE III

ANALYSIS OF RANDOM EQUILIBRIUM MIXTURES FOR OTHER SYSTEMS

The mole fraction of the first of the two radicals cited is denoted by r. The data are given in mole per cent.

[a] The [OEt] was augmented by the $Al(OEt)_3$ used as catalyst.

Quantitative data for some of the other systems tested are given in Table III. These data were mostly of a somewhat lower order of analytical accuracy than those given above, and it is seen that the deviations from the predicted values are considerably greater. However, the deviations appear to be well scattered and random, and show no statistically significant trends, and it may justifiably be concluded that in these cases also there is no deviation from the random distribution outside of the experimental error in each.

Experimental Method and Procedure.—The relative proportions of the various metal alkyls present in a given mixture were determined by fractional vacuum distillation, after removal of the catalyst and halide salts (if any) by filtration and washing or extraction. Standard distillation practice was followed, with adaptations appropriate to the particular mixtures.

The equipment used, shown schematically in Fig. 1, comprised a small fractionating column, vacuum jacketed and electrically heated; a 100-ml. three-necked distilling flask, fitted with a nitrogen inlet tube and heated with an oil-bath; a still head, fitted with a thermometer, and partial or total condenser; a graduated receiver kept in a transparent Dewar-flask cooling bath; an additional trap kept in a dry-ice-bath; together with a vacuum pump, an adjustable mercury U-tube pressure regulator, manometers for normal and low pressures, a controlled nitrogen supply, and other usual accessory equipment.

The column, 32 cm. long and 14 mm. i. d., was packed with 4.76-mm. ($^3/_{16}$-in.) filed aluminum balls.[2] The still head was designed to reduce the dead space to a minimum, using a partial condenser, but better results were obtained with only a slight increase in hold-up, by using a total con-

(2) This packing is prepared by rubbing the balls between 6-in. (15-cm.) circular flat steel files. It has a fairly low H. E. T. P., a very low hold-up, and high maximum throughput.

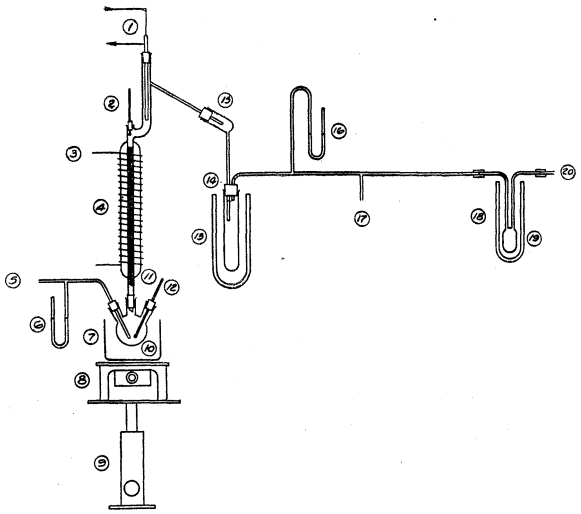

Fig. 1.—Distillation equipment: 1, condenser with regulated water flow; 2, thermometer, range 30–90°; 3, jacket heating wire; 4, evacuated glass jacket; 5, nitrogen inlet; 6, manometer; 7, oil-bath; 8, hot plate; 9, movable platform; 10, 100-ml. flask; 11, 14-mm. i. d. column with 32 cm. of filed aluminum ball packing; 12, thermometer; 13, unsilvered Dewar flask and bath at −30°; 14, 80-ml. graduated receiver; 15, adapter; 16, low-pressure manometer; 17, nitrogen inlet; 18, Dewar flask and bath at −75°; 19, trap; 20, line to pressure regulator, high-pressure manometer, and exhaust.

denser and controlling the delivery of product by the adjustment of a grooved stop-cock. Reflux ratios, and also the correct heating current for the column jacket, were estimated by counting drops. The graduated receiver was kept at about −30° in a trichloroethylene bath with dry-ice. All liquid volumes were corrected to 20° by an arbitrary temperature coefficient of 0.1% per degree. Since the temperature of observation, as well as the true temperature coefficient, was usually almost identical for all the distillate, this arbitrary procedure produced only negligible errors. The pressure was lowered at intervals during the progress of the distillation, and the temperature and level of the heating bath were adjusted, so as to maintain a temperature in the neighborhood of 50–75° at the still head, thus minimizing the thermal decomposition of the higher-boiling metal alkyls. The reflux ratio was maintained at about 5 to 1 over the flat portions of the distillation curves, and was increased to about 10 to 1 at the point of separation between compounds.

The observed temperatures at any given pressure were converted to a common basis of 50 mm. pressure. Inspection of vapor pressure data for the five methyl and ethyl tetraalkyllead compounds, obtained from the literature and in this Laboratory, showed that the vapor pressures are given very accurately by the five equations in Table IV which have a common point of intersection[3] at log P = 4.8566 and $1/(t + 230) = 0.0015097$, where t = °C.

TABLE IV

VAPOR PRESSURES OF LEAD ALKYLS

$\text{Log}_{10} P$ (mm. Hg) $= A - B/(t + 230)$; t = °C.

Compound	A	B	t at 50 mm., °C.
Me_4Pb	6.9381	1378.7	33.2
Me_3EtPb	7.2760	1602.5	57.3
Me_2Et_2Pb	7.5903	1810.7	77.4
$MeEt_3Pb$	7.8768	2000.5	93.8
Et_4Pb	8.1547	2184.6	108.4

The assumption was made that any other similar metal alkyl (or mixture) would have a similar vapor pressure line passing through the same point of intersection. Accordingly a nomogram was constructed to give the temperature at 50 mm. pressure corresponding to any observed pressure and temperature.

The distillation data were plotted to give the volume of distillate corrected to 20° as a function of the temperature corrected to 50 mm. pressure. Good curves usually were obtained and the identity of the distillate over the various flat portions of the curve as a rule was defined beyond question by the nature of the materials taken for the reaction. In these cases the volume of each constituent in the distillate was estimated by dividing the distillation curve into segments at points halfway between the boiling points (at 50 mm.) of the various compounds. While such a method of division is theoretically not strictly accurate, the errors so introduced are very small, and the personal equation is eliminated.

In those cases where the composition of the distillate over each portion of the curve was not unequivocally known (for example, in the product from a mixture of tetramethyltin and tetraethyllead, or in cases where a solvent might also be present), the distillate was taken in separate cuts which were analyzed for the metals present by conventional methods. When most of the charge had been distilled, and no further fractionation was possible, the distillation was stopped, the column allowed to drain, and the volume of residue measured. This volume was taken to consist solely of the highest-boiling constituent, when no other than that one constituent was conceivably present; otherwise, it was taken to comprise all the possible remaining constituents.

From the volumes of the constituents and their known

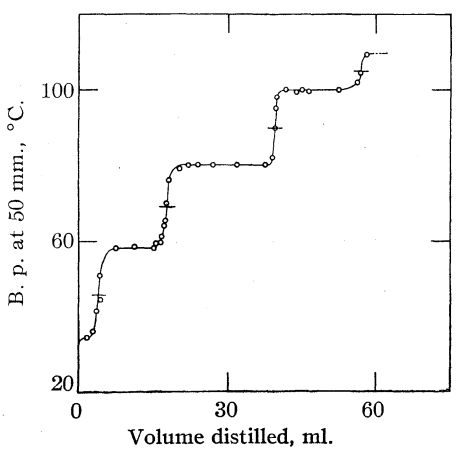

Fig. 2.—Typical distillation curve: —points of division between compounds; ---undistilled residue.

(3) Calingaert and Davis, *Ind. Eng. Chem.*, **17**, 1287 (1925).

densities and molecular weights, the mole fractions of each component of the metal alkyl portion of the product were calculated. In those relatively few cases where two or three components were expected to be present in the residue, a reasonable estimate of each was made; inasmuch as the amounts of these involved were always small and their various molecular volumes did not differ greatly, this procedure introduced no significant uncertainty in computation of the total amount of each kind of metal and alkyl group present.

The observed and derived data and the distillation curve for a typical example of a satisfactory analysis of a mixture of the five methyl and ethyl tetraalkyllead compounds are given in Table V and Fig. 2.

Summary

The procedure used for the analysis of volatile metal alkyl mixtures by distillation is described, and is shown by tests to give results accurate to less than 1% of the total volume.

Analyses of a series of mixtures of methyl and ethyl lead alkyls which have undergone the redistribution reaction show, within this experimental error, exact agreement with the compositions predicted for random equilibrium mixtures; individual analyses for other systems are also in satisfactory accord with prediction.

The Redistribution Reaction. III. Determination of a Material Balance

BY GEORGE CALINGAERT AND HAROLD SOROOS

The first paper[1] of this series reported, as a distinctive characteristic of the redistribution reaction, its essential freedom from side reactions and decomposition. This was evidenced, for many different systems, by the absence of gas evolution, precipitation, tar formation, or heat of reaction, and by satisfactory recoveries of material. To provide a quantitative measure of this, for one case at least, the present work was undertaken, and consisted in carrying out a representative redistribution reaction in the usual manner, obtaining an accurate material balance, and testing for secondary products.

Such a determination can be made with a high degree of accuracy for a reaction involving tetraalkyllead compounds, since any side reactions will convert the lead to other forms, which can be separated readily from the tetraalkyllead compounds constituting the bulk of the reaction mass. Accordingly, a mixture of tetramethyl- and tetraethyllead was used for this test.

Table I gives the material balance on a lead basis for two tests in which a mixture of the two

Pb as R_4Pb	56.7827	274.04	98.13	60.0334	289.72	98.75
Pb as R_3PbCl	0.7803	3.77	1.35	0.9053	4.37	1.49
Pb as $PbCl_2$	0.0470	0.22	0.08	0.0654	0.31	0.11
Loss (or gain)	+0.2540	+1.22	+0.44	−0.2106	−1.01	−0.35
Total	57.8640	279.25	100.00	60.7935	293.39	100.00

lead alkyls was diluted with hexane and treated with aluminum chloride. The recovery of tetraalkyllead averaged 98.5%; the remaining 1.5% was principally trialkyllead chloride. A trace of lead chloride was found, as was to be expected since this is a normal decomposition product of trialkyllead chlorides. No metallic lead was formed. Aluminum chloride is known to react with tetraalkyllead,[2] and the trialkyllead halide found corresponded approximately to the aluminum chloride taken, in accordance with the equation $AlCl_3 + R_4Pb \rightarrow RAlCl_2 + R_3PbCl$.

These results suggested that the use of alkylaluminum chlorides as catalysts might reduce the formation of the lead salts, and this was found to be so. Table II gives the data for two tests in which the mixture of the two lead alkyls, without solvent, was treated with methylaluminum dichloride and dimethylaluminum chloride, respectively. In order to obtain readily-measurable quantities of the products of the reaction with the catalysts, the amounts of the latter used were very much greater than necessary for complete redistribution. Analyses were made only for the alkyllead chlorides and lead chloride formed; again, there was no metallic lead. The amount of lead thus found in the form of salts equalled only 0.10 and 0.04 mole, respectively, per mole of catalyst. A parallel test using aluminum chloride confirmed the results given in Table I, yielding 1.46 moles of lead chlorides per mole of catalyst.

TABLE II

TETRAALKYLLEAD CONVERTED TO LEAD CHLORIDES BY DIFFERENT ALUMINUM CATALYSTS

Pb input, as R_4Pb, millimoles	Catalyst Compound	Catalyst Millimoles	Pb output, as chlorides, millimoles	Moles Pb chlorides per mole Al

300.81	$MeAlCl_2$	18.84	1.965	0.104
297.19	$AlCl_3$	3.12	4.540	1.455

(2) Gilman and Apperson, *J. Org. Chem.*, **4**, 162 (1939).

In these three tests, the tetraalkyllead product of the reaction was distilled as described in the preceding paper[3] and the redistribution was found to be complete. In the first tests using aluminum chloride the distillation was omitted, since concurrent experiments showed that the reaction was complete, under the conditions used, with lower concentrations of the catalyst.

It is, therefore, evident that the redistribution reaction is quantitative, apart from such irreversible interaction with the catalyst as may be imposed by the selection of one particular catalyst or another.

Experimental

Determination of a Material Balance.—The determination of a material balance was carried out in the following manner.

Approximately 0.15 mole each of tetramethyl- and tetraethyllead with 40-ml. of *n*-hexane were placed in a glass-stoppered flask and weighed. After a sample was withdrawn for a lead analysis, a small amount of anhydrous aluminum chloride was added and its weight determined. A reflux condenser, the top of which was connected to a dry-ice trap, was attached to the flask and the mixture was refluxed at 80° for four hours. The contents of the trap and condenser were washed into the reaction mixture with 5-ml. of *n*-hexane. The main body of the reaction mixture, containing the tetraalkyllead compounds and dissolved trialkyllead chlorides, was filtered by nitrogen pressure through a sintered-glass filter-stick into a tared flask, using several small portions of *n*-hexane to wash the residue. Samples of the filtrate and the hexane washings were analyzed for lead. An aliquot of the filtrate was extracted with four 25-ml. portions of concentrated ammonia solution to remove the dissolved trialkyllead chlorides, and after filtering the combined extracts through a wet filter paper, the lead content was determined. The residue was washed with five 10-ml. portions of benzene, followed by filtration through the filter-stick to remove the undissolved trialkyllead chlorides, and the lead content of the washings was determined. About 100 ml. of water in small portions was next used to wash the residue free of lead chloride. The lead content of the washings was determined. The flask and filter-stick were finally washed with

(3) Calingaert, Beatty and Neal, THIS JOURNAL, **61**, 2755 (1939).

nitric acid and the lead was determined. The analytical data for the two experiments are given in Table III.

TABLE III

LEAD ANALYSIS

	Input	Pb found, g. Test 1	Test 2
R_4Pb	(Hexane solution)	57.8640	60.7935
	Recovery		
R_4Pb, R_3PbCl	(Hexane solution)	55.5530	58.8735
R_4Pb, R_3PbCl	(Hexane washings)	1.4430	1.5290
R_3PbCl	(NH_3 extraction)	0.2133	0.3691
R_3PbCl	(Benzene washings)	.5670	.5362
$PbCl_2$		.0440	.0639
Residue	(HNO_3 washings)	.0030	.0015

Determination of Lead Chlorides Formed with Different Catalysts.—The determination of the amount of tetraalkyllead compounds converted to alkyllead chlorides and lead chloride using different aluminum catalysts was carried out in the following manner.

To a weighed amount of the catalyst, contained in a 500-ml. 3-necked flask equipped with vapor-proof mechanical stirrer, thermometer, and reflux condenser, the tetraethyllead followed by the tetramethyllead was added slowly from a dropping funnel in the top of the condenser. The flask was cooled in an ice-bath and an atmosphere of nitrogen was maintained within the flask during the addition of the alkyllead compounds. Failure to follow the experimental procedure and precautions outlined above may result in violent decomposition of the tetraalkyllead, especially of the tetramethyllead. The ice-bath was then removed and replaced by an oil-bath; the mixture was stirred and maintained at 80° in an atmosphere of nitrogen for two hours.

The reaction flask was then cooled and the catalyst decomposed by shaking with 100 ml. of distilled water. The aqueous layer, containing alkyllead chlorides and lead chloride, was separated, filtered through a wet filter paper and analyzed for lead. The alkyllead layer was extracted with four 25-ml. portions of concentrated ammonia solution, to remove trialkyllead chlorides. The extracts were combined, filtered through a wet filter paper, and analyzed for lead. The filter papers were finally washed with nitric acid to dissolve any lead residue, and the washings were analyzed for lead.

The alkyllead layers were finally distilled to ascertain the extent of redistribution. The reaction was complete in every case. Table IV gives the analyses of products for lead chlorides.

TABLE IV

LEAD ANALYSIS

Products	Catalyst Me_2AlCl	$MeAlCl_2$	$AlCl_3$
Pb in Aq. layer, g.	0.1296	0.3150	0.9220
Pb in NH_3, g.	.0000	.0926	.0193
Pb in residue, g.	.0000	.0000	.0000
Pb (total), g.	.1296	.4076	.9413

Summary

By determination of an accurate material balance, the redistribution of a mixture of tetramethyl- and tetraethyllead in hexane solution is shown to be quantitative. When aluminum chloride is used as the catalyst, it is found to react irreversibly with the alkyllead compounds, as expected, forming alkyllead chlorides in very small quantities, equivalent to about 1.5 moles per mole of catalyst. When methylaluminum chlorides are used as catalysts, this amount becomes negligible.

The Reaction of the Grignard Reagent with Homophthalic Anhydride

BY CHARLES C. PRICE, FREDERICK M. LEWIS AND MORRIS MEISTER

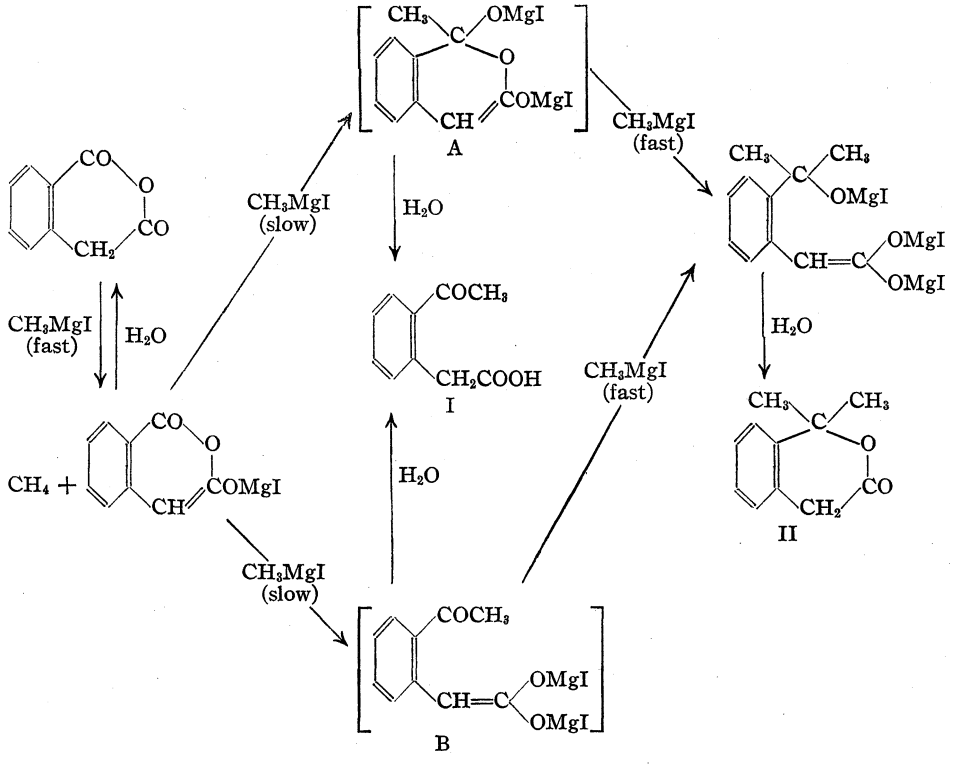
The reaction of methylmagnesium iodide with homophthalic anhydride has been investigated as a possible method for the preparation of the unreported keto acid, *o*-acetylphenylacetic acid (I), which was desired in connection with another investigation.

Bauer and Wolz,[1] in determining the products from the action of an excess of several Grignard reagents on homophthalic anhydride, obtained only the various homophthalides. Since Simonis and Arand and Weizmann, Bergmann and Bergmann[2] have reported keto acids as well as phthalides from phthalic anhydride, the reaction with homophthalic anhydride has been studied under conditions more favorable for the formation of the desired keto acid. However, in spite of using the inverse procedure, *i. e.*, adding the Grignard reagent to a solution of the anhydride, and using just the calculated amount of reagent, one-half of the starting material was converted to dimethylhomophthalide (II), the remainder was recovered unchanged. No *o*-acetylphenylacetic acid was obtained, although in a few cases the recovered homophthalic acid had a low melting point and gave an iodoform test, indicating the possible presence of small amounts of this substance.

(1) Bauer and Wolz, *Arch. Pharm.*, **249**, 454 (1911).

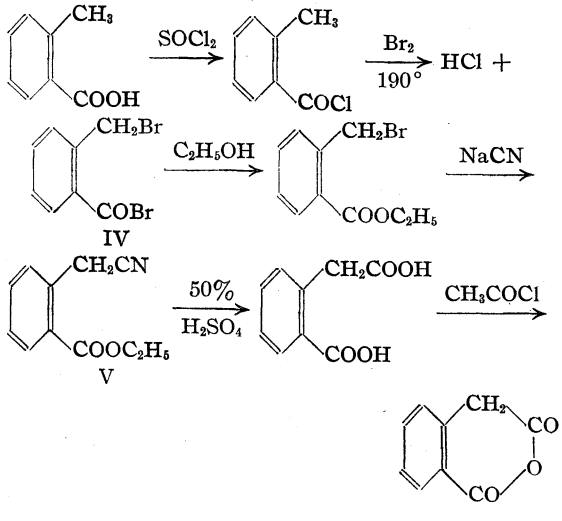
(2) (a) Simonis and Arand, *Ber.*, **42**, 3721 (1909); (b) Weizmann, Bergmann and Bergmann, *J. Chem. Soc.*, 1369 (1935).

Since the anhydride enolizes readily, the first mole of Grignard reagent is converted to methane. The theoretical amount of reagent for the formation of the keto acid is, therefore, two moles. The non-formation of the keto acid by the second mole of reagent under these conditions indicates that the reaction must follow either of the two courses outlined below.

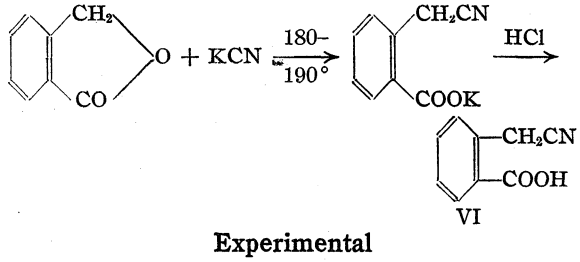


It is the opinion of the authors that the reaction through intermediate A is the more likely.

A procedure for the preparation of homophthalic acid from *o*-toluic acid has been developed. The latter acid is converted to its acid chloride and brominated according to the directions of Davies and Perkin.[3] Treatment with alcohol and sodium cyanide converted the bromo acid bromide (IV) to the nitrile ester (V) of homophthalic acid. Hydrolysis to the acid was accomplished by warming with 50% sulfuric acid. The preparation is relatively simple since the first product isolated is the nitrile-ester and the over-all yield from *o*-toluic acid to homophthalic anhydride is 70–75% of the theoretical.



Another simple preparation, which apparently has been neglected, is that reported by Wislicenus[4] starting from phthalide. The yield of acid nitrile obtained in this Laboratory by this method was as high as 80–85%.



Experimental

o-**Carbethoxyphenylacetonitrile (V).**—*o*-Toluic acid (100 g.) was refluxed for two hours with twice the theoretical

(3) Davies and Perkin, *J. Chem. Soc.*, **121**, 2202 (1922).
(4) Wislicenus, *Ber.*, **17**, 2178 (1884).

quantity of thionyl chloride. After the excess thionyl chloride had been removed by distillation, the acid chloride was heated to 185–195° in an oil-bath and 135 g. of bromine was added slowly (one to two hours) through a separatory funnel the tip of which was below the surface of the reaction mixture. After cooling in an ice-bath, 200–250 cc. of absolute alcohol was added. The alcoholic solution of the bromoester was then poured into a solution of 40 g. of sodium cyanide in 30 cc. of warm water, the mixture refluxed for five hours and then half the alcohol removed by evaporation or distillation.

The ester was extracted with several portions of ether, the ethereal solution washed three times each with water, with sodium bicarbonate and again with water and then dried over sodium sulfate. Evaporation of the ether left a dark brown oil from which 85–90 g. (71–76%) of colorless material was obtained by distillation (16 mm.), b. p. 170–170.5°. This compound had the following properties: d^{20}_{20} 1.1246; $n^{20}D$ 1.5172; M_D calcd., 51.2; M_D found, 50.8. *Anal.* Calcd.: N, 7.4. Found: N, 7.7.

Homophthalic Anhydride.—The hydrolysis of the nitrile and ester groups in the above compound was accomplished readily in over 90% yield by the action of an equal volume of 50% sulfuric acid at 100° for twelve hours. Longer reaction time or higher or lower acid concentration decreased the yield. The reaction mixture was poured over an equal weight of ice and the precipitated acid collected and dried. Conversion to the anhydride was accomplished readily by refluxing a solution of the acid in three times its weight of acetyl chloride for half an hour and precipitating the anhydride with petroleum ether (60–90°). The product was obtained in 90–95% yields and melted at 140–141°.

***o*-Carboxyphenylacetonitrile (VI)**[5] was prepared according to the directions of Wislicenus.[4] A mixture of 40 g. of phthalide and 40 g. of potassium cyanide yielded 35 g. (82%) of crystalline acid nitrile, m. p. 114–115°. Seven grams of phthalide was recovered unchanged.

Experimental Procedure.—A solution of methylmagnesium iodide was prepared by treating 2 g. of magnesium turnings with 4.7 cc. of methyl iodide and 39 cc. of ether for one hour. The solution, under an atmosphere of nitrogen at all times, was transferred to a separatory funnel and added to 5 g. of homophthalic anhydride dissolved in ether in a flask equipped with a mechanical stirrer and a reflux condenser. During the addition of the first half of the reagent, methane was evolved with the formation of a yellow precipitate. The time for the addition of the remaining reagent varied from one to six hours, that of subsequent refluxing from three to six hours, and that of standing at room temperature after refluxing from zero to fifteen hours with no appreciable difference in the products of the reaction.

At the end of the specified time, the reaction mixture was poured into ice and 35 cc. of hydrochloric acid. Unreacted homophthalic anhydride precipitated. It was collected, recrystallized from ether and weighed 1.3–1.8 g., m. p. 140–141°. The ether layer in the first filtrate was washed thoroughly with sodium bicarbonate solution. Addition of acid to this bicarbonate extract precipitated homophthalic acid which was dried and weighed 0.4–0.6 g., m. p. 173–175°. In a few cases the precipitated acid melted low and over a wider range and gave an iodoform test indicating the presence of at least a small amount of *o*-acetylphenylacetic acid. The pure keto acid could not be isolated, however.

The ether solution was next dried and evaporated, leaving a neutral yellow oil and white solid. The solid was collected by filtration, washed with a minimum amount of ether and then recrystallized from ether. The white needle-like crystals were weighed 1.9–2.3 g., m. p. 94–95°. The combined ethereal mother liquors were evaporated and the residual yellow oil weighed 0.6–0.8 g. No pure compound was isolated from this material.

(5) This compound was prepared by Richard G. Rogers.

Summary

The addition of the calculated amount of methylmagnesium iodide to homophthalic anhydride does not lead to the formation of a keto acid. Instead one-half of the starting material is recovered unchanged; the other half is converted to dimethylhomophthalide.

Chemistry and Chemotherapy of 4,4′-Diaminodiphenylsulfone, 4-Amino-4′-hydroxydiphenylsulfone and Related Compounds[1]

BY G. W. RAIZISS, L. W. CLEMENCE, M. SEVERAC AND J. C. MOETSCH

4,4′-Diaminodiphenylsulfone was prepared by Fromm and Wittmann[2] by reduction of the corresponding dinitro compound which they obtained by the oxidation of 4,4′-dinitrodiphenylsulfide. They prepared the latter compound by action of sodium sulfide on *p*-chloronitrobenzene according to Nietzki and Bothof.[3] Our attempts to follow this method had produced an impure product from which the dinitrosulfide could be obtained only in very poor yields, after numerous recrystallizations. This was in accordance with the findings of Kehrmann and Bauer,[4] who showed that the reaction between sodium sulfide and *p*-chloronitrobenzene could produce a mixture of seven compounds.

We prepared the diaminosulfone by oxidation of the 4,4′-diaminodiphenylsulfide (thioaniline), protecting the amino groups by acetylation, and subsequently hydrolyzing. Hoffman[5] had prepared thioaniline by heating aniline, sulfur, and lead oxide (PbO). The yields were not good and the method rather unwieldy. We chose as our starting material 4-nitro-4′-aminodiphenylsulfide which Hodgson and Rosenberg[6] had prepared by reaction of sodium *p*-aminothiophenol and *p*-chloronitrobenzene. Lantz[7] described a two-stage reaction in which an excess of sodium sulfide reacted with *p*-chloronitrobenzene to form sodium *p*-aminothiophenol and without isolating the material another equivalent of *p*-chloronitrobenzene was added to the reaction mixture, the final product was 4-nitro-4′-aminodiphenylsulfide in good yields and fairly pure.

4′-Amino-4′-hydroxydiphenylsulfone was prepared by diazotization of 4-amino-4′-acetylaminodiphenylsulfone and simultaneous deacetylation and replacement of the diazo group by hydroxyl. The 4-amino-4′-acetylamino compound was prepared by reduction of 4-nitro-4′-acetylaminodiphenylsulfone which was obtained by oxidation of the corresponding sulfide.

Buttle[8] and others[9,10] discovered that 4,4′-diaminodiphenylsulfone had a better curative effect in β-hemolytic streptococcus infection of mice than sulfanilamide. In a recent publication we have shown[11] that diaminodiphenylsulfone and the corresponding sulfide were more toxic for rabbits than sulfanilamide. The diacetyl derivatives of the sulfone and sulfide were, however, considerably less toxic than sulfanilamide. We found that the therapeutic effect of diaminodiphenylsulfone was considerably better than that of sulfanilamide. Therapeutic effects of the sulfide and the diacetyl derivatives of the sulfone and sulfide compared favorably with that of sulfanilamide. 4-Amino-4′-acetylaminodiphenylsulfone, 4-amino-4′-hydroxydiphenylsulfone, 4-acetylamino-4′-hydroxydiphenylsulfone and 4-acetylamino-4′-acetoxydiphenylsulfone were of about the same therapeutic effectiveness in experimental streptococcic infection as sulfanilamide, but they were inferior to diaminodiphenylsulfone.

Experimental Part

Preparation of 4,4′-Diaminodiphenylsulfone

4-Nitro-4′-aminodiphenylsulfide.—The method was essentially that of Lantz: a mixture of 480 g. of sodium sulfide, dissolved in 2000 cc. of water, and 128 g. of *p*-chloronitrobenzene was refluxed for eight hours; 128 g. of *p*-chloronitrobenzene was added and refluxing was continued for fifteen hours. The mixture was steam distilled to remove unchanged *p*-chloronitrobenzene, breaking up lumps which had tendency to form. After cooling the non-volatile portion, the crude orange-yellow crystals were filtered off; yield, 160 g. (80%). The material was recrystallized from alcohol.

4,4′-Diaminodiphenylsulfide (Thioaniline).—To a boiling suspension of 200 g. of nitroaminosulfide in a mixture of 530 cc. of concd. hydrochloric acid and 500 cc. of water, 180 g. of tin turnings was added slowly and after solution was complete, 40 cc. of concd. hydrochloric acid and 22 g. of tin were added. After ten minutes of boiling, 2 g. of "darco" was added, the solution then boiled fifteen minutes longer and filtered hot. After thorough cooling, 40% sodium hydroxide solution was added until strongly alka-

line, the thick pasty precipitate changing to a gray-colored curd which was filtered and washed with water until washings were neutral to litmus, and drained well. The material was suspended in 1200 cc. of boiling alcohol, 5 g. of "darco" added and refluxed for thirty minutes. The hot, almost colorless filtrate was added to 10 liters of cold water with stirring, precipitating a white, fluffy precipitate which was filtered and dried in vacuum; yield, 140 g. (80%). The product was fairly pure, it was recrystallized further from 50% alcohol.

4,4'-Diacetylaminodiphenylsulfide.—To 140 g. of diaminodiphenylsulfide suspended in 200 cc. of glacial acetic acid, 140 cc. of acetic anhydride was added gradually with stirring, the mixture then refluxed for one hour and poured into 8 liters of ice and water, stirring well to break up lumps. The precipitate was filtered and washed with water until free of acetic acid and dried in vacuum; yield, 190 g. (97%). It was purified by recrystallization from alcohol.

4,4'-Diacetylaminodiphenylsulfone.—One hundred and fifty grams of potassium dichromate was dissolved in 2000 cc. of water and 1400 cc. of concd. sulfuric acid added. After cooling to 15° the mixture was added slowly with stirring to a solution of 100 g. of diacetylaminodiphenylsulfide in 1000 cc. of glacial acetic acid (dissolved by warming, then cooled to 20°). The reaction mixture was kept below 20° by external cooling and, after addition was complete, allowed to stand at room temperature for ninety minutes. It was then poured into 24 liters of ice and water, with stirring; the precipitate was filtered and washed with water until free of acid; yield, 70 g. (63%). It was purified by dissolving 50 g. in a boiling mixture of 1500 cc. of alcohol and 200 cc. of water; after adding 2.5 g. of "darco" and refluxing for thirty minutes, it was filtered hot and added to 6000 cc. of ice water; yield 35 g.

4,4'-Diaminodiphenylsulfone.—A suspension of 100 g. of crude diacetylaminodiphenylsulfone in 360 cc. of concd. hydrochloric acid and 300 cc. of water was heated under reflux for two hours. To the solution which was obtained 4 g. of "darco" was added and heating continued twenty minutes, then filtered and cooled well. Solid sodium carbonate was added with stirring until slightly alkaline to litmus. The precipitate was filtered and washed with water. The crude product, after vacuum drying, weighed 65 g. (87%). It was purified by refluxing in 1000 cc. of 40% alcohol, to which 5 g. of "darco" was added, for thirty minutes, and after filtering through a steam funnel and adding to 1000 cc. of hot water, it was mixed well with 3000 g. of ice; yield, 55–60 g.

Preparation of 4-Amino-4'-hydroxydiphenylsulfone

4-Nitro-4'-acetylaminodiphenylsulfide.—Two hundred and fifty grams of 4-nitro-4'-aminodiphenylsulfide was suspended in 500 cc. of glacial acetic acid and 150 cc. of acetic anhydride added gradually with stirring. The mixture was refluxed for two hours and poured into 7500 cc. of ice water with efficient stirring to break up lumps, then filtered and the crystalline precipitate washed with water until free of acid; yield, 290 g. (98%). It was purified by recrystallization from alcohol.

4-Nitro-4'-acetylaminodiphenylsulfone.—One hundred grams of nitro-acetylaminosulfide was oxidized using the quantities and method described in the case of diacetylaminosulfide; yield, 90 g. (81%). The material was only slightly soluble in hot alcohol and required a large volume for recrystallization.

4-Amino-4'-acetylaminodiphenylsulfone.—A solution of 203 g. of stannous chloride in 600 cc. of alcohol was added to a boiling suspension of 100 g. of the crude nitro compound in 600 cc. of alcohol; the mixture was refluxed for fifteen minutes and a clear solution was obtained. After thorough cooling an excess of 40% sodium hydroxide solution (about 750 cc.) was added, followed by the addition of 10 liters of water, stirring to break up lumps. The precipitate was filtered and washed with water until the washings were neutral, and sucked fairly dry on the funnel; it was then refluxed in 1300 cc. of alcohol for one hour with 5 g. of "darco" added, filtered hot, and the solution diluted with five volumes of ice water. On stirring a crystalline precipitate separated; yield, 60 g. (66%). It was purified by recrystallization from 50% alcohol.

4-Amino-4'-hydroxydiphenylsulfone.—A suspension of 50 g. of aminoacetylamino in 380 cc. of water and 33 cc. of concd. sulfuric acid, was cooled to 0–5°, and diazotized by a solution of 12.5 g. of sodium nitrite in 40 cc. of water. The nitrite solution was added dropwise, with mechanical mixing, in thirty minutes. The mixture was further stirred until a test with starch–iodide paper, which was strongly

[a] Kehrmann and Bauer and Lantz reported 143°. [b] Merz and Weith [*Ber.*, **4**, 390(1871)] reported 213–215°, Nietzki and Bothof reported 211°. [c] Kehrmann and Bauer reported 193°. [d] Fromm and Wittmann reported 174° for diamino, 280° for diacetyl.

positive at first, no longer diminished in intensity; it was then added in several portions to a boiling solution of 250 cc. of concd. sulfuric acid and 500 cc. of water, and boiling continued for ninety minutes, under reflux. After cooling, solid sodium carbonate was added until just neutral to litmus and the precipitate filtered, washed with water and suspended in 500 cc. of water containing 4.5 g. of sodium hydroxide. After agitating vigorously, any undissolved material was filtered off, and hydrochloric acid (1:1) added to filtrate until just acid to litmus. The precipitate was purified by crystallization from 1000 cc. of boiling water using 2.5 g. of "darco"; yield, 18–20 g. (42–46%).

4 - Acetylamino - 4' - hydroxydiphenylsulfone.—Twenty-five grams of aminohydroxysulfone was suspended in 125 cc. of ice water and 25 cc. of acetic anhydride gradually added with mechanical mixing. A gummy mass separated, but on further stirring it hardened to a white crystalline precipitate. After stirring one hour, the material was filtered and washed with water, crystallized from 300 cc. of 50% alcohol, using 1 g. of "darco"; yield, 22 g. (76%).

4 - Acetylamino - 4' - acetoxydiphenylsulfone.—Twenty-five grams of aminohydroxysulfone was suspended in 50 cc. of acetic anhydride and 10 drops of concd. sulfuric acid added; the mixture became hot; after boiling under reflux for twenty minutes, the clear solution was cooled and stirred to prevent crystallization to a hard mass, and the crystalline mush added to 500 cc. of water. After adding 40% sodium hydroxide solution until alkaline to litmus, it was filtered and washed well with water, then crystallized from 700 cc. of 50% alcohol using 1 g. of "darco"; yield, 26 g. (78%).

Summary

Chemical properties and methods of preparation of 4,4'-diaminodiphenylsulfone, 4,4'-diaminodiphenylsulfide, 4-amino-4'-hydroxydiphenylsulfone and their acetyl derivatives are described. The diaminodiphenylsulfone is superior, while the aminohydroxydiphenylsulfone and the acetyl derivatives are about equal to sulfanilamide in their therapeutic effect.

Thio Compounds Derived from Aroyl-*o*-benzoic Acids[1]

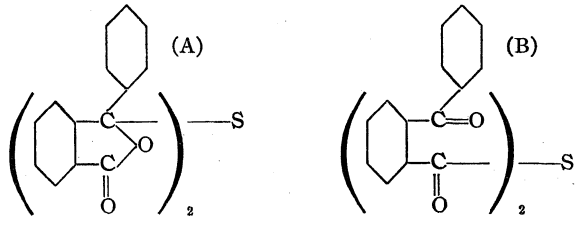
BY JOHN O'BROCHTA AND ALEXANDER LOWY

Introduction

Aroyl-*o*-benzoic acids are of theoretical importance because of their peculiar reactivity to form isomeric derivatives.[2] Blicke and Swisher[3] gave a summary of the evidence for the pseudo and normal forms of these derivatives. A search of the literature revealed no thio compounds of any of the aroyl-*o*-benzoic acids. Hence, a study was undertaken with the object of synthesizing sulfur derivatives of some of these acids, and of investigating their properties. Phosphorus pentasulfide and also hydrogen sulfide were selected as a means for the introduction of sulfur.

A schematic summary of the studies undertaken is given in Chart A. The chart contains the formulas of compounds prepared from *o*-benzoylbenzoic acid. Wherever CH_3 and Cl appear with Roman numerals and arrows on the chart, the analogous types of compounds have also been prepared; these substituents are in the para position.

The mechanism of the reaction of phosphorus pentasulfide upon *o*-benzoylbenzoic acid (I), *p*-toluyl-*o*-benzoic acid (IX) and 4'-chloro-*o*-benzoylbenzoic acid (XIV), to form 3,3'-diphenyldiphthalidyl sulfide (II), 3,3'-di-(*p*-tolyl)-diphthalidyl sulfide (X) and 3,3'-di-(*p*-chlorophenyl)-diphthalidyl sulfide (XV), respectively, shows the pseudo structures of the aroyl benzoic acids. The fact that hydrogen peroxide oxidation gave (I) and phenyl phthalide (VII), along with the molecular weight indication of a dimolecular type, suggested that the sulfur atom may be attached to a (I) and a (VII) fragment. The analysis checked for the following structures for compound (II)



Both structures (A) and (B) could yield *o*-benzoylbenzoic acid by hydrolysis but it was difficult to account for the formation of phenyl phthalide (VII) by hydrogen peroxide oxidation of a compound with the structure of (B). The graphic representation (B) was further eliminated

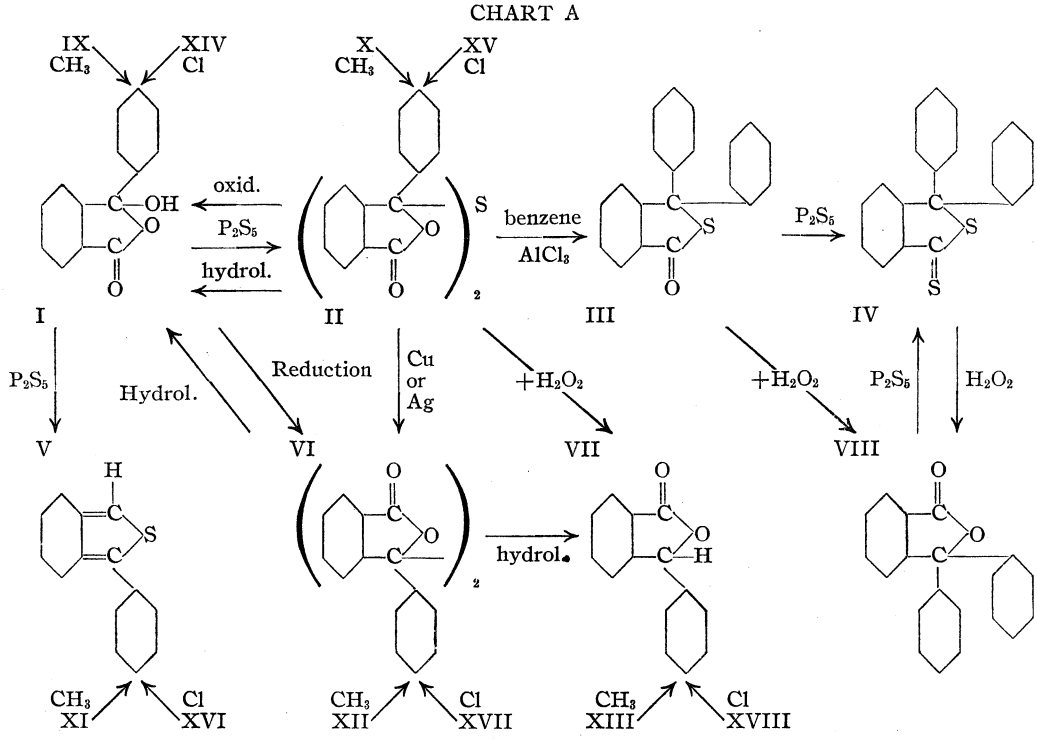
CHART A



in that normal *o*-benzoylbenzoic acid anhydride has a melting point of only 120°.[4] It did not appear probable that a sulfur atom substitution would raise the m. p. by 127°. Structure (A) was further substantiated by the formation of 3,3′-diphenyldiphthalidyl (VI) from 3,3′-diphenyldiphthalidyl sulfide (II) on reaction with metals. By a different procedure the action of phosphorus pentasulfide on compound (I) produced a compound containing no oxygen. Structure (V) has been proposed for this reaction product. This reaction is analogous to the action of phosphorus pentasulfide on γ-ketonic acids[5] for the formation of thiophene type compounds. *o*-Benzoylbenzoic acid may be looked upon as a γ-ketonic acid. Dufraisse and Daniel[6] already have synthesized a product of this type of structure, namely, α,α′-diphenylisobenzothiophene. The *p*-methyl and *p*-chloro compounds (IX) and (XIV), respectively, behaved in analogous manner in all of the above reactions.

Experimental

3,3′-Diphenyldiphthalidyl Sulfide (II). Preparation (a) from *o*-Benzoylbenzoic Acid (I) and Phosphorus Pentasulfide in Benzene.—Twenty grams of the anhydrous form of (I) was mixed in a three-necked one-liter flask with 20 g. of phosphorus pentasulfide in 700 cc. of dry benzene. The condenser was equipped with a calcium chloride tube. The mixture was refluxed on an oil-bath, with mechanical stirring. Hydrogen sulfide was evolved. At the end of twenty-five hours, the hot mixture was filtered and the solvent distilled with suction. The residual solid was dried at room temperature, triturated in 200 cc. of 3% sodium hydroxide, filtered, washed free of alkali with water and dried. On acidification, the filtrate evolved hydrogen sulfide but no precipitate was formed, showing the absence of any unchanged (I). The alkali-insoluble residue was crystallized four times from xylene, filtered, washed with petroleum ether and dried at 100°; yield 11 g. of white odorless crystals, m. p. 247°. The compound was very soluble in hot cymene and chloroform; fairly soluble in hot benzene, toluene, xylene and glacial acetic acid and insoluble in petroleum ether, cyclohexane and hot or cold aqueous media.

Anal. Calcd. for $C_{28}H_{18}O_4S$: C, 74.65; H, 4.03; S, 7.12; mol. wt., 450. Found: C, 74.60, 74.45; H, 4.00, 4.07; S, 7.07, 6.97; mol. wt., 423, 445.

(b) From (I) and Phosphorus Pentasulfide.—Ten grams of (I) was ground together with 10 g. of phosphorus pentasulfide. The mixture was heated on an oil-bath at 115° (bath temp.) and stirred occasionally. After fifteen minutes of heating, the mass changed to a brick-red color, began to liquefy and hydrogen sulfide was evolved. It gradually formed into a thick gum and finally solidified at the end of one hour of heating. The solid was cooled, pulverized, and extracted with 200 cc. of cold 3% sodium hydroxide solution; 2.5 g. of (I) was recovered upon acidification of the filtrate. The alkali-insoluble fraction was crystallized from 200 cc. of glacial acetic acid. On further recrystallization from xylene, 5 g. of product (II) resulted.

(4) Von Pechmann, *Ber.*, **14**, 1865 (1881).
(5) Kues and Paal, *ibid.*, **19**, 3141 and 555 (1886).
(6) Dufraisse and Daniel, *Bull. soc. chim.*, [5] **4**, 2063 (1937).

The m. p. 247° and a mixed m. p. of 247° checked with the previously prepared (II).

(c) **From the Acid Chloride of (I) and Hydrogen Sulfide.**—Compound (I), 100 g., was converted to the acid chloride by the thionyl chloride method.[7] The resultant thick sirup was dissolved in 400 cc. of dry benzene and dry hydrogen sulfide was passed into the boiling solution. There was an immediate and strong evolution of hydrogen chloride. Hydrogen sulfide was passed through the dry solution until the evolution of hydrogen chloride ceased. A heavy white precipitate formed. After cooling, precipitation was completed by adding 200 cc. of petroleum ether. The resultant solid was filtered and extracted with cold 3% sodium hydroxide solution, filtered, and washed free of alkali. A very small amount of (I) was recovered on acidification. After drying the alkali-insoluble residue, followed by three recrystallizations from xylene, washing with petroleum ether, and drying, 60 g. of a white crystalline product resulted; m. p. 246–247°. A mixed m. p. of the product with compound (II), as prepared by the above phosphorus pentasulfide methods, showed no depression.

Reactions of 3,3′-Diphenyldiphthalidyl Sulfide (II).—Sodium hydroxide fusion[8] gave a positive test for a divalent sulfur atom. Hydrolysis by refluxing with a 5% alcoholic potassium hydroxide solution and subsequent purification yielded compound (I). The sulfur of (II) was eliminated as hydrogen sulfide. Dehydration with sulfuric acid, according to the conditions prescribed for *o*-benzoylbenzoic acid dehydration,[9] gave anthraquinone. Oxidation with chromic or nitric acid in glacial acetic acid resulted in the formation of (I). Oxidation with 30% hydrogen peroxide at 100° in glacial acetic acid yielded (I) and phenyl phthalide (VII), m. p. 115°.[10] Boiling with aqueous-alcoholic lead acetate solution resulted in the elimination of sulfur from (II) with the formation of lead sulfide and (I). Reactions with phenylhydrazine, aniline and phenol yielded compounds which checked for those obtained by the corresponding reactions of these reagents with the acid (I).[11–13]

3,3′-Diphenyldiphthalidyl (VI).—Three grams of 3,3′-diphenyldiphthalidyl sulfide (II) and 6 g. of copper dust were refluxed for three hours in 40 cc. of freshly distilled cymene. A grayish-black precipitate formed. The mixture was filtered hot and the solution deposited a grayish-white solid upon cooling. This was filtered, washed with petroleum ether, and dried. After two recrystallizations from xylene, 2 g. of a white compound (VI) resulted; m. p. 265–266°. The m. p. had to be determined by very slow heating. The mixed m. p. and hydrolytic products, *o*-benzoylbenzoic acid (I) and phenyl phthalide (VII), checked with a purified sample of 3,3′-diphenyldiphthalidyl, prepared according to the method of Eckert and Pollak.[14] This reaction was repeated with thin silver foil and an analogous result was obtained.

Thiodiphenyl phthalide (III).—Twenty-five grams of 3,3′-diphenyldiphthalidyl sulfide (II) was mixed with 25 g. of anhydrous aluminum chloride in 300 cc. of benzene. The mixture was heated at 75–78° for eighteen hours in analogous manner to the preparation of *o*-benzoylbenzoic acid (I) from phthalic anhydride and benzene. Hydrogen chloride was evolved copiously but only traces of hydrogen sulfide. The reddish-brown mass was cooled, decomposed with cold dilute hydrochloric acid, and was extracted with 200 cc. of benzene. The extract was washed with water and vacuum distilled to dryness; a faintly yellow solid remained. Four recrystallizations from ethanol and a final recrystallization from a 2:1 benzene–petroleum ether solution yielded 6 g. of white crystals (III); m. p. 162°. A mixed m. p. checked with thiodiphenyl phthalide as prepared by Kleibacker.[15] Diphenyl phthalide (VIII)[4] was recovered from the filtrates.

Anal. Calcd. for $C_{20}H_{14}OS$: S, 10.60. Found: S, 10.77; 10.84.

Kleibacker's structure for thiodiphenyl phthalide (III) was concurred by hydrogen peroxide oxidation in acetic acid of (III) to (VIII) and by the conversion with phosphorus pentasulfide of (III) to dithiodiphenyl phthalide (IV).

Anal. Calcd. for $C_{20}H_{14}S_2$: S, 20.14. Found: S, 20.05, 20.08.

Hydrogen peroxide oxidation in acetic acid of (IV) yielded diphenyl phthalide (VIII).

2-Phenyl-3,4-benzothiophene (V).—Fifty grams of (I) was mixed in 600 cc. of xylene in a reflux apparatus equipped with a calcium chloride drying tube. The mixture was heated to boiling on an oil-bath; 50 g. of phosphorus pentasulfide was added, and the mixture refluxed for four hours. Hydrogen sulfide was evolved and a purplish-brown color appeared within an hour. This coloration deepened as the reaction proceeded. The hot solution was filtered; a charry residue and some unchanged phosphorus pentasulfide remained. The xylene solution was steam distilled, leaving a reddish-brown gum which solidified on cooling. It was boiled for two hours with 10 g. of sodium hydroxide in 300 cc. of 80% ethanol. The mixture was cooled and filtered. The filtrate was reddish-brown in color but on acidification it gave only traces of hydrogen sulfide and a slight turbidity; no *o*-benzoylbenzoic acid (I) was recovered. The alcoholic-alkali insoluble residue was washed with water and dried in a vacuum desiccator. The solid was then boiled in 200 cc. of xylene and filtered hot. Upon cooling, the filtrate yielded a reddish-brown solid It was filtered; the residue weighed 7 g. after drying. It was treated again with alcoholic sodium hydroxide and then recrystallized 3 times from xylene. Four grams of reddish-brown needles (V), m. p. 236–237°, was obtained. The combined xylene filtrates were steam distilled and 35 g. of a brownish-red gum remained in the distilling flask. The gum was dried, after which it solidified to a brittle mass. Attempts to crystallize something from it proved unsuccessful. By dissolving the gum in 500 cc. of xylene and refluxing for three hours with 25 g. of phosphorus pentasulfide, as in its original preparation, three more

[a] (X) was prepared (60% yield) by the action of hydrogen sulfide on the acid chloride of (IX) as described above for (II). [b] (XV) was prepared (68% yield) by the action of hydrogen sulfide on the acid chloride of (XIV) as described above for (II). [c] Previously prepared by phosphorus–hydriodic acid reduction of (IX), reported by Limaye [*Chem. Zentr.*, **104**, I, 1777 (1933)]. [d] Previously prepared by aluminum–sulfuric acid reduction of (XIV), method described by Eckert and Pollak.[14] [e] Previously prepared by reduction of (IX) with zinc dust and ammonia, Limpricht [*Ann.*, **314**, 251 (1901)]. [f] Converted to (XIV) by chromic anhydride oxidation according to the method described for the oxidation of (VII) to (I), (Beilstein, "Handbuch der organischen Chemie," fourth edition, Band XVII, System No. 2467, p. 361). [g] At 100°.

grams of compound (V) was recovered. The combined products (V), 7 g., were recrystallized from xylene; m. p. 236–237°. 2-Phenyl-3,4-benzothiophene (V) is slightly soluble in cold benzene, toluene, xylene, carbon disulfide and hot glacial acetic acid; very soluble in hot xylene and nitrobenzene; insoluble in hot or cold alcohol, ether, petroleum ether and aqueous media.

Anal. Calcd. for $C_{14}H_{10}S$: C, 79.96; H, 4.79; S, 15.25; mol. wt., 210. Found: C, 80.01, 80.29; H, 4.72, 4.73; S, 15.02, 15.05; mol. wt., 223, 239.

Reactions of 2-Phenyl-3,4-benzothiophene (V).—Sodium hydroxide fusion was carried out according to the method described by Mulliken,[8] except that a steel bomb and five minutes of heating at 340–350° were used. A positive test for a divalent sulfur was obtained. Attempted hydrolysis with alcoholic sodium hydroxide resulted in no change. Stability toward metals: 2 g. of (V) and 8 g. of copper powder were heated in diphenyl at 255–265° for four and one-half hours. Compound (V) was recovered unchanged. Boiling the compound in xylene with an equal weight of metallic sodium or mercuric oxide gave the same result. The isatin thiophene test was negative. Oxidations of (V) in glacial acetic acid with potassium permanganate, hydrogen peroxide, 1:1 nitric acid or chromium anhydride yielded a yellow compound melting at 186°.

In addition to the above compounds, the following homologs and analogs have been prepared and their data given in Table I. The respective oxidation, reduction and hydrolytic products are given in Chart A.

Summary

1. Thio compounds and derivatives of three aroyl-*o*-benzoic acids have been prepared and their properties studied.

2. The following new compounds have been prepared by the reaction of phosphorus pentasulfide in benzene: (a) 3,3′-diphenyldiphthalidyl sulfide (II), (b) 3,3′-di-(*p*-tolyl)-diphthalidyl sulfide (X), (c) 3,3′-di-(*p*-chlorophenyl)-diphthalidyl sulfide (XV). These sulfides were also prepared by the corresponding reactions of the acid chlorides with hydrogen sulfide.

3. The reaction of phosphorus pentasulfide in boiling xylene produced colored sulfur-containing compounds to which a thiophene type structure was ascribed tentatively: (a) 2-phenyl-3,4-benzothiophene (V), (b) 2-(*p*-tolyl)-3,4-benzothiophene (XI), (c) 2-(*p*-chlorophenyl)-3,4-benzothiophene (XVI).

4. A new method of preparation of the following compounds is reported: (a) 3,3′-diphenyldiphthalidyl (VI), (b) 3,3′-di-(*p*-tolyl)-diphthalidyl (XII), (c) 3,3′-di-(*p*-chlorophenyl)-diphthalidyl (XVII).

PITTSBURGH, PENNA. RECEIVED JULY 29, 1939

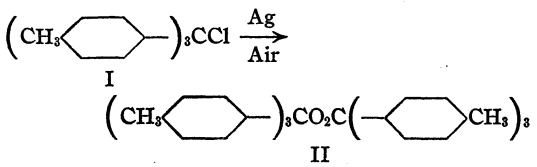
Effect of Substitution on the Dissociation of Hexaarylethanes. VIII.[1] The Disproportionation of Tri-*p*-tolylmethyl

BY C. S. MARVEL, WILLIAM H. RIEGER AND MAX B. MUELLER

Gomberg[2] has found that hexa-*p*-tolylethane does not dissociate reversibly to give a stable triarylmethyl radical as do many hexaarylethanes. The radical is formed when tri-*p*-tolylmethyl chloride (I) is treated with silver as shown by the fact that the expected peroxide (II) is obtained when the reaction is carried out in the presence of air or oxygen. If a benzene solution of the chloride is treated with silver in the absence of oxygen a light orange colored solution is produced but the color fades rapidly. Removal of the solvent at this stage leaves a glassy residue which has never been satisfactorily characterized.



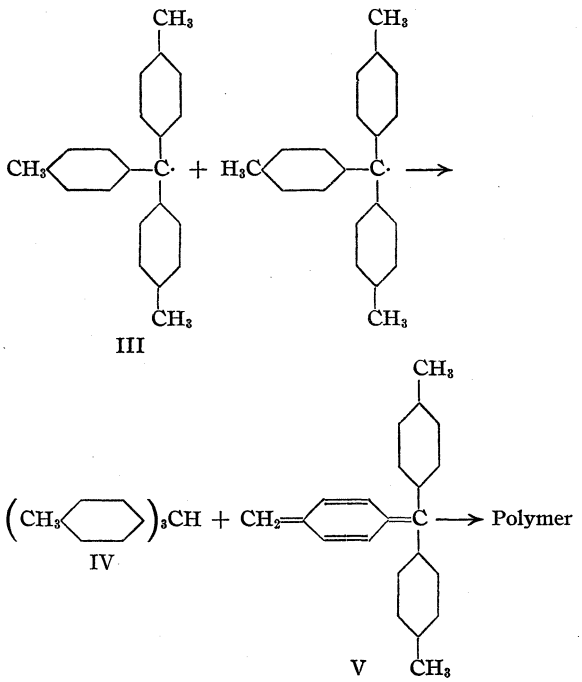
I

II

A further study of hexa-*p*-tolylethane now has been undertaken in connection with the study of the effect of alkyl groups on the dissociation of hexaarylethanes. When tri-*p*-tolylmethyl chloride (I) was purified carefully to remove all traces of moisture and hydrogen chloride before treating it with silver, it was possible to obtain a benzene solution of hexa-*p*-tolylethane which was light orange in color. Magnetic susceptibility[3] measurements showed that this ethane was dissociated to the extent of at least 16%. If the solution was allowed to stand at room temperature (25–30°) for a few hours the color disappeared entirely and magnetic susceptibility measurements showed that no free radical remained.

The solvent was removed from this decolorized solution and the glassy residue described by Gomberg[2] was obtained. By putting this residue in a molecular still[4] and warming it to about 85° under a pressure of 10^{-4} mm., a distillate consisting of pure tri-*p*-tolylmethane (IV) was obtained. The material which did not distill consisted of a brownish-yellow powder soluble in hexane and benzene but almost insoluble in ether. It was obviously polymeric in nature. Attempts to determine a molecular weight by cryoscopic methods gave no satisfactory results.

The identification of tri-*p*-tolylmethane (IV) and a polymeric residue as the products of disproportionation of tri-*p*-tolylmethyl (III) makes



III

IV

V

it possible to suggest a mechanism for the reaction. If one free radical strips a hydrogen atom from one of the *p*-methyl groups of another radical to give tri-*p*-tolylmethane (IV), the dehydrogenated radical can stabilize itself by assuming the quinoid structure (V). This molecule is one of the activated vinyl types and it should be expected to polymerize with ease. Since the polymer is not a pure hydrocarbon, some oxidation must occur during its isolation. The color change from an orange to an almost colorless solution shows that the polymerization must have occurred before the tube was opened to the air.

Confirmation of this explanation of the disproportionation reaction has been obtained. Schlenk and Meyer[5] have found that pyridine will remove

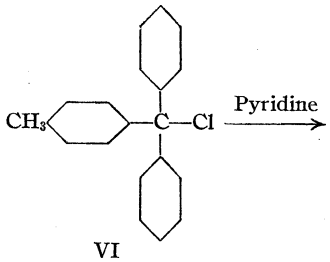
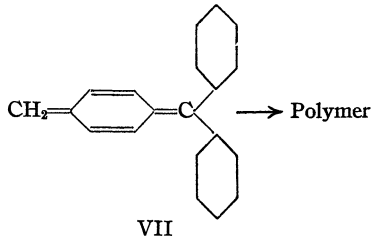
hydrogen chloride from diphenyl-*p*-tolylmethyl chloride (VI) to give a polymeric product. They postulate a quinoid intermediate (VII) and have actually isolated properly substituted molecules of this type.



VI



VII

Treatment of tri-*p*-tolylmethyl chloride with pyridine in an oxygen-free atmosphere produced a solution which was qualitatively indistinguishable in color from the corresponding free radical solution. When this solution was allowed to stand, the color faded and when the pyridine hydrochloride and excess pyridine were removed a polymeric residue remained. This residue had approximately the same solubilities and carbon and hydrogen content as did the polymer obtained by disproportionation of the free radical. While comparisons of polymers are not completely satisfactory for identification purposes, there seems to be little doubt that these products were the same.

Experimental

Tri-*p*-tolylmethyl Chloride.—The tri-*p*-tolylmethylcarbinol was obtained in 65% yield from *p*-tolylmagnesium bromide and diethyl carbonate.[6] It was converted to the chloride by treating its dry ether solution with dry hydrogen chloride. The chloride was recrystallized from carefully dried ethyl acetate and stored in a desiccator over solid potassium hydroxide under reduced pressure. This product melted at 171–172° (literature[2] gives m. p. at 173°).

Anal. Calcd. for $C_{22}H_{21}Cl$: Cl, 11.08. Found: Cl, 11.10.

Dissociation of Hexa-*p*-tolylethane.—A benzene solution of 1.032 g. of tri-*p*-tolylchloromethane was shaken with 3 g. of molecular silver for ten minutes in the apparatus described previously.[3b] The radical solution was filtered immediately from the silver–silver chloride residue and its magnetic susceptibility was determined. Two more determinations were made at ten-minute intervals. Extrapolation to zero time (see graph) indicates that hexa-*p*-tolylethane is 20% dissociated in 0.05 molar benzene solution. Assuming that the dissociation of hexaarylethanes obeys the mass law, this corresponds to a dissociation of 16% in 0.08 molar benzene solution.

These calculations are based upon the assumption that the reaction between tri-*p*-tolylchloromethane and molecular silver is 80% complete at the end of ten minutes. This assumption is supported by the observation that about 80% of the theoretical amount of oxygen is absorbed in ten minutes by a similarly treated bromobenzene solution of the chloromethane. Since the ethane is so unstable no more satisfactory determination was possible; however, it seemed probable that the assumed concentration is accurate within ±10%. A variation in concentration within these wide limits would cause a maximum variation of only ±2% in the value of the dissociation.

Disproportionation of Radical.—A solution of 2 g. of tri-*p*-tolylmethyl chloride in 150 cc. of dry benzene was frozen in a dry-ice–acetone bath and 0.8 g. of molecular silver was added. The flask was swept out with dry nitrogen, evacuated and sealed. The solution was allowed to warm to room temperature and it took on the characteristic light orange color. The flask was shaken for twenty-four to thirty hours at which time the color had faded to a very light yellow. The flask was opened, the silver recovered by filtration and the solvent removed under reduced pressure. The residual amber colored oil set to a hard glassy solid on cooling to room temperature.

A sample (1.219 g.) of this glassy solid was placed in a molecular still under a pressure of 10^{-4} mm. The bath temperature was maintained at about 85°. The distillate (0.239 g.) was a white solid which melted at 57°. A mixture of this material with an authentic specimen of tri-*p*-tolylmethane showed no depression in melting point.

The residue which did not distill was a light brown powder. It was fairly soluble in benzene and hexane and almost insoluble in ether. Attempts to determine its molecular weight in freezing benzene gave erratic results typical of polymeric materials.

Anal. Found: C, 89.79; H, 7.48.

This analysis shows the carbon and hydrogen ratio is that expected for a polymer of the quinoid type of molecule shown in formula V but there apparently has been added about one atom of oxygen for each quinoid unit. A poly-

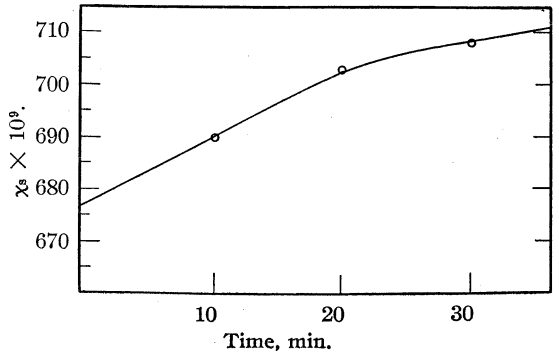


Fig. 1.—Change of magnetic susceptibility (χ_s) of hexa-*p*-tolylethane solution with time.

(6) Copenhaver, Roy and Marvel, THIS JOURNAL, 57, 1311 (1935).

merization of the vinyl type would still leave a conjugated system in each unit which might readily add oxygen.[7]

Preparation of Polymer from Tri-*p*-tolylmethyl Chloride and Pyridine.—A solution of 2.72 g. of tri-*p*-tolylmethyl chloride in 15 cc. of pure dry pyridine was heated under a reflux condenser in an atmosphere of dry nitrogen. The solution became yellow almost at once, then light orange and wine red. In about five minutes the color began to fade and heating was stopped. In about thirty minutes the solution was a yellowish brown and white crystals of pyridine hydrochloride had separated in the cold solution. Some dry ether was added and the pyridine hydrochloride was removed by filtration. The ether and excess pyridine were removed by evaporation under reduced pressure. A yellowish oil remained and on cooling in air it set to a hard, glassy solid. This solid was also soluble in benzene and hexane and almost insoluble in ether.

Anal. Found: C, 87.62, 87.93; H, 7.16; 7.45.

Summary

1. Determination of the degree of dissociation of hexa-*p*-tolylethane on a rapidly prepared benzene solution shows it is dissociated to the extent of 16 ± 2% in 0.08 molar solution in benzene at 30°.

2. Tri-*p*-tolylmethyl rapidly undergoes disproportionation in benzene solution to give tri-*p*-tolylmethane and a polymeric material.

3. Removal of hydrogen chloride from tri-*p*-tolylmethyl chloride by the action of pyridine leads to a polymer apparently identical with that obtained by disproportionation of the radical. These facts are used to explain the course of the disproportionation reaction.

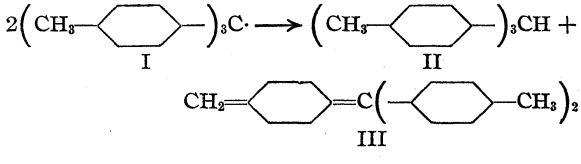
The Disproportionation of Hexa-*p*-alkylphenylethanes and the Effect of ortho-, meta-, and para-Alkyl Groups on Dissociation of Hexaarylethanes[1]

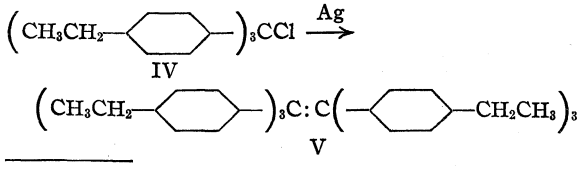
BY C. S. MARVEL, MAX B. MUELLER, CHESTER M. HIMEL AND JULIUS F. KAPLAN

The discovery[1] that tri-*p*-tolylmethyl (I) undergoes rapid disproportionation to yield tri-*p*-tolylmethane and a quinoid residue (III) which rapidly polymerizes, has made it seem probable that groups other than methyl which still have hydrogen on the alpha carbon should likewise cause instability of the radical. Accordingly we



have reinvestigated the series of *p*-alkylphenylethanes which was recently described from this Laboratory.[2]

When tri-*p*-ethylphenylchloromethane (IV) in benzene solution was shaken with molecular silver

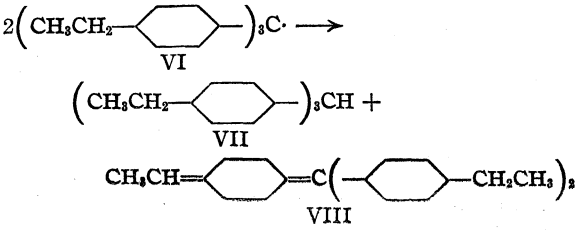


(1) This is the ninth communication on the effect of alkyl groups on the dissociation of hexaarylethanes. For the eighth, see THIS JOURNAL, **61**, 2769 (1939).

(2) (a) Copenhaver, Roy and Marvel, *ibid.*, **57**, 1311 (1935); (b) Roy and Marvel, *ibid.*, **59**, 2622 (1937).

for only fifteen minutes and the magnetic susceptibility of the resulting solution was examined, it was found that the free radical was present to the extent of 17%. On standing there was little change in the color of the solution but the change in magnetic susceptibility showed that the free radical was disappearing very rapidly. The experiments were carried out at higher temperatures (30°) than had been used previously (20°)[2b] and in the present series of tests no radical remained in the solution after twenty-four hours, the time used before for the preparation of the solutions to be studied.

The fact that the color of the solution did not fade appreciably during the disproportionation of the free radical (VI) is of interest. It indicates that in the series above methyl the quinoid hydrocarbon (VIII) produced in the disproportionation does not polymerize. This is to be expected



since substituted vinyl residues having one substituent on each of the carbon atoms rarely polymerize easily. The color of the solution obtained by treating tri-*p*-ethylphenylchloromethane with silver was qualitatively the same as the color of the solution obtained by treating the same chloride with pyridine in the manner used by Schlenk and Meyer[3] to obtain quinoid derivatives related to VIII. The fact that the color does not change to an appreciable extent as the radical changes into a mixture of triarylmethane and the quinoid derivative is evidence in favor of Gomberg's well-known idea that the quinoid ring structure of the radical is the form which contributes the color to the solution.[4]

In addition to the *p*-ethyl derivative, the *p*-*n*-propyl, *p*-isopropyl, *p*-isobutyl and *p*-*s*-butyl derivatives also have been reëxamined.[5] In each case the solution of the hydrocarbon first obtained showed a high free radical content and this disappeared on standing. The rate of disproportionation of the various free radicals was determined by following the change in magnetic susceptibility The order of increasing stability of the various free radicals agreed exactly with the previously reported order of increasing dissociation. The results are plotted in Fig. 1.

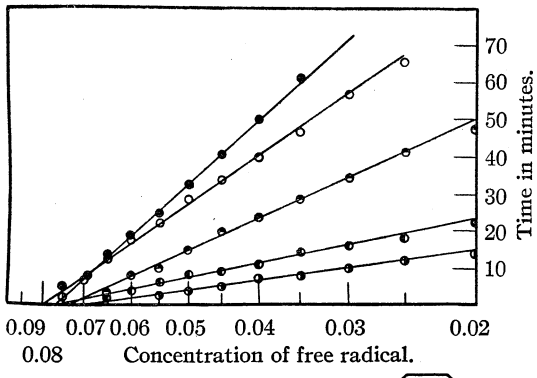


Fig. 1.—Rate of decomposition of (R⟨⟩)$_3$C—: ◑, R = Et; ◐, R = *n*-Pr; ◒, R = *i*-Pr; ○, R = *s*-Bu; ●, R = *i*-Bu.

By use of the data on the rate of disproportionation it was possible to calculate the dissociation of the various ethanes at zero time and thus to obtain fairly accurate estimates of the effects of the various para-alkyl groups on the degree of dissociation. These effects were much more marked than had been anticipated and it is obvious that the size and shape of a para-alkyl group is an important factor in the amount of radical formation in the hexa-*p*-alkylphenylethane series. Table I contains a summary of the new results.

TABLE I

DISSOCIATION OF HEXA-*p*-ALKYLPHENYLETHANES

Alkyl group	Degree of dissociation, %
Ethyl	17 ± 2
n-Propyl	21 ± 2
Isopropyl	26 ± 2
s-Butyl	33 ± 2
Isobutyl	27 ± 2

Certain other observations also contribute evidence to support the above view of the disproportionation of these *p*-alkylphenylethanes. Hexa-*m*-tolylethane[6] was prepared in benzene solution and it was stable more or less indefinitely. The magnetic susceptibility of its solutions did not change over a twenty-four hour period. This stability was expected as meta-quinone structures cannot form. The meta-methyl group was even more effective than the para-methyl group in producing dissociation since hexa-*m*-tolylethane existed to the extent of at least 40% as the free radical. No other crystalline tri-*m*-alkylphenylchloromethane has been obtained, so the effect of other meta-alkyl groups cannot yet be reported.

It might be predicted that an ortho-methyl group also would contribute to the instability of the radical since ortho-quinoid molecules form rather easily. It has not been possible to prepare tri-*o*-tolylchloromethane due apparently to steric factors but *o*-tolyldiphenylchloromethane with silver gave a stable ethane which was dissociated to the extent of 25%. This result showed the very marked effect of introducing more steric hindrance around the central carbon atom of the free radical since one ortho-methyl group was more effective in producing dissociation than were three para-methyl groups. These steric factors must also explain the stability of the ortho-methyl derivative. If it is assumed that a free radical must collide with the methyl group of another radical before a hydrogen atom can be removed it is rather easy to see why the ortho-methyl compound (IX) does not undergo the disproportionation reaction characteristic of the para-series.

p-*t*-Butylphenyldiphenylchloromethane (X) has been prepared and converted to the correspond-

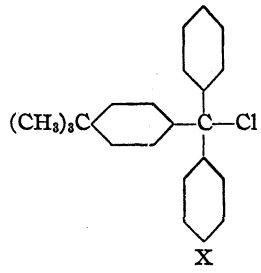
IX



X

ing ethane. Since there are no hydrogen atoms on the alkyl carbon attached to the ring, this compound did not undergo the disproportionation observed with the other *p*-alkyl derivatives. For comparison the mono-*p*-methyl and *p*-isopropyl derivatives were prepared. Both of these radicals showed the disproportionation reaction but both decomposed more slowly than did the corresponding tri-*p*-alkylphenylmethyl radicals. This increased stability was expected as the chance of the radical colliding with an active hydrogen atom is much less in the monosubstituted series than in the trisubstituted series. In Table II are recorded the degrees of dissociation of these dialkylphenyltetraphenylethanes.

TABLE II

DEGREE OF DISSOCIATION OF SOME DIALKYLPHENYLTETRAPHENYLETHANES

Alkyl group	Degree of dissociation, %
p-Methyl	5 ± 1.0
o-Methyl	25 ± 1.0
p-Isopropyl	8–10 ± 1.0
p-*t*-Butyl	8–9 ± 1.0

Thus all the *p*-alkylphenylmethyl radicals which can lose hydrogen from the α-carbon of the para-alkyl group undergo rather rapid disproportionation. When there is no possibility of quinoid structure formation by loss of hydrogen, the radicals are relatively stable as is triphenylmethyl. Alkyl groups in the para-position have a marked effect on increasing the dissociation of hexaphenylethane and the larger groups are more effective than the smaller ones. A meta-methyl group is more effective than a para-methyl group in promoting dissociation. An ortho-methyl group is very effective in this regard. These effects of ortho- and meta-substituents must be due in part to steric factors.

Experimental

Preparation of *p*-*t*-Butylbromobenzene.—This compound was prepared by Schramm[7] by the bromination of *t*-butylbenzene; however, no specific directions for the preparation were given. The following procedure has been found to give satisfactory results. A solution of 80 g. (0.5 mole) of bromine in 67 g. (0.5 mole) of *t*-butyl benzene[8] in a 500-cc. round-bottomed flask connected to a reflux condenser by a ground-glass joint was exposed to sunlight for four days. The initial reaction was rather vigorous and it was necessary to cool the flask in ice for the first four or five hours. When the evolution of hydrogen bromide ceased (four days), the reaction mixture was washed with 10% sodium bisulfite solution, water, 10% sodium carbonate solution and water. The organic layer was separated, dried and distilled through a fourteen-inch (35-cm.) modified Widmer column. A small low boiling fraction consisting chiefly of unreacted *t*-butylbenzene was obtained, but the bulk of the distillate was collected at 230°. The yield was 64 g. which is 60% of the theoretical.

Preparation of *p*-Isopropylphenyldiphenylcarbinol.—The Grignard reagent was prepared from 100 g. of *p*-bromoisopropylbenzene and 12 g. of magnesium in about 200 cc. of anhydrous ether. After the addition of the bromide the mixture was stirred and refluxed for two hours. Then 88 g. of benzophenone in 100 cc. of dry benzene was added and the mixture was stirred and refluxed for an additional three hours. The reaction mixture was decomposed by pouring it into dilute sulfuric acid containing some cracked ice. The organic layer was separated and the ether and benzene removed by distillation. The residue was distilled with steam until no trace of organic material was detectable in the distillate. The carbinol was obtained as a clear glass. No attempt was made to purify it. Instead the impure product was used directly in the preparation of the chloromethane.

Preparation of *p*-*t*-Butylphenyldiphenylcarbinol.—This carbinol was prepared from *p*-*t*-butylbromobenzene by the same procedure used for *p*-isopropylphenyldiphenylcarbinol. Again the impure carbinol was used directly in the preparation of the corresponding chloromethane.

Preparation of Triarylchloromethanes.—The procedures used in the preparation of most of the chloromethanes reported in this communication were those reported by Marvel, Copenhaver and Roy.[2a] It was discovered, however, that chloromethanes which melted above 130° were prepared more easily by dissolving the corresponding impure carbinol in acetyl chloride.[9] The crystalline chloromethane was obtained by concentrating and cooling the solution. The chloromethanes were purified as before by recrystallization from ethyl acetate. The following compounds were prepared in this way: tri-*p*-ethylphenylchloromethane, tri-*p*-isopropylphenylchloromethane, tri-*p*-*s*-butylphenylchloromethane and tri-*p*-isobutylphenylchloromethane.

Analysis of *p*-isopropylphenyldiphenylchloromethane, m. p. 90–91°. Calcd. for $C_{22}H_{21}Cl$: C, 82.37; H, 6.55. Found: C, 83.41; H, 7.06. *Analysis* of *p*-*t*-butylphenyldiphenylchloromethane, m. p. 133–134°. Calcd. for $C_{23}H_{23}Cl$: C, 82.53; H, 6.88. Found: C, 82.53; H, 7.02.

The melting points of the previously known triarylchloromethanes are listed in Table IIA.

Tri-*m*-tolylchloromethane	83–84	84–85[5]
Tri-*p*-ethylphenylchloromethane	156–157	157–158[2a]
Tri-*p*-*n*-propylphenylchloromethane	89–90	90[2a]
Tri-*p*-isopropylphenylchloromethane	166–167	167–168[2a]
Tri-*p*-isobutylphenylchloromethane	134–135	135–136[2a]
Tri-*p*-*s*-butylphenylchloromethane	130–131	132[2a]

Preparation of Peroxides.—Five-thousandths of a mole of the appropriate triarylchloromethane was shaken with three grams of molecular silver for fifteen minutes in the apparatus described previously.[2b] The solution was filtered from the silver–silver chloride, removed from the apparatus and exposed to the air until it was entirely decolorized. The solvent was removed and the residue was purified by several recrystallizations from a mixture of benzene and absolute ethanol.

Analysis of *o*-tolyldiphenylmethyl peroxide, m. p. 148–149°. Calcd. for $C_{40}H_{34}O_2$: C, 87.91; H, 6.23. Preparation of Hexaarylethanes.—Because of the instability of the *hexa-p*-alkylphenylethanes reported in this communication it was necessary to determine the time required for the completion of the reaction between molecular silver and triarylchloromethanes. This was done by measuring the amount of oxygen absorbed by a sample of the chloromethane when it was shaken with molecular silver in the presence of oxygen.[11] The results are tabulated in Table III.

	20	90

The Dissociation of Hexaarylethanes.—The degree of dissociation of the hexaarylethanes studied was measured by the magnetic susceptibility method[12] in the apparatus described previously.[2b] In the case of the hexa-*p*-alkylphenylethanes which decompose rapidly, 0.02 molar solutions of the chloromethanes were shaken with molecular silver for fifteen minutes, filtered and the magnetic susceptibility of the solutions determined immediately. Determinations were then made on the same sample at ten or fifteen minute intervals until the sample showed a constant magnetic susceptibility. By extrapolation from these values the magnetic susceptibility at zero time (*i. e.*, before any decomposition took place) was calculated. These extrapolations are shown in Fig. 2.

In order to calculate the degree of dissociation from these data, it is necessary to know the concentration of the ethane. Since oxygen absorption experiments under similar conditions have shown that the chloromethane is converted to the ethane to the extent of at least 80% in every case, the ethane solution was assumed to be 0.08 ± 0.01 molar. This comparatively large possible variation in concentration, however, causes a maximum uncertainty of only ±2% in the degree of dissociation.

In the case of the more stable ethanes, the chloromethanes were shaken with molecular silver until parallel oxygen absorption experiments indicated that the reaction was complete. The experimental data for all of the ethanes reported are collected in Table IV.

Rate of Decomposition of Hexa-*p*-alkylphenylethanes.—From the values of α listed in Table IV

(12) Müller, *et al.*, *Ann.*, **520**, 235 (1935); **521**, 89 (1935); see also ref. 2b.

TABLE IV

Ethane	$T°$	% ethane	$-\chi_s \times 10^6$	α
Di-*p*-tolyltetraphenylethane	28	4.74	0.695	0.053 ± 0.02
Di-*o*-tolyltetraphenylethane	30	5.85	.632	.267 ± .02
Di-*p*-isopropylphenyltetraphenylethane	28	6.77	.680	.083 ± .02
Di-*p*-*t*-butylphenyltetraphenylethane	29	6.09	.688	.078 ± .02
Hexa-*m*-tolylethane	28	6.47	.594	.400 ± .02
Hexa-*p*-ethylphenylethane	29	6.06	.670	.167 ± .03
Hexa-*p*-*n*-propylphenylethane	29	6.81	.662	.209 ± .03
Hexa-*p*-isopropylphenylethane	28	6.85	.650	.260 ± .03
Hexa-*p*-isobutylphenylethane	29	7.65	.650	.269 ± .03
Hexa-*p*-*s*-butylphenylethane	29	7.66	.635	.330 ± .03

it is possible to calculate the equilibrium constant for the dissociation of any ethane from the equation

$$K = \frac{\alpha^2 w_0}{1 - \alpha}$$

where w_0 = initial concentration of the ethane.

Then from the equation

$$\chi_\rho = \frac{1233}{w_1}\sqrt{K^2 + 4Kw_1} - K$$

where w_1 = the concentration of the ethane, it is possible to calculate the paramagnetic susceptibility due to the free radical for any value of w_1, and from the equation

$$\chi_s = \frac{\chi_d}{M}w_0 + 0.708w_2 - \frac{\rho}{M}w_1$$

where w_2 = the weight fraction of the solvent, the corresponding measured susceptibility of the solution. Using the values of χ_s obtained in this way, the amount of undecomposed ethane present at any given time may be obtained from Fig. 2. When the logarithms of the concentrations so obtained are plotted against time (see Fig. 1) a series of straight lines are obtained indicating that the decomposition is apparently a first order reaction.

Summary

1. Hexa-*p*-alkylphenylethanes in which the alkyl group has a hydrogen atom on the carbon atom attached to the ring have been found to dissociate to free radicals which undergo disproportionation.

2. The degree of dissociation of ethanes in this series has been found to be much higher (17–33%) than was previously thought (2–6%).

3. Ortho- and meta-methyl substituents in hexaphenylethanes have a greater effect on the degree of dissociation than do para-methyl substituents and the ortho- and meta- derivatives give relatively stable radicals.

4. A few di-*p*-alkylphenyltetraphenylethanes have been described. They are more highly dissociated than hexaphenylethane and disproportionate less rapidly than the corresponding hexaalkyl derivatives. In this series the *t*-butyl derivative did not undergo disproportionation.

The Alleged *cis-trans* Isomerism of alpha- and beta-*p*-Azophenol

BY W. M. LAUER, H. P. KLUG AND S. A. HARRISON[1]

The existence of isomeric forms of *p*-azophenol was reported in 1906 by Willstätter and Benz.[2] One form, designated α, was obtained by coupling *p*-hydroxybenzenediazonium chloride with phenol or preferably by the fusion of *p*-nitrophenol with potassium hydroxide, while the second form, designated β, resulted from the reduction of benzoquinoneazine with phenylhydrazine.[3] An analysis of the evidence at their disposal led these investigators to the view that *cis–trans* isomerism was the most likely basis upon which to account for the existence of isomers in this case. This interpretation also was favored by Hantzsch,[4] who studied the absorption spectra of α- and β-azophenol and their sodium salts. Several years later, Robertson[5] also concluded that this was a case of *cis–trans* isomerism on the basis of a difference in behavior of the two forms, which he observed on bromination and nitration. Thus, he reported that nitration of α-azophenol gave a tetranitro derivative (m. p. 230°), whereas dinitroazophenol (m. p. 240°) was obtained from β-azophenol, and that bromination produced different tetrabromo derivatives (m. p. 250–252°, m. p.

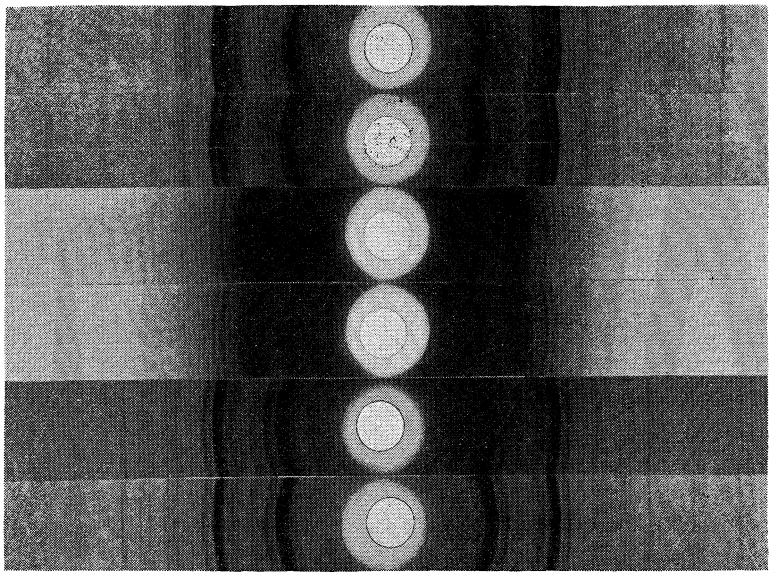

Fig. 1.—Powder photographs of *p*-azophenol.

271°) in the two cases.[6] This difference in behavior was attributed to steric hindrance in the case of the β-azophenol, to which Robertson assigned the *cis* configuration.

An important contribution to this problem was made recently by Dostrovsky and Le Fèvre.[7] They found that the dipole moments of α- and β-azophenol are identical, and consequently it is very improbable that the α- and β- forms are *cis–trans* isomers. Furthermore, in view of the lability of the *cis* form of azobenzene, it appeared unlikely that the *cis* form of azophenol would maintain its configuration when subjected to bromination and nitration. These considerations, together with evidence, which was accumulated in the present work, lead to the conclusion that the alleged isomers, α- and β-azophenol, are in reality identical. Hydrated *p*-azophenol upon dehydration gives the anhydrous compound, which exists in two solid modifications, brick-red and green. The transformation of the brick-red metastable form to the green form is subject to various influences (*e. g.*, impurities) which were not investigated. That the so-called α-azophenol is identical with the azophenol designated as the β-form and produced by the reduction of quinoneazine becomes evident from the following studies.

(6) The use of an excess of bromine and rapid addition of this reagent gave the higher melting tetrabromo derivative with both forms of the azophenol. However, Hunter and Barnes [*J. Chem. Soc.*, 2051 (1928)] also reported a tetrabromo derivative, melting at 252° with decomposition.

(7) Dostrovsky and Le Fèvre, *J. Chem. Soc.*, 535 (1939).

X-Ray Diffraction Studies.—Powder photographs of eight different samples of *p*-azophenol were taken using a camera of approximately 57.4 mm. radius and FeK radiation. The history of each of the eight samples follows: (1) hydrated α-azophenol, purified chromatographically and precipitated from a potassium hydroxide solution by means of carbon dioxide; (2) hydrated β-azophenol, purified by recrystallization from alcohol and precipitation from a potassium hydroxide solution by means of carbon dioxide; (3) anhydrous brick-red modification produced by sublimation of α-azophenol; (4) anhydrous brick-red modification prepared by heating hydrated β-azophenol; (5) anhydrous green α-azophenol obtained by heating hydrated α-azophenol; (6) anhydrous green β-azophenol produced by heating relatively large crystals of the hydrated β-form; (7) hydrated α-azophenol obtained from sample 5 by rehydration; and (8) hydrated β-azophenol obtained from sample 4 by rehydration. All samples were ground in an agate mortar to 200-mesh size before mounting on or in a thin-walled glass capillary tube. The exposures in all cases except 3 and 4 were approximately four hours at 12.5 m. a. and 34 k. v. Samples 3 and 4 were sealed inside a thin-walled glass tube and required exposures of approximately twenty-four hours.

Six of the photographs are reproduced in Fig. 1. They show unequivocally that the hydrated α- and β- varieties, 1 and 2, are in reality the same substance, that the two anhydrous brick-red modi-

fications, 3 and 4, are identical but different from the hydrated or anhydrous green forms, and that the two anhydrous green varieties, 5 and 6, likewise are the same but are different in crystal structure from the anhydrous brick-red forms. Samples 7 and 8 gave patterns identical with those of 1 and 2. The X-ray photographs for each of the pairs correspond not only in the positions but also in the intensities of the lines.

Ebullioscopic Studies.—Since α- and β-azophenol decompose on melting, mixed melting point determinations are of little value as a test for identity in this case. However, a method, developed by Halford,[8] of determining the identity of solids, by measuring the rise in boiling point on the addition of one substance to a saturated solution of the other, proved to be of considerable value. An application of this method showed that the α- and β-forms of *p*-azophenol, as usually prepared and purified, were not pure substances. The pure α-variety could be obtained by chromatographing an ethyl acetate solution, using calcium carbonate as the adsorbent. When this carefully purified α-form was added to a saturated solution of the so-called β-form in ethyl ether only a negligible rise in the boiling point was obtained. The addition of the β-form as ordinarily prepared to a solution saturated with the pure α-form was accompanied by a small rise which was of the same order of magnitude as that obtained by the addition of the β-form to a solution saturated with β-azophenol.

Polarographic Studies.—*p*-Azophenol can be oxidized to quinoneazine, and if α- and β-azophenol are in reality *cis* and *trans* forms, oxidation should take place at different potentials in the two cases. Therefore, dropping mercury electrode studies were carried out. Oxidation was first attempted in a buffer of *p*H 5.75 but it was found that the oxidation potential of *p*-azophenol at this *p*H was above that for mercury. However, both forms could be reduced at this *p*H. Identical cathodic waves were obtained for the α- and β-forms.[9]

It was possible to oxidize *p*-azophenol in a buffer of *p*H 9.2. The anodic waves were identical for the two forms.

Chemical Studies.—The chemical evidence which was cited in favor of isomerism of *p*-azophenol was reëxamined. Several derivatives of α- and β-azophenol were prepared by Willstätter and Benz,[10] but only in the case of the diacetates did they find indication of any difference. Thus, it was reported that the α-azophenol diacetate melted at 198–199°, and that the melting point of β-azophenol diacetate was 192°, but that, upon repeated crystallization, the lower melting diacetate was transformed into the higher melting one. Repetition of these acetylations led only to the higher melting diacetate. Furthermore, the diacetate obtained from the β-azophenol did not depress the melting point of the diacetate derived from the so-called α-form.

The work of Robertson concerning nitration and bromination of α- and β-azophenol also was repeated. Instead of isolating the tetranitro-*p*-azophenol in the case of the α-azophenol, which according to previous work melts at 230° and is the expected product, a dinitro compound (m. p. 235–236°) was obtained from both the α- and β-forms. In order to produce the tetranitro compound it was necessary to use more drastic conditions and the product obtained in this way melted with decomposition at 261–262°. The α-

and β-azophenols upon bromination also gave only one tetrabromoazophenol, melting at 273–274° with decomposition, in spite of many attempts to obtain the lower melting isomer previously reported.

Experimental

α- and β-azophenol were prepared according to the directions of Willstätter and Benz.

Chromatographic Studies.—Anhydrous (green) α-azophenol (1 g.) was dissolved in ethyl acetate (100 ml.) and the solution passed through a column of precipitated calcium carbonate, 12 cm. long and 1.5 cm. in diameter. The α-azophenol was weakly adsorbed, but could be completely washed through with additional ethyl acetate. As the solution passed through the column a pink zone developed at the top which was not washed down by ethyl acetate. Elution of this zone with methanol gave a small amount of an oily red substance which was not investigated. The ethyl acetate solution of α-azophenol which had passed through the column yielded 0.93 g. of *p*-azophenol, which was crystallized from an aqueous ethanol solution in orange-yellow plates.

One gram of the anhydrous (brick-red) β-azophenol was chromatographed in the same manner. No pink zone was obtained. Crystallization produced β-azophenol in orange-red plates with a blue reflex.

Several mixtures of α- and β-azophenol were chromatographed using different solvents and adsorbents, but no separation was obtained. Likewise attempts to obtain *cis* and *trans* forms by irradiation according to the method which was successfully employed by Cook[11] were fruitless. However, irradiation of *p*-azoanisole in petroleum ether brought about deepening in the color of the solution. When this solution was passed through a column of aluminum oxide, an orange zone of rather strongly adsorbed material appeared at the top of the column. Below this the normal yellow zone of azoanisole was obtained. The orange zone gave a red solid upon elution with ether. Heated to temperatures above 50° it rapidly changed to yellow, the color of ordinary *p*-azoanisole, and melted at 162–164°, the m. p. of ordinary azoanisole. Cook reported a similar behavior in the case of *p*-benzeneazophenetole.

Miscellaneous Observations.—It was noted that the method of separation of β-azophenol from solution had much to do with its appearance. Slow crystallization from an ethanol–water (1:1) solution yielded relatively large crystals which turned green rather than brick-red on heating to 120°. However, if this same material was dissolved in alcohol and rapidly precipitated by the addition of water, the small crystals so produced turned brick-red on heating to 120°, but continued heating transformed this brick-red material to a green product. The time required to bring about the change from brick-red to green varied considerably with different samples.

When pure α-azophenol was precipitated in small crystals from an ethanol–water solution and then heated to 100°, it turned red, but the red material changed to a green within a few minutes. At higher temperatures the change was so rapid that in many cases the hydrated form appeared to go directly to the anhydrous green form.

Sublimation at a pressure of 10^{-2} mm. produced the anhydrous red variety in the case of both α- and β-azophenol. The conversion of this anhydrous red to the anhydrous green modification required only a few seconds at 120°.

Ebullioscopic Studies.—Absolute ether (20 ml.) was used as the solvent in each of the following determinations: (1) boiling point elevation on saturation of ether with pure anhydrous α-azophenol, 0.384°; (2) amounts of pure α-azophenol required for saturation, 0.55 g.; (3) boiling point elevation on the addition of 0.2 g. of anhydrous α-azophenol, prepared and purified in accordance with earlier methods, to solution saturated with α-azophenol, 0.03°; (4) average boiling point elevation on the addition of 0.2 g. of anhydrous β-azophenol to solution saturated with β-azophenol, 0.038°; (5) boiling point elevation on the addition of 0.2 g. of α-azophenol, purified by chromatographing, to solution saturated with α-azophenol, 0.00°; (6) boiling point elevation on the addition of 0.7 g. of pure anhydrous α-azophenol to a solution saturated with β-azophenol, 0.01°; (7) boiling point elevation on addition of 0.42 g. of anhydrous β-azophenol to a solution saturated with anhydrous α-azophenol, 0.09°.

Polarographic Studies.[12]—The set-up used was essentially the same as that described by Kolthoff and Lingane.[13] Measurements were made with reference to a saturated calomel electrode. The α- and β-azophenols were dissolved in the following buffer solutions: (1) a buffer of *p*H 5.75 prepared by combining 200 ml. of 0.999 *N* acetic acid, 100 ml. of 0.982 *N* sodium hydroxide and 300 ml. of absolute alcohol; (2) a buffer of *p*H 9.2 prepared by combining 80.9 ml. of 0.0982 *N* sodium hydroxide, 6.184 g. of boric acid, 209 ml. of conductivity water and 300 ml. of absolute alcohol. To this solution was added 2.5 g. of potassium nitrate to serve as an electrolyte. The molar concentrations of the azophenols were as follows:

	*p*H 5.75	*p*H 9.2
α-Azophenol	1.016×10^{-3}	1.004×10^{-3}
β-Azophenol	1.005×10^{-3}	1.017×10^{-3}

The results are shown in Fig. 2.

Nitration of α- and β-Azophenol.—Following the procedure of Robertson, anhydrous α-azophenol (1.5 g.) was dissolved in glacial acetic acid (75 ml.) by warming. The solution was then cooled until the acetic acid began to crystallize, at which time concd. nitric acid (7 ml.) was added with stirring over a period of fifteen minutes. The reaction mixture was then placed in an ice box overnight. Yellow needle-like crystals (m. p. 230–232°; 0.48 g.) separated. This crude product was extracted twice with hot ethanol and the residue crystallized twice from glacial acetic acid. The dinitro-*p*-azophenol obtained in this manner melted at 235–236°, and yielded a dinitrodibromo-*p*-azophenol (m. p. 281–282°) on bromination.

β-Azophenol (1.5 g.), nitrated in the same manner, yielded 0.46 g. of slightly impure dinitro-*p*-azophenol, which upon purification also melted at 235–236°. A mixed melting point of the two nitration products showed no depression.

(12) The authors are indebted to Mr. Carl Miller for valuable assistance during these studies.

(13) Kolthoff and Lingane, *Chem. Rev.*, 24, 12 (1939).

Tetranitro-*p*-azophenol (m. p. 261–262°, with dec.) was obtained by slowly adding dinitro-*p*-azophenol (1 g.) to fuming nitric acid (5 ml.), cooled in an ice–salt bath. After stirring for five minutes, the reaction mixture was poured on ice. The crude product (1 g.) was purified by crystallization from glacial acetic acid.

Anal. Calcd. for $C_{12}H_6O_{10}N_6$: C, 36.55; H, 1.52; N, 21.32. Found: C, 36.93; H, 1.73; N, 21.45.

Tetrabromoazophenol (m. p. 273–274°) was obtained in equal yield from both α- and β-azophenol. To a solution of the monohydrate of *p*-azophenol (2 g.) and sodium acetate (3 g.) in glacial acetic acid (130 ml.) was added a solution of bromine (3 g.) in glacial acetic acid (50 ml.). Mechanical stirring was employed during the period (twenty-five minutes) that bromine was added and for thirty minutes thereafter. A dark green precipitate (1.3 g.) was filtered off. After four crystallizations from glacial acetic acid, the tetrabromo derivative melted at 273–274°.

Anal. Calcd. for $C_{12}H_6O_2N_2Br_4$: C, 27.20; H, 1.14. Found: C, 27.04; H, 0.87.

The diacetate (m. p. 263–264°) was prepared in the usual way.

Anal. Calcd. for $C_{16}H_{10}O_4N_2Br_4$: C, 31.27; H, 1.63. Found: C, 31.32; H, 1.73.

The dibenzoate (m. p. 297–298°) was obtained by benzoylation in pyridine with benzoyl chloride.

Anal. Calcd. for $C_{26}H_{14}O_4N_2Br_4$: C, 42.28; H, 1.90. Found: C, 42.12; H, 2.37.

Summary

The recorded evidence for *cis–trans* isomerism in the case of *p*-azophenol has been reëxamined and new findings have been introduced with the result that it may now be concluded that the so-called α- and β-forms of *p*-azophenol are not *cis–trans* isomers. The anhydrous *p*-azophenol does exist in two solid modifications, however.

The Effect of Nuclear and Side Chain Substitution on the Oxonium Ion Catalyzed Iodination of Acetophenone Derivatives

BY LOIS ZUCKER[1] AND LOUIS P. HAMMETT

Nathan and Watson,[2a] and Evans,[2b] measured the rates of bromination of a number of acetophenone derivatives in acetic acid–water solutions containing hydrochloric acid, and found the effect on the rate of substitution of a methyl group for hydrogen in the side chain much greater than the effect of substitution in the ring. Since the reaction is subject to general acid catalysis,[3] the specific bromination rate in a given medium is the sum of a series of specific catalytic bromination rates, one for each catalyst present, and the effect of a given substitution cannot be expected to be the same for different catalysts. This makes the observed rate in this medium an unnecessarily complicated function of the structure of the ketone,[4] since undissociated acetic acid, hydrogen ion solvated with water (oxonium ion), and hydrogen ion solvated with acetic acid are possible catalysts. A more easily interpretable catalytic system is found in a not too concentrated aqueous solution of a strong monobasic acid, which can contain only one effective catalyst, oxonium ion. Accordingly, we have measured the rates of iodination (equal to the rates of enolization) of some of these ketones, together with that of 2,4,6-trimethylacetophenone (not on the previous list), in 1.388 molar aqueous perchloric acid solution, using a colorimetric technique.

Experimental

Apparatus.—The iodinating solution was contained in a closed glass cell shown in Fig. 1, closure being made with a very well fitting ground glass joint, of which the colorimeter plunger forms the stopper. Error introduced by this closure, as far as optical alignment and effective depth of layer are concerned, was within the ordinary precision of matching, ±0.17 mm. under the conditions of a kinetic run. A really well fitting glass joint is also necessary to retain iodine in an aqueous solution containing no iodide over a period of many hours. The double lines indicate brass, the single lines glass. The cell stood directly on a plane glass disk (removable for cleaning) which formed part of the bottom of a flattened cylindrical brass water jacket, of 80 cc. capacity with the cell mounted, which in turn was fastened to the colorimeter platform with a lock nut. Water was circulated from a large thermostat through insulated tubing and the likewise well insulated jacket at the rate of 5 cc. per sec. Temperature in the cell could be maintained at 25.00 ± 0.01°, as checked by thermocouple, even when room temperature was as low as 17°.

The colorimeter was the Klett–Beaver model,[5] with the above-described cell mounted on one side, and on the other side the standard two-cup, two-plunger system for maintaining a constant 5 cm. depth of absorbing layer, with variable contributions from the colorimetric standard and pure water. The fields were viewed through a dense blue filter, Wratten L50; applied to the usual incandescent bulb it supplies a deep blue–violet light representing a fairly narrow spectral band. The filters were placed inside the prism housing immediately over the ends of the plungers.

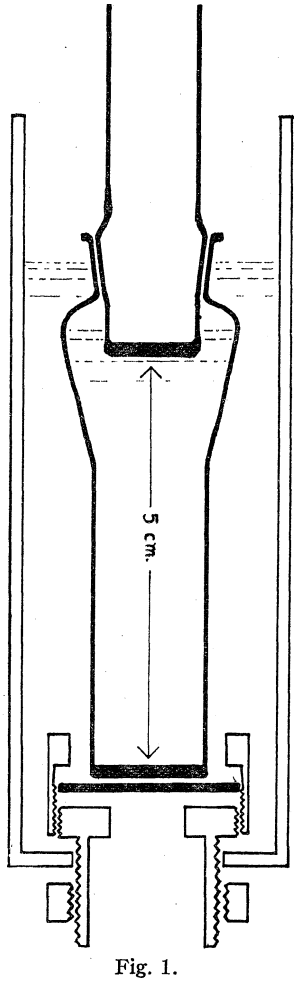

Fig. 1.

Method.—The reaction products, derivatives of phenacyl iodide, are rather insoluble in any aqueous media. The maximum concentration of iodine which can disappear from solution before the appearance of insoluble phenacyl iodide is 17×10^{-5} molar, and some of the substitution products of phenacyl iodide are considerably less soluble. Iodine concentrations used in runs were accordingly of this order of magnitude, so that large relative changes in iodine concentration could be observed; the range of iodine concentrations covered was 30 to 0.5×10^{-5}. The more dilute of these solutions, although hardly distinguishable from water by general illumination, have reasonably strong color when viewed through the blue filter used, since the filter cuts out most of the light not appreciably absorbed by aqueous iodine solutions.

Because of the great instability in an open cup of aqueous iodine solutions containing no iodide, we had to use an artificial colorimetric standard—a dilute (4 mg. per liter) solution of methyl orange in water. Although this solution differs markedly in color from iodine solutions in general illumination, when viewed by the light transmitted by the filter methyl orange and iodine solutions are indistinguishable by eye over the range of concentrations covered.

Beer's law was shown to apply to this system by determining the depth of layer of the standard methyl orange solution necessary to match the same 5-cm. layer of at least eight different iodine solutions covering the range of iodine concentrations used, and made up by adding an excess of sodium iodate or sodium nitrite to a known acidified solution of potassium iodide. Then

$$c_{I_2} = \frac{c_{MeO}\bar{k}_{MeO}}{h_{I_2}\bar{k}_{I_2}} \times h = mh$$

where c_{I_2} and c_{MeO} are the molar concentrations of iodine and methyl orange, $\bar{k}_{I_2}$ and $\bar{k}_{MeO}$ are the effective molecular extinction coefficients of iodine and methyl orange for the spectral region employed,[6] h_{I_2} is the depth of layer of iodine solutions (close to 5 cm.), h the depth of layer of methyl orange solution necessary for match, and m is the slope of the linear plot of c_{I_2} against h.

Under ordinary conditions only one atom of iodine from each iodine molecule is introduced into the ketone, the other being liberated as iodide ion. Because the resultant gradual increase in concentration of the intensely yellow polyiodide ions would cause a change in the color value and intensity of the solution, and because iodide ion undergoes oxidation by dissolved oxygen which is relatively rapid in acid solution, and finally to avoid reversal of the reaction, most of the runs were made in the presence of an oxidizing agent, either sodium nitrite or sodium iodate, which converts iodide to iodine as fast as it is formed. This device is due to Bartlett,[7] who used nitric acid as the oxidizing agent in glacial acetic acid. Then

$$\Delta c_{KH} = f\Delta c_{I_2} = mf\Delta h \qquad (1)$$

where Δc_{KH} is the change in concentration of the ketone as a result of the iodination, Δc_{I_2} and Δh are the corresponding changes in iodine concentration and in colorimeter setting. The factor f has the value 2.5 if the oxidizing agent is iodate, 2 if it is nitrite. Some runs were made with each ketone with nitrite, some with iodate—agreement of the rates is evidence that neither oxidizing agent is interfering with the rate measurement. Good agreement was found for all the ketones except 2,4,6-trimethylacetophenone and isobutyrophenone; in the latter case both oxidizing agents obviously were causing some other reaction, accom-

panied by the production of a brown color in the case of the iodate, and a precipitate in the case of the nitrite. Runs were made with both these ketones without any oxidizing agent, small portions of the reacting solution being read in the colorimeter at suitable time intervals, immediately after the addition of a slight excess of nitrite. The reverse reaction between iodide ion and phenacyl iodide derivative cannot be neglected if iodide is allowed to accumulate, so that the apparent rate does fall off; nevertheless the initial part of the reaction is not affected appreciably. Isobutyrophenone could be studied only by this method. The rate of iodination of 2,4,6-trimethylacetophenone in the absence of an oxidizing agent was found to be in excellent agreement with the rate in the presence of nitrite; it was therefore concluded that the discrepancy between runs with nitrite and with iodate is in this case due solely to some side reaction with the iodate.

The usual procedure was to weigh a suitable quantity (about 9 cc.) of a solution containing known concentrations of ketone and perchloric acid into the reaction cell, which was equipped with a spare stopper, and bring to temperature in the large thermostat while water was circulated through the water jacket on the colorimeter. About 0.2 cc. of a known aqueous potassium iodide solution was added from a weight pipet, the solution mixed, and left in the thermostat ten minutes longer. The reaction was started by the addition of a small crystal of solid oxidizing agent, the cell was transferred to the colorimeter, and readings were taken. The total time of mixing and transfer from one thermostat to the other was not more than twenty seconds. Time was measured from the instant of addition of oxidizing agent to the nearest one-tenth minute with a stop watch calibrated against an electric clock. This procedure allows a very satisfactory approximation to instantaneous mixing since the ketone concentration, upon which alone the rate depends, is at its correct initial value even before mixing.

For the runs without oxidizing agent each point on the time curve had to be determined on a separate portion of the reacting solution. In the case of 2,4,6-trimethylacetophenone it was most convenient to make up the solution in the colorimeter cell by the rapid addition from a weighing bottle of about 9 cc. of a solution of the ketone in perchloric acid, already at temperature, to about 0.1 cc. (known weight) of an aqueous solution containing potassium iodide and not quite an equivalent of sodium iodate, in the colorimeter cell also at temperature. After a suitable time interval a drop of an aqueous sodium nitrite solution was added, amounting to a slight excess over the concentration necessary to take care of the probable iodide concentration in the reacting solution. Readings were completed within five minutes of this addition.

This procedure applied to isobutyrophenone would have made the reaction cell unavailable for other measurements for weeks; therefore the initial solution was made up in 130-cc. quantities in bottles of about 140-cc. capacity with very well ground glass stoppers, and at suitable intervals a portion of the solution was poured into the dry cell for reading. Experiments showed that with smooth pouring the first portion run into the cell is of the same iodine concentration as that in the bottle before pouring; however, with each opening of the bottle to pour out a portion, the iodine concentration of the solution in the bottle decreases slightly and this effect is the more pronounced the larger is the ratio of gas volume to liquid volume in the bottle. (The vapor pressure of iodine at 25° is 0.311 mm.[8]; these solutions have approximately one-fourth of the saturation concentration.) Only two portions could be taken from each bottle.

Materials.—Aqueous acid iodine solutions prepared from weighed portions of potassium iodide with an excess of either sodium iodate or sodium nitrite, formed the primary colorimetric standards. The sample of potassium iodide used throughout was of C. P. grade. It was dried at 105° and kept in a desiccator. At various times solutions prepared from the standard sample of potassium iodide were compared with solutions nominally of the same iodine concentration prepared from two other samples of potassium iodide of different origins and a sample of sodium iodide, and found to have the same color intensity within the error of the determination. Sodium iodate and sodium nitrite were of C. P. grade. Iodine solutions made up from the same iodide solution with iodate and with nitrite had the proper concentration ratio of 6 to 5.

Methyl orange was of the ordinary commercial grade for indicator use. The sample used appeared not entirely homogeneous with respect to depth of color of various particles. The secondary colorimetric standard was a stock solution of 100 mg. of methyl orange in 1 liter of aqueous solution, from which the working standard was prepared at frequent intervals by a 1 to 25 dilution. The stock solution retained the same iodine equivalence for over a year.

Perchloric acid solutions were made up from 60% reagent grade, ACS specification, and standardized against 0.1 normal sodium hydroxide, the primary standard being Bureau of Standards potassium acid phthalate.

Acetophenone,[9a,b] *p*-methylacetophenone,[9c] 2,4,6-trimethylacetophenone and *p*-bromoacetophenone[9c] previously had been purified carefully. The first three were purified further by fractionating three times *in vacuo;* the *p*-bromoacetophenone was recrystallized once from ethanol–water solution. Propiophenone and *n*-butyrophenone obtained from the Eastman Kodak Company, and isobutyrophenone, made by Friedel–Crafts synthesis from benzene and isobutyryl chloride (Eastman), were recrystallized several times each from purified petroleum ether in an acetone–dry-ice bath, separation between crystals and liquid being effected by an Emig immersion filter. They were then each fractionated three times *in vacuo*. The purified samples all distilled within a temperature range of 0.2°.

2,4,6-Trimethylacetophenone	105	9		1.51444

Rate Calculations.—The reaction is first order in ketone and independent of iodine concentration, following the equation

$$-dc_{KH}/dt = kc_{KH} = k(c^0_{KH} - \Delta c_{KH})$$

where c^0_{KH} is the initial concentration of ketone. Substitution of equation (1) converts this to

$$-mf\frac{dh}{dt} = mfk\left(\frac{c^0_{KH}}{mf} - \Delta h\right)$$

whose integrated form is

$$\log\left(\frac{c^0_{KH}}{mf} - \Delta h\right) = -\frac{k}{2.303}t + \log\frac{c^0_{KH}}{mf} \quad (2)$$

If only a small fraction of the total ketone present reacts

$$\frac{c^0_{KH}}{mf} >> \Delta h, \text{ and } -h = \frac{kc^0_{KH}}{mf}t - h^0 \quad (3)$$

Since in all runs the change in iodine concentration during the run was limited to $\Delta c_{I_2} = m\Delta h \leq 17 \times 10^{-5}$, equation (3) could be applied to most of these ketones in spite of their small solubility. Equation (2) had to be used only for the most insoluble ketones, *p*-bromoacetophenone, isobutyrophenone, and 2,4,6-trimethylacetophenone.

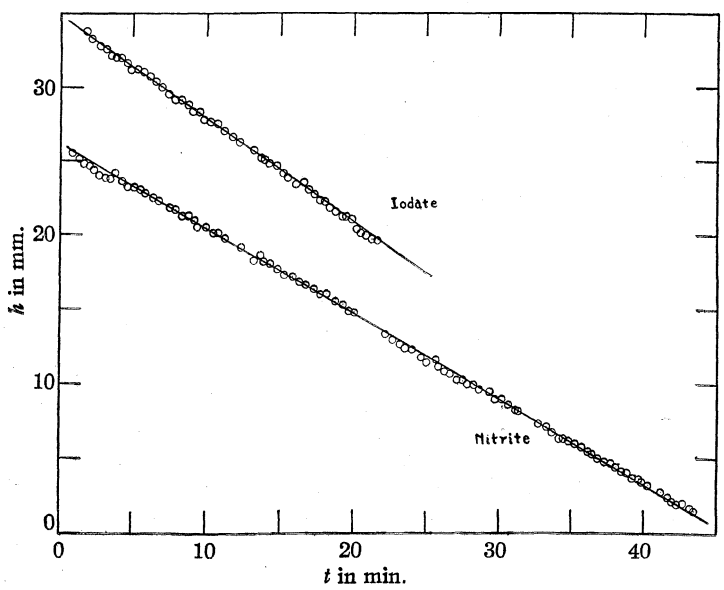

Fig. 2.

In all cases k was calculated from the slope of the line fitted by eye to the appropriate graphical plot of the data. The ketone concentration used in equation (3) was actually the average concentration for the run, which in no case differed from the initial concentration by more than 2%. The value of h^0 necessary for the application of equation (2) could be obtained either by extrapolation of a plot of h against t, or from the known initial iodide concentration of the solution by the application of the formulas

$$h^0 = \frac{c^0_{I_2}}{m} = \frac{c^0_{I^-}}{m(1-1/f)}$$

for solutions made up with excess oxidizing agent, and

$$h^0 = \frac{c^0_{I_2}}{m} = \frac{1}{2m}(c^0_{I^-} - c^0_{NaIO_3})$$

for solutions made up with iodide in excess over iodate, the oxidation being completed later with nitrite. Agreement of h^0 determined in these two ways shows the absence of any appreciable concentration of the enols of these ketones.

Precision.—The error in k calculated by the method outlined using equation (3) depends on the error in m (0.5%), in c^0_{KH} (0.1%) and in the slope of the line fitted to the plotted points by eye. The important factors in the error in slope are the number of points (from 80 to 100 for most of these experiments) and the average deviation of the points from the best line, measured along the h-axis relative to the total length of the h-axis (Δh_{max}). The error in measurement of time can be neglected by comparison with the error in h. To estimate the error for one experiment (the longer run shown in Fig. 2), we have combined the standard deviation of the slope of the line[10] calculated by the least squares technique (0.25%) with a reasonable estimate of the average deviation of the slope of a line fitted by eye from that of the least squares line (0.75%), the resultant figure being 0.8%. The error in the slope for other experiments, for which a least squares line has not been calculated, was obtained from the 0.8% figure in the following way. The

(10) Wright and Hayford, "The Adjustment of Observations," D. Van Nostrand Company, New York, N. Y., 1906, p. 132.

average deviation in h, based on a large series of readings, is 0.17 mm. for h in the range 45–5 mm. The average deviation put on a comparable basis for a series of experiments is $0.17/\Delta h_{max}$. The error in the slope certainly increases with an increase in this figure; we have assumed that the error in the slope is inversely proportional to Δh_{max}, so that the estimated precision of the slope for the shorter run in Fig. 2 is 1.3%. Including the effect of the 0.5% error in m, the precision measures for all the runs using equation (3) range from 1 to 1.4%.

It can be shown that the error due to Δh in the ordinate, log $(c^0_{KH}/mf - \Delta h)$, used in plotting equation (2), relative to the maximum value of that ordinate is

$$\frac{\epsilon_{\Delta h}}{\Delta h_{max} + \frac{\Delta h_{max}}{c^0_{KH}/mf}(1/2\,\Delta h_{max} - \Delta h)}$$

where ϵ represents error in the sense of average deviation. This is not a general equation, but is a valid approximation for all our experiments, since $\Delta h_{max}/(c^0_{KH}/fm)$ (fraction of ketone reacting during the run) was maximally 1/4. This average deviation of points from the line increases with extent of reaction, but even in the most extreme case differs from $\epsilon_{\Delta h}/\Delta h_{max}$ by ±13%. The average deviation is still approximately inversely proportional to Δh_{max}. The situation is illustrated in Fig. 3, which shows plots according to equation (2) of one run with *p*-bromoacetophenone, with $\Delta h_{max} = 15$, $\Delta h_{max}/(c^0_{KH}/fm) = 0.1$, and one run with 2,4,6-trimethylacetophenone, with $\Delta h_{max} = 5.4$, $\Delta h_{max}/(c^0_{KH}/fm) = 0.25$. Precision measures have been calculated for these two ketones in the same way as before, and are 1.5 and 3.6%, respectively. The isobutyrophenone experiments are characterized by considerably greater experimental error, besides having a Δh_{max} of only 6; the assigned precision measure in this case is 6%.

Results

The results are presented in Table I. The iodination of acetophenone is accurately first order in acetophenone with a 7-fold variation in initial concentration, and zero order in iodine,

TABLE I

IODINATION RATES IN 1.388 MOLAR $HClO_4$ AT 25.00°

Ketone	No. of expts.	Av. k (min.$^{-1}$)
Acetophenone	4	0.001104
Propiophenone	3	.000513
n-Butyrophenone	2	.000418
Isobutyrophenone	3	.0000224
p-Methylacetophenone	2	.001305
p-Bromoacetophenone	2	.000850
2,4,6-Trimethylacetophenone	3	.001625

with a 3-fold variation in initial concentration, and an 11-fold variation in iodine concentration during the course of a single run, in all a 22-fold variation in iodine concentration. We did not investigate the dependence of the rate on the concentrations of the reactants for any of the other ketones so fully. Aside from acetophenone, *n*-butyrophenone was the only ketone whose rate was shown to be first order in ketone concentration. The dependence of rate on iodine concentration was shown to be zero order for propiophenone, *p*-methylacetophenone, and *p*-bromoacetophenone. The acid catalyzed iodination of the reaction product, substituted phenacyl iodide, is so slow by comparison with that of the original ketone that it does not take place to any appreciable extent under the experimental conditions. This is so even for 2,4,6-trimethylacetophenone, where the ratio product/reactant reached a maximum value of 1/4.

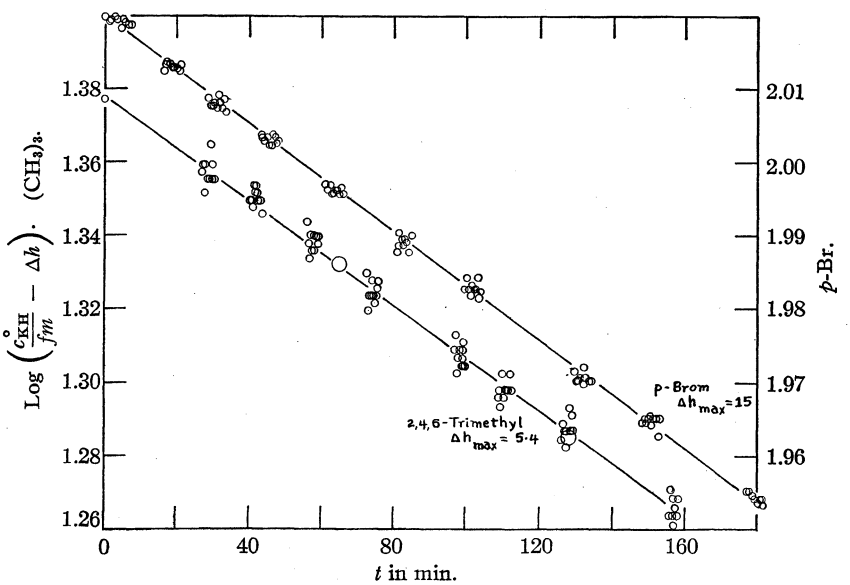

Fig. 3.—o, with oxidizing agent; O, without oxidizing agent.

Rough experiments showed the rates of iodination of these ketones in 0.01 molar perchloric acid to be negligible by comparison with the rates in 1.388 molar perchloric acid, proving the absence of any effective water catalysis. These rates cannot be expected to be identical with those calculated from the specific catalytic constants for the oxonium ion catalyzed reaction in dilute aqueous solution, because of salt effect, but the salt effect should be small, and consequently of approximately equal effect on all the rates. Actually for acetophenone the ratio of the rates in 1.388 molar and 0.210 molar perchloric acid solutions is only 7% greater than the ratio of the molar concentrations of perchloric acid in the two solutions.

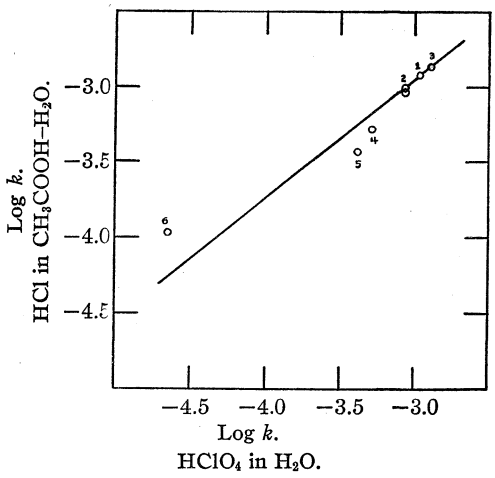

Fig. 4.—1, Acetophenone; 2, *p*-bromoacetophenone; 3, *p*-methylacetophenone; 4, propiophenone; 5, *n*-butyrophenone; 6, isobutyrophenone.

Discussion

Our results are in agreement with the conclusion of the Cardiff workers[2] as to the large effect of substitution on the alpha carbon on the rate of enolization. There is a quantitative difference in the results, whether due to the polycatalytic composition of the acetic acid medium, or to some other medium effect of unknown nature; these differences are presented in the form of a plot of the logarithms of the rates in one medium against those in the other (Fig. 4). If there were no medium effect, the points would all lie on a straight line of unit slope. Medium effects for substitutions not too close to the seat of the reaction usually cause the points to form a straight line of arbitrary slope, with points representing compounds differing by an alpha substitution showing no simple relation to each other.[4]

Previous work on the effect of ortho methyl substitution on the reactions of phenyl ketones[11] shows strong suppression of only those typical ketone reactions which involve addition at the carbon of the carbonyl group. The most probable enolization mechanism involves addition of a proton to the carbonyl oxygen and removal of a proton from the alpha carbon[12]; if the above generalization is correct no steric hindrance of enolization is to be expected with ortho methyl substitution. And in fact ortho methyl substitution increases the rate of enolization, just as *p*-methyl substitution does.

Summary

The rates of iodination of the ketones acetophenone, *p*-bromoacetophenone, *p*-methylacetophenone, 2,4,6-trimethylacetophenone, propiophenone, *n*-butyrophenone and isobutyrophenone in 1.388 molar aqueous perchloric acid, and of acetophenone in 0.210 molar aqueous perchloric acid, have been measured by a colorimetric method. The rates are compared with those reported for some of the same ketones in 75% acetic acid–water solution 0.5 molar to hydrochloric acid. No steric hindrance was found in the iodination of 2,4,6-trimethylacetophenone.

The Mechanism of the Acid Catalyzed Enolization of Acetophenone Derivatives

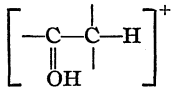
BY LOIS ZUCKER[1] AND LOUIS P. HAMMETT

The rate determining step in the enolization of ketones is probably a proton transfer, one of the two necessary to convert ketone to enol. The mechanism of this reaction when catalyzed by oxonium ion is[2]

$$KH + OH_3^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} IH_2^+ + H_2O$$

$$IH_2^+ + H_2O \xrightarrow{k_2} EH + OH_3^+$$

where KH is the keto form of the ketone, EH is the enol form, and IH_2^+ is the intermediate ion



In this reaction, as in most others subject to acid or base catalysis, more than one proton transfer is involved, and the question as to which of these is the rate determining step is an important one. Its significance is especially emphasized by the recent work of Bonhoeffer[3] on the relative rates of proton and deuteron transfer in the enolization reaction, and of Cohn and Urey[4] in the oxygen exchange of ketones with solvent.

A possible method of attack upon the mechanism problem is based upon the quantitative correlation which must exist between the rate of proton transfer to or from the substrate in a catalyzed reaction, and the acid or base strength of the substrate. The necessity of the correlation follows from the following considerations. A linear relation is quite generally observed between the logarithms of the ionization constants of a series of catalysts and the logarithms of the specific catalytic rate constants for a reaction with a single substrate.[2] All these specific rates are equal to, or proportional to, the specific rates of transfer of a proton either from acidic substrate to basic catalyst, or from acid catalyst to basic substrate.[2] Consequently, the observed linear relation must be based on a more general linear relation between the logarithms of the ionization constants of any series of bases (acids), and the logarithms of the specific rates of transfer of a proton between a given acid (base) and the series of bases (acids). Applying this generalization to the case of variable catalyst–fixed substrate gives the observed relation between rates and strengths of catalysts; applying it to the case of variable substrate–fixed catalyst, allows the prediction of a linear relation between the logarithms of the appropriate basic (acidic) ionization constants of a series of substrates which can undergo the same acid (base) catalyzed reaction, and the logarithms of the specific catalytic rate constants for the reaction with a single catalyst.[5]

Thus for the enolization catalyzed by oxonium ion, as outlined above, the following should be true equations when the ketone is varied

$$\log k_1 = -\alpha \log K_{KH} + \beta \quad (1)$$

$$\log k_2 = \alpha' \log K_{EH} + \beta' \quad (2)$$

where

$$K_{KH} = \frac{a_{H^+}\, a_{KH}}{a_{IH_2^+}}$$

and

$$K_{EH} = \frac{a_{H^+}\, a_{EH}}{a_{IH_2^+}} = K_{KH} K_{\text{Enolization}}$$

and α, β, α', β' are constants for the series of ketones with oxonium ion. If step 1 in the enolization is rate determining, it should be true that

$$\log k = \log k_1 c_{OH_3^+} = -\alpha \log K_{KH} + \beta'' \quad (3)$$

where

$$k = -\frac{1}{c_{KH}} \frac{dc_{KH}}{dt}$$

$c_{OH_3^+}$ is constant for all the ketones, and no other catalyst is present in the solution. If step 2 is rate determining

$$\log k = \log k_2 c_{OH_3^+}/K_{KH} = (\alpha' - 1) \log K_{KH} + \alpha' \log K_{Enol.} + \beta'''$$

and no linear relation is to be expected between log k and log K_{KH}, unless all changes in structure concerned have quantitatively similar effects on both equilibrium constants.

There are some limitations on the applicability of these rate–equilibrium constant relationships concerned with allowable differences in structure of the bases (acids) being compared, which can be

deduced from the results of comparing specific rates obtained for a series of catalysts and the acid (base) strengths of the catalysts. Acids with varying numbers of acidic hydrogens, or their conjugate bases, can be compared only if statistical corrections are applied to their experimentally determined ionization constants.[2] Acids or bases differing largely in structure cannot be compared; substitution on the same atom which carries or can receive the acidic hydrogen,[6] and changes in charge type appear to be such large changes in structure.

Lack of quantitative information about any basic or acidic ionization constants of typical substrates or their conjugate acids or bases, has prevented the practical application of these expectations. Recently, however, a method has been developed for measuring the basic ionization constants of extremely weak bases by the changes in their ultraviolet absorption spectra on ionization in various sulfuric acid–water solutions[7a]; pK's are already available for acetophenone,[7a] *p*-bromoacetophenone[7b] and *p*-methylacetophenone,[7b] and to these we have now added propiophenone, *n*-butyrophenone and isobutyrophenone. The rates of enolization of these ketones, the catalyst being oxonium ion, already have been reported.[8] Equation (1) should apply for all these acetophenone derivatives. They are all monoacid bases, so there is no necessity for statistical corrections. When substrate is fixed and catalyst changed, points for alpha substituted aliphatic carboxylic acids or their ions fall on the same line as points for substituted benzoic acids or their ions[2]; it is therefore very improbable that any of the substitutions involved with these ketones is sufficiently drastic to invalidate equation (1). (This set of ketones would not be suitable for a comparison involving the use of equation (2), because of the substitution on the carbon carrying the acidic hydrogen.) Then if step 1 is rate determining, equation (3) is a true equation and a plot of log k against log K_{KH} should be a straight line. If step 2 is rate determining, equation (3) is not a true equation, because the relative effects of side chain substitution and of ring substitution cannot be expected to be the same on log k_2 as on log K_{KH}; in this case the plot of log k against log K_{KH} will not be a straight line.

The rates actually measured were the rates of iodination of the ketones, which should equal the rates of enolization.[9,2] Before making the comparison between these rates and the base strengths of the ketones, we investigated the nature of the acid catalysis of the iodination of acetophenone, since if general acid catalysis as distinguished from specific hydrogen ion catalysis[2] is not proved definitely, there is the possibility of an iodination mechanism differing fundamentally from that outlined. General acid catalysis has been established for the halogenation of acetone alone among ketones.[10]

Experimental

Materials.—The physical constants and details of purification of the ketones used were given in the preceding paper.[8]

Chloroacetic acid was recrystallized four times from benzene, m. p. 63.0–63.2°; acid titration 99.83% of theoretical.

Method: pK' Measurements.—The method of Flexser, Hammett and Dingwall[7a] was used. In this technique the temperature of the solution was 22 ± 5°; closer temperature control was considered unnecessary because of the very small temperature coefficients characteristic of absorption of ultraviolet and visible light, and of the ionization equilibrium. However, the few cases known with very large temperature coefficients of light absorption, all involve ions.[11] We have measured the absorption of isobutyrophenone in 89.7% sulfuric acid, in which it is nearly completely ionized, at room temperature, and at 45 ± 0.2°. Since the results agreed within the error of measurement, and since the water jacketing is extremely troublesome in the small space available around the absorption cell, all the other measurements reported here were made without temperature control, as previously.

The sodium salicylate treatment[12] of photographic plates for increasing contrast at very short wave lengths was found very useful for determining extinction coefficients from 2100 to 2300 Å.

The "isobestic point" method[7a] of calculating the pK's was used. The use of areas under the curves representing extinction coefficients as a function of wave length, over intervals of 100 Å., gave only slightly better results than the use of the extinction coefficients themselves at wave lengths in the centers of these intervals.

Rate Measurements.—The reaction was studied by the colorimetric technique previously described.[8] Differences in technique arise from two features of these experiments, the low acidity of the solutions and the necessity for maintaining constant ionic strength. The rate of the oxidation of iodide ion to iodine, produced by potassium iodate in all cases, is too slow in this range of hydrogen ion concentration when only a slight excess of iodate is present. The concentration of potassium iodate necessary to prevent any accumulation of iodide ion could be calculated from the known rate of the iodide–iodate reaction,[13] the hydrogen ion concentration of the solution, and an approximate figure for the rate of the iodination reaction. In all runs except 18, 0.01 molar potassium iodate was more than sufficient; in run 18, with a hydrogen ion concentration of 0.001, the concentration of iodate used was 0.08. Because of the necessity of having known concentrations of potassium iodate it was not possible to start the reaction by the addition of an excess of solid potassium iodate as previously; instead, 0.1 cc. of an aqueous potassium iodide solution was added to a known volume of solution containing known concentrations of ketone, catalyst, potassium iodate, and sodium perchlorate.

The decrease in hydrogen ion concentration due to making up the iodine solution from iodide and iodate, equal to twice the initial iodine concentration (and most usually in the neighborhood of 0.0004) is just appreciable in the most dilute perchloric acid solutions; the calculated hydrogen ion concentration was corrected for this effect wherever necessary. The change in hydrogen ion concentration during a run, equal to half the change in iodine concentration, was negligible for all runs.

The ionic strength was maintained at 0.21 by the addition of the appropriate amount of sodium perchlorate. Buffer mixtures were made up from standard carbonate-free sodium hydroxide solution, and chloroacetic acid solution standardized against the sodium hydroxide. The composition of the buffer mixtures was calculated by the use of the value 0.0025 for the ionization constant of chloroacetic acid.[14]

The identity of the principal reaction product was checked by running a large scale bromination of acetophenone in 0.5 molar hydrochloric acid. The mechanism of the bromination should be identical with that of the iodination, and phenacyl bromide has the advantage over phenacyl iodide of being a solid at room temperature, and quite stable away from contact with the solution from which it is prepared. Bromine was added to five liters of a saturated solution of acetophenone (about 0.045 molar) in 0.5 molar hydrochloric acid, the bromine being at approximately a fifth the concentration of the acetophenone. By the time the solution was colorless (about twenty-four hours), a large portion of the product had come out of solution in well-formed crystals (about 6.5 g.). The melting point of the crystals after thorough washing was 47.5–50°. One recrystallization from petroleum ether brought the melting point to 49–50°.

Rate Calculations.—k, the first order specific rate, could in all cases be obtained from the slope of a plot of colorimeter settings against time, using the simplified form[8] which the integrated rate equation takes if only a few per cent. of the ketone present is allowed to react. The slope of the plot of the various values of k for perchloric acid solutions against concentration of perchloric acid is the specific catalytic constant for oxonium ion. The results in the buffer solutions were fitted to the equation

$$k - k_{OH_3^+} c_{OH_3^+} = k_{HC} c_{HC} + k_{C^-} c_{C^-}$$

by the method of least squares, using the value of $k_{OH_3^+}$ determined in perchloric acid solutions. HC refers to chloroacetic acid, C^- to chloroacetate ion.

Results

The results of the rate measurements are presented in Table I. The calculated k's were obtained by the use of the specific catalytic constants listed. Water catalysis is too small to measure. The effect of chloroacetate ion is small: only in experiment 18 does the calculated contribution of the chloroacetate catalysis amount to more than 4% of the total rate. While further iodination of the initial product, phenacyl iodide, by means of the acid catalyzed mechanism is so slow as to be negligible with these high constant acetophenone concentrations, iodine substitution very much favors further iodination by the basic mechanism.[15] The effect of a basic catalyst consequently is determined by a competition between the reaction with acetophenone, the reaction with ω-iodoacetophenone, with maximally one-fiftieth the con-

centration of the acetophenone but with a much higher specific reaction rate, and the reaction with ω,ω-diiodoacetophenone, maximum concentration unknown, but with a still very much higher specific reaction rate. Any appreciable amount of secondary iodination should produce curvature in the time curves (although possibly too small a curvature to be apparent), and a definite lack of constancy of the apparent specific catalytic rates with varying buffer concentration. Neither of these effects appeared in the results. The calculated k_C- is probably not a correct value for the specific catalytic constant for the introduction of the first iodine, but the whole effect of chloroacetate ion is so small that the calculated k_{HC} is undoubtedly quite good. The reaction is certainly subject to general acid catalysis.

The results of the absorption measurements are presented in Tables II–IV. Figures in parentheses are somewhat less reliable than the others. Methyl substitution in the side chain is much more effective in changing the base strength than it is in changing the absorption spectra of the ketone and its conjugate acid formed by the addition of a proton to the oxygen. The spectra of these ketones are practically identical with that of acetophenone within the error of measurement,[7a] (average deviation of the extinction coefficient from the mean 5%). Comparison of the spectra of the conjugate acids cannot be made so directly because data are not available for all the compounds in the same highly acid medium, and there is a medium effect on the absorption distinct from the effect of changing acidity on the ionization equilibrium[7a]; however, specific differences between the spectra of the conjugate acids of the various ketones are certainly small. Alpha

methyl substitution definitely reduces the base strength—compare acetophenone, with a pK' of −6.03,[7a] with the figures for propiophenone and isobutyrophenone. The difference between the pK's of propiophenone and *n*-butyrophenone is within the error of measurement.

Discussion

The comparison of the rates of enolization of these ketones with their base strengths is shown in Fig. 1; the rectangle about each point indicates the precision measures of the two measurements. There is obviously no simple functional relationship between the two sets of data, so that step 1 cannot be exclusively rate determining. Other possibilities which must be considered are (a) step 2 is rate determining, (b) steps 1 and 2 both affect the rate, (c) the enolization is a one step, termolecular reaction rather than two separate bimolecular reactions. Pedersen[2] objects to c, because product terms of the type $kc_{HA}c_{A^-}$ should be of much greater magnitude than terms kc_{HA} or kc_{A^-} in the rate equation. This is definitely not the case, although some of Dawson's experiments[10a] may be interpreted to indicate the presence of small product terms.

Both an acid and a base are necessary for any of these mechanisms. Mechanism c was rejected because both the acid and the base appear in the rate determining step and should therefore appear in the rate equation. But it would seem that mechanism b as well as mechanism c, should call for first order specific rates varying with the concentrations of two catalysts; the concentrations of one acid and one basic catalyst are certainly concerned in rate determining processes, and, in general, if more than one catalyst is present, catalyst pairs which are not conjugate are no less probable than catalyst pairs which are conjugate.

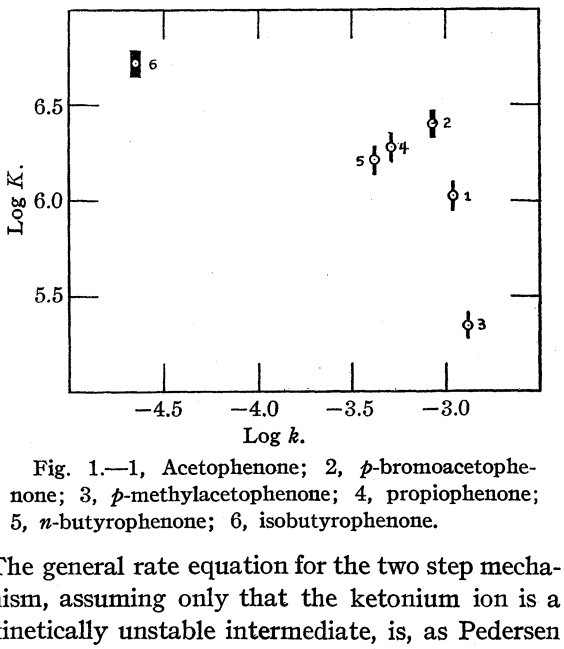

Fig. 1.—1, Acetophenone; 2, *p*-bromoacetophenone; 3, *p*-methylacetophenone; 4, propiophenone; 5, *n*-butyrophenone; 6, isobutyrophenone.

The general rate equation for the two step mechanism, assuming only that the ketonium ion is a kinetically unstable intermediate, is, as Pedersen has shown[2]

$$-\frac{1}{c_{KH}}\frac{dc_{KH}}{dt} = k = \frac{\Sigma k_{1BH^+}c_{BH^+}\Sigma k_{2B}c_B}{\Sigma k_{2B}c_B + \Sigma k_{-1B}c_B} = \frac{\Sigma k_{1BH^+}c_{BH^+}}{1 + \frac{\Sigma k_{-1B}c_B}{\Sigma k_{2B}c_B}}$$

where BH^+ represents any acid, B any base, and summation is to be taken over all acids and bases in the solution. These designations are not intended to specify the charge type of the acids and bases. Let

$$F = \frac{\Sigma k_{-1B}c_B}{\Sigma k_{2B}c_B}$$

When $F << 1$, step 1 is rate determining and $k = \Sigma k_{1BH^+}c_{BH^+}$; when $F >> 1$, step 2 is rate determining, and since

$$k_{1BH^+}c_{BH^+} = c_{H^+}k_{-1B}c_B/K_{KH} \qquad (4)$$

for every acid-base pair present, k reduces to

$$\sum \frac{k_{2B}K_{BH^+}c_{BH^+}}{K_{KH}},$$

which is in the proper experimental form. When $F \sim 1$, we have mechanism b, and it is usually assumed that k reduces to the observed form because F is independent of the relative concentrations of the various catalysts, and hence a constant. This would be true in general only if

$$\frac{k_{2B}}{k_{-1B}} = \frac{k_{2C}}{k_{-1C}} = \frac{k_{2D}}{k_{-1D}} = \cdots \qquad (I)$$

for all bases which might be present, but this is highly improbable. Application of the log–log relation between rates and equilibrium constants for protolytic reactions yields the following:

$$\log k_{-1B} = \alpha \log K_B + \beta$$
$$\log k_{2B} = \alpha' \log K_B + \beta'$$
$$k_{-1B} = bk_{2B}(K_B)^{(\alpha-\alpha')}$$
$$F = \frac{b\Sigma K_B{}^{(\alpha-\alpha')}k_{2B}c_B}{\Sigma k_{2B}c_B}$$

The requirement (I) and the constancy of F with changing relative catalyst concentrations are equivalent to the requirement that $\alpha = \alpha'$, *i. e.*, that the linear relation between the logarithms of the ionization constants of a series of bases and the logarithms of the rates of acceptance of one proton of the dibasic acid $[RC(OH)CH_3]^+$ shall have the same slope as that for the same set of bases and the other proton of the dibasic acid, the one hydrogen being bound to carbon, the other to oxygen. This is definitely not the case for the entirely equivalent example of two monobasic acids even for much smaller differences in structure. A statement equivalent to requirement (I), and one which is manifestly incorrect, is this: the log–log relations between rates and base strengths of a given series of catalysts should have the same slope for all general base catalyzed reactions.

In special cases F can still be constant; it is constant if there is only one catalyst present, or if only one base out of several present is effective in steps 2 and -1. That is, F is constant only if it is true for all the solutions studied that

$$k_{-1B}c_B >> k_{-1C}c_C + k_{-1D}c_D + \cdots$$
$$k_{2B}c_B >> k_{2C}c_C + k_{D2}c_D + \cdots$$

But equation (4), which applies whether there is equilibrium in step 1 or not, shows that the first inequality is identical with

$$k_{1BH^+}c_{BH^+} >> k_{1CH^+}c_{CH^+} + k_{1DH^+}c_{DH^+} + \cdots$$

If F is constant for these reasons, then

$$k = \frac{k_{1BH^+}c_{BH^+}}{1 + \frac{k_{-1B}}{k_{2B}}}$$

In other words, if F is constant with varying relative concentrations of two or more catalysts, it is because a single acid–base pair is causing practically all the reaction, and no other catalyst is very effective, either as acid in step 1, or as base in steps 2 and -1. Conversely, if it is possible to detect large catalytic effects of two or more catalysts present in the same solution, and to calculate specific catalytic constants for each which are truly constant as the relative concentrations are varied, then mechanism b, with neither step solely rate determining, can be rejected. In the particular case in question, the acid catalyzed enolization of acetophenone, the ratio of the contributions of chloroacetic acid and oxonium ion to the rate ranges from 1.5 to 4 in the buffer solutions, and is of course 0 in the perchloric acid solutions.

Since we have eliminated all other suggested mechanisms, it seems highly probable that mechanism a, in which step 2 is rate determining, is the correct one. The same conclusion is a necessary corollary of the mechanism proposed by Cohn and Urey[4] for the isotopic oxygen exchange between acetone and water. Thus two independent types of evidence strongly support both the proposed mechanism for the enolization and the proposed mechanism for the oxygen exchange reaction.

Summary

The basic ionization constants of propiophenone, *n*-butyrophenone and isobutyrophenone have been measured.

The iodination of acetophenone exhibits a general acid catalysis.

Direct evidence is offered to show that the proton removal is the rate determining step in the acid catalyzed enolization of ketones.

Kinetics of the Iodination of Acetophenone in Sulfuric and Perchloric Acid Solutions

BY LOIS ZUCKER[1] AND LOUIS P. HAMMETT

The acidity function H_0[2] for sulfuric acid–water solutions (and for aqueous solutions of some other strong acids) combines in one functional representation all effects of continuing increase in acid concentration on the ionization equilibria of electrically neutral monoacid bases. These effects are presumably two—the result of increasing the acidity *per se*, and the result of changing the thermodynamic nature of the medium. There is also excellent correlation between the rates of some acid catalyzed reactions in increasingly acid solutions, and the acidity function for these solutions[2,3] and consequently between the effects of increasing acid concentration on the rates of these acid catalyzed reactions, and on the ionization equilibria of electrically neutral monoacid bases. This is simply explained in terms of the transition state theory of reaction velocity if the equilibrium between reactants and activated complex, whose position determines the rate of the reaction, is or approximates an ionization equilibrium of the correct charge type.

On the other hand, the bromination of *m*-nitroacetophenone in moderately concentrated solutions of sulfuric acid in acetic acid–water mixtures shows no such correlation of rate with acidity function.[4] This might be a property of the acetic acid medium or it might be a characteristic property of the enolization reaction. We have therefore studied the rate of iodination of acetophenone in sulfuric acid–water and perchloric acid–water solutions.

Experimental

Rate Measurements.—The colorimetric method used was that previously described.[5]

The color of iodine in sulfuric acid solutions changes in hue from brown in the most dilute solutions to rose in 95% solution, and the effective extinction coefficient for the blue-violet light used slowly decreases. The change becomes perceptible with 46% sulfuric acid solution; for 46 and 51% solutions a pinker colorimetric standard is necessary to get a good match, and is supplied conveniently by an aqueous solution of methyl orange of the same concentration as that used for more dilute acid solutions, but buffered at *p*H 3.8 with 0.05 molar acetate buffer. The effective extinction coefficient of the iodine decreases by about 2% from 39.5 to 45.9% sulfuric acid, and by another 3% from 45.9 to 51% sulfuric acid. No hue which can be obtained from methyl orange at any reasonable acidity is sufficiently like that of iodine in 66% sulfuric acid solution with light of the spectral composition used to allow precise matching. The one experiment in 66% sulfuric acid was very crudely done by measuring the times at which the reacting solution matched, to the eye, various standard iodine solutions all in bottles of closely similar shape and color.

Both potassium iodate and sodium nitrite were satisfactory oxidizing agents for the more dilute acid solutions, up to and including 25% sulfuric acid. Potassium iodate could not be used in 39.5% sulfuric acid; iodine solutions made up from potassium iodide and excess potassium iodate increase steadily in depth of color for several minutes after mixing, although the iodine production should be practically instantaneous. If a large excess of potassium iodate is present, the color then decreases slowly over a period of days to weeks. In 70% sulfuric acid an iodine solution saturated with potassium iodate takes only a few days for complete decolorization. These two phenomena (production of more intense color, and decolorization) are instantaneous in 95% sulfuric acid with suitable relative concentrations of iodine and potassium iodate and are ascribed by Masson, *et al.*,[6] to the formation of stabilized ions on the oxidative level of I^+ (dark brown) and I^{+++} (colorless), respectively. One or both of these ions seems to be kinetically active in 39.5% sulfuric acid. No difficulties were observed with sodium nitrite which was used exclusively for all the sulfuric acid solutions more concentrated than 25%. The innocuousness of this oxidizing agent could not be tested by comparing results obtained with it with those obtained with some other agent, because no other suitable oxidizing agent was found. Nor could rates in the presence of

nitrite be compared with rates without any oxidizing agent, because the rate of the reverse reaction between phenacyl iodide and iodide ion increases rapidly with acidity; iodination in 39.5% sulfuric acid will hardly proceed at all without an oxidizing agent. The concentration of sodium nitrite used was approximately that necessary to cause the initial oxidation of iodide to iodine, and to take care of all the iodide which might be formed during the reaction, assuming nitrite and iodide equivalent on a molar basis. Since 1 mole of nitrite will oxidize somewhat more than 1 mole of iodide, this procedure left some factor of safety.[7] In 39.5% sulfuric acid, good agreement was obtained among the specific rates determined under these conditions over a 13-fold variation in acetophenone concentration, and a 700-fold variation in iodine concentration. The first effect of increasing the nitrite concentration was to cause some reversal of the reaction, probably due to replacement of iodide by nitrite in the phenacyl iodide. This reversal was only detected in the presence of two to three times the concentration of nitrite ordinarily used, and then only when over 30% of the ketone had reacted; the effect was most definitely observed in 51% sulfuric acid, where the reaction came to an almost complete stop after 35% of the ketone had reacted, and the iodine concentration was brought back almost to its initial value by the addition of about twenty times the usual concentration of sodium nitrite. Since the nitrite reaction causing reversal appears to increase with increasing acidity, the experiment in 66% sulfuric acid solution may be considerably in error on this account.

Because of the speed of the reaction in the stronger acid solutions, rather low initial ketone concentrations were necessary, with a large fraction of the ketone reacting. One experiment in 19% sulfuric acid showed that the introduction of a second iodine into the molecule does not become apparent until 55% of the acetophenone has reacted. (The ratio of the rate of introduction of the second iodine to that of the first is 0.033 in 19% sulfuric acid.) It was assumed that the ratio of the rates of introduction of the first and second iodines does not decrease with increasing acidity, and that it was perfectly safe to allow up to 40% of the acetophenone to react.

The procedure described previously[5] was used for all runs except those in 30% and more concentrated sulfuric acid. In these solvents oxidation of iodide to iodine by dissolved oxygen or by sulfuric acid itself,[8] is so fast that appreciable oxidation may take place in the fifteen minutes allowed for the solution to come to thermostat temperature, causing the iodination reaction to start prematurely. For these more concentrated solutions, the following procedure was used. A known solution of iodine in sulfuric acid was prepared in a tube of about 35-cc. capacity, with a well-fitting ground-glass stopper, by adding 25 cc. of sulfuric acid solvent from a pipet (recalibrated for each solvent) to a weighed out quantity of a known aqueous potassium iodide solution. Solid sodium nitrite (amounting to from 0.5 to 5 mg. weighed out on an analytical balance) was added, the solution stirred thoroughly, but smoothly without bubble formation, and the tube stoppered with the stirring rod inside. The ground-glass joint was kept dry. About 9 cc. of a known solution of acetophenone in the same sulfuric acid solvent was weighed in a small weighing bottle. The two solutions were brought to temperature in the large thermostat. The reaction was started by rapidly pouring the contents of the small weighing bottle into the tube, shaking thoroughly, and pouring about 9 cc. of the resulting solution into the dry reaction cell, which previously had been mounted on the colorimeter with water at 25.00 ± 0.01° circulating through the water jacket. The small weighing bottle wet with the acetophenone solution was put in a large stoppered weighing bottle and weighed at leisure. The addition of the ketone solution to the iodine solution took not more than one-tenth minute. The solutions were out of a thermostat for a total of about one minute. The first reading could be taken about two minutes after mixing.

The solubility of the reaction product, phenacyl iodide, is fortunately greater (up to 3 times) under the experimental conditions in the highly acid solutions than it is in more dilute solutions.

Although iodide ion is unstable in 95% sulfuric acid, and the equilibrium concentration of iodide which can exist in such a solution is certainly very small, the iodination reaction is highly reversible in 95% sulfuric acid. In a solution saturated with iodine (*ca.* 0.0001 molar)[6d] and 0.01 molar in acetophenone, iodination did not proceed noticeably, as measured by diminution of color perceptible to the eye, over a period of a month at room temperature. That no other reaction had intervened to prevent the iodination was shown from the following: iodine could be extracted from the solution with petroleum ether and tested for by contact with an aqueous starch–iodide solution. The acetophenone was liberated from its salt by dilution with water; the resulting solution was colorless, smelled of acetophenone, and took up freshly added iodine at approximately the correct rate (within 20%) for the acidity of the solution. A partly reacted system reverts to acetophenone in 95% sulfuric acid; phenacyl iodide, prepared in 40% sulfuric acid, was transferred first to petroleum ether solution, together with all the unreacted acetophenone but without the hydrogen iodide, and then from the petroleum ether to 95% sulfuric acid; after thirty-six hours the 95% sulfuric acid solution had approximately the full color of the iodine originally added to the 40% solution. The petroleum ether had been purified by repeated washing with 95% sulfuric acid over a period of a month, until no further color formation took place overnight with a fresh portion of sulfuric acid, followed by several distillations alternately from 95% sulfuric acid and solid sodium hydroxide. The stabilizing effect of 95% sulfuric acid on iodine at the oxidative level of I^{+}[6d] must mean that there is an I^{+} acceptor in this solvent, which may also be able to accept I^{+} from phenacyl iodide, or its conjugate acid, causing reversal of the iodination reaction.

The iodination is not catalyzed by the light source of the colorimeter in 40% sulfuric acid, since good agreement was found for duplicate runs, one with the light on throughout the run, the other with the light off except for one minute at the end of the run (after thirty minutes) when five readings were made.

Materials.—The purification and physical constants of the materials used were described in a previous paper.[5]

Results

Kinetic Formulation.—In dilute aqueous solutions the rate of halogenation of ketones has with one exception been found independent of the concentration of the halogen and first order in ketone, which is interpreted to mean that the rate is determined by a relatively slow enolization, the enol reacting with halogen as fast as it is formed. The exception[9] is chlorination in highly alkaline solution, in which the rate is first order in chlorinating agent (hypochlorite ion) as well as in ketone. The usual state of affairs is just reversed, and there is a rapid formation of enol or enolate ion, followed by a slow rate-determining reaction between enol or enolate ion and hypochlorite ion. A simple first order formulation fits our results in perchloric acid solutions up to and including 20%, and in sulfuric acid solutions up to and including 15%. In 51% sulfuric acid the reaction is second order. There are two possible explanations for the change in order. One is that the rate of enolization increases so rapidly that it first becomes comparable with, and finally very much greater than, the rate of iodination of the enol, so that the second step becomes rate determining. This is like the situation found by Bartlett, except that the same halogenating agent is involved in the second order as in the first order reaction. Or, perhaps the rose colored modification of iodine which begins to appear in the more concentrated acid solutions can directly iodinate the ketone without the necessity of a preliminary enolization. If this is the explanation, the order of the reaction in 51% sulfuric acid means that the direct iodination has completely supplanted iodination through the enol. For the mechanism

$$\mathrm{KH} \underset{k_{-\mathrm{E}}}{\overset{k_{\mathrm{E}}}{\rightleftarrows}} \mathrm{EH}$$

$$\mathrm{EH} + \mathrm{I_2} \xrightarrow{k_{\mathrm{I}}} \text{products}$$

making no assumptions as to the relative rates of the two steps, we have the following three equations connecting the unknowns c_{KH}, c_{EH} and $c_{\mathrm{prod.}}$, where c is concentration

$$c^0_{\mathrm{KH}} = c_{\mathrm{KH}} + c_{\mathrm{EH}} + c_{\mathrm{prod.}}$$
$$2\Delta c_{\mathrm{I_2}} = c_{\mathrm{prod.}}$$
$$k_{\mathrm{E}} c_{\mathrm{KH}} = k_{-\mathrm{E}} c_{\mathrm{EH}} + k_{\mathrm{I}} c_{\mathrm{I_2}} c_{\mathrm{EH}}$$

c^0_{KH} is the initial concentration of ketone. The factor 2 enters the second equation because of the presence of the sodium nitrite. The last equation represents the assumption that EH is a kinetically "unstable" intermediate.[10] Substitution in the rate equation

$$-2\frac{dc_{\mathrm{I_2}}}{dt} = k_{\mathrm{I}} c_{\mathrm{EH}} c_{\mathrm{I_2}}$$

leads to

$$-2\frac{dc_{\mathrm{I_2}}}{dt} = \frac{k_{\mathrm{E}}(c^0_{\mathrm{KH}} - 2\Delta c_{\mathrm{I_2}})c_{\mathrm{I_2}}}{k_{-\mathrm{E}}/k_{\mathrm{I}} + c_{\mathrm{I_2}}} \qquad (1)$$

Integrating, and substituting the equation

$$2m\Delta h \equiv 2\Delta c_{\mathrm{I_2}} = \Delta c_{\mathrm{KH}}$$

where h is the colorimeter setting, we get

$$(1 - B/A)\log\frac{c^0_{\mathrm{KH}}/2m}{c^0_{\mathrm{KH}}/2m - \Delta h} + B/A \log\frac{h^0}{h} = k_{\mathrm{E}}t/2.303 \qquad (2)$$

$$B = k_{-\mathrm{E}}/mk_{\mathrm{I}} \qquad A = c^0_{\mathrm{KH}}/2m - h^0$$

For the second possibility, which includes the additional reaction

$$\mathrm{KH} + \mathrm{I_2} \xrightarrow{k_{\mathrm{D}}} \text{prod.}$$

and the additional assumption that $k_{\mathrm{I}}c_{\mathrm{I_2}} \gg k_{-\mathrm{E}}$ (*i. e.*, the rate of enolization is rate determining for that part of the iodination which still goes through the enol), the differential equation is

$$-2\frac{dc_{\mathrm{I_2}}}{dt} = k_{\mathrm{D}}(c^0_{\mathrm{KH}} - 2\Delta c_{\mathrm{I_2}})(k_{\mathrm{E}}/k_{\mathrm{D}} + c_{\mathrm{I_2}}) \qquad (3)$$

The important difference between the two differential equations lies in this, that according to equation (1) the apparent order of the reaction with respect to iodine increases during the reaction, while according to equation (3) the apparent order decreases during the reaction; any reaction involving a sufficiently large change in iodine concentration cannot possibly be fitted by both these equations. The integrated form of equation (3) is very unsuccessful when applied to experiments in 39.5% sulfuric acid, in which the iodine concentration was varied more than 100-fold during the reaction; a value of $k_{\mathrm{D}}/k_{\mathrm{E}}$ suitable for the high initial iodine concentrations is much too large for the low iodine concentrations near the end of the reaction.

The lowest curve in Fig. 1 is a plot of the left side of equation (2) against time, for six experiments in 39.5% sulfuric acid. The value of B used to calculate the ordinate is 11; this was selected by trial and error, using the two criteria of freedom from curvature of the plot for a single experiment, and quality of agreement of the slopes

(9) Bartlett, THIS JOURNAL, **56**, 967 (1934); Bartlett and Vincent, *ibid.*, **57**, 1596 (1935).

(10) Skrabal, *Monatsh.*, **64**, 289 (1934).

of the plots of different experiments. Initial acetophenone concentration in these six runs ranged from 814 to 50.6 × 10^{-5} molar, initial iodine concentration from 49.4 to 7.24 × 10^{-5} molar, and the total range of iodine concentration covered was from 49.4 to 0.07 × 10^{-5} molar. The agreement of the data with equation (2) shows that the first explanation for the dependence of the rate on iodine concentration is the correct one.

Rate Calculations.—All the results in 30 to 51% sulfuric acid were fitted to equation (2), one

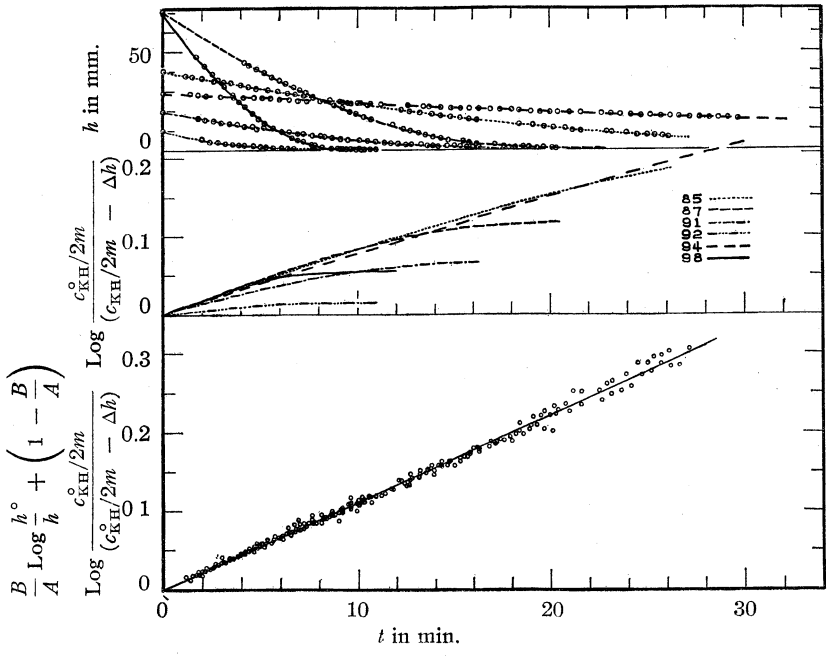

Fig. 1.

of the two unknowns in the equation being determined by trial and error in the manner described, the other calculated from the slope of the resulting plot. For each experiment the two quantities k_E and $K_E k_I$ were calculated, making use of the equation

$$K_E k_I = \frac{k_E}{k_{-E}} \frac{k_{-E}}{mB} = \frac{k_E}{mB}$$

In the more dilute acid solutions in which the rate is dependent on iodine concentration, it was possible to work with such high initial ketone concentrations that $c^0_{KH}/mf \gg \Delta h$ (f has the value 2 for nitrite oxidation, 2.5 for iodate oxidation) and equation (2) could be simplified to

$$h - \frac{Bc^0_{KH}/2m}{A - B} \ln \frac{h^0}{h} = \frac{Ac^0_{KH}/2m}{A - B} k_E t + h^0 \quad (4)$$

This equation requires much less computation than equation (2). The two equations corresponding to equations (2) and (4) for runs showing no dependence of rate on iodine concentration already have been derived,[5] or can be derived from equations (2) and (4), for $k_I \gg k_{-E}$. They are listed below for purposes of reference.

$$\log[c^0_{KH}/mf - \Delta h] = -\frac{k_E}{2.303} t + \log c^0_{KH}/mf \quad (5)$$

$$h = -\frac{c^0_{KH}}{mf} k_E t + h^0 \quad (6)$$

where

$$c^0_{KH}/mf \gg \Delta h$$

The average specific rates k_E and $K_E k_I$ for the various acid concentrations are presented in Table I. Acid concentrations of multiplicates were usually not quite identical; for averaging, the rates were all calculated to the same acid concentration, assuming the rate linear in the acid concentration. The number of experiments run with sodium nitrite is tabulated under the heading N and the number with potassium or sodium iodate under I. The precision of rates calculated by equations (5) and (6) already has been discussed[5]; where there are several multiplicates, the average deviation from the mean is well within the assigned precision measure in all cases. The tabulated $P.\ M.$ in per cent. was calculated by dividing the estimated average deviation from the mean by the square root of the number of experiments. Where k_E has little influence in determining the rate of the over-all reaction (46, 51% sulfuric acid), a considerable range of values of k_E will allow linear plots with very little variation in the value of $K_E k_I$, and the reverse is true when the reaction is nearly zero order in iodine. This range has been indicated in Table I. The difference between the best value and one end of this range is a maximum deviation rather than an average deviation, and is not strictly comparable with the precision measures tabulated for other runs. The experimental error certainly increases with increasing acidity. The increasing speed of the reaction reduces the number of readings which

can be made, and increases the importance of the error in measuring time. The method of mixing which must be used for the reactions in 30 to 51% sulfuric acid introduces further error because the time of mixing is of appreciable duration compared to the total reaction time (one- to two-tenths minute compared with six minutes or more), and during this time ketone concentration is higher than the calculated initial ketone concentration. Since equations (2) and (4) contain the absolute value of h, rather than only terms in Δh, the ever-present possibility of spoiling the optical balance of the colorimeter in mounting the cell at the beginning of the reaction supplies another source of error. Large errors caused by this trouble were avoided by rejecting all runs in which the calculated h^0 did not lie on a smooth extrapolation of the observed h's. It is necessary to include very low colorimeter settings to get sufficiently large changes in iodine concentration. The absolute error for settings below 5 mm. increases steadily above the 0.17 mm. found for settings from 45–5 mm., and of course the percentage error in h becomes very large.

Effect of Increasing Acidity on $K_E k_I$.—Values of $K_E k_I$ in sulfuric and perchloric acid solutions of the same concentration are equal, within the rather large error of measurement, and decrease steadily with increasing acidity. The mechanism of enol iodination is probably[11]

$$EH + I_2 \underset{}{\overset{k_I}{\rightleftharpoons}} EHI^+ + I^-$$
$$EHI^+ + B \rightleftharpoons KI + BH^+$$

Our experimental conditions were such that the reversal of the first step was suppressed, and k_I is simply the forward rate of the reaction between enol and iodine. The decrease in this rate can only be attributed to a medium effect of whose nature we are ignorant. The change in the color of the iodine–solvent complex with increasing acid concentration may be connected with a decrease in efficiency as a donor of I^+.

Effect of Increasing Acidity on k_E.—The probable mechanism of the enolization is[12]

$$KH + H^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} IH_2^+ \text{ equilibrium}$$
$$IH_2^+ + B^z \xrightarrow{k_2} EH + BH^{(z+1)} \text{ rate determining step}$$

z represents the charge on the base B. By the Brönsted rate equation

$$\frac{dc_{EH}}{dt} = \sum_{B^z} k_{2B^z} c_{IH_2^+} c_{B^z} \frac{f_{IH_2^+} f_{B^z}}{f_{[X^+]^*}}$$

where f is activity coefficient, $[X^+]^*$ is the activated complex $[IH^+_2 \cdot B^z]^*$, and summation is to be taken over all bases in the solution. Then

$$k_E = \frac{1}{c_{KH}} \frac{dc_{EH}}{dt} = \sum_{B^z} k_{2B^z} \frac{c_{IH_2^+}}{c_{KH}} c_{B^z} \frac{f_{IH_2^+} f_{B^z}}{f_{[X^+]^*}} \quad (7)$$

$c_{IH_2^+}/c_{KH}$ increases with increasing acidity according to the equations

$$\frac{c_{IH_2^+}}{c_{KH}} = \frac{a_{H^+} f_{KH}}{K_{KH} f_{IH_2^+}} = \frac{K_{BH^{(z+1)}} a_{BH^{(z+1)}} f_{KH}}{K_{KH} a_{B^z} f_{IH_2^+}} = \frac{h_0}{K_{KH}}$$

where h_0 is the negative antilogarithm of the acidity function H_0[2]. Substituting the last pair of equalities in equation (7), we arrive at the following pair of equations

$$k_E = \frac{1}{K_{KH}} \left[k_{2H_2O} c_{OH_3^+} \frac{f_{KH} f_{OH_3^+}}{f_{[X^+]^*}} + K_{HSO_4^-} k_{2SO_4^-} c_{HSO_4^-} \frac{f_{KH} f_{HSO_4^-}}{f_{(X^-)^*}} + \ldots \right] \quad (8)$$

$$k_E = \frac{1}{K_{KH}} \left[k_{2H_2O} h_0 a_{H_2O} \frac{f_{IH_2^+}}{f_{[X^+]^*}} + k_{2SO_4^-} h_0 a_{SO_4^-} \frac{f_{IH_2^+}}{f_{[X^-]^*}} + \ldots \right] \quad (9)$$

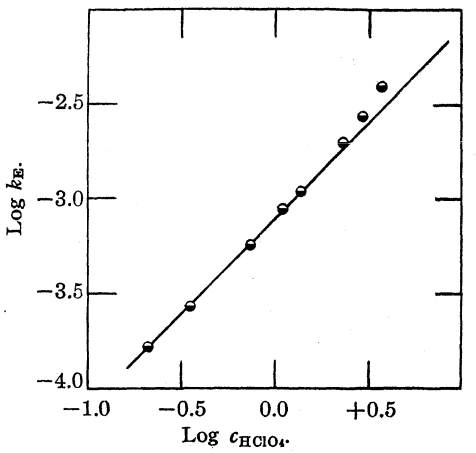

Fig. 2.

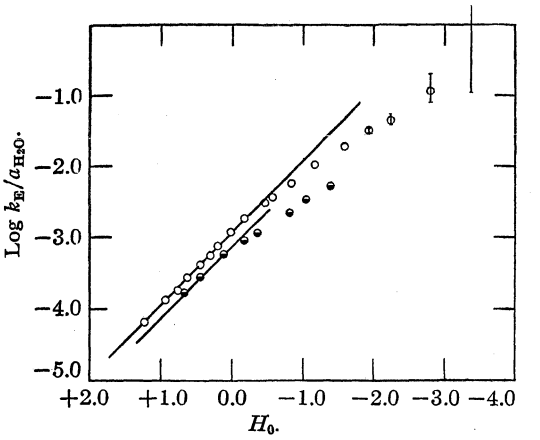

Fig. 3.—●, Expts. in $HClO_4$; ○, expts. in H_2SO_4.

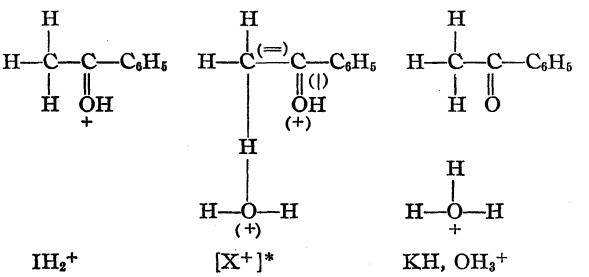
The first term in each equation represents acid catalysis by oxonium ion; the second term represents acid catalysis by bisulfate ion, and vanishes in the case of perchloric acid solutions; other terms which may enter the summation for both acids are those corresponding to catalysis by molecular acid, or by the acid conjugate to molecular acid. Bisulfate ion catalysis is very important in the sulfuric acid solutions, which therefore offer a more complicated case; this is shown by the fact that the specific rate in any sulfuric acid solution is always considerably larger than that in the perchloric acid solution of the same weight per cent., even though the two solutions are nearly identical in H_0 as well as in molarity, molality or mole fraction of any other catalyst present.

In dilute aqueous solutions the concentration of each catalyst can be determined independently; consequently the quantities of the form

$$k_{2B^z}\frac{f_{KH}f_{BH^{(z+1)}}}{f_{[X^{(z+1)}]^*}}$$

in equation (8) can be determined, and have been found to show a very small dependence upon the ionic strength of the medium. This is because the long range or coulombic forces which determine the activity coefficients under these conditions depend almost entirely upon the ionic charge; $f_{BH^{(z+1)}}$ therefore cancels $f_{[X^{(z+1)}]^*}$ since their charges are identical, and f_{KH} is nearly independent of medium. A similar argument would lead one to expect a cancellation of the $f_{IH_2^+}/f_{[X^+]^*}$ factor in the first term of equation (9). In more concentrated solutions in which the highly specific short range forces are important, one cannot predict any cancellation with certainty. Yet the data for the enolization in perchloric acid show a satisfactory proportionality to $c_{OH_3^+}$, and none to $h_0a_{H_2O}$. This is shown in Figs. 2 and 3 in which log k_E is plotted against log $c_{OH_3^+}$ and log k_E/a_{H_2O}[13] is plotted against log h_0, respectively. Proportionality requires a linear plot of unit slope. In terms of equations (8) and (9) this means that $f_{KH}f_{OH_3^+}/f_{[X^+]^*}$ is constant in this range of media while $f_{IH_2^+}/f_{[X^+]^*}$ is not. There must therefore be a fairly exact and complete cancellation of this type of medium effect in the one ratio which cannot take place in the other. If actual structures are compared, it is obvious that any



effect of the medium change specifically on the H–O–H part of $[X^+]^*$ which causes a change in the activity coefficient of $[X^+]^*$, cannot possibly be counterbalanced by any corresponding change in the activity coefficient of IH_2^+, whereas there might be a similar change in the activity coefficient of the oxonium ion. If one can generalize from this case, it must be possible to factor the activity coefficient, at least roughly, into one factor due to charge and another for each of the several parts of the molecule.

The relative degree of dependence on changing acid concentration of the two types of activity coefficient ratio involved in the comparison of

(13) Values of a_{H_2O} obtained from Pearce and Nelson, THIS JOURNAL, **55**, 3075 (1933).

rates with the two acidity measures may throw some light on the detailed nature of the rate-determining step of any acid-catalyzed reaction. There are three possibilities: (a) the rate determining step is a proton transfer as it is in the enolization; (b) it involves a water molecule in some other way than as a base, as in the following possible mechanism for the acid catalyzed hydration of an olefin

$$R_2C{=}CR_2 + HA \rightleftarrows [R_2CH{-}CR_2]^+ + A^-$$
$$[R_2CH{-}CR_2]^+ + H_2O \longrightarrow [R_2CH{-}CR_2OH_2]^+, \text{ etc.}$$

(c) it involves a spontaneous cleavage or other change of the conjugate acid of the substrate, as is possible in the acetal hydrolysis

$$R_2C(OR)_2 + HA \rightleftarrows \left[\begin{matrix} R \\ R \end{matrix}\!\!>\!C\!<\!\!\begin{matrix} OR \\ OR \end{matrix}\right]^+ + A^- \qquad \left[\begin{matrix} R \\ R \end{matrix}\!\!>\!C\!<\!\!\begin{matrix} OR \\ OR \end{matrix}\right]^+ + ROH$$

(H above the arrow)

In case (a) equations similar in form to (8) and (9) can always be derived; if the first rather than the second proton transfer is rate determining, k_1 is substituted for k_2/K_S, and $[X^+]^*$ is $[S{\cdot}OH_3^+]^*$ instead of $[SH^+{\cdot}OH_2]^*$, where S is substrate. All such reactions are subject to general acid catalysis. In case (b) the proper equations are the first terms only of the series in (8) and (9). The only possible catalyst is oxonium ion, no matter what the solvent. In case (c) we have the following pair of equations

$$-\frac{1}{c_S}\frac{dc_S}{dt} = k_a = \frac{k}{K_S}\frac{c_{OH_3^+}}{a_{H_2O}}\frac{f_S f_{OH_3^+}}{f_{[SH^+]^*}} = \frac{k}{K_S}h_0\frac{f_{SH^+}}{f_{[SH^+]^*}}$$

This type can show catalysis by the solvated proton only; in water the catalyst is oxonium ion, in 100% sulfuric acid it is $H_3SO_4^+$, etc. The last two types are usually not differentiated and are called together specific hydrogen ion catalysis; however, only the last is a true specific hydrogen ion catalysis in all solvents and the other might be called specific oxonium ion catalysis.

If general acid catalysis can be demonstrated for a reaction, it must have a mechanism of the first type. A reaction for which only oxonium ion catalysis can be demonstrated in aqueous solutions may belong in any one of the three classes. But if the reaction is in either of the first two classes, the activated complex contains a molecule of water, $f_S f_{OH_3^+}/f_{[SHOH_2^+]^*}$ should be more independent of changing acidity than $f_{SH^+}/f_{[SHOH_2^+]^*}$, and $c_{OH_3^+}$ should be a better measure of acidity than h_0. And if the reaction is in the third class, $f_{SH^+}/f_{[SH^+]^*}$ should be more independent of changing medium than $f_S f_{OH_3^+}/f_{[SH^+]^*}$, and h_0 should be a better measure of acidity than $c_{OH_3^+}$. In order to apply this criterion it is necessary to know the rates in solutions in which h_0 can be measured,[2] and in which $c_{OH_3^+}$ is known—*i. e.*, aqueous perchloric, hydrochloric or nitric acids. It is also necessary to carry the rate measurements into a region where h_0 and $c_{OH_3^+}$ are different. h_0 equals $c_{OH_3^+}$ for all these acids within the error of measurement of h_0 up to about 1 molar acid; it is only in more concentrated acid that h_0 becomes greater than $c_{OH_3^+}$, and not before about 1.5 molar acid that a very marked and rapidly increasing divergence sets in. By this criterion the hydrolyses of sucrose and of cyanamide belong to the third class, while that of ethyl acetate has not been studied in sufficiently acid solutions to make an unambiguous determination possible.[3]

Nachod[14] observed a decrease in the apparent equilibrium constant for the enolization of acetyl acetone with increasing concentration of hydrochloric acid in methanol solution. He suggested by way of explanation the formation of a coördination compound between ketone and acid, $R_2C{=}O{-}H{-}A$. If such a reaction took place with acetophenone in the solutions in which the iodination was studied, both k_E and $K_E k_I$ as defined could be expected to have a different dependence on the acidity of the solution than that previously derived, assuming no coördination. However, there are several reasons why this is unlikely. Hydrogen bonding of the sort suggested should cause any equilibrium constant involving the ketone, calculated for the total apparent ketone concentration, to vary with changing acidity; the effect should appear in the basic ionization constant as well as in the enolization constant, yet the ionization constant of acetophenone is independent of acidity over the entire region of ionization (55–86% sulfuric acid).[15] Coördination should cause the solubility of a ketone to increase with increasing acidity; actually the solubility of acetophenone decreases with increasing concentration of sulfuric acid and of perchloric acid, at least up to 1 molar solutions. And, finally, the phenomenon observed by Nachod cannot be of

(14) Nachod, *Z. physik. Chem.*, **A182**, 193 (1938).
(15) Flexser, Hammett and Dingwall, *ibid.*, **57**, 2103 (1935).

very widespread occurrence among ketones, because the enolization constant of acetoacetic ester (which is much more closely related structurally to the ketones studied by Nachod than is acetophenone), has been calculated from kinetic data for hydrochloric acid solutions from 0 to 0.370 molar,[16] and the values show no trend with increasing acidity.

Summary

The iodination of acetophenone has been studied in 2 to 30% aqueous perchloric acid solutions, and in 0.5 to 66% aqueous sulfuric acid solutions. The rate is determined by the rate of enolization of acetophenone in the more dilute acid solutions, and by the rate of reaction of the enol with iodine in 51% and more concentrated sulfuric acid solutions; at intermediate acidities these two rates are of comparable magnitudes.

Even in the simplest case, in aqueous perchloric acid solutions, the enolization rate is not proportional to h_0, but is proportional over a considerable range to $c_{OH_3^+}$. Reactions whose rates are directly proportional to h_0, when this is varied widely, are probably examples of specific hydrogen ion catalysis, and not of general acid catalysis.

Molecular Rotation and Polymorphism in the *t*-Butyl Halides

BY WILLIAM O. BAKER AND CHARLES P. SMYTH

A variety of roughly spherical molecules from methane to camphor is found to possess rotational freedom in the solid state, as well as polymorphic transitions at temperatures below which such freedom is generally lost.[1,2] The lower isomeric alkyl halides provide opportunity for studying the effect of structure on crystal form and molecular freedom in simple polar lattices by dielectric and optical measurements.[3,4] The tertiary butyl halides are the most symmetrical members of this series, and, despite their considerable dipole moments resulting from the dissimilar groups, they behave as spherical molecules in such a kinetic process as viscous flow.[3] Also, electron diffraction results on *t*-butyl chloride[5] indicate no appreciable distortion of the usual tetrahedral arrangement. The data of the present report on these compounds also may be compared with similar studies on the hydrogen halides.[6–9]

Preparation and Purification of Materials.—The final purification of the chloride and bromide was fractionation in an 80 × 2 cm. Pyrex glass column, packed with beads, wrapped, and jacketed. It had a still head equipped for reflux ratio control. Temperatures were measured by short-range Anschütz type thermometers previously calibrated by the Bureau of Standards. The *t*-butyl iodide sample finally was distilled through a shorter Vigreux-type column under reduced pressure. Refractive indices were obtained from a Pulfrich refractometer. Immediately upon distillation the samples were frozen and kept in the dark until the dielectric measurements were begun.

***t*-Butyl Chloride.**—The compound was prepared by the method of "Organic Syntheses,"[10] from *t*-butyl alcohol and hydrochloric acid. The usual precautions of neutralization and washing were followed by prolonged drying over calcium chloride. The product was twice fractionally distilled; b. p. 50.60°; f. p. −24.6°; $n^{20.0}D$ 1.38470. Material recrystallized from its own melt gave the same constants. Recent literature values give b. p. 51.0°,[11] and the refractive index noted above lies between the reported values 1.38528[12] and 1.3839.[13]

***t*-Butyl Bromide.**—As with the chloride, this compound was distilled from a mixture having the proportions of one mole of *t*-butyl alcohol and two moles of constant-boiling hydrobromic acid. After washing, it was dried for several days over anhydrous calcium bromide, and was thrice fractionated. Successive middle fractions had the same refractive index: b. p. 73.2°, f. p. −17.7°, $n^{20.0}D$ 1.42757. A separately prepared lot gave the same refractive index, and boiled at 73.3°. The best literature values include: b. p. 73.25°,[11] $n^{20}D$ 1.4275–1.4277.[14]

***t*-Butyl Iodide.**—The Eastman Kodak Co. product was distilled repeatedly under reduced pressure after thorough drying. Even though the best fractions came over colorless and were at once frozen, a light straw color always

developed in them, as was noted by Parts[15] also. However, if the samples were shaken with 1 cc. of pure mercury per 15 cc. of iodide, the sample became perfectly clear and could be distilled and preserved so. Indeed, liquid thus treated could be exposed to daylight for two days without noticeable discoloration, which suggests that minute traces of the decomposition products markedly accelerate the reaction. No reliable constants for this compound seem to be available in the literature. The melting point here found is −38.2°.

Experimental Method and Apparatus

The dielectric measurements were made with a shielded capacitance bridge coupled to a General Radio Company low frequency variable oscillator and vacuum tube amplifier, and operated in the general fashion previously described.[6,16] The dielectric constant determinations for *t*-butyl bromide near and through the melting point were made at 520 kilocycles frequency with a heterodyne beat apparatus. Residual inductances introduced by the cell, which would cause its apparent capacity as measured by the bridge to vary with frequency, were found to be negligible by a calculation following a recently suggested scheme.[17]

All temperature measurements were made with a platinum resistance thermometer. Temperature control was by a metal block–Dewar tube assembly[16,18] of high heat capacity into which liquid air could be injected and evaporated at desired rates. Precautions were taken to ensure temperature equilibrium during runs, and to free the samples from gas bubbles by evacuation and slow, repeated freezing.

The compounds were examined from the liquid to low temperature crystalline states with a polarizing microscope, the arrangement in Fig. 1 being employed. Such optical examinations previously have been found useful in conjunction with other dielectric investigations,[19] and have been employed also by Kruis and Clusius to supplement X-ray data on hydrides.[20,21] In Fig. 1, T is an unsilvered Pyrex Dewar tube 11 cm. long by 3 cm. in diameter. It is held by clips on the microscope stage between the polarizer P and object lenses M. A low power lens gives adequate magnification, but for shorter focal distances an indentation in the side of T would permit closer approach of M to the drop of sample which rests on a glass slide S. The slide S is supported by a slotted cork section C at one end and by the stopper B at the other. It also rests on a glass tube A, through which liquid air may be injected in desired amounts to cool the sample through the freezing and transition points. I is a tube through which the sample is introduced, while V is a vent. Through V also may be passed the wires of a thermal element that may be sealed on the under side of S below the sample, and used to measure the temperatures of solidification, fusion and transition, although accurate determinations are unlikely in the simple system shown. Observations with rising temperature are made by allowing the system to warm slowly, as the unsilvered Dewar permits. Under humid conditions, drying tubes are provided to prevent entrance and condensation of water vapor. Observations are conveniently made at least as low as liquid air temperatures. Such a scheme would seem to be of general use not only in preliminary investigations of solid state transitions, but also in rather striking visual demonstrations of transitions that are often found to cause large thermal, dielectric and density effects. The interpretation is by the usual polarizing microscope theory.[22]

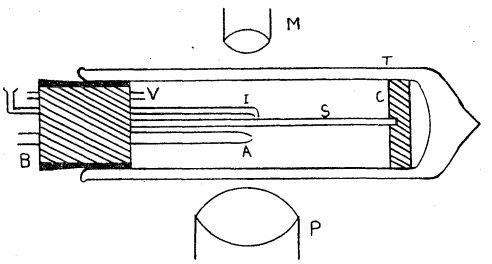

Fig. 1.—Vacuum-jacketed cell for use with polarizing microscope.

Experimental Results

The dielectric constants ϵ and specific conductances k(ohm^{-1} cm.$^{-1}$) are listed in Table I with appropriate temperatures and frequencies. The readings were made in the time sequence 50, 5, 0.5 kc., so that when the dielectric constant was falling rapidly and isothermally at a freezing or transition point, the smaller number of dipoles left free to orient when the 0.5 kc. reading was made as compared to that present an instant before when the higher frequency readings were made caused the actual dielectric constant values to be higher at the higher frequency. The specific conductance values near the melting points and in the liquid probably contain some d. c. conductivity contribution. Both preliminary runs and duplicate measurements have been omitted for the sake of brevity.

Discussion of Results

The cooling curve for *t*-butyl chloride in Fig. 2 reveals a previously unreported thermal transition at −53.8° whose latent heat considerably exceeds that of fusion. The variation of the dielectric constant with temperature is seen from Fig. 3 to resemble that of hydrogen chloride.[6,7] The portions of the curves obtained on cooling, however, slope downward with decreasing temperature while detailed results on the cooling behavior of hydrogen chloride are not available for comparison.

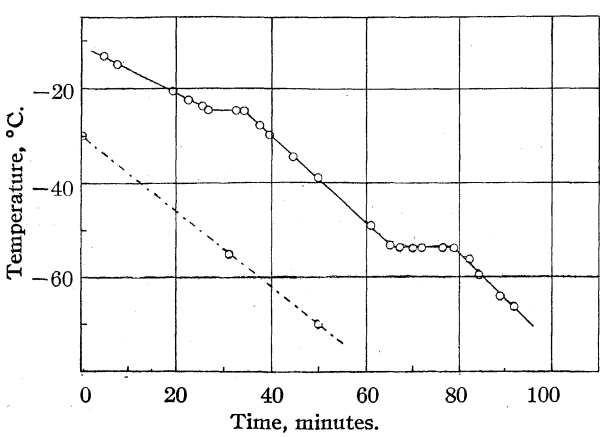

Fig. 2.—Temperature–time curve (cooling) for *t*-butyl chloride.

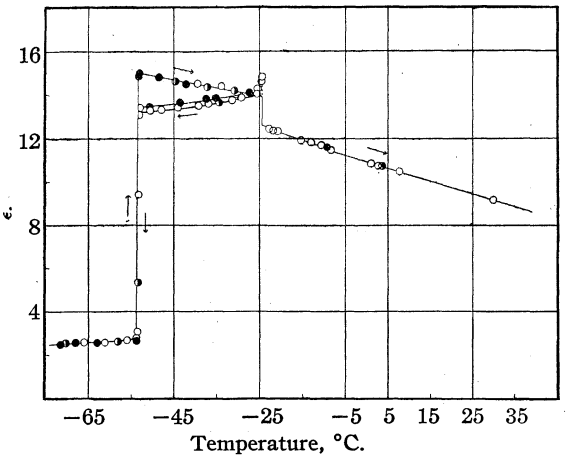

Fig. 3.—Temperature dependence of the dielectric constant of *t*-butyl chloride. (Hollow circles represent values at 50 kc., half-filled circles values at 5 kc., and filled circles values at 0.5 kc.)

The highest temperature point in the liquid on Fig. 3 was obtained independently[12] in a dipole moment study. On solidification the dielectric constant rises because of increase in density, shows a low sharp peak, presumably because of a small Maxwell–Wagner interfacial polarization, and then gradually declines with a small but definite dispersion. At the transition temperature, the dielectric constant drops sharply to a value near to the square of the refractive index, with disappearance of dispersion. The transition is shown by the polarizing microscope to be an enantiotropic transformation from a high temperature cubic to a low temperature form of lower symmetry. The abrupt lattice change into an anisotropic packing arrangement would follow from a coöperative interlocking of the dipoles when they had reached a sufficiently low temperature to lose most of their librational energy. Such a sharp interaction is indicated by Fig. 4, where the curve denoting the lower ϵ'' values in the region of −53.8° rises steeply to a maximum just at the temperature of the transition. Hence, a rapid and widespread interference to orientation is introduced by a loss maximum, so narrow that it is only a straight line for 50 kc. at the peak. Then the dipoles are immobilized in the low temperature crystal form.

The dielectric constant curve obtained with rising temperature, shown by arrows on Fig. 3, exhibits a sharp ascent at the transition, which is unaccompanied by thermal hysteresis, to a value which declines on further warming, as expected from the Debye relation. If the co-

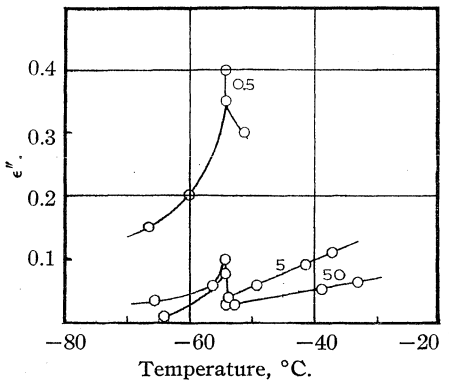

Fig. 4.—Temperature dependence of the imaginary part ϵ'' of the dielectric constant of *t*-butyl chloride.

operative[23] loosening of the molecules at the transition on warming is strong enough to give immediately the maximum orientational freedom of the cubic lattice, whereas, on cooling, a decrease in the molecular disorder probably existing immediately after solidification gradually reduces this freedom, the observed difference in the warming and cooling curves would be accounted for. Microscopic examination revealed qualitatively a considerable density increase on cooling through the transition.

Figure 5 contains the thermal arrests marking the two polymorphic transitions found for *t*-butyl bromide. The higher temperature transition, henceforth called I, is attended by supercooling but comparison of the heating and cooling curves, together with the dielectric results, indicates that it occurs without thermal hysteresis at −41.4°.

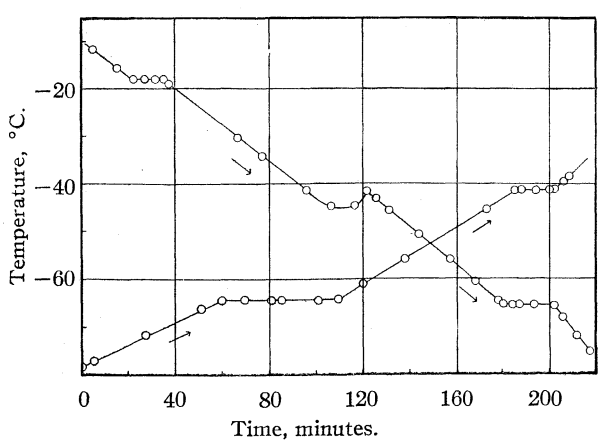

Fig. 5.—Temperature–time curves for *t*-butyl bromide.

The lower transition II shows no supercooling but occurs abruptly at −65.8° on cooling, and at −64.2° on warming. Evidently from Fig. 5 the heat of fusion is less than the heat of transition II, and much less than the sum of the heats of the two transitions.

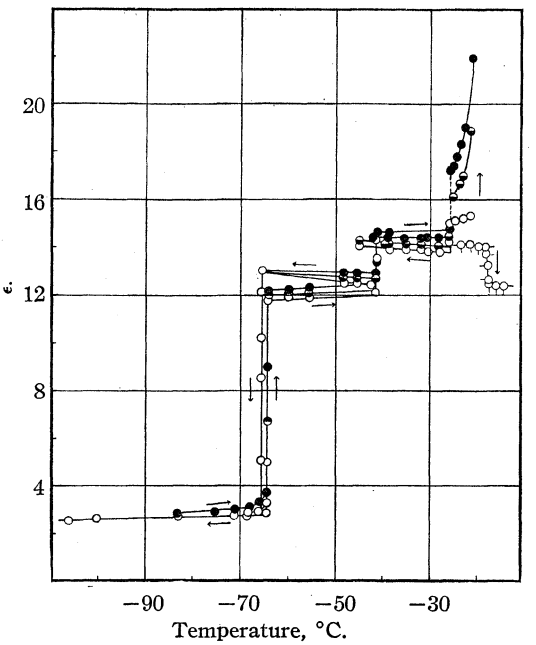

Fig. 6.—Temperature dependence of the dielectric constant of *t*-butyl bromide. (Hollow circles represent values at 50 kc., half-filled circles values at 5 kc., and filled circles values at 0.5 kc.)

An enhanced dispersion in the same frequency range results from replacement of a chlorine atom by the larger, more polarizable bromine, as demonstrated by Fig. 6. In some parts of the graphed data points at the three frequencies would have been superposed, so but one point was indicated, for example, the point immediately above transition II, on cooling. The data for the lower frequencies begin somewhat below the freezing point, for, just after solidification, bridge balancing became uncertain and large apparent dielectric constant values were obtained, probably because of interfacial polarization. This effect has been found by Yager and Morgan[24] for several camphor derivatives, and by White and Morgan[25] for ethylene cyanide, all of which possess rotational freedom in the solid. The effect here does not exceed a maximum apparent specific conductance of 5×10^{-8} ohm^{-1} cm.$^{-1}$, whereas they report values greater than 10^{-6} ohm^{-1} cm.$^{-1}$. The values obtained at 520 kilocycles with a

heterodyne beat apparatus are shown through the melting point by the tagged circles.

The supercooling at transition I is expressed on the dielectric graph by an exact continuation of the curves for the highest temperature solid form some 3° below −41.4°. Suddenly, the values revert back on just these lines, as far as could be determined experimentally, and the dielectric constant drops sharply at the transition to a new set of curves, which show diminishing dispersion with decreasing temperature. At −65.8°, a transition like that in *t*-butyl chloride occurs. However, below this point for a short temperature interval there is still dispersion, apparent in the data but too slight to be evident in Fig. 6. As with the chloride, a sharp rise in ϵ'' marks the interaction introduced by transition II.

On warming, a slight rotational pre-melting, consonant with the suggestion of coöperative lattice loosening with rising temperature noted for *t*-butyl chloride, is followed by the onset of rotation, now at −64.2°. This slight rotational freedom below a transition seems comparable to the pre-melting previously noted for many molecular lattices.[19] The latter behavior has been confirmed by X-ray and thermal analyses of highly purified hydrocarbons,[26] and has been given theoretical interpretation and justification by Frank's recent order–disorder treatment of melting.[27] It would seem that in a treatment of arrangement in terms of rotational disorder and of the corresponding lattice energy change dependent on the degree of such disorder, a transition state just below the observed transition temperature like that proposed by Frank just below the melting point would account for the experimental data.

The apparent 1.6° hysteresis in the temperatures of transition resembles the 1.1° difference in the case of the analogous transition in hydrogen sulfide,[28] the longer interval in ethylene cyanide,[25] and the less sharply defined hystereses in camphor and its derivatives.[24] The same hystereses are found in thermal measurements, and were thus discovered at the rotational transitions of methane and deuterated methane.[29]

Pressure studies by Clusius and Weigand[30] on the hydrogen sulfide transition reveal that it is accompanied by a volume change of about 7.6%, and by a mean lattice separation change so small that it might remain undetected in X-ray photographs. However, easily obtainable pressures with hydrogen gas broadened the hysteresis range, and the hysteresis area was found to be smaller in deuterium sulfide. Hence, apparent hysteresis in these transitions would seem to be sensitively affected by changes in structure and environment. The apparent temperature of the monotropic transition in ethyl stearate was found to depend on the temperature gradient to which the sample was exposed.[19] This result was confirmed for other similar long chain compounds.[31] It provides evidence for the idea that critical fluctuations in ΔF and ΔS must occur for the progression of spontaneous solid transformations. This concept has been elaborated by Ubbelohde.[32] The activation entropies for rotation of even simple molecules in the solid state have been found to be very high.[33] Therefore, it is possible that the *t*-butyl bromide hysteresis occurs because, in order that transformation may be induced, the substance must be cooled slightly below the true equilibrium point to produce an enhanced thermodynamic potential. Then, the material may lose heat to the environment so readily that the temperature of the sample never rises to the equilibrium value, despite the relatively large latent heat. This agrees with the observation that the sample could be cooled under a larger gradient and made to lose heat so rapidly that the transition appeared to occur at −67.2°. However, the process at −65.8° as shown by Figs. 5 and 6 is not an ordinary supercooling like that at transition I.

A macroscopic potential, or tension, in the crystal mass produced by the transition has been suggested by Frank[34,35] as the possible cause of hysteresis. The rate of temperature change as the transition is approached should strongly influence the hysteresis, it would seem. Further limitations on this idea have been noted by Eucken.[36]

An explanation applicable to certain examples of hysteresis is suggested by the dielectric and thermal results on *n*-amyl bromide,[3] and by the X-ray studies of Wallerant on camphor.[37] The

latter found that, besides the cubic form existing above the transition, three less symmetrical classes occur at successively lower temperatures. Monotropic transitions below a rotational transition would produce the same effect on it as that of the *n*-amyl bromide transition in raising the melting point several degrees above the freezing point. A careful thermal and X-ray analysis of other substances showing hysteresis might establish such low temperature polymorphism.

Examination with the polarizing microscope showed *t*-butyl bromide to form a translucent, isotropic, definitely crystalline lattice on solidification, which was transformed enantiotropically at transition II to or from an opaque, birefringent, anisotropic lattice. Transition I was accompanied by no change in the cubic form, but, apparently, by a contraction on cooling and an expansion on warming. This is indicated by the migration of the Beeke line across the sample as it transforms. In a homogeneous medium, differences in refractive index, detected under the polarizing microscope by brightness variations with a constant source, result from density differences. At the vertical junction between a more dense phase B and a less dense one A, $n_B > n_A$, where n is the refractive index. The rays which pass from A to the denser medium B are bent toward the normal to the junction within B. Rays passing from B toward the junction which impinge within the critical angle are totally reflected and emerge on the B side. The result of these combined effects is to illuminate more brightly the B side of the junction. Here the junction is the interface between the transformed and untransformed material, and, at the transition point, a darkish line is seen to move across the sample. It is concluded that I is an enantiotropic lattice change shown by Fig. 5 to possess a latent heat and accompanied by a density shift which does not destroy the cubic arrangement.

The supercooling at transition I, shown on Figs. 5 and 6, is like that frequently observed at solid–liquid transitions. Thermal measurements on phosphine disclosed a low temperature rotational transition and an intermediate one,[38] analogous to those of *t*-butyl bromide. The intermediate transition in phosphine also shows supercooling, whereas the lower one, which presumably marks the end of librational freedom, does not, in agreement with the *t*-butyl bromide results. The dielectric data provide a possible interpretation of the general property of supercooling in some polymorphic transitions, and its absence in others. Figure 5 indicates a much smaller latent heat for transition I than for transition II. The difference between the entropy changes at the two points is also large. A metastable condition of the solid phase which is stable above the temperature of transition I induced by cooling it somewhat below the transition temperature will be under a relatively small thermodynamic potential tending to force the transformation. Further, Fig. 6 indicates by the relatively small decrease in dielectric constant at transition I only a slight loss in orientational freedom of the dipoles. Hence, on cooling, the thermal agitation of the molecules which, at a given instant, have undergone the transition, will make them poor ordering centers for the coöperative formation of the lower temperature stable form. On the other hand, transition II, and, presumably also, as a dielectric study should reveal, the lowest transition in phosphine, marks the loss of most of the rotational molecular freedom. The molecules cease to exhibit nearly spherically symmetrical force fields, and become so definitely oriented that a rearrangement occurs, resulting in the formation of an anisotropic lattice. These effects are evidenced by the loss of orientational polarization seen in Fig. 6, and the large latent heat of the transition indicated in Fig. 5. The same causes account for the absence of supercooling at the transition in *t*-butyl chloride. Such considerations would seem generally adaptable to thermal studies of polymorphism in molecular and some ionic lattices. They are consonant with other ideas on the importance of orientation in supercooling.[4]

Figure 7 indicates the expected result that the least symmetrical most polarizable molecule of the series, t-C_4H_9I, interacts in the solid so strongly that it can rotate only with difficulty above the transition point $-79.4°$. This hindrance effects the pronounced dispersion seen on the graph, but the dielectric loss, proportional to the tabulated apparent specific conductance, contains a considerable d. c. conductance contribution from impurities which could not be removed. The critical frequency of the rotating dipoles is probably near 50 kc., as the dielectric constant values for this frequency rise from nearly the square of the refractive index, only shortly below the

(38) Clusius and Frank, *Z. physik. Chem.*, **34B**, 405 (1936).

melting point −38.2°. Sufficiently high frequencies might convert the chloride and bromide curves to ones resembling the iodide.

Examination with the polarizing microscope revealed an apparently anisotropic lattice above the transition, which was replaced by one of much stronger birefringence below it. Suspected impurities make uncertain a definite assignment of non-cubic class to the high temperature form.

The melting behavior of *t*-butyl iodide is in agreement with the theory of melting point variation in isomeric and otherwise similar substances previously proposed.[3] Its gain of librational freedom postpones the melting point to 234.9°K., 65.3° higher than *n*-butyl iodide, m. p. 169.6°K., and 55.3° higher than *i*-butyl iodide, m. p. 179.6° K., and 65.8° higher than *s*-butyl iodide, m. p. 169.1°K.

The present results show the variation in intermolecular action of nearly spherical molecules produced when atoms of gradually increasing size and polarizability are successively substituted as one of four groups about a central atom, the other three groups remaining unchanged. As noted previously,[3,4] the orientational interaction is found to be very sensitive to structure. A further method of studying the possible coupling is to dilute the dipoles in the solid state, preferably by solid solution formation with a similar, non-polar substance. A preliminary microscopic examination of a 50% by volume mixture of *t*-butyl chloride and carbon tetrachloride revealed that, as would be expected, the transition was made less sharp, and was displaced to lower temperatures, and that the whole solid formed an isotropic high temperature system, which would be anticipated from the known high temperature cubic form of carbon tetrachloride. However, partial melting was found to occur sharply and uniformly, leaving a skeleton-like isotropic lattice which itself melted sharply a few degrees higher. Dielectric measurements on such a system might show a complex behavior because of the coexistence of phases.

The discovery of rotational freedom in the solid forms of these simple molecules suggests

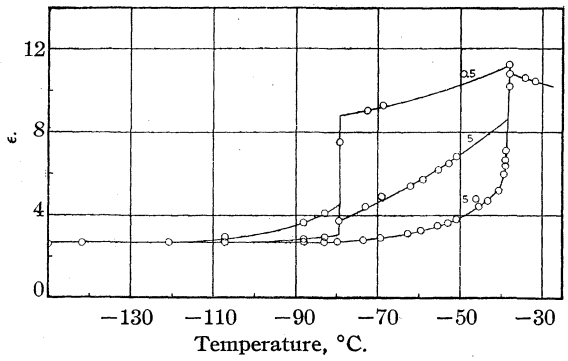

Fig. 7.—Temperature dependence of the dielectric constant of *t*-butyl iodide.

experiments to discover its effect on other physical properties. That is, the form of the solid above the transition might differ significantly from that below it in temperature coefficient of thermal conductivity, diffusion, solution rate and sublimation vapor pressure. If these processes were thus connected with rotation or non-rotation, information on their mechanism would be gained.

Summary

Polymorphism has been found and studied by means of thermal, optical and dielectric measurements in *t*-butyl chloride, bromide and iodide. Dispersion, hysteresis and supercooling effects have been interpreted in terms of possible molecular processes. Solid state transitions of the first kind are attended by supercooling when a relatively small free energy difference obtains between the metastable and the stable phases below the transition. The dielectric results indicate that this supercooling may be a function of the ordering ability of the molecules in the stable form. Rotational "premelting" before a solid state transition is analogous to the premelting found in solids near the melting point. Results with the polarizing microscope establish a correlation of lattice symmetry with molecular rotational freedom, and, conversely, the isotropic lattices previously found for many organic molecules above polymorphic transitions are associated with the development of rotational freedom at such transitions.

The Helium–Neon Content of Sea Water and its Relation to the Oxygen Content[1]

BY NORRIS W. RAKESTRAW, CLIFFORD E. HERRICK, JR.,[2] AND WM. D. URRY

One of the most widely discussed topics in the field of oceanography at the present time is the cause and significance of the "oxygen minimum zone." The vertical distribution of oxygen in the deeper parts of the ocean shows a minimum concentration at a depth which varies with the location, generally between 200 and 1000 meters. This minimum may be very pronounced, as in parts of the Pacific where there is virtually no oxygen. In the Atlantic the minimum zone is seldom less than 30% saturated, and in the far north and south there is sometimes no minimum.

Some time ago there were reported analyses of the helium–neon content of sea water,[3] the outstanding feature of which was an apparent minimum of the helium–neon mixture coinciding with the oxygen minimum in the same water. The significance of this was discussed briefly and some possible explanations suggested. All of these explanations, however, are in rather serious conflict with other oceanographic evidence. In view of this, as well as the limited number of observations made at that time, we have undertaken to repeat the work, on water from a variety of different locations, and with certain improvements in the analytical method.

The details of the technique are described in the references in the earlier paper, but briefly it consists of boiling the dissolved gas out of the water sample under reduced pressure, adsorption on charcoal at the temperature of liquid air, and measurement of the non-adsorbable residue (helium and a constant fraction of the neon) by means of a McLeod gage. High vacuum technique is used throughout, and great care must be exercised in flushing out the line with pure electrolytic oxygen, removing traces of hydrogen by repeatedly passing over hot palladium.

Slight modifications in the original method consisted of increasing the size of the water sample to about 300 ml., an addition to the line to permit flushing the gas out of the boiling flask by means of oxygen, instead of depending entirely upon water vapor, and a graphic method of calculating results from the McLeod gage readings.

Because of the extremely small size of the gas sample measured (less than 10^{-5} ml.) a capillary of about 0.1 mm. diameter must be used in the McLeod gage. To eliminate the effect of capillary depression upon the mercury level a series of readings was taken for each measurement, at different pressures. When these are plotted graphically the slope obtained is a measure of the volume of gas trapped. This practice largely overcame the great variability in capillary depression which was observed from time to time. It was impossible to determine a constant factor for a given tube. Electrodeless discharge in the capillary, for the purpose of testing the residual gas for hydrogen, was found to change the glass surface so much as to make the tube practically useless.[4]

Water samples were collected in the routine manner at sea, by means of reversing water bottles, and stored in glass citrate bottles, completely filled, to prevent exposure to the air. A method of doing this has been described.[5] From these the water was introduced into the boiler by direct mercury displacement, with only momentary and non-turbulent exposure to the air, a major improvement over the earlier method of pouring from the storage bottle.

The oxygen determinations were made by the routine Winkler method, on shipboard, immediately after collecting the samples.

The results are given in Table I. The five stations chosen present a complete array of conditions, in regard to the oxygen minimum. Four are in the Atlantic and one in the Pacific, the latter being almost entirely depleted of oxygen at a depth of about 600 meters. One of the Atlantic stations, 3113, is in the Sargasso Sea, south of the Gulf Stream; two others somewhat to the north. The oxygen minimum at these three varies from 200 to 900 meters. The last station, 2822CG, shows no oxygen minimum whatever.

In none of these is there any consistent relation between the oxygen and the helium–neon content, nor indeed any regular variation in the latter. We can only conclude that the earlier results, based upon a few observations at only two stations, were in some way fortuitous.

We were also unable to notice any significant difference between the solubility of the helium–neon mixture in sea water at 6 and at 23°, or in normal sea water diluted to half its original salinity, the figures obtained in these three respective cases being 16.9, 16.4, and 17.6.

Although the results obtained from the water of the Pacific are higher than all the others, we do not think this represents a real difference. These determinations were made several months after the others, with a different McLeod capillary and a number of other conditions altered. Nevertheless, although they probably cannot be compared

with those from the other stations, they clearly indicate a regular and consistent distribution at this particular station. This view is confirmed by the fact that at this stage two samples of sea water saturated with air at 23 and 24° showed helium–neon contents of 19.1 and 18.7, respectively, higher than the solubility measurements made earlier.

Occasionally, in the earlier part of this work, a determination yielded an impossibly low result, compared with a duplicate. This was sometimes the case even with water saturated with air. Although we never located the reason for this with complete certainty, it seemed to be connected with the process of letting the gas into the adsorption line from the boiling flask. After every movement at this point had been standardized, and especially after provision had been made for washing the gas into the line with excess oxygen, no trouble of this sort was experienced. It is possible that this was the cause of the two or three unusually low values in the previous investigation, leading to the assumption of a helium–neon minimum.

Summary

A repetition of earlier work, under more suitable and representative conditions, shows the sea to be practically saturated with helium and neon at all depths, with no evidence of any depth of minimum concentration, and hence no relation to the depth of oxygen minimum.

Partial Vapor Pressures of Aqueous Ethylamine Solutions

BY B. P. DAILEY WITH W. A. FELSING

Object of the Investigation.—In a previous paper[1] there were reported the partial vapor pressures of methylamine solutions, the investigation being one of a series dealing with the possible uses of these amines as refrigerating fluids in the absorption type of refrigerating units. The ethylamines have been suggested by Taylor[2] for use in such systems and Mehl[3] has investigated some of the pertinent properties of monoethylamine for the same purpose.

In this investigation it was decided to determine experimentally the partial vapor pressures of aqueous solutions of the ethylamines in order to aid in evaluating these substances as refrigerants. The data obtained were used to calculate the free energy decrease attending the solution of these amines in water.

Previous Investigations.—The literature records but few determinations of the partial vapor pressures of ethylamine solutions. Lattey[4] cites values for two concentrations at 2° intervals from 6 to 50°, which values were calculated from total pressure determinations. Doyer[5] gives one value at 60° for both mono- and diethylamine.

Method of the Investigation.—The method used was the dynamic, air-saturation method previously described.[1] The complete apparatus, as described there, was used in this investigation.

The amine solutions were prepared by dissolving in cold distilled water of conductivity grade either the gaseous or liquid amines. They were generated from repurified C. P. Eastman Kodak Co. hydrochlorides by the action of concentrated potassium hydroxide solution. Standard **acid** and **base** solutions were prepared with the usual precautions for highest accuracy. Weight burets were used throughout; the indicator was methyl red.

The Results Attained.—The partial vapor pressures were calculated by the procedure described[1]; five to six acceptable determinations were made at each concentration, the mean of which is reported in the table. The results are believed to be accurate to better than ±0.02 mm.

TABLE I

PARTIAL PRESSURES OF ETHYLAMINE SOLUTIONS AT 25°

Concn. C (moles/1000 g. H_2O)	Pressure, p, mm.	p/C (obsd.)	Best "K"
	Monoethylamine		
0.2529	1.97	7.789	
.5410	4.27	7.893	
1.0867	8.84	8.134	
2.2602	17.78	7.866	7.86
	Diethylamine		
0.2228	3.79	17.010	
.3926	6.28	15.995	
.8585	13.73	15.993	
1.8142	29.58	16.304	16.25
	Triethylamine		
0.0550	4.72	85.818	
.0919	8.84	96.191	
.2654	25.55	96.269	
.3330	31.43	94.384	95.00

The best "K" was obtained by plotting the pressure as a function of the molarity; a straight line reproduces well the observed data over the range of concentrations investigated.

The partial vapor pressures of the amine solutions at exactly 1 molar are calculated to be 7.86 mm. for the mono-, 16.25 mm. for the di-, and 95.0 mm. for the triethylamine. With the aid of these data, the following free energy values were calculated for the reaction: Amine (760 mm.) = Amine (1 M) + ($-\Delta F$). The values of $-\Delta F$ were found to be 2709 cal./mole for the mono-, 2278 cal./mole for the di-, and 1232 cal./mole for the triethylamine.

Mehl[3] has given vapor pressure relations for the three liquid amines; from these the vapor pressures at 25° were found to be 1059 mm. for the mono-, 235 mm. for the di- and 78.5 mm. for the triethylamine. From these values the free energy decrease attending the change: Amine (p, mm.) = Amine (760 mm.) was calculated and combined with the preceding free energy values to yield the free energy decrease attending the change: Amine (liquid) = Amine (1 M) + ($-\Delta F$). The results obtained for ($-\Delta F$) were

Infrared Absorption Studies. VIII. Hydrazoic Acid

BY A. M. BUSWELL, G. W. MCMILLAN, W. H. RODEBUSH AND F. T. WALL

In the study of the tendency of hydrogen compounds of nitrogen to form hydrogen bonds, our attention was attracted to hydrogen azide. This compound has interested inorganic chemists for many years but because of its dangerously explosive character it has remained a substance little known. Dr. L. F. Audrieth[1] of this Laboratory kindly furnished us with the material for, and advice concerning, the preparation of the pure substance and we wish to acknowledge our indebtedness to him.

Hydrazoic acid has about the same strength as acetic acid and readily forms salts. The molecule is supposed to involve a resonance between the two structures

$$N{=}N{=}N{-}H \text{ and } N{\equiv}N{-}N{-}H$$

while the ion has the possibility of at least one more resonance structure thus accounting to some extent for the acid strength. The azide group is known to be linear but the hydrogen must be attached at an angle with the azide group. Hydrogen azide is much more soluble in ether than in water, the distribution ratio being 7:1. This peculiar behavior would seem to require some explanation since acetic acid shows no such surprising behavior.

Experimental.—The prism spectrometer used in this work has been described previously.[2]

The hydrogen azide was generated by dropping concentrated sulfuric acid on the dry potassium salt. Since the vapor as well as the pure liquid is very explosive, the substance was prepared in carbon tetrachloride solution.

The salt was immersed in carbon tetrachloride which had been prepared from the technical material by chlorination and subsequent fractional distillation. A calculated amount of concentrated sulfuric acid was added slowly from a dropping funnel. A trap of methanol was set up beyond the generator to prevent diffusion of hydrogen azide into the laboratory. It was regarded as advisable to use a generator flask whose volume was some three to four times that of the solution it contained. After generation the solution was carefully decanted from the sulfuric acid layer into tubes and sealed until used. In this way solutions of the order of 0.1 molar could be obtained anhydrous with a minimum of handling. The entire operation was performed behind screens.

Careful tests showed that sulfuric acid did not dissolve in the carbon tetrachloride in sufficient amounts to produce any noticeable absorption in the infrared. The solution prepared in this way from the pure salt was evidently free from any appreciable contamination by impurities.

Deuterium azide was prepared by shaking the carbon tetrachloride solution of hydrogen azide with 99% D_2O. This resulted in a 75–80% conversion. Excess water and D_2O was removed with calcium chloride.

Results.—In the drawings the molal absorption coefficient (so-called) is plotted against wave number. This coefficient is defined by the expression

$$\frac{1}{cd} \log \frac{I_0}{I}$$

where c is the concentration (moles per liter of solution), d is the cell thickness in centimeters and I and I_0 the galvanometer deflections obtained through equal paths in solution and pure solvent, respectively. Since the control of concentrations was difficult the accuracy of the calculated coefficients is not good and it was not always possible to maintain constant values for cd.

Three frequencies are always observed in hydrogen azide which remain unchanged in intensity as long as cd is maintained constant. One of these occurs at 4.75 μ and is also found in deuterium azide and phenyl azide (Fig. 1). This is evidently the linear N–N–N vibration which already has been assigned to the 4.8 μ absorption

(1) For an excellent review of the literature concerning hydrogen azide see L. F. Audrieth, *Chem. Rev.*, **15**, 169 (1934).

(2) A. M. Buswell, Victor Dietz and W. H. Rodebush, *J. Chem. Phys.*, **5**, 501 (1937).

in lead azide by Sutherland and Penney.[3] The frequency of this vibration would decrease slightly with increasing weight of the attached group. In the case of the isostere molecule NNO the absorption for this vibration is found at 4.5 μ.[3]

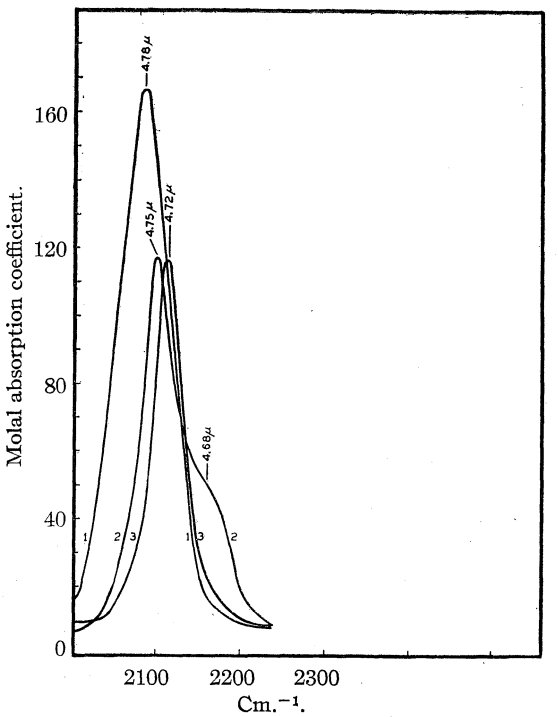

Fig. 1.—Absorption due to the azide group: (1) 0.035 molal phenyl azide in 0.3251 cm. cell; (2) 0.035 molal deuterium azide in 0.3251 cm. cell; (3) 0.035 molal hydrogen azide in 0.3251 cm. cell.

The absorption at 3.03 μ (Fig. 2) is evidently the unbonded N–H vibration. This frequency is lower than any other observed frequency of hydrogen in a N–H compound and might according to deductions previously drawn indicate a very high acidity. It must be remembered, however, that hydrogen azide is as a whole not a linear molecule since the hydrogen must lie at a considerable angle with the nitrogen group. For this reason the normal mode of vibration will not consist of a pure valence or stretching frequency but will be compounded with the much lower bending frequency. The acid strength, therefore, while greater than that of an acid amide is not as much greater as would be indicated by a shift of 0.15 μ in wave length.

The absorption at 4.35 μ must be attributed to an unbonded hydrogen frequency since it is un-

(3) G. B. B. M. Sutherland and W. C. Penney, *Proc. Roy. Soc.* (London), **A156**, 678 (1936).

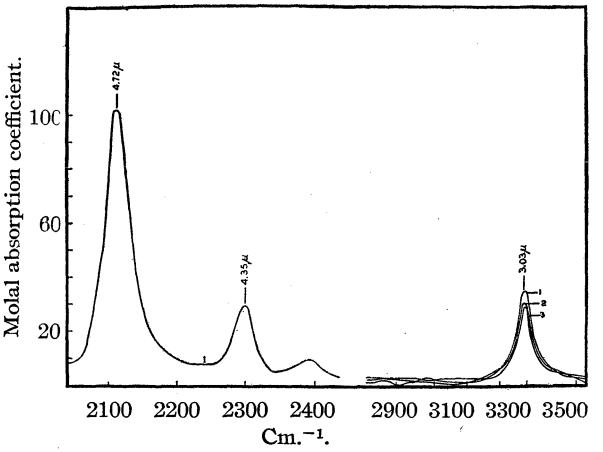

Fig. 2.—Hydrogen azide: (1) 0.34 molal in 0.3251 cm. cell; (2) 0.045 molal in 2.53 cm. cell; (3) 0.0012 molal in 10.2 cm. cell.

affected by anything except deuteration. As already has been said the non-linear character of the hydrogen azide molecule must lead to a mixing of the stretching and bending frequencies in the normal modes of vibration. In the case of chloroform absorption in this region was interpreted as an overtone of the bending frequency.[4]

It was hoped that hydrogen azide would furnish a good example of N–H → N bonding, but the acid does not show any evidence of association. This is perhaps not surprising since it contains no basic or amide nitrogen to act as donor. On the other hand, it is too strong an acid to form hydrogen bonded complexes with amines. Salt formation and precipitation result instead.

N–H → O bonding is of course to be expected and since ether has been found to be one of the best molecules for forming complexes of this type with an active hydrogen, we can be sure that the unusual solubility in ether is to be accounted for in this manner. However, we are confronted here with difficulty that because of the unusually low hydrogen frequency the rule of Venkateswaran[5] predicts that the N–H → O bonded frequency will lie under the ordinary C–H frequencies. Consequently the exact determination of the form and frequency of the hydrogen bond absorption is not possible. In Fig. 3 the curves show a marked increase in absorption in the C–H region when hydrogen azide is present and absorption at 3.19 which must have something to do with the formation of the ether complex since it is not

(4) A. M. Buswell, W. H. Rodebush and M. F. Roy, THIS JOURNAL, **60**, 2528 (1938).

(5) C. S. Venkateswaran, *Proc. Ind. Acad.*, **7**, 13 (1938).

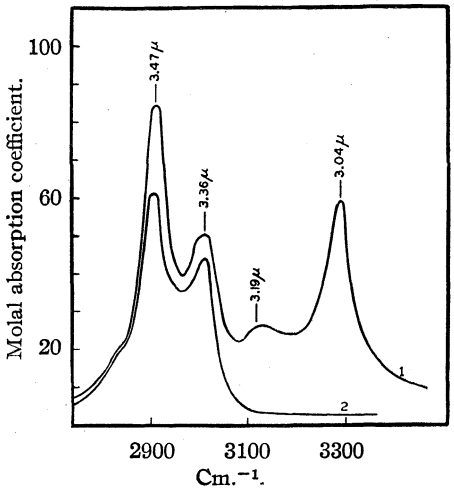

Fig. 3.—(1) 0.12 molal hydrogen azide and 0.05 molal ether in 0.325 cm. cell; (2) 0.05 molal ether in 0.325 cm. cell.

present for either constituent alone. Even more positive evidence of the formation of a complex is furnished by solutions of hydrogen azide in carbon tetrachloride saturated with water (Fig. 4). The solubility of water in carbon tetrachloride is always small but it is perhaps doubled in a dilute solution of hydrogen azide. There is evidence here both for the bonding of hydrogen azide to water and of water to hydrogen azide (or to itself). This may appear surprising in view of the low solubility of hydrogen azide in water as compared to ether but we interpret this fact as being due to the great amount of bonding between water molecules themselves in liquid water. In this figure only the logarithm absorption log I_0/I is plotted since it was not possible to determine concentrations exactly.

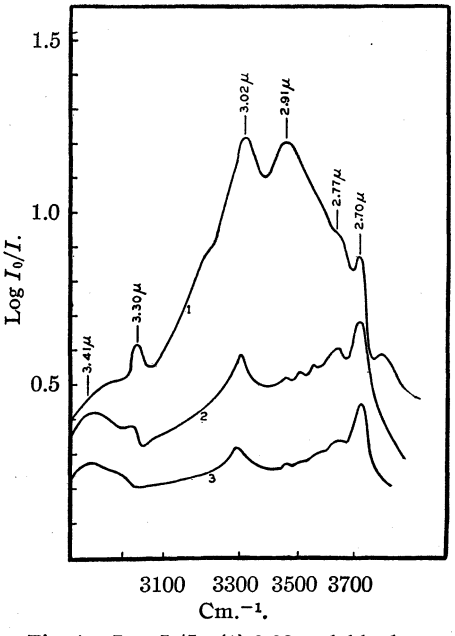

Fig. 4.—Log I_0/I: (1) 0.02 molal hydrogen azide saturated with water in 0.3251 cm. cell; (2) 0.01 molal hydrogen azide; water one-half of saturated concentration 0.640 cm. cell; (3) 0.005 molal hydrogen azide; water one-fourth of saturation concentration in 1.26 cm. cell.

Deuterium Azide.—In Fig. 5 are shown absorption curves for deuterium azide. In no case was the deuterium azide pure but always some unconverted hydrogen azide was present. Curve (1), however, may be taken as the characteristic absorption of deuterium azide. Here the deuterium frequency is found at 4.07 μ, which is about what one would calculate from the 3.03 μ frequency of hydrogen azide. (The absorption at 4.35 μ already has been shown to be characteristic of the hydrogen compound.)

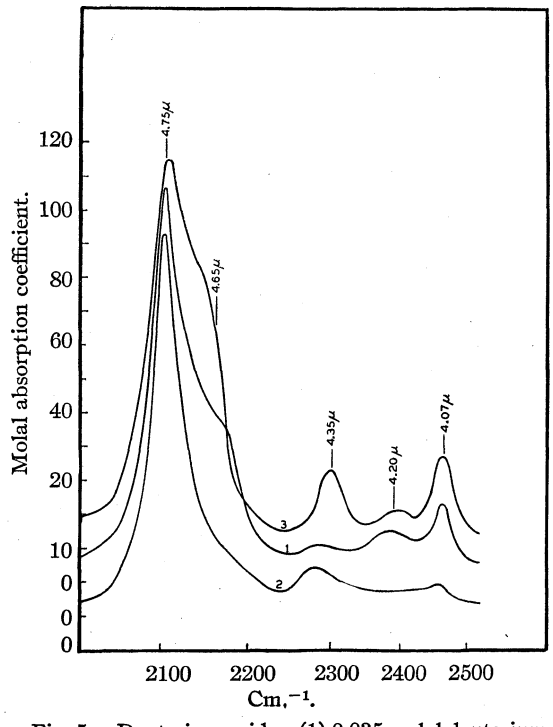

Fig. 5.—Deuterium azide: (1) 0.035 molal deuterium azide; (2) the same solution after exchange with water; (3) deuterium azide made with 85% deuterium azide.

Finally it will be noted that an absorption exists near 4.63 μ which is nearly obliterated by the N–N–N frequency which must be characteristic of the deuterium azide. This absorption suggests bonding when compared with a 3.30 μ ab-

sorption found for hydrogen azide when water was present. Since there is not enough water present to give this much absorption, one might be led to suspect N–D → N bonding as a result of association of the deuterium azide molecules. This in turn would imply that deuterium shows a stronger tendency toward bonding than hydrogen. This inference appears to be justified by a comparison of the physical properties of deuterium oxide with ordinary water.

It is evident that the hydrogen azide molecule shows a very interesting characteristic with considerable deviation from the normal behavior of hydrogen compounds. The only explanation for this behavior that we can offer is that the hydrogen is attached to a nitrogen which is part of a rigid linear group, the bond being predominantly of double bond character. There is no lack of evidence for the peculiar rigidity of the double bonded nitrogen atom. It is highly desirable that a sufficient number of frequencies be measured to make certain the assignment to the various modes of motion in order to get a clear understanding of the behavior of the hydrogen azide molecule.

The authors wish to acknowledge their indebtedness to the Rockefeller Foundation for funds which enabled them to conduct this research.

Summary

A number of frequencies have been observed for hydrogen and deuterium azides and some examples of hydrogen bonding by these molecules are shown. Certain peculiarities in the hydrogen frequencies are attributed to the non-linear character of the hydrogen azide molecule.

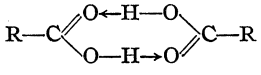
Infrared Absorption Spectra of Some Carboxylic Acids and of Dibenzoylmethane and Related Molecules

BY F. T. WALL AND W. F. CLAUSSEN

Of the various molecules capable of undergoing association through hydrogen bond formation, the carboxylic acids in particular show the effect to a considerable extent. This association, which was predicted by Latimer and Rodebush[1] and first demonstrated in the case of formic acid vapor by Pauling and Brockway,[2] leads to dimers in the case of monocarboxylic acids, with the following general structure



(1)

Evidence for hydrogen bond formation can be provided in numerous ways, but one of the most convenient methods involves infrared absorption measurements. Following the pioneer work of Wulf[3] and others, considerable research has been carried out in this way. Among these investigations have been numerous studies on the infrared absorption of carboxylic acids under various conditions.[4] Those acids which have been investigated most thoroughly are formic, acetic and benzoic, both ordinary and deuterated. In this paper there will be reported results for deutero-acetic, deutero-benzoic, ordinary and deutero-propionic acids, as well as for two dibasic acids, azelaic and diethylmalonic.

The studies were all made for carbon tetrachloride solutions of the substances at room temperature. Heavy acetic acid was investigated previously (in the vapor state) by Herman and Hofstadter,[4] but with lower dispersion than employed here. Heavy benzoic acid was studied by Buswell, Rodebush and Roy,[4] but their results were not quite complete, as mentioned in an earlier note.[5]

In addition to the carboxylic acids mentioned, dibenzoylmethane, diphenylmethane and benzil have been subjects for study in this research. Dibenzoylmethane was investigated by Wulf, *et al.*,[3] in the 1.5 μ region and by Buswell, Rodebush and Roy[6] in the 3 μ region. Their results were not in agreement, however, so it was felt desirable to

repeat the study and to publish the absorption curves. The curves for diphenylmethane and benzil are included to assist in the interpretation of the dibenzoylmethane absorption although diphenylmethane was more carefully investigated by Fox and Martin and by Wall and McMillan previously.[7]

Preparation of Substances.—The deutero-acetic and -propionic acids were prepared by treating the corresponding purified anhydrides with equimolar amounts of heavy water. Deutero-benzoic acid was prepared by heating benzoyl chloride with an excess of heavy water. The excess heavy water and the deuterium chloride which formed were then removed by pumping.

Dibenzoylmethane, diphenylmethane, benzil and the dibasic acids mentioned were obtained from the stock rooms of the organic chemistry division. They were purified carefully by recrystallizing from alcohol.

Experimental

The infrared absorption measurements were made on carbon tetrachloride solutions of the substances. The technique employed has been described previously.[4d] In the case of the deutero-acids, it was necessary to take precautions to prevent the solution from coming in contact with the air, else exchange takes place with the water vapor of the air. After the absorption of a deutero-acid was measured, however, a small amount of light water was added to the solution to bring about an exchange. After the exchange had occurred, the same solutions were run again, in order to get the absorption curve for the ordinary acid, which could be compared with previous direct measurements. In this way a check could be obtained on the materials and the interpretation of the results was facilitated.

Since we were interested primarily in hydrogen or deuterium bonding, only a limited region of the spectrum was studied. The range investigated was from 2.8 to 4.9 μ, which covers the absorption due to OH and OD bonds.

TABLE I

Substance	Wave lengths of maxima, μ					
Acetic acid (deutero)		4.42		4.71	4.87	
Acetic acid (ordinary)[a]	2.82	3.30	3.39	3.71	3.78	3.89

Discussion of Results

The infrared absorption curves are shown in Figs. 1–5. In each case log I_0/I is plotted against wave length where I_0/I is the ratio of the intensity of light transmitted by pure solvent to that of the solution. The positions of the maxima are tabulated in Tables I and II. Although the curves for the ordinary acids were those obtained after exchanging the heavy acid with light water, they

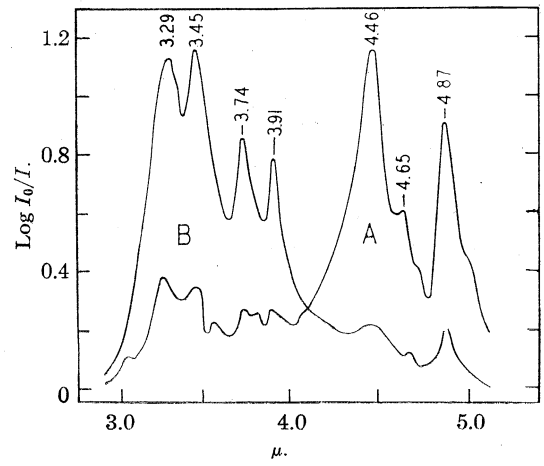

Fig. 1.—Infrared absorption curves: A, 0.032 M deuterobenzoic acid in 0.325-cm. cell; B, benzoic acid obtained by exchange from A.

are in excellent agreement with curves obtained directly from the pure substances. In the case of propionic acid the curves obtained by the two methods were so similar, the positions of maxima being in agreement to 0.01 μ, that it was not felt necessary to publish the directly obtained curve for ordinary propionic acid, although it had been run.

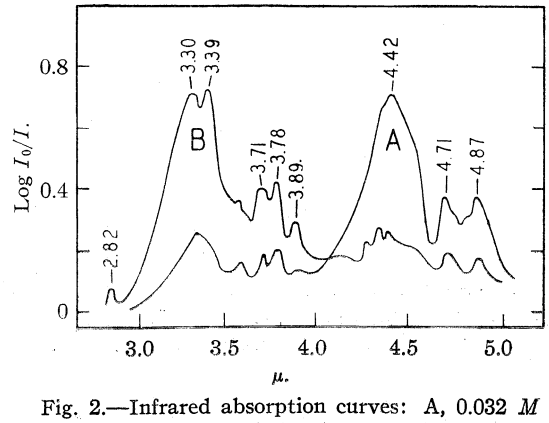

Fig. 2.—Infrared absorption curves: A, 0.032 M deuteroacetic acid in 0.325-cm. cell; B, acetic acid obtained by exchange from A.

It is apparent at a glance that considerable similarity exists between the absorption curves for

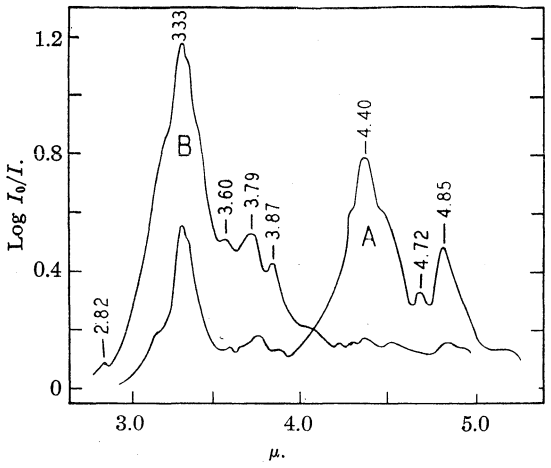

Fig. 3.—Infrared absorption curves: A, 0.04 *M* deuteropropionic acid in 0.325-cm. cell; B, propionic acid obtained by exchange from A (this curve is the same as that obtained by starting with pure ordinary acid).

acetic, benzoic and propionic acids, both heavy and light. This can be attributed to the common linkage indicated by (1). The most noticeable difference is the extra height of the 3.33 μ peak of propionic acid. This is due to the fact that the fundamental CH and OH absorptions overlap as suggested by Buswell, Dietz and Rodebush.[8] Since propionic acid has an extra CH_2 group, and accordingly has its methyl groups bent off to destroy much of the symmetry present in the acetic acid dimer, its CH absorption will be increased.

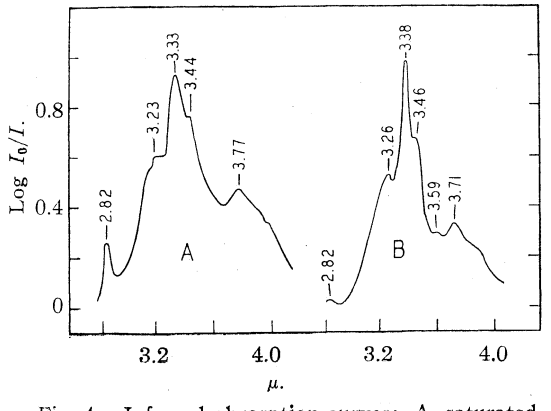

Fig. 4.—Infrared absorption curves: A, saturated solution of diethylmalonic acid in 10.18-cm. cell; B, saturated solution of azelaic acid in 10.18-cm. cell.

Although an exact interpretation of the results is difficult, the following conclusions can be arrived at from examination of the curves. For the three acids, acetic, propionic and benzoic, the absorption between 3.2 and 4.0 μ (aside from the CH mentioned above) is due principally to the hydrogens of the hydrogen bonds. This follows because of the fact that deuteration cuts down the absorption to such a great extent.

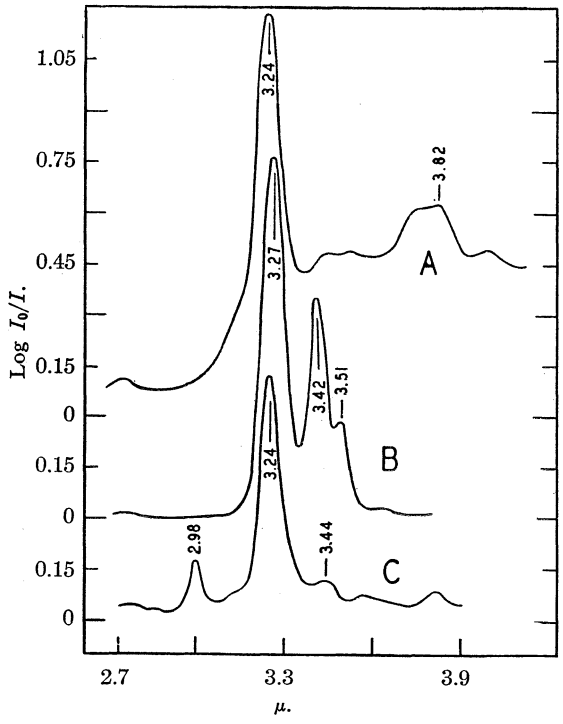

Fig. 5.—Infrared absorption curves, all 0.016 *M* in 2.53-cm. cell: A, dibenzoylmethane; B, diphenylmethane; C, benzil.

The four peaks of benzoic acid can be regarded as two doublets, each split as a result of some internal effects. These internal effects may arise from the double minima in the potential energy system. Upon deuteration the mean wave lengths of the doublets are shifted by a factor of about 1.3, which is close to the square root of the reduced mass ratio for hydrogen and deuterium vibrating against an oxygen atom. In addition a small intermediate peak appears, which is difficult to explain. The deutero compound does not show the well-defined double splitting, which fact might be expected from mass considerations if the splitting were due to the double minima.

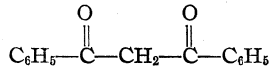
Although acetic and propionic acids do not give curves identical with that for benzoic acid, they doubtless behave much as benzoic acid does. The biggest difference between the various deutero curves is found in the relatively high intermediate absorption at 4.71 μ for deuteroacetic acid. In

(8) Buswell, Dietz and Rodebush, *J. Chem. Phys.*, **5**, 84, 501 (1937).

any case, the absorption between 4.3 and 4.9 μ can be attributed to deuterium bonds.

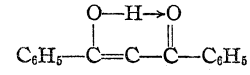
The lower dibasic acids were quite insoluble in carbon tetrachloride, but diethylmalonic and azelaic acids were sufficiently soluble to get the curves shown in Fig. 4. These curves are quite similar to the one for propionic acid. The abnormal heights of the 3.33 and 3.38 μ maxima are due, as for propionic acid, to the superposition of CH absorption upon that for the hydrogen bonds. The dibasic acids offer the possibility of forming monomolecular hydrogen bonded rings as well as dimers or even polymers. Unfortunately the data are not sufficient to tell precisely what is taking place, except that considerable hydrogen bonding does occur.

From the formulas for dibenzoylmethane ($C_6H_5COCH_2COC_6H_5$), diphenylmethane ($C_6H_5CH_2C_6H_5$) and benzil ($C_6H_5COCOC_6H_5$), one would expect certain similarities in their absorption spectra. All three compounds give the characteristic aromatic CH absorption in the neighborhood of 3.24 μ. The aliphatic CH absorption for diphenylmethane is easily accounted for,[7] but the broad absorption of the dibenzoylmethane near 3.8 μ needs some other explanation. It is evident that the aliphatic hydrogens of the conventional structure



(2)

have undergone some change. A plausible explanation is that advanced by Hilbert, Wulf, Hendricks and Liddel,[3] who suggested enolization followed by hydrogen bonding to give the structure



(3)

Since no fundamental OH absorption is observed, the hydrogen bonding of the enol must be complete. Benzil, on the other hand, cannot enolize and accordingly does not show the same absorption.

The authors are indebted to Professors W. H. Rodebush and A. M. Buswell for helpful suggestions and criticism.

Summary

The infrared absorption spectra for ordinary and deuterated acetic, benzoic and propionic acid have been investigated in the "hydrogen bond" region and the results interpreted on the basis of their structures. Likewise the absorption for diethylmalonic and azelaic acids has been studied and discussed. Infrared absorption measurements for dibenzoylmethane (and related molecules) suggest that dibenzoylmethane undergoes enolization followed by hydrogen bonding.

The Structure of Monocrotaline, the Alkaloid in *Crotalaria Spectabilis* and *Crotalaria Retusa*. I

BY ROGER ADAMS AND E. F. ROGERS

Crotalaria is a genus of leguminous plants, many species of which are commonly used in the southern part of the United States as soil-enriching legumes. *Crotalaria spectabilis* is perhaps the most important. Like many species of *Crotalaria* it is toxic and its toxicity has been shown to be due to an alkaloid monocrotaline.[1a] The same alkaloid has now been found also in the seed of the *Crotalaria retusa*.[1b]

(1) (a) Neal, Rusoff and Ahmann, THIS JOURNAL, **57**, 2560 (1935). (b) Greshoff, *Ber.*, **23**, 3537 (1890). The *Crotalaria spectabilis* strain grown in Florida and southern Georgia is toxic to chickens and larger animals. On the other hand, in South Carolina the seed of the early strain of *Crotalaria spectabilis* is non-toxic to blackbirds and partridge. Whether these birds are resistant to the alkaloid or whether the strain as grown in South Carolina contains no alkaloid or a different non-toxic alkaloid is now being studied.

Neal, Rusoff and Ahmann[1a] extracted monocrotaline from crushed seed by means of aqueous ammonia and reported a tentative formula of $C_{16}H_{26}O_6N$. The extraction proceeded much more smoothly, however, and the yields were improved several fold if ethanol was used as a solvent. A careful analysis of pure monocrotaline, its hydrochloride and methiodide revealed the molecular formula to be not that previously suggested but $C_{16}H_{23}O_6N$. Such a formula resembles closely those of the *Senecio*, *Heliotropium* and *Trichodesma* alkaloids, characteristic for which is alkaline hydrolysis to an acid and an alkanolamine. Hydrolysis of monocrotaline confirmed this supposition for cleavage yielded a basic product

which proved to be retronecine, the base obtained by hydrolysis of several of the *Senecio* alkaloids and an acid, $C_7H_{12}O_3$, monocrotic acid.

$$C_{16}H_{23}O_6N + H_2O(BaO_2H_2) \longrightarrow C_8H_{13}O_2N + C_7H_{12}O_3 + [CO_2]$$

From the above equation, it is obvious that carbon dioxide has been lost in the reaction due, presumably, to decomposition of the acid present in the monocrotaline.

Another mode of cleavage[2] successful on analogous alkaloids has been by hydrogenolysis. In those alkaloids previously studied which gave retronecine on hydrolysis, reduction gave retronecanol which has one less hydroxyl than retronecine and no olefin linkage. The acid part of the molecule unless containing an olefin linkage remained unaffected. Monocrotaline was readily reduced to retronecanol and an acid which will be designated as monocrotalic acid since it is presumably the acid present in the form of an ester in the alkaloid.

$$C_{16}H_{23}O_6N + 2H_2 \longrightarrow C_8H_{15}ON + C_8H_{12}O_5$$

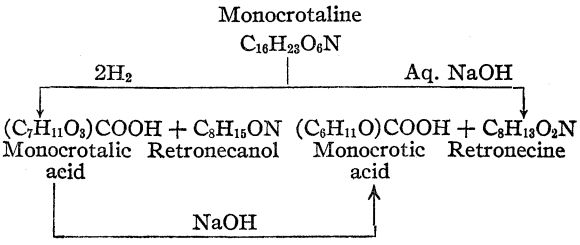
A mixed melting point of retronecine from monocrotaline with authentic retronecine, kindly furnished by Dr. R. H. F. Manske, gave no depression. A table showing the properties of retronecine and retronecanol from monocrotaline in comparison with those of the bases isolated from other sources is given below.

TABLE I

CONSTANTS ON ALKANOLAMINES FROM MONOCROTALINE

Alkanolamine	M. p., ° C.	Rot. $[\alpha]_D$	Alkanolamines from monocrotaline M. p.	Rot.	Solvent for rotation
Retronecine[2b]	121–122	+50.2	121	+49.3	Ethanol
Retronecine hydrochloride[2b]	161	−16.0	161–162	−15.4	Ethanol
Retronecine diac. picrate[2b]	146		146		
Retronecanol[3]	98–99 (92–93)		95–96	−91.1	Ethanol
Retronecanol hydrochloride			210		
Retronecanol methiodide[2b]			193	−52.8	Methanol
Retronecanol picrate	208 (211)		210		

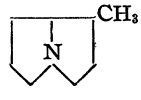
Monocrotalic acid is optically active. Direct titration indicates it to be monobasic but by addition of excess alkali and back titration, a higher neutral equivalent is found, strongly indicating the presence of a lactone linkage. It forms a *p*-bromophenacyl ester. By heating monocrotalic acid with alkali, decomposition occurs and a liquid monobasic acid, $C_7H_{12}O_3$, monocrotic acid, results. This acid is identical with that obtained by alkaline hydrolysis of the original alkaloid. It is optically inactive, monobasic, and forms a *p*-bromophenacyl ester. The transformations just discussed may be tabulated



The structure of the $C_6H_{10}O$ residue in monocrotic acid is now being studied.

The acid portions of the *Senecio*, *Heliotropium*, and *Trichodesma* alkaloids have received very limited examination. The facts that are known about them, however, lead us to believe that it is doubtful whether they are so dissimilar in constitution as expressed by a reviewer of the work in this field.[4] The acids are unknown in structure except *dl*-lactic acid, which is probably a degradation product of the acid occurring in the alkaloid trichodesmine, and angelic acid which is possibly a degradation product of the acid occurring in the alkaloid lasiocarpine.

The knowledge of the most commonly occurring base, retronecine, or the other very closely related bases is still limited. Menshikov[2a,5] has established the probable structure of the nucleus present in these bases as a methylpyrrolizidine



but no evidence is as yet available which will place the hydroxyls and olefin linkage.

A large number of alkaloids with different acids and identical or very similar bases has been shown to occur in four genera of plants, the *Senecio*, *Trichodesma*, *Heliotropium* and recently *Erechtites* to which must now be added a fifth genus, the *Crotalaria*. The relationship between the alkaloids now known is shown in the following table.

TABLE II

KNOWN ALKALOIDS OF THE ACID-ALKANOLAMINE TYPE

	Alkaloid	Alkanolamines	Acid
Crotalaria			
spectabilis[1a]	Monocrotaline, $C_{16}H_{23}O_6N$	Retronecine, $C_8H_{13}O_2N$	Monocrotalic, $C_8H_{12}O_5$
retusa[1b]	Monocrotaline, $C_{16}H_{23}O_6N$	Retronecine, $C_8H_{13}O_2N$	Monocrotalic, $C_8H_{12}O_5$
Trichodesma incanum[3a]	Trichodesmine, $C_{18}H_{27}O_6N$	Retronecine	*dl*-Lactic and isobutyl methyl ketone
Senecio			
cineraria[6]	Jacobine, $C_{18}H_{25}O_6N$	Retronecine	Jaconecic, $C_{10}H_{16}O_6$
jacobaea[6a,7]	Jacobine, $C_{18}H_{25}O_6N$	Retronecine	Jaconecic, $C_{10}H_{16}O_6$
	Jaconine, $C_{18}H_{25}O_8N$	.....	.....
	Jacodine, $C_{18}H_{25}O_5N$	.....	.....
aquaticus[6b]	Jacodine, $C_{18}H_{25}O_5N$	.....	.....
vulgaris[8]	Senecine, ...	.....	.....
	Senecionine, $C_{18}H_{25}O_5N$	Retronecine	Senecic, $C_{10}H_{14}O_4$
viscosus[8b]	Senecionine, $C_{18}H_{25}O_5N$	Retronecine	Senecic, $C_{10}H_{14}O_4$
aureus[6a,7a,13,14]	Senecionine, $C_{18}H_{25}O_5N$	Retronecine	Senecic, $C_{10}H_{14}O_4$
squalidus[8b]	Senecionine, $C_{18}H_{25}O_5N$	Retronecine	Senecic, $C_{10}H_{14}O_4$
	Squalidine, $C_{18}H_{25}O_5N$	Retronecine	Squalinecic, $C_{10}H_{14}O_4$ or $C_{10}H_{18}O_5$
stenocephalus[9]	Seneciphylline, $C_{18}H_{23}O_5N$	Retronecine	Seneciphyllic, $C_{10}H_{14}O_5$
platyphyllus[9,10]	Seneciphylline, $C_{18}H_{23}O_5N$	Retronecine	Seneciphyllic, $C_{10}H_{14}O_5$
	Platyphylline, $C_{18}H_{25}O_5N$	Platynecine, $C_8H_{15}O_2N$	Platynecic, $C_{10}H_{14}O_4$
retrorsus[2b,7a]	Retrorsine, $C_{18}H_{25}O_6N$	Retronecine	Retronecic, $C_{10}H_{16}O_6$
glaberrimus[6b]	Retrorsine, $C_{18}H_{25}O_6N$	Retronecine	Retronecic, $C_{10}H_{16}O_6$
venosus[6b]	Retrorsine, $C_{18}H_{25}O_6N$	Retronecine	Retronecic, $C_{10}H_{16}O_6$
isatideus[6b]	Retrorsine, $C_{18}H_{25}O_6N$	Retronecine	Retronecic, $C_{10}H_{16}O_6$
	Isatidine, $C_{18}H_{25}O_7N$	Isatinecine, $C_8H_{13}O_3N$	Isatinecic, $C_{10}H_{16}O_6$
erucifolius[6b]	....., $C_{18}H_{27}O_5N$	.....	.....
palustris[6b]	....., $C_{18}H_{27}O_5N$	.....	.....
latifolius[2b,11]	Senecifoline, $C_{18}H_{27}O_8N$	(Senecifolinine, $C_8H_{11}O_2N$)?	Senecifolic, $C_{10}H_{16}O_6$
	Senecifolidine, $C_{18}H_{25}O_7N$	.....	.....
mikanoides[8a]	Mikanoidine, $C_{21}H_{29}O_6N$	(Mikanecine, $C_8H_{15}O_2N$)?	Mikanecic acid, $C_{13}H_{16}O_5$
Heliotropium			
lasiocarpum[2a,5,12]	Heliotrine, $C_{16}H_{27}O_5N$	Heliotridine, $C_8H_{13}O_2N$	Heliotrinic, $C_8H_{16}O_4$
	Lasiocarpine, $C_{21}H_{33}O_7N$	Heliotridine, $C_8H_{13}O_2N$	Lasiocarpinic, $C_8H_{16}O_5$ and angelic

Experimental

Extraction of Monocrotaline from *Crotalaria spectabilis*.—Two kilograms of Florida grown *Crotalaria spectabilis* seed ground to 16-mesh was extracted continuously for seventy-two hours with 95% ethanol. The green-black solution was acidified to congo paper with citric acid, the solvent removed *in vacuo*, and the residue taken up in 400 cc. of water. The suspended fat was extracted with successive portions of ether until the ether extracts were colorless, then with two 100-cc. portions of chloroform. The aqueous solution was now treated with 200 cc. of chloroform and saturated aqueous sodium carbonate solution added with shaking, until the solution was distinctly alkaline to litmus. The color of the solution during this operation changes from a dull yellow-brown to a golden-yellow. The alkaloid was then extracted with two additional portions of 200 cc. and three portions of 100 cc. of chloroform. The combined chloroform extracts were evaporated to dryness *in vacuo* and the crude alkaloid obtained as a yellowish-white crystalline mass. It was purified by two crystallizations from absolute ethanol: white prisms, m. p., 197–198° (corr.) with decomposition; yield, 65 g. (3.2%).

Anal. Calcd. for $C_{16}H_{23}O_6N$: C, 59.06; H, 7.12; N, 4.30. Found: C, 59.14, 59.16; H, 7.05, 7.17; N, 4.42, 4.36.

Rotation. 0.5054 g. made up to 10 cc. in chloroform at 26°. α_D −5.54; *l*, 2; $[\alpha]^{26}D$ −54.7°.

The alkaloid does not react with nitrous acid. Methylimide and methoxyl determinations were negative.

No evidence indicating the presence of any other alkaloid could be secured either by fractional crystallization from absolute ethanol or fractional neutralization and extraction of a hydrochloric acid solution of the alkaloid.

Monocrotaline Hydrochloride.—The base was dissolved in ethanol and neutralized to congo paper with dilute hydrochloric acid. The solution was then evaporated to dryness, the hydrochloride taken up in the minimum

amount of hot methanol and ether added to turbidity. On cooling, the product crystallized: white prisms, m. p. 184° (corr.) with decomposition.

Anal. Calcd. for $C_{16}H_{23}O_6N\cdot HCl$: C, 53.11; H, 6.69; Cl, 9.79. Found: C, 53.22; H, 6.69; Cl, 9.87.

Rotation. 1.30 g. made up to 25 cc. in water at 28°. α_D −4.00; *l*, 2; $[\alpha]^{28}D$ −38.4°.

Monocrotaline Methiodide.—To a solution of 1 g. of monocrotaline in 10 cc. of chloroform and 1 cc. of methanol was added 2 cc. of methyl iodide. The oily methiodide which separated crystallized on cooling. Recrystallization from methanol–chloroform gave white prisms, m. p. 205° (corr.) with decomposition.

Anal. (Dried *in vacuo*.) Calcd. for $C_{16}H_{23}O_6N\cdot CH_3I$: C, 43.69; H, 5.61; I, 27.16. Found: C, 43.62; H, 5.54; I, 27.02. (Undried.) Calcd. for $C_{16}H_{23}O_6N\cdot CH_3I\cdot 3CH_3OH$: CH_3OH, 17.07. Found: CH_3OH, 17.11.

Rotation. (Dried sample.) 0.310 g. made up to 10 cc. in methanol at 28°. α_D +1.45; *l*, 2; $[\alpha]^{28}D$ +23.4°.

Extraction of Monocrotaline from *Crotalaria retusa*.—Extraction of 200 g. of *Crotalaria retusa* seed by the procedure described above for isolation of monocrotaline from *Crotalaria spectabilis* gave 3.77 g. (1.89%) of product, recrystallized from absolute ethanol. It proved to be monocrotaline as shown by m. p. 197–198° with decomposition, and rotation, as well as by the melting points of the hydrochloride, 185°, and of the methiodide, 205°.

Anal. (Base.) Calcd. for $C_{16}H_{23}O_6N$: C, 59.06; H, 7.12; N, 4.30. Found: C, 58.89; H, 7.05; N, 4.20.

Rotation. 1.05 g. made up to 25 cc. in chloroform at 28°. α_D −4.68; *l*, 2; $[\alpha]^{28}D$ −55.7°.

Anal. (Hydrochloride.) Calcd. for $C_{16}H_{23}O_6N\cdot HCl$: Cl, 9.79. Found: Cl, 9.80. (Methiodide.) Calcd. for $C_{16}H_{23}O_6N\cdot CH_3I$: I, 27.16. Found: I, 26.89.

Alkaline Hydrolysis of Monocrotaline

A. Monocrotic Acid, $C_7H_{12}O_3$.—A mixture of 20 g. of monocrotaline and 40 g. of barium hydroxide octahydrate in 250 cc. of water was refluxed for one hour. After cooling, the solution was saturated with carbon dioxide and the barium carbonate filtered. The filtrate was made just acid to congo and then submitted to continuous extraction with ether for twelve hours. The ether extract was dried over anhydrous sodium sulfate, the ether removed, and the residue distilled *in vacuo*. A second distillation gave a pure product, b. p. 145–146° (18 mm.); $n^{17.5}D$ 1.4449; d^{26}_4 1.072; yield, 4.2 g. (48%).

Anal. Calcd. for $C_7H_{12}O_3$: C, 58.31; H, 8.39: Found: C, 58.26; H, 8.37.

The neutral equivalent of this product always ran from 5–7% high for a monobasic acid. Undoubtedly this was due to presence of a few per cent. of anhydro compound formed during the distillation. The compound shows no optical rotation.

***p*-Bromophenacyl Ester of Monocrotic Acid.**—This was prepared from monocrotic acid by the usual procedure. It was purified from aqueous ethanol: white needles, m. p. 78°.

Anal. Calcd. for $C_{15}H_{17}O_4Br$: C, 52.79; H, 5.02. Found: C, 53.0; H, 5.25.

B. Base Hydrochloride, $C_8H_{13}O_2N\cdot HCl$.—The aqueous solution obtained after ether extraction of the acid just described was evaporated *in vacuo* to dryness. The sirup thus obtained was dissolved in about 100 cc. of absolute ethanol, and the solvent removed by evaporation. A crystalline mass thus resulted which was extracted with three 30-cc. portions of boiling absolute ethanol to free from barium salts. The combined ethanolic extracts were concentrated to about 20 cc. and allowed to cool. The salt separated and the filtrate yielded an additional amount by addition of a little ether. It was recrystallized from absolute ethanol: white prisms, m. p. 161–162° (corr.); yield, 10.3 g. (87%).

Anal. Calcd. for $C_8H_{13}O_2N\cdot HCl$: C, 50.11; H, 7.36 Cl, 18.51. Found: C, 50.43; H, 7.22; Cl, 18.77.

Rotation. 1.20 g. made up to 25 cc. in ethanol at 25°. α_D −1.48; *l*, 2; $[\alpha]^{25}D$ −15.4°.

Retronecine Base.—A solution of the base hydrochloride in water was treated with one equivalent of *N* aqueous sodium hydroxide. It was then evaporated to dryness *in vacuo*. The oily residue was extracted with hot dry acetone, from which, after concentration and cooling, the crystalline base separated; purified from dry acetone: white irregular prisms, m. p. 121°. A mixed melting point with an authentic sample kindly furnished by Dr. R. H. F. Manske of the National Research Council of Canada, Ottawa, showed no depression.

Anal. Calcd. for $C_8H_{13}O_2N$: C, 61.91; H, 8.44. Found: C, 61.80; H, 8.46.

Rotation. 1.3316 g. made up to 25 cc. in ethanol at 28°. α_D +5.25; *l*, 2; $[\alpha]^{28}D$ +49.3°.

Diacetylretronecine Picrate.—The base was acetylated according to the directions of Barger[2b] for retronecine and the picrate formed by his procedure: yellow prisms, m. p. 146° (corr.).

Anal. (Dried at 100°.) Calcd. for $C_8H_{11}O_2N(OCCH_3)_2\cdot C_6H_3O_7N_3$: N, 11.95: Found: N, 11.5.

Hydrogenolysis of Monocrotaline

Monocrotalic Acid, $C_8H_{12}O_5$.—A solution of 10.8 g. of monocrotaline in a mixture of 10 cc. of glacial acetic acid and 40 cc. of ethanol was hydrogenated at 2–3 atm. with 0.1 g. of platinum oxide catalyst. In about five hours two moles of hydrogen had been absorbed and the reduction was complete. The solution was filtered from the catalyst and evaporated *in vacuo*. The remaining sirup was taken up in 34 cc. of *N* hydrochloric acid and the aqueous solution thus obtained extracted continuously with ether for twenty-four hours. The ether solution was dried over anhydrous sodium sulfate, the solvent removed *in vacuo*, and the crystalline acid thus obtained was purified by recrystallization from acetone–petroleum ether (b. p. 30–60°): white plates, m. p. 181–182° (corr.).

Anal. Calcd. for $C_8H_{12}O_5$: C, 51.06; H, 6.43; neut. equiv., 188. Found: C, 51.06, 51.11; H, 6.43, 6.34; neut. equiv., 190.

Rotation. 1.1734 g. made up to 25 cc. in water at 28°. α_D −0.50; *l*, 2; $[\alpha]^{28}D$ −5.33.

If excess alkali is used in the determination of the neutral equivalent followed by back titration, values corresponding to between one and two carboxyls are obtained.

p-Bromophenacyl Ester of Monocrotalic Acid.—This was prepared by refluxing 0.68 g. of monocrotalic acid, exactly neutralized with alkali, with 1 g. of *p*-bromophenacyl bromide in 50% ethanol for five hours. The product was purified from ethanol: white crystals, m. p. 162–163° (corr.); yield, 0.47 g. (34%).

Anal. Calcd. for $C_{16}H_{17}O_6Br$: C, 49.87; H, 4.42. Found: C, 49.66; H, 4.46.

Rotation. 0.142 g. made up to 3.74 cc. in ethanol at 30.5°. α_D −1.07; *l*, 2; $[\alpha]^{30.5}D$ −14.1°.

Retronecanol, $C_8H_{15}ON$.—After extraction with ether of the acid just described, the aqueous solution was clarified with norite, filtered and made strongly alkaline with sodium hydroxide. It was then extracted with five 50-cc. portions of ether. The ether extracts were dried with anhydrous sodium carbonate and the ether removed *in vacuo*. The oily basic residue quickly solidified. It was best purified by distillation, 140° (30 mm.): white crystals, m. p. 95–96°.

Anal. Calcd. for $C_8H_{15}ON$: C, 68.04; H, 10.70; N, 9.91. Found: C, 67.90; H, 10.50; N, 10.09.

Rotation. 1.524 g. made up to 25 cc. in ethanol at 28°. α_D −11.0; *l*, 2; $[\alpha]^{28}D$ −91.1°.

Retronecanol Hydrochloride.—This product was prepared from retronecanol in the same manner as described for retronecine hydrochloride: white prisms from methanol–ether, m. p. 210° (corr.) with decomposition.

Alkaline Degradation of Monocrotalic Acid to Monocrotic Acid.—A mixture of 5 g. of monocrotalic acid and 30 cc. of 10% aqueous sodium hydroxide was heated under reflux for one hour. The solution was then acidified and extracted rapidly with ether. After drying the ether solution over anhydrous sodium sulfate, the solvent was removed and the product distilled, b. p. 145–147° (20 mm.), d^{26}_4 1.072; $n^{19}D$ 1.4480.

Anal. Calcd. for $C_7H_{12}O_3$: C, 58.31; H, 8.39. Found: C, 58.66; H, 8.39.

The acid gave a *p*-bromophenacyl ester, m. p. 78°, identical with that from monocrotic acid obtained directly from the monocrotaline.

Summary

The alkaloid, monocrotaline, is extracted by ethanol in good yields from *Crotalaria spectabilis* or *Crotalaria retusa*. It has the formula $C_{16}H_{23}O_6N$ and resembles the alkaloids occurring in various species of *Senecio, Heliotropium, Trichodesma* and *Erechtites*.

Monocrotaline undergoes alkaline hydrolysis to retronecine, $C_8H_{13}O_2N$, and an optically inactive, monobasic acid, $C_7H_{12}O_3$, called monocrotic acid. By hydrogenolysis monocrotaline gives retronecanol, $C_8H_{15}ON$, and an acid designated as monocrotalic acid, $C_8H_{12}O_5$.

It has been shown that monocrotalic acid is optically active, monobasic, and upon treatment with alkali gives the optically inactive acid, monocrotic acid, $C_7H_{12}O_3$, obtained by alkaline hydrolysis of the alkaloid.

Structure of Monocrotaline. II. Monocrotic Acid Obtained by Alkaline Hydrolysis of the Alkaloid[1]

BY ROGER ADAMS, E. F. ROGERS AND F. J. SPRULES[2]

By alkaline hydrolysis of monocrotaline, the alkaloid present in the seed of the *Crotalaria spectabilis* and *Crotolaria retusa*, there were obtained retronecine and an acid, $C_7H_{12}O_3$, called monocrotic acid.

$$C_{16}H_{23}O_6N + H_2O(BaO_2H_2) \longrightarrow \underset{\text{Retronecine}}{C_8H_{13}O_3N} + \underset{\text{Monocrotic acid}}{C_7H_{12}O_3} + [CO_2]$$

The same acid resulted when monocrotalic acid, $C_8H_{12}O_5$, obtained by hydrogenolysis of monocrotaline, was treated with aqueous alkali.

Monocrotic acid is optically inactive. It is monobasic and forms a monomethyl ester with diazomethane. The character of the third oxygen was determined by condensation of the methyl ester with dinitrophenylhydrazine. A hydrazone was formed in 85% yield and, since the ester shows no reducing action with Tollens' reagent or Feh-

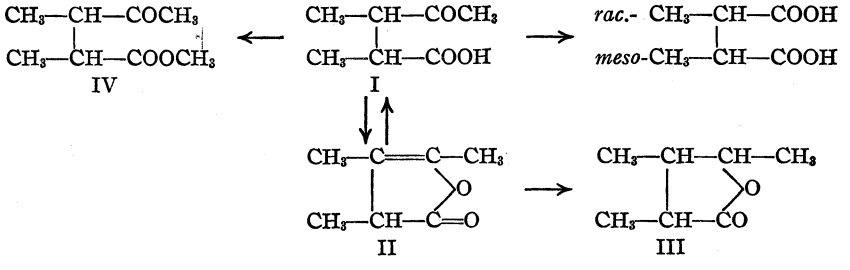
(2) An abstract of a portion of a thesis submitted in partial fulfilment of the requirements for the Degree of Doctor of Philosophy.

ling's solution, the presence of a ketone group was assumed. The action of iodine and alkali on the acid gave iodoform, thus indicating a CH_3CO- group. Oxidation with sodium hypobromite resulted in a mixture of two products which proved to be *meso* and racemic α,α'-dimethylsuccinic acids, identified by comparison with authentic samples. Certain derivatives also were compared and shown to be identical. On the basis of these data the structural formula of monocrotic acid may be postulated as α,β-dimethyllevulinic acid (I).



Monocrotic acid (I) on heating at atmospheric pressure loses water to give a neutral substance, $C_7H_{10}O_2$, which is reconverted to the acid by hydrolysis. Undoubtedly this is a lactone (II), and its formation may be explained by the loss of water between the enol form of the ketone group and the carboxyl, a reaction characteristic of γ-ketonic acids. Moreover, the lactone (II) was shown to be unsaturated by catalytic reduction to the saturated lactone (III). The lactone (II) also gave a positive test with Legal's reagent and Tollens' reagent, which is characteristic of β,γ-unsaturated γ-lactones.[3]

The formation of approximately an equal mixture of *meso* and racemic α,α'-dimethylsuccinic acids by hypobromite oxidation may be due to rearrangements taking place during the reaction, or it may be due to the fact that diastereoisomers exist in the monocrotic acid which cannot be separated by distillation. The former possibility is favored, since methyl monocrotate gives an 85% yield of pure dinitrophenylhydrazone. The clarification of this point must await synthesis.

Experimental

Methyl Monocrotate.—Pure monocrotic acid[1] was treated in ether solution with excess diazomethane, b. p. 94–96° (18 mm.); $n^{25}D$ 1.4273: $d^{25.5}_4$ 0.9968; yield 90%.

Anal. Calcd. for $C_8H_{14}O_3$: C, 60.75; H, 8.93. Found: C, 60.63; H, 8.77.

(3) Jacobs and Hoffman, *J. Biol. Chem.*, **61**, 333 (1925).

Esterification of monocrotic acid with methanol and sulfuric acid gave the same product in somewhat lower yields.

Methyl Monocrotate 2,4-Dinitrophenylhydrazone.—A mixture of 2 cc. of methyl monocrotate and 2.64 g. of 2,4-dinitrophenylhydrazine in 100 cc. of methanol was heated to boiling, 1 cc. of concentrated hydrochloric acid was added and the solution, after five minutes of refluxing, was allowed to cool. The orange crystals which separated were pure and the melting point did not change by recrystallization; m. p. 95–96°; yield, 3.63 g. (85%).

Iodoform Reaction and Hypobromite Oxidation of Monocrotic Acid

***Meso* and Racemic α,α'-Dimethylsuccinic Acids.**—From 1 g. of monocrotic acid dissolved in 13 cc. of 10% aqueous sodium hydroxide and treated with 35 cc. of a solution containing 10 g. of iodine and 20 g. of potassium iodide per 80 cc. of water, 0.157 g. of iodoform was isolated, m. p. 119°.

A solution of 5 g. of monocrotic acid in 30 cc. of water was made slightly alkaline with potassium hydroxide and cooled to 0°. A potassium hypobromite solution prepared by dissolving 18 g. of potassium hydroxide and 10 g. of bromine in 225 cc. of water was then added dropwise. The reaction mixture was stirred vigorously and maintained at 0° during the addition. After one and one-half hours at 0°, the solution was allowed to warm to room temperature, then concentrated to half its volume, acidified and extracted with ether. Upon evaporation of the ether, 4.6 g. of a yellow oily solid was obtained. This was dissolved in boiling water, treated with norite, then concentrated to 20 cc. and cooled. This caused 1.75 g. of an acid to separate which, after further purification from water, formed white crystals, m. p., 203–204° (the exact value depending upon the rate of heating). This compound gave no depression in a mixed melting point determination with authentic *meso*-α,α'-dimethylsuccinic acid.

Anal. Calcd. for $C_6H_{10}O_4$: C, 49.31; H, 6.90. Found: C, 49.33; H, 6.81.

The mother liquors from the isolation of the *meso* α,α'-dimethylsuccinic acid gave on concentration to 5 cc. 1.29 g. of acid which, on purification by crystallization from benzene, melted at 121–122.5°. This compound gave no depression in a mixed melting point determination with racemic α,α'-dimethylsuccinic acid.

Anal. Calcd. for $C_6H_{10}O_4$: C, 49.30; H, 6.90. Found: C, 49.50; H, 7.03.

These two products were converted to their half anilides by the method of Auwers[4] and compared with synthetic half anilides of *meso* and racemic α,α'-dimethylsuccinic acids. From 203° melting acid was obtained a half anilide, m. p. 169–170°, and from the 121° melting acid, a half anilide, m. p. 135–136°.

Anal. (Half-anilide, m. p. 169–170°.) Calcd. for $C_{12}H_{15}O_3N$: C, 65.15; H, 6.84; N, 6.34. Found: C, 65.14; H, 7.09. (Half anilide, m. p. 135–136°.) Found: N, 6.29.

p-Bromophenacyl Ester of Acid, M. P. 203°.—This was made by the usual procedure. It was purified from ethanol and gave white needles, m. p. 155–156°. The *p*-bromophenacyl ester of authentic *meso*-α,α'-dimethylsuccinic acid gave the same product.

Anal. Calcd. for $C_{22}H_{20}O_6Br_2$: C, 48.93; H, 3.73. Found: C, 48.78; H, 3.66.

Anhydride of Acid, M. P. 121°.—This was prepared according to the procedure of Bone and Sprankling.[5] It was purified by crystallization from dry ether, m. p. 88°. It proved to be racemic α,α'-dimethylsuccinic anhydride.

Anal. Calcd. for $C_6H_8O_3$: C, 56.25; H, 6.25. Found: C, 55.58; H, 6.39.

Dehydration of Monocrotic Acid to a Lactone; α,β,γ-Trimethylangelicalactone.—In a distillation apparatus 5 g. of monocrotic acid was heated to 240–250° at atmospheric pressure. At this temperature a colorless neutral liquid distilled. The product was taken up in ether, the ether solution washed with aqueous sodium bicarbonate and dried. The product boiled at 121° (20 mm.); $n^{19}D$ 1.4665; $n^{29}D$ 1.4640; d^{29}_4 1.024.

Anal. Calcd. for $C_7H_{10}O_2$: C, 66.66; H, 7.94; M_D 33.95. Found: C, 66.09; H, 7.90; M_D 33.55.

This compound decolorizes permanganate, gives a positive test with Tollens' reagent and with sodium nitroprusside (Legal's test). These latter two tests were performed according to the procedure recommended by Jacobs and Hoffman.

A solution of 5 g. of the lactone in 20 cc. of 10% ethanolic potassium hydroxide was refluxed for one hour. It was then neutralized with hydrochloric acid to litmus and the ethanol evaporated *in vacuo*. The residue was taken up in water, ether was added and hydrochloric acid also. Continuous extraction took up the acid: colorless liquid, 145–147° (20 mm.), which was identical with the acid from which the lactone was formed.

Anal. Calcd. for $C_7H_{12}O_3$: C, 58.31; H, 8.79. Found: C, 58.40; H, 8.40.

Hydrogenation of Lactone: α,β-Dimethyl-γ-valeroactone.—A solution of 10 g. of the lactone just described n 100 cc. of ether was hydrogenated under 2000-lb. (133 atm.) pressure at 120° in the presence of 2 g. of Raney nickel. Reduction was complete in three hours; yield, 9.8 g. The product boiled at 106–107° (20 mm.); $n^{19}D$ 1.4382; $n^{29}D$ 1.4348; d^{27}_4 0.987.

Anal. Calcd. for $C_7H_{12}O_2$: C, 65.62; H, 9.44; M_D 34.02. Found: C, 65.28; H, 9.62; M_D 33.84.

The same product resulted when methyl monocrotate was hydrogenated under similar conditions except that reduction was carried on for seven hours.

Anal. Found: C, 65.18; H, 9.39.

Summary

Monocrotic acid, $C_7H_{12}O_3$, was obtained from the alkaloid monocrotaline by alkaline hydrolysis or by the action of alkali on monocrotalic acid.

It is optically inactive, monobasic and forms a monomethyl ester by the action of diazomethane. The methyl ester gives a dinitrophenylhydrazone indicating the presence of a ketone group. The acid is oxidized by sodium hypobromite to *meso* and racemic α,α'-dimethylsuccinic acid.

Monocrotic acid dehydrates on heating to a neutral lactone which can be hydrolyzed to the acid. The lactone gives the color reactions characteristic for β,γ-unsaturated lactones.

It is concluded, therefore, that monocrotic acid is α,β-dimethyllevulinic acid.

The Structure of Monocrotaline. III. Monocrotalic Acid[1]

BY ROGER ADAMS, E. F. ROGERS AND R. S. LONG[2]

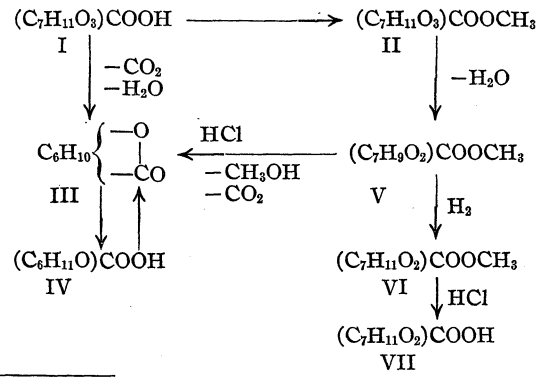
On catalytic hydrogenation of monocrotaline, two moles of hydrogen are absorbed with formation of an alkanolamine, retronecanol, and an optically active acid, $C_8H_{12}O_5$, called monocrotalic acid.[3]

$$C_{16}H_{23}O_6N + 2H_2 \longrightarrow \underset{\text{Retronecanol}}{C_8H_{15}ON} + \underset{\text{Monocrotalic acid}}{C_8H_{12}O_5}$$

Monocrotalic acid (I) contains one carboxyl group. On back titration of the acid from excess alkali, the presence of a lactone group is indicated. The acid gives a crystalline monomethyl ester (II) with diazomethane which shows one active hydrogen by a Zerewitinoff determination. Esterification of the acid with methanol and sulfuric acid was unsuccessful and only a very poor yield of ester was obtained with methanol saturated with hydrogen chloride.

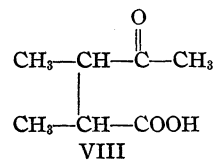
The acid decomposes on heating past its melting point to give an optically inactive neutral compound, $C_7H_{10}O_2$ (III or IX), which is identical with α,β,γ-trimethylangelicalactone obtained by dehydration of monocrotic acid, $C_7H_{12}O_3$ (IV or VIII).

The same lactone can be obtained by a two-step procedure which clarifies the reaction. Methyl monocrotalate (II) on heating *in vacuo* loses water to give an unsaturated ester $(C_7H_9O_2)$-$COOCH_3$ (V), together with a small amount of lactone (III). This ester reduces acid permanganate and can be hydrogenated under high pressure to a dihydro ester (VI) which in turn may be hydrolyzed to a crystalline lactonic acid, $(C_7H_{11}O_2)COOH$ (VII). The unsaturated ester (V) on hydrolysis with concentrated hydrochloric acid, yields the same lactone, $C_7H_{10}O_2$ (III), which is obtained by thermal decomposition of monocrotalic acid. It is obvious then that upon heating monocrotalic acid two reactions occur, dehydration and decarboxylation. These reactions just discussed are shown in tabular form.

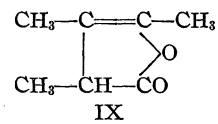


The above observations show that monocrotalic acid contains a lactone group which, while stable to heat and strong acid, cleaves readily with alkali to give an unstable, easily decarboxylated acid which could not be isolated. The ease of dehydration of monocrotalic acid and especially of its methyl ester is best explained by the presence of a tertiary hydroxyl group.

It has been demonstrated[1] that the acid obtained by alkaline hydrolysis of monocrotalic acid is α,β-dimethyllevulinic acid (VIII).



VIII



IX

Since IV has the structural formula VIII, it follows that the corresponding lactone (III) must be α,β,γ-trimethylangelicalactone (IX) which was obtained by the dry distillation of monocrotalic acid (I). Three structures of monocrotalic acid (I) may be considered, XI, XII and XIII.

Structures XIV, XV and XVI would then represent, respectively, the anhydromonocrotalate (V). All three of these structures have as a common feature the grouping 
which explains the smooth formation of a keto acid on breaking the lactone ring. The structures differ in the position given the free carboxyl group.

Structure XIII appears unlikely due to the fact that monocrotalic acid is esterified with acid and methanol only with great difficulty. This is indicative of a tertiary carboxyl. Structure XIII should not decarboxylate as readily on heating as was actually observed. Moreover, methyl anhydromonocrotalate does not give a Legal test al-

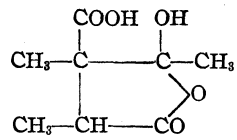
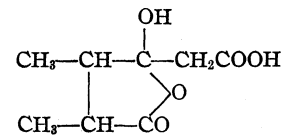
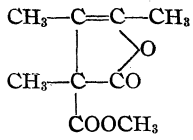
XI



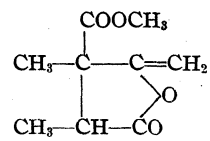
XII



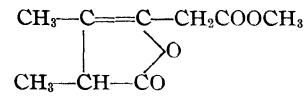
XIII



XIV



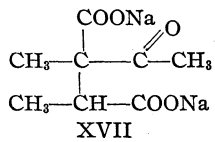
XV



XVI

though the unsaturated ester (XVI) derived from an acid of structure XIII should do so, since this test is specific for β,γ-unsaturated γ-lactones containing a free hydrogen in the α-position.[4] On the basis of this evidence, structure XIII may be excluded.

The degradation of monocrotalic acid (I) with alkali goes smoothly and quantitatively to monocrotic acid (VIII).[3] This reaction proceeds equally well whether dilute or concentrated alkali is used. Unquestionably the first step in the degradation is the formation of the salt of the tautomeric keto acid. Thus, XII would be converted to XVII, which is a β-ketonic acid. A difference

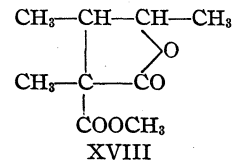


XVII

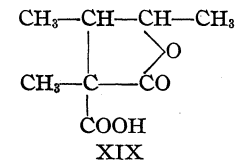
in the decarboxylation products should result whether diluted or concentrated alkali is used, for the former should give a ketone splitting to a levulinic acid derivative, whereas the latter should give at least partially an acid splitting with formation of a α,α'-dimethylsuccinic acid. None of the latter product could be isolated.

Methyl anhydromonocrotalate can be reduced catalytically only under high pressure. This fact is better reconciled with a substituted angelicalactone of formula XIV rather than XV. It is concluded, therefore, that formula XI represents the most likely structure for monocrotalic acid, namely, α-carboxy-α,β-dimethyl-γ-hydroxy-γ-valerolactone. It explains also the presence of one active hydrogen in methyl monocrotalate.

On this basis, the other degradation products would have the structures: hydrogenated methyl anhydromonocrotalate (XVIII) and its acid hydrolysis product (XIX).



XVIII



XIX

Monocrotalic acid and all of its derivatives in which the carboxyl group is intact are optically active, whereas the lactone obtained from monocrotalic acid or its derivatives is inactive due probably to its ease of enolization.

Experimental

Methyl Monocrotalate.—To a suspension of 5 g. of monocrotalic acid[3] in 30 cc. of chloroform was added slowly with stirring an ether solution of diazomethane until a slight excess was present as evidenced by a yellow color in the solution. The temperature was not allowed to rise above 10°. Evaporation of the ether and chloroform under diminished pressure left an oil which crystallized rapidly. The product was purified by recrystallization from ether: white crystals, m. p. 79–80° (corr.); yield, 5.17 g. (97%).

Anal. Calcd. for $C_9H_{14}O_5$: C, 53.47; H, 6.93. Found: C, 53.87; H, 7.09.

Rotation. 0.502 g. made up to 10 cc. at 30° in absolute ethanol. α_D −1.63; *l*, 2; $[\alpha]^{30}D$ −16.24°.

A Zerewitinoff determination showed 1.18 active hydrogens.

Heat Decomposition of Monocrotalic Acid: α,β,γ-Trimethylangelicalactone.—In a small modified Claisen distilling flask immersed in a Woods' metal bath was placed 15 g. of pure monocrotalic acid. Heat was applied and, at a bath temperature of 200°, the evolution of carbon dioxide and water was apparent. When this had ceased the bath was cooled and the residue distilled: colorless liquid, b. p. 82–83° (1 mm.); d^{29}_4 1.024; $n^{20}D$ 1.4664; yield, 8.6 g. (86%).

Anal. Calcd. for $C_7H_{10}O_2$: C, 66.67; H, 7.94. Found: C, 66.45; H, 8.04.

(4) Jacobs and Hoffman, *J. Biol. Chem.*, **61**, 333 (1925).

Methyl Anhydromonocrotalate.—In a small modified Claisen distilling flask 15 g. of methyl monocrotalate was heated at 200–210° until the evolution of water was complete. Fractionation of the residue gave 4.5 g. of material, b. p. 100–115° (3 mm.), and 7.5 g. of pure methyl anhydromonocrotalate, b. p. 115–116° (3 mm.); $n^{20}D$ 1.4700; d^{32}_4 1.131.

Anal. Calcd. for $C_9H_{12}O_4$: C, 58.70; H, 6.52. Found: C, 58.83; H, 6.82.

Rotation. (Pure liquid at 30°) αD +58.22; *l*, 2; $[\alpha]^{30}D$ +25.74.

A second fractionation of the low boiling portion gave 1.8 g. of low boiling material and 1.7 g. of pure methyl anhydromonocrotalate. Further purification of the low boiling material from this distillation gave 0.5 g. of pure α,β,γ-trimethylangelicalactone identical with that obtained directly from monocrotalic acid, b. p. 92° (3 mm.); $n^{20}D$ 1.4658.

Anal. Calcd. for $C_7H_{10}O_2$: C, 66.67; H, 7.94. Found: C, 66.10; H, 8.02.

Hydrogenation of Methyl Anhydromonocrotalate and α,β,γ-Trimethylangelicalactone: α-Carbomethoxy-α,β-dimethyl-γ-valerolactone and α,β-Dimethyl-γ-valerolactone.—Unfractionated methyl anhydromonocrotalate (9 g.) containing α,β,γ-trimethylangelicalactone was dissolved in 70 cc. of ether and hydrogenated at 2200 pounds (167 atm.) and 125° using Raney nickel as the catalyst. The theoretical amount of hydrogen was absorbed and the residue, after removal of the ether, was carefully fractionated; yield, 0.8 g. of α,β-dimethyl-γ-valerolactone, b. p. 67–69° (2 mm.); $n^{20}D$ 1.4382; d^{29}_4 0.987, and 6.0 g. of hydrogenated methyl anhydromonocrotalate, b. p. 115–117° (1 mm.); $n^{20}D$ 1.4510; d^{28}_4 0.996.

Anal. (α,β-Dimethyl-γ-valerolactone.) Calcd. for $C_7H_{12}O_2$: C, 65.63; H, 9.38. Found: C, 65.43; H, 9.57. (Hydrogenated methyl anhydromonocrotalate.) Calcd. for $C_9H_{14}O_4$: C, 58.06; H, 7.53. Found: C, 58.09; H, 7.70.

Rotation. (Pure liquid at 29°) αD +11.15; *l*, 2; $[\alpha]^{29}D$ +5.60.

When pure methyl anhydromonocrotalate was hydrogenated under similar conditions, a pure reduced product was obtained with constants identical with those just described.

Hydrolysis of Dihydromethyl Anhydromonocrotalate: α-Carboxy-α,β-dimethyl-γ-valerolactone.—A mixture of 4.6 g. of dihydromethyl anhydromonocrotalate and 20 cc. of concentrated hydrochloric acid was refluxed for five hours. Evaporation of the water under reduced pressure left 2.7 g. (63%) of crude acid which after purification by recrystallization from benzene gave 2.5 g. of pure acid: white crystals, m. p. 131–132° (corr.).

Anal. Calcd. for $C_8H_{12}O_4$: C, 55.81; H, 6.98. Found: C, 55.57; H, 6.98.

Rotation. 0.303 g. made up to 10 cc. of absolute ethanol at 30°. αD +0.23; *l*, 2; $[\alpha]^{30}D$ +3.80°.

The *p*-bromophenacyl ester was prepared from 0.1 g. of the acid and an equivalent amount of *p*-bromophenacyl bromide according to the standard procedure. Purified from ethanol it formed white crystals, m. p. 142–143° (corr.); yield, 0.12 g. (57%).

Anal. Calcd. for $C_{16}H_{17}O_5Br$: C, 52.03; H, 4.61. Found: C, 52.33; H, 4.91.

Rotation. 0.2315 g. made up to 5 cc. in acetone at 29°. αD −0.36; *l*, 2; $[\alpha]^{29}D$ −3.89°.

Hydrolysis of Methyl Anhydromonocrotalate: α,β,γ-Trimethylangelicalactone.—A solution of 6 g. of methyl anhydromonocrotalate in 10 cc. of concentrated hydrochloric acid was refluxed for eight hours. The oil which separated was extracted with ether and the ether solution was dried over anhydrous sodium sulfate. The product was pure, inactive α,β,γ-trimethylangelicalactone, b. p. 90–92° (3 mm.); $n^{20}D$ 1.4659 identical with that obtained directly from monocrotalic acid by heat decomposition.

Anal. Calcd. for $C_7H_{10}O_2$: C, 66.67; H, 7.94. Found: C, 65.97; H, 8.23.

Summary

Monocrotalic acid, obtained by hydrogenolysis of monocrotaline, has been shown to be monobasic with the carboxy group tertiary, and to contain a lactone grouping. It decomposes when heated to lose water and carbon dioxide with formation of α,β,γ-trimethylangelicalactone. It was possible to form this same lactone by heat decomposition of methyl monocrotalate and hydrolysis of the resulting methyl anhydromonocrotalate.

The discussion of the possible structure for monocrotalic acid is given with the conclusion that it is optically active α-carboxy-α,β-dimethyl-γ-hydroxy-γ-valerolactone.

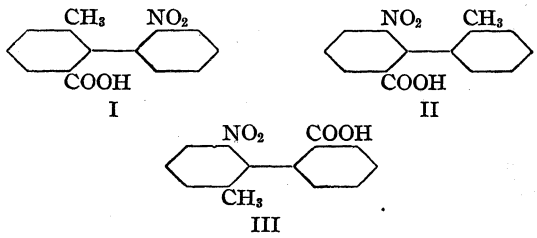
Stereochemistry of Biphenyls. XLVIII. A Comparison of the Racemization Rates of Three Isomeric 2,2′,6-Nitro-, Carboxy-, Methyl-biphenyls[1]

BY ROGER ADAMS AND J. B. HALE[2]

A previous study of various easily racemized biphenyls[3] has demonstrated that various substituents in positions other than the 2,2′,6,6′ materially affect the rate of racemization of the active molecules. A study now has been made of the three possible isomeric 2,2′,6-trisubstituted biphenyls (I, II and III) in which the substituents are methyl, nitro and carboxyl groups.



If, in these three compounds, the two phenyl groups are assumed to be rigidly coaxial and the distance between the rings essentially constant, it might be anticipated that the relative rates of racemization would be dependent primarily upon the blocking effect of the two smaller interfering groups present in the 2,2′-positions. Previous study of various substituted biphenyls as well as X-ray data indicate that semiquantitatively the size of the groups is in the following order: nitro > methyl > carboxyl. Accepting these facts, compounds II and III should be of essentially the same stability (CH_3, COOH collision) and both of these should be less stable than compound I (COOH, NO_2 collision).

The actual experimental results failed to conform to this postulation. It was found that compound II was the least stable, compound I more stable, and compound III the most stable. The half-life periods of these three compounds (Table I) were sufficiently different to eliminate the possibility of experimental error.

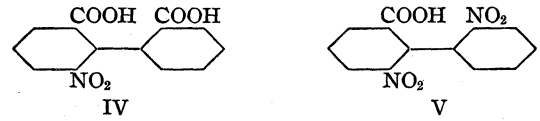
The solvent used in the racemization experiments affects the rate. In Table I acetic acid and *n*-butanol, two solvents which boil within a degree of each other, are compared.

(1) For previous paper see Adams and Finger, THIS JOURNAL, **61**, 2182 (1939).

(2) An abstract of a thesis submitted in partial fulfilment of the requirements for the degree of Doctor of Philosophy in chemistry.

(3) Kuhn and Albrecht, *Ann.*, **455**, 272; **458**, 221 (1927); Chien and Adams, THIS JOURNAL, **56**, 1787 (1934); Hanford and Adams, *ibid.*, **57**, 1592 (1935); Yuan and Adams, *ibid.*, **54**, 2996, 4434 (1932).

A comparison of two other 2,2′,6-trisubstituted biphenyls also has been made, namely, 6-nitrodiphenic acid (IV) and 2,2′-dinitro-6-carboxybiphenyl (V). As deduced merely from the size of groups, compounds IV and V (COOH, NO_2 collision) should have essentially the same stability. Experimental results indicated that compound IV was more stable in *n*-butanol, less stable in acetic acid, and far less stable in aqueous sodium hydroxide than compound V (Table I).



The conclusion to be drawn from these data is that the relative positions of the different groups to each other is a factor in the rate of racemization of the molecules.

Experimental

2-Methyl-6-nitro-2′-carboxybiphenyl.—The data used in the tables on this compound were those previously described by Stoughton and Adams.[4]

2-Carboxy-6-nitro-2′-methylbiphenyl.—A mixture of 20 g. of methyl 3-nitro-2-bromobenzoate and 34 g. of *o*-iodotoluene in a three-necked flask with reflux condenser and stirrer was heated in a metal bath at 225° (bath temp.). Over a period of one hour, 40 g. of copper powder was added with stirring. The bath temperature was then raised to 230° for thirty minutes. After cooling, the reaction mixture was extracted with three 100-cc. portions of hot ethanol. These filtered extracts were mixed with 400 cc. of 5% aqueous sodium hydroxide and refluxed for eight hours. The solution was then boiled for an additional two hours to remove a large proportion of the ethanol. Upon cooling, an oil separated which was chiefly the excess of *o*-iodotoluene. The aqueous solution was removed, treated with norit, filtered, and acidified with concentrated hydrochloric acid. An oil separated which soon solidified. This crude material was extracted with hot benzene in which the 2-nitro-6-carboxy-2′-methylbiphenyl was soluble, and the 6,6′-dinitrodiphenic acid practically insoluble. The benzene solution was extracted with dilute aqueous sodium hydroxide and the aqueous solution acidified with hydrochloric acid.

The product was purified by several recrystallizations from dilute ethanol: white crystals, m. p. 162–163°; yield, 3 g. (15%).

(4) The data given for compound III are those of Stoughton and Adams, *ibid.*, **52**, 5263 (1930), and were observed at a temperature of 20°.

TABLE I

Compound	Solvent	Sample in g. made up to cc.	α_D $l = 2$	$[\alpha]^{25}D$	Av. K	Half-life period, min.

Anal. Calcd. for $C_{14}H_{11}O_4N$: C, 65.4; H, 4.28; N, 5.45. Found: C, 65.38; H, 4.1; N, 5.41.

Resolution of 2-Methyl-6-nitro-2′-carboxybiphenyl.—To a boiling solution of 3.28 g. of 2-nitro-6-carboxy-2′-methylbiphenyl in 500 cc. of 60% ethanol was added 4.13 g. of quinine. After standing overnight 3.8 g. of crystals separated which were purified by crystallization three times from 200 cc. of hot 50% ethanol. The salt thus obtained gave a constant rotation and weighed 1.7 g. Before drying, the product had a melting point of 135–140° and after drying, 168–171°.

Rotation (dry l salt). 0.05 g. made up to 15 cc. in chloroform at 25°. α_D −0.89°; $l = 2$; $[\alpha]^{25}D$ −133.5°.

Anal. Calcd. for $C_{34}H_{35}O_6N_3$: N, 7.22. Found: N, 7.53.

Rotation (solvated l salt) 0.05 g. made up to 15 cc. in chloroform at 25°. α_D −0.83°; $l = 2$; $[\alpha]^{25}D$ −124.2°.

On cooling the original mother liquor from the less soluble salt, a small crop of crystals separated which were discarded. The alcohol solution was then allowed to evaporate until the more soluble salt separated. This was purified by three crystallizations from 100 cc. of hot 30% ethanol. The precaution was taken during the first two crystallizations to discard the first third of the salt which separated. The final product gave a constant rotation, m. p. 118–123° before drying and 128–131° after drying.

Anal. (dry d-salt) Calcd. for $C_{34}H_{35}O_6N_3$: N, 7.22. Found: N, 7.12.

Rotation (solvated d-salt) 0.10 g. made up to 15 cc. in chloroform at 25°. α_D −1.40°; $l = 2$; $[\alpha]^{25}D$ −105°.

The solvation of these salts appeared not to be constant so that the rotations of the solvated salts are not significant.

d- and l-2-Nitro-6-carboxy-2′-methylbiphenyl.—A suspension of 2 g. of the less soluble salt in 10 cc. of water was cooled in an ice-bath and treated with 10 cc. of cold dilute hydrochloric acid. After stirring for a few minutes the mixture was extracted with ether and the ether extracts washed several times with dilute hydrochloric acid and then with water. The ether solution was then treated with 10 cc. of dilute sodium hydroxide and the aqueous alkaline extract acidified in the cold with hydrochloric acid. The l-form of the product separated and was recrystallized from dilute ethanol: white crystals, m. p. 153–155°.

Rotation. (l-acid) 0.10 g. made up to 25 cc. in ethanol at 25°. α_D −0.52; $l = 2$; $[\alpha]^{25}D$ −65°.

The d-acid was obtained in a similar manner and had a melting point of 153–156°.

Rotation. (d-acid) 0.0464 g. made up to 15 cc. in ethanol at 25°. α_D +0.38°; $l = 2$; $[\alpha]^{25}D$ +61.5°.

2-Methyl-6-carboxy-2′-nitrobiphenyl.—*m*-Toluic acid was nitrated to 2-nitro-3-methylbenzoic acid according to the method of Findeklee.[5a] This was esterified[5b] and then reduced by means of stannous chloride and hydrochloric acid[6] to the amine. The amino group was replaced by iodine[7] to give methyl 2-iodo-3-methylbenzoate.

A mixture of 24 g. of methyl 2-iodo-3-methylbenzoate and 60 g. of *o*-iodonitrobenzene was heated in a metal bath with stirring at 230°. Copper-bronze powder (65 g.) was added at such a rate that the temperature of the reaction mixture never rose above 245°. The bath temperature was then raised to 250° and maintained at that temperature for fifteen minutes. After cooling, the reaction mixture was extracted with 300 cc. of hot ethanol, filtered, and refluxed for eight hours with 400 cc. of 5% aqueous sodium hydroxide. The reaction mixture was then boiled for two hours and the ethanol allowed to distill. Upon cooling, a brown semi-solid mass separated and was filtered. The solution was treated with norit, filtered, and acidified with dilute hydrochloric acid. The yellow oil which separated soon solidified. The product thus obtained was dissolved in 200 cc. of hot benzene, filtered, and the desired acid extracted with aqueous sodium hydroxide. After acidification the crude 2-methyl-6-car-

(5) (a) Findeklee, *Ber.*, **38**, 3553 (1905); (b) Jurgens, *ibid.*, **40**, 4409 (1907).

(7) Mayer, *ibid.*, **44**, 2298 (1911).

boxy-2′-nitrobiphenyl was filtered and crystallized several times from 80% ethanol: yellowish white crystals, m. p. 157°; yield, 12 g. (50%).

Anal. Calcd. for $C_{14}H_{11}O_4N$: N, 5.45; neut. equiv., 257. Found: N, 5.55; neut. equiv., 260.

Resolution of 2-Methyl-6-carboxy-2′-nitrobiphenyl.—A solution of 3 g. of 2-methyl-6-carboxy-2′-nitrobiphenyl in 20 cc. of boiling methanol was mixed with a boiling solution of 5.43 g. of anhydrous brucine in 50 cc. of methanol. After standing for three hours, 5 g. of salt deposited. After three recrystallizations from 50 cc. of methanol a constant rotation was obtained: white crystals, m. p. 165–167°.

Rotation. 0.05 g. made up to 15 cc. in chloroform at 25°. α_D +0.32; $l = 2$; $[\alpha]^{25}D$ +48°.

Anal. Calcd. for $C_{37}H_{37}N_3O_6$: N, 6.97. Found: N, 7.02.

Upon cooling the mother liquor, 2.4 g. of salt separated. This was dissolved in 40 cc. of methanol and cooled slowly. The first portion of crystals was discarded and finally 1.6 g. of salt was collected. Recrystallization of this from methanol did not change the melting point or the rotation: white crystals, m. p. 153–160°.

Rotation. 0.05 g. made up to 15 cc. in chloroform at 25°. α_D −0.34; $l = 2$; $[\alpha]^{25}D$ −51°.

Anal. Calcd. for $C_{37}H_{37}N_3O_6$: N, 6.97. Found: N, 6.86.

***d*- and *l*-2-Methyl-6-carboxy-2′-nitrobiphenyl.**—The active acids were formed as previously described for the active 2-carboxy-6-nitro-2′-nitrobiphenyls. The active acids were purified by recrystallization from dilute ethanol, *d*-acid m. p. 179–181°, *l*-acid m. p. 175–179°.

Rotation. (*d*-acid) 0.05 g. made up to 15 cc. in chloroform, α_D +0.49; $l = 2$; $[\alpha]^{25}D$ +73.5°. (*l*-acid) 0.0485 g. made up to 15 cc. in chloroform. α_D −0.47; $l = 2$; $[\alpha]^{25}D$ −72.6°.

6-Nitrodiphenic Acid.—This was prepared and resolved according to the method of Bell and Robinson[8] using morphine.

Rotation. (less soluble salt) 0.1 g. made up to 15 cc. in pyridine at 25°. α_D −1.04; $l = 2$; $[\alpha]^{25}D$ −78°.

The active acids were liberated from the salt in the way previously described and were purified by dissolving in dilute aqueous ammonia and precipitating with dilute hydrochloric acid.

Rotation. *d*-acid (from less soluble salt) 0.05 g. made up to 15 cc. in ethanol at 25°. α_D +0.26; $l = 2$; $[\alpha]^{25}D$ +39.0°; α_{5461} +0.44; $l = 2$; $[\alpha]^{20}_{5461}$ +66.0°. *l*-acid (from soluble salt) 0.05 g. made up to 15 cc. in ethanol at 25°. α_D −0.25; $l = 2$; $[\alpha]^{25}D$ −37.5°.

2,2′-Dinitro-6-carboxybiphenyl.—A mixture of 20 g. of methyl-3-nitro-2-bromobenzoate and 34 g. of *o*-iodonitrobenzene was heated in a metal bath at 220°. Copper-bronze powder (40 g.) was then added at such a rate that the temperature of the reaction mixture did not exceed 225°. The bath temperature was raised to 225° for a period of thirty minutes. After cooling the reaction mixture was extracted with three 100-cc. portions of hot ethanol, the filtered extracts added to 400 cc. of 5% aqueous sodium hydroxide and the mixture refluxed for eight hours. The reaction mixture was then boiled for about two hours to remove most of the alcohol. On cooling a dark solid mass separated and was filtered. The solution was treated with norit and acidified with concentrated hydrochloric acid to congo red. A crude oil separated which soon solidified. This was extracted with hot benzene in which the by-product of dinitrobiphenyl is practically insoluble. The benzene solution was then extracted with dilute aqueous sodium hydroxide and upon acidification crude 2,2′-dinitro-6-carboxybiphenyl separated. It was purified by crystallization from dilute acetic acid: m. p. 164°; yield, 6 g. (30%).

Anal. Calcd. for $C_{13}H_8O_6N_2$: C, 54.1; H, 2.78; N, 9.72; neut. equiv., 288. Found: C, 53.97; H, 2.89; N, 10.0; neut. equiv., 283.

Resolution of 2,2′-Dinitro-6-carboxybiphenyl.—To a warm solution of 4 g. of 2,2′-dinitro-6-carboxybiphenyl in 800 cc. of 75% ethanol was added with stirring 4.5 g. of quinine. After standing overnight approximately half of the salt separated. It was purified by crystallization twice from 400 cc. of 50% ethanol. The salt then had a constant rotation, m. p. 156–191°. After drying the melting point was 195–197°.

Rotation. (dry *d*-salt) 0.05 g. made up to 15 cc. in chloroform. α_D +0.35; $l = 2$; $[\alpha]^{25}D$ +52.5°.

Evaporation of the mother liquor from the less soluble salt resulted in the separation of an oil which after standing for a few days gradually solidified. The solid was thoroughly pulverized and allowed to stand in 200 cc. of ethanol with occasional stirring. The solution was filtered and upon evaporation of the solvent the salt obtained solidified rapidly: m. p. 121–125°; yield, 2.5 g.

Rotation. (more soluble salt) 0.1 g. made up to 15 cc. in chloroform at 25°. α_D −3.16; $l = 2$; $[\alpha]^{25}D$ −238°.

Anal. Calcd. for $C_{33}H_{32}O_8N_4$: N, 9.15. Found: N, 8.96.

***d*- and *l*-2,2′-Dinitro-6-carboxybiphenyl.**—The active acids were liberated from the salts in the manner previously described. The active acids were obtained as oils which solidified upon standing in a vacuum desiccator overnight. They were recrystallized from dilute acetic acid; m. p. of *d*-acid from the less soluble salt was 135–137°; the *l*-acid 127–130°.

Rotation. (*d*-acid) 0.10 g. made up to 15 cc. in ethanol at 25°. α_D +2.69; $l = 2$; $[\alpha]^{25}D$ +201.5°. (*l*-acid) 0.05 g. made up to 15 cc. in ethanol at 25°. α_D −1.33; $l = 2$; $[\alpha]^{25}D$ −199.5°.

Summary

The preparation of 2-methyl-6-carboxy-2′-nitrobiphenyl, 2-nitro-6-carboxy-2′-methylbiphenyl, and 2-methyl-6-nitro-2′-carboxybiphenyl is described. They were resolved and the rates of racemization compared. The half-life periods do not correspond to what might be anticipated merely from the relative size of the groups as deduced from X-ray data or from the rates of racemization of previously studied biphenyls. The

(8) Bell and Robinson, *J. Chem. Soc.*, 1695 (1927).

relative positions of the groups have a marked effect on the stability of the molecule. The rate of racemization is modified by the solvent used.

A comparison of the rates of racemization of optically active 6-nitrodiphenic acid with optically active 2,2′-dinitro-6-carboxybiphenyl also has been made. The latter is the more stable.

URBANA, ILLINOIS RECEIVED JULY 24, 1939

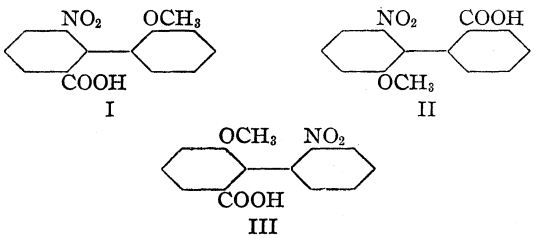
Stereochemistry of Biphenyls. XLIX. Comparison of the Racemization Rates of the 2,2′,6-Nitro-, Carboxy- and Methoxy-biphenyls[1]

BY ROGER ADAMS AND G. C. FINGER[2]

In the previous paper the relative stabilities of biphenyls containing nitro, methyl and carboxyl in the three possible combinations in the 2,2′,6-positions were described. Another similar series has been prepared now in which the nitro, methoxyl and carboxyl groups occupy the three possible positions in biphenyl.



Based upon the expectations from the relative size of the groups, compounds I and II (CH_3O, COOH collision) should have essentially the same stability and compound III should be more stable. Experimentally compound I proved to be very unstable while compounds II and III were much more stable. The value of the half-life period obtained for compound II is possibly unreliable due to the fact that the formation of the salt and the decomposition to the active acid was abnormal, and the yields of the acid were poor. It is likely, therefore, that the half-life period is more in error than usual.

The variation in stability of these molecules is concordant with the results described in the previous paper[1] in which the methyl group was present in place of the methoxyl.

Experimental

2-Methoxy-6-carboxy-2′-nitrobiphenyl.—The 1-methoxy-2-iodo-3-carbomethoxybenzene was prepared by the method of Stanley, McMahon and Adams.[3]

In a large Pyrex test-tube a mixture of 5 g. of 1-methoxy-2-iodo-3-carbomethoxybenzene, 4.3 g. of *o*-iodonitrobenzene and 10 g. of copper-bronze powder was heated under reflux in an oil-bath for two hours at 200°. The reaction mixture was extracted with acetone, the acetone solution refluxed with norit, and the solvent concentrated to small volume.

The crude material, which separated, was refluxed for eighteen hours with a mixture of 2 g. of sodium hydroxide and 8 g. of sodium carbonate in 350 cc. of water and 50 cc. of ethanol. The saponification mixture was filtered from the alkali-insoluble 2,2′-dinitrobiphenyl. The alkaline filtrate was diluted to 1500 cc. and acidified with dilute sulfuric acid to precipitate the product. The crude material which amounted to about 5 g. was crystallized from 80% ethanol, from which it formed white needles, m. p. 234–236°.

5.16; neut. equiv., 273. Found: C, 61.58; H, 4.1; N, 5.24; neut. equiv., 269, 273.

Resolution of 2-Methoxy-6-carboxy-2'-nitrobiphenyl.—To a warm solution of 0.72 g. of 2-methoxy-6-carboxy-2'-nitrobiphenyl in 35 cc. of ethanol was added a solution of 1.05 g. of anhydrous brucine in 50 cc. of ethanol. The mixture was allowed to stand in the ice box for two days. The brucine salt separated as white powdery crystals; m. p. 222–225°, yield 0.92 g.

Anal. Calcd. for $C_{37}H_{37}N_3O_9$: C, 66.54; H, 5.59. Found: C, 66.30; H, 5.54.

Mutarotation. 0.1060 g. of brucine salt was made up to 20 cc. in dry chloroform. α_D (after six minutes) −0.49; $l = 2$; $[\alpha]^{27}D$ −47.1°.

The rotation was read at first every two minutes then every ten and finally every hour until seven hundred forty-five minutes had elapsed: α_D −0.16; $[\alpha]^{27}D$ −15.1°. The half-life period calculated on the basis of a monomolecular reaction is 99 ± 11 min.

***l*-2-Methoxy-6-carboxy-2'-nitrobiphenyl.**—A mixture of 0.4 g. of brucine salt and 25 cc. of dilute hydrochloric acid (1:1) was kept in an ice-bath and shaken occasionally over a period of an hour. The mixture was filtered rapidly and washed with a small amount of ice-cold water. The precipitate was again treated with 25 cc. of dilute acid and allowed to stand overnight at 0°. The active acid was washed with ice-cold dilute hydrochloric acid and water until completely free from brucine and chloride ion. The acid weighed 0.14 g. and had a melting point of 229–232°.

2-Methoxy-6-nitro-2'-carboxybiphenyl

1-Methoxy-2-chloro-3-nitrobenzene.—The 2-chloro-3-nitrophenol was made by the method of Erp[4] and esterified by the method described below.

To a hot solution of 39 g. of 2-chloro-3-nitrophenol in 250 cc. of hot xylene was added slowly with rapid stirring 40 g. of finely powdered anhydrous potassium carbonate. The red phenol salt separated and in some instances it was necessary to add more xylene to facilitate the agitation. To this mixture was now added 30 cc. of dimethyl sulfate at such a rate that the reaction mixture boiled rather vigorously. After continued stirring and refluxing for an hour, the mixture was treated with a little dilute sodium hydroxide and then steam distilled. After all the xylene had come over, the distillation was stopped and the residual material cooled. The crude 1-methoxy-2-chloro-3-nitrobenzene solidified, yield, 39 g. (92%). It was purified from 40% ethanol and formed white flake-like crystals, m. p. 93–94°. Erp reported m. p. 94°.

A mixture of 14 g. of 1-methoxy-2-chloro-3-nitrobenzene and 20 g. of methyl *o*-iodobenzoate was heated in an oil-bath to 255°. The temperature was raised gradually to 275° over a period of one hour and during this period 32 g. of copper-bronze powder was added in about 5-g. quantities at regular intervals. The mixture was stirred rapidly during the addition. After the addition was completed, the temperature was raised to 280° for about five to ten minutes and then allowed to drop.

The reaction product was refluxed with ethanol for two hours, the solvent decanted and the residual material again extracted for several hours with fresh ethanol.

After evaporation of the solvent, a black semi-solid mass was obtained weighing 13 g. This was refluxed for ten to twelve hours with a mixture of 5 g. of sodium hydroxide, 10 g. of sodium carbonate, 50 cc. of ethanol and 200 cc. of water. After cooling, the mixture was filtered and the insoluble residue separated from the alkaline solution. It proved to be 2,2'-dimethoxy-6,6'-dinitrobiphenyl. The alkaline solution was refluxed with norit for two hours, then filtered and acidified with dilute hydrochloric acid. The precipitated product was extracted with ether, the ether solution dried over anhydrous magnesium sulfate and the solvent evaporated. The product thus obtained which appeared to be a mixture of a solid and a very viscous oil was heated with successive portions of 25 cc. of benzene, the extracts were combined and allowed to cool. Diphenic acid separated. The benzene was evaporated gradually and intermittently cooled. When a volume of about 20 cc. had been reached, crude 2-methoxy-6-nitro-2'-carboxybiphenyl separated and by further evaporation of the filtrate a second crop could be obtained. The product was purified by recrystallization from 50% methanol: pale cream colored crystals, m. p. 196–198°; yield, 1.5 g.

Anal. Calcd. for $C_{14}H_{11}NO_5$: C, 61.53; H, 4.03; N, 5.16; neut. equiv., 273. Found: C, 61.76; H, 4.02; N, 5.24; neut. equiv., 271, 272.

2,2'-Dimethoxy-6,6-dinitrobiphenyl.—The alkali-insoluble material obtained in the condensation of 1-methoxy-2-chloro-3-nitrobenzene and methyl *o*-iodobenzoate was purified by crystallization from ethanol in the presence of norit. It formed yellow crystals.

The same product was prepared by heating a mixture of 5 g. of 1-methoxy-2-chloro-3-nitrobenzene in 30 g. of anhydrous nitrobenzene at 180° and adding gradually with stirring 5 g. of copper-bronze powder. The reaction mixture was then maintained at a temperature of 200–210° for five hours, cooled and filtered. The copper residue was extracted carefully with acetone.

The nitrobenzene solution and acetone extracts were subjected to steam distillation, whereupon the solvent was removed as well as some of the unreacted chloro compound. The crude residual product was filtered and dissolved in acetone. This solution was then heated with norit, filtered, and evaporated on a steam cone. Upon treatment of this residue with 50 cc. of hot ethanol, the oily material went into solution and yellow crystals of the 2,2'-dimethoxy-6,6'-dinitrobiphenyl remained undissolved; yield 2.8 g. from ethanol, m. p. 226–228°. The compound can also be purified very satisfactorily from hot glacial acetic acid.

Anal. Calcd. for $C_{14}H_{12}O_6N_2$: N, 9.2. Found: N, 9.13.

Resolution of 2-Methoxy-6-nitro-2'-carboxybiphenyl.—To a warm solution of 0.72 g. of 2-methoxy-6-nitro-2'-carboxybiphenyl in 25 cc. of absolute ethanol was added a warm solution of 1.05 g. of brucine in 50 cc. of absolute ethanol. After filtration, the mixture was allowed to stand at 0° for thirty hours. Yellow needle-like crystals separated; yield, 0.83 g. A second crop could be obtained by allowing the mother liquor to stand at 0° for several days.

(4) Erp, *J. prakt. Chem.*, **127**, 20 (1930).

The product was purified by dissolving 0.91 g. in 40 cc. of hot absolute ethanol and allowing to stand at 0° for thirty hours. Cream colored crystals were thus obtained.

The melting point of the brucine salt showed unusual irregularity, some samples partially melting around 70°, others at 80 or 90°. The decomposition points ranged from 108–125°.

The brucine salt had practically a zero rotation and no mutarotation was observed over a period of several hours. In spite of this, active acid was obtained from the salt by hydrolysis. Although the salt was well crystallized, the analyses did not indicate absolute purity.

l-2-Methoxy-6-nitro-2′-carboxybiphenyl

A. Hydrolysis with Acid.—The brucine salt was hydrolyzed with dilute hydrochloric acid (1:1) as described previously for 2-methoxy-6-carboxy-2′-nitrobiphenyl. An exceedingly low yield of active acid resulted.

B. Hydrolysis with Dilute Sodium Hydroxide.—At 0° 0.1 g. of brucine salt was shaken with 15 cc. of aqueous 10% sodium hydroxide for one hour. Extraction with chloroform served to remove the brucine. After filtering the alkaline solution, it was acidified with dilute hydrochloric acid (1:1) at 0°. The *l*-acid separated but, as it was too fine for filtrations, it was extracted with ether. The solvent was evaporated at a low temperature and the residue dried in a vacuum desiccator at room temperature; weight, 0.022 g., m. p. 195–199°.

Anal. Calcd. for $C_{13}H_{11}O_5N$: N, 5.16. Found: N, 5.10.

Summary

The following compounds have been prepared: 2-methoxy-6-carboxy-2′-nitrobiphenyl, 2-nitro-6-carboxy-2′-methoxybiphenyl, and 2-methoxy-6-nitro-2′-carboxybiphenyl. The 2-nitro-6-carboxy-2′-methoxybiphenyl proved to be unstable and the least stable of the three. The other two were relatively stable compounds. A more exact comparison of the stability of the latter two was impossible due to the fact that the purity of one of them appeared to be questionable.

Synthesis in the 1,2,3,4-Tetrahydroquinoline Series

BY WILLIAM S. EMERSON AND J. W. DAVIS

The N-alkyl-1,2,3,4-tetrahydroquinolines represent an interesting and but little studied group of compounds. Very few containing alkyl groups in the benzene ring have ever been prepared, much less, thoroughly examined.

These compounds can be prepared readily from the corresponding quinolines either by reduction of the quinoline methiodides[1] or by first reducing the quinolines and then treating the tetrahydro compounds with methyl iodide.[1,2] In examining the second method we were surprised to find that 1,2,3,4-tetrahydroquinolines vary markedly in their stability and reactivity. This paper reports the great differences in these respects between 2,6- and 2,8-dimethyl-1,2,3,4-tetrahydroquinoline.

While the 2,8-compound is relatively stable, forming a well defined picrate and zinc chloride–hydrochloric acid double salt, the corresponding derivatives of the 2,6-compound are unstable, decomposing when attempts are made to crystallize them. In the case of the picrate, 2,6-dimethylquinoline picrate subsequently was isolated from the filtrate. The 2,6-compound also reacted much more violently with methyl iodide than the 2,8-compound. On the other hand, the N-methyl derivative of 2,6-dimethyl-1,2,3,4-tetrahydroquinoline was found to be stable and normal in its reactions.

Reduction studies of alkyl and aryl quinolines[3] showed that 2,6-dimethylquinoline was reduced readily with nickel and hydrogen at 105°. At the same pressure three monomethylquinolines were reduced at 120°, while a temperature of at least 150° was required in all other cases. 2-Methylquinoline could be reduced at temperatures as low as 110°, but the reaction proceeded more smoothly at 150°. Since this type of hydrogenation is reversible, it is interesting that the tetrahydroquinoline which we have found to be unstable was prepared at the lowest temperature in these reduction studies.

Experimental

2,8-Dimethylquinoline was prepared by the method of Doebner and v. Miller; b. p. 245–255°; $n^{20}D$ 1.5955; d^{20}_4 1.036; M_D calcd. 51.73; M_D found 51.60. Its identity was checked by means of the picrate, m. p. 177–179° (180°).[4]

The zinc chloride–hydrochloric acid double salt was prepared by mixing one part of the base with two parts of a solution of 13.6 g. of zinc chloride in 20 cc. of concentrated hydrochloric acid and 10 cc. of glacial acetic acid. After filtration from the reaction mixture the white needles were recrystallized from glacial acetic acid. They were filtered and washed free of acid with ether, m. p. 270° dec. This is a modification of Craig's procedure[5] for preparing the zinci-hydrochloride of methyldiphenylamine.

Anal. Calcd. for 2 $2C_{11}H_{11}N \cdot 2HCl \cdot ZnCl_2$: Cl, 27.2. Found: Cl, 26.9.

2,8-Dimethyl-1,2,3,4-tetrahydroquinoline was prepared by dissolving 39 g. of 2,8-dimethylquinoline in 100 cc. of water and 200 cc. of concentrated hydrochloric acid and refluxing the resulting solution for fifteen hours with an excess of tin.[2] The product was isolated by making the mixture alkaline with sodium hydroxide and distilling with steam. After the distillate was extracted with ether, the ether solution dried over sodium hydroxide and the ether distilled, the base distilled at 250–255°: yield 27.9 g. or 69%; $n^{20}D$ 1.5610; d^{20}_4 1.000; M_D calcd. 51.90; M_D found 52.24. The picrate crystallized from alcohol in yellow needles, m. p. 159.5–161.0°.

Anal. Calcd. for $C_{17}H_{18}O_7N_4$: C, 52.3; H, 4.62. Found: C, 52.3; H, 4.62.

The zinc chloride–hydrochloric acid double salt melted at 270° with decomposition. A mixed melting point determination with the zinc chloride–hydrochloric acid double salt of 2,8-dimethylquinoline showed a depression of fifteen degrees.

Anal. Calcd. for $2C_{11}H_{15}N \cdot 2HCl \cdot ZnCl_2$: Cl, 26.7. Found: Cl, 26.5.

The benzoyl derivative, prepared by the Schotten–Baumann method, crystallized from aqueous alcohol in white plates, m. p. 118.5–120°.

Anal. Calcd. for $C_{18}H_{19}ON$: N, 5.28. Found: N, 5.42.

1,2,8-Trimethyl-1,2,3,4-tetrahydroquinoline hydriodide was prepared by allowing a mixture of 20 g. of 2,8-dimethyl-1,2,3,4-tetrahydroquinoline and 17.6 g. of methyl iodide to stand for sixteen hours. The white crystals were recrystallized from absolute alcohol; yield 26.5 g. or 70%, m. p. 154.5–155.5°.

Anal. Calcd. for $C_{12}H_{18}NI$: I, 41.9. Found: I, 42.0.

1,2,8-Trimethyl-1,2,3,4-tetrahydroquinoline was prepared by dissolving 20 g. of 1,2,8-trimethyl-1,2,3,4-tetrahydroquinoline hydriodide in 20 cc. of water and adding 30 cc. of 10% sodium hydroxide. The oil so formed was extracted with ether and the ether solution dried over potassium hydroxide. After the ether had been distilled, the product was distilled at 21 mm., b. p. 130°: yield 10.2 g. or 88%; $n^{20}D$ 1.5450; d^{20}_4 0.9826; M_D calcd. 57.30; M_D found 56.43.

The picrate was crystallized from alcohol, m. p. 177–178°. A mixed melting point determination with the picrate of 2,8-dimethylquinoline (m. p. 177–179°) showed a depression of twenty-seven degrees.

Anal. Calcd. for $C_{18}H_{22}O_7N_4$: N, 13.88. Found: N, 14.04.

The zinc chloride–hydrochloric acid double salt was also prepared as white crystals, m. p. 213–214°.

Anal. Calcd. for $2C_{12}H_{17}N \cdot 2HCl \cdot ZnCl_2$: Cl, 25.4. Found: Cl, 25.4.

The hydriodide was prepared by mixing equal volumes of the base and hydriodic acid of sp. gr. 1.50. After crystallization had been induced by adding ethyl acetate, the product was filtered and crystallized from absolute alcohol to give white crystals, m. p. 155–157°. A mixed melting point determination with a sample prepared by treating 2,8-dimethyl-1,2,3,4-tetrahydroquinoline with methyl iodide (m. p. 154.5–155.5°) gave 155–157°.

2,6-Dimethylquinoline was prepared by the method of Doebner and v. Miller[2]; b. p. 255–265°; m. p. 60°.

The picrate was crystallized from alcohol in yellow needles, m. p. 186–187°. Doebner[6] gives 178° as the melting point of this compound.

Anal. Calcd. for $C_{17}H_{14}O_7N_4$: N, 14.51. Found: N, 14.45.

The zinc chloride–hydrochloric acid double salt was prepared as white crystals, m. p. 211.5–213°.

Anal. Calcd. for $2C_{11}H_{11}N \cdot 2HCl \cdot ZnCl_2$: Cl, 27.1. Found: Cl, 27.1.

2,6-Dimethylquinoline methiodide was prepared by warming equimolar quantities of methyl iodide and 2,6-dimethylquinoline. It crystallized from absolute alcohol in yellow crystals, m. p. 239–240° (236–237°,[7] 246–247°[8]).

2,6-Dimethyl-1,2,3,4-tetrahydroquinoline was prepared by reducing 52 g. of 2,6-dimethylquinoline with tin and hydrochloric acid using the same procedure as for 2,8-dimethyl-1,2,3,4-tetrahydroquinoline. In this way 37.3 g. (70%) of product was obtained; b. p. 142–149° (25 mm.).

To a solution of 6 g. of this crude product in a mixture of 10 cc. of concentrated hydrochloric acid and 30 cc. of water was added 3 g. of sodium nitrite. After the oil which separated had been extracted with ether, the ether was evaporated in the cold and the residue added with cooling to 15 g. of stannous chloride and 75 cc. of concentrated hydrochloric acid. This mixture was allowed to stand for one-half hour before being heated on the steam-bath for fifteen minutes. It was then diluted with water and made basic with sodium hydroxide. The oil which volatilized on steam distillation was extracted from the distillate with ether. After drying over potassium hydroxide, the ether was distilled and then the product was distilled at 24 mm.; b. p. 147–149°; yield 2.5 g.

The benzoyl derivative prepared by the Schotten–Baumann method and crystallized from aqueous alcohol melted at 104–105° (103–105°).[9]

The zinc chloride–hydrochloric acid double salt melted at 187–195° after one crystallization from acetic acid.

The picrate when first prepared melted at 126–128°. After one crystallization from alcohol it melted at 150–155°. Another raised it to 165–169°. In both cases the solution turned red on heating, and, while the color disappeared on cooling, it reappeared after the filtrate had stood for one hour. (This red color was not encountered

(6) Doebner, *Ber.*, **33**, 677 (1900).
(7) Möller, *Ann.*, **242**, 300 (1887).

in recrystallizing the picrate of 2,8-dimethyl-1,2,3,4-tetrahydroquinoline and filtrates from this recrystallization were yellow after standing for thirty days.)

When the deep red filtrate from the recrystallization of the picrate of 2,6-dimethyl-1,2,3,4-tetrahydroquinoline was allowed to stand for thirty days, orange crystals separated. They were recrystallized from alcohol, m. p. 185–186°; mixed m. p. with the picrate of 2,6-dimethylquinoline (m. p. 186–187°) 186–187°. No crystals separated from the orange filtrate from the recrystallization of the picrate of 2,8-dimethyl-1,2,3,4-tetrahydroquinoline.

1,2,6-Trimethyl-1,2,3,4-tetrahydroquinoline hydriodide was prepared by mixing 17.6 g. of methyl iodide and 20.6 g. of the crude tetrahydroquinoline. So vigorous a reaction immediately took place that the mixture boiled violently. The resulting sticky red product was crystallized from alcohol giving 24 g. of a mixture of yellow and white crystals. Two crystallizations from water dissolved the yellow crystals to leave the white crystals, m. p. 187–188.5°. A mixed melting point of these with the hydriodide of 1,2,6-trimethyl-1,2,3,4-tetrahydroquinoline prepared below (m. p. 187.5–188.5°) was 187–188°.

1,2,6-Trimethyl-1,2,3,4-tetrahydroquinoline was prepared by refluxing 22 g. of 1,2,6-trimethylquinoline hydriodide with excess tin and hydrochloric acid for seven hours. The product obtained as in preceding preparations weighed 8.3 g. (64%); b. p. 145° (20 mm.); $n^{20}D$ 1.5611; d^{20}_4 0.9906; M_D calcd. 57.29; M_D found 57.31.

The hydriodide prepared by mixing equal volumes of the base and hydriodic acid of sp. gr. 1.50 crystallized from water in white crystals, m. p. 187.5–188.5°.

Anal. Calcd. for $C_{12}H_{18}NI$: I, 41.8. Found: I, 41.8.

The picrate after four crystallizations from alcohol appeared as yellow crystals, m. p. 141–142°.

Anal. Calcd. for $C_{18}H_{22}O_7N_4$: N, 13.88. Found: N, 13.76.

Summary

2,6-Dimethyl-1,2,3,4-tetrahydroquinoline has been found to be very much more unstable and reactive than 2,8-dimethyl-1,2,3,4-tetrahydroquinoline. Its N-methyl derivative, however, is stable. Eleven new compounds in the 2,6- and 2,8-dimethylquinoline series have been prepared and characterized.

Osage Orange Pigments. II. Isolation of a New Pigment, Pomiferin[1]

BY M. L. WOLFROM, F. L. BENTON, A. S. GREGORY, W. W. HESS, J. E. MAHAN AND P. W. MORGAN

The isolation of a new yellow pigment from the fruit of the osage orange (*Maclura pomifera* Raf.) has been reported previously[2] from this Laboratory. The name osajin was assigned to the substance and the data reported were shown to be in harmony with a provisional formula of $C_{25}H_{22}O_3(OH)_2$.

Osajin melts at 189°[3]. In the preparation of further material from the natural source it was found that material of this same melting point could be prepared which, however, depressed the melting point of highly purified samples of osajin that melted at the same point. Further investigation showed that two yellow pigments were present, the original osajin of melting point 189° and a second of melting point 200.5°. The name pomiferin is suggested for this second product. The data so far obtained for pomiferin and its derivatives indicate a probable formula of $C_{25}H_{21}O_3(OH)_3$, thus differing from osajin by the presence of one additional oxygen atom combined as an hydroxyl group. We now find that the substance described by us[2] as osajic acid di-*p*-toluenesulfonate was actually pomiferin di-*p*-toluenesulfonate (m. p. 148°) of high purity. The correct *p*-toluenesulfonate derivative of osajin has been prepared and has been found to be a mono-*p*-toluenesulfonate (m. p. 152°) crystallizing in beautiful, lustrous plates of a golden yellow color. We have also established the melting point of osajin diacetate as 164°. Other than this, the properties of osajin (m. p. 189°), osajin monoacetate (m. p. 159°), and of osajin diacetate (m. p. 164°) have been found correct as previously reported.

We also postulated the probable presence of a lactone group in osajin. We now believe that no lactone group is present but that the consumption of one equivalent of alkali by osajin is due to the presence of an acidic phenolic group, such as is present in gossypol and in other naturally occurring phenolic structures.

Pomiferin has been characterized by a number of derivatives. It forms a diacetate and a triacetate, a dimethyl ether and a trimethyl ether, and also a dimethyl ether monoacetate.

Both osajin and pomiferin are isomerized to

(1) Presented before the Division of Organic Chemistry at the 97th Meeting of the American Chemical Society, Baltimore, Maryland.

(2) E. D. Walter, M. L. Wolfrom and W. W. Hess, THIS JOURNAL, **60**, 574 (1938).

(3) All melting points herein reported are uncorrected.

high melting, colorless products by the action of sulfuric acid in glacial acetic acid. These substances have been designated iso-osajin and iso-pomiferin, respectively. Iso-osajin gives no phenolic ferric chloride test, while iso-pomiferin does. Pomiferin di-*p*-toluenesulfonate, which initially gives a phenolic ferric chloride test and possesses a slight tinge of yellow color, is isomerized under these same conditions to a colorless isomer which no longer gives a phenolic test with ferric chloride and which is identical with the product obtained by the reaction of the isomerized pomiferin with *p*-toluenesulfonyl chloride. It would thus appear that a phenolic or enolic group is concerned in this isomerization.

The relationship of the various derivatives of osajin and pomiferin described in this paper are given in Fig. 1.

Further work on these two pigments of the fruit of the osage orange is in progress in this Laboratory.

Experimental

Isolation and Properties of a Second Pigment (Pomiferin) from the Osage Orange.—The ground and dried meal of the whole, ripe fruit of the osage orange tree (*Maclura pomifera* Raf.) was extracted with petroleum ether and ether as described previously.[2] The ether-soluble material was recrystallized repeatedly from xylene until material of melting point 200.5° was obtained. This material was unchanged in melting point on further recrystallization from xylene, benzene or ethanol. The crystals were of a yellow color and were of a deeper tinge than osajin. The substance was slightly less soluble than osajin in the same organic solvents. The properties of the substance were similar to those of osajin and it exhibited the same general behavior with chemical reagents as described previously for osajin.[2] It also showed the same evidence of possessing phenolic rather than carboxylic acidity, as described below for osajin.

Both osajin and pomiferin give only yellow colorations with pyroboroacetate in acetic anhydride and with alcoholic nickel acetate.

Anal.[4] Calcd. for $C_{25}H_{24}O_6$: C, 71.42; H, 5.75; mol. wt., 420.4; Found: C, 71.47, 71.36; H, 5.90, 5.90; mol. wt. (Rast), 388, 361.

The mother liquor material from the pomiferin isolation was repeatedly recrystallized from ethanol and yielded the previously described osajin[2] of melting point 189°.

Evidence of Phenolic Nature of Osajin Acidity.—Osajin (1 g.), dissolved in 50 cc. of ether, was placed in a 200-cc. separatory funnel and the air displaced with methane (natural gas). The top of the funnel was connected to the outlet of a 60-cc. separatory funnel containing 20 cc. of a 10% sodium hydroxide solution. As the sodium hydroxide was allowed to drop, with shaking, into the ether solution of osajin, the yellow color in the ether layer gradually disappeared and the aqueous hydroxide layer became the characteristic greenish-yellow color of alkaline osajin. After the ether layer had become completely colorless, the upper funnel was removed and a stream of carbon dioxide was passed into the funnel containing the two layers. The color in the aqueous layer disappeared completely and the yellow color of osajin returned to the ether layer. Osajin was recovered on evaporation of the ether layer.

Pomiferin exhibited the same behavior when subjected to the identical treatment described above for osajin.

Osajin Mono-*p*-toluenesulfonate.—Osajin (1 g.) was dissolved in 10 cc. of dry pyridine and treated with a solution of *p*-toluenesulfonyl chloride (4 g.) in 15 cc. of dry pyridine. The solution stood at room temperature for eighteen hours and was then poured into 400 cc. of ice and water. The resultant gum hardened readily on standing at ice-box temperature for a few hours. It was removed by filtration, washed with water and recrystallized from absolute ethanol. Pure material was obtained on several recrystallizations from absolute ethanol; m. p. 152°, unchanged on further recrystallizations from either absolute ethanol or xylene–methanol. The substance crystallized as lustrous plates of a golden yellow color and gave a green coloration, in alcoholic solution, with ferric chloride.

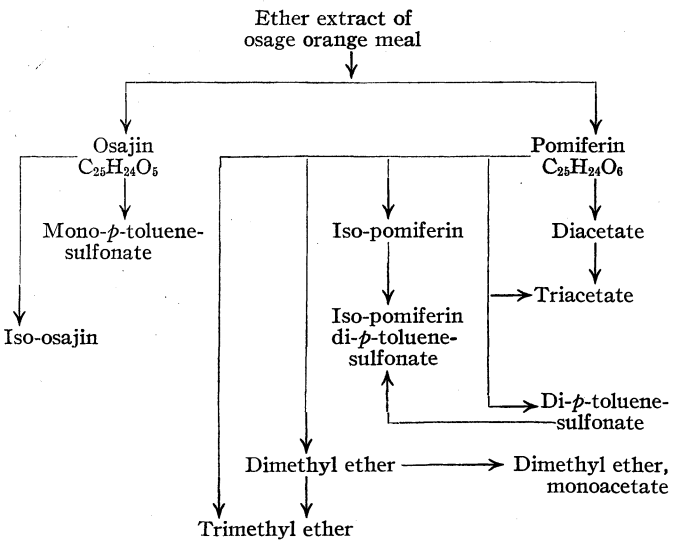

Fig. 1.

Anal. Calcd. for $C_{25}H_{23}O_4(OSO_2C_6H_4CH_3)$: C, 68.79; H, 5.41; S, 5.73; mol. wt., 558.5. Found: C, 68.84, 68.83; H, 5.42, 5.40; S, 5.79; mol. wt. (Rast), 584, 531.

Iso-osajin.—Osajin (5 g.) was dissolved in 75 cc. of boiling glacial acetic acid and 3 cc. of concentrated sulfuric acid added dropwise to the hot solution. The resulting dark orange solution was allowed to stand overnight at room temperature, after which an equal volume of water

(4) All combustion analyses herein reported were made by Dr. Ing. A. Schoeller, Berlin.

was added. The thick, curdy mass which separated crystallized on standing at ice-box temperature for an hour. The light yellow crystals were separated by filtration and washed several times with water; yield 4.1 g., m. p. 200–201°. Concentration of the mother liquors under reduced pressure yielded additional material; 0.56 g., m. p. 139°; total yield, 4.66 g. Recrystallization from absolute ethanol yielded pure colorless crystals, m. p. 285° (dec.).[5]

Iso-osajin is more difficultly soluble in organic solvents than osajin. An alcoholic solution of the substance shows no coloration with ferric chloride; it reduces Fehling's solution and, in pyridine solution, reduces Tollens' reagent. Iso-osajin was recovered unchanged when treated with an alcoholic solution of hydroxylamine acetate (refluxed for ten minutes and allowed to stand overnight). Iso-osajin is insoluble in cold 20% potassium hydroxide, but dissolves on boiling to give a greenish-yellow solution from which the substance can be recovered unchanged by acidification. The addition of a few drops of concentrated sulfuric acid to a solution of iso-osajin in glacial acetic acid gave only a deep yellow coloration. A negative test for sulfur was obtained by sodium fusion methods and by the Parr bomb. Iso-osajin also can be prepared by using an equivalent amount of concentrated hydrochloric acid in place of the sulfuric acid.

Anal. Calcd. for $C_{25}H_{24}O_5$: C, 74.25; H, 5.98; mol. wt., 404.4. Found: C, 74.24, 74.33; H, 6.00, 5.88; mol. wt. (Rast), 396, 361, 364.

Pomiferin Di-*p*-toluenesulfonate.—Pomiferin (2 g.) was treated as described for the prepartion of osajin mono-*p*-toluenesulfonate[2]; yield 2.9 g., m. p. 148°. This substance was identical (mixed m. p. unchanged) with the product of m. p. 148° previously described[2] as osajic acid di-*p*-toluenesulfonate.

Anal.[2] Calcd. for $C_{25}H_{22}O_4(OSO_2C_6H_4CH_3)_2$: C, 64.3; H, 4.98; S, 8.80; mol. wt., 728.8. Found: C, 64.4; H, 5.08; S, 8.75; mol. wt. (Rast), 680.

Iso-pomiferin.—Pomiferin was isomerized with sulfuric acid in glacial acetic acid as described for the preparation of iso-osajin and was purified by recrystallization from absolute ethanol; m. p. 265°.[5] The substance formed colorless needles and gave a green coloration with ferric chloride, changing to violet on the addition of ammonium hydroxide. It reduces Fehling's solution and, in pyridine solution, reduces Tollens' reagent. In cold 20% potassium hydroxide it turns yellow but does not dissolve; upon boiling, brownish yellow flocs form and the solution becomes dark yellow. Concentrated sulfuric acid added to a glacial acetic acid solution of the substance produces only a deep yellow color.

Anal. Calcd. for $C_{25}H_{24}O_6$: C, 71.42; H, 5.75; mol. wt., 420.4. Found: C, 71.53, 71.53; H, 5.69, 5.83; mol. wt. (Rast), 423, 399.

Iso-pomiferin Di-*p*-toluenesulfonate.—Pomiferin di-*p*-toluenesulfonate (1 g.) was isomerized with sulfuric acid in glacial acetic acid as described for the preparation of iso-osajin and the product was purified by recrystallization from alcohol followed by recrystallization from xylene by the addition of methanol; yield 0.72 g., m. p. 194°.

(5) Taken on a modified Berl–Kullman block as described by F. W. Bergstrom, *Ind. Eng. Chem., Anal. Ed.*, **9**, 340 (1937).

An alcoholic solution of the product shows no coloration with ferric chloride and does not reduce Fehling's solution or Tollens' reagent. A few drops of concentrated sulfuric acid added to a glacial acetic acid solution of the substance impart a very light yellow color. The compound was recovered unchanged after refluxing with acetic anhydride and sodium acetate for two hours.

Iso-pomiferin di-*p*-toluenesulfonate was also prepared by treating iso-pomiferin in pyridine solution with a pyridine solution of *p*-toluenesulfonyl chloride. The identity of the products was established by melting point and mixed melting point.

Anal. Calcd. for $C_{25}H_{22}O_4(OSO_2C_6H_4CH_3)_2$: C, 64.3; H, 4.98; S, 8.80; mol. wt., 728.6. Found: C, 64.1, 64.0; H, 5.11, 5.11; S, 8.55; mol. wt. (Rast), 645, 633.

Pomiferin Diacetate.—Pomiferin (1 g.) was dissolved in 12 cc. of pyridine and 24 cc. of acetic anhydride and placed in the ice-box overnight. This solution was poured into water and the crude material which separated was crystallized from methanol by the addition of water. The crystals were in the form of bright yellow plates; yield 1 g., m. p. 134.5°. Recrystallization from benzene and petroleum ether gave long, radiating needles. The melting point was not raised by recrystallization from benzene or ethanol.

The reactions and solubilities of this compound are similar to those of the monoacetate of osajin previously described.[2] The substance gave a green coloration, in alcoholic solution, with ferric chloride. Yellow crystals, m. p. 198.5°, were recovered after treatment of the compound with sodium hydroxide at ice-box temperature for three hours followed by acidification. The saponification was carried out in an atmosphere of nitrogen. A mixed melting point with pomiferin and this product showed no depression.

Anal. Calcd. for $C_{25}H_{22}O_4(OCOCH_3)_2$: C, 69.03; H, 5.59; saponification equivalent, 252.3 (3.96 cc. of 0.1 *N* NaOH per 100 mg.); mol. wt., 504.5. Found: C, 69.02, 69.22; H, 5.61, 5.57; saponification equivalent (Freudenberg method[6]), 255, 258 (3.93 cc. and 3.88 cc. of 0.1 *N* NaOH per 100 mg.); mol. wt. (Rast), 430.

Iso-pomiferin was recovered from the Freudenberg acetyl analyses and identified by melting point and mixed melting point. Pomiferin subjected to the conditions of this analysis yielded iso-pomiferin and no volatile esters.

Pomiferin Triacetate.—Pomiferin (1 g.) was refluxed for three hours with 75 cc. of acetic anhydride and 6 g. of fused sodium acetate. The mixture was poured into water and kept overnight at ice-box temperature. The crystalline material was removed by filtration; yield 1.2 g., m. p. 154°, unchanged on recrystallization from alcohol or from benzene by the addition of petroleum ether. The substance crystallized as colorless needles and gave no coloration, in alcoholic solution, with ferric chloride. Its solubilities and other reactions were much like those of osajin diacetate.

This compound also was prepared by treating pomiferin diacetate in the same manner.

Anal. Calcd. for $C_{25}H_{21}O_3(OCOCH_3)_3$: C, 68.1; H, 5.53; saponification equivalent, 182.2 (5.49 cc. of 0.1 *N* NaOH per 100 mg.); mol. wt., 546.6. Found: C, 68.07,

(6) K. Freudenberg and M. Harder, *Ann.*, **433**, 230 (1923).

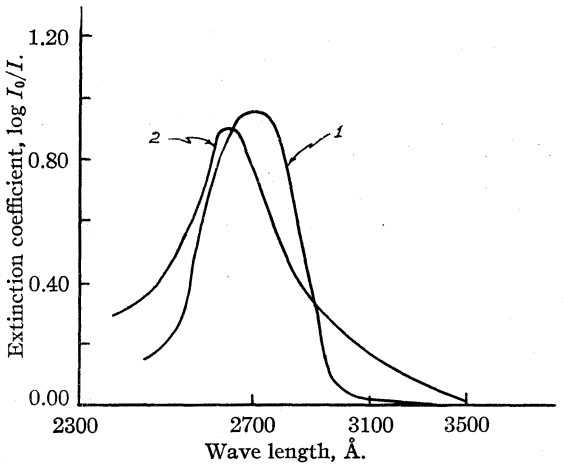

Fig. 2.—Curve 1—Absorption spectra of osajin: maximum at 2730 Å.; solvent, absolute ethyl alcohol; concentration 0.00166 g. /100 cc. Cell 0.4 cm. Curve 2—Absorption spectra of iso-osajin: maximum at 2660 Å.; solvent, absolute ethyl alcohol; concentration 0.00142 g./100 cc. Cell, 0.4 cm.

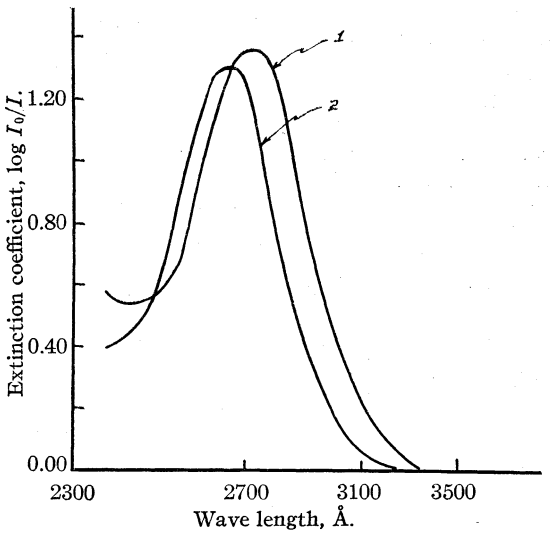

Fig. 3.—Curve 1—Absorption spectra of pomiferin: maximum at 2750 Å.; solvent, absolute ethyl alcohol; concentration 0.00303 g./100 cc.; cell 0.4 cm. Curve 2—Absorption spectra of iso-pomiferin: maximum at 2680 Å.; solvent, absolute ethyl alcohol; concentration, 0.00289 g./100 cc.; cell, 0.4 cm.

68.08; H, 5.59, 5.57; saponification equivalent (Freudenberg method,[6] 190, 191 (5.26 cc. and 5.25 cc. of 0.1 *N* NaOH per 100 mg.); mol. wt. (Rast), 540, 570.

Iso-pomiferin was recovered from the Freudenberg acetyl analyses and identified by melting point and mixed melting point.

Osajin acetylated as above yielded the previously described[2] diacetate, m. p. 164°.

Pomiferin Dimethyl Ether.—Pomiferin (1 g.) was methylated in 45 cc. of methyl alcohol under an atmosphere of nitrogen, by first adding a solution of 2.5 g. of potassium hydroxide in 40 cc. of methanol, cooling the mixture to 0° and, finally, adding 18 cc. of dimethyl sulfate with vigorous shaking of the mixture. The mixture was allowed to stand for an hour and was then poured into ice and water, filtered, and thrice recrystallized from ethanol; yield 1.1 g., m. p. 132°.

The substance crystallizes in fluffy masses of light yellow needles and is soluble in the common organic solvents. An alcoholic solution of the substance gives a green coloration with ferric chloride, but no violet coloration on the further addition of ammonia. In glacial acetic acid solution, it gives an orange coloration on the addition of sulfuric acid. It does not reduce Fehling's solution or Tollens' reagent (in pyridine solution). In carbon tetrachloride solution it shows bromine and iodine absorption. It is insoluble in hot aqueous solutions of sodium carbonate and potassium hydroxide. The substance shows no loss in weight on heating at 125–130° for several hours over phosphorus pentoxide under reduced pressure.

Anal. Calcd. for $C_{25}H_{22}O_4(OCH_3)_2$: C, 72.3; H, 6.29; OCH_3, 13.8; mol. wt., 448.4. Found: C, 72.2; H, 6.33; OCH_3, 13.6; mol. wt. (Rast), 428, 387.

The compound gives no positive saponification value even when heated at 90° with alcoholic sodium hydroxide for several hours.

Pomiferin Dimethyl Ether Monoacetate.—Pomiferin dimethyl ether (0.4 g.) was treated with 2 g. of anhydrous sodium acetate and 20 cc. of acetic anhydride and the mixture refluxed for three hours. The mixture was poured into ice and water, allowed to stand overnight and the product removed by filtration; yield, 0.43 g. Pure material was obtained on recrystallization from ethanol; m. p. 128–129°.

The substance crystallized as a fluffy mass of white needles. When dissolved in alcohol, it gives no coloration on the addition of ferric chloride. In glacial acetic acid solution, it gives a light yellow coloration on treatment with sulfuric acid. It gives no positive tests with Fehling's solution or Tollens' reagent (in pyridine). It is insoluble in aqueous sodium hydroxide.

Anal. Calcd. for $C_{25}H_{21}O_3(OCH_3)_2(OCOCH_3)$: C, 71.00; H, 6.16; sap. equiv., 490.4 (2.04 cc. of 0.1 *N* NaOH per 100 mg.); mol. wt., 490.4. Found: C, 71.16, 70.96; H, 6.14, 6.19; sap. equiv. (Freudenberg method,[6] 472, 483 (2.12 cc. and 2.07 cc. of 0.1 *N* NaOH per 100 mg.); mol. wt. (Rast), 458, 454.

Pomiferin Trimethyl Ether.—Pomiferin (2 g.) was dissolved in 130 cc. of acetone under reflux and to this solution, maintained at the boiling point, was added 24 cc. of dimethyl sulfate followed by six alternate portions of 6 cc. each of dimethyl sulfate and 8 cc. of 50% aqueous potassium hydroxide, all added as rapidly as possible. The solution was refluxed for two hours, during which time a white precipitate of potassium methyl sulfate separated, leaving a clear yellow solution. The mixture was cooled to room temperature, poured into one liter of ice and water and the excess methyl sulfate just neutralized with 10% potassium hydroxide. The white crystalline product which separated was removed by filtration and washed with water; yield 2.3 g., m. p. 120–125°. Pure material was obtained on recrystallization from ethanol; m. p. 139.5°, unchanged on further recrystallization. The substance was unchanged in weight on heating

at 110° for several hours over phosphorus pentoxide under reduced pressure.

An alcoholic solution of the product shows no coloration with ferric chloride and it does not reduce Fehling's solution. A chloroform solution of the substance absorbs bromine and it shows a yellow coloration in acetic acid on the addition of a few drops of sulfuric acid. The product was recovered unchanged after refluxing with acetic anhydride and sodium acetate for two hours. It was not affected by cold 20% potassium hydroxide but dissolved slowly on boiling to produce a light yellow solution.

Anal. Calcd. for $C_{25}H_{21}O_3(OCH_3)_3$: C, 72.7; H, 6.57; OCH_3, 20.1; mol. wt., 462.4. Found: C, 72.9; H, 6.69; OCH_3, 20.06; mol. wt. (Rast), 420, 437.

The same product was obtained by application of the same methylation procedure to pomiferin dimethyl ether. The identity of the products was established by melting point and mixed melting point.

Absorption Spectra.[7]—The absorption spectra of osajin, iso-osajin, pomiferin and iso-pomiferin were observed in absolute ethanol. The data are shown in Fig. 2 and Fig. 3. A single band spectrum was obtained for each compound.

Acknowledgment is gratefully made to the National Youth Administration for assistance rendered in this investigation.

Summary

1. A second yellow pigment has been isolated from the fruit of the osage orange tree (*Maclura pomifera* Raf.). The name pomiferin is assigned to this substance and it is shown that the experimental data so far obtained harmonize with a provisional formula of $C_{25}H_{24}O_6$.

2. The basicity of osajin is shown to be more in harmony with an acidic phenolic structure than with a lactone structure.

3. The substance previously described as osajic acid di-*p*-toluenesulfonate[2] is shown to be pomiferin di-*p*-toluenesulfonate.

4. Osajin forms a mono-*p*-toluenesulfonate (m. p. 152°).

5. The melting point of osajin diacetate is established as 164°.

6. A diacetate, triacetate, dimethyl ether, trimethyl ether, and dimethyl ether monoacetate of pomiferin have been prepared.

7. Both osajin and pomiferin are isomerized by sulfuric acid–glacial acetic acid mixtures to high-melting, colorless, crystalline substances.

8. Pomiferin di-*p*-toluenesulfonate is isomerized under the same conditions and the product is identical with the reaction product formed between iso-pomiferin and *p*-toluenesulfonyl chloride.

9. The absorption spectra of osajin, iso-osajin, pomiferin and iso-pomiferin have been observed.

COLUMBUS, OHIO RECEIVED AUGUST 9, 1939

(7) The absorption spectra measurements were made by Miss J. Appleton of this Laboratory, according to the method described in Brode, "Chemical Spectroscopy," John Wiley and Sons, Inc., New York, N. Y., 1939, p. 273.

Dibenzofuran. XIII. Orientation and Substituted Amines[1]

BY HENRY GILMAN, PAUL T. PARKER, JAMES C. BAILIE AND GEORGE E. BROWN

Introduction

Incidental to the determination of structure of substituted amines, it is now shown that the generalizations on orientation postulated previously[2] are adequate for the predominant products which result from polysubstitution of the dibenzofuran nucleus.

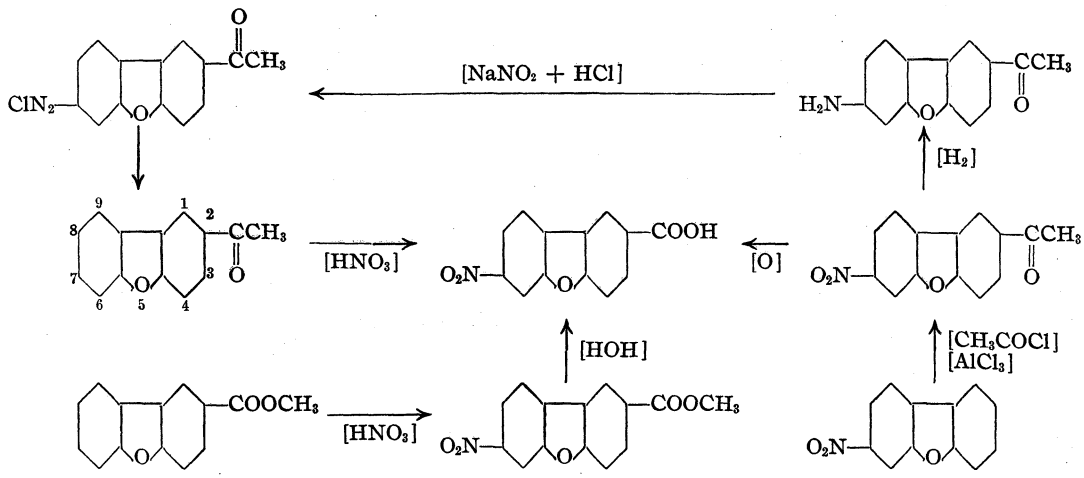
Nitration.—Nitration of a monosubstituted dibenzofuran having a strongly meta-orienting group proceeded heteronuclearly and the entering nitro group went largely to the 7-position, and the 8-position was involved only to a subordinate extent. The nitro acid obtained from nitration of 2-acetyldibenzofuran was identical with that obtained from nitration of methyl 2-dibenzofurancarboxylate. The same acid resulted by oxidation of the acetyl-3-nitrodibenzofuran prepared by a Friedel–Crafts reaction with 3-nitrodibenzofuran.

The chief nitro ester obtained by nitration of methyl 3-dibenzofurancarboxylate was methyl 2-nitro-7-dibenzofurancarboxylate. The position of the nitro group was shown by hydrolysis to a nitro acid which on decarboxylation yielded 2-nitrodibenzofuran.

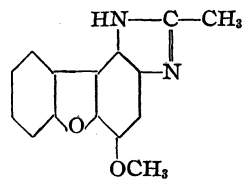
Nitration of 1-acetamino-4-methoxydibenzofuran took place homonuclearly, as might have been predicted, and the nitro group was directed ortho to the acetamino group. The structure of

(1) Paper XII, THIS JOURNAL, **61**, 1371 (1939).

(2) Gilman, Brown, Bywater and Kirkpatrick, *ibid.*, **56**, 2473 (1934); Gilman, Van Ess and Hayes, *ibid.*, **61**, 643 (1939). See, also, Cullinane, *J. Chem. Soc.*, 2365 (1932).



the 1-acetamino-2-nitro-4-methoxydibenzofuran was established by reduction and cyclization to a methoxy-imidazole. Incidentally, it was shown



that the nitro group did not go ortho to the methoxy group, for the replacement of the original acetamino group by hydrogen gave a nitro-4-methoxydibenzofuran unlike the known 3-nitro-4-methoxydibenzofuran.[3]

The nitration product of 1-bromo-4-methoxydibenzofuran was shown to be 1-bromo-3-nitro-4-methoxydibenzofuran, for debromination and reduction gave a quantitative yield of the known 3-amino-4-methoxydibenzofuran.[3]

Nitration of 2-acetyl-7-acetaminodibenzofuran must have introduced a nitro group ortho to the acetamino group because reduction and cyclization gave an acetyl-imidazole. The nitro group undoubtedly entered the 8-position rather than the 6-position, for there is no case of direct nuclear substitution (other than metalation) into the 4- or the 6-position.[4]

Nitration of 4-bromo- and 4-iododibenzofuran would be expected to go heteronuclearly to a predominant extent, for nitration of 2-bromodibenzofuran gave 2-bromo-7-nitrodibenzofuran.[5] Furthermore, the nitrobromo compound obtained by nitration of 3-bromodibenzofuran[5] has now been shown to be 3-bromo-7-nitrodibenzofuran because catalytic reduction replaced the bromine by hydrogen and reduced the nitro group to give 3-aminodibenzofuran. A similar reduction of the nitro-4-iododibenzofuran did not reduce the nitro group appreciably, and the chief product was 3-nitrodibenzofuran.

Bromination and Thiocyanogenation.—Bromination of ethyl 2-dibenzofurancarboxylate gave ethyl 2-bromo-8-dibenzofurancarboxylate. This structure followed from the fact that the bromo acid obtained by hydrolysis of the bromo ester was identical with the bromo acid obtained by oxidation of the Friedel–Crafts acetylation product of 2-bromodibenzofuran.

Thiocyanogenation of 3-aminodibenzofuran introduced the thiocyanogen group either into the 2- or the 4-position because the aminothiocyanogen compound could be rearranged to a thiazole. The thiocyanogen group undoubtedly entered the 2-position. Thiocyanogenation is like halogenation, and it is known that bromination of 3-acetaminodibenzofuran gives 2-bromo-3-acetaminodibenzofuran.[5] In addition, we already have mentioned the improbability of direct substitution into a 4- or 6-position.

Friedel–Crafts Reactions.—Diacetylation of dibenzofuran[6] and acetylation of 2-acetyldibenzofuran gave 2,8-diacetyldibenzofuran, identified by oxidation to the corresponding dibasic acid. Acetylation of methyl 4-dibenzofurancarboxylate gave methyl 2-acetyl-6-dibenzofurancarboxylate, the structure of which was established by hydrolysis and then decarboxylation to yield 2-acetyldi-

(3) Gilman, Jacoby and Swislowsky, THIS JOURNAL, **61**, 954 (1939).

(4) In the preparation of pyridodibenzofurans by the Skraup synthesis with 3-aminodibenzofuran, one of the isomers involves a ring closure in the 4-position. See Mosettig and Robinson, *ibid.*, **57**, 902 (1935), and Kirkpatrick and Parker, *ibid.*, **57**, 1123 (1935). It is understood that a suitable accumulation of groups might force a direct nuclear substitution to the 4- or 6-position.

(5) Gilman, Brown, Bywater and Kirkpatrick, *ibid.*, **56**, 2473 (1934).

(6) Borsche and Schacke, *Ber.*, **56**, 2498 (1923).

benzofuran, and by making the reasonable assumption that heteronuclear substitution occurs when a strongly meta-orienting group is present. This assumption has great validity because bromine, which has a less marked heteronuclear orientation effect than a carbomethoxy group, directs acylation heteronuclearly. For example, acetylation of 2-bromodibenzofuran gave 2-acetyl-8-bromodibenzofuran, the structure of which was established by oxidation to a 2-bromodibenzofurancarboxylic acid, which on debromination yielded 2-dibenzofurancarboxylic acid.

Acetylation of 2,8-dibromodibenzofuran gave 2,8-dibromo-3-acetyldibenzofuran. The structure of this product was proved by debromination and then oxidation of the resulting 3-acetyldibenzofuran to the known 3-dibenzofurancarboxylic acid.

Other Friedel–Crafts reactions have been mentioned in the discussion of nitration, and the Experimental Part describes additional reactions of this kind leading to amino derivatives of the brazan and other types. A miscellany of reactions other than those concerned with direct nuclear substitution are also contained in the Experimental Part.

Experimental Part

Nuclear Substitutions of 4-Derivatives

1-Bromo-4-methoxydibenzofuran.—A solution of 27.5 g. (0.17 mole) of bromine in 170 cc. of acetic acid was added in several portions to a solution of 34 g. (0.17 mole) of 4-methoxydibenzofuran in 340 cc. of acetic acid at room temperature with shaking. Decolorization was immediate. After standing overnight the product was thrown out of solution by diluting with water. Crystallization from ethanol gave 42 g. (88%) of material melting at 96–97°. A second recrystallization gave the pure product melting at 97–97.5° which showed no depression in melting point when mixed with an authentic specimen prepared by the methylation of 1-bromo-4-hydroxydibenzofuran.[7]

4-Methoxy-1-dibenzofurancarboxylic Acid.—The Grignard reagent prepared from 5 g. (0.018 mole) of 1-bromo-4-methoxydibenzofuran and 0.5 g. (0.02 g. atom) of magnesium in a mixture of 25 cc. of ether and 10 cc. of benzene was carbonated in the customary manner. A yield of 2.7 g. (62%) of the pure compound (crystallization from ethanol) was obtained melting at 279–280° with decomposition.

Anal. Calcd. for $C_{14}H_{10}O_4$: C, 69.40; H, 4.13. Found: C, 69.67 and 69.00; H, 4.61 and 4.90.

1-β-Hydroxyethyl-4-methoxydibenzofuran.—To an ice-cold solution of the Grignard reagent prepared from 22.2 g. (0.08 mole) of 1-bromo-4-methoxydibenzofuran was added 8.0 g. (0.18 mole) of ethylene oxide. The solution was allowed to warm to room temperature and then refluxed for one hour. After standing overnight, most of the ether was distilled off and replaced by dry benzene, and refluxing was continued for one hour. The resulting mixture was hydrolyzed by ice and 30% sulfuric acid, and the benzene layer was washed with sodium carbonate solution, dried and distilled under reduced pressure. The material, 11.5 g. (59%), distilled between 195–206° (2 mm.). Recrystallization from petroleum ether (b. p., 60–68°) gave crystals melting at 96–96.5°.

Anal. Calcd. for $C_{15}H_{14}O_3$: C, 74.35; H, 5.83. Found: C, 74.42; H, 6.03.

1-β-Diethylaminoethyl-4-methoxydibenzofuran Hydrochloride.—Dry hydrogen bromide was bubbled through 8.8 g. (0.028 mole) of molten 1-β-hydroxyethyl-4-methoxydibenzofuran for two and one-half hours at 100°. After washing with water and recrystallizing twice from ethanol, the product weighed 2.0 g. and melted at 91–91.5°. The 1-β-bromoethyl-4-methoxydibenzofuran was mixed with 2.0 g. (0.016 mole) of diethylamine and 2 cc. of ethanol and heated for six hours at 100°. When cool the reaction product was treated with 5% sodium hydroxide solution and extracted with ether. The ether solution was evaporated and the residue warmed to drive off the excess diethylamine. Saturating an ether solution of the residual oil with dry hydrogen chloride precipitated the salt which was purified by recrystallizing from an acetone–ether mixture. The yield was 1.5 g. (68%) of hydrochloride melting at 187° with decomposition.

Anal. Calcd. for $C_{19}H_{24}O_2NCl$: N, 4.20. Found: N, 4.26 and 4.43.

1-Acetyl-4-methoxydibenzofuran.—A Friedel–Crafts reaction was effected with 10 g. (0.05 mole) of 4-methoxydibenzofuran in 50 cc. of carbon disulfide, 6.8 g. (0.05 mole) of aluminum chloride and 4.0 g. (0.05 mole) of acetyl chloride. One recrystallization of the crude material from ethanol gave 8.0 g. (66%) of product melting at 132–133°. A second recrystallization raised the melting point to 134–134.5°.

Anal. Calcd. for $C_{15}H_{12}O_3$: C, 74.97; H, 5.04. Found: C, 74.66 and 75.30; H, 5.42 and 5.39.

Oxidation of 1 g. (0.004 mole) of the 1-acetyl-4-methoxydibenzofuran in 130 cc. of water containing 2 g. of sodium hydroxide with 3 g. (0.019 mole) of potassium permanganate gave a 90% yield of 4-methoxy-1-dibenzofurancarboxylic acid (mixed m. p.).

The oxime of 1-acetyl-4-methoxydibenzofuran was obtained in an 88% yield, and melted at 176–177.5° after crystallization from ethanol.

Anal. Calcd. for $C_{15}H_{13}O_3N$: N, 5.49. Found: N, 5.44.

Beckmann Rearrangement of the Oxime from 1-Acetyl-4-methoxydibenzofuran.—The rearrangement was effected in 95% yield by treating a suspension of the oxime in benzene with phosphorus pentachloride. The resulting **1-acetamino-4-methoxydibenzofuran** melted at 222–223° after crystallization from ethanol.

Anal. Calcd. for $C_{15}H_{13}O_3N$: N, 5.49. Found: N, 5.43 and 5.47.

Refluxing a solution of 2 g. (0.008 mole) of the 1-acetamino-4-methoxydibenzofuran in 200 cc. of 95% ethanol with 50 cc. of concd. hydrochloric acid gave a 91% yield

(7) Gilman and Van Ess, THIS JOURNAL, **61**, 1365 (1939).

of 1-amino-4-methoxydibenzofuran hydrochloride. The free base melting at 103–104° showed no depression in melting point with the 1-amino-4-methoxydibenzofuran obtained by reduction of 1-nitro-4-methoxydibenzofuran.[3]

1-Acetamino-2-nitro-4-methoxydibenzofuran.—Nitration of 0.8 g. (0.003 mole) of 1-acetamino-4-methoxydibenzofuran in glacial acetic acid with 1 cc. of fuming nitric acid gave a 74% yield of the nitro compound which melted at 244° after recrystallization from acetic acid.

Anal. Calcd. for $C_{15}H_{12}O_5N_2$: N, 9.33. Found: N, 9.30 and 9.69.

The acetamino compound was hydrolyzed in essentially quantitative yield by refluxing with concd. hydrochloric acid in ethanol. The **1-amino-2-nitro-4-methoxydibenzofuran** melted at 206–207° after crystallization from toluene.

Anal. Calcd. for $C_{13}H_{10}O_4N_2$: N, 10.85. Found: N, 10.36 and 10.70.

2-Nitro-4-methoxydibenzofuran.—The 1-amino-2-nitro-4-methoxydibenzofuran could not be diazotized by usual procedures; however, diazotization was effected in essential accordance with the directions of De Milt and Van Zandt.[8]

A mixture of 15 cc. of concd. sulfuric acid and 7.5 cc. of water was cooled to 5° in an ice-bath. Six-tenths of a gram (0.009 mole) of sodium nitrite was added and the mixture was warmed gently on the steam-bath until a clear solution resulted. This solution was cooled to 5–10° and a solution of 0.6 g. (0.0023 mole) of the 1-amino-2-nitro-4-methoxydibenzofuran in 12 cc. of pyridine was added dropwise over a period of forty-five minutes with continuous shaking. The temperature was maintained below 10° at all times. Following the addition of the pyridine solution the mixture was allowed to stand at this temperature for one-half hour and then stirred into 50 g. of ice. To remove the excess of nitrous acid, 0.6 g. of urea was added and the mixture stirred until foaming had ceased. Fifteen cc. of ethanol was added and the clear solution was refluxed for five minutes on the hot plate. When cool, the red-brown precipitate was recrystallized repeatedly from methanol, and there resulted a 35% yield of the 2-nitro-4-methoxydibenzofuran as light yellow, feathery needles melting at 185–186°.

Anal. Calcd. for $C_{13}H_9O_4N$: N, 5.76. Found: N, 5.72 and 5.66.

2-Amino-4-methoxydibenzofuran.—A suspension of 0.1 g. of the 2-nitro-4-methoxydibenzofuran in 25 cc. of ethanol was reduced at room temperature under forty-five pounds (4 atm.) gage pressure of hydrogen using Raney nickel as a catalyst. The amine was obtained in fine, slightly colored crystals melting at 127–127.5° after crystallization from ethanol.

Anal. Calcd. for $C_{13}H_{11}O_2N$: N, 6.57. Found: N, 6.74.

3-Dibenzofurylurea.—A solution of 9.15 g. (0.05 mole) of 3-aminodibenzofuran and 6.0 g. (0.057 mole) of nitrourea in 150 cc. of ethanol was allowed to stand at room temperature. A pearly, crystalline precipitate of pure 3-dibenzofurylurea had settled at the end of two days, weighing 7.5 g. (66.5% yield). In a capillary tube the material shows signs of softening at 215–220°, but does not melt up to 325°. On a nickel block the substance melts and resolidifies immediately at 222–223°.

Anal. Calcd. for $C_{13}H_{10}O_2N_2$: N, 12.38. Found: N 12.65 and 12.52.

Buck and Ferry[9] have observed that ethanol is a better medium than water for the reaction between amines and nitrourea.

4-Bromodibenzofuran.—An ether solution of 4-dibenzofuryllithium was prepared by metalating 42 g. (0.25 mole) of dibenzofuran with *n*-butyllithium. To the cooled solution was admitted a slow stream of bromine vapor obtained by bubbling nitrogen through 40 g. (0.25 mole) of bromine. The yield of 4-bromodibenzofuran melting at 70–71° was 40.5%.

Anal. Calcd. for $C_{12}H_7OBr$: Br, 25.05. Found: Br, 25.19.

4-Bromo-7-nitrodibenzofuran.—An acetic acid solution of 4-bromodibenzofuran was nitrated by fuming nitric acid to give 4-bromo-7-nitrodibenzofuran which melted at 205° after crystallization from acetic acid.

Anal. Calcd. for $C_{12}H_6O_3NBr$: N, 4.79. Found: N, 5.10 and 5.18. The residues are being examined for isomers.

4-Iodo-7-nitrodibenzofuran.—To a solution of 10 g. (0.034 mole) of 4-iododibenzofuran in 50 cc. of glacial acetic acid was added 8 cc. of fuming nitric acid, and the mixture was warmed and stirred for three hours. The yellow 4-iodo-7-nitrodibenzofuran was obtained in 32.4% yield, and melted at 223° after crystallization from acetic acid.

Anal. Calcd. for $C_{12}H_6O_3NI$: N, 4.13. Found: N, 4.13 and 4.14.

Reduction of 4-Iodo-7-nitrodibenzofuran and 3-Bromo-7-nitrodibenzofuran.—An absolute ethanol solution of 0.25 g. of 4-iodo-7-nitrodibenzofuran was reduced in essential accordance with the directions of Busch and Stöve[10] using the palladium catalyst and shaking for one and one half hours under a 15-pound gage pressure of hydrogen. A 32% yield of 3-nitrodibenzofuran (mixed m. p.) was obtained.

Under corresponding conditions, 3-bromo-7-nitrodibenzofuran[5] gave a 40% yield of 3-aminodibenzofuran (mixed m. p.).

Methyl 2-Acetyl-6-dibenzofurancarboxylate.—To a suspension of 13.5 g. (0.06 mole) of methyl 4-dibenzofurancarboxylate and 10.6 g. (0.08 mole) of aluminum chloride in 100 cc. of carbon disulfide was added 4.7 g. (0.06 mole) of acetyl chloride. After refluxing for eight hours and then allowing to stand overnight, there was obtained 2.5 g. (15.5%) of methyl 2-acetyl-6-dibenzofurancarboxylate which melted at 174–175° subsequent to recrystallization from ethanol. In addition there was recovered 9.6 g. of the initial ester.

Anal. Calcd. for $C_{16}H_{12}O_4$: C, 71.64; H, 4.48. Found: C, 71.47 and 71.38; H, 4.65 and 4.56.

Hydrolysis of the acetyl ester by heating with 20% sodium hydroxide gave 2-acetyl-6-dibenzofurancarboxylic acid, which when crystallized from dilute ethanol melted

(8) De Milt and Van Zandt, THIS JOURNAL, **58**, 2044 (1936).

(9) Buck and Ferry, *ibid.*, **58**, 854 (1936).

(10) Busch and Stöve, *Ber.*, **49**, 1063 (1916).

at 262–265°. This acetyl acid was decarboxylated by heating with copper bronze and quinoline for one-half hour at 235–240° to give 2-acetyldibenzofuran (mixed m. p.).

Nuclear Substitutions of 3-Derivatives

2-Acetyl-7-nitrodibenzofuran.—A Friedel–Crafts reaction was carried out with a suspension of 56 g. (0.26 mole) of 3-nitrodibenzofuran in 400 cc. of nitrobenzene, 53 g. (0.40 mole) of powdered aluminum chloride, and 33 g. (0.42 mole) of acetyl chloride. Subsequent to hydrolysis the aqueous layer was decanted from the resulting gelatinous precipitate and nearly all of the nitrobenzene was removed by steam distillation. Complete removal of the solvent was effected by shaking the residue with methanol, filtering, and washing the material with an additional small quantity of methanol. The crude product weighed 62 g. (93.5%) and melted at 208–210°. Crystallization from acetic acid gave the pure compound melting at 212–213°.

Anal. Calcd. for $C_{14}H_9O_4N$: N, 5.49. Found: N, 5.58 and 5.62.

When carbon disulfide was used as the medium, the 3-nitrodibenzofuran was recovered unchanged after heating for eight hours.

2-Acetyl-7-aminodibenzofuran.—If the nitro compound used in this preparation was washed with dilute ammonium hydroxide and thoroughly dried, it was hydrogenated easily with Raney nickel catalyst. Twenty grams (0.079 mole) of 2-acetyl-7-nitrodibenzofuran suspended in 150 cc. of absolute ethanol was reduced with hydrogen at steam temperature under forty-five pounds gage pressure using approximately 10 cc. of an alcoholic suspension of Raney nickel catalyst. Reduction required about an hour and gave practically a quantitative yield of the crude amine melting at 156°. After recrystallization from ethanol the 2-acetyl-7-aminodibenzofuran melted at 158–159°.

Anal. Calcd. for $C_{14}H_{11}O_2N$: N, 6.22. Found: N, 6.26 and 6.54.

2-Acetyl-7-acetaminodibenzofuran and Its Oxime.—A nearly quantitative yield of the crude monoacetamino compound was obtained, at room temperature, by adding 8.7 g. (0.08 mole) of acetic anhydride to a well-stirred solution of 15.3 g. (0.068 mole) of the 2-acetyl-7-aminodibenzofuran in 150 cc. of acetic acid diluted with 35 cc. of water. The acetamino compound, which precipitated immediately, was recrystallized from ethanol and finally from benzene to yield cotton-like needles melting at 203°.

Anal. Calcd. for $C_{16}H_{13}O_3N$: N, 5.24. Found: N, 5.32.

A portion of this compound was converted to the oxime to make certain that reduction of the ketone group had not occurred in the preceding hydrogenation. A solution of 0.5 g. of potassium hydroxide in 5 cc. of water was added to a solution of 1.35 g. (0.005 mole) of the 2-acetyl-7-acetaminodibenzofuran and 0.5 g. (0.007 mole) of hydroxylamine hydrochloride in 75 cc. of ethanol. After four and one-half hours of refluxing the solution was poured into water and the precipitate filtered off. Crystallization from ethanol gave a 64% yield of colorless crystals of **1-acetyl-7-acetaminodibenzofuran oxime** melting at 203°. A mixed melting point with the starting material was 176–178°.

Anal. Calcd. for $C_{16}H_{14}O_3N_2$: N, 9.92. Found: N, 9.92.

Replacement of Amino Group in 2-Acetyl-7-aminodibenzofuran by Hydrogen.—The acetyl-amino compound was diazotized, and by customary procedures, using ethanol, the diazonium group was replaced by hydrogen. The resulting 2-acetyldibenzofuran was identified by mixed melting point.

Oxidation of 2-Acetyl-7-nitrodibenzofuran.—A solution of 16 g. of the acetyl-nitro compound in 150 cc. of acetic acid was oxidized by heating for three hours with 80 g. of chromic acid in 150 cc. of acetic acid. The resulting 3-nitro-7-dibenzofurancarboxylic acid, purified through the sodium salt, was obtained in a yield of 11.5 g. (72%) and was observed to soften at 295° and decompose at 300°.

Anal. Calcd. for $C_{13}H_7O_5N$: N, 5.45; neut. equiv., 256. Found: N, 5.53 and 5.51; neut. equiv., 251 and 252.

The following oxidizing agents were not satisfactory: acid or neutral potassium permanganate, bromine, sodium dichromate and sulfuric acid, and "Perchloron" (70% calcium hypochlorite).

Nitration of Methyl 3-Dibenzofurancarboxylate.—The 3-dibenzofurancarboxylic acid (m. p. 270°) was prepared in an 84% yield by carbonation of 3-dibenzofurylmagnesium bromide. Esterification by methanol and hydrogen chloride gave a quantitative yield of methyl 3-dibenzofurancarboxylate.

Nitration of 6 g. (0.0265 mole) of methyl 3-dibenzofurancarboxylate by a mixture of 32.5 cc. of concd. nitric acid and 5 cc. of fuming nitric acid gave 2.5 g. (34.8%) of **methyl 2-nitro-7-dibenzofurancarboxylate** which melted at 235–236° after recrystallization from acetic acid.

Anal. Calcd. for $C_{14}H_9O_5N$: N, 5.17. Found: N, 5.28 and 5.13.

In addition to some unaltered ester, there was isolated another nitro ester which melted at 202–203° and which was probably **methyl 3-nitro-7-dibenzofurancarboxylate.**

Hydrolysis of the methyl 2-nitro-7-dibenzofurancarboxylate by heating with a mixture of acetic and hydrochloric acids gave **2-nitro-7-dibenzofurancarboxylic acid** which did not melt at 330°. This nitro acid was decarboxylated, by heating with quinoline and copper, to yield 2-nitrodibenzofuran (mixed m. p.).

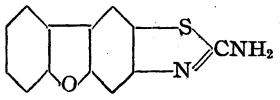
3-Amino-2-dibenzofurylthiocyanate.—Five grams (0.027 mole) of 3-aminodibenzofuran and 8.5 g. (0.11 mole) of ammonium thiocyanate were dissolved in 400 cc. of 95% acetic acid and cooled to 1–3°. A solution of 4.3 g. of bromine in 25 cc. of acetic acid was then added dropwise over a period of fifteen minutes to the vigorously stirred mixture. Despite the addition of 100 cc. more of 95% acetic acid a complete solution could not be maintained at this temperature. The crude material was recrystallized from hot ethanol to yield 2.8 g. (43%) of slightly crude 3-amino-2-dibenzofurylthiocyanate. Further recrystallization gave the pure product melting at 175° with immediate resolidification.

Anal. Calcd. for $C_{13}H_8OSN_2$: N, 11.66. Found: N, 11.88 and 11.62.

The compound gave the characteristic yellow precipitate always formed when an alkaline lead tartrate solution is

added to an ethanolic solution of a thiocyanate.[11] Rearrangement had not taken place to the thiazole, for the thiazole compound (described below) gave a white precipitate under corresponding conditions.

2 - Aminobenzofuro[2,3-*f*]benzothiazole.—A rearrangement of the 3-amino-2-dibenzofurylthiocyanate to the thiazole compound was effected by refluxing an ethanolic



solution with hydrochloric acid for one-half hour. A quantitative yield of the crude compound was obtained which was recrystallized several times from benzene to give the pure product melting at 268–269°.

Anal. Calcd. for $C_{13}H_8OSN_2$: N, 11.66. Found: N, 11.64 and 11.62.

The hydrochloride, precipitated from an ether solution of the base by dry hydrogen chloride, decomposed above 300°.

Nuclear Substitutions of 2-Derivatives

2,8-Diacetyldibenzofuran.—This diacetyl derivative was prepared by Friedel–Crafts reactions starting with either dibenzofuran or 2-acetyldibenzofuran. To a solution of 67.2 g. (0.4 mole) of dibenzofuran and 80 g. (0.6 mole) of aluminum chloride in 200 cc. of carbon disulfide was added 31.4 g. (0.4 mole) of acetyl chloride. The reaction products were fractionated under reduced pressure. The yield of pure 2-acetyldibenzofuran ranged from 46 to 57%, and the yield of 2,8-diacetyldibenzofuran was about 8%. With acetic anhydride, the yield of diacetyl compound increased somewhat at the expense of the monoacetyl compound. Nitrobenzene appeared less satisfactory as a medium, for the yield of monoacetyl compound was 40% and the mixture was worked up with greater difficulty.

Under essentially corresponding conditions, 18 g. (0.086 mole) of 2-acetyldibenzofuran, 22.8 g. (0.17 mole) of aluminum chloride, 7.3 g. (0.09 mole) of acetyl chloride and 100 cc. of carbon disulfide yielded 7 g. (32%) of 2,8-diacetyldibenzofuran. The diacetyl compound melted in all cases at 160° and not at 140° as reported previously.[6] The identity of our diacetyl compound was established by oxidation to 2,8-dibenzofurandicarboxylic acid. Incidentally this dibasic acid was also synthesized in a low yield by carbonation of the di-Grignard reagent prepared from 2,8-dibromodibenzofuran. It was, however, best prepared by carbonation of the dilithium compound obtained by interaction of *n*-butyllithium and 2,8-dibromodibenzofuran. Metalation of 2,8-dibromodibenzofuran by means of phenylcalcium iodide, and then carbonation yielded 2,8-dibromo-4,6-dibenzofurandicarboxylic acid.[12]

The oxime of 2-acetyldibenzofuran was obtained in a 97% yield, and melted after crystallization from ethanol at 139–140°.

Oxidation of 10 g. (0.03 mole) of 2-acetyldibenzofuran by an alkaline solution of "Perchloron" gave a 97% yield of 2-dibenzofurancarboxylic acid melting at 236–242°. Recrystallization from ethanol raised the melting point to 247–248°. The procedure described was less satisfactory when larger quantities of reactants were used. 2-Acetyldibenzofuran was first oxidized to 2-dibenzofurancarboxylic acid by means of calcium hypochlorite.[13]

2,8-Dibromo-3-acetyldibenzofuran.—From reaction between 22.8 g. (0.07 mole) of 2,8-dibromodibenzofuran, 13.3 g. (0.1 mole) of aluminum chloride and 5.5 g. (0.07 mole) of acetyl chloride in 150 cc. of carbon disulfide was obtained 10 g. (35%) of 2,8-dibromo-3-acetyldibenzofuran melting at 157–157.5° after crystallization from acetic acid.

Anal. Calcd. for $C_{14}H_8O_2Br_2$: Br, 43.48. Found: Br, 43.67 and 43.72.

The structure of the dibromo-acetyl compound was established by first replacing the bromines by hydrogen (palladium–calcium carbonate catalyst) to get a relatively pure 3-acetyldibenzofuran which melted at 120–122° after crystallization from ethanol; and then oxidizing the acetyl compound by alkaline permanganate to 3-dibenzofurancarboxylic acid, which was compared with an authentic specimen.

Nitration of 2-Acetyldibenzofuran.—The nitro-acetyl compound obtained by earlier workers[6] was not isolated by us; instead, a nitro acid was obtained which melted at 290°.

Methyl 3-Nitro-8-dibenzofurancarboxylate.—A 95% yield of methyl 2-dibenzofurancarboxylate, melting at 73–74° after crystallization from petroleum ether (b. p. 60–68°), was obtained by the rapid addition of hydrogen chloride to a heated suspension of 2-dibenzofurancarboxylic acid in methanol. When the ester was nitrated in essential accordance with the directions described recently[14] for the nitration of methyl 4-dibenzofurancarboxylate, one of the products isolated melted at 239–240°.

Acetylation of 2-Bromodibenzofuran.—A 32% yield of 2-bromo-8-acetyldibenzofuran distilling at 205° (4 mm.) was obtained by a Friedel–Crafts reaction between 2-bromodibenzofuran and acetyl chloride in carbon disulfide. Oxidation of the bromo-acetyl compound by means of hypochlorite gave 2-bromo-8-dibenzofurancarboxylic acid melting at 328°. Debromination of the bromo acid by means of hydrogen and the palladium–calcium carbonate catalyst gave 2-dibenzofurancarboxylic acid (mixed m. p.).

Ethyl 2-Bromo-8-dibenzofurancarboxylate.—Ethyl 2-dibenzofurancarboxylate, prepared by the addition of absolute ethanol to the reaction mixture of 2-dibenzofurancarboxylic acid and thionyl chloride, melted at 54°. To 5 g. (0.02 mole) of this ester in 30 cc. of glacial acetic acid was added 3.33 g. (0.02 mole) of bromine. The mixture was heated for eight hours at 70° and finally for four hours at 115° before bromine vapors ceased refluxing. A part of the product was 2-bromo-8-dibenzofurancarboxylic acid. The main fraction (28% yield) was ethyl 2-bromo-8-dibenzofurancarboxylate which melted at 130°.

Anal. Calcd. for $C_{15}H_{11}O_3Br$: Br, 32.36. Found: Br, 32.53 and 32.40.

The ester was hydrolyzed quantitatively, by refluxing with a mixture of acetic and concd. hydrochloric acids, to 2-bromo-8-dibenzofurancarboxylic acid which melted with decomposition at 328°.

Neutralization equivalent. Calcd. for $C_{13}H_7O_3Br$: 291.

Found: 290. A comparison of this bromo acid with that obtained from the Friedel-Crafts reaction with 2-bromodibenzofuran showed them to be the same.

1-Bromo-3-nitro-4-methoxydibenzofuran and its Reduction to 3-Amino-4-methoxydibenzofuran.—A mixture of 10 g. (0.036 mole) of 1-bromo-4-methoxydibenzofuran, 10 cc. of fuming nitric acid (sp. gr. 1.50) and 75 cc. of glacial acetic acid was heated with stirring for one and one-half hours at 90–95°. The yield of 1-bromo-3-nitro-4-methoxydibenzofuran, melting at 160–161°, was 47.5%. The acetic acid filtrate from the nitration contains the initial compound which can be recovered readily and used in a second nitration.

Anal. Calcd. for $C_{13}H_8O_4NBr$: N, 4.35. Found: N, 4.31.

When an ethanolic solution of the bromonitromethoxy compound was reduced using the palladium–calcium carbonate catalyst, there resulted a quantitative yield of 3-amino-4-methoxydibenzofuran (mixed m. p.).

1-Bromo-3-amino-4-methoxydibenzofuran.— Reduction of an acetic acid solution of the bromonitromethoxy compound by stannous chloride and hydrochloric acid gave a practically quantitative yield of 1-bromo-3-amino-4-methoxydibenzofuran which melted at 135–136° after crystallization from ethanol.

Anal. Calcd. for $C_{13}H_{10}O_2NBr$: N, 4.79. Found: N, 4.95.

1-Bromo-3-acetamino-4-methoxydibenzofuran prepared by acetylation of the corresponding amine melted at 178–179° after crystallization from ethanol.

Anal. Calcd. for $C_{15}H_{12}O_3NBr$: N, 4.19. Found: N, 4.50.

Brazan Derivatives

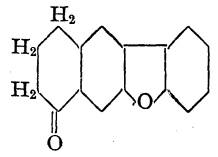
β-[2-Dibenzofuroyl]-propionic Acid.—This compound was originally prepared by Mayer and Krieger[13,15] but the method by which it was obtained was not described. The following procedure is based on the one used by Fieser and Hershberg[16] for the Friedel–Crafts reaction of succinic anhydride with phenol ethers.

Dibenzofuran, 84.0 g. (0.5 mole), and succinic anhydride, 55.0 g. (0.55 mole), were suspended in a mixture of 400 cc. of tetrachloroethane and 200 cc. of nitrobenzene. With the temperature of the mixture held at 0–5°, 147.0 g. (1.1 moles) of powdered aluminum chloride was added in small portions with vigorous stirring. Subsequent to hydrolysis and steam distillation, the residue was filtered and extracted several times with hot sodium carbonate solution. The combined filtrates were acidified with dilute hydrochloric acid and the dried precipitate recrystallized from ethyl acetate to give 111 g. (83%) of the purified compound which melted at 185–186° in agreement with the value reported by Mayer and Krieger.[13]

β-[2-Dibenzofuryl]-*n*-butyric Acid.—For the reduction of the dibenzofuroylpropionic acid, the modified Clemmensen method reported by Martin[17] was employed.

Fifty-five grams of β-[2-dibenzofuroyl]propionic acid was suspended in a mixture of 100 cc. of toluene, 75 cc. of water and 175 cc. of concd. hydrochloric acid, and refluxed for twenty-five hours with 100 g. of amalgamated zinc. Three additional 50-cc. portions of concd. hydrochloric acid were added at approximately six-hour intervals. Crystallization from petroleum ether (b. p. 80–100°) gave 43.6 g. (83%) of the pure compound melting at 112–113°, in agreement with the melting point reported.[13]

7 - Keto - 7,8,9,10 - tetrahydrobenzo[*b*]naphtho[2,3-*d*]-furan.—Five grams (0.02 mole) of β-[2-dibenzofuryl]-*n*-



butyric acid was stirred into 100 g. of 88% sulfuric acid and the mixture allowed to stand at room temperature for fifteen minutes. The resulting deep red solution was poured on ice and the dilute acid decanted from the precipitate. The crude material was washed by decantation and warmed with 50 cc. of 10% sodium carbonate solution. The insoluble product was filtered off and recrystallized from ethanol to give 2.0 g. (45%) of pure compound melting at 137°.

Anal. Calcd. for $C_{16}H_{12}O_2$: C, 81.32; H, 5.12. Found: C, 81.53; H, 5.56.

Using sulfuric acid as the cyclizing agent none of the isomeric keto compound was isolated.[18] Later, Robinson and Mosettig[15] used phosphoric acid as the condensing agent and obtained a 3–4% yield of the isomer, and also established the structure of the 137° compound by conversion to brazan (benzo[*b*]naphtho[2,3-*d*]furan).

The **oxime of 7-keto-7,8,9,10-tetrahydrobenzo[*b*]-naphtho[2,3-*d*]furan,** obtained in 85% yield, melted at 212–213° after crystallization from ethanol.

Anal. Calcd. for $C_{16}H_{13}O_2N$: N, 5.58. Found: N, 5.48.

7 - Amino - 7,8,9,10 - tetrahydrobenzo[*b*]naphtho[2,3-*d*]furan Hydrochloride.—Fifty grams of freshly prepared 2% sodium amalgam was added in small portions to a well-stirred solution of 1.7 g. (0.007 mole) of the oxime of 7-keto-7,8,9,10-tetrahydrobenzo[*b*]naphtho[2,3-*d*]furan in 65 cc. of absolute ethanol at a temperature of 55–60°. The solution was constantly maintained slightly acid by the dropwise addition of acetic acid. When reduction was complete the solution was decanted away from the mercury into several times its volume of water. The solution was made acid to litmus with acetic acid and extracted once with ether. The ether extract was discarded and the aqueous layer was made alkaline with dilute sodium hydroxide solution and extracted twice with ether. The ether extracts were dried, and dry hydrogen chloride passed into the solution. The amine hydrochloride was obtained in a 54% yield and melted at 266–267° after crystallization from an ethanol–ether mixture.

Anal. Calcd. for $C_{16}H_{16}ONCl$: N, 5.12. Found: N, 4.95 and 5.23.

7-Keto - 8 - dimethylaminomethyl - 7,8,9,10 - tetrahydrobenzo[*b*]naphtho[2,3-*d*]furan Hydrochloride.—The

method of Mannich and Braun,[19] as modified by Burger and Mosettig,[20] for the preparation of amino ketones was used in this synthesis.

A suspension of 2.4 g. (0.01 mole) of the 7-keto-7,8,9,10-tetrahydrobenzo[*b*]naphtho[2,3-*d*]furan, 1.0 g. (0.012 mole) of dimethylamine hydrochloride and 0.9 g. (0.03 mole) of trioxymethylene in 25 cc. of amyl alcohol was refluxed for five minutes. The hydrochloride was purified by carefully reprecipitating it several times from an absolute ethanolic hydrogen chloride solution with ether. The salt formed lustrous prisms melting at 185–186°. The yield of pure compound was 0.45 g. (14.3%).

Anal. Calcd. for $C_{18}H_{18}O_2NCl$: N, 4.43. Found: N, 4.39.

A repetition of this procedure with a longer time of refluxing gave no improvement in the yield.

Lateral Amino Derivatives

2-α-Aminoethyldibenzofuran Hydrochloride.—Interaction of 10.5 g. (0.05 mole) of 2-acetyldibenzofuran, 20 g. of ammonium formate and 5 cc. of acetic acid gave 2-α-aminoethyldibenzofuran hydrochloride which melted at 222–223° after crystallization from an acetone–ethanol mixture.

Anal. Calcd. for $C_{14}H_{13}ONCl$: N, 5.66. Found: N, 5.57 and 5.92.

2-α-Diethylaminoethyldibenzofuran Picrate.—Methyl-2-dibenzofurylcarbinol was prepared from 2-dibenzofurylmagnesium bromide and acetaldehyde.[21] The corresponding bromide, prepared by means of dry hydrogen bromide, was treated with diethylamine to give the highly hygroscopic diethylamino salt. The picrate of the amine melted at 173–174° after crystallization from aqueous acetone.

Anal. Calcd. for $C_{24}H_{24}O_8N_4$: N, 11.29. Found: N, 11.45.

2-β-Dimethylaminopropionyldibenzofuran.—A mixture of 20.0 g. (0.095 mole) of 2-acetyldibenzofuran, 7.8 g. (0.096 mole) of dimethylamine hydrochloride and 3.0 g. (0.096 mole) of trioxymethylene suspended in 40 cc. of absolute ethanol was heated on the steam-bath for twelve hours. When cool the precipitate was filtered off and the filtrate evaporated. The combined residues were shaken with ether to remove unchanged 2-acetyldibenzofuran. The ether-insoluble crude 2-β-dimethylaminopropionyldibenzofuran hydrochloride weighing 21.4 g. (74%) was purified by recrystallizing from ethanol to give crystals melting at 194–195°. The free base, obtained by adding dilute ammonium hydroxide to an aqueous solution of the salt, was recrystallized from petroleum ether (b. p. 60–68°) and melted at 88–89°.

Anal. Calcd. for $C_{17}H_{17}O_2N$: N, 5.24. Found: N, 5.30.

3-Ethylaminodibenzofuran Hydrochloride.—The experiments in this section provide a new physical constant[22] as well as some reactions of this compound. A mixture of 9.15 g. (0.05 mole) of 3-aminodibenzofuran and 10.5 g. (0.0525 mole) of ethyl *p*-toluenesulfonate was heated at 175–185° for one hour. After treatment with ammonium hydroxide and then with hydrogen chloride, the amine hydrochloride (3.5 g.) (33%) was found to melt at 228–229° with decomposition. Crystallization was from ethanol.

Anal. Calcd. for $C_{14}H_{14}ONCl$: N, 5.66. Found: N, 5.67.

The hydrochloride and sodium acetate in an ether–water medium gave a colorless oil which solidified to crystals melting at 69–70°.

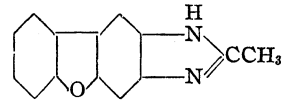
The **3-ethylnitrosoaminodibenzofuran** (prepared from the hydrochloride, sodium nitrite and dilute hydrochloric acid) crystallized from ethanol as bright orange crystals melting at 136–137°.

Anal. Calcd. for $C_{14}H_{12}O_2N_2$: N, 11.66. Found: N, 11.12.

Reduction of the nitrosoamine with stannous chloride and concd. hydrochloric acid gave the 3-ethylaminodibenzofuran hydrochloride (mixed m. p.).

Imidazoles

2-Methyl-1-benzofuro[2,3-*f*]benzimidazole.—3-Aminodibenzofuran was monoacetylated by adding 12 g. (0.12



mole) of acetic anhydride to a solution of 20 g. (0.11 mole) of 3-aminodibenzofuran in a mixture of 150 cc. of acetic acid and 200 cc. of water at a temperature between 40 and 50° with vigorous stirring. The thick, heavy precipitate which resulted in a few seconds was poured into water and filtered off to give a 97% yield of material suitable for nitration.

Nitration was effected by adding 3.5 cc. of fuming nitric acid (sp. gr. 1.50) to a solution of 10 g. (0.04 mole) of 3-acetaminodibenzofuran in 60 cc. of glacial acetic acid at 85–90°. The 2-nitro-3-acetaminodibenzofuran separated almost at once. The mixture was poured into an excess of water and filtered. Crystallization of the crude product from acetic acid yielded 9.2 g. (76%) of light yellow crystals melting at 196°.

To a hot solution of 2.0 g. (0.0074 mole) of 2-nitro-3-acetaminodibenzofuran in 25 cc. of acetic acid was cautiously added in several portions with shaking a solution of 8.0 g. (0.035 mole) of hydrated stannous chloride in 8.0 cc. of concd. hydrochloric acid and the solution heated for a few minutes. The crude imidazole was purified through its hydrochloride by recrystallizing from dilute hydrochloric acid. The hydrochloride (melting above 335°) was converted to the free base which melts at 270°, and was obtained in a yield of 0.9 g. (55%).[23]

Anal. Calcd. for $C_{14}H_{10}ON_2$: N, 12.61. Found: N, 12.79 and 12.87.

2-Methyl-5-methoxy-1-benzofuro[3,2-*e*]benzimidazole.—To a hot solution of 3.0 g. (0.01 mole) of 1-

(19) Mannich and Braun, *Ber.*, **53**, 1874 (1920).

(20) Burger and Mosettig, THIS JOURNAL, **58**, 1570 (1936).

(21) This compound was prepared earlier by Mosettig and Robinson, *ibid.*, **57**, 2186 (1935), by the catalytic hydrogenation of 2-acetyldibenzofuran.

(22) Kirkpatrick and Parker, *ibid.*, **57**, 1123 (1935).

(23) Weidenhagen and Weeden, *Ber.*, **71**, 2347 (1938), have reported a melting point of 264.5° for the free base and a decomposition point at about 278° for the hydrochloride.

acetamino-2-nitro-4-methoxydibenzofuran in 75 cc. of glacial acetic acid was added in several portions a solution of 12.5 g. (0.055 mole) of hydrated stannous chloride in 13.5 cc. of concd. hydrochloric acid. The mixture was then refluxed for five and one-half hours on the hot-plate. After diluting with 200 cc. of water the solution was made alkaline with 33% sodium hydroxide solution and the precipitate filtered off. The crude material was purified by boiling its methanol solution with Norite and saturating the cooled solution with dry hydrogen chloride. The hydrochloride precipitated in fine needles melting at 306–307° with decomposition. From the hydrochloride was obtained the free base in a yield of 1.8 g. (72.5%), melting at 222–222.5°.

Anal. Calcd. for $C_{15}H_{12}O_2N_2$: N, 11.10. Found: N, 10.95 and 11.16.

2 - Methyl - 8 - acetyl - 1 - benzofuro[2,3-*f*]benzimidazole.—First, **2-acetyl-7-acetamino - 8 - nitrodibenzofuran** was prepared. A solution of 5.4 g. (0.02 mole) of 2-acetyl-7-acetaminodibenzofuran in 120 cc. of glacial acetic acid was heated on the steam-bath with stirring, and 6 cc. of fuming nitric acid (sp. gr. 1.50) was added in one portion. The practically pure material thus obtained weighed 4.0 g. (64%) and melted at 269–270°. Crystallization from acetic acid raised the melting point to 270–271°.

Anal. Calcd. for $C_{16}H_{12}O_5N_2$: N, 8.97. Found: N, 9.19 and 9.00.

Four grams (0.013 mole) of 2-acetyl-7-acetamino-8-nitrodibenzofuran was suspended in 80 cc. of ethanol and reduced with hydrogen at 100° for one-half hour under a gage pressure of forty-five pounds using Raney nickel catalyst. The crude 2-acetyl-7-acetamino-8-aminodibenzofuran was refluxed one hour with 50 cc. of glacial acetic acid. The crude imidazole was obtained by diluting the acetic acid solution with water and making alkaline with ammonium hydroxide. The product was dissolved in hot methanol, boiled with Norite, and the solution saturated with dry hydrogen chloride. The pure hydrochloride precipitated in fine needles melting with decomposition at about 325°. From the hydrochloride was obtained the free base melting at 298° in a yield of 2.3 g. (55%).

Anal. Calcd. for $C_{16}H_{12}O_2N_2$: N, 10.59. Found: N, 10.73 and 10.96.

4-Dibenzofuryl Derivatives

1-(4-Dibenzofuryl)-isoquinoline.—This compound was prepared in essential accordance with the directions of Ziegler and Zeiser[24] for 1-*n*-butylisoquinoline, and the method is being extended to other dibenzofurylnitrogen heterocycles.

A solution of *n*-butyllithium prepared from 27.4 g. (0.2 mole) of *n*-butyl bromide and 2.8 g. (0.4 g. atom) of lithium in 300 cc. of ether was refluxed with 30 g. (0.18 mole) of dibenzofuran under a nitrogen atmosphere for four and one-half hours. The resulting solution of 4-dibenzofuryllithium was cooled to 0–5° in an ice-bath and 19.3 g. (0.15 mole) of isoquinoline in 50 cc. of dry ether was added with stirring. Subsequent to hydrolysis and treatment with ammonium hydroxide, several recrystallizations from ethanol gave 5.0 g. (a 11.3% yield based on isoquinoline) of the free base melting at 137–138°.

Anal. Calcd. for $C_{21}H_{13}ON$: N, 4.74. Found: N, 4.83 and 4.82.

The hydrochloride is immediately hydrolyzed in water.

4-Dibenzofurylacetamide.—This synthesis was based on the general procedures of Arndt and Eistert.[25] 4-Dibenzofurancarboxylic acid chloride was prepared by treating the acid with thionyl chloride in the usual manner. A more convenient purification was effected, however, by recrystallizing the acid chloride from petroleum ether (b. p. 60–68°).

To a diazomethane solution in ether, prepared from 50 g. (0.485 mole) of nitrosomethylurea was added 25 g. (0.11 mole) of 4-dibenzofurancarboxylic acid chloride in several portions. The crude diazomethyl 4-dibenzofuryl ketone was obtained in a quantitative yield, and a portion recrystallized once from petroleum ether (b. p. 60–68°) melted at 72–75°. This material was used directly in the following procedure.

Conversion of the diazo compound to the 4-dibenzofurylacetamide is accomplished in a better yield if too large a run is not made. A solution of 5.0 g. (0.02 mole) of the diazomethyl 4-dibenzofuryl ketone in 100 cc. of dioxane was heated on the steam-bath, and 25 cc. of concd. ammonium hydroxide was added followed by 5 cc. of a 10% solution of silver nitrate. The precipitated crude 4-dibenzofurylacetamide was obtained in a 67% yield. Recrystallization from ethanol gave the pure compound melting at 211–212°.

Anal. Calcd. for $C_{14}H_{11}O_2N$: N, 6.22. Found: N, 6.10 and 5.98.

4-Dibenzofurylacetic Acid.—Five grams (0.022 mole) of the 4-dibenzofurylacetamide suspended in 150 cc. of 15% sodium hydroxide solution was refluxed for five hours. Acidification of the solution with dilute hydrochloric acid precipitated the crude 4-dibenzofurylacetic acid in an 82% yield, which melted at 213.5–214.5° after crystallization from ethanol.

Anal. Calcd. for $C_{14}H_{10}O_3$: C, 74.31; H, 4.46. Found: C, 74.57; H, 4.66.

3,4 - Dimethoxy - α - (4 - dibenzofurylacetamino) - acetophenone.—Two grams (0.009 mole) of 4-dibenzofurylacetic acid and 10 cc. of thionyl chloride were gently refluxed together for three hours. The excess thionyl chloride was removed under reduced pressure and the residual oil dissolved in petroleum ether (b. p. 60–68°) and filtered to remove a slight amount of insoluble residue. Evaporation of the petroleum ether left the 4-dibenzofurylacetyl chloride as a viscous oil which was dissolved in 95 cc. of ether and added to 20 cc. of an aqueous solution of 1.5 g. (0.0065 mole) of 3,4-dimethoxy-α-aminoacetophenone hydrochloride.[26] A solution of 2.5 g. of potassium hydroxide in 15 cc. of water was added, and the mixture shaken for ten minutes and allowed to stand overnight. The emulsion which had formed was filtered, leaving a residue of 2.6 g. of the crude amide. Acidification of the

(26) Prepared according to the procedure of Pictet and Gams, *ibid.*, **42**, 2943 (1909).

filtrate yielded 0.3 g. of crude 4-dibenzofurylacetic acid. The crude amide was recrystallized from benzene to yield 1.5 g. (57% yield based on amine) of the pure amide melting at 186–187°.

Anal. Calcd. for $C_{24}H_{21}O_5N$: N, 3.47. Found: N, 3.71 and 3.72.

3,4 - Dimethoxy - α - (4 - dibenzofuroylamino) - acetophenone.—The reaction between 0.1 g. of 4-dibenzofurancarboxylic acid chloride and 0.1 g. of 3,4-dimethoxy-α-aminoacetophenone hydrochloride was carried out by the same procedure as that just given. The product was recrystallized from ethanol and melted at 178–179°.

Anal. Calcd. for $C_{23}H_{19}O_5N$: N, 3.71. Found: N, 3.68.

Acknowledgment.—The authors are grateful to H. B. Willis for assistance.

Summary

Experiments are described concerning the preparation and proof of structure of some substituted amines and other derivatives of dibenzofuran. The generalizations on orientation postulated previously have been shown to be adequate for the predominant products which result from polysubstitution of the dibenzofuran nucleus.

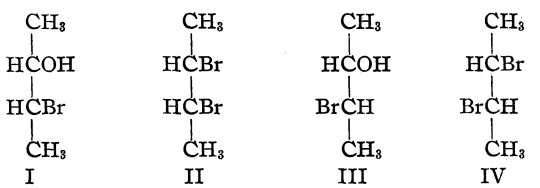
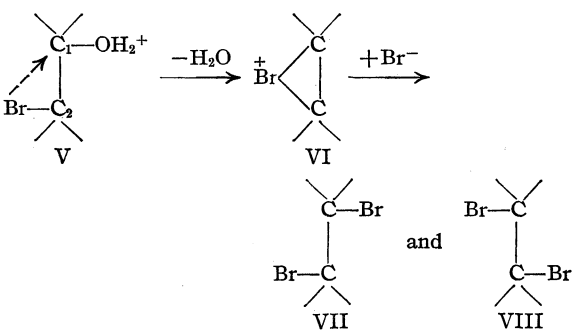
The Loss of Optical Activity in the Reaction of the Optically Active *erythro-* and *threo*-3-Bromo-2-butanols with Hydrobromic Acid

BY S. WINSTEIN[1] AND H. J. LUCAS

Recently it was shown[2] that *dl-erythro*-3-bromo-2-butanol I is converted into *meso*-2,3-dibromobutane II, and *dl-threo*-3-bromo-2-butanol III, is converted into *dl*-2,3-dibromobutane IV, by the action of fuming hydrobromic acid, with complete retention of configuration.[3,4]



In order to account for this unusual behavior, it was assumed that the replacement of the hydroxyl group by the bromine atom took place by a mechanism involving attack by the bromine atom on the adjacent carbon atom of the bromohydrin. This bromine atom, simultaneously with the removal of the OH_2^+ group V (which is formed from the OH group and a proton), forms a bond with the carbon atom on the face away from the OH_2^+ group, thus leading to the formation of the positively charged cyclic intermediate, VI,[5] of Roberts and Kimball[6] which then reacts with bromide ion to produce the two possible dibromides VII and VIII.



On the basis of this mechanism two inversions take place, for the formation of the intermediate, VI, is accompanied by an inversion of carbon atom C_1, and the reaction of this with bromide ion is accompanied by a second inversion. If VII is the product, C_1 is inverted twice, while if VIII is the product C_1 and C_2 are each inverted once. This explains the formation of *meso*-2,3-dibromobutane from the *erythro*-bromohydrin, and of *dl*-2,3-dibromobutane from the *threo*-bromohydrin. In fact, each of the active forms of the *threo*-bromohydrin is predicted by this mechanism to give *dl*-2,3-dibromobutane, since VII and VIII would be formed in equal amounts.

It was pointed out that this feature could be used as a test for the mechanism by starting

(1) At present National Research Fellow in Chemistry at Harvard University.

(2) Winstein and Lucas, THIS JOURNAL, **61**, 1576 (1939).

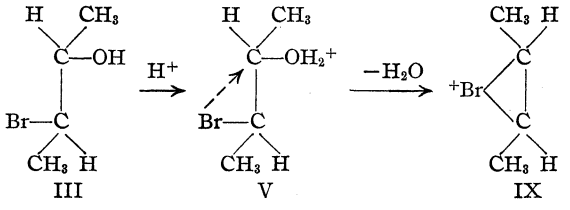
(3) Only one of the two antipodes of the *dl*-compounds is shown.

(4) By retention of configuration in these cases is meant merely that an *erythro*-bromohydrin gives rise to a *meso*-dibromide and a *threo*-bromohydrin to a *dl*-dibromide. Strictly speaking, configuration is not retained.

(5) We propose to call the simplest ion having this structure, ethylenebromonium ion.

(6) Roberts and Kimball, THIS JOURNAL, **59**, 947 (1937).

with optically active *threo*-bromohydrin III. The predicted loss in activity in going from an active *threo*-bromohydrin to an inactive dibromide may be better understood perhaps by noting that the cyclic intermediate IX has the internally compensated *cis* configuration, and thus can give rise to only inactive products.



It has now been found that both the *erythro*- and *threo*-bromobutanols in the active form give rise to inactive dibromides. Moreover, optically active acetates of these two bromobutanols also give rise to inactive dibromides. The conversion was carried out with optically active forms of both the *erythro*- and *threo*-bromohydrins so as to make the test of the proposed mechanism free of any doubt that might be cast on it by questioning the assignment of configurations to the 3-bromo-2-butanols or the 2,3-dibromobutanes.

Optically active bromobutanols and acetates were obtained by partial acetylation of the bromohydrins with acetic anhydride in carbon tetrachloride containing brucine, according to the method which Wegler[7] used in other cases. The *dl-erythro*-3-bromo-2-butanol gave rise to a (+)-*erythro*-3-bromo-2-butanol and a (−)-*erythro*-3-acetoxy-2-bromobutane, while the *dl-threo*-3-bromo-2-butanol gave rise to a (−)-*threo*-3-bromo-2-butanol and a (−)-*threo*-3-acetoxy-2-bromobutane. The resolution to be expected from the method employed is of course quite incomplete.

TABLE I

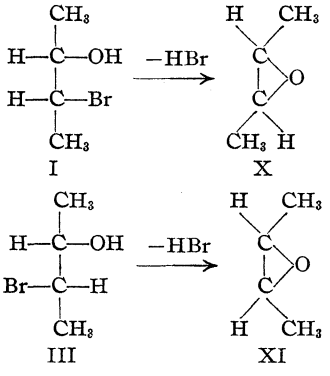
SUMMARY OF THE OPTICAL ROTATION DATA

	Substance	Config.	α_D (1 dcm.)
1	3-Bromo-2-butanol	*erythro*	+1.91 ± 0.02°
2	2-Acetoxy-3-bromobutane	*erythro*	−3.01 ± .03
3	2,3-Dibromobutane from 1	*meso*	0.00 ± .02
4	2,3-Dibromobutane from 2	*meso*	0.01 ± .02
5	2,3-Epoxybutane from 1	*trans*	+4.37 ± .01
6	3-Bromo-2-butanol	*threo*	−1.17 ± .02
7	3-Bromo-2-butanol	*threo*	−1.04 ± .01
8	2-Acetoxy-3-bromobutane	*threo*	−0.31 ± .01
9	2,3-Dibromobutane from 6	*dl*	.00 ± .01
10	2,3-Dibromobutane from 7	*dl*	.00 ± .02
11	2,3-Dibromobutane from 8	*dl*	.00 ± .01
12	2,3-Epoxybutane from 7	*cis*	.01 ± .01

(7) Wegler, *Ann.*, **506**, 77 (1933).

The optical rotations of these compounds, as well as optical data on the oxides and dibromides, are given in Table I.

To make certain that the optical activity in the case of the (−)-*threo*-bromohydrin was not due largely to the presence of a quite small amount of an optically active *erythro* isomer, which would give optically inactive dibromobutane, some of the active *erythro*- and *threo*-bromohydrins were converted to oxides. One would expect active *erythro*-3-bromo-2-butanol I to yield an active *trans*-2,3-epoxybutane X, and active *threo*-3-bromo-2-butanol III to yield inactive internally compensated *cis*-2,3-epoxybutane XI since one inversion accompanies the formation of the oxide ring.[2]



The active bromobutanols behaved as expected on conversion to oxides. It was found that the *trans* oxide from (+)-*erythro*-3-bromo-2-butanol has a (+) rotation while the *cis* oxide from (−)-*threo*-3-bromo-2-butanol was inactive (Table I). Thus, the active *threo*-bromohydrin was not contaminated with appreciable amounts of an active *erythro*-bromohydrin.

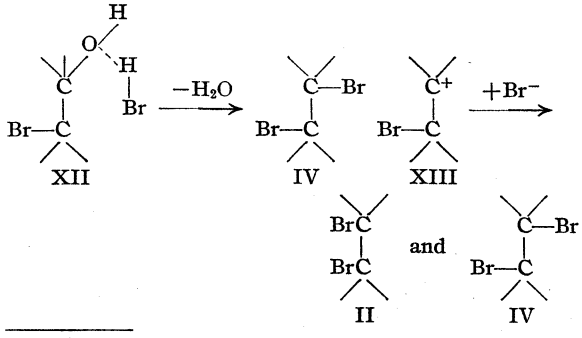
The inactivity of the dibromide from the active *threo*-3-bromo-2-butanol (Table I) hardly can be explained on the basis of a low specific rotation for a *d*- or *l*-2,3-dibromobutane.[8] It seems quite unlikely that the rotation to be expected from (+)- or (−)-2,3-dibromobutane would be smaller than the rotation of (−)-*threo*-3-bromo-2-butanol by a factor of approximately 50 or 100, and thus be within experimental error of zero. Thus it must be that (−)-*threo*-3-bromo-2-butanol gives *dl*-2,3-dibromobutane. This definitely confirms

(8) In many cases, the optical activity of an alcohol is comparable to or less than that of the corresponding halide; see for example, Kenyon, Phillips and Pittman, *J. Chem. Soc.*, 1072 (1935); Levene and Rothen, *J. Biol. Chem.*, **127**, 237 (1939); Hughes, Ingold and Masterman, *J. Chem. Soc.*, 1196 (1937); Hughes, Ingold and Scott, *ibid.*, 1201 (1937); Cowdrey, Hughes and Ingold, *ibid.*, 1208 (1937); Stevens and McNiven, THIS JOURNAL, **61**, 1295 (1939).

the proposed mechanism, which involves the formation of 1,2-dimethylethylenebromonium ion, VI.

It is evident from Table I that the active bromoacetates behave as the bromohydrins do, to give inactive dibromides. This is to be expected since the bromoacetates presumably are converted to the dibromides by way of the bromohydrins.[9] It must be recognized that the butylenebromonium ion can react with water, as well as with bromide ion. The reaction with water, in the case of the *cis* ion, will give rise to *dl-threo*-3-bromo-2-butanol. Here then is a way for the active *threo*-bromohydrin to become inactive. It is probable, however, that the positive ion reacts practically exclusively with bromide ion in the present reaction medium. This statement is based upon the observations that the corresponding oxide is converted almost quantitatively to bromohydrin,[2] not glycol in concentrated hydrobromic acid, and that in bromine additions to double-bonded compounds, in which bromonium ions[10] are intermediates,[2,6,11] bromide ion competes much better than solvent molecules.

Other Possible Mechanisms.—The results obtained show that two other possible mechanisms, which have been proposed for the conversion of monohydric alcohols to bromides, are not operative here. One such mechanism is the internal, cyclic reaction of a bromohydrin–hydrogen bromide complex.[12] This type of reaction which seems to occur in some cases[8] cannot be operative here, otherwise the dibromide IV, resulting from optically active *threo*-3-bromo-2-butanol XII, would possess optical activity.



Another such mechanism is the dissociation[12] of the bromohydrin–proton complex, V, to give a halogen substituted carbonium ion XIII, with subsequent reaction of this ion with bromide ion. In the case of both the active *erythro-* and active *threo*-bromohydrins, this would lead to the production of a mixture of the *meso*-dibromide II and an active dibromide IV, unless one postulates that the configuration of the carbonium ion is stabilized in the pyramidal form. If it is possible for the configuration to be so stabilized, then the resulting dibromide from the active *threo*-bromohydrin would possess optical activity. Thus the carbonium ion mechanism, which has been postulated in other cases[12] but which has been the subject of considerable discussion recently,[13] definitely is not operative in the case of these 3-bromo-2-butanols.

While it might turn out to be useful to think that the chief "driving force"[14] of the reaction of formation of the butylenebromonium ion VI is the tendency for the $-OH_2^+$ group to be dissociated off as a water molecule, nevertheless we must not regard XIII as an intermediate. The bond between bromine and carbon is formed essentially simultaneously with the dissociation of the $-OH_2^+$ group from the rest of the molecule.

Other Changes Involving Halonium Ions.—In addition to the reactions of bromohydrins with acids and of bromine and bromine-donating substances with ethylenic compounds, as discussed previously,[2] there must be other situations in which bromonium ions are intermediates. This would be expected when there is a tendency to remove one group in a molecule in which there is a bromine substituent able to attack the back face of the carbon atom losing the group. Thus, for example, the production of *cis*-1,2-diacetoxycyclohexane from the action of silver acetate on 1,2-dibromocyclohexane in acetic acid does not necessarily indicate that the 1,2-dibromocyclohexane is the *cis* isomer.[15] We prefer the explanation that an odd number of inversions are involved in the transformation to the diacetate and that 1,2-dibromocyclohexane has the *trans* configuration. It seems plausible that the bromonium ion is produced by the action of a silver ion[14,16] simultaneously with the attack by the bromine

XIV XV

atom of carbon atom C_2 as shown by XIV and that this ion reacts with solvent as shown by XV. An inversion at the replacement of the second bromine atom by acetate would result in there being three inversions in the whole transformation. It seems plausible that presently the steric course of reactions of dihalides, halohydrins, etc., will be better understood when it is realized to what extent bromonium ions and hitherto unknown compounds of a similar sort play a part.

Besides bromonium ions there may be chloronium and iodonium ions of similar structure.

Experimental

Materials.—The *dl-erythro*-3-bromo-2-butanol was prepared from the pure *trans*-2,3-epoxybutane and the *dl-threo*-3-bromo-2-butanol from both pure *cis*-2,3-epoxybutane or *cis*-2-butene according to directions previously given.[2]

Merck brucine was employed and the acetic anhydride was purified by fractionation.

Partial Resolution of *erythro*-3-Bromo-2-butanol and Conversion to 2,3-Dibromobutane.—In 500 ml. of pure carbon tetrachloride was dissolved with heating 50 g. of brucine, then 50 ml. of *dl-erythro*-3-bromo-2-butanol and 22 ml. of acetic anhydride were added in turn and the reaction mixture was refluxed for two hours. After the reaction mixture was cool, it was washed first with dilute hydrochloric acid and then sodium carbonate solution. The mixture was dried over potassium carbonate, most of the carbon tetrachloride was distilled off through a 15-cm. column of glass helices at about 40°, and the residue was fractionated through a 40-cm. Weston[17] column. There was obtained 38 ml. of distillate, 12 ml. being essentially pure bromohydrin, b. p. (13 mm.) 53.1–53.7°, $n^{25}D$ 1.4762 and 19 ml. being pure acetoxybromobutane, b. p. (13 mm.) 67.0–67.2°, $n^{25}D$ 1.4488. Intermediate fractions made up the remainder of the material. The rotation αD (1 dcm.) of the bromohydrin was 1.91° and of the acetate −3.01°. Half of the bromohydrin sample was converted to oxide as previously described,[2] the oxide exhibiting αD (1 dcm.) +4.37°. The oxide and bromohydrin were dissolved in fuming hydrobromic acid, the dibromide b. p. (50 mm.) 73.2°, $n^{25}D$ 1.5090, possessing αD (1 dcm.) 0.00°. The acetate similarly gave rise to dibromide b. p. (50 mm.) 73.2°, $n^{25}D$ 1.5090 which possessed αD (1 dcm.) 0.00°. The intermediate fractions also were converted to dibromide. The combined and redistilled dibromobutane from the bromohydrin and oxide, acetoxybromobutane, and the intermediate fractions, b. p. (50 mm.) 73.3°, $n^{25}D$ 1.5091 possessed a dielectric constant[2,18] of 6.208. This indicates a few % of *dl*-dibromobutane in the *meso*-dibromide. Some stereomutation from *erythro* to *threo* apparently takes place during the procedure for partial resolution of the bromohydrin.

Partial Resolution of *threo*-3-Bromo-2-butanol and Conversion to 2,3-Dibromobutane.—From the treatment of 44 ml. of *threo*-3-bromo-2-butanol with 44 g. of brucine and 22 ml. of acetic anhydride in 440 ml. of carbon tetrachloride as described above in the case of the *erythro*-bromohydrin and subsequent washing, drying and distillation was obtained 39 ml. of distillate, 8 ml. being quite pure bromohydrin, b. p. (13 mm.) 50.0–50.8°, $n^{25}D$ 1.4757, 13 ml. being quite pure acetoxybromobutane, b. p. (13 mm.) 69.6°, $n^{25}D$ 1.4491, the rest of the material consisting of intermediate fractions. The bromohydrin exhibited αD (1 dcm.) −1.17° while the acetoxybromobutane possessed αD (1 dcm.) −0.31°. The bromohydrin, acetoxybromobutane and the combined intermediate fractions were converted to dibromobutanes in the usual way. The dibromobutane b. p. (50 mm.) 76.1° from the bromohydrin exhibited αD (1 dcm.) 0.00°, that from the intermediate fractions, b. p. (50 mm.) 76.0° possessed αD (1 dcm.) 0.00°, and the dibromide b. p. (50 mm.) 76.2° from the bromohydrin acetate yielded αD (1 dcm.) 0.00°. The combined and redistilled dibromobutane b. p. (50 mm.) 75.9–76.2°, $n^{25}D$ 1.5121, possessed a dielectric constant of 5.797. Here, too, a little stereomutation must have been involved in the procedure for the partial resolution of the bromohydrin.

When 46 ml. of *threo*-3-bromo-2-butanol was partially resolved with the aid of 46 g. of brucine, 20 ml. of acetic anhydride and 500 ml. of carbon tetrachloride and distillation was carried out, 10 ml. of bromohydrin fraction b. p. (13 mm.) 50.2–50.7°, $n^{25}D$ 1.4749, αD (1 dcm.) −1.04° was obtained. Three ml. of this bromohydrin yielded an oxide having αD (1 dcm.) 0.01°. The remainder of the bromohydrin yielded a dibromide, b. p. (50 mm.) 76.3°, $n^{25}D$ 1.5121, which showed αD (1 dcm.) 0.00°.

In Table I the indicated possible errors in the optical rotations are the sum of the mean deviations for a set of readings on the zero point and a set of readings on the substance in question. For the readings a Zeiss 0.01° instrument and a small capacity 1-dcm. tube were employed.

Summary

There is complete loss of optical activity when active *erythro*- or *threo*-3-bromo-2-butanol is converted to 2,3-dibromobutane. This confirms the mechanism previously proposed in connection with the conversion of *dl-erythro*- and *dl-threo*-3-bromo-2-butanol to *meso*- and *dl*-2,3-dibromobutane, respectively. The mechanism consists of the production of a butylenebromonium ion, and the subsequent reaction of this ion with bromide ion, two inversions occurring in the transformation. Other possible mechanisms for the transformation of bromohydrin to dibromide are discussed and rejected.

Structures of Complex Fluorides. Potassium Hexafluogermanate and Ammonium Hexafluogermanate

BY J. L. HOARD AND W. B. VINCENT

Among compounds of type formula R_2MX_6, in which R = K, NH_4; M = Si, Ge, Sn, Ti, Zr, Mn, only the fluosilicates have been prepared in crystalline modifications possessing the familiar fluorite-like arrangement of R^+ and $MX_6^=$ ions known as the ammonium chloroplatinate structural type.[1] Most of these complex fluorides crystallize in the hexagonal system with crystal habits and axial ratios which suggest a general isomorphism within the group. In the present paper we report the determination by means of X-rays of the atomic arrangement which exists within crystals of ammonium and potassium fluogermanates. The structure of these compounds proves to be of the same general type as that of the hexagonal modification of ammonium fluosilicate, which has been studied by Gossner and Kraus.[2]

Using filtered CuK α radiation complete sets of oscillation photographs were prepared from small, well-formed crystals of both compounds. In each case the symmetry of the patterns obtained from carefully oriented specimens is that of $D_3^d - \bar{3}\,m$. The fundamental lattice is hexagonal with the following values of the lattice constants, accurate to within 0.01 Å.: ammonium fluogermanate, $a = 5.85$, $c = 4.775$ Å., $c/a = 0.816$; potassium fluogermanate, $a = 5.62$, $c = 4.65$ Å., $c/a = 0.827$. Groth[3] gives $c/a = 1.6078$ for the potassium salt as derived from goniometric measurements.

For one stoichiometric molecule within the unit cell the calculated densities are 2.60 g./cc. for the ammonium salt and 3.43 g./cc. for the potassium compound; approximate experimental values determined by the pycnometer method are, respectively, 2.64 g./cc. and 3.32 g./cc.

Symmetry planes belong to the form {11·0} rather than to {10·0}. Since, moreover, all classes of reflections are observed, the possible space groups are limited to $C_{3v}^1 - C3\,m$, $D_3^2 - C32$, and $D_{3d}^3 - C\bar{3}\,m$. The actual atomic arrangement is found to possess the complete symmetry of D_{3d}^3, and we shall base our description of the structure upon this space group.

Using the standard notation,[4] we place Ge in (a): 000; 2K or $2NH_4$ in 2(d): $^1/_3$, $^2/_3$, u; $^2/_3$, $^1/_3$, $\bar{u}$; 6F in 6(i): $x\bar{x}z$; x, $2x$, z; $2\bar{x}$, $\bar{x}$, z; $\bar{x}x\bar{z}$; $\bar{x}$, $2x$, $\bar{z}$; $2x$, x, $\bar{z}$ of D_{3d}^3. The values of these atomic coördinates as derived from the diffraction data are as follows: ammonium fluogermanate, $u = 0.695$, $x = 0.143$, $z = 0.214$; potassium fluogermanate, $u = 0.700$, $x = 0.148$, $z = 0.220$. Table I contains a comparison of observed with calculated reflection amplitudes for several types of reflections. The agreement is seen to be very good; details of the calculations follow.

[a] Temperature factor and absorption correction not included.

The intensities of reflections appearing on photographs taken from hexagonal tablets, of diameter about 0.25 and 0.50 mm., respectively, for potassium and ammonium fluogermanate, were visually estimated by comparison with an intensity scale prepared for this purpose; the observed amplitudes of Table I are proportional to the square roots of these data. Theoretical amplitudes were calculated by means of the formula

$$I = \text{Constant}\left(\frac{1+\cos^2 2\theta}{2\sin 2\theta}\right)^{1/2} S$$

in which the structure factor is

$$S = f_{Ge} + 2f_N \cos 2\pi\left(\frac{h+2k}{3} + lu\right) + 2f_F\,[\cos 2\pi\,(hx - kx + lz) + \cos 2\pi\,(hx + 2kx + lz) + \cos 2\pi\,(2hx - kx + lz)]$$

The atomic f-values of Pauling and Sherman[5] are used throughout this paper.

As a matter of fact, the calculated amplitudes are but little altered by introducing small variations from the coördinates of fluorine and ammonium listed above. The parameter values given are essentially those derived from approximate Fourier projections of relative electron density on (1$\bar{2}$·0) using experimental (*h*0*l*) data. The reflection amplitudes used in calculating these projections were taken proportional to the square roots of the quantities obtained after correction of the estimated intensities by the Lorentz and polarization factor. The formula required in making the projection is

$$\rho(x,z) = \Sigma_h \Sigma_l \, F_{(h0l)} \cos 2\pi(hx + lz)$$

The method of Lipson and Beevers[6] was used in making the summations.

The resulting simple projections of relative electron density need not be reproduced here since their important features can be described in

(5) L. Pauling and J. Sherman, *Z. Krist.*, **81**, 1 (1932).
(6) Lipson and Beevers, *Phys. Soc. London*, **48**, 772 (1936).

few words. Excepting that potassium shows up more prominently than does ammonium, the contour maps are very similar for the two compounds. The values of the fluorine parameters as read from the peak arising from the superposition of two fluorine atoms on the projection are for ammonium fluogermanate $x = 0.147$, $z = 0.205$; for potassium fluogermanate $x = 0.148$, $z = 0.215$. The corresponding Ge–F separations in the almost regular octahedral GeF_6 groups are, respectively, 1.77 and 1.755 Å. Neither the ammonium nor the potassium peak is completely resolved from that of a single fluorine atom in each plot but it is possible, nevertheless, to determine the atomic positions with a fair degree of accuracy. It is probable that $u_K = 0.700$ is reliable to within a few thousandths, and that $u_N = 0.695$ is not in error by more than 0.015.

We see that the parameter values derived from the Fourier analyses of the (*h*0*l*) data are very nearly those used in calculating the reflection amplitudes of Table I. In the latter case we have assumed the complex anions to be regular octahedra with Ge–F = 1.77 Å.

An additional Fourier projection of relative electron density on (00·1) using experimental (*hk*·0) reflection amplitudes was made for ammonium fluogermanate. Peaks for germanium at 00; for ammonium at $^1/_3$, $^2/_3$ and $^2/_3$, $^1/_3$; and for fluorine at x, $2x$, etc., with $x = 0.150$ are observed. The value of the fluorine parameter is slightly larger than that obtained from the analysis of the (*h*0*l*) data. The Fourier data do not indicate completely regular complex anions for either compound: in ammonium fluogermanate the octahedron appears to be slightly flattened perpendicular to the unique axis; in potassium fluogermanate the octahedron appears to be slightly elongated along this axis. Within the accuracy of the data, however, we may conclude that both compounds contain practically regular octahedral GeF_6 groups with Ge–F = 1.77 Å.

The experimental Ge–F separation, 1.77 Å., may be compared with the sum of the "univalent" ionic radii[7] corrected for the actual ionic charges, 1.74 Å., with the sum of the "normal valence" radii,[8] 1.86 Å., and with the quite approximate value, 1.8 Å., derived from the X-ray study of the cubic cesium fluogermanate.[9] The more appropriate "octahedral" radius of germanium is probably somewhat larger than the "normal valence" or "tetrahedral" value. In the light of numerous electron diffraction data dealing with gaseous fluorides, however, we might well expect the Ge–F separation to be appreciably smaller than the sum of the covalent radii.

The parameter data used in calculating the reflection amplitudes of Table I lead to a regular GeF_6 group with Ge–F = 1.77 Å., F–F = 2.51 Å. Between adjacent anions, F–F = 3.11 Å. $(K–F)_1 = 2.84$ Å. (six of these), $(K–F)_2 = 2.86$ Å. (3), $(K–F)_3 = 3.01$ Å. (3), $(NH_4–F)_1 = 2.97$ Å. (6), $(NH_4–F)_2 = 3.00$ Å. (3), $(NH_4–F)_3 = 3.14$ Å. (3). We may accept the conclusion that three of the twelve potassium–fluorine separations are appreciably larger than the others; this is very probably true for the ammonium–fluorine separations as well. The coördination number of the univalent cation is then nine, although the approximation to coördination number twelve is not bad.

Drawings of the structure of potassium fluogermanate are shown in Fig. 1. The atomic arrangement can be described qualitatively as based on hexagonal closest-packing of fluorine and potassium atoms, from which, however, there are very considerable distortions. With the cubic ammonium chloroplatinate arrangement, fluorine and potassium atom would be in approximate cubic closest-packing, potassium being required by symmetry to possess twelve equidistant neighbors. These relations have been pointed out previously in the case of the dimorphous ammonium fluosilicate by Gossner and Kraus.[2] These authors have suggested approximate values for the parameters of ammonium and fluorine in the hexagonal modification of ammonium fluosilicate which lead to nine ammonium–fluorine separations of about 2.92 Å. as compared with about 2.98 Å. in the present work on the fluogermanate.

The hexagonal or low temperature modification of ammonium fluosilicate has a density about 7% larger than that of the cubic or high temperature form. As mentioned previously, the fluogermanates have been prepared only with the hexagonal structure.

Qualitatively, it appears that a considerable degree of ionic character in the M–F bonds of the complex would favor the assumption of the hexagonal rather than the cubic structure. This conclusion could be checked by calculating

the difference of potential energy between the two structural types for various distributions of charge over the anion, assuming an equal contribution of covalent binding to the M–F bond in both structures. With absorption of thermal energy the more symmetrical cubic structure becomes relatively more stable, although it is not possible at present to set up the partition functions required for quantitative calculations. Only complex fluorides have been prepared with the hexagonal structural type.

We have found that crystals of rubidium fluogermanate prepared at ordinary temperatures possess neither of the structures discussed above. Although hexagonal, the unit cell of this compound contains two stoichiometric molecules with the approximate axial lengths $a = 5.96$ Å., $c = 9.72$ Å. Our diffraction data are incomplete as yet, but the values of the lattice constants suggest that the structure is one in which rubidium ion has accurately a coördination number of twelve.

Although it appears certain that a system of fixed hydrogen bridges does not exist in ammonium fluogermanate, it is probable, nevertheless, that the interactions of hydrogen with fluorine are larger than would be the case for any structural type in which ammonium would have twelve equidistant neighbors. In ammonium fluogermanate it is reasonable to suppose that the ammonium ion is oriented so that three protons lie nearly in the plane of the six fluorine atoms which are about 2.97 Å. from each nitrogen atom. In the absence of any effect of this kind we would expect ammonium and rubidium fluogermanates to be isomorphous.

Summary

It is deduced from X-ray data that crystals of the isomorphous ammonium and potassium fluogermanates possess one-molecule hexagonal units of structure with $a = 5.85$ Å., $c = 4.775$ Å. and $a = 5.62$ Å., $c = 4.65$ Å., respectively, space-group D_{3d}^3–$C3\ m$. The structure is an aggregate of univalent cations (K^+, NH_4^+) and nearly regular octahedral anions (GeF_6^{-4}) with Ge–F = 1.77 Å. Each cation is surrounded by nine nearly equidistant fluorine atoms and three others at somewhat greater distances. This structure has been found only in the case of complex fluorides, for which at ordinary temperatures it is usually preferred to the cubic ammonium chloroplatinate structural type.

The Structure of Potassium Molybdocyanide Dihydrate. The Configuration of the Molybdenum Octocyanide Group

BY J. L. HOARD AND H. H. NORDSIECK

Potassium molybdocyanide dihydrate, $K_4Mo(CN)_8 \cdot 2H_2O$, is one of the more familiar examples of the class of compounds containing discrete coördination groups in which eight atoms or radicals are bound to a common central atom. The configuration of a molecule or complex ion of formula MX_8 has not been established with certainty in any single case heretofore, although the cube and the square Archimedean antiprism have been regarded as geometrically plausible possibilities. In the present paper we describe an X-ray study of potassium molybdocyanide dihydrate from which we have succeeded in deducing the complete atomic arrangement existing within the crystal. We shall show that the actual configuration of the molybdenum octocyanide ion, $Mo(CN)_8^{-4}$, is of a less obvious but apparently at least as satisfactory a type as either the cube or the antiprism.

The potassium molybdocyanide dihydrate used in this work was prepared and analyzed by Professor H. H. Willard and Dr. R. C. Thielke,[1] who very kindly supplied us with samples of two different preparations. The color of the crystals varied from a nearly pure yellow to an orange yellow depending, apparently, on their size and habit; the lighter colored preparation was made up of particularly thin leaflets. The crystals belong to the orthorhombic system,[2] being tabular on (100). When examined with a polarizing microscope they exhibit the required parallel extinction.

Using Cu–Kα radiation complete sets of fifteen degree oscillation photographs were prepared with each of the three crystallographic axes in turn as the rotation axis. The reflections were recorded on film in a cylindrical camera of 5 cm. radius, the positions of the knife edges corresponding to $2 \sin \theta = 1.990$. For the photographs with b and c vertical, it was possible to cut and grind the crystals into cylindrical form; the specimens used in these two cases were very nearly 0.10 mm. in diameter and about 0.50 mm. long. For the case of a vertical it was not feasible to prepare an entirely satisfactory specimen because of the habit and the cleavage properties of the crystals. Photographs taken with a specimen approximately $0.28 \times 0.60 \times 0.70$ mm. in size afforded diffraction data which proved to be very useful even though the estimated intensities were necessarily quite approximate.

As required by the orthorhombic system, the X-ray photographs exhibit the complete symmetry of the point group $D_2^h - mmm$. The lattice constants are $a = 16.55$ Å., $b = 11.70$ Å., $c = 8.68$ Å., $a:b:c = 0.7073:1:0.3709$. Goniometric measurements[2] give $a:b:c = 0.7028:1:0.3711$. Using these lattice constants to construct reciprocal lattice plots, it was possible to index all reflections appearing upon our photographs.[3]

Examination of the data demonstrates the regular and complete absence of $\{hk0\}$ reflections with h odd, and $\{0kl\}$ reflection with $k + l$ odd. These data render it almost certain that the space group[4] is either $D_{2h}^{16} - pnma$ or $C_{2v}^{9} - pna$. (The sequence of axes chosen on the basis of the crystallographic data happens to be the same as that used in the International Tables in describing these space groups.) The crystallographic data quoted by Rosenheim[2] assign the crystals to the point group D_2^h, and we assume accordingly the isomorphous space group D_{2h}^{16}. All later developments support this choice.

The space group requires that the unit cell contain 4, 8, 12, . . . $4n$ molecules of $K_4Mo(CN)_8 \cdot 2H_2O$. An approximate experimental determination of the density by the pycnometer method resulted in $d = 1.94$ g./cc.; the calculated density with four stoichiometric molecules per unit cell is 1.964 g./cc. We are required then to place 4Mo, 16K, 32C, 32N, and $8H_2O$ within the unit cell.

During indexing the relative intensities of all $\{hk0\}$, $\{h0l\}$, and $\{0kl\}$ reflections (appearing on the equators of photographs taken with c, b, and a, respectively, as rotation axes) were carefully estimated by visual comparison with an intensity

scale prepared for this purpose. To obtain the important $\{hk0\}$ and $\{h0l\}$ data each of the authors independently went through the entire experimental procedure of photographing (different) specimens, indexing the reflections, and estimating the relative intensities. Using cylindrical specimens very nearly 0.10 mm. in diameter, the resulting photographs were exceptionally clear.

Comparison of the independently derived $\{hk0\}$ data disclosed that the intensities estimated by the senior author showed a larger spread in magnitudes by a factor of about two in going from reflections with small $\sin\theta$ to those with large $\sin\theta$. The two sets of data for $(h0l)$ reflections were in rather closer agreement. For each set of reflections mean intensities were computed, and these were divided by the Lorentz and polarization factor to obtain values of $|F_{(hkl)}|^2$. The $(hk0)$ and the $(h0l)$ reflections were not corrected for absorption of X-rays in the irradiated specimens. Approximate absorption corrections were required in the case of the $(0kl)$ data. Questions having to do with the self-consistency and probable accuracy of our data are considered in greater detail later in this paper.

Following methods which were employed to determine the structures of potassium heptafluocolumbate and potassium heptafluotantalate,[5] we use the $|F_{(hkl)}|^2$ data to make Patterson projections upon each of the three axial planes in order to place approximately molybdenum and potassium atoms within the unit cell. A knowledge of the positions of molybdenum and potassium suffices to determine the signs of the more important reflection amplitudes required in making approximate Fourier projections of relative electron density upon the axial planes. Refinement of these projections by a process of successive approximations leads ultimately to a complete structural determination.

The formula required for computing the Patterson projection on (010) is

$$P(X,Z) = \Sigma h \Sigma l \mid F_{(h0l)} \mid^2 \cos 2\pi(hX + lZ)$$

Similar expressions apply to the calculations of the projections on (100) and (001). The actual summations were carried out by the method of Lipson and Beevers[6] using a set of the Lipson and Beevers strips. Collected data from the three projections are given in Table I.

Remembering that coördinates of maxima on the Patterson plot represent components of interatomic distances in the projections on (010) of the contents of the actual unit structure, four molybdenum atoms placed in the centers of symmetry[4]—either 4(a) or 4(b) of D_{2h}^{16}—would require very large maxima at $X = 1/2$, $Z = 1/2$. This is not observed. The remaining possibility for molybdenum is 4(c); x, $1/4$, z; $\bar{x}$, $3/4$, $\bar{z}$; $1/2 - x$, $3/4$, $1/2 + z$; $1/2 + x$, $1/4$, $1/2 - z$. These would lead to maxima on the Patterson plot at the following values of X, Z: $\pm 2x$, $\pm 2z$; $\pm(1/2 - 2x)$, $1/2$; $1/2$, $\pm(1/2 - 2z)$; 0, 0. Large peaks (Table I) are observed at 0.28, 0.20; 0.22, $1/2$; $1/2$, 0.30, in addition to the identity maximum at 0,0. Upon solution we obtain $x = \pm 0.14$, $z = \pm 0.10$, of which the positive values may be chosen arbitrarily provided that a consistent selection of positions for other atoms be made thereafter.

The next most prominent set of peaks on the projection are in general to be associated with molybdenum–potassium separations. A large peak comparable in magnitude with those associated with molybdenum–molybdenum separations is observed at $X = 0$, $Z = 0.375$. This peak is most reasonably interpreted as involving potassium in the general positions 8(d): xyz; $1/2 + x, 1/2 - y, 1/2 - z$; $\bar{x}, 1/2 + y, \bar{z}$; $1/2 - x, \bar{y}, 1/2 + z$; $\bar{x}, \bar{y}, \bar{z}$; $1/2 - x, 1/2 + y, 1/2 + z$; $x, 1/2 - y, z$; $1/2 + x, y, 1/2 - z$, since these atoms superimpose in pairs on any (010) projection. Maxima are expected then at $X = 0.14 \pm x$, $Z = 0.10 \pm z$. Upon solution we find for K_I the values $x = 0.14$, $z = 0.475$ or 0.725 of which the latter value is shown later to be roughly correct. This peak, in fact, involves also several other atomic separations and the z parameter of K_I turns out to be about 0.690. On the basis of $x = 0.14$, $z = 0.725$ for K_I three other molybdenum–potassium maxima are expected at 0.28, 0.18; 0.22, 0.075; 0.50, 0.29. These may be supposed to contribute to the observed peaks at 0.28, 0.20; 0.20, 0.14; 0.50, 0.30. These comparisons are improved on the average by using $z = 0.69$ for K_I.

Indications of the positions of other potassium atoms on this projection are quite indefinite. It turns out later that another structurally different type of potassium atom has very nearly identical x and z coördinates as molybdenum and contributes to the set of peaks first discussed.

The Patterson projection on (001) possesses a plane of symmetry at $X = 1/4$ since only even

values of h are permitted for ($hk0$) reflections. With molybdenum placed in 4(c) we expect maxima at $\pm 2x$, $1/2$; $\pm(2x - 1/2)$, $1/2$; 0, 0; $1/2$, 0. Large peaks (Table I) are observed at 0.28, $1/2$; 0.22, $1/2$; 0, 0; $1/2$, 0, the symmetry of the plot causing two Mo–Mo separations to be included in the identity peak. These data lead to molybdenum parameters of $x = 0.14$, $y = 1/4$.

With potassium in the general positions, Mo–K_I maxima are expected at $\pm(x - 0.14)$, $\pm(y - 1/4)$; $\pm(x + 0.36)$, $\pm(y - 1/4)$; $\pm(x + 0.14)$, $\pm(y + 1/4)$; $\pm(x - 0.36)$, $\pm(y + 1/4)$. Using the large peaks at $X = 0$ (or $1/2$), $Y = 0.20$ and $X = 0.22$ (or 0.28), $Y = 0.30$, we obtain $x = 0.14$, $y = 0.05$ (or 0.45) for K_I, the alternative values for y referring to a pair of equivalent atoms related one to the other through the symmetry plane of the unit cell at $y = 1/4$.

It is possible to associate the peaks observed at $X = 0$ (or $1/2$), $Y = 1/2$ and $X = 0.22$ (or 0.28), $Y = 0$ with Mo–K separations involving four potassium atoms in 4(c). Maxima are then expected at $\pm(0.14 - x)$, 0; $\pm(0.14 + x)$, $1/2$; $\pm(0.36 - x)$, $1/2$; $\pm(0.36 + x)$, 0. Approximate parameter values for K_{II} are then $x = 0.36$ (or 0.86), $y = 1/4$, the alternative values for x referring to two equivalent atoms related through the screw axis lying in the plane $y = 1/4$.

Since there is no indication that the centers of symmetry 4(a) or 4(b) are occupied, the remaining four potassium atoms must be placed in 4(c) also. Peaks observed at $X = 0.18$ (or 0.32), $Y = 0$ and $X = 0.10$ (or 0.40), $Y = 1/2$ are interpreted in terms of Mo–K_{III} separations, the atomic coördinates of K_{III} being then $x = -0.04$ (or 0.46), $y = 1/4$.

The projection on (100) possesses a center of symmetry at $Y = 1/4$, $Z = 1/4$ in addition to the usual one at the origin. Four molybdenum atoms placed in 4(c) should lead to large maxima at 0, $\pm(1/2 - 2z)$; $1/2$, $\pm 2z$; $1/2$, $1/2$; 0, 0. These are observed (Table I) at 0, 0.30; $1/2$, 0.20; $1/2$, $1/2$; 0, 0, all atoms contributing, of course, to the identity peak. As anticipated, these data lead to $y = 1/4$, $z = 0.10$.

The peaks observed at 0.30, 0.21; 0.30, 0.09; 0.20, 0.41; 0.20, 0.29 are interpreted as arising from Mo–K_I separations, such maxima being expected at $\pm(y + 1/4)$, $\pm(z + 0.10)$; $\pm(y + 1/4)$ $\pm(z + 0.40)$; $\pm(1/4 - y)$, $\pm(z - 0.10)$; $\pm(1/4 - y)$, $\pm(z - 0.40)$. These data lead to $y = 0.05$ (or 0.45), $z = 0.69$ (or 0.81), the alternative values for z referring to equivalent atoms related through the screw axis mentioned above.

With potassium in 4(c) Mo–K maxima are expected at 0, $\pm(z - 0.10)$; $1/2$, $\pm(z + 0.10)$; $1/2$, $\pm(z + 0.40)$; 0, $\pm(z - 0.40)$. The peaks observed at 0, $1/2$; $1/2$, 0.30; $1/2$, 0; 0, 0.20 lead to $y = 1/4$, $z = 0.60$ (or 0.90) as coördinates of K_{II}.

The peaks observed at 0, 0.40; $1/2$, 0.40; $1/2$, 0.10; 0, 0.10 are associated with Mo–K_{III} separations, yielding $y = 1/4$, $z = 0.50$ (or 0) for K_{III}.

By considering simultaneously the results derived from the three projections, we get for Mo, $x = 0.14$, $y = 1/4$, $z = 0.10$; for K_I, $x = 0.14$, $y = 0.05$ (or 0.45), $z = 0.69$. Since we obtained no information about the positions of K_{II} and K_{III} from the (010) projection we have in each case two possible non-equivalent combinations of x and z coördinates for $y = 1/4$. The correct combinations turn out to be for K_{II}, $x = 0.36$, $y = 1/4$, $z = 0.60$ (or $x = 0.86$, $y = 1/4$, $z = 0.90$); for K_{III}, $x = -0.04$, $y = 1/4$, $z = 0.50$ (or $x = 0.46$, $y = 1/4$, $z = 0$). Some information on this point was derived from Patterson–Harker[7] summations, which will not be described here.

Table I lists the approximate values of the parameters of molybdenum and potassium together with the coördinates of the observed peaks on the projections from which the parameter data were derived. The brief account of the treatment accorded the Patterson data which we have presented is in some respects quite incomplete, and is probably somewhat misleading with regard to the apparent simplicity of the interpretations. We doubt, however, that we could have arrived at the approximate positions of potassium atoms in a reasonable period of time by any purely trial and error process.

In order to make a Fourier projection of relative electron density on any axial plane of potassium molybdocyanide dihydrate, for instance on (001), a double sum of the following type must be calculated.

$$\rho(x,y) = \Sigma h \Sigma k F_{(hk0)} \cos 2\pi(hx + ky)$$

The relative magnitudes of the $F_{(hk0)}$ are given by the square roots of the $|F_{(hk0)}|^2$ which were used in the computation of the Patterson projection. The signs to be attached to the more important reflection amplitudes can be computed on the basis of the approximate molybdenum and potassium positions of Table I. The pertinent

The atomic f-values of Pauling and Sherman[8] are used throughout this paper.

Table II gives the relative reflection amplitudes for $(hk0)$ and $(h0l)$ reflections. It was possible to assign correctly about 85% of the phases for the first projections, those for which the sign seemed seriously in doubt being omitted.

The actual projections were calculated by the method of Lipson and Beevers.[6] For the (001) projection $\rho\,(x,y) = A(x,0) + \sum_k A(x,k) \cos 2\pi\, ky - \sum_k B(x,k) \sin 2\pi\, ky$, in which $A(x,0) = F_{(000)} + 2\sum_h F_{(h00)} \cos 2\pi\, hx$, $A\,(x,k) = 2F_{(0k0)} + 4\sum_h F_{(hk0)} \cos 2\pi\, hx$, and $B(x,k) = 4\sum_h F_{(hk0)} \sin 2\pi\, hx$. Since $F_{(\bar{h}k0)} = F_{(hk0)}$ for k even, and $F_{(\bar{h}k0)} = -F_{(hk0)}$ for k odd, the A-series includes only reflections with k even, the B-series only those with k odd. Expressions of a similar kind apply to the (010) projection.

From the first incomplete Fourier projections it was possible not only to conclude that an essentially correct assignment of positions to molybdenum and potassium had been derived from the Patterson data but also to secure more accurate values of their atomic coördinates for use in subsequent calculations. In addition, certain minor peaks which appeared were indicative of the positions of carbon, nitrogen, and oxygen atoms.

Some of these minor peaks were immediately interpretable as cyanide groups linearly attached to molybdenum atoms with approximately the interatomic separations calculated from the "Tables of Covalent Radii"[9] (using the "trigonal prism" radius of molybdenum). These separations are 2.14 Å. for Mo–C, 1.15 Å. for C–N (triple bond), and therefore 3.29 Å. for Mo–N. On the basis both of theory and of many experimental data the bond angle Mo—C≡N is expected to be 180°.

During the course of attempts to use the molybdenum and potassium positions as a framework into which to fit various geometrically plausible configurations for the $Mo(CN)_8$ complex which would be compatible with the indications of carbon and nitrogen positions given by the projections, the following possibilities for placing eight cyanide groups about a central molybdenum atom were excluded quite definitely: (a) the configuration outlined (exactly or approximately) by the vertices of a cube; (b) the configuration outlined by the corners of an (approximately) square Archimedean antiprism; and (c) the configuration outlined by the vertices of a figure derived from a trigonal prism by adding two extra cyanide groups along normals to two of the rectangular faces. All of these possibilities, moreover, could be excluded also by arguments based on considerations of interatomic distances, since in every case one or more improbably small N–N separations between adjacent anions were encountered.

[a] Exclusive of reflections incompatible with the symmetry of the space group.

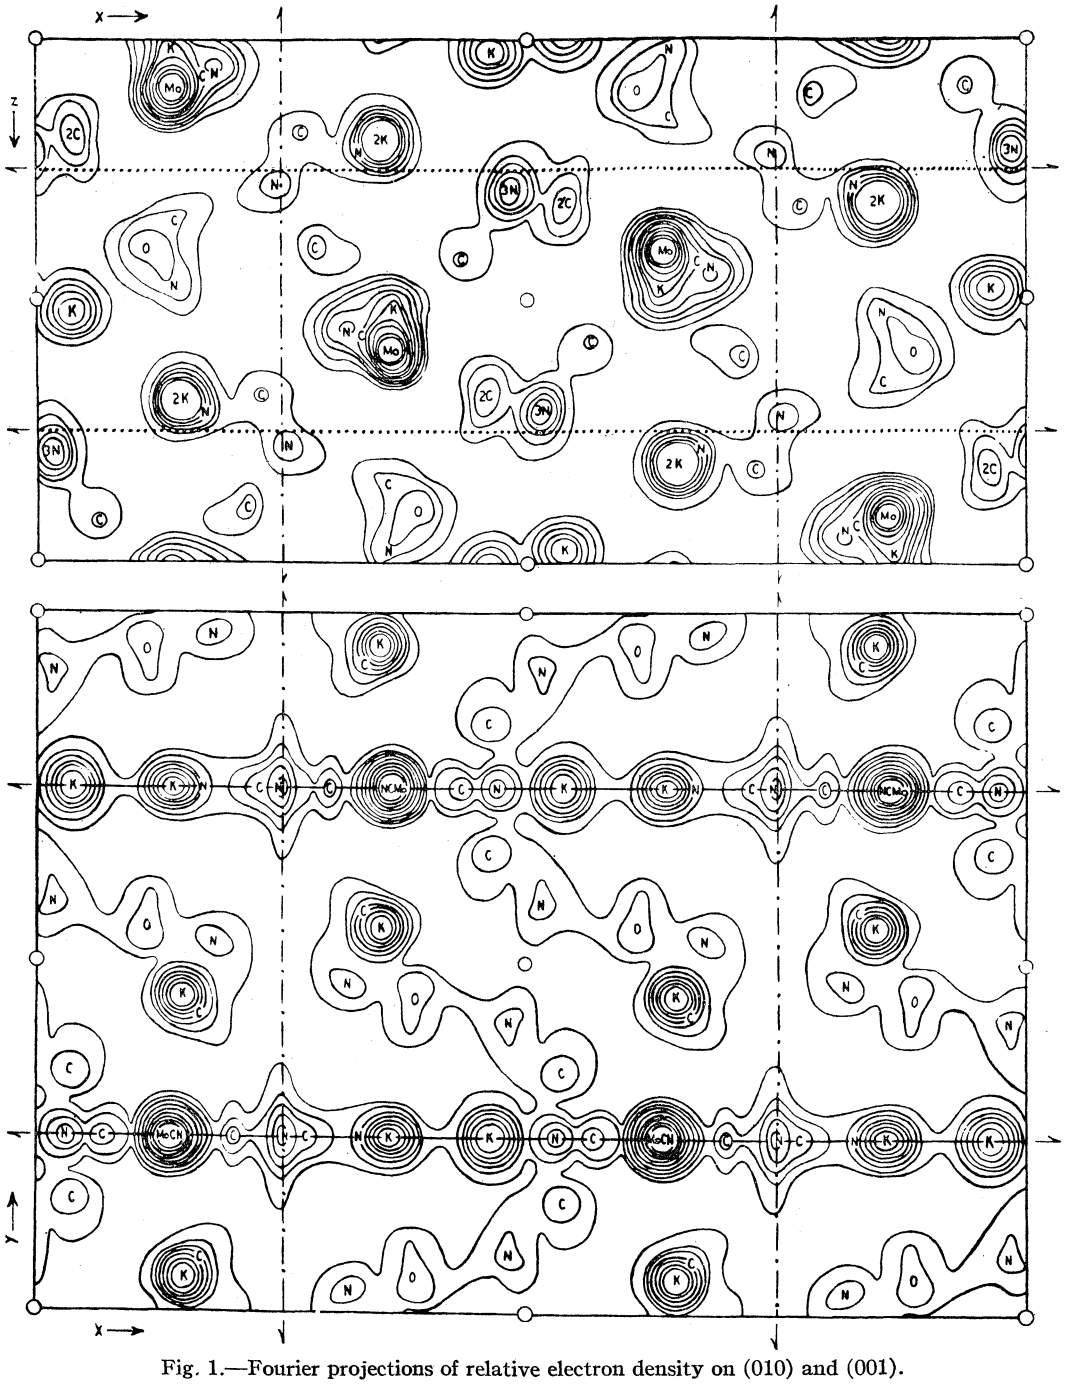

Fig. 1.—Fourier projections of relative electron density on (010) and (001).

The complete structure of potassium molybdocyanide dihydrate (Fig. 2) was gotten as a direct interpretation of the final Fourier projections (Fig. 1) of relative electron density on (001) and (010), without the use of any preconceived notions as to the geometric form of the complex. To obtain the projections in the final form of Fig. 1 it was necessary to recalculate each set of data several times, taking advantage in each calculation of the more nearly complete phase data resulting from the previous approximation.

The peaks on the contour maps of Fig. 1 are marked with the symbols of the atoms whose projections they represent. The atomic positions given by the Fourier analyses are shown still more clearly and completely in Fig. 2, in which diagram-

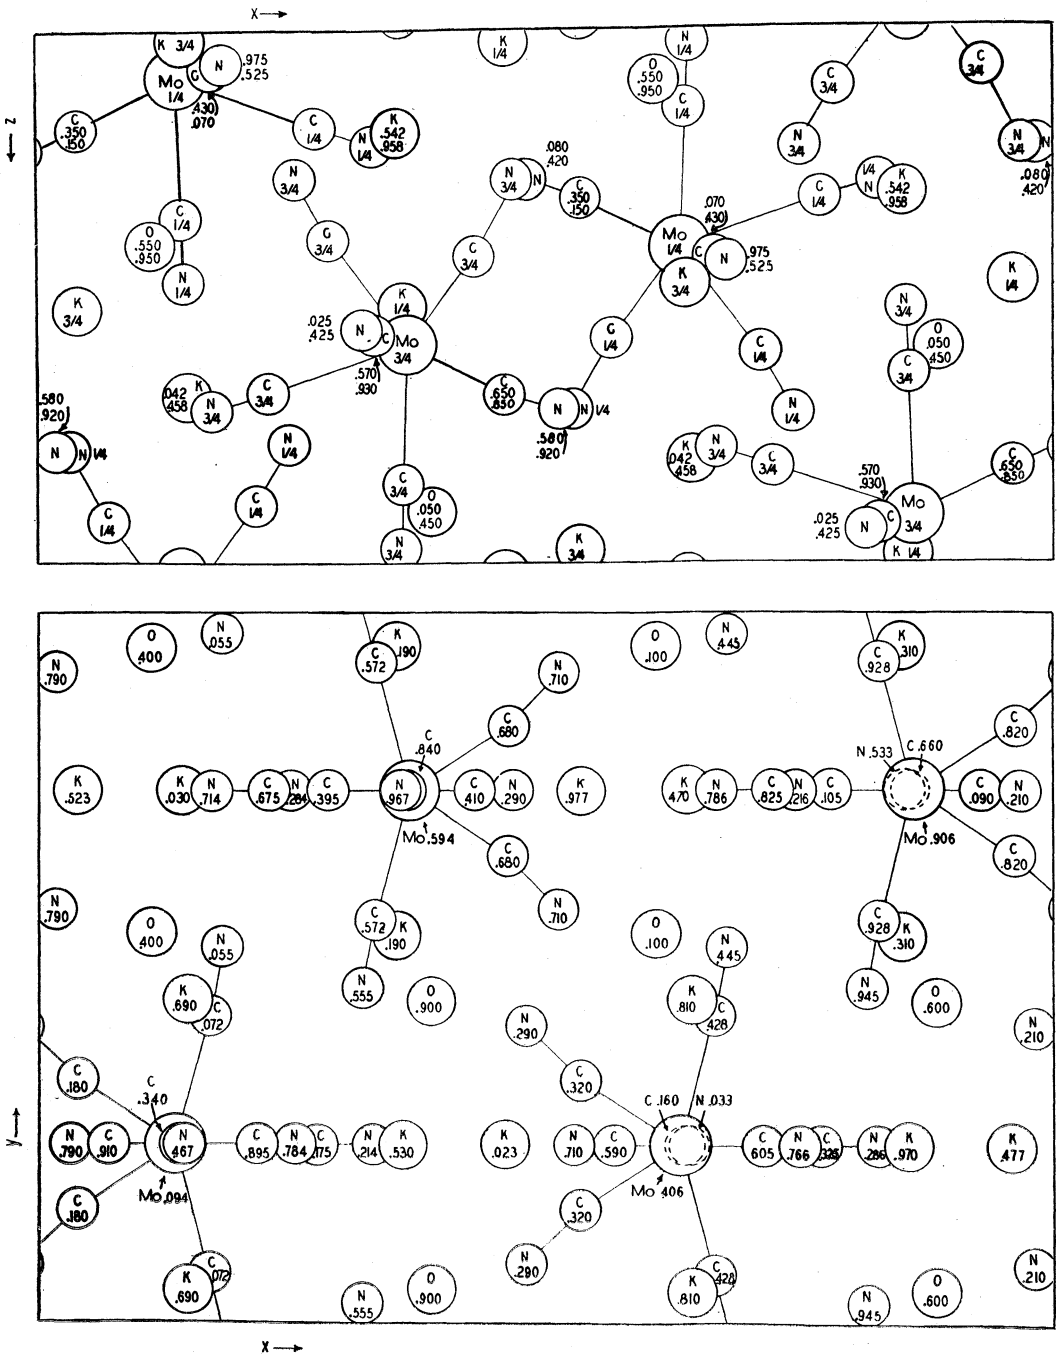

Fig. 2.—Diagrammatic projections of the unit of structure on (010) and (001). The distance of each atom above the plane of projection is indicated.

matic projections of the unit of structure on (010) and (001) are reproduced. Parameter data for all atoms (except hydrogen) as derived from these projections are listed in Table III. The positions of molybdenum and potassium given by the Fourier projections are appreciably different from the approximate values derived from the Patterson data.

A brief critical discussion of the Fourier plots and of the data used in their calculation is appropriate. For those peaks which are completely resolved on the projections the contour lines are nearly circular for the most part, the principal exceptions being oxygen and one type of nitrogen (N_I) on the (001) map. The especial

prominence of the molybdenum peaks is not fully indicated in Fig. 1, since it was not practicable to maintain the density interval characteristic of the rest of the plot in drawing in the contour lines of high density on these peaks.

The maximum relative electron density observed for carbon or nitrogen on the (001) projection is appreciably greater for an atom situated in one of the densely populated symmetry planes than for a chemically similar atom in the general position. When similarly situated, however, the densities of peaks due to structurally non-equivalent, but chemically identical, atoms are seen to be nearly equal.

Nitrogen peaks, for the most part, are observed to be larger than those of similarly situated carbon atoms. Otherwise stated, we may conclude from the relative values of the peak densities that carbon rather than nitrogen of the cyanide group is bonded to molybdenum.

There are on each plot several cases of partial superposition of two or more peaks. By considering the two projections simultaneously and taking into account the observed asymmetry of the peaks, there prove to be no difficulties of interpretation, and a reasonable estimate can be gotten for every parameter value.

A comparison of corresponding values of the x-parameters as read from the two plots furnishes a partial test of the internal consistency of the Fourier data. We find virtually identical values for molybdenum and potassium and, at most, slight variations for less prominent atoms. In general, however, we should expect both projections to furnish more accurate values of the x-parameters than of the variable parameters along the other axes.

A comparison of calculated with observed relative reflection amplitudes for ($hk0$) and ($h0l$) reflections is given in Table II. The observed amplitudes are those used in the calculation of the Fourier projections. The calculated amplitudes contain no temperature factor and are, therefore, just the corresponding structure factors. The agreement is quite satisfactory on the whole, but seems to be slightly better for ($hk0$) than for ($h0l$) reflections.

Considering that the effects of thermal agitation are included in the experimental amplitudes, their values seem to be *relatively* somewhat large for the larger values of the scattering angle. Correction of these amplitudes for absorption in the crystal would result in some improvement in this respect, since for the specimens used the relative correction factor varies from 1.0 for the amplitude of smallest sin θ to about 0.9 for that of largest sin θ. The experimental amplitudes do fall off so rapidly with increasing angle of scattering that it is probable that slightly large values for them at large sin θ are of less significance in limiting the precision of the Fourier projections than are the errors in estimating intensities of the strong reflections appearing at small sin θ.

On the average, the amplitude data seem to be satisfactory. Each Fourier series, moreover, contains an unusually large number of terms. The satisfactory character of the results is to be understood in terms of these factors.

We have made also an approximate Fourier projection of relative electron density on (100), using the ($0kl$) amplitudes for which the phases could be assigned readily on the basis of the parameter values resulting from the first Fourier projections on (010) and (001). This incomplete contour map proved to be quite useful during the early stages of refining the (010) and (001) projections. Since the irregular shape and comparatively large size of the specimen used made the absorption corrections on the ($0kl$) data subject to considerable uncertainty, and since, moreover, but few of the minor peaks in which we are mainly interested at this stage are completely resolved on the (100) projection, we have not attempted to put these Fourier data into final

form. While not giving accurate values for the parameters of carbon, nitrogen, and oxygen, the (100) projection constitutes a satisfactory check upon our general conclusions about the structure.

Diagrammatic projections of the structure on (010) and (001) are shown in Fig. 2 and a drawing of the complex $Mo(CN)_8$ group is shown in Fig. 3. Table IV contains interatomic distances as calculated from the parameter data of Table II.

TABLE IV

INTERATOMIC DISTANCES IN POTASSIUM MOLYBDOCYANIDE DIHYDRATE

Atom pair	Separation, Å.	Atom pair	Separation, Å.

Molybdenum–carbon separations lie between 2.04 and 2.24 Å., the average being 2.15 Å. The sum of the covalent radii,[9] using the "trigonal prism" radius for molybdenum, is 2.14 Å. The carbon–nitrogen separations are between 1.07 and 1.27 Å., the average being 1.15 Å., just the "triple bond" value. The average molybdenum–nitrogen separation is 3.29 Å., and the individual Mo—C≡N chains are practically linear throughout. The carbon–carbon separations of adjacent pairs of

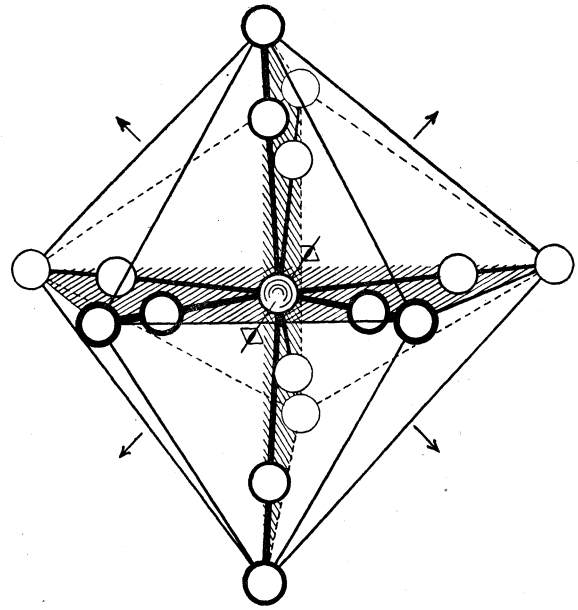

Fig. 3.—The configuration of the idealized molybdenum octocyanide group of symmetry D_{2}^{d}.

atoms within the complex vary between 2.34 and 3.18 Å. The separations may be divided empirically into two types: four longer distances, averaging 3.14 Å., and fourteen shorter distances, averaging 2.59 Å. The corresponding nitrogen–nitrogen separations lie between 3.64 and 4.82 Å., the average of the four longer distances being 4.75 Å., and of the fourteen shorter distances 3.98 Å.

The potassium ion in the general position K_I is surrounded by a rather irregular coördination figure consisting of seven nitrogen, one oxygen, and two carbon atoms, at distances ranging from 2.82 Å. (K_I–O) to 3.43 Å. Each potassium ion of the second kind, K_{II}, has five close neighbors at positions approximating to the vertices of a trigonal bipyramid, the average K–N separation being 2.82 Å. There are two additional nitrogen atoms about 3.58 Å. from each potassium of this kind. The coördination group of the third type of potassium ion consists of an oxygen atom at a distance of 2.83 Å., two carbon atoms at 3.08 Å., and five nitrogen atoms at an average distance of 2.95 Å.

There is no evidence for the existence of a definite hydrogen bridge between nitrogen of a cyanide group and oxygen of the water molecule, since the smallest O–N separation is about 2.99 Å.

The closest distance of approach between two nitrogen atoms of adjacent complexes is in no case less than 3.25 Å.

The complex anion, $Mo(CN)_8^{-4}$, which is shown to exist within crystals of potassium molybdocyanide dihydrate, is required by the space group to possess only a plane of symmetry. A study of the structure shows, however, that the configuration departs but little from the symmetry of the point group $D_2^d-\bar{4}2m$, that is, a fourfold axis of rotary inversion with two mutually perpendicular two-fold axes and two diagonal planes of symmetry. The $Mo(CN)_8$ polyhedron is a duodecahedron with eight vertices and triangular faces. It can be described as the figure outlined by the vertices of two interpenetrating bisphenoids oriented in the same way as the positive and negative tetrahedra of a cube; as compared with these regular tetrahedra one bisphenoid is considerably elongated, and the other is much flattened along the unique axis.

The symmetry of D_2^d divides the eighteen nitrogen–nitrogen (or carbon–carbon) separations of the complex into four structurally distinct types. Corresponding to the empirical distinction already noted it is convenient to divide these distances into but two classes. Assuming linear Mo—C≡N chains with Mo–C = 2.15 Å., C≡N = 1.15 Å., we calculate the separations listed in Table V for the idealized $Mo(CN)_8$ group of symmetry D_2^d. We see at once that there are no significant differences between these calculated distances and the corresponding experimentally determined average values.

TABLE V

DIMENSIONAL COMPARISON OF VARIOUS ANION CONFIGURATIONS

(Mo–N = 3.30 Å.)

Configuration	Separation, Å. C–C	N–N
Experimental $Mo(CN)_8$		
Four longer distances (av.)	3.14	4.75
Fourteen shorter distances (av.)	2.59	3.98
Idealized $Mo(CN)_8$		
Four longer distances	3.09	4.75
Fourteen shorter distances	2.58	3.96
Cube—twelve distances	2.48	3.81
Antiprism—sixteen distances	2.62	4.01

Table V contains also nitrogen–nitrogen and carbon–carbon separations for the cube and the square Archimedean antiprism as calculated for linear Mo—C≡N chains with Mo–N = 3.30 Å. No quantum mechanical treatment of the directional characteristics of quadrivalent molybdenum forming eight bonds has been reported, but the configuration established for the $Mo(CN)_8$ group in this paper seems to compare very favorably with either the cube or the antiprism from a stereochemical point of view. The repulsive potential energy arising from the interpenetration of the closed valence shells of adjacent coördinated atoms in the $Mo(CN)_8$ type of complex is certainly smaller than in the cube, and is not much different from that in the antiprism.

Crystals of potassium tungstocyanide dihydrate, $K_4W(CN)_8\cdot 2H_2O$, and potassium molybdocyanide dihydrate are almost surely isomorphous, and the $W(CN)_8^{-4}$ ion probably has the configuration established for the $Mo(CN)_8$ group. This configuration is also a reasonable one for the TaF_8^{-3} ion in crystals of sodium fluotantalate, Na_3TaF_8, and for the osmium octofluoride molecule, for which the osmium–fluorine distance is known from electron diffraction studies.[10]

It has been pointed out to us by Professor Linus Pauling that the arrangement of eight oxygen atoms around zirconium in zircon,[11] $ZrSiO_4$, is similar to that of the eight cyanide radicals around molybdenum in potassium molybdocyanide dihydrate. In zircon each oxygen atom is at once a part of two such ZrO_8 groups and one tetrahedral SiO_4 group. Other crystals having the zircon type of structure include yttrium phosphate, yttrium vanadate, and calcium chromate.

Subtracting the carbon "single bond" radius,[9] 0.77 Å., from the experimental molybdenum–carbon separation, 2.15 Å., we get 1.38 Å. for the radius of quadrivalent molybdenum form-eight bonds.

Summary

It is shown from X-ray data that the orthorhombic unit cell in crystals of potassium molybdocyanide dihydrate contains four molecules with $a_0 = 16.55$ Å., $b_0 = 11.70$ Å., $c_0 = 8.68$ Å., space-group D_{2h}^{16}–*Pnma*. Patterson projections on the three axial planes together with Patterson–Harker summations calculated from visually estimated intensity data were used to obtain approximate coördinates for molybdenum and potassium (Table I). These data were sufficient to determine the phases of the more important (*hk*0) and (*h*0*l*) reflection amplitudes (Table II) so that incomplete Fourier projections on (001) and (010) could be calculated. Recalculation and refine-

ment of these projections by familiar methods of successive approximations lead to the complete determination of the structure (Figs. 1 and 2). The parameter data of Table III account satisfactorily for the intensities of X-ray reflections (Table II) and lead to generally reasonable interatomic distances (Table IV).

The structure (Fig. 2) is an aggregate of K^+ ions, $Mo(CN)_8^{-4}$ ions, and water molecules. The configuration of the $Mo(CN)_8$ group (Fig. 3) seems to be stereochemically very reasonable. The $Mo(CN)_8$ polyhedron is a duodecahedron with eight vertices and triangular faces. Although required by the space group to possess only a plane of symmetry, the complex ion in the crystal approximates to the symmetry of the point group D_2^d-$\bar{4}2m$.

Phase Equilibrium Relations in the System, Na_2SiO_3–Li_2SiO_3–SiO_2*

BY F. C. KRACEK

The work described in this paper concerns itself with the general equilibrium relations at one atmosphere pressure in the system Na_2SiO_3–Li_2SiO_3–SiO_2, and comprises the experimental determination of the temperatures at which the various crystalline phases are in equilibrium with one another, and with melts of the appropriate composition. The crystallization relations are comparatively simple, being only slightly complicated by the occurrence of solid solutions arising from a partial mutual replacement of sodium and lithium in the silicate compounds. Only one ternary compound is present in the system. This is $NaLiSiO_3$, formed by replacement of Li for Na in Na_2SiO_3; it is the Li-rich limit of the solid solution series $(Na_2,NaLi)SiO_3$. The other silicates in the system, Li_2SiO_3, $Na_2Si_2O_5$, and $Li_2Si_2O_5$, all form solid solutions of only limited extent.

Experimental Methods

The methods of study were in all respects similar to those already made familiar through the publications of this Laboratory on phase equilibrium relations. The liquidus and other significant temperatures were determined by quenching combined with microscopic examination,[1] except in compositions high in lithium metasilicate which crystallize too rapidly for the quenching technique to be effective. In such cases the temperatures were established by heating curve thermal analysis for the liquidus, and by both heating and cooling curve methods in studying transition phenomena.[2]

Homogeneous glasses of the various compositions in the system were prepared from purified silica, used in the form of cristobalite derived from powdered quartz heated at 1500°, and from reagent grade lithium carbonate and sodium carbonate. Analyses proved the reagents all to be of high purity.[3] The preparations were made up quantitatively from the thoroughly dried reagents, special care being taken to avoid losses, either mechanical, or by volatilization. Losses by volatilization were negligible except in the lithium metasilicate region of the system, where they approached 0.1% of the weight of the preparation. They were almost entirely of lithium, and could be compensated for by small additions of lithium carbonate to the original mixture. The fusions were made in platinum crucibles. To avoid attack on the crucibles by the corrosive melts of the easily fusible carbonate mixtures, it is necessary to exclude oxygen during the initial stages of the heating, until the reaction of the melt with the silica has absorbed most of the free alkali present. This was done by heating the mixtures in covered crucibles over carefully controlled Méker burners (the more convenient initial sintering of the mixtures by heating in electric furnaces always resulted in bad attack on the crucibles), the temperature being kept at the point of incipient fusion until most of the carbon dioxide was driven off. The final heatings were

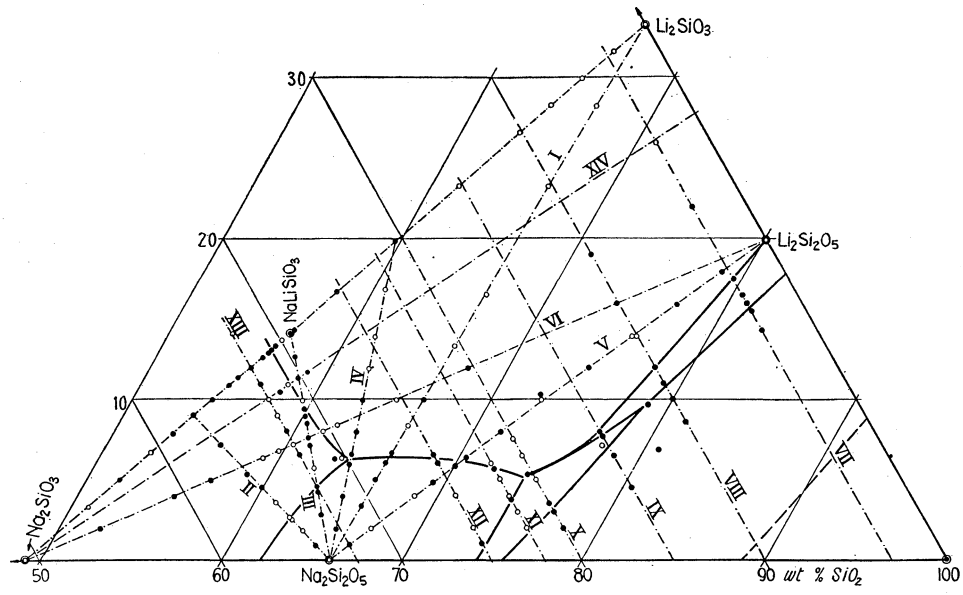

Fig. 1.—Ternary diagram of the system, Na_2SiO_3–Li_2SiO_3–SiO_2, showing the equilibrium fields at the liquidus, and location of the experimental points. Black dots represent compositions for which refractive indices of glasses are included in Table I.

made in electric furnaces in the usual manner, keeping the temperature as low as possible, consistent with complete displacement of the carbon dioxide. The more alkali-rich glasses were crystallized several times during the process, to drive off the carbon dioxide at lower temperatures, and thus to avoid losses by volatilization. The safe maximum temperatures, at which losses are negligible, are roughly, 1100° in the metasilicate, and 1300° in the disilicate regions of the system.

The temperatures were measured by means of platinum against platinum–10% rhodium thermoelements, using a shielded Feussner potentiometer system. The readings of the calibrated thermoelements were converted into temperatures on the Day and Sosman gas thermometer scale with the help of standard tables.[4]

The temperatures of the quenching furnaces were controlled automatically with a precision of ±0.3 to ±0.5°. The time of the individual runs, several of which are needed for each determination by the quenching method, varied from one hour to several days, depending upon the speed with which equilibrium is reached in the different regions of the system. This is most rapid for the metasilicates, and slowest for quartz at the Na_2O–SiO_2 side-line. The rate of dissolution of quartz increases rapidly with even small additions of lithium and, within the system, the reactivities of quartz and tridymite are sufficiently high to permit their mutual conversion (quartz $\rightleftarrows$ tridymite) near the inversion temperature in about twenty-four hours. This has made it possible to redetermine the inversion temperature with somewhat less uncertainty than before.

In presenting the experimental results below, certain minor revisions of previously published data are made. Such revisions are primarily based on very frequent recalibrations of the thermoelements, combined with a general improvement both in apparatus and technique (see ref. 2). Particular attention was given to the attainment of equilibrium in the charges. This is especially important in the cases of the more sluggish reactions, such as the mutual conversion of quartz and tridymite, and the various eutectic meltings, where certain phases tend to persist above the reaction temperatures for considerable periods of time. The measured limits of uncertainty of each determination are given by means of a ± bracket, or by quoting the measured temperature limits, as the case may be.

Experimental Results

The distribution of the compositions studied in the ternary system is represented in Fig. 1, which also shows the boundary curves between the fields. The experimental points are located mainly along certain sections across the ternary

(4) L. H. Adams, "International Critical Tables," Vol. I, 1925, p. 57.

system, chosen so as to present a net of points which would allow for easy interpolation in deriving the liquidus surfaces for the various primary phases. These sections are numbered in the figure by Roman numerals to correspond with the numbering of the sections in Table I. This table contains the experimentally determined temperatures for the various phase reactions. The temperatures given are the nearest determined temperatures, above, and below, the transformation point in question—in other words, the phase reaction temperature lies between the values given. Most of the measurements represent determinations of the liquidus temperatures; at appropriate places in the table, however, temperatures for other phase reactions,

mainly eutectics, are given, in connection with the composition for which they were determined. The coördinates of the invariant points for the pressure of one atmosphere are collected in Table III.

The Binary Systems on the Side Lines

Before proceeding to a discussion of the relations brought out in the ternary system, it is necessary to describe the fundamental binary systems on the sides of the triangle, Na_2SiO_3–Li_2SiO_3–SiO_2. It will be noted that one of these, Na_2SiO_3–Li_2SiO_3, is a binary section across the larger triangle, Na_2O–Li_2O–SiO_2.

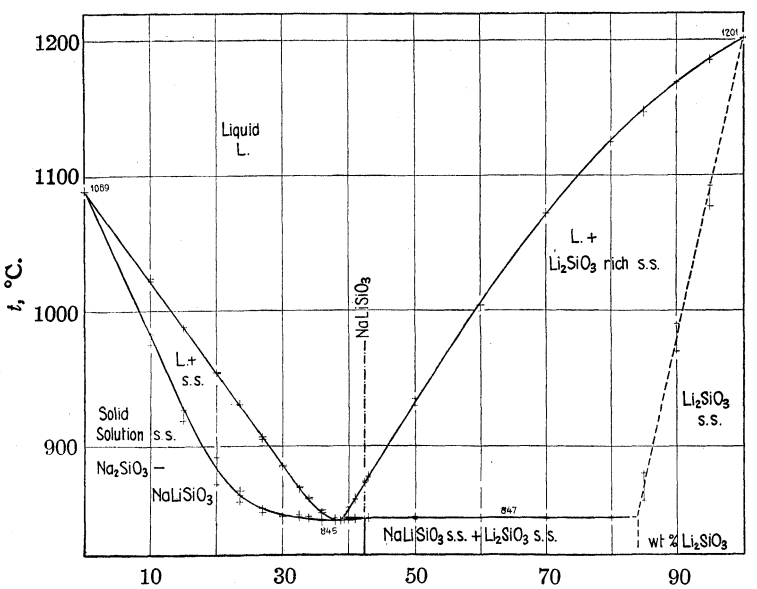

Fig. 2.—The binary system, Na_2SiO_3–Li_2SiO_3. Reprinted from Ref. 3.

1. The System, Na_2SiO_3–Li_2SiO_3.—The data on this system have been published recently.[3] This system is of special interest in that sodium metasilicate crystals are capable of exchanging sodium for lithium in solid solution until the composition sodium lithium (1,1) metasilicate is reached. Lithium metasilicate, on the other hand, takes up only a minor proportion of sodium into its lattice. The compound sodium lithium (1,1) metasilicate melts incongruently at 847°, yielding a liquid of 39.3 wt. per cent. lithium metasilicate, and the sodium-bearing lithium metasilicate crystals. The solid solution series, $(Na_2,NaLi)SiO_3$, has a minimum on its liquidus at 845°, 38.5 wt. per cent. lithium metasilicate (binary compositions). The equilibrium relations are illustrated in Fig. 2 (see also Fig. 2 of ref. 3).

2. The System, Na_2SiO_3–SiO_2.—This system has been studied by Morey and Bowen,[5] and by Kracek[6] who extended the investigation to include the orthosilicate, Na_4SiO_4.

(a) **Polymorphism of Sodium Disilicate.**—Measurements, supplementing those earlier made by Kracek,[6] of thermal arrests in the sodium disilicate region with the improved apparatus now in use (see ref. 2) were made

(5) G. W. Morey and N. L. Bowen, *J. Phys. Chem.*, **28**, 1167 (1924).

(6) F. C. Kracek, *ibid.*, **34**, 1583 (1930).

on pure sodium disilicate (65.95% silicon dioxide), on two preparations toward sodium metasilicate, at 62.5 and 64.2% silicon dioxide, and on three preparations toward silicon dioxide, at 68.3, 69.0, and 73.0% silicon dioxide. Each of these preparations yielded two arrests, one at 678°, the other at 707° (average temperatures), as illustrated in Figs. 3 and 4. The heat effects are relatively small, probably of the order of 2 cal./g. for the 678° arrest, and 1 cal./g. for the 707° arrest. The 707° arrest had escaped detection previously in preparations containing excess silicon dioxide. An arrest, not included in Fig. 4, previously recorded at 768° in silicon dioxide-rich preparations only, is again recorded in the same region, both of temperature and composition, and probably is due to eutectic melting of small amounts of tridymite and cristobalite present.

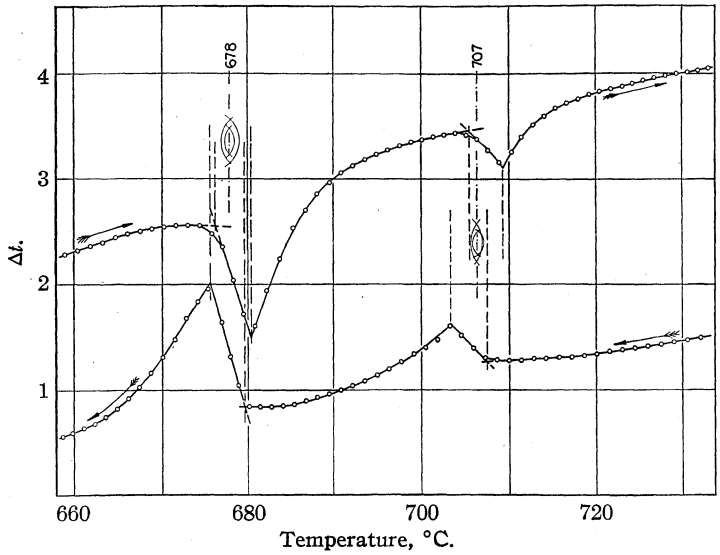

Fig. 3.—Typical differential heating and cooling curves of phase transitions in $Na_2Si_2O_5$, giving geometrical construction for deducing the average transition temperatures.

These measurements lead to the conclusion that sodium disilicate is trimorphous with inversions located at atmospheric pressure at the average temperatures of 678 and 707°. Presence of lithium silicates influences these temperatures, as stated at a later point in the paper (see Figs. 8 and 9).

(b) **The $Na_2Si_2O_5$–Quartz Eutectic.**—The determination of the $Na_2Si_2O_5$–quartz eutectic by heating curves is inexact, yielding an arrest which is spread rather indefinitely over the temperature interval from about 788 to nearly 800°. To verify the location of this eutectic, we have heated completely crystalline preparations of 74.8 and 76.0% silicon dioxide at various temperatures, and quenched. When heated for two days at 786°, the preparations remained powdery. At 788° they sintered to porous lumps, with little or no glass evident under the microscope. At 790° there was much glass, in which were imbedded sharply faceted quartz crystals, and larger eroded quartz grains, with very little unevenly scattered remnants of sodium disilicate crystals. The eutectic temperature is accordingly 789 ± 1°. The quartz liquidus on the 74.8% silicon dioxide preparation (compare Kracek's earlier preparation 571, 74.81% silicon dioxide, 838°) was found by similar procedure to be 822 ± 4°. The intersection of the liquidus curves for sodium disilicate and quartz, at the newly determined eutectic temperature of 789°, is located at 74.2 ± 0.3% silicon dioxide. The former values for the eutectic were 793°, and 73.4% (Morey and Bowen) and 73.9% (Kracek) silicon dioxide.

(c) **The Na_2SiO_3–$Na_2Si_2O_5$ Eutectic.**—Precrystallized preparations of 61.5 and 62.5% silicon

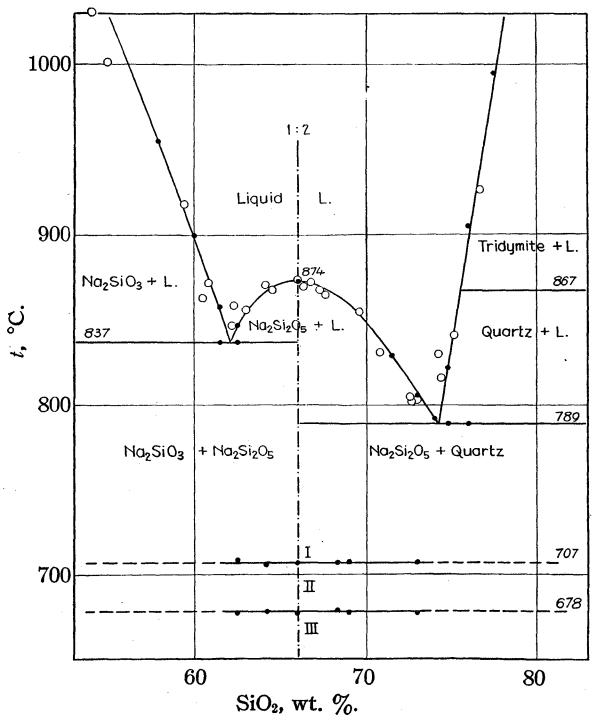

Fig. 4.—The disilicate region of the system, Na_2SiO_3–SiO_2: open circles by Morey and Bowen,[5] and Bowen, Schairer and Willems (unpublished); black dots, Kracek.

dioxide remained unsintered at 836°, and contained much glass at 838°. If 837 ± 1° is taken as the eutectic temperature, the eutectic composition is 62.1 ± 0.2% silicon dioxide. The former values were 840°, 60.8% silicon dioxide (Morey and Bowen), and 846°, 62.1% silicon dioxide (Kracek).

(d) **The Cristobalite Liquidus.**—The liquidus temperatures published earlier by the writer[7] for cristobalite in the system, Na_2O–SiO_2, are slightly higher than those determined in the present work. The high values in the earlier determinations can be ascribed only to the existence of a temperature gradient in the quenching furnace then used. The newly determined values are: 1532 ± 5° at 91.5, 1580 ± 3° at 95.0, and 1628 ± 3° at 97.5% silicon dioxide.

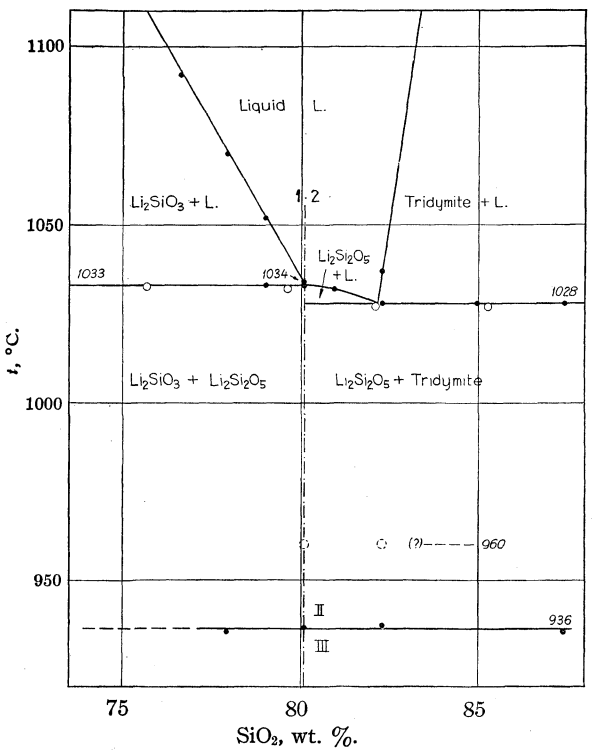

Fig. 5.—The disilicate region of the system, Li_2SiO_3–SiO_2: open circles, Jaeger and van Klooster; black dots and dotted circles, Kracek.

The revisions discussed above have been incorporated in Fig. 4, which represents the phase relations in the system, Na_2SiO_3–SiO_2, for the region in the neighborhood of sodium disilicate.

3. The System, Li_2SiO_3–SiO_2.—The equilibrium relations in this system were studied by Jaeger and van Klooster[8] and by Kracek,[7,9] among others.

(a) **The Cristobalite Liquidus.**—A redetermination was made of the liquidus temperatures for cristobalite as the primary phase. It was found that the published temperatures[7] in this system also are slightly high; the new values are 1508 ± 4° at 92.5, 1561 ± 3° at 95.0, and 1605 ± 3° at 97.0% silicon dioxide.

(b) **Polymorphism of Lithium Disilicate.**—To verify the former[9] thermal analysis measurements in the lithium disilicate region of the system, we have made new determinations on crystallized preparations of 77.9, 80.08 ($Li_2Si_2O_5$), 82.3, and 87.4% silicon dioxide. A small arrest, with a thermal effect of 1 to 2 cal./g. in pure lithium disilicate, was found in all the preparations, at the average temperature of 936°. This arrest has the characteristics associated with typical polymorphic inversions, with hysteresis.

The very small irregularity in differential temperature, formerly noted at 960°, could not be reproduced with certainty. It was noted once, but only during the first heating, in the 80.08 and 82.3% silicon dioxide preparations. It did not reappear during subsequent heat treatments, or in any of the other preparations; hence, its significance remains unexplained.

Addition of sodium silicates to lithium disilicate lowers the 936° inversion to 930° (see the section, $Na_2Si_2O_5$–$Li_2Si_2O_5$).

The phase relations in the neighborhood of lithium disilicate for the system Li_2SiO_3–SiO_2 are illustrated in Fig. 5.

The Ternary System

The only ternary compound in the system is sodium lithium (1,1) metasilicate. This compound is an end-member of the $(Na_2,NaLi)SiO_3$ series of solid solutions, and has no separate field of its own in the ternary system. Hence, the primary phases at the liquidus are the $(Na_2,NaLi)SiO_3$ solid solutions, Li_2SiO_3, $Na_2Si_2O_5$, $Li_2Si_2O_5$, and silica in its three major modifications. The compounds Li_2SiO_3, $Li_2Si_2O_5$, and $Na_2Si_2O_5$ all form limited series of solid solutions with small mutual replacements of lithium and sodium.

Only one section within the system, namely, $Na_2Si_2O_5$–Li_2SiO_3, is binary at the liquidus; the other possible binary section, $Na_2Si_2O_5$–$Li_2Si_2O_5$,

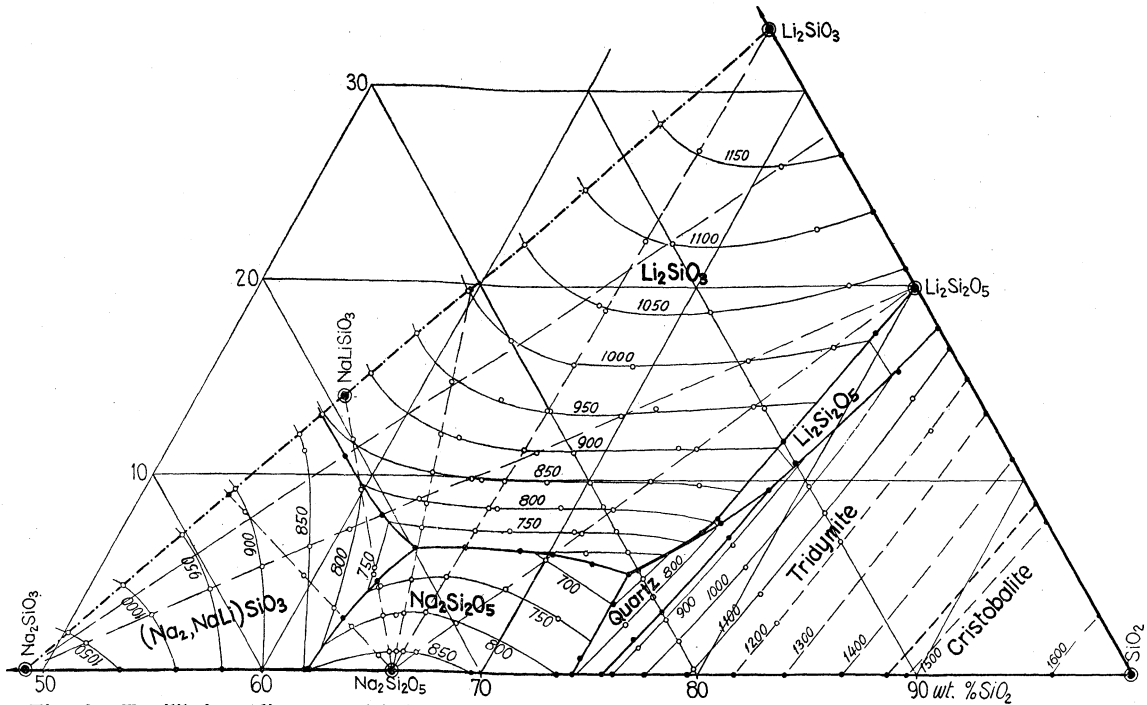

Fig. 6.—Equilibrium diagram with isotherms, of the system, Na_2SiO_3–Li_2SiO_3–SiO_2. Open circles represent interpolated temperatures corresponding to the various isotherms. Black dots give the location of boundary curves as measured or deduced by interpolation from the data on the various cross-sections in the system.

is partly ternary at the liquidus; this is due to the incongruent melting relations of lithium disilicate.

Method of Interpolation in Deriving Isotherms.—The data for each of the sections I to VI across the system, as indicated in Fig. 1, were plotted on a sufficiently large scale to allow for interpolation with a precision of ±0.5°. The compositions corresponding to even temperatures at 50° intervals were then read off from the graphs, and plotted in the ternary system, as indicated in Fig. 6 by the open circles.

Cross interpolation was employed for the remaining sections, VII to XIV. For this purpose the temperatures of intersection of these sections with the sections I to VI were read off from the above graphs, and were then plotted, together with the data for preparations on the individual sections, as indicated in Fig. 7, the abscissa being progressively shifted so as to bring the metasilicate composition for each of the sections VII to XIII upon the vertical line at the left of the diagram. This was done by adding to the lithium oxide content for each section the quantity

$$\%\ Li_2O\ \text{added} = \%\ Na_2O\ \text{along the section} \times \frac{Li_2O\ \text{in}\ Li_2SiO_3}{Na_2O\ \text{in}\ Na_2SiO_3} = 0.6541 \times \%\ Na_2O\ \text{along the section}$$

The resulting figure, Fig. 7, represents a *t*–*x* (temperature–composition) projection of a part of the system upon the plane of the side system, Li_2SiO_3–SiO_2. To avoid confusion in the diagram, only sections up to 25% sodium oxide are represented. The sections I, V, and VI, appear as curved dotted lines, with the interpolated loci of the intersections marked by crosses. Other *t*–*x* projections of the system were constructed to facilitate cross-interpolations in regions not covered by Fig. 7. The data so obtained are plotted in Fig. 6.

The Boundary Curves.—The coördinates of the boundary curves between the various primary phases, as deduced by interpolation from the graphs, or directly from the experimental data, are given in Table II. The boundary curves meet at the invariant points, which are collected for reference in Table III.

1. The System, $Na_2Si_2O_5$–Li_2SiO_3.—The relations in this system are illustrated in Fig. 8. The system is simply eutectoid; both the end-members are present in limited solid solution. The extent of the solid solution in lithium metasilicate is approximately the same as in the system Na_2SiO_3–Li_2SiO_3, as judged from the values of the refractive indices of the crystals. The solid solution

in sodium disilicate is approximately 5 ± 3% lithium metasilicate, as indicated in the diagram; the 678° transition in sodium disilicate is raised to 688°, while the 707° transition is lowered to 699°, as measured by thermal analysis on preparations 31 and 32 (see Table I). The binary eutectic is at 709 ± 3°, 19.20% lithium metasilicate in the binary system (6.38% lithium oxide, 27.50% sodium oxide, 66.12% silicon dioxide in ternary compositions).

2. The Section, $Na_2Si_2O_5$–$Li_2Si_2O_5$.—The phase relations along this section are only partly binary at the liquidus. Lithium disilicate melts incongruently at 1033 ± 1°, the primary phase at the liquidus, 1034 ± 1°, being lithium metasilicate. Additions of sodium disilicate to lithium disilicate lower the peritectic temperature more rapidly than the liquidus, as shown in Fig. 9, so that lithium metasilicate continues to be the primary phase down to the boundary with sodium disilicate, 693°. Beyond this boundary the liquidus relations are binary, sodium disilicate being the primary phase, but the sub-liquidus relations remain ternary to 641 ± 3°, at which temperature the last of the lith-

ium metasilicate crystals, and liquid, disappear.

The solid solution relations for sodium disilicate and lithium disilicate are indicated in Fig. 9 by dotted lines, the extent in either constituent being estimated to be 5 ± 3% of the other, as based on measurements of the transition temperatures. As already mentioned in discussing the binary system, $Na_2Si_2O_5$–Li_2SiO_3, additions of lithium silicates to sodium disilicate lower the 707° inversion to 699°, and raise the 678° inversion to 688°. On the other hand, the 936° inversion in lithium disilicate is lowered by additions of sodium disilicate to 930°.

The Quartz–Tridymite Inversion.—The temperature of this sluggish, but reversible, transformation is given by Fenner as 870 ± 10°, from measurements made in the presence of sodium tungstate, Na_2WO_4, as flux.[10] Many other substances, such as phosphorus pentoxide, lithium carbonate, potassium carbonate, sodium carbonate, and tungsten trioxide, have been suggested as fluxing agents for accelerating the inversions in silica. Among these, only lithium carbonate holds, *a priori*, any promise of being a more efficient "catalyst" than the sodium tungstate used by Fenner. Van Nieuwenburg[11] reports the conversion of quartz to tridymite in the presence of 1% of lithium carbonate, but he apparently has made no effort to measure the equilibrium temperature closer than about ±30°. Since carbon dioxide is displaced rapidly from such mixtures, the action depends on the speed of reaction between the quartz and the small quantity of crystalline lithium disilicate formed. Fluxing action becomes important only above 1028° (see Fig. 4). For this reason, additions of lithium carbonate to quartz are actually less efficient than those of sodium tungstate in promoting the inversion to tridymite (unpublished experiments by the writer). However, since lithium ions, presumably because of their small dimensions, tend to act as efficient devitrifying agents, it is reasonable to suppose that the inversion would be accelerated by lithium-bearing melts, fluid below the inversion temperature. Compositions in the present system, in the silica field, with liquidus temperatures above 900° fulfil this requirement, and it was

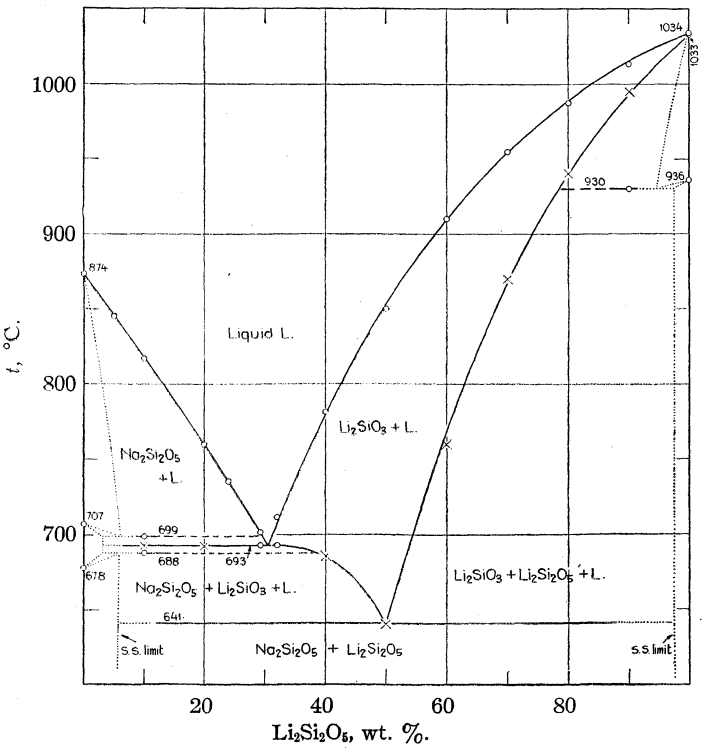

Fig. 9.—The ternary section, $Na_2Si_2O_5$–$Li_2Si_2O_5$. Binary at the liquidus of $Na_2Si_2O_5$, and below 641°. Estimated solid solution relations are indicated by dotted lines.

found that the most suitable were those whose liquidus lies in the range between 900 and 1000°. The melts of compositions still richer in silicon dioxide tend to be too viscous to act efficiently as fluxes. In the region mentioned (see Fig. 6) quartz is converted into tridymite almost completely (only the larger grains remaining undissolved, but rounded) in twenty-four hours at 869°, and in forty-eight hours at 868°. In the reverse direction, tridymite is converted into sharply faceted crystallites of quartz in twenty-four hours at 866°, and in less than twenty-four hours at 865°. Similar conversions were obtained with all the following compositions: nos. 131, 132, 141, 142, 151, 152. It is concluded that the inversion temperature at one atmosphere pressure is 867 ± 3°, as measured by thermoelements calibrated at the sodium chloride (800.4°) and gold (1062.6°) points. This confirms Fenner's temperature of 870 ± 10°. The temperature 867° is used in presenting the experimental results of this paper.

The liquidus fields of the various primary crystalline phases are smooth sheets pointing down to two ternary eutectics E_1 and E_2 (Table III).

Eutectic E_1 represents the junction of the boundaries between the fields of Li_2SiO_3, $Na_2Si_2O_5$ and $(Na_2,NaLi)SiO_3$, at 697 ± 3°. Of these boundaries, the one between Li_2SiO_3 and $(Na_2,NaLi)SiO_3$ has some theoretical interest. Within the triangle, Na_2SiO_3–$Na_2Si_2O_5$–$NaLiSiO_3$, this boundary is a peritectic (reaction) curve and represents the lowering of the incongruent melting point of sodium lithium (1,1) metasilicate (847° in the pure compound) with the changing compositions of the melts in equilibrium with the crystals. There is no eutectic, but only a minimum on the liquidus of the solid solutions $(Na_2,NaLi)SiO_3$ in the binary system, Na_2SiO_3–Li_2SiO_3 (see also Fig. 2 of ref. 3). As the boundary curve crosses the join, $Na_2Si_2O_5$–$NaLiSiO_3$, this minimum coincides with the curve, which then takes on the character of a eutectoid trough, within the larger triangle, Na_2SiO_3–$Na_2Si_2O_5$–Li_2SiO_3, and finally ends at the ternary eutectic.

The boundary between sodium disilicate and lithium metasilicate, beginning at the ternary eutectic E_1, 697°, rises to the temperature of the binary eutectic between these two compounds, 709 ± 3°, and then descends to the quintuple point Q_1, 641 ± 3°, which is the lowest temperature on the peritectic curve for the incongruent melting relations between lithium disilicate and lithium metasilicate. The ternary eutectic E_2, at 637 ± 3°, practically coincides with the quintuple point Q_1; similarly, the two boundary curves, one between lithium disilicate and lithium metasilicate, the other between lithium disilicate and quartz, lie very close to each other for a considerable portion of their lengths. However, they cannot coincide, since the ternary eutectic E_2 is located within the triangle, $Na_2Si_2O_5$–$Li_2Si_2O_5$–SiO_2, so that the eutectic relations demand that lithium disilicate, and not lithium metasilicate, be one of the eutectic constituents. This will be made clear also by a study of the crystallization relations in Figs. 6 and 9.[11a]

Refractive Indices of the Glasses

Each preparation studied in the course of this work was obtained in the form of a homogeneous glass. A measurement was made of the refractive index of the glass of each composition represented by a black dot in Fig. 1. These measurements were made on crushed, quenched glasses only, by the immersion method, and are estimated to be accurate to ±0.003. The measured values are recorded in Table I, and values along several of the ternary sections in the system are plotted in Fig. 10. This figure also includes published values for Li_2O–SiO_2 glasses,[9] and an interpolated curve for annealed Na_2O–SiO_2 glasses.[12,13]

Cocrystallization of Sodium and Lithium Compounds in Solid Solutions.—Mutual replacement of sodium and lithium plays a sufficiently important part in the crystalline phases of this system (see Figs. 2, 8, 9) to make it desirable to inquire into the general problem of solid solution formation between other sodium and lithium compounds, particularly since it appears to be held by some writers that no such solid solutions have been established[14] for these and other pairs of compounds with cations of the helium and neon-like structures. This view is based on a consideration of the ionic radii, and the differences between the structures of the cations.

(11a) The principles involved in this and the immediately preceding paragraph are discussed in standard books on heterogeneous equilibria, *e. g.*, Rudolf Vogel, "Die heterogenen Gleichgewichte," Akademische Verlagsgesellschaft m. b. H., Leipizig, 1937, pp. 410 *et seq.*

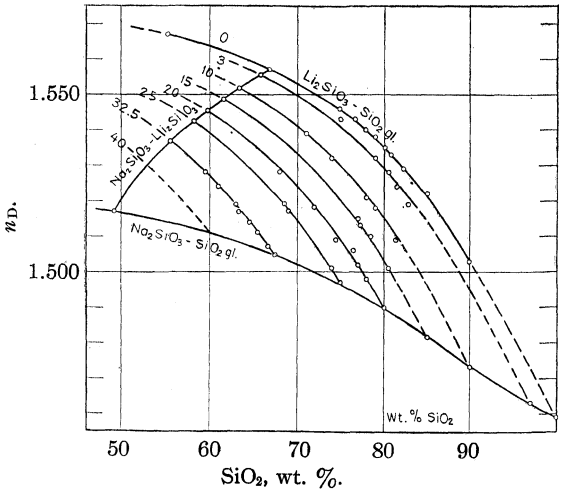

Fig. 10.—Refractive indices of quenched glasses in the system, Na_2SiO_3–Li_2SiO_3–SiO_2. Numbers identifying the curves denote percentage content of Na_2O. The curve for Na_2SiO_3–SiO_2 interpolated from data of Faick and Finn, and of Morey and Merwin, on annealed glasses.

Sodium and lithium compounds probably present the only exception to the rule, and, for that reason, a discussion of the known experimental data is desirable at this point.

The existence of solid solutions in systems of sodium and lithium compounds having the same anion is quite general. The following systems have been studied: LiCl–NaCl,[15] LiBr–NaBr,[16] Li_3AlF_6–Na_3AlF_6,[17] $LiNO_3$–$NaNO_3$,[18] Li_2SO_4–Na_2SO_4,[19] $LiBO_2$–$NaBO_2$,[20] Li_2CO_3–Na_2CO_3,[21] Li_2MoO_4–Na_2MoO_4,[22] Li_2WO_4–Na_2WO_4.[22] The experimental data are indecisive or insufficient for the nitrates, borates, carbonates, molybdates, and tungstates; in all the other cases, considerable miscibility is found at the liquidus, the chlorides, bromides, and the fluoaluminates forming continuous series with a minimum, while the sulfates present two series with an intermediate compound, analogous in principle to the system Na_2SiO_3–Li_2SiO_3[3] (Fig. 2). On the basis of lattice dimensions, it is probable that the iodides also would present a complete series of solid solutions. In the chlorides unmixing occurs below the critical temperature, 270–300°, 58 mole per cent. lithium chloride, the minimum on the liquidus being 553°, 72 mole per cent. lithium chloride; the fluorides may thus be expected to yield continuous solid solutions with unmixing very near the minimum on the liquidus, or actually above it, that is, two series with eutectoid relations. The carbonates, molybdates and tungstates are especially interesting. The sodium compounds are all three, at least partially, miscible with sodium sulfate; among the corresponding lithium compounds only the carbonate is known to be miscible with lithium sulfate; the tungstate and molybdate have not yet been investigated, and crystal structure information is also lacking. It is highly probable that miscibilities analogous to those in the sodium compounds will be found, and that, consequently, small amounts of solid solution will be found also, by sufficiently sensitive methods, in the corresponding systems of lithium and sodium compounds. The data on these systems, as they stand, are decidedly insufficient to deny the existence of such small amounts of solid solutions as exist between crystalline sodium and lithium disilicates (Fig. 9); on the other hand, it is certain that the miscibility, if it exists, must be very limited.

One further case requires consideration. The minerals jadeite ($NaAlSi_2O_6$) and spodumene ($LiAlSi_2O_6$) are found by crystal structure methods to be isomorphous with diopside ($CaMgSi_2O_6$).[23] The symmetry is that of the monoclinic pyroxenes, of which diopside is the type, but the spodumene structure is somewhat distorted by the substitution LiAl for CaMg, allowing the Si–O chains to pack somewhat closer together. It is to be expected, therefore, that spodumene will be only partially miscible with the other pyroxenes.

Summary

The phase equilibrium relations in the system, Na_2SiO_3–Li_2SiO_3–SiO_2 are described in this paper. The work was carried out by the method of quenching supplemented by thermal analysis.

There is one ternary compound, $NaLiSiO_3$, which is an end-member of the solid solution series $(Na_2,NaLi)SiO_3$. It melts incongruently at 847°. At the liquidus in the system, the pri-

mary phases are $(Na_2,NaLi)SiO_3$ solid solutions, Li_2SiO_3, $Na_2Si_2O_5$ and $Li_2Si_2O_5$, all three of which form solid solutions of limited extent, and the three modifications of silicon dioxide, namely, quartz, tridymite, and cristobalite. The liquidus fields meet at two ternary eutectics: one at 697°, with $(Na_2,NaLi)SiO_3$, Li_2SiO_3 and $Na_2Si_2O_5$, the other at 637°, with $Li_2Si_2O_5$, $Na_2Si_2O_5$ and quartz as the eutectic constituents. $Li_2Si_2O_5$ melts incongruently throughout its region of existence in the system, the reaction temperature descending from 1033° in the binary system, Li_2SiO_3–SiO_2, to 641°, the peritectic end-point in the ternary system, with $Li_2Si_2O_5$, Li_2SiO_3, $Na_2Si_2O_5$ and liquid in coexistence.

The inversion temperature of quartz and tridymite has been redetermined. The temperature of 870 ± 10°, given by Fenner in 1913, is confirmed, the value obtained being 867 ± 3°.

Refractive indices of glasses of various compositions in the system were measured.

A discussion of solid solution relationships of sodium and lithium compounds in general is given, with particular reference to the theoretical aspects of the subject.

Minor revisions of the phase relations in the systems, Na_2SiO_3–SiO_2 and Li_2SiO_3–SiO_2, particularly with respect to the polymorphic behavior of $Na_2Si_2O_5$ and $Li_2Si_2O_5$, are presented.

Pressure–Volume–Temperature Relations in Solutions. III. Some Thermodynamic Properties of Mixtures of Aniline and Nitrobenzene

BY R. E. GIBSON AND O. H. LOEFFLER

A few months ago we noted[1] that the absorption of light by mixtures of aniline and nitrobenzene was strongly influenced by pressure changes. In investigating this effect we thought it desirable to examine thoroughly the volume changes which take place when these two liquids are mixed in different proportions at different pressures and temperatures. Furthermore, we have noticed in the pure liquids[2] that, whereas the internal pressure $(\partial E/\partial V)_T$ varies with temperature at constant volume, another quantity, P_A, computed from the P–V–T data is independent of temperature at constant volume and is expressible as a'/V^n. We have tentatively identified P_A as the attractive internal pressure of the liquid. In this paper we shall give data from which the volumes of aniline–nitrobenzene mixtures may be determined at all concentrations, between 25 and 85° and between 1 and 1000 bars, and we shall examine the behavior of P_A in these solutions.

Experimental Results

The solutions were all made up independently from weighed amounts of samples of aniline and nitrobenzene purified to a degree which already has been described.[2] The specific volumes of these solutions were determined at 25.00° in 55-ml. U-tube pycnometers, and the thermal expansions were measured[3] at 10° intervals from 25 to 85° in a weight dilatometer of 18 ml. capacity made of vitreous silica.

The volumes of the solutions were expressed as functions of the temperature by empirical equations of the form

$$v = v_{55} + a(t - 55) + b(t - 55)^2 + c(t - 55)^3 \quad (1)$$

We already have published for the pure components such equations whose coefficients we may call a_1^0, a_2^0, b_1^0, b_2^0, etc. From them we computed[4] $\Delta_T v_1^0$ and $\Delta_T v_2^0$ at each temperature, using 55° as the base temperature, and thence the quantity $\Delta_T v - (x_1\Delta_T v_1^0 + x_2\Delta_T v_2^0) \equiv \delta_T$. This function measures the departures of the thermal expansions

(2) R. E. Gibson and O. H. Loeffler, THIS JOURNAL, **61**, 2515 (1939).

(3) For details of the procedure in these measurements the reader is referred to the second paper of this series (ref. 2).

(4) The symbols used here are as follows. The subscripts 1 and 2 refer to nitrobenzene and aniline in solution, respectively, the superscript 0 implies the pure components, and symbols without subscripts refer to the solutions. The weight and mole fractions are given by x and X, respectively, $R_2 = X_2/X_1$, and v and V mean the specific and molal volumes. For a solution $V = v/(x_1/M_1 + x_2/M_2)$, M being the molecular weight. Φ is the apparent molal volume of a component. Δv and ΔV are the volume changes on mixing per gram and per mole of solution. All volumes are given in milliliters.

The pressure in kilobars is given by P, the temperature by t (centigrade scale) or T (absolute), and the total energy by E. Δ_T and Δ_P denote the finite changes with temperature and pressure, respectively, of the quantities to which they are prefixed. $k = -\Delta_P v/v_P = 0$. $z_1 = 1/(1 + R_2V_2^0/V_1^0)$, $z_2 = (1 - z_1)$ are the volume fractions of the components.

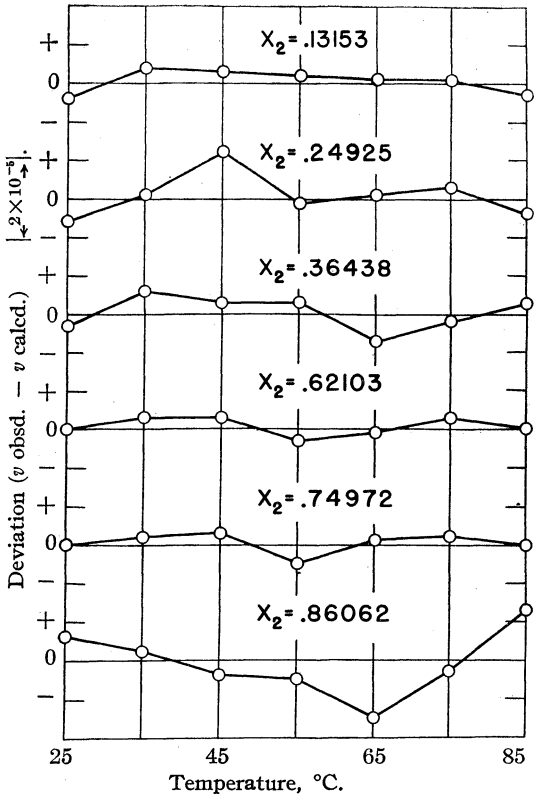

Fig. 1.—Deviations of the values of the specific volumes of aniline–nitrobenzene solutions as calculated from equation (1) from the observed ones at different temperatures.

from the ideal law of mixtures, and it may be represented accurately by the relation

$$\delta_T = l + m(t - 55) \qquad (2)$$

In these solutions $(x_1 \Delta_T v_1^0 + x_2 \Delta_T v_2^0)$ is always numerically greater than $\Delta_T v$. The coefficients l and m were determined by a simplified method of least squares.[5] It will be seen that the coefficients in equation (1) were therefore obtainable from the following relations

$$a = x_1 a_1^0 + x_2 a_2^0 + m; \qquad b = x_1 b_1^0 + x_2 b_2^0$$
$$c = x_1 c_1^0 + x_2 c_2^0 \qquad v_{55} = v_{\text{obsd.}} + l$$

The coefficients a, b, c, and m are given in Table I and the deviation curves in Fig. 1 indicate how well the equations fit the data. It is of interest to note that the coefficients of the second and third powers of the temperature are found directly from the simple law of mixtures.

The compressions of the solutions from 1 to 500 and from 1 to 1000 bars were measured in exactly the same way as those of the pure components[2] and the relative volume changes were expressed as functions of the pressure by the Tait equation

$$k = C \log [(B + P)/(B + P_0)] \qquad (3)$$

where C has the same value as for aniline and nitrobenzene, *viz.*, 0.21591 at all temperatures. The constant B was determined at each temperature from the compressions to 1000 bars. The compressions to 500 bars computed by the appropriate Tait equation always agreed with the observed ones within experimental error. The compressions were measured at 25, 45, 65, and 85°, and the constant B was expressed as a function of the temperature by equations of the type

$$B = B_{25} + \alpha(t - 25) + \beta(t - 25)^2 \qquad (4)$$

which were fitted to the data at 25, 45, and 85°. In Table II we give the values of B_{25}, α and β for the various solutions together with the differences between the observed and calculated values of B at 65° as an illustration of the fit of the empirical equations.

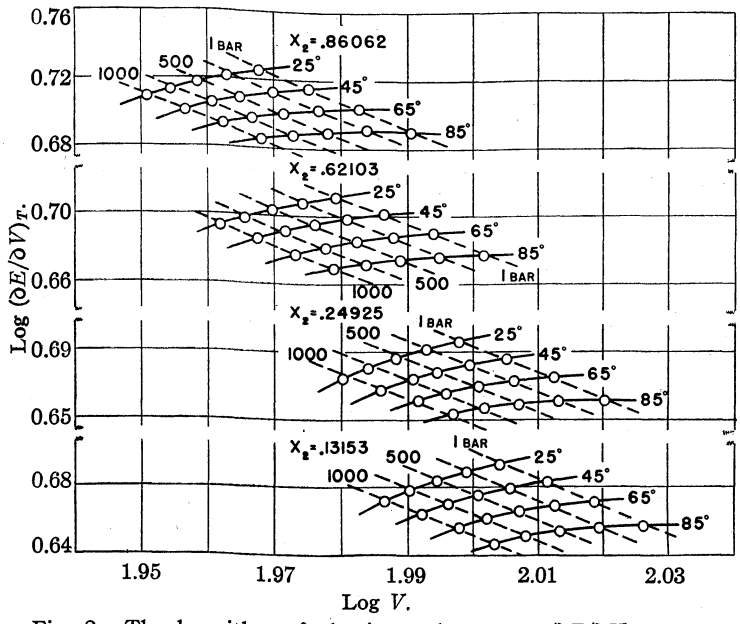

Fig. 2.—The logarithm of the internal pressure $(\partial E/\partial V)_T$ of some aniline–nitrobenzene solutions as a function of the logarithm of the molal volume. Note the different curves for the different temperatures.

The Internal Pressures $(\partial E/\partial V)_T$ and Related Quantities

From equations (1) and (3) the expansion coefficients $(\partial v/\partial T)_P$ and the compressibilities were computed at different pressures and temperatures[6] and hence the coefficients $(\partial P/\partial T)_V$ and $(\partial E/\partial V)_T$ were calculated readily for each solution at 25, 45, 65, and 85°, and at 1, 250, 500, 750, and 1000 bars. The curves of $(\partial E/\partial V)_T$ vs. V, or of $(\partial P/\partial T)_V$ vs. V, for the solutions resembled those for the pure liquids in all major respects[2]; in particular, $(\partial E/\partial V)_T$ decreased with rise of temperature at constant volume. A sample of our results illustrating this temperature effect is given in Fig. 2 where log $(\partial E/\partial V)_T$ is plotted against log V for several solutions.

Applying the method of analysis that we developed for the pure liquids to the results for the solutions,[2] we computed the quantity $(T(\partial P/\partial T)_V + B) = P_A$ which we have interpreted as the attractive internal pressure set up by the intermolecular forces, $(B + P)$ being assumed to be a measure of the repulsive pressure. In Fig. 3 we have plotted log P_A vs. log V for all the solutions including the end members, and in order to facilitate a comparison of Figs. 2 and 3, we have used the same scale in both diagrams. It will be seen that in Fig. 3 the points for the different temperatures all fall on the same straight line for each solution and that the lines for the different solutions all have the same slopes. Over the region we have studied we may, therefore, write

$$P_A = a'/V^{2.737} \qquad (5)$$

2.737 being the constant slope of the lines in Fig. 3. The constants a' were determined from the data and average values are given in Table III. It should be noted that the points at 65 and 85° for nitrobenzene lie on a line which is slightly below that drawn through the points for the lower temperatures. We are not certain that this deviation is a real one and that it does not arise in the equations used for computing the derivatives; but it is significant that the same deviations are found in the solutions rich in nitrobenzene and gradually vanish as the concentration of aniline increases.

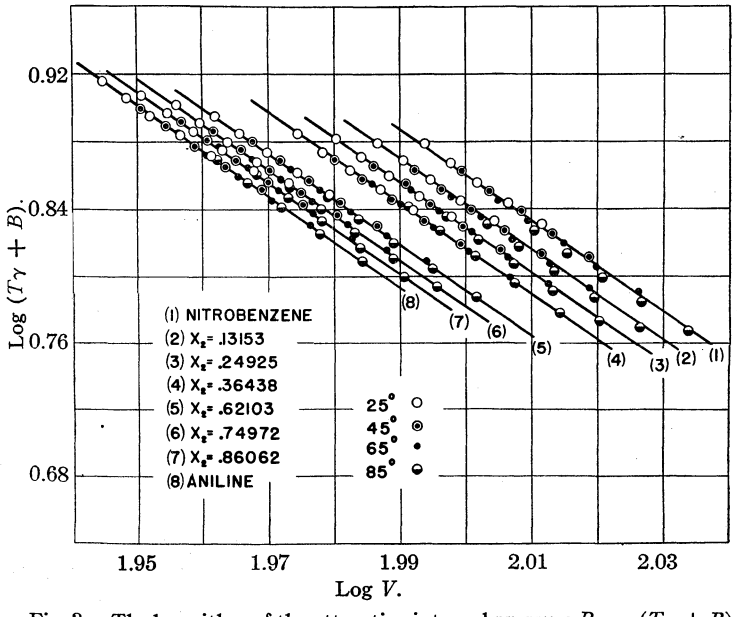

Fig. 3.—The logarithm of the attractive internal pressure $P_A = (T\gamma + B)$ of aniline–nitrobenzene solutions as a function of the logarithm of the molal volume. Note that the points for different temperatures fall on the same line for each solution. The scale in this diagram is the same as in Fig. 2. γ represents the coefficient $(\partial P/\partial T)_V$.

(6) For details of these calculations, see ref. 2.

The Variation of P_A with Concentration

We shall now attempt to calculate P_A and a' for the solutions from a knowledge of the properties of the pure components. If V is the volume of 1 mole of solution,[4] V^0 the volume of the corresponding amounts of the components (*i. e.*, the ideal molal volume of the solution) and if P_A is the observed attractive pressure in the solution, then P_A^0, the attractive pressure of the solution at volume V^0, is given by

$$P_A^0(V^0)^{2.737} = P_A V^{2.737} = a' \qquad (6)$$

If, furthermore, we suppose the attractive pressures set up between like molecules in the solution to be the same as in the pure liquids, *viz.*, P_{11} for nitrobenzene and P_{22} for aniline, and call the attractive pressure between the unlike molecules P_{12}, we may write

$$P_A^0 = y_1^2P_{11} + y_2^2P_{22} + 2y_1y_2P_{12} \qquad (7)$$

where y_1 and y_2 are concentration functions that indicate the probabilities of significant interactions between the molecules,[7] and are defined as $y_1 = 1/(1 + R_2U_2/U_1)$ and $y_2 = (1 - y_1)$. The parameter U_2/U_1 may be regarded as an empirical constant which is equal to unity when y is the mole fraction and is V_2^0/V_1^0 when y is the volume fraction.

When the mole fractions or the volume fractions were used in equation (7) no results of any special interest were found, and the computed values of P_{12} varied with concentration. We, therefore, assumed[8] that P_{12} was equal to a constant, *viz.*, $(P_{11}P_{22})^{\frac{1}{2}}$, and, using the relation

$$P_A^0 = (y_1P_{11}^{\frac{1}{2}} + y_2P_{22}^{\frac{1}{2}})^2 \qquad (8)$$

we computed U_2/U_1 from our results at 25° and 1 bar and found it to be practically independent of concentration having the average value 0.5263.[9]

Combining equations (5), (6), and (8) we get equation (9)

$$a' = \left\{y_1a_{11}^{\frac{1}{2}}\left(\frac{V^0}{V_1^0}\right)^{1.368} + y_2a_{22}^{\frac{1}{2}}\left(\frac{V^0}{V_2^0}\right)^{1.368}\right\}^2 \qquad (9)$$

which should enable us to calculate a' for any solution in terms of the constants a_{11}, a_{22}, V_1^0, and V_2^0 for the pure liquids, the *ideal* molal volume of the solution and the fraction y_1 which contains the disposable constant U_2/U_1. In Table III we list values of y_1 computed on the assumption that $U_2/U_1 = 0.5304$ (the reason for the choice of this figure, which differs slightly from that given above, will appear under the discussion of the volume change on mixing) together with the values of a' obtained directly from our data for the solutions and values of a' computed from equation (9) when the volumes at 25° and 1 bar were used. The agreement between these two series of figures indicates that equation (9) does give an adequate representation of a' as a function of concentration. Moreover, V^0/V_1^0 changes very little with pressure and temperature, the extreme variation over the range we have studied being less than 0.4%. We may, therefore, conclude that y_1, y_2 and hence U_2/U_1 are independent of pressure and temperature within the limits of accuracy of our results.

The Volume Changes on Mixing

The changes in volume which occur when the components are mixed in different proportions at different pressures and temperatures may be expressed conveniently in terms of the apparent

(7) This treatment, which partly follows that proposed by Scatchard [*Chem. Rev.*, **8**, 321 (1931)], does not limit y_1 and y_2 to the volume fractions based on the volumes of the liquids under ordinary conditions. We also wish to point out that our method of analysis implies that P_A depends chiefly on the mean distance between the molecules and is not greatly influenced by their distribution in the liquid, whereas the repulsive internal pressure depends strongly on the distribution of the molecules in the liquid. This seems plausible because the attractive forces between the molecules vary much less rapidly with distance than do the repulsive forces.

(8) See G. Scatchard, *Trans. Faraday Soc.*, **33**, 162 (1937); S. E. Wood, THIS JOURNAL, **59**, 1511 (1937); J. H. Hildebrand and J. M. Carter, *ibid.*, **54**, 3599 (1932).

(9) In terms of the principle of independent surface or group action [I. Langmuir, *Colloid Symposium Monograph*, **III**, 48 (1925); J. A. V. Butler, D. W. Thomson, and W. H. MacLennan, *J. Chem. Soc.*, 674 (1933)] y_1 and y_2 may be regarded as the volume fractions of the active groups in the nitrobenzene and aniline molecules. An examination of the parachors of benzene, nitrobenzene, and aniline suggests that the molal volume of the NH_2 group is approximately one-half that of the NO_2 group (Landolt-Börnstein, "Tabellen," Erganzungsband II(a), p. 178). Roughly the same result is obtained if one compares the molal volumes of benzene, nitrobenzene, and aniline under pressures where the liquids have the same compressibilities (ref. 1). There is, therefore, some justification for associating y_1 and y_2 with the volume fractions of the NO_2 and NH_2 groups in the solutions.

volumes of one of the components. It will be recalled that if

$$\Delta V = V - (X_1V_1^0 + X_2V_2^0) \text{ then } \Delta V = X_2(\Phi_2 - V_2^0)$$

In the aniline–nitrobenzene system an expansion occurs when the components are mixed, $(\Phi_2 - V_2^0)$ being always positive. Increase of pressure and of temperature both diminish $(\Phi_2 - V_2^0)$, an observation to which special attention is drawn.

A clue to the origin of these volume changes may be obtained from an examination of the effect of temperature on the volume changes on mixing when the volumes of the unmixed components are kept constant. In Fig. 4 we have plotted ΔV against V^0 for various solutions. It will be seen that at constant volume, and presumably constant attractive pressure, ΔV decreases quite rapidly as the temperature rises, and that this decrease is roughly proportional to ΔV itself. Having in mind the interpretation we gave of similar changes in the $(\partial E/\partial V)_T$–$V$ curves, we suggest the following explanation of this decrease of ΔV with rise of temperature at constant V. We assume that the change with temperature in the randomness of the distribution of the molecules in a liquid is proportional to the order already existing in the liquid, and that in a solution of aniline in nitrobenzene the molecular distribution is more random than in the pure liquids at the same temperature (the increase in disorder determining to some extent the volume change on mixing). We should, therefore, expect that a given rise of temperature would have a greater disordering effect on the unmixed liquids than on the solution, and that at high temperatures the change in randomness on mixing should approach zero, and the volume change on mixing should decrease accordingly. The change of $(B + P)$ with temperature at constant volume has been associated[2] with the change in the repulsive pressure due to increase in the randomness of the molecular distribution. Our data show that $(B + P)_V$ increases more rapidly with temperature for the pure liquids than for the solutions.

In a recent paper[1] we attempted to express Δv in terms of the net internal (or repulsive) pressures B' of the solutions and B_1 and B_2 of the pure components by the relation

$$\Delta v/C(x_1v_1^0 + x_2v_2^0) - (z_1 \log B_1 + z_2 \log B_2) = \log B' \quad (10)$$

It was assumed that, on forming the solution at atmospheric pressure, the pure components first expanded or contracted until their repulsive pressures came to the common value B' and then mixed without further change. We indicated also that the values of $\log B'$ computed from the observed values of Δv by means of equation (10) were *smaller* than the observed values of $\log B'$. As equation (10) represents the volume change on mixing on the assumption that mixing introduces no change in the distribution of the molecules, it is suggested that the discrepancy between the observed and calculated values of B' is due to an increase in randomness on mixing. In other words, on the formation of the actual solution a given volume increase (Δv) results in a smaller decrease in $\log B'$ than would be expected if no increase in randomness accompanied the mixing of the components. It is of interest to note that the values of B' computed by equation (10) approach the observed ones more closely as the temperature is raised. These effects are small but they contribute qualitatively to the evidence correlating an increase in the randomness of the molecular distribution with an increase in the

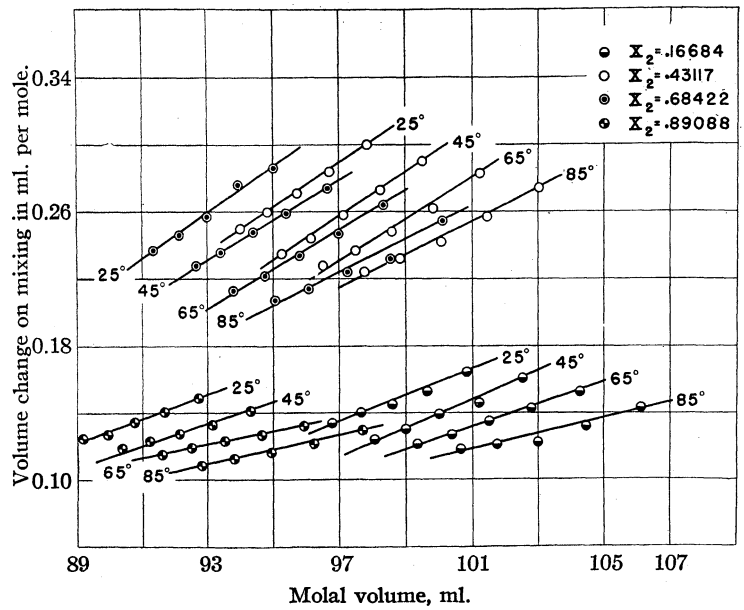

Fig. 4.—The volume changes on mixing per mole of solution in four solutions of aniline in nitrobenzene as functions of the volume at different temperatures.

quantity B' or $(B + P)$ which we have tentatively identified as the repulsive internal pressure of the liquid or solution.

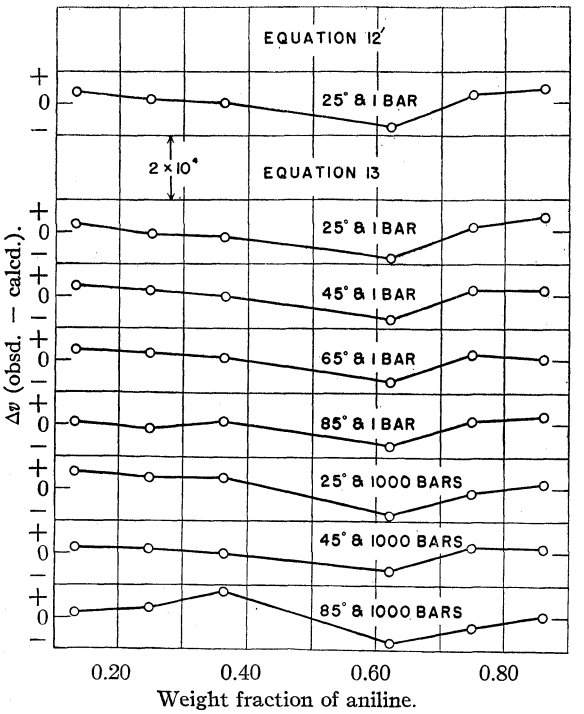

Fig. 5.—Deviations of the values of the volume change on mixing in aniline–nitrobenzene solutions as computed from equation (12′) or (13) from the observed values at different pressures, temperatures and concentrations.

In order to represent the volume changes on mixing as functions of the composition of the solutions, we used equations of the type[10]

$$\Delta V/(X_1V_1^0 + X_2V_2^0) = pz_1z_2(1 + qz_2^3) \quad (11)$$

where z_1 and z_2 are the volume fractions, to represent our data. At 25° with $p = 0.01230$ and $q = 0.341$, equation (11) reproduced the results quite well, the average deviation and the largest deviation corresponding to errors of 1.6 and 3 × 10^{-5}, respectively, in the specific volume. Equally satisfactory fits were obtained at the other temperatures and pressures. The term qz_2^3 in equation (11) shows that the curve of $\Delta V/(X_1V_1^0 + X_2V_2^0)$ vs. z_1 is unsymmetrical, the maximum lying between $z_1 = 0.5$ and $z_1 = 0$. As this asymmetry is found in the effect of concentration on the absorption of light and on the attractive internal pressures of mixtures of nitrobenzene and aniline, it is of interest to examine equations which express the dependence of ΔV on concentration in terms of the general fractions y_1 and y_2. It should also be remarked that the usefulness of equation (11) is diminished somewhat by the fact that z_1, z_2, p, and q all vary with temperature and pressure.

A trial of equation (12) (or its equivalent form equation 12′) which is analogous to equation (11) showed that it gave a good but not altogether satisfactory representation of our data.[11]

$$\Delta V/(X_1U_1 + X_2U_2) = Ky_1y_2 \quad (12)$$

$$(\Phi_2 - V_2^0) = ky_1 = k/(1 + R_2U_2/U_1) \quad (12')$$

The constants k and U_2/U_1 in equation (12′) determined from the data by the method of least squares[12] are given in Table IV and the differences between the observed and calculated values of Δv at 25° and 1 bar are plotted in Fig. 5. The largest deviation corresponds to an error of -7×10^{-5} in Δv. The deviation curves for the results at the other temperatures and pressures are the same as the curve we have given in Fig. 5 within an error of 2×10^{-5} in Δv. In order to give an idea of the numerical value of Δv we have recorded Δv at 25° and 1 bar in the last column of Table III. The parameter U_2/U_1 as obtained from equation (12) varies greatly with temperature and is considerably larger than we found from the attractive pressure equation. In view of our discussion of the effect of change in molecular distribution on the volume change on mixing, of the complicated nature of this quantity, and of the fact that the compressibility of the solution is an important factor in determining the volume

TABLE IV

THE CONSTANTS k AND U_2/U_1 AS OBTAINED BY THE METHOD OF LEAST SQUARES FROM EQUATION (12′) REPRESENTING THE VOLUME CHANGE ON MIXING AS A FUNCTION OF THE GENERALIZED VOLUME FRACTIONS AT DIFFERENT PRESSURES AND TEMPERATURES

(10) G. Scatchard, S. E. Wood and J. M. Mochel, *J. Phys. Chem.*, **43**, 122 (1939).

(11) From equation (12) it may be seen that $(V_2 - V_2^0) = ky_1^2$, V_2 being the partial molal volume. The analogy with Hildebrand's equation for regular solutions is evident [THIS JOURNAL, **51**, 78 (1929)]. Furthermore, as $y_1 = 1/(1 + R_2U_2/U_1)$, this is the same type of equation that was proposed by van Laar [*Z. physik. Chem.*, **72**, 723 (1910)].

(12) We are indebted to Dr. W. Edwards Deming of the U. S. Department of Agriculture for valuable suggestions concerning these calculations.

change on mixing,[13] it seemed legitimate to regard equation (12) as too simple to be of much physical significance and to examine the behavior of U_2/U_1 in some empirical equations.

The parameters k_1 and U_2/U_1 in equation (13) were evaluated by a least squares method at 25, 45, 65, and 85° both at 1 and 1000 bars.

$$(\Phi_2 - V_2^0) = Vk_1y_1/\log (B' + P) \qquad (13)$$

The results are given in the third and fourth columns of Table V. Although U_2/U_1 obtained in this way is very sensitive to small fluctuations in the specific volume–concentration data, the values we obtained were practically constant over the whole temperature range at 1 bar, and varied no more at 1000 bars than might be expected from the greater uncertainty of the experimental data at the higher pressures. The average value of U_2/U_1 at 1 bar, which was found to be 0.5304, was assumed to be a constant characteristic of the liquid mixture and independent of the pressure, temperature, and concentration. From it we computed the values of y_1 given in Table III. In the fifth column of Table V we give the average values of k_1 consistent with $U_2/U_1 = 0.5304$; and in Fig. 5 we have plotted the differences between the observed values of Δv and those computed from equation (13) with these adjusted values of y_1 and k_1. The deviation curves for the different pressures and temperatures being very much alike, we have given only a few examples. These curves indicate that equation (13) does not represent the volume change on mixing as well as might be desired; indeed, the deviations are only slightly smaller than those given by equation (12′). There is always a deviation of approximately -7×10^{-5} in Δv in the 62% solution. Experimental checks have failed to show that there is any reason to suspect the original data and, as this point occurs near the middle of the concentration range, its importance cannot be minimized. However, the simplicity of equation (13) together with the fact that it yields a value of U_2/U_1 which not only is independent of temperature, pressure, and concentration but also is the same as appears in the equations relating the attractive internal pressures and the optical absorption coefficients[14] to the compositions of the solutions, gives the equation a significance which justifies further study of its applicability.

TABLE V

THE CONSTANTS k_1 AND U_2/U_1 IN EQUATION (13) AS OBTAINED BY THE METHOD OF LEAST SQUARES AT DIFFERENT TEMPERATURES AND PRESSURES. IN THE LAST COLUMN ARE GIVEN AVERAGE VALUES OF k_1 CONSISTENT WITH A VALUE OF U_2/U_1 INDEPENDENT OF PRESSURE AND TEMPERATURE

The quantity $-(\Delta_P\Phi_2 - \Delta_P V_2^0)$ which is a measure of the departures of the compressions (from 1 to 1000 bars) from the ideal law of mixtures is always positive in nitrobenzene–aniline solutions. This is an example of a case where the solutions are more compressible than the pure components and therein it differs from aniline–benzene or aniline–chlorobenzene mixtures. As far as we can tell from our data $-(\Delta_P\Phi_2 - \Delta_P V_2^0)$ for each solution is independent of the temperature; and although $-(\Delta_P\Phi_2 - \Delta_P V_2^0)$ may be calculated satisfactorily from a simple modification of equation (13), we may say that for interpolation purposes the equation $-(\Delta_P\Phi_2 - \Delta_P V_2^0) = 0.1899\ x_1$ gives a simple and adequate expression of the compression data at all temperatures.

The fact that when aniline and nitrobenzene are mixed only a small amount of heat is absorbed and an expansion occurs, together with the fact that this expansion diminishes as the temperature rises, is contributory evidence against compound formation in the ordinary sense of the term and the volume relations are such that on any simple hypothesis we must consider that if a compound were formed in these solutions, it would be destroyed by rise of pressure.

Summary

We have measured the specific volumes at 25°, the thermal expansions at 10° intervals between 25 and 85°, and the compressions to various pressures up to 1000 bars at 25, 45, 65, and 85° of six solutions of aniline in nitrobenzene covering the whole range of concentration. These data have been represented by suitable equations from which the volumes, the thermal expansibilities

(13) R. E. Gibson, THIS JOURNAL, 59, 1521 (1937).

(14) Unpublished results obtained in this Laboratory.

and the compressibilities may be computed at any pressure and temperature within the range of our observations.

Our data enable us to compute $(\partial P/\partial T)_V$, $(\partial E/\partial V)_T$ and the volume changes on mixing for the various solutions, and to examine the variation of these quantities when the temperature is changed at constant volume. In the light of the results of this analysis, we suggest a correlation between the effect of temperature and of mixing on the molecular distribution in the liquids on the one hand and the internal pressures and the volume changes on mixing on the other.

The attractive pressures of the solutions were calculated in the same way as those of the pure liquids and were reproduced by the formula $P_A = a'/V^{2.737}$. An equation was developed whereby the constants a' for the solutions were represented as a function of the concentration in terms of constants for the pure components and the generalized volume fractions y_1 and y_2 which contain an empirical constant, U_2/U_1.

Although the volume changes on mixing were well represented as functions of the ordinary volume fractions of the components by equations of a conventional type, we also examined several equations expressing this quantity in terms of significant properties of the solutions and the fractions y_1 and y_2. These equations reproduced the volume changes on mixing fairly well. One of them had the form of the equations developed for regular solutions and another gave a value of the empirical constant, U_2/U_1, which was independent of temperature and pressure and was approximately equal to the corresponding constant obtained from the attractive pressure–composition equation.

Serum Albumin. I. The Preparation and Properties of Crystalline Horse Serum Albumin of Constant Solubility

BY T. L. McMEEKIN

Since the crystallization of serum albumin by Gürber in 1894,[1] many investigators have doubted its homogeneity. Fractional crystallization from salt solutions has yielded products that vary widely in solubility,[2] chemical composition,[3,4] and dielectric properties.[5] Despite this evidence of inhomogeneity, the recognition and separation of constituent proteins has proved difficult. Perhaps the most important advance in its purification was the separation of carbohydrate-containing globulins[6] from the albumin fraction and the recognition that serum albumin does not contain carbohydrate.[3,4]

Serum albumin has been reported to be homogeneous in respect to size[7] and electrophoretic mobility.[8] Ultracentrifugal studies have shown it to have a molecular weight of 67,500,[7] independent of *p*H between 4 and 9. In solutions more acid than *p*H 4 it was decomposed into smaller molecules, the process being found to be reversible.

This paper first describes our present procedure for the separation of the serum proteins and the preparation of crystalline carbohydrate-free serum albumin homogeneous with respect to electrophoresis at neutral reactions.[9] This highly purified serum albumin can be separated further into two crystalline fractions differing in chemical composition and electrophoretic mobility in acid but not in neutral solution.[9] The separation of serum albumin into two fractions is based on the discovery made in this Laboratory by J. D. Ferry,[10] that a salt-free concentrated solution of serum albumin crystallizes when brought to *p*H 4.0 with sulfuric acid.[11] The solubility of the

albumin sulfate, and of the regenerated protein, has been found to be essentially independent of the amount of saturating body and certain of its properties have been investigated and are reported.

Fractionation of Serum Proteins.—The proteins of serum were divided into three fractions depending on solubility in salt as a preliminary to further purification. These were: (a) the fraction insoluble in 1.6 *M* ammonium sulfate (0.4 saturated); (b) that soluble in 1.6 *M* but insoluble in 2.1 *M* ammonium sulfate; and (c) that soluble in 2.1 *M* ammonium sulfate but insoluble in 2.8 *M* ammonium sulfate. These fractions were stored in closed containers at 4°.

Fresh serum[12] was diluted with an equal volume of water and the calculated amount of ammonium sulfate (either in the form of a solid or solution) to make the solution 1.6 molar was placed in a cellophane membrane and rotated until equilibrium with the salt had been reached on both sides of the membrane (Fig. 1), usually within forty-eight hours. The precipitate was allowed to settle and the supernatant solution siphoned off. Protein precipitated in this manner was granular, resulting in better separations than when precipitation was more rapid. Because of the granular nature of the precipitates, filtration was carried out on a Büchner funnel, using Schleicher and Schull No. 575 hardened filter paper. The resulting filter cake was washed free from mother liquor.

The filtrate was brought to 2.1 molar ammonium sulfate by adding the calculated quantity of solid ammonium sulfate in a membrane and rotating until equilibrium was reached. After removing the precipitate in the usual manner the filtrate was brought to 2.8 *M* ammonium sulfate by equilibrating with the calculated amount of solid ammonium sulfate in a cellophane membrane. The protein fraction that was soluble in 2.1 molar and insoluble in 2.8 molar ammonium sulfate contains serum albumin as well as many other substances. The yield from each liter of serum was approximately 20 g. of protein soluble in 2.1 *M* and insoluble in 2.8 *M* ammonium sulfate. No acid was added during this separation.

The fraction precipitated per liter of serum between 2.1 and 2.8 molar ammonium sulfate, was dissolved in 80 cc. of water and diluted to 800 cc. with 1.6 molar ammonium sulfate and the *p*H adjusted to 6.4. The solution was then equilibrated at 2.1 molar ammonium sulfate in a membrane. The globulin precipitate was removed and the filtrate was brought to 2.4 molar ammonium sulfate again by equilibrating in a membrane. The precipitate formed was largely crystalline and was removed by filtration. It contained about 10 g. of protein and was the starting material for further purification of albumin.

The precipitate insoluble in 2.4 *M* ammonium sulfate was dissolved in the smallest possible quantity of water, forming practically a sirup and the *p*H adjusted to 5.5. A saturated ammonium sulfate solution was added from a pipet with stirring until near the point of precipitation. On allowing the clear solution to stand overnight turbidity developed and well-shaped, large, long, hexagonal crystals of serum albumin separated.

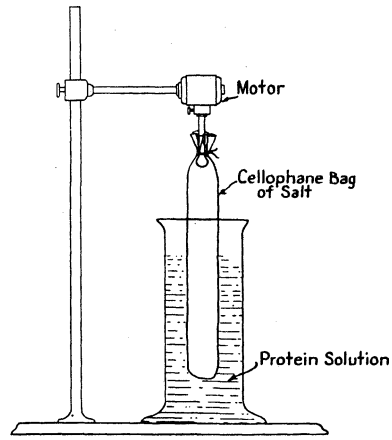

Fig. 1.—Diagram of the apparatus used for adding reagents to protein solutions.

The crystals were removed by centrifugation. Small amounts of globulin did not settle on centrifugation and were thus separated from the crystals. After centrifugation, the crystals were filtered on a Büchner funnel and washed with 2.0 *M* ammonium sulfate. Two further recrystallizations in this manner were usually found adequate for the removal of carbohydrate. Further quantities of carbohydrate-free crystalline albumin were prepared from the supernatant liquors by diluting with 1.6 *M* ammonium sulfate so that the protein concentration was about 1–2% and then gradually adding ammonium sulfate, 0.1 or 0.2 mole greater in concentration than the protein solution, through a rotating membrane.

The crystalline fractions were collected and recrystallized from concentrated solution. The yield of carbohydrate-free albumin as tested for by the Orcin method following the procedure of M. Sörensen and Haugaard[3] has thus far not been greater than 3 g. per liter of original serum.

The proteins soluble in 2.4 *M* ammonium sulfate at *p*H 6.4 and insoluble at 2.8 *M* ammonium sulfate contain besides serum albumin, a considerable amount of globulin, as has been shown by Hewitt,[6] most of the pigments of serum, and choline esterase.[13] Haemocuprein, the copper-containing albumin,[14] was crystallized from this fraction with ammonium sulfate.

Solubility in Ammonium Sulfate of Carbohydrate-free Crystalline Serum Albumin.—The solubility of serum albumin in ammonium sulfate even after repeated recrystallization from this solvent has been shown by Sörensen[2] to depend largely upon the amount of saturating body with which it is in equilibrium, increasing with increase in the total protein in the system. This phenomenon might be expected if more than one protein component were present; that is to say, if the protein had not been

(12) We are indebted to the Massachusetts Antitoxin Laboratory for the horse serum albumin employed in these investigations. In several preparations of the albumin fraction, large amounts of the filtrate from *anti*-pneumococcus serum were employed from which the immune proteins had been removed by 1.6 *M* ammonium sulfate.

isolated as a chemical individual, and is characteristic also of other proteins.[15] Mellanby[16] demonstrated that for the serum globulins that he studied a definite ratio obtained between solubility and the amount of total protein in the system. A comparable relation obtained for the various serum proteinsstudied by Sörensen[2,17] and for our repeatedly recrystallized carbohydrate-free serum albumin even after exhaustive fractionation with ammonium sulfate, as is demonstrated by the measurements in Table I of solubility in 1.8 *M* ammonium sulfate at *p*H 4.9. The solubility measurements were made by the method previously described.[18] Not only was the solubility of the albumin greater the greater the amount of saturating body in the system but it diminished at each equilibration of approximately twenty-four hours with fresh aliquots of solvent.

Further Fractionation of Carbohydrate-free Crystalline Serum Albumin.—The procedure of J. D. Ferry for "crystallization of a fraction of horse serum albumin from salt-free solution"[10] was followed next. A salt-free solution of purified albumin containing 26 g. of protein in 260 cc. was brought cautiously to *p*H 4.0 by adding 0.1 normal sulfuric acid (approximately 0.00025 mole of acid being required for each gram of protein) and then concentrated in a negative pressure dialyzing apparatus[19] at 4°. When the protein concentration reached about 25% the solution was brought to room temperature. Crystallization began within an hour and was allowed to continue for four hours. The crystals were removed by centrifugation and washed three times, each time with a volume of water equal to the volume of the precipitate. The supernatant liquor was again concentrated at 4° and a second and third crop of crystals removed. Crystallization was continued until no further separation occurred. The first crop of crystals generally amounted to 10 g. of protein, the second to 3 g. and the third to 0.3 g., leaving 12.5 g. of protein dissolved in solution under these conditions. Thus, about one-half of the original serum albumin was converted into water insoluble crystalline material.

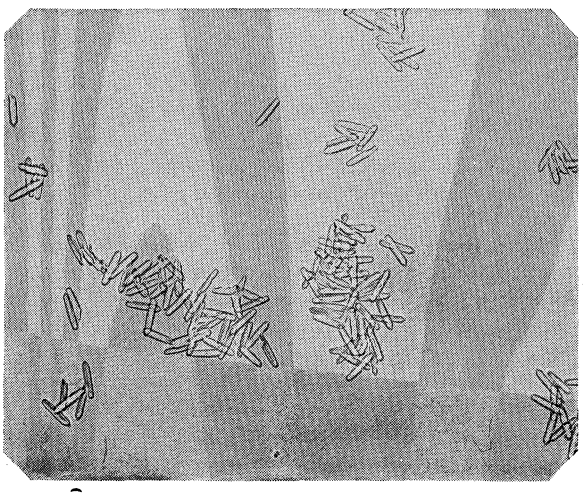

Fig. 2.—Microphotograph of serum albumin sulfate crystallized from water.

Properties of Serum Albumin Crystallized from Water at *p*H 4.0.—The serum albumin sulfate had the same crystal form of hexagonal prisms with pointed ends as the serum albumin from which it was derived. A solution obtained by repeated extraction of the crystals always had a *p*H of 4.0 ± 0.05 and gave a test for sulfate ions indicating that the substance was an albumin sulfate. For complete removal of sulfate, precipitation with barium or electrodialysis was required. After the removal of sulfate by electrodialysis, the solution had a *p*H close to that of the solution from which the albumin sulfate was prepared, indicating that the isolectric points of the several proteins were not sensibly different and close to *p*H 4.8.

The nitrogen factor of the albumin crystallized as sulfate was appreciably higher than that of the carbohydrate-free crystalline serum albumin from which it was derived. The latter carbohydrate-free unfractionated serum albumin was estimated to contain 16.1% nitrogen by macro-Kjeldahl and 16.2% nitrogen by Nesslerization. These results are in good agreement with the older values, but are higher than some recent reports. Abderhalden[20] found the nitrogen content of serum albumin to be 15.89, while Hewitt[4] reports from 14.1 to 14.4%, and Adair and Robinson[21] 15.6% nitrogen.

The isoelectric albumin prepared from the crystalline sulfate was found to contain 16.8% nitrogen by the Kjeldahl method. Protein concentration was determined by evaporation to constant weight of the salt-free solution at the isoelectric point in an oven at 105°, and also by weighing the dried coagulated protein. The results from the two methods were in good agreement.

Tryptophan has been present in the purest preparations of serum albumin but to a very small extent and it therefore seemed important to determine the amount of this amino acid in our preparations both before and after crystallization of the albumin sulfate. For this purpose Lugg's modification[22] of the Folin–Ciocalteu–Marenzi[23] method was used and a tryptophan content of 0.53% estimated for the albumin both before and after crystallization as a sulfate. This value is in good agreement with that of Folin and Marenzi[23] and is approximately double the value reported by Hewitt.[4,24]

The albumin sulfate was electrophoretically homogeneous at *p*H 7.4, but still showed a small quantity of a second component at *p*H 4.0. Its solubility in water at 4° was very high but at room temperature only moderate. The data in Table II illustrate its solubility in water at 25°. The *p*H was 4.0 ± 0.02 and the solvent was saturated with toluene.

TABLE II

SOLUBILITY OF CRYSTALLINE SERUM ALBUMIN SULFATE AT *p*H 4.0 AND 25°

No. of equilibrations of one day each	Vol. of solvent, cc.	Soly., g./liter: Solute A 0.6 g. protein	Solute B 3.0 g. protein

4	5	14.2[a]	45.0
5	5		43.9
6	5		41.4
			26.0[a]

[a] The solute protein was largely denatured at this stage as was shown by absence of crystalline form and almost complete insolubility in water.

Analysis for the sulfate ion in these crystals yielded the result that each gram of the protein was combined with 0.00035 equivalent of sulfate, a value considerably in excess of the amount of sulfate, 0.00026 equivalent per gram, necessary to titrate the albumin from the isoelectric point to a *p*H 3.95.

The sulfate ion was removed from albumin sulfate by dialysis and electrodialysis and the protein again crystallized from ammonium sulfate. The solubility of these crystals at 25° was determined in a 1.47 *M* ammonium sulfate solution, and the results are given in Table III. Although

TABLE III

SOLUBILITY IN 1.47 *M* AMMONIUM SULFATE OF ALBUMIN ISOLATED BY CRYSTALLIZATION AS SULFATE AT *p*H 4.0 AND 25°

No. of equilibrations of one day each	Vol. of solvent, cc.	Soly., g./liter[a]: Solute A 0.2 g. protein	Solute B 1.0 g. protein
2	40	0.62	(1.03)
3	40	.54	0.50
4	40	.80	.54
5	40	(1.07)	.57
6	40		.49

[a] The *p*H of the filtrate was determined each day. For the more dilute series it always remained 4.8 ± 0.04 and for the more concentrated series 4.63 ± 0.03. In subsequent experiments it should be possible to control the *p*H in these unbuffered solutions even more carefully.

there is some drift from day to day in these unbuffered solutions, there is no evidence of increase in solubility with increase in saturating body or of decrease in solubility with increase in the number of days during which the saturating body was equilibrated with fresh aliquots of solvent. The extent of the purification achieved by crystallization as the albumin sulfate is perhaps best demonstrated by a comparison of Table III with Table I. The results reported in Tables II and III indicate that at least one component of the serum albumin system has been separated as a chemical individual. Further studies both of its composition and properties are being undertaken and will be reported subsequently.

I am indebted to Professor Edwin J. Cohn for his suggestions and advice throughout this investigation.

Summary

1. Carbohydrate-free crystalline serum albumin has been separated into two fractions by crystallizing the sulfates from water.

2. The solubility in salt solution of the protein regenerated from the insoluble albumin sulfate was found to be essentially independent of the amount of protein in the system, and of the volume of solvent with which it was equilibrated, suggesting that this albumin component had been separated as a chemical individual.

3. The percentage of nitrogen in this serum albumin was found to be higher, tyrosine lower, and tryptophan the same as in unfractionated carbohydrate-free crystalline serum albumin.

Serum Albumin. II. Identification of More than One Albumin in Horse and Human Serum by Electrophoretic Mobility in Acid Solution

BY JOHN A. LUETSCHER, JR.

The albumins of serum have constituted a problem of importance both for protein chemistry and clinical medicine. The serum albumins of the horse are readily crystallizable, and those of man have been crystallized, though with greater difficulty.[1,2] The beautifully crystalline albumin of normal horse serum has, however, been shown not to consist of a single chemical individual, as judged by solubility,[3] although it appears to be homogeneous as to molecular weight as judged by the ultracentrifuge,[4] and to migrate with uniform velocity in the electric field at neutral reaction.[5]

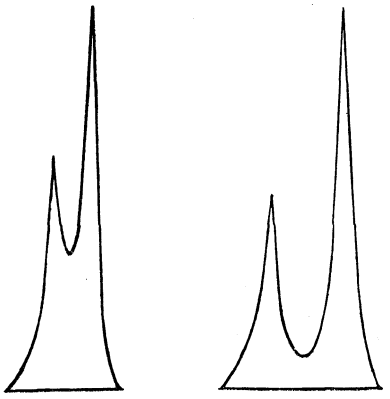

Fig. 1.—Schlieren diagrams (diaphragm level against distance moved) of electrophoresis at *p*H 4.0 and ionic strength 0.02 of (a) horse serum albumin, and (b) normal human serum albumin. Area under each peak is proportional to concentration of that component.

In the preceding paper,[6] McMeekin has succeeded in purifying crystalline serum albumin so as to yield at least one component of constant solubility. This was accomplished by "crystallization of horse serum albumin from salt-free solution" following an observation of J. D. Ferry.[7] The crystallization as an albumin sulfate was carried out at *p*H 4.0 and 25°. The serum albumin so fractionated previously had been crystallized repeatedly so as to free it from carbohydrate and had a single electrophoretic mobility in the Tiselius apparatus at neutral reactions where it has been studied as a function of *p*H, ionic strength, and protein concentration.

It seemed important to investigate the electrophoretic mobility of horse serum albumin at the *p*H at which Ferry and McMeekin have demonstrated that a portion of the albumin can be crystallized as the sulfate. Measurements were therefore undertaken on the same carbohydrate-free crystalline albumin that served as starting material for McMeekin's investigations[6] and which migrated in the electric field with uniform mobility at a great variety of ionic strengths at neutral reactions. When studied in acetate buffers at *p*H 4.0 of ionic strength 0.02, however, two boundaries were clearly visible, as represented in Fig. 1a. Migration was followed by the Toepler–Schlieren method,[8] ordinates and abscissas representing diaphragm level and distance moved. The amount of protein is proportional to the area under the curves. The albumin mobilities were 6.80 and 6.44 $\times 10^{-5}$ cm.^{2}/volt-sec., respectively, about 60% of the protein moving at the faster, 40% at the slower, rate. The protein in this solution, which thus revealed two boundaries when studied at *p*H 4.0, subsequently migrated with a single boundary at *p*H 7.4 of the same mobility as before.

When normal human serum albumin was investigated under precisely the same conditions, two boundaries were also clearly distinguishable, as represented in Fig. 1b. The mobilities of the two human serum albumin components at *p*H 4.0 and $\Gamma/2$ 0.02 were 7.25 and 5.95 $\times 10^{-5}$ cm.^{2}/volt-sec., respectively. The component of greater mobility of human serum albumin therefore moves appreciably faster as a cation than the faster component of horse serum albumin, and the slower component of human serum albumin more slowly than the slower component of horse serum albumin under these conditions. The

(8) An automatic camera for producing these diagrams has been described by Longsworth, THIS JOURNAL, **61**, 529 (1939).

separation achieved between the components of human serum albumin during electrophoresis is thus by far the greater, as is indicated by the greater separation of the peaks in Fig. 1b than in 1a. The protein migrating with the greater mobility represented approximately 67% and that with the slower mobility 33% of the albumin. Although there is approximately the same proportion of components in horse and man, the difference between the mobilities is sufficient to render practicable electrophoretic separation under these or closely similar conditions, at least in the case of the human protein. Human serum albumin, as in the case of the horse, migrates uniformly at neutral reactions.

Although the loss of serum proteins into the urine in certain diseases involves not only the albumin, but also the globulin fractions, the albumin molecules are generally lost in larger amount. It seemed desirable to investigate the albumin components of blood and urine from patients with certain types of kidney and liver disease. In the nephrotic syndrome, where large amounts of serum albumin are known to be lost and where the concentration of globulins (especially the α- and β-fractions of Tiselius) and fibrinogen in blood is increased, the albumin both in the blood and the urine has been investigated under the same conditions as that of normal human serum albumin, namely, in acetate buffers at *p*H 4.0, and found to be divisible into two components. Unlike normal human albumin, however, the component of slower mobility has been found to be present in larger amount (Fig. 2b). Since the ratio of components appears to be the same in both urine and blood, this abnormality cannot be considered as due to urinary excretion but rather to a difference in protein production. The total amount of albumin is much reduced in these cases, as is indicated by comparing the shaded area under the curves, representing the albumins of nephrotic syndrome, with the area under the outline curve of the normal serum. Taking average concentrations of the normal components, respectively, as 1.3 and 2.7 g. per hundred cc., the concentration of the slower component would be reduced to one-sixth but of the faster component almost to one-thirtieth that of the normal. It follows that the production of the slower component is less affected than that of the faster. It was the urinary albumin from a similar case that had "a dielectric constant increment of 0.5 per gram per liter, higher than any thus far obtained for crystallized horse serum albumin, and a mean relaxation time in dilute solution of 0.2×10^{-6} seconds,"[9] close to that observed for horse serum albumin.[10]

The above condition may be contrasted with that of the blood and urine of patients in the non-edematous end-stage of nephritis. Then the blood proteins approximate the normal picture, both as to the albumins and the globulins, although there would appear in the cases thus far investigated to be very little loss of the slower and a somewhat greater loss of the faster moving component (Fig. 2a).

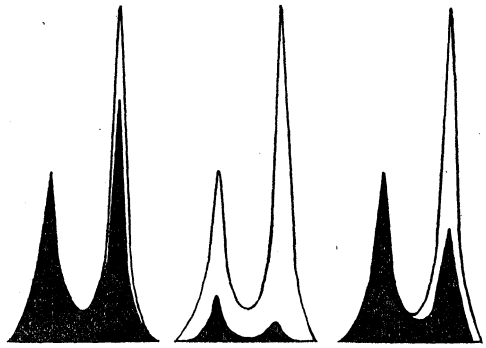

Fig. 2.—Schlieren diagrams of electrophoresis of pathological human albumins compared in each case with the normal picture. Concentrations of components in normal serum are 1.3 and 2.7 g. %; in terminal nephritis (a), 1.2 and 1.9; in nephrotic syndrome (b), 0.24 and 0.10; and in cirrhosis (c), 1.3 and 0.9 g. %, respectively. Ratio of albumins in urine was same as in serum.

In cirrhosis with ascites, where the principal factor in the lowering of plasma proteins is probably a failure of production, the albumin fraction may be much lowered, and in such cases the ratio of albumin components at *p*H 4.0 resembles that of the nephrotic syndrome, with the slower component predominating (Fig. 2c). Indeed, in cases thus far investigated no, or very slight, diminution in the concentration of the slower moving albumin has been detected, whereas the fast moving component has been reduced to one-third of the normal level. The role of the albumins which readily can be distinguished by electrophoresis at *p*H 4.0 is clearly different. That the difference in composition is not due to a gradual change in part of the albumin under

(9) Friend, Ferry and Oncley, *J. Biol. Chem.*, **123**, Proc. XXXIX (1938).

(10) Ferry and Oncley, THIS JOURNAL, **60**, 1123 (1938).

these conditions has been demonstrated by studying electrophoretic mobility of human serum albumin soon after equilibration with acetate buffer and again after a period of some days at 4° when no alteration in the electrophoretic mobility of either component or in the ratio of the components was detected.[11]

The separation and characterization not only of the albumin but also of the various globulin components of normal and pathological sera[12] are being investigated further.

Summary

1. Although crystalline serum albumin has been demonstrated to consist of more than one chemical individual, it has been reported to migrate with uniform velocity both during ultracentrifugation and electrophoresis at neutral reactions.

2. At *p*H 4.0, where a fraction of horse serum albumin crystallizes as a sulfate, the protein exhibits two boundaries in the Tiselius electrophoresis apparatus, which migrate, respectively, with mobilities of 6.80 and 6.44 × 10^{-5} cm.²/volt-sec. in acetate buffers of *p*H 4.0 and Γ/2 0.02.

3. Human serum albumin also consists of at least two components, migrating with velocities of 7.25 and 5.95 × 10^{-5} cm.²/volt-sec., respectively, under the above conditions.

4. In normal sera, the faster moving component constitutes nearly two-thirds of the albumin, but in certain pathological conditions in man, both serum and urinary albumins show a greater diminution of the faster component, leaving the slower component preponderant.

The Synthesis of Certain Substituted Quinolines and 5,6-Benzoquinolines

BY R. GORDON GOULD, JR., AND WALTER A. JACOBS

The synthesis of ergoline (I) and of several of its mono- and dimethyl derivatives by the sodium reduction of 3′-amino-5,6-benzoquinoline-7-carboxylic acid lactam and of the corresponding methyl derivatives already has been reported.[1] Although the yields were only about 5 to 10%, the method appeared to be of fairly general application to the alkyl derivatives. When, however, a free or esterified carboxyl group was present in the pyridine ring, the isolation of a crystalline ergoline derivative became extremely difficult. The preparation of ergoline-7-carboxylic acid in a yield of about 1% and in still somewhat impure condition already has been reported,[2] but all attempts to prepare the isomeric ergoline-8-carboxylic acid have given only amorphous products. This plan of attack on the problem of the synthesis of dihydrolysergic acid has therefore not been so promising as had been anticipated.

In the course of this work several new methods of synthesis of certain quinoline and benzoquinoline derivatives were developed, which are the subject of the present paper.

Conrad and Limpach[3] first prepared 4-hydroxyquinaldine (II) by condensation of aniline with acetoacetic ester at room temperature followed by cyclization at 250°, and Limpach[4] forty-four years later improved the yield from about 30 to 90–95% by the use of mineral oil as a diluent in the cyclization step.

This method of synthesis has now been found to be sufficiently general to be applicable not only to substituted anilines and β-naphthylamines, but also has been extended to the synthesis of 4-hydroxyquinoline-3-carboxylic acids (III) by the use of ethoxymethylenemalonic ester and of 4-hydroxyquinaldine-3-carboxylic acids (IV) by the use of acetylmalonic ester.

As examples, aniline condensed with ethoxymethylenemalonic ester to give anilidomethylenemalonic ester, as reported by Claisen.[5] Cyclization of the latter in mineral oil gave the previously known[6] 4-hydroxyquinoline-3-carboxylic acid (III).

$$C_6H_5NH_2 + C_2H_5OCH{=}C(COOR)_2 \longrightarrow C_6H_5NHCH{=}C(COOR)_2$$

Aniline condensed with acetylmalonic ester and the resulting intermediate alkylidene derivative was cyclized in mineral oil. The resulting ester after saponification proved to be the previously known 4-hydroxyquinaldine-3-carboxylic acid[7] (IV).

$$C_6H_5NH_2 + CH_3COCH(COOR)_2 \longrightarrow C_6H_5NHC(CH_3)=C(COOR)_2$$

In the case of acetoacetic ester and of ethoxymethylenemalonic ester, the condensation to the intermediate alkylidene derivatives went smoothly and apparently in only one sense, with all of the amines used, but acetylmalonic ester was found to give poorer yields of the alkylidene derivatives because of competing side reactions. With aniline, a yield of about 30% of acetanilide and of about 70% of the normal anilidomethylmethylenemalonic ester was obtained.

The condensation of acetylmalonic ester with 3-aminonaphthostyril gave another type of abnormal product which was possibly the result of the condensation of an ester linkage rather than that of the carbonyl group, with the amino group, thus

$$(C_{11}H_6ON)NH_2 + CH_3COCH(COOR)_2 \longrightarrow (C_{11}H_6ON)NHCOCHCOCH_3 \quad (\text{COOR on the CHCO group})$$

The alkylidene derivatives which resulted from the normal condensation of the three esters used with amines cyclized smoothly at 250°, and gave in each case the quinoline derivative. In the case of acetoacetic ester, this was a 4-hydroxyquinaldine or benzoquinaldine derivative, and in the cases of ethoxymethylenemalonic ester and acetylmalonic ester the products were derivatives of 4-hydroxyquinoline or benzoquinoline-3-carboxylic acids.

In addition to the examples already cited, the following new substances were prepared by the two steps of condensation, *viz.*, formation of the intermediate alkylidene derivative and subsequent cyclization to the quinoline or benzoquinoline. Acetoacetic ester and 3-amino-1-naphthoic acid (or its ester) gave **4-hydroxy-5,6-benzoquinaldine-7-carboxylic acid** (or its ester) **(V)**. 3-Aminonaphthostyril and acetoacetic ester gave **3′-amino-4-hydroxy-5,6-benzoquinaldine-7-carboxylic acid lactam (VI)**.

Ethoxymethylenemalonic ester and 3-amino-1-naphthoic acid gave **4-hydroxy-5,6-benzoquinoline-3,7-dicarboxylic acid (VII)**, and the same ester with 3-aminonaphthostyril gave **3′-amino-4-hydroxy-5,6-benzoquinoline-3,7-dicarboxylic acid lactam (VIII)**.

Since in the attempt to prepare **3′-amino-4-hydroxy-5,6-benzoquinaldine-3,7-dicarboxylic acid lactam (IX)** from 3-aminonaphthostyril and acetylmalonic ester the reaction proceeded abnormally, this substance was obtained instead by the following series of reactions. 4-Hydroxy-5,6-benzoquinaldine-7-carboxylic acid (V), when condensed with carbon tetrachloride and potassium hydroxide by the Reimer–Tiemann reaction, gave **4-hydroxy-5,6-benzoquinaldine-3,7-dicarboxylic acid (X)**. This dibasic acid was characterized also as the **monomethyl ester,** the **dimethyl ester,** and as the **4-methoxy dimethyl ester.** Nitration of the hydroxy dibasic acid gave a mixture of mononitro derivatives which was directly reduced as such. After treatment of the reduction product with acid, 3′-amino-4-hydroxy-5,6-benzoquinaldine-3,7-dicarboxylic acid lactam (IX) was isolated as well as a simultaneously formed free amino derivative which did not lactamize. The latter was possibly **6′-amino-4-hydroxy-5,6-benzoquinaldine-3,7-dicarboxylic acid (XI)**.

Several examples have been reported of the oxidation by selenium dioxide of the 2- or 4-methyl group in pyridine or quinoline derivatives to a carboxyl group[8] and of the 2-methyl group in 5,6-benzoquinaldine-7-carboxylic acid.[2] The presence of a 4-hydroxy group appears to block this type of oxidation, however, since none of the 4-hydroxy-5,6-benzoquinaldine derivatives described above were oxidized by selenium dioxide under the conditions usually employed.

The 4-hydroxyl group similarly appeared to block the catalytic hydrogenation of the nitrogen ring of such substances to the tetrahydro derivatives. Ruzicka and Fornasir[9] reported that 4-hydroxypyridine could not be hydrogenated catalytically under ordinary conditions of temperature and pressure and our experience with 4-hydroxyquinoline and -benzoquinoline derivatives appears to confirm this. Also in the case of 3′-amino-4-hydroxy-5,6-benzoquinoline-3,7-dicarboxylic acid lactam (VIII), reduction with amalgamated zinc and acetic acid appeared to stop at the dihydro stage, with the formation

of **3′-amino-4-keto-1,2,3,4-tetrahydro-5,6-benzoquinoline-3,7-dicarboxylic acid lactam (XII).**

A few substituted 5,6-benzoquinoline-4-carboxylic acids were prepared by the application of the condensation of aromatic amines with pyruvic acid and aldehydes.[10] With formaldehyde, only complex dimolecular products were obtained, but with acetaldehyde the reaction went smoothly although the yields were poor. 3-Amino-1-naphthoic methyl ester gave **7-carbomethoxy-5,6-benzoquinaldine-4-carboxylic acid (XIII)** which after saponification and oxidation with selenium dioxide yielded **5,6-benzoquinoline-2,4,7-tricarboxylic acid (XIV).** Attempts to prepare lactam derivatives from both the dibasic and tribasic acids by successive nitration and reduction were unsuccessful. Nitration in the 3′ position was apparently not favored.

3-Aminonaphthostyril on condensation with pyruvic acid and acetaldehyde gave **3′-amino-5,6-benzoquinaldine-4,7-dicarboxylic acid lactam (XV)** in poor yield.

Finally, the method developed for the preparation of 3-hydroxy-1,2,3,4-tetrahydro-7,8-benzoquinoline derivatives by the condensation of epichlorohydrin with α-naphthylamine derivatives[11] was tried with several β-naphthylamine derivatives. It was found that β-naphthylamine gave **3-hydroxy-1,2,3,4-tetrahydro-5,6-benzoquinoline (XVI),** but 3-aminonaphthostyril yielded an anomalous product, the nature of which has not been determined.

Experimental

For the preparation of alkylidene derivatives, except where otherwise stated, the condensations with acetoacetic ester and acetylmalonic ester were carried out at room temperature and with ethoxymethylenemalonic ester by heating on the steam-bath. In some cases methyl or ethyl alcohol was used as a solvent. The cyclizations of the alkylidene derivatives were carried out in 10–30 parts of mineral oil at 250–265°, in an atmosphere of dry nitrogen, and with good mechanical stirring. The substance was added in small portions and heating was continued for about fifteen minutes. After cooling, the mixture was treated with the appropriate solvent and the crystalline product was collected.

(3-Naphthyl-1-carboxylic Acid)-β-aminocrotonic Ethyl Ester.—Twenty grams of 3-amino-1-naphthoic acid and 20 g. of acetoacetic ester condensed readily in methyl alcoholic solution. After removal of the solvent *in vacuo* the crystalline product was collected with a cold ether–petroleum ether mixture. The yield was almost quantitative. For analysis it was recrystallized from ether and formed rosets of needles which melted at 157–158°.

Anal. Calcd. for $C_{17}H_{17}O_4N$: C, 68.19; H, 5.73. Found: C, 68.08; H, 5.40.

4-Hydroxy-5,6-benzoquinaldine-7-carboxylic Acid (V).—Cyclization gave an almost quantitative yield of the benzoquinoline derivative. It was purified by recrystallization from 1% hydrochloric acid solution as the hydrochloride which separated as needles.

Anal. Calcd. for $C_{15}H_{11}O_3N \cdot HCl$: C, 62.16; H, 4.18. Found: C, 61.96; H, 4.40.

After liberation from the salt, the substance was obtained as a microcrystalline powder which did not melt below 360°.

Anal. Calcd. for $C_{15}H_{11}O_3N$: C, 71.10; H, 4.38. Found: C, 70.87, 71.34; H, 4.81, 4.50.

The Methyl Ester.—Treatment with boiling methyl alcohol and hydrogen chloride gave the ester, which after recrystallization melted at 295–296° with decomposition.

Anal. Calcd. for $C_{16}H_{13}O_3N$: C, 71.88; H, 4.91. Found: C, 71.74; H, 5.01.

The Ethyl Ester.—The ester was obtained with absolute alcohol and sulfuric acid and formed lustrous leaflets from alcohol, which melted at 295–297°.

Anal. Calcd. for $C_{17}H_{15}O_3N$: C, 72.56; H, 5.38. Found: C, 72.78; H, 5.32.

N-(3-Naphthostyryl)-β-aminocrotonic Ethyl Ester.—Two and one-half grams of 3-aminonaphthostyril was refluxed with an excess of acetoacetic ester in alcohol solution for several hours. The condensation product was collected in a yield of 3.2 g. After recrystallization from alcohol, it melted at 180–182°.

Anal. Calcd. for $C_{17}H_{16}O_3N_2$: C, 68.88; H, 5.44. Found: C, 68.65; H, 5.28.

4-Hydroxy-3′-amino-5,6-benzoquinaldine-7-carboxylic Acid Lactam (VI).—The above aminocrotonic ester was cyclized in mineral oil at 250° and the product was purified through the sparingly soluble hydrochloride which formed needles from dilute hydrochloric acid solution.

Anal. Calcd. for $C_{15}H_{11}O_2N_2Cl$: C, 62.81; H, 3.87. Found: C, 62.96; H, 3.51.

The free hydroxy lactam was insoluble in ammonia and very sparingly soluble in hot pyridine or dilute pyridine. It did not melt below 360°.

Anal. Calcd. for $C_{15}H_{10}O_2N_2$: C, 71.97; H, 4.03. Found: C, 71.49; H, 4.41.

4-Hydroxyquinaldine-3-carboxylic Ethyl Ester.—Ten and one-tenth grams of acetylmalonic ester[12] and 4.7 g. of aniline were allowed to stand at room temperature for three days. Acetanilide separated and was collected in a yield corresponding to about 30% of the aniline used. The filtrate was cyclized in mineral oil, and the product collected with ether. After recrystallization from alcohol, the substance melted at 104–107°.

Anal. Calcd. for $C_{13}H_{13}O_3N$: C, 67.50; H, 5.67. Found: C, 66.97; H, 5.46.

4-Hydroxyquinaldine-3-carboxylic Acid (IV).—Saponification gave the free acid which melted at 245–247° with decomposition. Camps[6] gave 247–248° with decomposition.

Anal. Calcd. for $C_{11}H_9O_3N$: C, 65.00; H, 4.47. Found: C, 65.20; H, 4.38.

(12) H. Lund, *Ber.*, **67**, 937 (1934).

α-Carbethoxyacetoacetyl-3-aminonaphthostyril.—One and eight-tenths grams of 3-aminonaphthostyril and 4 g. of acetylmalonic ester were allowed to stand at room temperature for several months. After recrystallization from alcohol, the substance melted at 268–270° with decomposition.

Anal. Calcd. for $C_{18}H_{16}O_5N_2$: C, 63.50; H, 4.71. Found: C, 63.19; H, 4.65.

4-Hydroxyquinoline-3-carboxylic Acid (III).—One gram of anilidomethylenemalonic ester[5] was cyclized in mineral oil and the crystalline product was collected in a yield of about 60%. Acidification of the aqueous alkaline solution gave long needles which melted at 267–268°. Camps[6] gave 266–267°.

Anal. Calcd. for $C_{10}H_7O_3N$: C, 63.47; H, 3.72. Found: C, 63.60; H, 3.79.

N-(3-Naphthyl-1-carbomethoxy)-β-amino-α-carbethoxyacrylic Ethyl Ester.—One gram of 3-amino-1-naphthoic methyl ester and 1.08 g. of ethoxymethylenemalonic ester[13] were heated for fifteen minutes at 100°. On cooling, a crystalline cake formed which was recrystallized from ether. It formed voluminous long needles melting at 89–90°.

Anal. Calcd. for $C_{20}H_{21}O_6N$: C, 64.66; H, 5.70. Found: C, 64.99; H, 5.62.

4-Hydroxy-5,6-benzoquinoline-3,7-dicarboxylic Acid (VII).—One gram of the above alkylidene derivative at 250° gave 0.73 g. of cyclization product. This monomethyl ester was saponified by heating in dilute sodium hydroxide and the dibasic acid was recrystallized from sodium acetate solution as the beautifully crystalline monosodium salt. It was then isolated as the free acid which did not melt below 360°.

Anal. Calcd. for $C_{15}H_9O_5N$: C, 63.59; H, 3.22. Found: C, 63.91; H, 3.37.

N-(3-Naphthostyryl)-β-amino-α-carbethoxyacrylic Ethyl Ester.—To 104.6 g. of 3-aminonaphthostyril dissolved in 185 cc. of boiling alcohol was added 6 g. of ethoxymethylenemalonic ester, and the solution was refluxed for one hour. The crystalline product was collected in about 75% yield. With material recovered from the mother liquor, the yield was almost the theoretical.

The substance formed light yellow needles from alcohol which melted at 231–232°.

Anal. Calcd. for $C_{19}H_{18}O_5N_2$: C, 64.38; H, 5.12. Found: C, 64.85; H, 5.10.

4-Hydroxy-3′-amino-5,6-benzoquinoline-3,7-dicarboxylic Acid Lactam (VIII).—Six and three-tenths grams of the above substance on cyclization gave an almost quantitative yield of the benzoquinoline derivative. Purification was effected by boiling in 5% sodium hydroxide solution for one hour in order to open the lactam group. After treatment with norite, the clear light yellow solution was made strongly acid to congo red with hydrochloric acid and brought to a boil. The lactam acid formed microscopic needles which did not melt below 360°.

It is soluble in dilute sodium bicarbonate on warming and in dilute piperidine. It forms a sparingly soluble sodium

(13) L. Claisen, *Ann.*, **297**, 76 (1897); H. L. Wheeler and C. O. Johns, *Am. Chem. J.*, **40**, 238 (1908).

salt in more concentrated alkaline solutions, and it is not appreciably soluble in the ordinary organic solvents.

Anal. Calcd. for $C_{15}H_8O_4N_2$: C, 64.27; H, 2.88; N, 10.00. Found: C, 64.01, 64.23; H, 3.09, 3.05; N, 10.20.

The free amino dibasic acid formed a dark red gelatinous precipitate.

3′ - Amino - 4 - hydroxy - 2,3 - dihydro - 5,6 - benzoquinoline-3,7-dicarboxylic Acid Lactam (XII).—The 3′-amino-4-hydroxy-5,6-benzoquinoline-3,7-dicarboxylic acid lactam was suspended in acetic acid and refluxed for about five hours with an excess of amalgamated zinc shot. The supernatant suspension was decanted from the excess zinc and was then collected. It was purified by reprecipitation from a dilute pyridine solution by addition of acetic acid, and did not melt below 350°.

Anal. Calcd. for $C_{15}H_{12}O_4N_2$: C, 63.81; H, 3.57. Found: C, 63.92; H, 3.84.

4 - Hydroxy - 5,6 - benzoquinaldine - 3,7 - dicarboxylic Acid (X).—To 11 g. of 4-hydroxy-5,6-benzoquinaldine-7-carboxylic acid (V) were added 60 cc. of 50% potassium hydroxide, 5 cc. of carbon tetrachloride, about 1 g. of copper powder, and a few cc. of alcohol, and the mixture was refluxed for twenty-four hours. It was then diluted with 5 volumes of water and filtered. The clear, dark-colored filtrate was made just acid to congo red by the addition of hydrochloric acid and then enough excess hydrochloric acid was added to bring the concentration to 1%. After bringing to a boil, the undissolved material was collected. It was again boiled in 200 cc. of 1% hydrochloric acid and collected hot. The insoluble material consisted of the dibasic acid. Unchanged monobasic acid was recovered from the combined filtrates. The yields of dibasic and recovered monobasic acids were respectively 3 g. and 6 g.

The dicarboxylic acid was purified by the following steps: extraction with hot alcohol (in which it is insoluble); recrystallization as the salt from sodium acetate solution; as the nitrate from nitric acid (1.4); and finally from dilute pyridine. It formed leaflets which did not melt below 360°.

Anal. Calcd. for $C_{16}H_{11}O_5N$: C, 64.63; H, 3.73. Found: C, 64.44, 64.57; H, 3.39, 3.74.

A **monomethyl ester** of undetermined identity was obtained by esterification with boiling methyl alcoholic hydrogen chloride. The hydrochloride crystallized from the boiling solution. The free ester, after recrystallization from aqueous pyridine, melted at 290–295°, with decomposition.

Anal. Calcd. for $C_{17}H_{13}O_5N$: C, 65.57; H, 4.21. Found: C, 65.56; H. 4.33.

The **dimethyl ester** was obtained from the dibasic acid in poor yield with methyl alcohol and sulfuric acid. When recrystallized from methyl alcohol it melted at 239–240°.

Anal. Calcd. for $C_{18}H_{15}O_5N$: C, 66.43; H, 4.65. Found: C, 66.72; H, 5.06.

4 - Methoxy - 5,6 - benzoquinaldine - 3,7 - dicarboxylic Dimethyl Ester.—This substance resulted from treatment of a methyl alcoholic suspension of the dibasic acid with diazomethane. It formed long colorless needles from ether or methyl alcohol, which melted at 142–144°.

Anal. Calcd. for $C_{19}H_{17}O_5N$: C, 67.23; H, 5.05. Found: C, 67.19; H, 5.17.

3′ - Nitro - 4 - hydroxy - 5,6 - benzoquinaldine - 3,7 - dicarboxylic Acid.—The preceding dicarboxylic acid was nitrated with fuming nitric acid (1.58). The material which separated on dilution was a mixture of isomeric mononitro derivatives, and was used directly for the following reduction without attempting a separation.

Anal. Calcd. for $C_{16}H_{10}O_7N_2$: C, 56.12; H, 2.95. Found: C, 55.63; H, 3.03.

3′ - Amino - 4 - hydroxy - 5,6 - benzoquinaldine - 3,7 - dicarboxylic Acid Lactam (IX).—The previously described method[1,2] with ferrous hydroxide was used for the reduction of the preceding substance. The crude product was collected after acidification to congo red and boiling for a short time. This material was found on analysis to consist approximately of 30% of the lactam of the 3′-amino derivative and 70% of an isomeric aminodicarboxylic acid, which did not lactamize. The mixture was separated by trituration with half saturated sodium bicarbonate solution at 60° which appeared to dissolve mainly the amino dicarboxylic acid. The lactam acid was purified by recrystallization as the sodium salt from sodium carbonate solution. After liberation from the salt, the lactam acid formed an orange-yellow microcrystalline powder, which did not melt below 360°.

Anal. Calcd. for $C_{16}H_{10}O_4N_2$: C, 65.28; H, 3.43; N, 9.53. Found: C, 65.39; H, 3.61; N, 9.70.

(?) - Amino - 4 - hydroxy - 5,6 - benzoquinaldine - 3,7-dicarboxylic Acid (XI).—The above sodium bicarbonate solution on acidification yielded the by-product which was obtained colorless after purification by repeated recrystallization as the hydrochloride from dilute hydrochloric acid. The free amino acid was obtained as a microcrystalline powder which did not melt below 360°.

Anal. Calcd. for $C_{16}H_{12}O_5N_2$: C, 61.51; H, 3.88. Found: C, 61.12; H, 4.22.

7 - Carbomethoxy - 5,6 - benzoquinaldine - 4 - carboxylic Acid (XIII).—Four grams of 3-amino-1-naphthoic methyl ester, 0.88 g. of pyruvic acid, and 0.88 g. of acetaldehyde were dissolved in 50 cc. of alcohol and the mixture was refluxed for four to five hours. A yield of 0.7 g. of the product crystallized on cooling; 0.2 g. more was obtained from the mother liquor.

The acid formed aggregates of fine white needles from a mixture of pyridine and alcohol, which melted at 265–266°, with decomposition.

Anal. Calcd. for $C_{17}H_{13}O_4N$: C, 69.13; H, 4.44. Found: C, 69.46; H, 4.56.

Saponification of the above monomethyl ester gave the **dibasic acid** as a colorless microcrystalline powder which melted at 298–299°, with decomposition.

Anal. Calcd. for $C_{16}H_{11}O_4N$: C, 68.30; H, 3.95. Found: C, 68.08; H, 3.82.

7 - Carbomethoxy - 5,6 - benzoquinoline - 2,4 - dicarboxylic Acid.—The previous monomethyl ester was oxidized with excess selenium dioxide in pyridine solution. The resulting product was recrystallized from a mixture of pyridine and methyl alcohol from which it separated as diamond-shaped prisms. It melted at 199–200° with decomposition and contained pyridine of crystallization which was not removed by heating to 100° *in vacuo*.

Anal. Calcd. for $C_{17}H_{11}O_6N \cdot C_5H_5N$: C, 65.32; H, 3.99. Found: C, 65.22; H, 4.01.

Saponification of the above oxidation product yielded **5,6-benzoquinoline-2,4,7-tricarboxylic acid (XIV)**, which melted at 285–286° with decomposition.

Anal. Calcd. for $C_{16}H_9O_6N$: C, 61.72; H, 2.92. Found: C, 61.81; H, 3.19.

3′ - Amino - 5,6 - benzoquinaldine - 4,7 - dicarboxylic Acid Lactam (XV).—Three and sixty-eight hundredths grams of 3-aminonaphthostyril, 0.88 g. of acetaldehyde, and 0.88 g. of pyruvic acid dissolved in 200 cc. of alcohol were refluxed for four hours. After concentration a yellow crystalline precipitate was obtained, which was purified from non-acidic material and was finally obtained in a yield of 0.5 g. It melted at 340–342° with decomposition.

Anal. Calcd. for $C_{16}H_{10}O_3N_2$: C, 69.04; H, 3.62. Found: C, 69.04; H, 3.40.

3-Hydroxy-1,2,3,4-tetrahydro-5,6-benzoquinoline (XVI).—β-Naphthylamine was condensed with an equimolecular amount of epichlorohydrin by the method recently developed for α-naphthylamine derivatives,[11] and the resulting product was purified as the hydrochloride, from dilute hydrochloric acid.

Anal. Calcd. for $C_{13}H_{14}ONCl$: C, 66.22; H, 5.99. Found: C, 66.41; H, 5.95.

The free base after recrystallization melted at 82–83°.

Anal. Calcd. for $C_{13}H_{13}ON$: C, 78.35; H, 6.58. Found: C, 78.65; H, 6.95.

Summary

1. A convenient method of synthesis of certain 4-hydroxyquinoline and 4-hydroxy-5,6-benzoquinoline derivatives has been found in the condensation of aniline and β-naphthylamine derivatives with acetylmalonic ester or ethoxymethylenemalonic ester followed by cyclization at 250°.

2. The method of Conrad and Limpach for the synthesis of 4-hydroxyquinaldine from acetoacetic ester and aniline has been extended to include certain substituted β-naphthylamines.

3. The introduction of a carboxyl group in position 3 of 4-hydroxy-5,6-benzoquinaldine-7-carboxylic acid was accomplished by means of the Reimer–Tiemann reaction.

4. Epichlorohydrin on condensation with β-naphthylamine gave 3-hydroxy-1,2,3,4-tetrahydro-5,6-benzoquinoline.

Cleavage of Quaternary Ammonium Salts by Sodium Sulfide. II

BY H. R. SNYDER AND J. C. SPECK

In an earlier communication[1] it was shown that benzyldimethylphenylammonium chloride (I) is cleaved readily by aqueous sodium sulfide to yield benzyl sulfide and dimethylaniline. A number of other salts containing sulfur in its lower valences were also found to be effective cleaving agents. The reaction is of the same type as that observed in the splitting of thiamin[2] (vitamin B_1) with sodium bisulfite, in which a group similar to benzyl is detached from a quaternary nitrogen atom.

$$2[C_6H_5CH_2N(CH_3)_2C_6H_5]^+Cl^- + Na_2S \longrightarrow (C_6H_5CH_2)_2S + 2C_6H_5N(CH_3)_2 + 2NaCl$$

It now has been found that the groups other than benzyl attached to the nitrogen atom play an important part in the cleavage. For instance, benzyltrimethylammonium chloride was completely unaffected under conditions which brought about rapid decomposition of benzyldimethylphenylammonium chloride. That this difference is not due merely to the weight of the phenyl group was shown by the fact that benzylcyclohexyldiethylammonium chloride also resisted the action of aqueous sodium sulfide. Phenyltrimethylammonium iodide, and tetra-*n*-butylammonium iodide also failed to undergo cleavage. Even the presence of two benzyl groups on the nitrogen atom does not produce an activation similar to that in benzyldimethylphenylammonium chloride, since dibenzyldiethylammonium iodide was only very slightly cleaved. Benzylpyridinium chloride, on the other hand, underwent rapid scission to pyridine and benzyl sulfide. It appears, therefore, that the linkage between an alkyl group and the nitrogen atom of a quaternary salt is labilized when the nitrogen is attached to or is part of an aromatic system.

It might be predicted that the allyl group would display a mobility similar to that of

benzyl. This prediction was confirmed by the rapid cleavage of allyldimethylphenylammonium bromide by aqueous sodium sulfide.

It seemed likely that the less reactive quaternary salts might undergo the cleavage if more vigorous conditions were employed. This was accomplished by the use of the high-boiling solvent, diethylene glycol. Benzyltrimethylammonium bromide, which was unaffected by boiling aqueous sodium sulfide, gave more than 50% of cleavage products when the reaction was carried out at 135–150°. Tetra-*n*-butylammonium iodide, which would be expected to fall among the most stable quaternary salts, underwent cleavage to the extent of at least 70% at 175°.

Since sodium hydrosulfite has been used for the reduction of certain quaternary ammonium compounds,[3] it was desirable to test its action on an easily cleaved salt such as benzyldimethylphenylammonium chloride.[4] Rapid cleavage occurred when an aqueous solution of these reagents was heated. The products were dimethylaniline and a neutral salt which proved to be benzyldimethylphenylammonium-S-benzylthiosulfate (II), identical with the product from the action of sodium thiosulfate on the quaternary salt.[1] Meyer[5] has shown that sodium hydrosulfite undergoes hydrolysis to sodium thiosulfate and sodium bisulfite. This may account for the formation of a thiosulfate derivative in the present case, although the possibility of benzylation prior to conversion to thiosulfate is not excluded.

$$2Na_2S_2O_4 + H_2O \longrightarrow Na_2S_2O_3 + 2NaHSO_3$$

Experimental

Benzylcyclohexyldiethylammonium chloride was prepared by heating benzyl chloride and N,N-diethylcyclohexylamine in absolute alcohol; m. p. 179° (dec.).

Anal. Calcd. for $C_{17}H_{28}NCl$: Cl, 12.6. Found: Cl, 12.7.

Allyldimethylphenylammonium bromide was prepared from allyl bromide and dimethylaniline in anhydrous ether at room temperature. Because of the extreme hygroscopicity of this salt, its melting point was not determined.

Anal. Calcd. for $C_{11}H_{16}NBr$: Br, 33.0. Found: Br, 32.6.

Cleavage with Aqueous Sodium Sulfide.—The procedure employed was that previously described.[1] No evidence of cleavage was observed with benzyltrimethylammonium bromide, phenyltrimethylammonium iodide or tetra-*n*-butylammonium iodide. Benzylcyclohexyldiethylammonium chloride underwent some cleavage, as shown by the formation of a small amount of a water-insoluble oil. Dibenzyldiethylammonium iodide, heated with aqueous sodium sulfide for three hours, gave about 3% of benzyl sulfide. Benzylpyridinium chloride gave 65% of pyridine and 69% of benzyl sulfide. Allyldimethylphenylammonium bromide gave 41% of dimethylaniline and 44% of allyl sulfide.

Cleavage with Sodium Sulfide in Aqueous Diethylene Glycol.—To a solution of 12.0 g. of sodium sulfide hydrate in 80 cc. of diethylene glycol was added 23.0 g. of phenyltrimethylammonium bromide. The solution was heated to reflux for one hour at 135°, read on a thermometer immersed in the solution. Additional diethylene glycol was added until the boiling point rose to 150°, and refluxing was continued one-half hour. The trimethylamine liberated during the heating was absorbed in standard acid; yield 54%. Benzyl sulfide was extracted from the cold reaction mixture with benzene and crystallized from ether; yield 47%.

Fourteen grams of sodium sulfide hydrate was dissolved in 50 cc. of diethylene glycol and the solution was boiled in an open vessel until the temperature was 175°. To the cooled solution was added 22.0 g. of tetra-*n*-butylammonium iodide. The solution was heated under reflux for fifteen minutes. The cooled solution was extracted with petroleum ether. The tri-*n*-butylamine was separated from the solvent by extraction with dilute acid and treatment with alkali. The yield of tri-*n*-butylamine boiling at 205° was 7.5 g. (70%).

Cleavage with Sodium Hydrosulfite.—To 100 cc. of water was added 24.8 g. of benzyldimethylphenylammonium chloride and 17.4 g. of sodium hydrosulfite. The solution was heated under reflux for fifteen minutes. After cooling it was shaken with ether, which caused crystallization of the heavy oil that had formed during the heating. From the ether extraction of the solid and mother liquor there was obtained 3.5 g. (58%) of dimethylaniline. The dry solid weighed 12.4 g. (60%). A sample crystallized from alcohol and ether melted at 104°; this melting point was not depressed by admixture of authentic benzyldimethylphenylammonium-S-benzylthiosulfate.[1]

Anal. Calcd. for $C_{22}H_{25}O_3NS_2$: C, 63.7; H, 6.03; N, 3.38. Found: C, 63.77; H, 6.26; N, 3.20.

Summary

Quaternary ammonium salts containing both an aromatic group and a benzyl or allyl group attached to the nitrogen atom are readily cleaved by boiling aqueous sodium sulfide, yielding benzyl
