in which w_A is the work of adhesion between the oil and water and w_{C_0} is the work of cohesion of the oil. The next paper of this series, which will give values of f_0 for the 13, 15, and 16 carbon atom acids, should make it possible to show more clearly what the relations are. At present it seems likely that the theory in its use of $-f_0 = f_S$ overemphasizes somewhat the attraction between the hydrocarbon chains and the water. Additional determinations of the value of f_S are needed to ascertain the magnitude of this overemphasis.

The values of a_0 for myristic acid (Table IV) are not constant, but increase with temperature from 12.6 sq. Å. at 12.5° to 14.7 sq. Å. at 25°, so the areas are much too small to agree with those of hydrocarbon chains, since the minimum given by films is 20 sq. Å. and the value given by X-rays is not much less than this.

TABLE IV

VALUES OF THE CONSTANTS a_0 AND f_0 IN THE EQUATION OF STATE FOR EXPANDED FILMS OF MYRISTIC AND PENTADECYLIC ACIDS

Temp., °C.	Area range, sq. Å. per molecule	a_0, sq. Å. per mol.	f_0, dynes per cm.	Root-mean-square devn., dynes per cm.
		Myristic Acid		
12.5	28–50	12.6	12.4	0.46
14.9	30–50	12.4	12.3	.46
16.6	28–50	13.4	13.0	.30
21.7	28–50	14.3	12.7	.53
25.0	26–50	14.7	12.7	.61
		Pentadecylic Acid		
21.7	33–48	14.6	13.5	.21
25.0	31–48	12.0	12.4	.16

In section 4 and Figs. 2, 3, 4, and 5, it has been shown that with intermediate films the product fa increases with the time of compression. That is, in the compression of these films there is a process which takes time for its completion, and this process is in the direction of an expansion with time after any given compression. Thus this process does not seem to be a growth either in size or in number of micelles present in the film, since this would be expected to result in a contraction.

In considering the applicability of Equation (1) to expanded films in general it should be kept in mind that no experimental work as yet done subjects the equation to a critical test. This is due to the fact that although the pressure–area curves approximate rectangular hyperbolas, the approach to the asymptotes is so slow that any curves as yet observed cover only a small fraction of the range necessary to give any uniqueness to this special equation. Thus, with myristic acid at 25° the range covered is only from 30 to 50 sq. Å. and from 0 to 20 dynes per cm. Let it be supposed that the asymptotes lie at $f = -11$ dynes per cm., and $a_0 = 16$ sq. Å. Then in order to approach within 1 dyne and 1 sq. Å. of the asymptotes the respective area and pressure must be 400 dynes per cm. and 400 sq. Å., so the observations extend over only a small part of the curve. At other temperatures the conditions for such a test of the equation are not more favorable.

The extent of the hysteresis observed in the f–a relations of the intermediate state make it difficult to apply Langmuir's theory of this state without a more extensive study of the phenomena involved.

8. Summary

1. The effect of temperature upon the pressure (f) at constant molecular area (a) of monolayers of myristic and pentadecylic acid has been determined. The value of the slope $(\partial f/\partial T)_a$ has been found to be of the order of 0.8 to 1.2 for intermediate, and of 0.15 to 0.2 for expanded films.

2. Pressure–area isotherms for myristic acid have been determined at temperatures from 6.7 to 25°.

3. The compression of intermediate films is found to involve a process which takes time for its completion, and in which at constant temperature the pressure increases with time at constant area, or the area with time at constant pressure.

4. At constant temperature an intermediate film seems to undergo a gradual transition into a condensed liquid film by increase of pressure and the resulting decrease of molecular area. The condensed liquid film exhibits a linear pressure–area relation, and in the case of pentadecylic acid at 25° undergoes a sharp transition to a "plastic" solid film at 21.3 dynes per cm. and 20.52 sq. Å. For any long straight chain molecules the molecular area for the transition Liquid → Solid is very much more independent of the material of the film than the pressure.

Dependence of Conductance on Field Strength. I. Tetrabutylammonium Picrate in Diphenyl Ether at 50°

BY DARWIN J. MEAD WITH RAYMOND M. FUOSS

I. Introduction

In 1924, Wien[1] showed experimentally that the conductance of electrolytes under high field strengths was abnormal. He first ascribed the effect to a change of the temperature coefficient of conductance with field strength, but subsequent work in his Laboratory[2] showed that the abnormalities were due to an actual failure of Ohm's law for electrolytes.[3] He showed that two effects were present, one quadratic in the field and one linear. The first Wien effect appears in strong electrolytes when the distances the ions move during their relaxation time become of the order of the diameter of the ionic atmosphere Then the retarding effects on mobility of the atmosphere are diminished, with consequent increase of conductance. In weak electrolytes, the conductance is further increased by increased dissociation in the field. The second Wien effect has been treated theoretically by Onsager,[4] who showed that the slopes of the conductance–field curves could be predicted from the dielectric constant and temperature of the solvent and the valence type of the electrolyte.

Because the Wien effects are direct experimental evidence for the existence of the ionic atmosphere and for the pairwise association of ions under their mutual coulomb fields, and also on account of general interest in the behavior of dielectrics under high fields, it seemed worthwhile to study by bridge methods several carefully selected systems in some detail.

Diphenyl ether at 50° was chosen as our solvent on account of its ease of purification, low solvent conductance and high solvent power for substituted ammonium salts, which are convenient 1–1 electrolytes for work in non-aqueous solvents. Its dielectric constant at 50° and 60 cycles is 3.53, which is low enough to give marked ion association. In it, the conductance of tetrabutylammonium picrate satisfies the simple binary association law from below millionth normal up to concentrations of the order of 10^{-4} normal. Consequently the system permitted a test of the theory over a wide range of conductance and concentration. Above 10^{-4} normal, triple ion formation[5] becomes appreciable; in this range a dependence of the Wien coefficient on concentration was observed.

From the initial part of the conductance–field curves, the activity coefficient of the solute can be determined.[4] With our present methods, our precision in activity coefficient is not high, because it is determined as a small difference between two large quantities, one of which depends on an extrapolation, but we can show that our experimental coefficients are in approximate agreement with the values calculated by the limiting law of Debye and Hückel. The present results therefore demonstrate the existence of an ionic atmosphere in a solvent of quite low dielectric constant.

From the linear part of the curves, we find at low concentrations an increase in conductance of 1.6% per kilovolt, which is in good agreement with the theoretical value, 1.32%, calculated by Onsager's theory. Since this theory postulates pairwise association of ions, and explains the second Wien effect as a displacement of this equilibrium in the field, our results give experimental proof of the existence of ionic association.

Further work on different types of electrolytes and on solvents of lower dielectric constant, where still higher field strengths can be studied, is in progress. It will be interesting to see whether the shape (electrical and physical) and size of the ions influence the Wien coefficient and also to study the effect in the range of higher association than pairwise.

II. Materials, Apparatus and Method

Diphenyl ether was purified by recrystallization, after which it was dried first with calcium chloride, and finally with activated alumina. Our highest freezing point was 27.1°. The average solvent conductance was 0.3×10^{-12}; our best value was 0.06×10^{-12}.

Tetrabutylammonium picrate was prepared as described by Fuoss and Kraus,[6] m. p. 89.2–90.0° (corr.).

Conductance cells of several types were used. Some determinations were made in the cell described by Deitz and Fuoss,[7] and others in the cell described by Elliott and Fuoss.[8] The former cell showed a pronounced Parker effect at 1000 cycles and was only used for preliminary 60-cycle work. The second cell (cell no. 2) gave results independent of frequency (except for a normal polarization effect) and was used for about half of the work reported in this paper. For the final work, two platinum cells were used, which had two advantages over Elliott's cell: they could be cleaned with hot nitric acid or chrome–sulfuric acid between runs, and they had no movable parts. Cell no. 3 is shown in Fig. 1. The high potential electrode (8.25 cm. long, 2.540 cm. inside diameter, 0.5 mm. wall thickness) was simultaneously the outer cell wall. It and the guard-test combination (outside diameter 2.060 cm.) were sealed to a hollow ring of soft glass, to which were sealed filling tubes. The volume was 25 cc. A shielded lead ran to the test electrode; the shield was connected to the guard electrode, and the shielding was unbroken from cell to bridge. At final balance, the guard and test electrodes are at the same potential, so that except for an insignificant amount of fringing at the glass joint between the guard and test electrodes, the flux is normal over the entire test electrode. The latter condition is essential, because it was necessary to calculate field strength from cell geometry and the voltage applied to the cell. Cell 4 was similar to cell 3, except that the electrode spacing was 0.491 cm., or about twice that of cell 3.

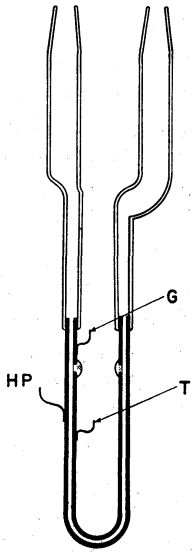

Fig. 1.—Guarded conductance cell.

Cell Comparison and Calculation of Field Strength.—In Fig. 2 are shown conductance–field curves, in which cells 2, 3 and 4 are compared. For convenience in drawing, the ratio of the specific conductance at field strength E to the low voltage conductance is plotted against field strength. Cell 2 had about twice the area and nearly the same spacing as cell 3 (cell constants 0.002727 and 0.004605, respectively), while cells 3 and 4 had about the same area, but quite different spacings (constants 0.004605 and 0.01064). The effect in question is a *linear* field effect; in this case, the average field strength E is given by

$$E = \int_{r_1}^{r_2} E(r)\mathrm{d}r/(r_2 - r_1) = V/(r_2 - r_1) \quad (1)$$

where V is the voltage applied to the high potential electrode. It will be seen that the agreement between the cells checks our calculation of field strength.

Voltage Sources and Scales.—Most of our voltage work was done at 60 cycles; examination with a cathode ray oscilloscope showed that the transformer output was free from harmonics. Some work was done at 500–1500 cycles; here graphical integration of the oscilloscope curves showed the presence of not more than 5% harmonics. The question of harmonics is important, because the second Wien effect is linear in cell voltage and all our voltmeters read mean square voltage. The linear average V was computed from the r. m. s. average V_r by the relations

$$V = (V_{max}/\pi)\int_0^{\pi} \sin x\, \mathrm{d}x = 2\, V_{max}/\pi \quad (2)$$

$$V_r = \left[(V_{max}^2/\pi)\int_0^{\pi} \sin^2 x\, \mathrm{d}x\right]^{1/2} = V_{max}/\sqrt{2} \quad (3)$$

whence

$$V = (2\sqrt{2}/\pi)\, V_r \quad (4)$$

A number of voltage scales were used in order to obtain cross checks. First, the output of the transformer to the cell and bridge network was fed simultaneously to a step-down transformer of known ratio under zero load (potential transformer), and the output voltage of the latter was used as a measure of the cell voltage. The ratio of the potential transformer was determined by

A. I. E. E. data relating sparking distance with voltage. Second, an electrostatic voltmeter, also calibrated by spark data, was used. Finally, the calibration of the electrostatic voltmeter was checked by direct determination of the current read on a milliammeter through a voltage insensitive resistor. The resistor was the 100,000 ohm wire wound standard used ordinarily as one arm of our resistance bridge.[9] The voltage calculated from the current and resistance by Ohm's law agreed with that read on the electrostatic voltmeter. The various voltage scales were self-consistent within 2%.

Bridges.—The conductance–field curves were determined using the resistance and Schering bridges which have been described previously.[9,10] Voltages up to 25 kv. were available at 60 cycles by means of transformers on the shop line. In the range 500–2000 cycles, an alternator was used to supply a tapped transformer, whose maximum output was 10 kv.

Low voltage determinations in the audiofrequency range were made on a parallel bridge. The Wagner ground and guard circuits were combined, so that three terminal cells could be used. Two arms of the bridge were reactance-free 10^5 ohm resistors; the other two arms were 10^5 ohm resistors with about 350 $\mu\mu f$ capacity in parallel with each. After obtaining zero-balance, the cell was connected parallel to one of the latter arms, and from the changes in resistance and capacity necessary to restore balance, the conductance and capacitance of the cell could be determined.

Procedure.—Solutions were made up by weight in a dilution flask and the density (1.0440 at 50°) of the solvent was used in calculating normality. (Our highest concentration was about 3×10^{-3} N.) In order to eliminate errors due to sorption effects[11] the cell was filled with successive portions of the same solution from the dilution flask, until the conductance of two consecutive fillings differed by less than 0.1%. Several dilution runs were made, covering the concentration range 10^{-6} to 3×10^{-3} N. For establishing the general conductance concentration curve, the low voltage parallel bridge was used. All electrical measurements were made with the cell in an oil-filled thermostat, maintained at 50 ± 0.02°.

At a series of concentrations, the dependence of conductance on field strength was determined. After the cell came to temperature equilibrium in the thermostat, the conductance at 60 cycles and low voltage was determined, low voltage being defined as a voltage so low that doubling it produced no visible change in bridge setting. Then the conductance was determined at a high voltage, and immediately thereafter again at low voltage. By bracketing the high voltage determinations by low, we were always certain that heating by measuring current was not a cause of the increased conductance. An input of one watt in the platinum cells was sufficient to show a drift in conductance of about 3% per minute. The bridge voltage was applied through a combination of relays and push buttons, and could be turned on or off very quickly; consequently we were able to get reliable readings even at voltages so high that they produced appreciable heating on prolonged exposure. An approximate balance was obtained at high voltage, and then the low voltage conductance was followed until it reached its previous steady state. Then the bridge was set to the approximate high voltage setting first obtained, high voltage was applied for a few seconds, and successive adjustments were made, until a setting was found such that the bridge was in balance when high voltage was flashed on and off. Immediately after this final reading, the low voltage conductance was again checked. A simpler technique was used when the temperature drift caused not more than 1% change in conductance per minute: high voltage was applied at a noted time and the bridge was balanced as quickly as possible. Then the sliding balance was followed and recorded at thirty-second intervals. Extrapolation to zero time gave the true high voltage conductance. For the more dilute solutions, of course, the resistance was so high that temperature drift due to heating by bridge current was negligible.

Polarization.—As anticipated, the apparent conductance varied with frequency. An example is shown in Fig. 3, where the conductance of a 4.22×10^{-4} N solution is plotted against reciprocal root of frequency. A straight line is obtained, which is the normal polarization curve found by Jones and Christian.[12] Several voltage runs were made at 500–1500 cycles. In this range of frequency, the conductance–field curves were less steep than at 60 cycles by about 20% in slope. Further work on the frequency dependence is planned; we expect a decrease of the Wien coefficient with increasing frequency, when the field reverses so rapidly that the ions do not travel far in one cycle, but this effect should not appear until quite high frequencies. The large difference between the slopes at 60 cycles and at 1000 cycles is more likely due to a dependence of polarization on field strength. The question must remain unanswered until more data are available.

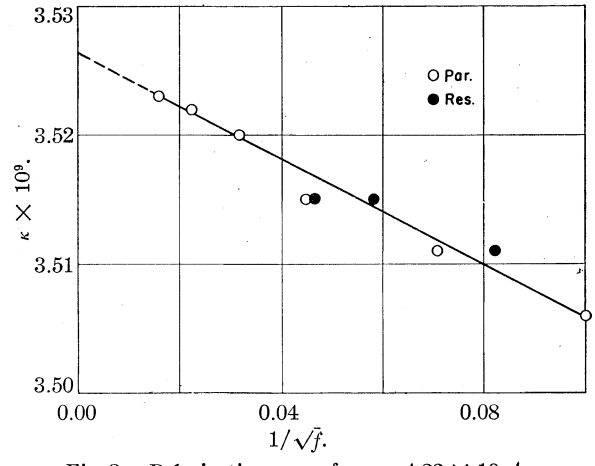

Fig. 3.—Polarization curve for $c = 4.22 \times 10^{-4}$.

Another interesting phenomenon was observed on di-

lute solutions placed in a clean cell, that is, on the initial filling before adsorption was saturated. If high voltage at 60 cycles was left on the cell for a short interval, and then the conductance followed at low voltage, a change with time was noted. For example, a millionth normal solution in the platinum cell was subjected to 25 kv. per centimeter for forty seconds. The conductance measured at low voltage was 15% *lower* than the initial value five minutes after the high voltage was removed; the difference decayed slowly with time, dropping to half value in about twenty minutes. The return behaved like a diffusion mechanism. An increase in cell resistance could not have been produced by heating; these solutions have positive temperature coefficients. Again more information is needed.

Viscosity.—In order to calculate ionic concentrations from conductances, it was necessary to know the limiting mobility. Since extrapolation was impossible, the viscosity of diphenyl ether at 50° was determined, and the limiting conductance calculated by Walden's rule. An Ostwald viscometer was used, whose specifications were as follows: length of capillary 10.0 cm., diameter of capillary 0.0968 cm., average head 20 cm., efflux volume 25 cc. The working volume was 50 cc. Dibenzyl ether (dried over sodium and distilled; b. p. 115–126° at about 1 mm.) was used as the calibrating liquid, and absolute values were based on the data of Bingham and Spooner.[13] At 50°, the viscosity of diphenyl ether was found to be 0.0209 poise.

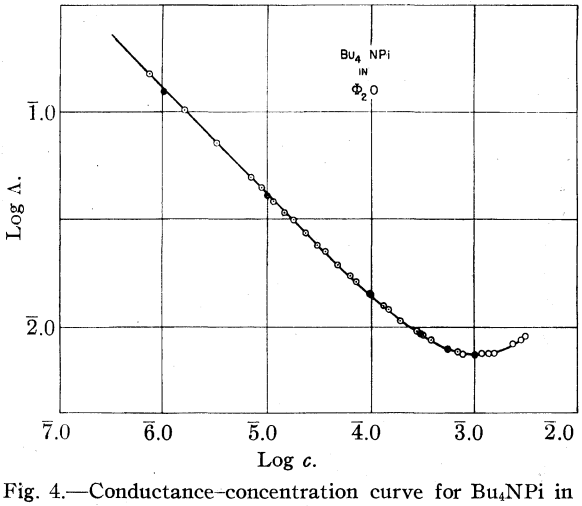

Fig. 4.—Conductance-concentration curve for Bu_4NPi in Ph_2O at 40°.

III. Experimental Results.—In Table I are given the low voltage conductances determined at 1000 cycles on the parallel bridge.

These results are summarized in Fig. 4, where the logarithm of the equivalent conductance is plotted against the logarithm of the concentration. The curve is the normal type expected for a 1–1 salt in a solvent of low dielectric constant.

Typical voltage runs are summarized in Table II. The field strength given is average kilovolts per centimeter, calculated from cell voltage and cell geometry by equations (1) and (4). All data in Table II are for 60-cycle fields; we hope to present data covering higher frequencies in a later paper, after the dependence of polarization on field strength has been studied.

IV. Discussion and Comparison with Theory

It will be noted in Fig. 4 that the log Λ–log c plot is linear, with slope $(-1/2)$ in the dilute region. This slope corresponds to a simple association of ions pairwise.[14] At about 10^{-3} normal, a minimum appears, due to the association of ion pairs with free ions.[5] In order to obtain the constants for the system, $\Lambda\sqrt{c}\ g(c)$ was plotted against c, as shown in Fig. 5. From the slope and intercept, we obtain $\Lambda_0\sqrt{K} = 1.274 \times 10^{-4}$ and $\lambda_0\sqrt{K}/k = 0.105$, where Λ_0 and λ_0 are the limiting conductances of the types $A^+\cdot B'$ and $A_2B^+\cdot AB_2'$, respectively, and K and k are the corresponding dissociation constants. In ethylene chloride ($\eta_{25} = 0.007853$), Mead[15] found $\Lambda_0 = 57.40$ for tetrabutylammonium picrate at 25°, giving $\Lambda_0\eta = 0.4508$. In tricresyl phosphate ($\eta_{40} = 0.295$), Elliott[8] found $\Lambda_0 = 1.95$, giving $\Lambda_0\eta = 0.575$. Diphenyl either is about intermediate in size between ethylene chloride and tricresyl phosphate, so we take the average of the above values of the $\Lambda_0\eta$ product in order to allow for the deviation from Walden's rule due to size and shape of solvent molecules.[8] Using $\eta\ (Ph_2O)_{50°} = 0.0209$, we find $\Lambda_0 = 24.5$ for tetrabutylammonium picrate in diphenyl ether at 50°. Combining this value with the analysis of Fig. 5, and using the value

$\lambda_0/\Lambda_0 = 0.82$ found by Bien[16] for the same electrolyte in anisole, we find $K = 2.70 \times 10^{-11}$ and $k = 1.00 \times 10^{-3}$.

From the values of the dissociation constants, we can calculate the corresponding ion sizes, assuming that the association is due entirely to Coulomb forces.[17] For the binary association of tetrabutylammonium ion and picrate ion, we find $a = 5.33 \times 10^{-8}$ cm. This is somewhat smaller than previous values for this salt (5.83×10^{-8} in ethylene chloride[15] at 25°, 5.80×10^{-8} in tricresyl phosphate[8] at 40°, and 5.60×10^{-8} in anisole[16] from −33 to 95.1°); there seems to be a trend of a values with D. For the triple ion equilibrium, we find $a_3 = 7.9 \times 10^{-8}$ cm., which checks Bien's value[16] in anisole at 61.3°. The fact that $a_3 > a$ for picrates has already been discussed.[16]

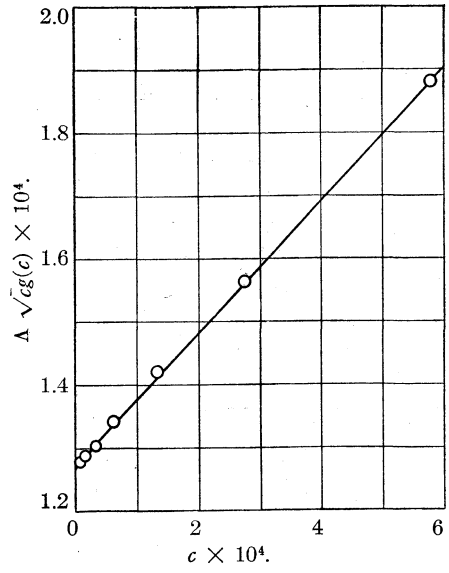

Fig. 5.—Evaluation of dissociation constants by graphical analysis.

We next consider the conductance–field curves. At low concentrations, where the free ion concentration is extremely small, the curve is substantially linear over the whole voltage range studied, as is shown in Fig. 6 for a millionth normal solution. As the concentration increases, the initial part of the conductance–field curve be-

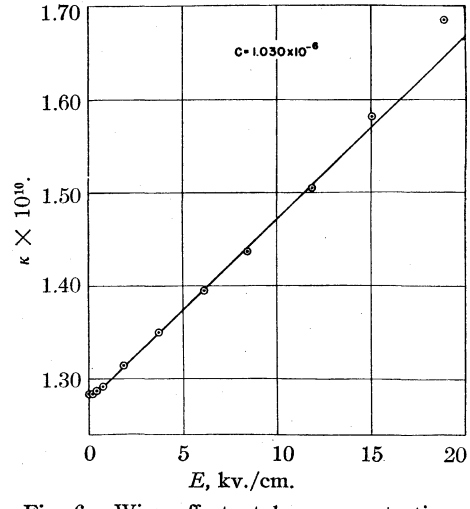

Fig. 6.—Wien effect at low concentration.

comes concave up, and eventually approaches linearity, as is shown in Fig. 7. The curved re-

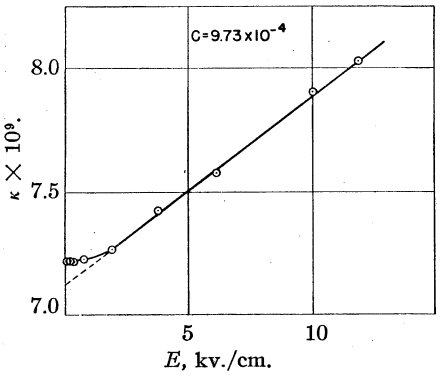

Fig. 7.—Wien effect at high concentration.

gion is due to the presence of an ionic atmosphere and once the ions move so fast in the field that this distribution can no longer be maintained, the curve becomes linear, as predicted by Onsager's theory.[4] Onsager's result, for the case of small degree of dissociation of 1–1 salts (in our case, $K = 2.70 \times 10^{-}$)[11] is

$$\kappa/\kappa_0 = 1 + (\epsilon^3/4Dk^2T^2)\overline{X} \qquad (5)$$

where κ is the conductance at field strength $\overline{X}$, κ_0 is the conductance at zero field strength and the other symbols have their usual meaning. For diphenyl ether at 50°, (5) becomes

$$\kappa/\kappa_0 = 1 + 0.0132\,E \qquad (6)$$

where E is the field strength in kilovolts per centimeter. The data of Table II (see also Figs. 2, 6, 7) all give linear portions at higher field strengths, after the initial concave-up section. The slopes are somewhat higher than predicted by (6), ranging from 1.3 to 1.6% per kilovolt, depending on the concentration. The dependence on concentration is systematic, and therefore, despite the rather large experimental error involved in determining a slope, we believe that it is real. The values of the slope are plotted against concentration in Fig. 8. Below 10^{-4} normal, the slopes are, within our present experimental error, equal to 1.6% per kilovolt, independent of concentration. It is interesting and perhaps significant that the dependence on concentration of the Wien coefficient begins at the concentration where triple ion formation causes the log Λ–log c plot to start to deviate from linearity. The present theory calls for concentration independence of the Wien coefficient. We plan to study systems in solvents of still lower

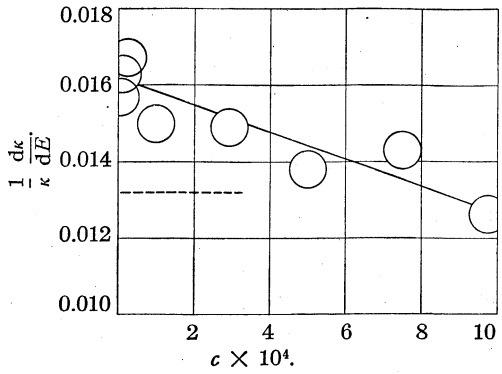

Fig. 8.—Dependence of Wien coefficient on concentration.

dielectric constant, so that the region of complex association can be studied. (It was impossible to work at higher concentrations in diphenyl ether, on account of heating.)

The difference in absolute value between our limiting experimental value of 1.6% at low concentrations and the theoretical value of 1.32% may be due to the dissymmetry of the picrate ion; the theoretical treatment implies a spherical ion. Work in progress on other salts will give information bearing on this question.

If the linear portions of the conductance–field curves are extrapolated to zero field strength, the low voltage conductance is obtained which the ions would have if the activity coefficient were unity.[4] Consequently the ratio of the actual conductance at low voltage to the extrapolated value measures the activity coefficient for the particular concentration involved. We have made the corresponding calculation for the data of Table II; the results are shown in Fig. 9. As abscissa, we used the square root of total *ionic* concentration, which was calculated from

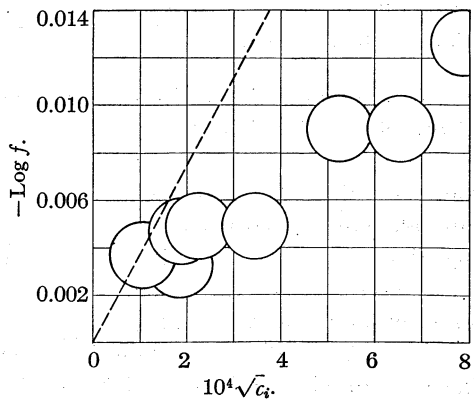

Fig. 9.—Activity coefficients determined by Wien effect.

the stoichiometric concentration and our experimental values of dissociation constants. The dotted line in Fig. 9 is the Debye–Hückel limiting slope, which is given by the following equation for 1–1 salts in diphenyl ether at 50°

$$-\log f = 33.8\sqrt{c_i} \qquad (7)$$

where c_i is total ionic concentration. Considering the large error in the experimental values of f, the results are not disappointing. The fact that we actually find a deviation of the right order of magnitude, which varies in the proper way with concentration, in a solvent of dielectric constant 3.53, is significant, if we recall that K is 2.7×10^{-11}. The highest ionic concentration in Fig. 9 is 6×10^{-7}.

Summary

1. The conductance of tetrabutylammonium picrate in diphenyl ether at 50° has been measured at 1000 cycles and low voltage and at 60 cycles under field strengths up to 15 KV/cm., over the approximate concentration range 10^{-3} to 10^{-6} normal.

2. Onsager's theory of the Wien effect is in good agreement with our data.

3. Deviations of activity coefficients from unity calculated by the limiting law of Debye and Hückel agree in order of magnitude with the experimental values obtained from the conductance curves.

The Reduction of Carbon Dioxide by Graphite and Coke

BY MARTIN A. MAYERS

The rates of reaction of monolithic samples of artificial graphite with carbon dioxide and steam at atmospheric pressure and temperatures from 850° have been reported previously.[1] In that work the limiting effect of the diffusion field adjacent to the surface of the sample was eliminated and the measured reaction rates were considered to be true heterogeneous reaction rates and were referred to unit area of the surface exposed to the action of the gas. Later measurements of the reaction with carbon dioxide of artificial graphite and coke in granular form and of monoliths of both artificial and natural graphite have shown that in artificial graphite and in coke, the reaction rate measured depends not only on the surface exposed, but is the total of the contributions of elementary surfaces reached by the oxidizing gas by its perfusion throughout the body of these porous materials. This result suggests a possible explanation of part of the discrepancy between the measurements by this method and those made under high vacuum.[2]

Apparatus and Materials.—Carbon dioxide was withdrawn from a cylinder through a reducing valve, passed through a flowmeter and a purifying train consisting of a heated quartz tube containing reduced copper and copper oxide and a drying tower containing calcium chloride followed by Anhydrone, and then into the furnace. Leaving the furnace the gas stream flowed through a cooling section, and then by way of a three-way stopcock, either direct to the analyzer, or into the large gasometer used in the tests reported before. The gas analyzer was the same one previously described, in which the carbon monoxide is oxidized by iodine pentoxide and its quantity determined by the titration of the iodine liberated which was collected in a condenser cooled by dry ice.

The furnace and sample holder differ from those used in the previous work and are shown in Fig. 1. The smaller diameter of the furnace tube permitted the attainment of high gas velocities without using extremely large volumes of gas. The mullite boat, used as a sample holder, permitted the use of either granular or monolithic samples of carbon. It was streamlined as shown in order to eliminate, as completely as possible, disturbances of the flow across the reacting surface.

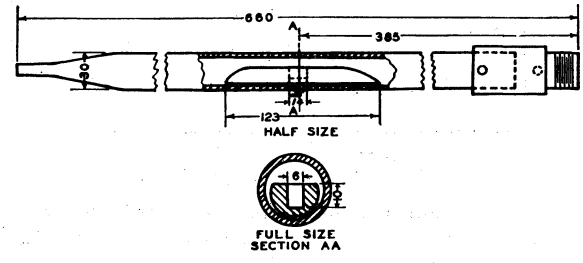

Fig. 1.—Reaction tube and sample boat. All dimensions in millimeters.

Granular samples were prepared for test by crushing coke in a small jaw crusher and by turning off heavy chips of graphite from cylindrical electrodes, and sieving the granular material between standard metal cloth sieves.

The graphite electrodes were of Acheson graphite of spectroscopic grade, and were from the same lot as that used in the work reported previously. The cokes were experimental cokes made from a Pittsburgh Seam coal with controlled rates of heating to 1000°.[3] Table I gives the details of the treatment of the various cokes tested. The boats were filled to the desired depth, shaken down, and uniformly compacted by pressing down the charge with a brass gage block of known dimensions which fitted the depression in the boat. The depth of the sample below the top surface of the boat was then determined by measuring the height of the top of the gage block above the top of the boat by the use of a vernier depth gage reading to 0.02 mm.

TABLE I

LABORATORY COKES MADE FROM PITTSBURGH SEAM COAL (EDENBORN MINE)

Designation	Maximum temp., °C.	Rate of heating, °C./min.
W 85	1000	1.4
W 88	1000	1.4
W 92	1000	21.8
W 93	1000	21.8

Monolithic samples of different thicknesses were cut out of portions of artificial graphite electrode, and from a single mass of foliated Ceylon graphite, to fit the depression in the boat. They were cut out with a sharp knife and finished with a steel file, and then were cemented into the boats so that their top surfaces were not more than 0.5 mm. above the top of the boat. A commercial cement with a sodium silicate base (Insa-lute) was used to seal the samples into the boat. Great care was taken to prevent the cement from coming in contact with the top surface of the sample, and the cement was carefully finished off, after partial drying, to give a smooth contour rising from the boat surface to the surface of the sample.

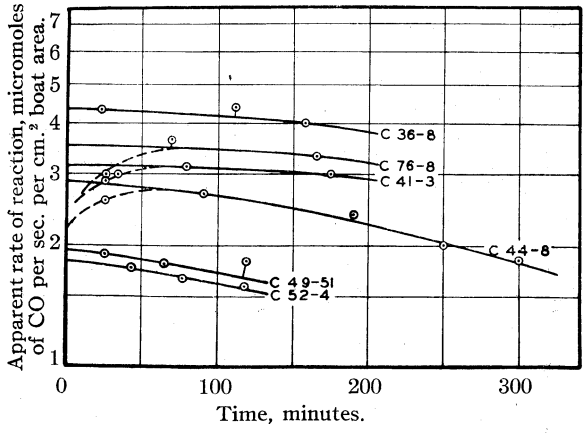

Fig. 2.—Reaction in micromoles of carbon monoxide per second per sq. cm. at various times for several samples of granular graphite.

Procedure and Calculations.—When a boat had been filled as described above, it was introduced into the furnace, and advanced in about fifteen minutes to the center. During this time the furnace was maintained at the temperature at which runs were to be made, and carbon dioxide was passed through the furnace but was not collected. The slow advance of the boat was necessary to prevent breakage of the boat or the mullite furnace tube by thermal shock. Immediately after introducing the boat, and at thirty-five to forty-five-minute intervals thereafter, runs were made in which the gas leaving the furnace was collected and analyzed, the duration of each run being two to three minutes. During the runs, the temperature, the rate of gas flow, and the gas pressure at the inlet and outlet of the furnace were read every minute. Three to six runs were made on each sample.

The rates of reaction measured in several groups of runs at 1000° are plotted in Fig. 2 against the time after the boat was inserted in the furnace. It will be observed that the reaction rates rise to a maximum and then fall off. Since the quantity and approximate condition of the graphite are known only at the time the sample was inserted into the furnace, it is necessary to refer the reaction rate to that time. In performing this extrapolation, the rapidly rising initial portion of the curve is neglected. This is believed to be justified on the ground that this portion of the curve represents a transient condition, while the normal concentration gradients through the body of the sample are being set up. Such an assumption is supported by the fact that this portion of the curve was less pronounced in the measurements on granular samples, when the normal gradient might be expected to be attained more rapidly, than it was in measurements on monolithic samples. The differences in the intercepts at zero time in Fig. 2 are due to differences in the thicknesses of the samples tested, the thickest sample producing the largest reaction.

Theoretical.—In order to interpret these results it is necessary to analyze the conditions under which the reaction takes place. Let the concentration of carbon dioxide in the porous bed be p_1 and that of carbon monoxide be p_2. Since the reaction takes place under a constant total pressure, and these are the only gases present

$$p_1 + p_2 = P \qquad (1)$$

where P is the constant total pressure, atmospheric. Then, if D is the diffusion coefficient, a the void volume in the bed, v the gas velocity in the bed caused by the expansion due to the reaction, μ the reaction rate per unit of carbon crystallite surface, and s the surface of carbon crystallites per unit volume of bed, and if a steady state is reached, p_1 and p_2 must obey the differential equations

(3) Wm. B. Warren, *Ind. Eng. Chem.*, **27**, 72–77 (1935).

$$aD\frac{d^2p_1}{dx^2} + a\frac{d}{dx}(p_1v) - \mu s p_1 = 0$$
$$aD\frac{d^2p_2}{dx^2} + a\frac{d}{dx}(p_2v) + 2\mu s p_1 = 0 \qquad (2)$$

with the boundary conditions

$$dp_1/dx = dp_2/dx = 0 \qquad x = c;$$
$$v = 0, x = c; \text{ and } p_1 = P_1, x = l \qquad (3)$$

where x is the distance below the top of the boat, l is the level of top of the sample, and c is the level of its bottom. Combining (1) and (2), it is found that v satisfies

$$\frac{dv}{dx} = -\frac{\mu s}{a}\frac{p_1}{P} \qquad (4)$$

Eliminating p_1 between (4) and the first of (2), the non-linear equation

$$\frac{d^2v}{dx^2} + \frac{1}{D}v\frac{dv}{dx} - \frac{\mu s}{aD}v = 0 \qquad (5)$$

is obtained, whose solution, by the use of (4), could be used to calculate the total reaction per unit of sample surface by means of the integral

$$R = \int_c^l 2\mu s p_1 dx = 2aPv(l)$$

A general solution to equation (5) has not been found, but a series expansion can be set up[4] for small values of $\mu s/aD(c-l)^2$ in the form

$$R \sim 2\mu s(c-l)\left\{1 - \frac{2}{3}\frac{\mu s}{aD}(c-l)^2 + \frac{2}{3}\left[\frac{\mu s}{aD}(c-l)^2\right]^2 - \ldots\right\} \qquad (6)$$

which, however, converges very slowly. If the coefficient of p_1 in the second of equations (2) were μs instead of $2\mu s$, v would vanish and a simple analytic solution is possible in the form

$$R = 2\sqrt{\mu s aD}\tanh\sqrt{\frac{\mu s}{aD}}(c-l) \sim 2\mu s(c-l)\left\{1 - \frac{1}{3}\frac{\mu s}{aD}(c-l)^2 + \ldots\right\} \qquad (7)$$

Hence, it seems probable that the effect of the non-linearity of equation (5) is merely to change the rate of convergence of R in the neighborhood of $(c-l) = 0$; the similarity between (6) and (7) suggests that near $(c-l) = 0$ there will be a linear relation between $R/(c-l)$ and $(c-l)^2$, and that the value of $2\mu s$, the true rate of formation of carbon monoxide per unit volume of sample, will be given by the intercept of the line at $(c-l)^2 = 0$.

Results

The tests on granular samples of artificial graphite were made on beds of such thickness that this method of plotting gave straight lines, as shown in Fig. 3, in which the reaction rates per unit area at zero time determined from the curves of Fig. 2, divided by the sample thickness, are plotted against the square of the sample thickness. The fact that the experimental results appear to fit straight lines on this plot indicates that the analysis given above may apply to the experimental condition, while the departures from the lines at values of $(c-l)^2$ greater than about 0.4 show that the higher order terms begin to be of influence above the corresponding value of $\mu s/aD(c-l)^2$. The intercepts of these lines, representing the rate of formation of carbon monoxide at 1 atmosphere pressure per unit volume of the bed of granules, can then be plotted as the triangles in Fig. 5, to the coördinates of the Arrhenius equation, showing that the reaction rate has a temperature coefficient corresponding to the heat of activation of 52.3 kcal. The departure of the points from the line corresponds to a probable error of a single determination of about 17%.

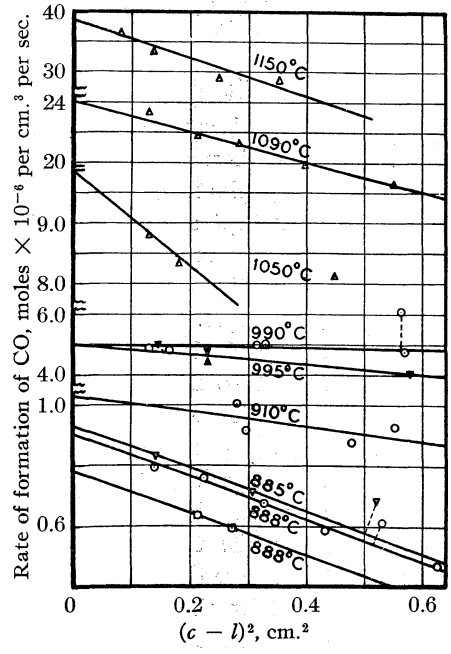

Fig. 3.—Determination of reaction rate per unit volume for granular graphite passing no. 16 and on no. 20 U. S. std. mesh sieves: △, gas velocity 1.9 l./min.; ○, gas velocity 2.5 l./min.; ▽, gas velocity 3.4 l./min.

When the data for monolithic samples are plotted as in Fig. 4 it is observed that the points do not fall on a straight line, but appear to approach

(4) H. G. Landau, to be published.

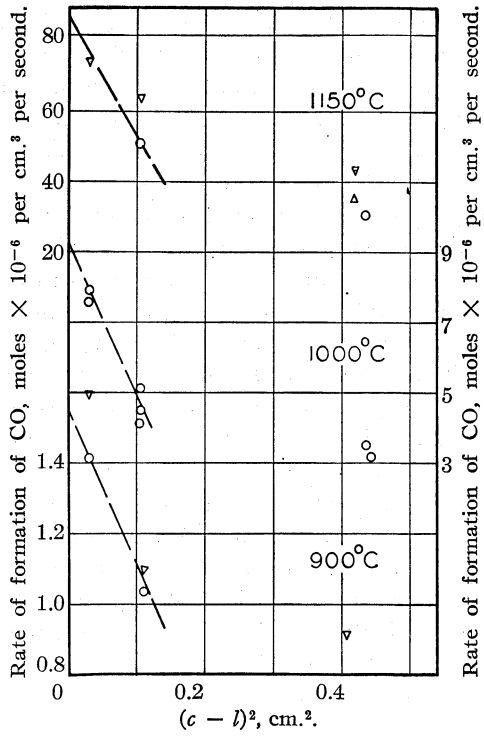

Fig. 4.—Determination of reaction rate per unit volume for monolithic graphite.

a hyperbolic form. This might be taken to indicate that the monolithic samples have a true surface reaction with carbon dioxide, whose value might be obtained by plotting R against $(c - l)$ and reading the intercept at zero thickness. It must be observed, however, that the quantity $\mu s/aD(c - l)^2$ is a function of the porosity, or the void volume of the sample. Comparing samples of the same material packed to different densities, it will be observed that $\mu s/aD$ varies as $(1 - a)/a$. Since the volume of voids of the monolithic samples, determined by comparing their true density determined with helium[5] as the displacing fluid with their apparent densities as shown in Table II, is about 29%, while that for the granular samples may be expected to be about 50%, the value of $\mu s/aD$ for the monolithic sample would be nearly three times that for the granular sample at the same temperature. Since the results for the granular samples departed from the straight line at values of $(c - l)^2$ of about 0.4, those for the monolithic samples may be expected to do so at about 0.13. Because of the difficulty of cutting out thin samples of graphite, there are only two points at each temperature at values of $(c - l)^2$ less than 0.13, but passing straight lines through these points permits making an estimate of the value of $2\mu s$ for the monolithic samples. These values have been plotted on Fig. 5 as circles. The line passing through them corresponds to a heat of activation of about 50.6 kcal. The difference between the heats of activation of the reaction on monolithic and on granular samples indicates the order of the precision of the determination of this quantity, or about ±1.7 kcal. The ratio between the rates of reaction in the two kinds of samples, which is almost constant at a value of 1.58, indicates that the volume of voids in the granular sample is about 55%, corresponding to particles packed to a density of 64%.

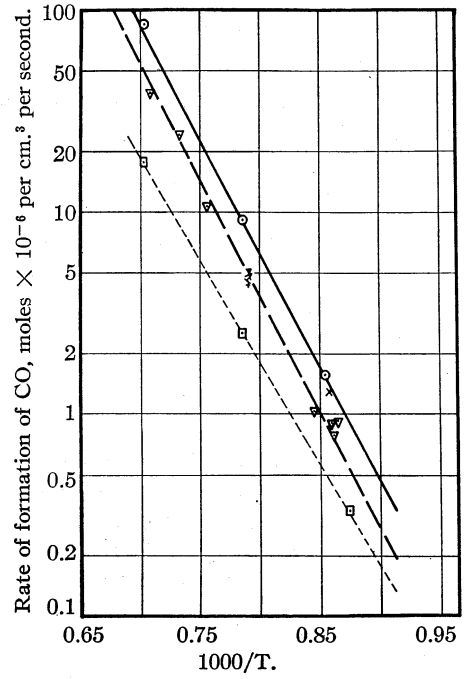

Fig. 5.—Reaction rates per unit volume at various temperatures: ○, monolithic samples of artificial graphite; ▽, artificial graphite −16 +20 mesh; □, natural graphite—read scale in moles × 10^{-6} per sq. cm. per sec. Laboratory cokes: ×, W 85; +, W 88; ⊙, W 92; ø, W 93.

The data on cokes were analyzed by the same methods as described above, and the results are shown by various symbols in Fig. 5. Measurements on natural graphite were made on samples of different orientations with respect to the grain of the sample. The results of these measurements were very erratic, being greatly affected by the quantity of ash exposed, the ash being distributed

(5) H. C. Howard and G. A. Hulett, *J. Phys. Chem.*, **28**, 1082 (1924).

irregularly through the foliated mass from which samples were cut. The results on this material were so erratic as to obscure any differences of reaction rate with orientation of the face or with thickness of the sample that may have been present. The order of magnitude of the reaction rate with this material was, however, the same as that of the monolithic samples, considered as a reaction rate per unit area. These values are also shown in Fig. 5.

Discussion

While the precision of the results is not high, it is great enough to make it certain that the results obtained in this work differ from those previously reported on the same material. The hypothesis that the monoliths of artificial graphite were actually porous, required to correlate the results, was checked by comparing the true density determined by displacement with helium with the apparent density of several samples as shown in Table II. It may be noted that the results of these experiments agree with those previously reported if the correction for volume reaction is not made. Thus it must be concluded that the earlier work is in error because of failure to take account of the perfusion process.

TABLE II

TRUE DENSITIES OF VARIOUS GRAPHITES

Sample, Acheson graphite	True density in g./cc.
Monolith	2.07
Monolith, heat treated at about 2200°	2.08
−16 +20 mesh	2.08
−140 mesh	2.11

APPARENT DENSITIES OF VARIOUS MONOLITHIC SAMPLES OF ACHESON GRAPHITE

Sample	Apparent density in g./cc.
25	1.47
26	1.50
27	1.48
Apparent volume of voids	29%

This result suggests the explanation for some of the discrepancies that exist in the literature concerning this reaction. The present value of the temperature coefficient for the reaction of carbon dioxide with artificial graphite is in approximate agreement with the value that may be calculated from the work of Blakeley and Cobb.[6] It also suggests an explanation of the peculiar temperature coefficient of the reaction rate of artificial graphite with oxygen calculated by Davis and Hottel[7] from their experiments on the burning of carbons in oxygen under conditions in which the diffusion path was fixed and known. From this work both the diffusion coefficient and the specific reaction rate could, theoretically, be calculated, if the reaction took place on a geometrical surface at the end of the diffusion path. However, the reaction rates calculated on this assumption had abnormal temperature coefficients that did not follow the Arrhenius equation, and the reaction rates for different forms of carbon crossed in a peculiar fashion. Davis and Hottel were unable to give an explanation for this behavior; it is suggested, in the light of the results reported here, that the reason for the apparently abnormal behavior may be sought in the perfusion phenomena accompanying the reaction, since the samples used in that work also were porous. The differences in the behavior of the two kinds of carbon for which data are reported probably arise from their having both different porosities and different reactivities, which easily could lead to the change in order of apparent reaction rate that was observed with changes in temperature.

Finally, this work suggests the possibility of partly reconciling the discrepancies observed between determinations of the reaction rates at normal pressures, and those determined in high vacuum.[2] The reaction rates observed at normal pressures, when referred to unit area of the carbon used, are of the order of thousands of times as great as those determined under vacuum. Since, however, the samples tested in the vacuum work[8] had uniform solid surfaces of deposited graphite whose basal planes were parallel to the geometrical surface, the discrepancy must arise in part from the porous nature of the carbons used in the experiments at normal pressures, in almost all of which a large internal surface, which easily could be a thousand times the exposed geometrical surface, was available for reaction. This hypothesis fails to explain, however the large difference in temperature coefficient, which in the vacuum experiments[2] corresponds to a heat of activation of the order of 90 kcal. This extraordinarily high value may be due to the fact that, in the vacuum experiments, only the graphite filament was heated, while the gas was cold.

Conclusions

Measurements of the rates of reaction of carbon dioxide with both artificial and natural graphite and with several high temperature cokes of known history have been reported. The results have been calculated to give the reaction rates per unit volume of coke or graphite and have been corrected for the perfusion of the reacting gas throughout the body of the porous samples. Because of this manipulation, the results are not particularly precise, errors of the order of 20% being possible.

It is shown that artificial graphites and cokes behave, in reaction, like porous bodies whose internal surface contributes to the reaction rate. The reaction of carbon dioxide with artificial graphite has a temperature coefficient corresponding to a heat of activation of about 52 kcal. That of the reaction with natural graphite is more uncertain because of the marked effect of the mineral impurities which the sample contained, but it appears to be of the order of 44 kcal.

The Colorimetric Determination of Palladium with *p*-Nitrosodiphenylamine[1]

BY JOHN H. YOE AND LYLE G. OVERHOLSER

The colorimetric methods available for the determination of palladium have been developed in connection with platinum analysis,[2,3] and while they do provide rapid and accurate methods for the determination of quantities of palladium of the order of 0.1 mg., no colorimetric method has been reported that will yield reasonably accurate results with quantities of the order of a few γ. Studies have been made on reagents for the detection and approximate estimation of minute quantities of palladium. *p*-Dimethylaminobenzylidene rhodanine[4] has been used for the detection of palladium, but no application of this reagent for the quantitative determination of the metal has been reported. This reagent is extremely sensitive for palladium but not so nearly specific as *p*-nitrosodiphenylamine. Feigl and Fränkel[5] report that as little as 0.0025 γ of palladium per ml. (1:400,000,000 can be detected by the catalytic effect of palladium on the reduction of nickel salts by sodium hypophosphite. Pierson[6] utilized the reducing action of mercurous chloride for the detection and approximate estimation of minute quantities of the metal by observing the shades of color produced by the adsorbed metal. But there is need of a method that may be used for the determination of minute quantities of palladium and that is not rendered useless by the presence of the other metals frequently accompanying palladium.

p-Nitrosodiphenylamine has been found to react with palladous chloride in neutral and weakly acid solution to give either a deep red colored solution or a purplish-brown precipitate, depending on the concentration of the metal. The reaction is extremely sensitive, permitting the detection of 0.005 γ of palladium by the spot-plate technique, and compares favorably with *p*-dimethylaminobenzylidene rhodanine. The reagent is practically specific for palladium, in the sense that the only other metals forming colored compounds are gold and silver. The sensitivity for gold and silver, however, is much less than for palladium. Oxidizing agents interfere by giving colored solutions; cyanides and iodides prevent the formation of the colored compound. The sensitivity is affected by the *p*H of the solution and the concentration of salts present, but these can be controlled easily.

If the reagent is added in excess to a weakly acidic palladous chloride solution, the palladium is quantitatively precipitated. On the other hand, if a sodium acetate–hydrochloric acid buffer of the proper *p*H and salt concentration is used, a deep red colored solution results which may

(1) This investigation was partly supported by a grant-in-aid from the Carnegie Corporation. It is the first of a projected series based upon studies of inorganic reagents in organic analysis. These studies are being conducted as a coöperative effort in which eight Virginia institutions are participating under the direction of John H. Yoe. Those coöperating with the University of Virginia are: Hampden-Sydney, Mary Baldwin, Randolph-Macon (Ashland), Virginia Military Institute, Virginia Polytechnic Institute, Washington and Lee, and William and Mary.

be satisfactorily used for the colorimetric determination of palladium in the range 0.5–50 γ.

This paper presents various aspects of the new reaction, details for the colorimetric method, and procedures for the determination of palladium when accompanied with gold and platinum.

Materials Used

Palladium Chloride.—A stock solution was prepared by dissolving a 1.74-g. sample of palladous chloride (57.5% of palladium) in 85 ml. of hydrochloric acid and diluting to 1 liter with water. This gave a solution 1 *M* with respect to hydrochloric acid and contained 1.003 mg. of palladium per ml. as determined by analysis with dimethylglyoxime. Solutions containing 1 and 10 p. p. m. of palladium, respectively, were prepared by diluting the stock solution with water.

Acids.—Unless otherwise indicated, all acids used in this study were concentrated C. P. reagents.

***p*-Nitrosodiphenylamine.**—The product used was obtained from the Eastman Kodak Company and had a m. p. of 143–144°. A solution of the reagent was prepared by dissolving 50 mg. of the solid in 500 ml. of 95% ethyl alcohol and diluting to 1 liter with water. This solution had a yellowish-orange color and was stable for several months.

Sodium Acetate–Hydrochloric Acid Buffer.—This buffer solution was prepared by adding 240 ml. of 1 *M* hydrochloric acid to 200 ml. of 1 *M* sodium acetate and diluting the mixture to 1 liter with water. The *p*H of the solution, as measured by the quinhydrone electrode, was 1.6. Upon diluting 25 ml. of this buffer to 100 ml. with water a *p*H value of 2.1 was obtained.

Procedure Recommended for the Determination of Small Quantities of Palladium.—The method may be applied successfully to the determination of quantities of palladium not exceeding 50 γ, although it is preferable that the amount present be less than 30 γ. Palladium may be determined in such materials as crude platinum and the various alloys, provided interfering substances are first removed. Directions are given in another section for the separation from platinum and gold, since these metals frequently accompany palladium. Palladium may be determined in the presence of iridium and rhodium, provided the ratio of iridium to palladium and that of rhodium to palladium does not exceed 20 to 1.

Several precautions must be observed in order to obtain reliable results. The palladium should be present as palladous chloride in a solution containing not more than 0.5 mmol. of hydrochloric acid or a total salt concentration of not over 3 mmol. The reagent should be added to all solutions (unknowns and standards) at as nearly the same time as possible (within fifteen minutes), and all the solutions should be at room temperature when the reagent is added. Finally, the matching should be completed within one hour after the addition of the reagent.

Procedure.—Prepare the standard series by using the following increments of palladium in the respective concentration ranges: 0–10 γ, 0.5 γ; 11–25 γ, 1 γ; 26–35 γ, 2 γ; 36–50 γ, 5 γ. Transfer the solutions containing the palladous chloride (standards and unknowns) to 100 ml. volumetric flasks, add 25 ml. of the sodium acetate–hydrochloric acid buffer from a pipet, 2 ml. of reagent from a pipet, and dilute to 100 ml. with water. Before matching the solutions, thoroughly mix and allow them to stand at room temperature for about thirty minutes.

Color matching in our work was done with a roulette comparator[7] using 100-ml. tubes (160 mm.). At the lower palladium concentrations, Corning Filter no. 512 was used advantageously, while filters nos. 585 and 556 were employed at the higher concentrations. In some cases the matching was also carried out in 50-ml. Nessler tubes (220 mm.). The latter method is as sensitive at the lower concentrations but less so at the higher ones, because filters are not applicable. Since the observed color is a mixture of the yellow color of the reagent and that of the red palladium compound, the Duboscq colorimeter is of little use due to the change in the shade of color obtained with different amounts of palladium. The photoelectric colorimeter may be used but no increase in the actual sensitivity is obtained because of the influence of several uncontrollable factors.

Experimental Development of the Procedure

Reaction of *p*-Nitrosodiphenylamine with Palladous Chloride.—The greatest difficulty encountered during the development of the method was the formation of turbid solutions. In unbuffered as well as with biphthalate buffers, turbid solutions always resulted. The sodium acetate–hydrochloric acid buffers were unique because they gave clear red solutions, when buffers having a relatively high salt concentration and a low *p*H were used. If more than 2 ml. of the reagent was used, however, turbid solutions were obtained, even in the presence of the prescribed buffer medium.

A sample of the solid compound was obtained in the following manner: 50 ml. of a solution of palladous chloride containing 50 mg. of palladium was diluted to 500 ml. with water. To this solution was added 50 ml. of a filtered alcoholic solution containing 100 mg. of *p*-nitrosodiphenylamine. The precipitate was filtered off, dried for twelve hours at 110° and analyzed. *Anal.* Calcd. for $C_{24}H_{20}N_4O_2PdCl_2$: C, 50.21; H, 3.51; Pd, 18.59; Cl, 12.35. Found: C, 50.15; H, 3.85; Pd, 18.52; Cl, 12.21.[8]

The composition corresponds to the formula $Pd[C_6H_5NHC_6H_4NO]_2Cl_2$, which is a coördination compound analogous to the other numerous ammino compounds of palladium, exemplified by $Pd(NH_3)_2Cl_2$. Palladous nitrate also reacts with the reagent to give a compound having a similar color which is probably an analogous coördination compound.

The sample analyzed was precipitated from a solution containing an excess of palladium, because the precipitate so obtained was handled more easily than that obtained by using an excess of the reagent. Samples were also prepared by using an excess of reagent, as well as by precipitating the palladium from a sodium acetate–hydrochloric acid buffer under the same conditions used in the colorimetric procedure. In these samples, only palladium was

(7) J. H. Yoe and T. B. Crumpler, *Ind. Eng. Chem., Anal. Ed.*, **7**, 78 (1935).

(8) The authors are indebted to Miss Elizabeth C. Johnson of this Laboratory for the halogen determination.

determined but the values obtained checked that of the compound reported above, leaving no doubt that the samples prepared in the different ways all had the same composition.

The compound appears as a purplish-brown amorphous precipitate which adheres tenaciously to glassware and is very difficult to filter. It loses water slowly when dried at 110°, but if heated above 120° it undergoes a very gradual decomposition. The compound is insoluble in water but moderately soluble in 95% ethyl alcohol, yielding a deep red colored solution. It dissolves in moderately strong hydrochloric, nitric, or sulfuric acid, giving solutions ranging in color from red to yellow. With ammonia and sodium hydroxide, yellow solutions are formed.

Although the composition of the precipitate is satisfactorily constant and has the advantage of a low palladium content, the difficulties encountered in filtering and drying prevent it from having a practical value in gravimetric analysis, especially since other more suitable organic precipitants are available.

The relative absorption curves for solutions of the reagent and of the palladium compound are given in Fig. 1.

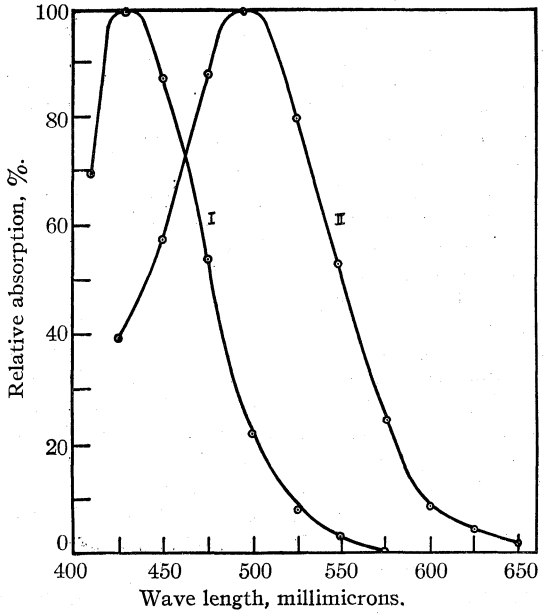

Fig. 1.

The data for the curves were obtained with a photoelectric spectrophotometer.[9] Curve I, the reagent curve, was obtained for a solution prepared by adding 10 ml. of the reagent to 25 ml. of standard buffer solution and diluting to 100 ml. with water (*p*H 2.1). Curve II, the compound curve, was obtained for a solution containing 70 γ of palladium prepared in the same manner as for the colorimetric determination. It will be observed that the maximum for the reagent and that for the compound occur near each other. Consequently, it is difficult to eliminate, by the use of a color filter, the absorption by the reagent.

Effect of Concentration of Salts.—The presence of small amounts of salts, such as sodium chloride, have a marked effect on the reaction when carried out in solutions of low ionic strength. For example, using 5 γ of palladium and a final concentration of hydrochloric acid of 10^{-4} or 10^{-5} *M* it was found that as small a concentration of sodium chloride as 10^{-4} *M* caused a slight decrease in the intensity of the color. With larger amounts of sodium chloride, a corresponding decrease in the red color was observed and with a concentration as great as 1 *M* practically none of the red colored compound formed. Other sodium salts such as the nitrate and sulfate, as well as the corresponding potassium and ammonium salts, exhibit a similar behavior.

Under the conditions recommended, *i. e.*, the use of a buffer with a final salt concentration of 0.05 *M*, the maximum color or sensitivity is not obtainable because of the salt effect. It is necessary to use the buffer to prevent turbidity, and to minimize the effect of additional salts, as well as to control the *p*H. In the buffer system used, the presence of additional salts in amounts to give a final concentration of 0.01 *M* is without effect and the maximum concentration allowable without error is 0.03 *M*.

Effect of Hydrogen-Ion Concentration.—The intensity of the color of the reagent and that of the palladium compound depends upon the *p*H of the solution. The reagent exhibits a yellowish-orange color of maximum intensity at a *p*H of 5 to 6. Above or below these values the intensity of the color decreases, attaining a pale yellow in strongly acidic and basic solutions. The intensity undergoes a pronounced change in the *p*H region in which the determinations are carried out, a change of 0.2 of a *p*H unit giving a difference in color just detectable.

The formation of the colored palladium compound does not occur in strongly acidic or basic solutions. In sodium acetate buffers having a salt concentration of 0.05 *M*, the intensity of the red color increases from a *p*H of 1.7 to 3, where it attains a maximum and then decreases. The change is more pronounced from a *p*H of 1.7 to 3 than from 3 to 5. The maximum sensitivity appears to be at a *p*H of 3, but as the ionic strength of the buffers differed, part of the effect attributed to *p*H may be due to the salt effect. Using 20 γ of palladium, it was found that turbid solutions resulted in all cases where the *p*H was greater than 2.1. Thus the method is limited to a narrow *p*H range, as well as being confined to the sodium acetate–hydrochloric acid buffers. The *p*H of 2.1 was selected for the method as it affords the maximum sensitivity without producing turbid solutions. The solutions are reasonably well buffered. The equivalent of 0.5 ml. of 1 *M* hydrochloric acid may be present without causing any visible change in color intensity and 0.75 ml., which is the maximum allowable, causes no serious error. The latter amount of acid produces a *p*H change of 0.2 unit as measured by the quinhydrone electrode. The presence of equivalent amounts of nitric acid produces a similar effect.

Formation and Stability of Color.—The effect of salts and of the hydrogen-ion concentration on the extent of the development of the color has just been considered. An increase in the amount of salts present or a decrease in the *p*H of the solution causes an increase in the time required for development of the maximum color. Usually, under the conditions giving maximum sensitivity, the development of the color is nearly instantaneous but turbid solutions result. In the colorimetric procedure which

(9) Description of this instrument to be published soon by Barton and Yoe.

yields clear solutions, the development is slow, about thirty minutes being required for the attainment of maximum intensity.

With an increase of temperature, the rate of development increases markedly, but above 50 or 60° the color fades completely. Temperature changes seem to affect only the rate of development and not the final maximum intensity. Although a temperature difference of 5° is noticeable, no special precautions are required other than that the solution be at room temperature when the reagent is added.

All solutions of the colored compound tend to give a precipitate upon aging. Under the conditions used in the method, the clear solutions are reasonably stable for several hours, but upon longer standing they fade and give a precipitate. Because of this limited stability, it is necessary that the reagent be added to all solutions at as nearly the same time as is possible and that the matching be completed within one hour after the addition of the reagent. These conditions are especially important with quantities of palladium exceeding 10 γ.

The colors obtained are satisfactorily reproducible and the order of addition, *i. e.*, reagent to palladium and buffer or palladium to reagent and buffer, has no effect.

Interference of Other Elements.—No reaction between the reagent and any of the following ions was observed. The tests were made on a spot-plate by adding a drop of the reagent to a drop of the solution containing the respective ions (approx. 0.05 mg.). Ions tested: Al^{+3}, As^{+3}, AsO_4^{-3}, $B_4O_7^{-2}$, Ba^{+2}, Be^{+2}, Bi^{+3}, Br^-, CO_3^{-2}, Ca^{+2}, CbO_4^{-3}, Cd^{+2}, Ce^{+3}, Cl^-, Co^{+2}, Cr^{+3}, Cs^+, Cu^{+2}, Dy^{+3}, Er^{+3}, Eu^{+3}, F^-, $Fe^{+2,+3}$, Ga^{+3}, Gd^{+3}, Ge^{+4} (aqueous solution of GeO_2), Hf^{+4}(HfO^{+2}), $Hg^{+,+2}$, I^-, In^{+3}, Ir^{+4}, K^+, La^{+3}, Li^+, Mg^{+2}, Mn^{+2}, MoO_4^{-2}, NO_2^-, NO_3^-, Na^+, Nd^{+3}, Ni^{+2}, OsO_5^{-2}, HPO_4^{-2}, Pb^{+2}, Pr^{+3}, Rb^+, ReO_4^-, Rh^{+3}, Ru^{+3}, S^{-2}, SO_4^{-2}, Sb^{+3}, Sc^{+3}, SeO_3^{-2}, SiO_3^{-2}, Sm^{+3}, $Sn^{+2,+4}$, Sr^{+2}, TaO_4^{-3}, TeO_4^{-2}, Ti^{+4}-(Ti_2O^{+6} or TiO^{+2}), Th^{+4}, Tl^{+3}, Tm^{+3}, UO_2^{+2}, VO^+, WO_4^{-2}, Y^{+3}, Yb^{+3}, Zn^{+2}, Zr^{+4}(ZrO^{+2}).

The auric ion reacts with the reagent to form a purple colored solution. The reaction is not as sensitive as that for palladium, but the presence of gold in amounts exceeding 1 p. p. m.[10] interferes with the method and must be removed.

The first solution of platinic chloride tested yielded a slight red coloration. Later it was found that palladium was present as an impurity, and a subsequent test with a pure solution gave no color reaction. After standing for several hours in direct sunlight, however, platinum does react to give a very faint coloration; after several days an intense red color is formed that may serve as a sensitive test for platinum. Under the conditions of the method, however, platinum does not interfere, except by its color which becomes troublesome at concentrations exceeding 20 p. p. m.

In neutral solution, silver ions react with the reagent to give a red precipitate. The reaction is not sensitive, nor does it occur in acid solution. However, because it is necessary to use a buffer containing hydrochloric acid, silver must be absent to prevent turbid solutions due to silver chloride.

Ceric and bromate ions as well as other strong oxidizing agents interfere. Substances reacting with the palladous ion such as iodide, cyanide, and strong reducing agents, must necessarily be absent.

With the exception of silver and mercurous ions, colorless metallic ions do not interfere. The following were tested at a concentration of 100 p. p. m. and found to be without effect: Al, Cd, Hg^{+2}, Mn^{+2}, Pb, and Zn.

The following colored ions interfere only when present in large enough amounts to produce an interfering color. The ions and limiting concentrations are: Co, 10 p. p. m.; Cu, 50; Fe^{+3}, 30; Ir, 2; Ni, 25; Rh, 2.

Separation of Gold from Palladium.—Gold in excess of 1 p. p. m. must be removed, for it interferes seriously with the method. The removal was attempted unsuccessfully by reduction to the metal with oxalic acid. A single precipitation of the gold resulted in a loss of most of the palladium; a reprecipitation, although improving the separation, did not make it quantitative. Repeated precipitations perhaps would give a satisfactory separation, but such operations are tedious and since another satisfactory method was available, the former method was discarded. Gold may be removed satisfactorily by extraction with either ethyl acetate[11] or ether[12] from a solution containing hydrochloric acid. The following procedure is satisfactory for the removal of gold.

Procedure.—Add sufficient hydrochloric acid to the solution (volume of 15 ml. or less) containing auric and palladous chlorides to give a final concentration of approximately 10%. Transfer the solution to a small separatory funnel, add 10 ml. of ethyl acetate (or ether), shake for a few seconds and draw off the acid layer. Shake the ethyl acetate layer with a few ml. of 10% hydrochloric acid and combine the wash solution with the other acid portion. If necessary, repeat the extraction with another 10-ml. portion of ethyl acetate. Evaporate the solution to dryness on the steam-bath, take up the residue in a few ml. of hydrochloric acid and evaporate almost to dryness (no more than a drop remaining). Add water and determine palladium by the standard procedure.

The results given in Table I were obtained for solutions containing varying amounts of auric and palladous chlorides. The removal of gold has been sufficiently complete to avoid interference in all cases except in the experiments in which the solutions containing 5 mg. of gold

TABLE I

Extractions	Au added, mg.	Pd found: Pd added, γ	Pd found: Ethyl acetate γ	Pd found: Ether γ	Au/Pd

3	50	5.0	5.0	5.5	10000

[a] High results were due to the interference of gold.

(10) This and similar notations refer to a volume of 100 ml. and a solution height of 160 mm.

(11) V. Lenher and C. H. Kao, *J. Phys. Chem.*, **30**, 126 (1926).

(12) F. Mylius, *Z. anorg. Chem.*, **70**, 203 (1911).

were extracted only once with ether and a satisfactory recovery of palladium resulted even where the ratio of gold to palladium was 10,000:1. Ether appears to be the more suitable extractant, yielding slightly higher results in most cases than those obtained with ethyl acetate and if a complete removal of gold is not required it would be preferable. Ethyl acetate is, however, a more efficient extractant; if the most nearly complete removal of gold with the least number of extractions is desired, it is preferable to ether.

Separation of Palladium from Platinum.—Amounts of platinum exceeding 2 mg. produce an interfering yellow color, making it necessary to separate the two metals. The removal of platinum was attempted by precipitation with ammonium chloride. This method was found to be entirely unsatisfactory, resulting in the loss of most of the small amounts of palladium present. Even the use of solutions not saturated with ammonium chloride, and which did not give a quantitative precipitation of platinum, gave unsatisfactory results. The reaction between stannous chloride and platinic chloride in hydrochloric acid and the subsequent extraction with ether[13] or ethyl acetate[14] was also employed. This method was not satisfactory, the loss of palladium perhaps being caused by the presence of hydrated stannic oxide formed in subsequent operations. Palladium could not be precipitated with dimethylglyoxime at such low concentrations. The use of small amounts of nickel as a collector resulted in a partial precipitation of palladium by dimethylglyoxime. The method finally adopted—which involved the precipitation of palladium as the hydrated dioxide as given by Gilchrist and Wichers[15]—gave a very satisfactory separation. This method gives a remarkably clean-cut separation of extremely small amounts of palladium from relatively large amounts of platinum. In our experiments, a small amount of iron was used as a collector, though it was later found that as little as 5 γ of palladium could be separated without the use of a collector. The procedure given is that of Gilchrist and Wichers[15] applied to small quantities of the metals.

Procedure.—Add 0.2 ml. of ferric nitrate (0.2 mg. of iron) to the solution containing platinum and palladium, a few ml. of hydrochloric acid, and approximately 100 mg. of sodium chloride. Evaporate the solution to dryness, add hydrochloric acid, and once more evaporate to dryness. Add 4–5 drops of hydrochloric acid and 40 ml. of water, heat the solution to boiling and add 2 ml. of a filtered 10% sodium bromate solution. Then add dropwise a 10% solution of sodium bicarbonate until cresol red turns pink. (Test a drop of solution on the stirring rod with the indicator.) Add 2 ml. of the sodium bromate solution and boil for fifteen minutes. Filter through a fritted glass funnel or crucible, wash the precipitate several times with a few ml. of a 1% sodium chloride solution, having a *p*H of 6 or 7, dissolve the precipitate in 5 ml. of hydrochloric acid, and wash the filter with water. Evaporate the solution to dryness on the steam-bath, add a few ml. of hydrochloric acid, evaporate almost to dryness (not more than a drop) and take up in water. Determine the palladium in this solution by the standard procedure.

The results obtained by using this procedure for the analysis of solutions containing palladium and platinum were entirely satisfactory. For instance, in an experiment using 20 mg. of platinum and 5 γ of palladium, all the palladium was found. In another set with 20 mg. of platinum and 2 γ of palladium (ratio of Pt/Pd = 10,000), 2 γ of palladium was recovered. The method may be extended to even greater ratios by using larger amounts of platinum.

The method was applied to the analysis of metallic platinum samples. The samples were dissolved in *aqua regia*, the nitric acid removed by repeated evaporation with hydrochloric acid in the presence of sodium chloride and the residues taken up in water. The palladium was then determined. One sample contained 0.09% of palladium; another contained less than 0.002%, this being the limit of sensitivity with a 20-mg. sample.

Several experiments were also run in which palladium was determined in solutions containing the chlorides of palladium, gold, and platinum. The gold was removed by extraction with ethyl acetate and the palladium then determined after separation from platinum by the method given above. Satisfactory results were obtained in all experiments.

Separation of Silver from Palladium.—In the analysis of materials containing silver and "platinum group" metals, silver is usually removed as the chloride and would not be found in the solution prepared for the analysis of palladium. It was of interest, however, to determine whether or not small amounts of palladium might be carried down with the silver chloride. Accordingly, a few experiments were performed in which silver was precipitated as the chloride in the presence of small amounts of palladium. The general procedure followed was to take solutions containing known amounts of silver and palladium, dilute to 100 ml., acidify with nitric acid and precipitate the silver with hydrochloric acid. Each solution was filtered through a fritted glass crucible, the precipitate washed well with very dilute hydrochloric acid and palladium determined in the filtrate by the standard procedure, after the removal of nitric acid by repeated evaporation with hydrochloric acid in the presence of a few mg. of sodium chloride.

The results showed that palladium was lost in the separation. For example, using 20 mg. of silver and 10 γ of palladium only 7.5 γ of palladium was found. In several instances the silver chloride was dissolved in ammonium hydroxide, the filter thoroughly washed and then treated with *aqua regia*. Part of the palladium was recovered by this treatment, indicating that a partial reduction of the palladous ion to the metallic state had occurred. This reduction was probably due to the presence of a small amount of metallic silver formed by the action of light. This does not account, however, for all the palladium lost, and it seems probable that the loss is, at least in part, due to occlusion or adsorption by the silver chloride. Prolonged digestion or a reprecipitation afforded little or no improvement in the separation.

Sensitivity and Accuracy of the Determination.—Using a spot-plate, 0.005 γ of palladium (0.05 ml. of a solution containing 1 part of Pd in 10,000,000) may be detected.

(13) E. Langstein and P. H. Prausnitz, *Chem.-Ztg.*, **38**, 802 (1914).
(14) H. W. Wölbling, *Ber.*, **67B**, 773 (1934).
(15) R. Gilchrist and E. Wichers, THIS JOURNAL, **57**, 2565 (1935).

The paper spot method is sensitive to about 0.01 γ. In solutions of extremely low ionic strength, as little as 1 part of palladium in 300,000,000 parts of solution may be detected in 50-ml. Nessler tubes (220 mm.). Under the conditions in which the determinations are carried out, the concentration limit is 1:200,000,000, using either Nessler tubes or the roulette comparator. This corresponds to 0.25 γ of palladium with the former and 0.5 γ with the latter. The method may be made more sensitive by the use of smaller volumes. For instance, using 2 ml. of solution in small test-tubes which gave a column of liquid 50 mm. in height, 0.04 γ was detectable. With 10 ml. of solution and a column height of 80 mm., 0.1 γ was detectable.

The accuracy of the determination depends upon the concentration of palladium present, the volume of solution used, the method of matching, and the presence or absence of interfering substances. The accuracy reported below for the different amounts of palladium is based on a volume of 100 ml. using a roulette comparator (100 ml. tubes, 160 mm. to mark) with a Corning Filter no. 512 for amounts of palladium up to 20 γ and Filter no. 585 for larger amounts. The accuracy found under the most favorable conditions was as follows: 0.5–10 γ, 0.25 γ; 10.5–25 γ, 0.5 γ; 26–35 γ, 1 γ; 36–50 γ, 2.5 γ.

Acknowledgment.—The authors wish to express their appreciation to Charles J. Barton of this Laboratory for the data used in the relative absorption curves.

Summary

The reaction between *p*-nitrosodiphenylamine and palladous chloride has been described. This reaction is extremely sensitive and nearly specific for palladium. Studies have been made on the effect of salts, of hydrogen-ion concentration, of temperature, and of interfering substances on the color formation and stability of the compound.

The composition of the compound has been determined and found to correspond to the coordination compound $Pd[C_6H_5NHC_6H_4NO]_2Cl_2$. The compound has a purplish-brown color in the solid state but under the experimental conditions used in the colorimetric procedure it forms a red solution.

Relative absorption curves are given for solutions of the reagent and of the palladium compound.

Details are presented for a new colorimetric method permitting the determination of quantities of palladium of the order of a few γ, as well as results of its application. Procedures are also given for the determination of palladium when accompanied by gold and platinum.

The Vitrification and Crystallization of Organic Molecules and the Dielectric Behavior of *i*-Butyl and *i*-Amyl Bromides

BY WILLIAM O. BAKER AND CHARLES P. SMYTH

The relation of molecular structure to molecular interaction and rotational freedom in the solid state has been studied by means of dielectric constant and dispersion measurements on a series of molecules of differing shapes. In investigating the connection between the symmetry of the crystal lattice and the symmetry of the molecule, *i*-butyl and *i*-amyl bromides were examined as pear-shaped forms intermediate between the rod-like long[1] chain compounds, and the nearly spherical *t*-butyl halides.[2] Their ready vitrification permitted analysis of both crystalline and glassy behavior.

A capacity bridge coupled to a low-frequency, variable oscillator, and to a vacuum tube, six-stage amplifier was employed for the dielectric measurements in the same general fashion as that already described.[3] Temperatures were obtained from a platinum resistance thermometer. The crystals and glasses were examined over a wide temperature range with a polarizing microscope equipped with a transparent Dewar tube mounted on the stage. The cell containing the material to be measured was inserted in a brass block into which liquid air could be injected at any desired rate.[3] Further the block assembly was suspended in a large Dewar vessel, from the lower portion of which liquid air could be evaporated to provide a very slow rate of temperature change in the cell. The usual care was taken to reduce void formations between the condenser walls by pumping off dissolved gases from the liquid in the cell, by subsequent freezings and meltings, and by slow final freezing from the bottom of the cell upward.

Purification of Materials

The fractionation of these compounds was by a packed column of satisfactory efficiency, elsewhere described.[4]

***i*-Butyl Bromide.**—The Eastman Kodak Co. product was dried over pure calcium bromide, and was fractionally distilled five times; the five fractions in the right boiling range were combined and refractionated. The final criteria for purity were the absence of Maxwell–Wagner polarization on melting, and a low specific conductance for the liquid: b. p. 91.9°; m. p. −118°; $n^{20.0}D$ 1.43440. A separately purified sample gave: b. p. 91.9°; $n^{20.0}D$ 1.43430. Skau and McCullough[5] report for a highly-purified sample, b. p. 91.72°; m. p. −118°. Kharasch and Potts[6] give $n^{20}D$ 1.4355. The tendency for rearrangement to *t*-butyl bromide of this compound was realized, but, under the conditions of distillation, very little should occur,[7] as indicated by the sensitive conductance measurements.

***i*-Amyl Bromide.**—Material of the best Eastman Kodak Co. quality was dried over pure calcium bromide, and thrice fractionated: b. p. 120.5°; m. p. −112°; $n^{20.0}D$ 1.44154. The Landolt–Börnstein "Tabellen" (with $n^{20}D$ from "I. C. T.") give: b. p. 120.65°, m. p. −112.0°, $n^{20}D$ 1.4412.

Experimental Results

Table I contains the dielectric constants ϵ, the specific conductances k (ohm^{-1} cm.$^{-1}$), and the imaginary part of the dielectric constant ϵ'', which is related to the loss factor by $\tan \delta = \epsilon''/\epsilon'$, where ϵ' is the normally recorded dielectric constant, ϵ. The columns of data are headed by the appropriate frequencies in kilocycles, and the temperatures are in °C.

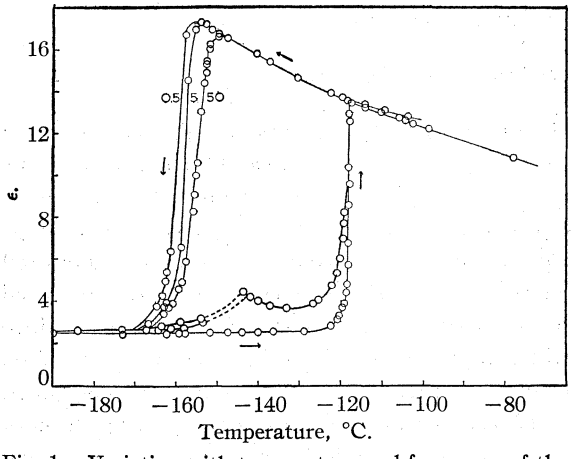

Fig. 1.—Variation with temperature and frequency of the dielectric constant of *i*-butyl bromide.

The data recorded were obtained from at least four separate runs, each of which reproduces the curves of Figs. 1 and 3 exactly. Exceptions, of course, are the cases of those representing partial devitrification, which were dependent on previous treatment, and will be noted later. Values at intermediate temperatures have been omitted for the sake of brevity. The apparent values of ϵ'' for the liquid are too high because of a certain amount of direct current conductance.

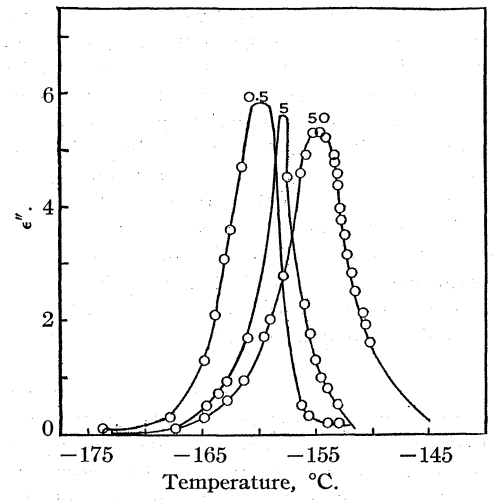

Fig. 2.—Variation with temperature and frequency of ϵ'' for *i*-butyl bromide.

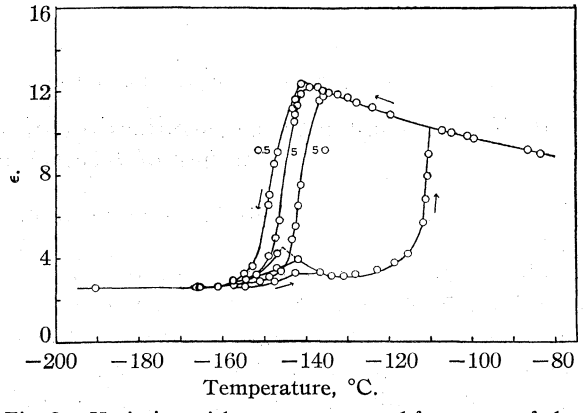

Fig. 3.—Variation with temperature and frequency of the dielectric constant of *i*-amyl bromide.

Discussion of Results

There is still uncertainty about the thermal and optical properties of glasses, about their mechanism of viscous flow, and about the question of their possessing definite vitrification and devitrification temperatures.[8] Commercial glasses, generally used as dielectrics, have been studied as to dielectric constant and loss, and breakdown potential, usually over short temperature ranges.[9]

These, like ordinary organic glasses, such as sugars and glycerol, have strong intermolecular bonding, which complicates dielectric interpretations of structure. The simple bromides here investigated, although they have no hydrogen bonds linking the molecules, invariably form clear glasses on cooling.

Previous dielectric studies on organic glasses over a temperature interval are reviewed in the Landolt–Börnstein "Tabellen."[10] The curves of Figs. 1 and 3 obtained with decreasing temperature resemble those found for liquid and glassy glucose by Thomas,[11] who used the frequency range 92 to 2600 kilocycles. Similar, more detailed studies on glucose,[12] glycerol and several monohydric alcohols[13] by Kobeko and co-workers produced the same sort of marked dispersion and decrease of dielectric constant over a short temperature range, the position of which was determined by the frequency of the applied field. Loss factors of commercial glasses have been measured at high frequencies by Hackel,[14] who used the immersion method of finding a polar liquid mixture with the same dielectric constant as the glass.

Basic postulates of the present report are supported by Hägg's[15] conclusion from X-ray data that organic glasses contain large groups of molecules linked together by strong associative forces. Glycerol glass has been found truly amorphous.[16] X-Ray patterns have been established as valid proofs of the non-crystalline nature of a glass.[17]

The curves of Figs. 1 and 3 obtained on cooling follow the Debye temperature dependence for a polar liquid down to the regions −150 to −165° for *i*-butyl bromide and −135 to −155° for *i*-amyl bromide. In these ranges, there is a gradual, frequency-dependent drop of the dielectric constant to values approaching the square of the refractive index. This apparent rotational freezing differs from ordinary rotational immobilization on solidification in at least two ways. It does not occur sharply and shows no latent heat under the conditions of measurement. The gradual loss of rotational freedom suggests that the individual dipoles are orienting in a viscous medium, for, at a given temperature, it is seen that the molecules may be able to follow quite completely a field of frequency 500, and show little or no rotation in a field of 50,000 cycles.

Mechanically, it was found that *i*-butyl bromide became stiff at about −120°, and *i*-amyl bromide at about −115°. It would seem that, with decreasing temperature and increasing density, enhanced molecular field interaction removes librational freedom even in the absence of a phase change. An artificially increased interaction, such as that caused by high pressures, should then produce the same effect as lowering the temperature. This is confirmed by the experiments of Danforth,[18] who introduced pronounced dispersion at given frequencies in some ten compressible liquids like glycerol and isobutyl alcohol by measuring the dielectric constants under high pressures.

The range of temperature required for the setting of the dipoles with respect to a given frequency in liquids and glasses provides a contrast of the interaction of their molecules with the intermolecular action in crystals which have rotational transitions occurring within a very short or zero temperature interval.[2,3,19] In the latter, the sudden rearrangement of the crystal transition would seem to effect a critical interaction that blocks

dipole orientation almost completely. However, the curves of Figs. 1 and 3 suggest that the glass slowly contracts with decreasing temperature so that there is a gradual immobilization of dipoles. This may be further evidence for a random molecular arrangement in glasses.

Even before the dipole theory, it was realized that the constituent particles of a dielectric did not all have necessarily the same relaxation time.[20] This concept has been applied to a variety of dielectrics by many workers, and recently Yager[21] has reviewed and extended the method of quantitatively estimating the distribution. The ordinary experimental values represent an average. A rough qualitative idea of the breadth of the distribution may be gained from a calculation of the ideal maximum value of ϵ'' for a given frequency as was done for several compounds by Morgan.[22] An observed maximum value obtained from Fig. 2 or Fig. 4 will deviate the more from the ideal value, which it would have if all the particles had a single relaxation time, the less uniform are the constituent units of the dielectric. The calculation of the ideal $\epsilon''_{max.}$ follows from the observation that the absorption is greatest when $x = 1$ in the Debye expression for ϵ.[23] That is, $\epsilon'' = x(\epsilon_1 - \epsilon_0)/(1 + x^2)$, where $x = \omega\tau(\epsilon_1 + 2)/(\epsilon_0 + 2)$, in which ϵ_1 = dielectric constant at zero frequency, obtained from graphical extrapolation of low frequency values; ϵ_0 = dielectric constant at infinite frequency, obtained from low temperature values of the crystalline solid; $\omega = 2\pi \times$ frequency in cycles; τ = relaxation time of particles. Then, $\epsilon''_{max.} = (\epsilon_1 - \epsilon_0)/2$.

TABLE II

	f, kc.	$\epsilon''_{max.}$ Calcd.	$\epsilon''_{max.}$ Obsd.
i-Butyl bromide	50	7.5	5.3
	5	6.7	5.6
	0.5	4.8	5.9
i-Amyl bromide	50	5.0	3.8
	5	3.9	4.5
	0.5	3.0	5.0

The most uniform relaxation times seemingly are characteristic of the temperature region in which ϵ'' is a maximum for a frequency of 5 kc. as the difference between observed and calculated values, which arises from variation in particle size, is smallest at this frequency for the values in Table II. Figures 2 and 4 confirm this conclusion in showing the 5 kc. dispersion curves to be narrowest, with the sharpest peaks, for, as Yager[21] notes, the narrower the ϵ'' *vs.* temperature peak, the narrower the distribution of relaxation times, and hence of constituent units.

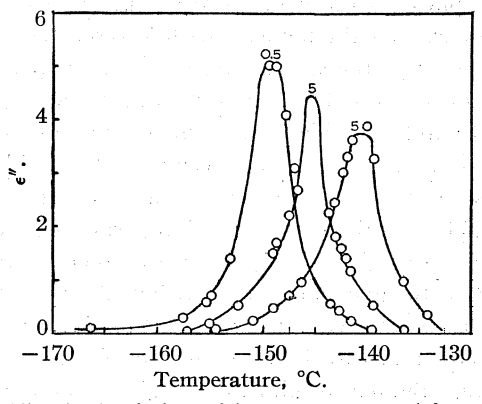

Fig. 4.—Variation with temperature and frequency of ϵ'' for *i*-amyl bromide.

Isobutyl bromide glass appears to be most homogeneous at about −158°, and isoamyl bromide at about −145.5°, whereas a greater variety of agglomerates exists above and below these temperatures. A glass probably contains molecular aggregates[9,15] which must dissociate before molecules can orient to form a crystal lattice. The ordered crystalline state has a lower free energy than the glass, and hence the latter is forced toward the former by a thermodynamic potential that increases with decreasing temperature. It would seem that at just about the temperature of the maximum absorption for 5 kc. in the two glasses, dissociation of the vitreous aggregates has resulted in a maximum homogeneity of particle size. Because of the generally similar behavior of the molecules of the two substances, like relations should obtain for each between the temperature T_i at which the re-ordering enters and the lower temperature T_f of apparent rotational freezing, if temperature difference may be considered as measuring thermodynamic potential. As will be noted below, some devitrification was found to enter at the temperatures of rotational freezing, T_f. The relations found are

i-butyl bromide $T_i(-158°) - T_f(-170°) = 12°$
i-amyl bromide $T_i(-145.5°) - T_f(-160.0°) = 14.5°$

These temperature intervals are, as would be expected, approximately the same, with the larger molecule showing the larger interval.

The portions of Figs. 1 and 3 indicated as ob-

tained with rising temperature are next noted. The physical states of *i*-butyl bromide at −175°, and of *i*-amyl bromide at −165°, are those of undercooled liquids (glasses) far below their normal freezing points. Their instability as non-crystalline forms increases with decreasing temperature, but the fruition of this crystallizing tendency is opposed by the increase with lowered temperature of the relaxation times of the molecules. However, around −170° for *i*-butyl and −160° for *i*-amyl bromide, a certain amount of devitrification has occurred, because the dielectric constant–temperature curve from measurements at 0.5 kc. on Fig. 1, was completely reversible with temperature anywhere down to about −167°, while if the glass was cooled below about −167°, and then warmed, the dielectric constant values did not return to those required by the reversible curve. Similar results at a higher temperature were found for *i*-amyl bromide. Moreover, the isotropic glasses began to show scattered areas of double refraction when examined with the polarizing microscope. Because of relaxation effects, the amount of crystal formation observed at −170° for *i*-butyl and −160° for *i*-amyl bromides should depend on the length of time the sample is held at the given temperature after the liquid is cooled. The upper of the two rising temperature curves on Fig. 1 was obtained when the specimen was held near −180° for upwards of thirty minutes. Similar treatment produced the heating curve on Fig. 3. Evidently there was not time for complete crystallization. Presumably, crystallization had proceeded from many nuclei scattered throughout the glass, but there were still vitreous regions when the measurements with rising temperature were begun. Molecules in the crystal lattice of *i*-butyl bromide cannot rotate in the applied field, as the lower curve with rising temperature on Fig. 1 shows, for the dielectric constant is there produced only by atomic and electronic polarization, except in the region of some rotational pre-melting as often observed.[1,24,25] However, molecules still in the glass distributed among the crystal groups should be able to orient as soon as a sufficiently high temperature is reached. For *n*-amyl bromide, as seen in Fig. 3, an increase in dielectric constant is found in about the same temperature region in which it declined on the cooling of the pure glass. For *i*-butyl bromide, the region of increase is shifted to somewhat higher temperatures. A speculation on the reason for this is that, in the sample of *i*-butyl bromide for which the data are graphed, crystallization has progressed so far that the large crystalline groups in a predominantly crystalline lattice inhibit, by their locally oriented force fields, the rotation of the glass molecules dispersed among them. This is consistent with the fact that the maximum dielectric constant on the warming curve of *i*-amyl bromide, although occurring at a lower temperature, is a larger percentage of the true glass value than that for the *i*-butyl bromide. In the curves for both compounds, the dispersion characteristic of the glass is found. Further, the dielectric loss data in Table I for both compounds show a maximum with rising temperature in the region of the temperature of the dielectric constant maximum. This also demonstrates the regaining of partial rotational freedom by those molecules still in the vitreous condition.

Finally, the reason for decrease of the dielectric constant with further temperature rise, as seen on the lower curves of Figs. 1 and 3, is probably that, at the temperature of the maximum, the molecules still in the vitreous state have again acquired sufficiently short relaxation times to crystallize, especially under the orienting influence of numerous crystalline groups. That these latter do predominate is confirmed by the maximum dielectric constant, in the case of *i*-butyl bromide 4.5, instead of the 17.3 of the true glass. As crystallization in the solid state proceeds, the dielectric constant falls to the true crystal value, and then rises again on melting.

The above explanation may be applied to a recent report on the first production of boron trioxide crystals by McCulloch.[26] An ordinary boron trioxide glass held at 250° for three days, after it had stood at room temperature for a much longer period, showed a considerable amount of crystallization as indicated by X-ray analysis. The melting point of a nearly glass-free mass of boron trioxide crystals (99.6%) was found to be 460–470°. The glass at room temperature, 450° below the normal freezing point, may now be regarded as under a large thermodynamic potential tending toward crystallization. Some few very minute crystal nuclei are actually formed, as, indeed, such are found in laboratory glass at

(26) McCulloch, THIS JOURNAL, **59**, 2650 (1937).

ordinary temperatures.[27] However, precisely as here indicated for *i*-butyl and *i*-amyl bromides on Figs. 1 and 3, an increase in temperature to shorten the relaxation time of the molecules facilitates widespread devitrification and is actually essential for a substance with intermolecular bonding like that in boron trioxide. It is suggested that efforts to crystallize organic glasses and sirups might be facilitated by cooling the substance to low temperatures, and then re-warming to a point near, but well below, the melting point of the crystals sought. The dielectric results show mechanically the reorientation that must accompany the crystallization.

The present results, together with those of other work involving a variety of molecular structures,[1,2,4] indicate relations of the structure of the liquid state to the tendency toward glass formation as follows:

a. Moderately unsymmetrical, say pear-shaped, molecules, like *i*-butyl and *i*-amyl bromide, can pack randomly in the liquid with an economical use of volume. Hence, although the molecules are on the whole disordered, their efficient packing permits them to remain in the liquid arrangement far below the normal crystallization temperature. Such substances should vitrify.

b. Long-chain compounds, although they often form viscous liquids, do not generally supercool, as dielectric studies, a sensitive test for supercooling, have shown for several examples including the associated cetyl alcohol. Here, it is probable that the rod-like molecules are already locally, at least, quite well aligned in crystal-like array in the liquid. Random scattering would waste a relatively large volume, and hence would be energetically unfavorable. Indeed, X-ray data indicate alignment along the long axis even in *n*-heptane.[28,29] Hence, when long-chain compounds are cooled to the freezing point, they simply set into the crystal lattice and do not form glasses.

c. Very symmetrical, nearly spherical molecules which form cubic lattices, and especially those which are known to exhibit a rotational freedom in the crystal comparable to that in the liquid,[2,30] in agreement with the above postulates, commonly do not supercool. They may be considered to compose a liquid structure of close-packed spheres, which set into the cubic lattice with little rearrangement and probably no reorientation, and thus have no tendency toward glass formation.

d. As expected, and noted elsewhere,[4] molecules of symmetry intermediate between the pear-shaped and rod-like structures show degrees of supercooling varying with their particular shapes, and very rarely leading to true glass formation.

Extensive inter-molecular bonding in a liquid may so effectively alter the shape of the constituent particles as to require modification of the above conclusions from molecular data alone.

In addition to the data already cited in support of these conclusions, the evidence given by recent work[31] on some pure hydrocarbons may be noted. It was reported that the normal paraffins crystallized readily without supercooling, whereas certain branch-chained paraffins, conforming with the conditions of paragraph above, solidified to glasses. Also, it has been reported[32] that two of the branched heptanes, unlike their other isomers, failed to crystallize even when cooled to 70°K. An efficient but random packing should, therefore, be assigned to their liquid structures.

Summary

The dielectric constants and conductances of isobutyl and isoamyl bromides have been measured with a capacity bridge at frequencies of 0.5, 5 and 50 kilocycles at temperatures from −190 to 30° above their melting points. The substances have also been examined with a polarizing microscope over these wide temperature ranges.

It is found that, when the substances in the liquid state are cooled, they form glasses, which crystallize at low temperatures, their properties depending upon the degree of crystallization brought about by thermal treatment. Examination of these and other, previously studied molecules leads to generalizations as to glass formation. It is concluded that molecules which pack efficiently in the liquid, but which do not form isotropic lattices, should tend to vitrify. The temperature of narrowest distribution of relaxation times may indicate the point at which the vitreous aggregates begin to dissociate.

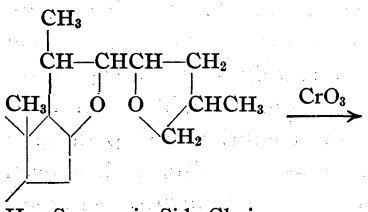
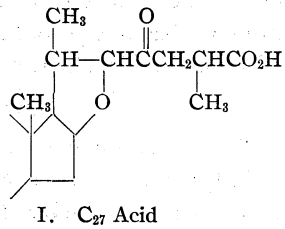
Sterols. LXIX. Oxidation Products of Sarsasapogenin. Sarsasapogenoic Acid and Related Substances

BY RUSSELL E. MARKER AND EWALD ROHRMANN

Fieser and Jacobsen[1] in their investigation of the chromic anhydride oxidation products of sarsasapogenin acetate obtained an acid, $C_{27}H_{42}O_5$, which was designated as sarsasapogenoic acid and which is undoubtedly analogous to an acid obtained by Tschesche and Hagedorn[2] by a somewhat similar oxidation of tigogenin acetate. Tschesche and Hagedorn assigned to this the structure of a γ-keto acid, I.



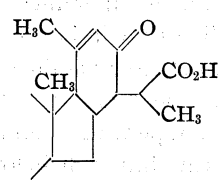
II. Sapogenin Side Chain (Tschesche and Hagedorn[2])



I. C_{27} Acid

It is evident that this structure is based almost entirely upon the assumption that the sapogenin side chain is correctly represented by II.

While Tschesche and Hagedorn[2] found that the C_{27} acid from tigogenin was inert toward hydrogenation and did not react with carbonyl reagents, Fieser and Jacobsen[1,3] found that sarsasapogenoic acid was somewhat more reactive. Treatment with hydroxylamine at 135° yielded a dioxime. Catalytic hydrogenation gave an acid of the probable composition $C_{27}H_{44}O_4$ designated as anhydrotetra-(or di)-hydrosarsasapogenoic acid. When heated with aqueous alcoholic alkali, sarsasapogenoic acid yielded anhydrosarsasapogenoic acid, $C_{27}H_{40}O_4$, a product which was shown to contain an alpha-beta unsaturated ketone grouping[3,4] and to which structure III was assigned.



III. Anhydrosarsasapogenoic acid (Fieser and Jacobsen[3])

Fieser and Jacobsen[3] regarded this structure for anhydrosarsasapogenoic acid as secure and offered it as confirmatory evidence in support of the formulations I and II of Tschesche and Hagedorn.[2]

Inasmuch as most of the available evidence now indicates that the sapogenin side chain is not correctly represented by II,[5] it is evident that the structure of the sapogenoic acid is open to serious question. In conformity with our recently proposed structure IV[5] for sarsasapogenin we believe sarsasapogenoic acid to be a diketo acid best represented by V. The two carbonyl groups in such a molecule would be expected to be sterically hindered, which would explain the difficult formation of a dioxime.[3]

The formation of anhydrotetrahydrosarsasapogenoic acid[3] by catalytic hydrogenation of sarsasapogenoic acid is explained by the conversion of the diketone with loss of water to a tetrahydrofuran derivative, VI. This acid appears to be identical with sarsasapogentic acid[5] which we previously prepared by the oxidation of 3-acetoxydihydrosarsasapogenin (VII). This conclusion is based upon a comparison of the free acids, the methyl esters, the methyl ester benzoates and the 3-dehydro acids.

The suggestion of Fieser and Jacobsen[3] that anhydrotetrahydrosarsasapogenoic acid is a saturated γ-keto acid is hardly in accordance with the properties of known γ-keto acids.

Inasmuch as the identity of anhydrotetrahydrosarsasapogenoic acid and sarsasapogentic acid appears to be conclusive, we propose in order to avoid further confusion that the nomenclature of Fieser and Jacobsen[3] be retained and the term sarsasapogentic acid be discontinued.

The difficulty encountered in purification of the hydrogenation product of sarsasapogenoic acid is

(1) Fieser and Jacobsen, THIS JOURNAL, **60**, 28 (1938).

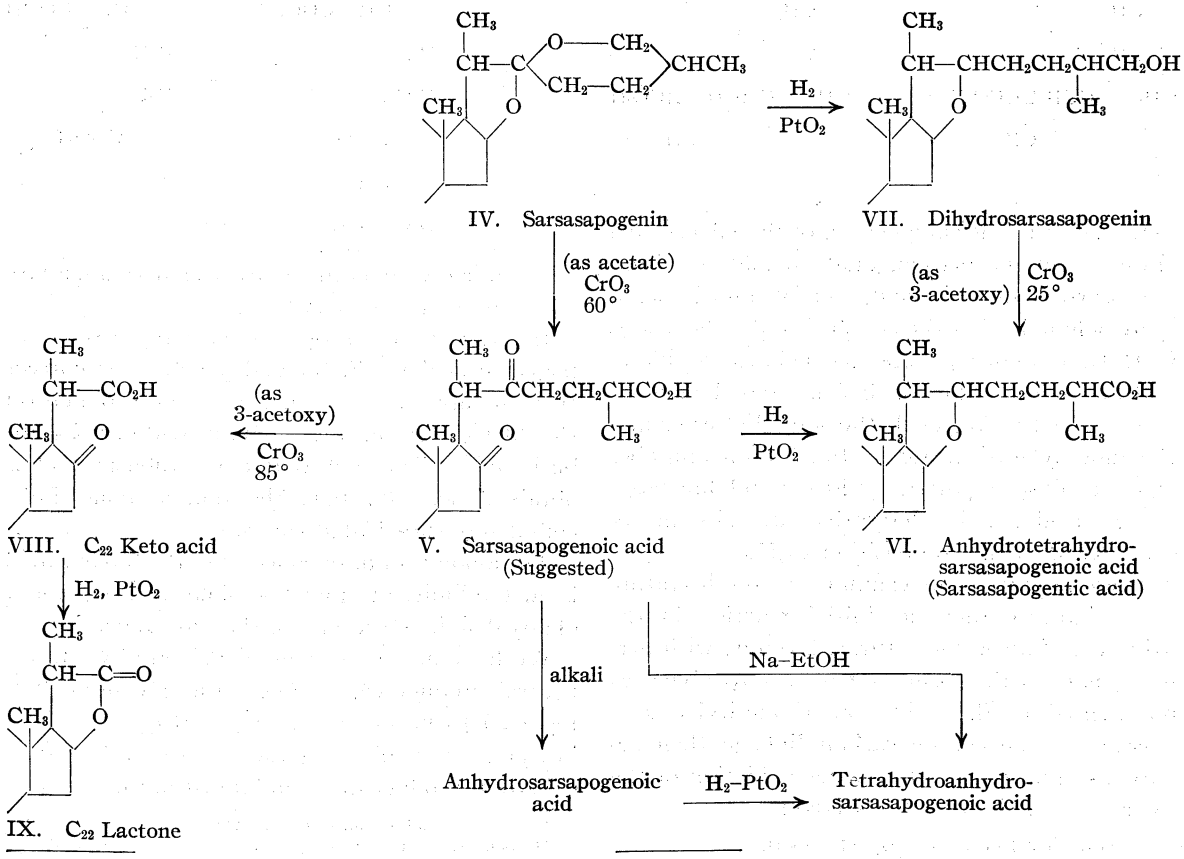
possibly due to the formation of an isomeric mixture which would not be unexpected.

Reduction of sarsasapogenoic acid with sodium and ethanol readily yielded tetrahydroanhydrosarsasapogenoic acid which Fieser and Jacobsen[3] first prepared from anhydrosarsasapogenoic acid by catalytic hydrogenation and by reduction with sodium and *n*-propyl alcohol. Reduction of sarsasapogenoic acid with aluminum isopropylate gave a poor yield of an acidic substance of the probable composition $C_{27}H_{46}O_5$. This reduction product was not studied further.

On mild oxidation with chromic anhydride sarsasapogenoic acid yields 3-dehydrosarsasapogenoic acid, m. p. 163–164°. This acid is very probably identical with an acid of the composition $C_{27}H_{40}O_5$, m. p. 162°, obtained by Jacobs and Simpson[6] by the oxidation of sarsasapogenin with chromic anhydride at 25–30°. The 3-dehydro acid reacts with one mole of bromine to yield a monobromo derivative $C_{27}H_{39}O_5Br$. Sarsasapogenoic acid showed no tendency to react with bromine under similar conditions.

If sarsasapogenoic acid is a γ-keto acid, I, it is obvious that the acid would have to be considered as an intermediate product formed in the oxidation of the sapogenin to the C_{22} lactone (IX). Further oxidation should yield the C_{22} lactone. Fieser and Jacobsen[3] failed to obtain an appreciable neutral fraction when sarsasapogenoic acid acetate was oxidized with chromic anhydride at 95°. By carrying out the oxidation at 85° we were likewise unable to obtain an appreciable neutral fraction. However, a 5% yield of a C_{22} keto acid was obtained. This was identical with the C_{22} keto acid (VIII) previously reported[7] from the chromic anhydride oxidation products of sarsasapogenin acetate. The acid was further identified by its conversion to the C_{22} lactone by catalytic hydrogenation.

Anhydrosarsasapogenoic acid was prepared in 20% yield by allowing sarsasapogenoic acid to stand at 25° for nine hours with aqueous alcoholic potassium hydroxide solution. In preparing anhydrosarsasapogenoic acid by the method of Fieser and Jacobsen,[1] we encountered a more soluble acid (m. p. 184°) having the same composition as the anhydro acid, C_{27}-



(6) Jacobs and Simpson, *J. Biol. Chem.*, **109**, 565 (1935).

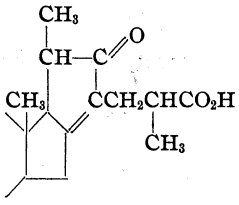
(7) Marker and Rohrmann, THIS JOURNAL, **61**, 1285 (1939).

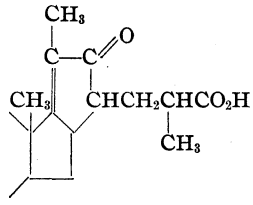
$H_{40}O_4$, m. p. 243°. This isomeric acid on heating with aqueous alcoholic alkali is converted into anhydrosarsasapogenoic acid. This lower melting isomeric acid could not be isolated when the preparation was carried out at 25°, probably due to the presence of unreacted sarsasapogenoic acid which appears to have about the same solubility.

The facile elimination of a molecule of water from sarsasapogenoic acid under the influence of alkali to yield an acid containing an α,β-unsaturated ketone grouping suggests that the reaction involves an intramolecular aldol condensation followed by elimination of a molecule of water.

The fact that anhydrosarsasapogenoic acid gives no semicarbazone under the usual conditions indicates that the carbonyl group is hindered. More difficult to understand is the fact that the acid is not reduced by aluminum isopropylate but this likewise may be attributed to the hindered nature of the group.

At present anhydrosarsasapogenoic acid has not been characterized sufficiently to be assigned a definite structure. However, it seems that the following formulations are the most likely possibilities

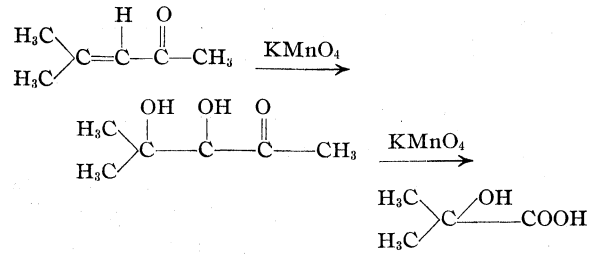




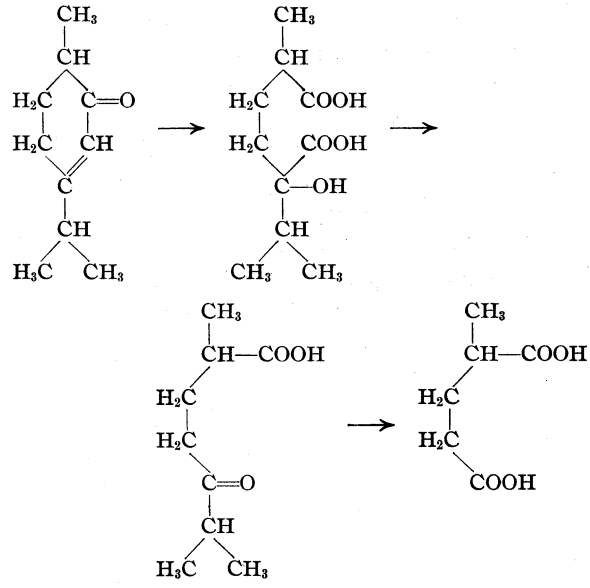
In regard to the composition of the dibasic acid obtained by the permanganate oxidation of anhydrosarsasapogenoic acid,[3] our results indicate quite definitely that the composition of the acid is $C_{27}H_{42}O_7$ and not $C_{27}H_{40}O_7$ as concluded by Fieser and Jacobsen.[3] This conclusion is based on check analyses of the free acid, the dimethyl ester and the dimethyl ester acetate. In addition a number of the analyses reported by Fieser and Jacobsen[3] for the acid and its derivatives are also in accordance with the composition $C_{27}H_{42}O_7$.

There are numerous examples in the literature which indicate that the initial reaction in the oxidation of an α,β-unsaturated ketone with permanganate is the formation of a keto glycol as represented in the oxidation of mesityl oxide.[8] Scission of the carbon–carbon linkage then occurs[9] as indicated, while further oxidation of the hydroxy acid gives further scission.

(8) Harries and Pappos, *Ber.*, **34**, 2979 (1901).
(9) Pinner, *ibid.*, **15**, 591 (1882).



Perhaps a more striking and more pertinent example of the mechanism of permanganate oxidations is afforded by the work of Tiemann and Semmler[10] on the oxidation of carvenone, the reaction going through the stages



A similar case is given by the permanganate oxidation of piperitone.[11]

If structure III proposed for anhydrosarsasapogenoic acid by Fieser and Jacobsen is correct then it appears that permanganate oxidation should yield either a C_{27} tribasic acid or a C_{26} dibasic acid. The fact that a C_{27} dibasic acid is obtained suggests that the double bond links completely substituted carbons.

The amount of data concerning the dibasic acid is far too limited to make possible the assignment of any definite structure for the substance.

We have also investigated incidentally the C_{29} neutral product which Fieser and Jacobsen[1] first reported to be unreacted sarsasapogenin acetate but later[3] recognized as the acetate of a neutral oxidation product of an unknown nature. They

(10) Tiemann and Semmler, *ibid.*, **31**, 2889 (1898).
(11) Simonsen, "The Terpenes," Vol. I, Cambridge University Press, London, 1931, p. 323.

reservedly suggested the substance to be a hydroxysarsasapogenin.

Our analyses of the neutral acetate (m. p. 164°) do not distinguish between $C_{29}H_{44}O_5$ and $C_{29}H_{46}O_5$. In agreement with Fieser and Jacobsen[3] we find that the carbon analyses for the hydrolyzed product (m. p. 217°) are about 0.7% high for the composition $C_{27}H_{44}O_4$.

The neutral acetate readily forms a semicarbazone indicating the presence of a free carbonyl group or possibly of a potential aldehyde group. Reduction of the neutral acetate by the Clemmensen method gave a good yield of tetrahydrosarsasapogenin previously obtained by an analogous reduction of sarsasapogenin.[5] Oxidation of the neutral acetate with chromic anhydride at 80° yielded some of the C_{22} keto acid.[7]

The neutral acetate appeared to be unaffected by catalytic hydrogenation with Adams catalyst in neutral medium while in acidic medium it yielded after hydrolysis a product of the probable composition $C_{27}H_{46}O_4$ or $C_{27}H_{48}O_4$.

The results concerning this neutral substance are difficult to interpret, especially in view of the uncertainty of the analytical data. We feel that the formation of the neutral substance probably represents an important stage of the oxidation of the sapogenin to the various oxidation products. The neutral product was not encountered when the oxidation of sarsasapogenin acetate was carried out at 80–85°.

We wish to thank Parke, Davis and Company for their generous assistance in the various phases of this work.

Experimental Part[12]

Reduction of Sarsasapogenoic Acid. (a) **By Catalytic Hydrogenation.**—Catalytic hydrogenation of sarsasapogenoic acid in acetic acid at 3 atmospheres pressure at 25° with Adams catalyst gave a product which after crystallization from acetone formed white needles, m. p. 180–184°, which agrees with **anhydrotetrahydrosarsasapogenoic acid.**[12] No lactonic material was obtained in the reduction.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 75.0; H, 10.25. Found: C, 75.0; H, 10.25.

In another preparation the reduction product was crystallized first from acetone and then from aqueous methanol to give flat white needles, m. p. 183–187°. Mixed with a sample of sarsasapogentic acid (m. p. 185–187°) the melting point range was 182–187°.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 75.0; H, 10.25. Found: C, 74.7; H, 10.2.

(12) Compounds previously reported by Fieser and Jacobsen.

With diazomethane anhydrotetrahydrosarsasapogenoic acid yielded a **methyl ester** which was crystallized from ether–pentane as small white plates, m. p. 125–127°. This gave no depression with a sample of the methyl ester of sarsasapogentic acid (m. p. 123.5–126°).

Anal. Calcd. for $C_{28}H_{46}O_4$: C, 75.3; H, 10.4. Found: C, 75.3; H, 10.3.

Anhydrotetrahydrosarsasapogenoic acid when treated with chromic anhydride in acetic acid at room temperature for one hour gave **3-dehydroanhydrotetrahydrosarsasapogenoic acid** which after treatment with Norite was crystallized from acetone as white needles, m. p. 196–199°. This gave no depression with a sample of 3-dehydrosarsasapogentic acid.[5]

Anal. Calcd. for $C_{27}H_{42}O_4$: C, 75.3; H, 9.8. Found: C, 75.1; H, 9.9.

Anhydrotetrahydrosarsasapogenoic acid with benzoyl chloride in pyridine gave the **methyl ester, benzoate,**[12] m. p. 140–141.5°.

Anal. Calcd. for $C_{35}H_{50}O_5$: C, 76.3; H, 9.15. Found: C, 76.0; H, 9.1.

The methyl ester of sarsasapogentic acid with benzoyl chloride in pyridine yielded a **methyl ester benzoate** which after sublimation in high vacuum at 140–180° was crystallized from methanol as small white plates, m. p. 139–141°. This gave no depression with the methyl ester benzoate of the anhydrotetrahydro acid described above.

Anal. Calcd. for $C_{35}H_{50}O_5$: C, 76.3; H, 9.15. Found: C, 76.2; H, 9.2.

(b) **With Sodium and Ethanol.**—To a boiling solution of 500 mg. of sarsasapogenoic acid in 150 cc. of absolute ethanol was added 12 g. of sodium over a period of two hours. The solution was cooled, diluted with water, acidified with hydrochloric acid and the precipitated solid extracted with ether. The residue remaining upon evaporation of the ether was crystallized from ether–acetone–pentane as small white needles, m. p. 179–181° dec. This gave no depression with a sample of tetrahydroanhydrosarsasapogenoic acid[12] (m. p. 179–181°) obtained by the catalytic hydrogenation of anhydrosarsasapogenoic acid.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 75.0; H, 10.25. Found: C, 74.9; H, 10.2.

(c) **With Aluminum Isopropylate.**—A solution of 600 mg. of sarsasapogenoic acid and 1 g. of aluminum isopropylate in 30 cc. of isopropyl alcohol was refluxed for fifteen hours. The solvent was then distilled off over a period of one hour. The residual material yielded a product which crystallized from ether–pentane as compact white crystals, m. p. 206–208° dec.

Anal. Calcd. for $C_{27}H_{44}O_5$: C, 72.3; H, 9.9. Calcd. for $C_{27}H_{46}O_5$: C, 71.95; H, 10.3. Found: C, 71.9, 71.9; H. 10.2, 10.3.

3-Dehydrosarsasapogenoic Acid.—To a solution of 500 mg. of sarsasapogenoic acid in 30 cc. of glacial acetic acid was added a solution of 300 mg. of chromic anhydride in 10 cc. of 80% acetic acid. The mixture was allowed to stand at room temperature for thirty minutes. Dilution with water gave a solid which was taken up in ether, treated with Norite and crystallized from ether–pentane as small white plates, m. p. 162–164°.

Anal. Calcd. for $C_{27}H_{40}O_5$: C, 72.9; H, 9.1. Found: C, 72.9; H, 9.2.

With an ethereal solution of diazomethane the acid yielded a **methyl ester** which crystallized from ether–pentane as white needles, m. p. 125°.

Anal. Calcd. for $C_{28}H_{44}O_5$: C, 73.0; H, 9.6. Found: C, 73.0; H, 9.3.

3-Dehydro-4-bromosarsasapogenoic Acid.—To a solution of 1.2 g. of 3-dehydrosarsasapogenoic acid in 30 cc. of acetic acid acidified with a few drops of 48% hydrobromic acid was added 2.7 cc. of 1.05 *M* bromine in acetic acid. The solution was diluted with water and the precipitated solid collected, washed with water and dried. After treatment with Norite the substance was crystallized from acetone to give white crystals, m. p. 188.5–191°.

Anal. Calcd. for $C_{27}H_{39}O_5Br$: C, 61.9; H, 7.5. Found: C, 61.4; H, 7.3.

3-Dehydro-$\Delta^{4,5}$-sarsasapogenoic Acid.—A solution of 800 mg. of the 3-dehydro-4-bromo acid in 20 cc. of dry pyridine was refluxed for six hours. The solution was poured into an excess of dilute sulfuric acid and the precipitated solid taken up in ether. The material was crystallized from acetone–ether as white plates, m. p. 199–201°.

Anal. Calcd. for $C_{27}H_{38}O_5$: C, 73.25; H, 8.7. Found: C, 73.4; H, 8.5.

Oxidation of Sarsasapogenoic Acid Acetate.—A solution of 5 g. of chromic anhydride in 30 cc. of 80% acetic acid was added dropwise with stirring over a period of ninety minutes to a solution of 2.5 g. of sarsasapogenoic acid acetate in 60 cc. of glacial acetic acid at 80–85°. The stirring and heating were continued for an additional two hours after which the mixture was evaporated *in vacuo* to 40 cc. The residue was diluted with water and extracted with ether. The ethereal extract, after thorough washing with water, was washed with 3% sodium hydroxide solution. Evaporation of the remaining ethereal extract gave an insignificant amount of neutral material which was not investigated further.

The sodium hydroxide extract was warmed on the steam-bath for fifteen minutes to hydrolyze any remaining acetates. The solution was then cooled, acidified with hydrochloric acid and the precipitated gum extracted with ether. The ethereal extract was washed with water and the ether allowed to evaporate to a volume of 20 cc. at room temperature over a period of three days. At the end of this time compact white crystals separated. These were collected, washed with ether and crystallized from methanol–ether to give a product, m. p. 287° dec. This gave no depression with an authentic sample of the C_{22} keto acid previously described.[7]

Anal. Calcd. for $C_{22}H_{34}O_4$: C, 72.9; H, 9.5. Found: C, 72.5; H, 9.5.

When shaken with hydrogen (3 atm.) and Adams catalyst in ethanol solution the keto acid yielded a neutral product, m. p. 199–201°. This gave no depression with an authentic sample of the hydroxy lactone of sarsasapogenin.

Anhydrosarsasapogenoic Acid.[12]—A solution of 500 mg. of sarsasapogenoic acid in 5 cc. of ethanol and 10 cc. of 30% aqueous potassium hydroxide solution was allowed to stand at room temperature for nine hours. The solution was then diluted with water, acidified with hydrochloric acid and the precipitated solid taken up in ether. Evaporation of the ether yielded a product which was crystallized from ether–chloroform to give compact white crystals (150 mg.), m. p. 242–244° dec.

Anal. Calcd. for $C_{27}H_{40}O_4$: C, 75.7; H, 9.4. Found: C, 75.4, 75.3; H, 9.2, 9.4.

Catalytic hydrogenation of the anhydro acid in ethanol with Adams catalyst yielded **tetrahydroanhydrosarsasapogenoic acid,**[12] m. p. 179–181°. In another preparation the acid was obtained as white needles, m. p. 194–196°. This gave no depression with the lower melting product.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 75.0; H, 10.25. Found: C, 74.8; H, 10.1.

When anhydrosarsasapogenoic acid was refluxed with semicarbazide hydrochloride and sodium acetate in 85% ethanol solution for one hour the acid was recovered unchanged. Anhydrosarsasapogenoic acid was also recovered unchanged after refluxing for fourteen hours with aluminum isopropylate and dry isopropyl alcohol.

Anhydrosarsasapogenoic acid was also prepared as described by Fieser and Jacobsen.[1] The filtrate remaining after removal of the anhydro acid yielded a relatively soluble isomeric acid, which crystallized from ethyl acetate–ether as compact white crystals, m. p. 181–184° dec. (gas). The yield was less than that of the anhydro acid.

Anal. Calcd. for $C_{27}H_{40}O_4$: C, 75.7; H, 9.4. Found: C, 75.4; H, 9.4.

A mixture of 500 mg. of this isomeric acid, 60 cc. of 95% ethanol, 2 cc. of water, and 200 mg. of sodium hydroxide was refluxed for two hours. The product was worked up as described for anhydrosarsasapogenoic acid to yield 200 mg. of compact white crystals, m. p. 241–243°. This gave no depression with anhydrosarsasapogenoic acid.

Attempts to prepare a crystalline acetate, methyl ester, or methyl ester acetate of the isomeric acid were unsuccessful. The acid readily reacted with alkaline potassium permanganate at 0°, but no crystalline products were obtained. Catalytic hydrogenation in ether–ethanol at three atmospheres pressure gave a non-crystalline product.

Dibasic Acid.[12]—The dibasic acid was prepared as described by Fieser and Jacobsen.[3]

Anal. Calcd. for $C_{27}H_{40}O_7$: C, 68.04; H, 8.46. Calcd. for $C_{27}H_{42}O_7$: C, 67.74; H, 8.84. Found: C, 67.40, 67.68; H, 8.94, 8.80.

An attempt to prepare a crystalline acetate by heating with acetic anhydride was unsuccessful.

The acid appears to be altered by treatment with periodic acid in methanol solution at room temperature for eighteen hours but no crystalline products were isolated even after sublimation in high vacuum. Treatment of the dibasic acid with chromic anhydride at 20° for fifteen hours in acetic acid gave a gum which did not crystallize even after sublimation in high vacuum.

The acid was recovered unchanged after treatment with semicarbazide acetate under the usual conditions.

When subjected to catalytic hydrogenation in ethanol–ether with Adams catalyst at 3 atmospheres pressure for fourteen hours the acid was recovered unchanged. Hydrogenation in ethanol acidified with hydrochloric acid with Adams catalyst at 3 atmospheres pressure for twenty-four hours gave a sirup which could not be crystallized.

The acid gave a **dimethyl ester,**[12] m. p. 161–162°.

Anal. Calcd. for $C_{29}H_{44}O_7$: C, 69.0; H, 8.79. Calcd. for $C_{29}H_{46}O_7$: C, 68.73; H, 9.15. Found: C, 68.63, 68.58; H, 9.20, 9.21.

Treatment of the dimethyl ester with boiling acetic anhydride for twenty minutes gave a product which was crystallized from ether–pentane to give long white needles of the **dimethyl ester acetate,** m. p. 158–160°.

Anal. Calcd. for $C_{31}H_{46}O_8$: C, 68.10; H, 8.47. Calcd. for $C_{31}H_{48}O_8$: C, 67.85; H, 9.01. Found: C, 67.74, 67.93; H, 8.93, 8.91.

C_{27} Neutral Oxidation Product from Sarsasapogenin.—The neutral fraction obtained in the chromic anhydride oxidation of sarsasapogenin acetate was crystallized from acetone to give white needles, m. p. 162–164°, of a **neutral acetate.**[12]

Anal. Calcd. for $C_{29}H_{44}O_5$: C, 73.65; H, 9.4. Calcd. for $C_{29}H_{46}O_5$: C, 73.4; H, 9.8. Found: C, 73.2; H, 9.7.

Hydrolysis of this product with an excess of ethanolic potassium hydroxide gave the **3-hydroxy compound**[12] which crystallized from acetone as small white plates, m. p. 215–217°.

Anal. Calcd. for $C_{27}H_{42}O_4$: C, 75.3; H, 9.85. Calcd. for $C_{27}H_{44}O_4$: C, 74.9; H, 10.2. Found: C, 75.6, 75.7; H, 10.0, 10.1.

The neutral acetate when treated with semicarbazide hydrochloride under the usual conditions gave a **semicarbazone** which crystallized from acetone as small white needles, m. p. 249–251° dec.

Anal. Calcd. for $C_{30}H_{47}O_5N_3$: C, 68.0; H, 9.0; N, 7.9. Calcd. for $C_{30}H_{49}O_5N_3$: C, 67.75; H, 9.3; N, 7.9. Found: C, 67.5, 67.5; H, 8.9, 8.7; N, 7.6.

Reduction of C_{27} Neutral Oxidation Product. (a) **By Catalytic Hydrogenation.**—A mixture of 1.5 g. of the neutral acetate, 1 g. of Adams catalyst, 100 cc. of glacial acetic acid and 30 cc. of 99% ethanol was shaken with hydrogen at 3 atmospheres pressure at 25° for fourteen hours. The mixture was filtered and the filtrate diluted with water, the precipitated solid was extracted with ether and the ethereal extract washed with sodium carbonate solution. The ether was evaporated and the residue refluxed for twenty minutes with an excess of ethanolic potassium hydroxide. The product was crystallized from methanol–ethanol as white plates, m. p. 215–217°.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 74.9; H, 10.3. Calcd. for $C_{27}H_{46}O_4$: C, 74.6; H, 10.7. Calcd. for $C_{27}H_{48}O_4$: C, 74.26; H, 11.1. Found: C, 74.6, 74.4; H, 10.7, 10.9.

The neutral acetate was recovered unchanged after shaking with Adams catalyst and hydrogen at 3 atmospheres pressure for six hours at 28° in ethanol solution.

(b) **By Clemmensen Reduction.**—To a boiling solution of 300 mg. of the neutral acetate in 100 cc. of 95% ethanol with 20 g. of amalgamated 20-mesh zinc was added 16 cc. of concentrated hydrochloric acid over a period of nine hours. The solution was decanted into water and the precipitated solid extracted with ether. The ether was evaporated and the residue crystallized from acetone–ethyl acetate to give 200 mg. of compact white crystals, m. p. 191–193°. This gave no depression with a sample of tetrahydrosarsasapogenin.

Anal. Calcd. for $C_{27}H_{48}O_3$: C, 77.1; H, 11.5. Found: C, 76.8; H, 11.5.

Summary

The structure of sarsasapogenoic acid and its transformation products is discussed in terms of the ketone spiro acetal structure for the sapogenin side chain.

Structure of Gossypol. XXII. Gossypol Ethers and their Reduction Products[1]

BY ROGER ADAMS AND W. R. DIAL[2]

Gossypol hexamethyl ether[3] was one of the most important gossypol derivatives since it served as the compound from which many significant degradation products were obtained.[4] It was assigned the structure I on the basis of its reactions with a drop of sulfuric acid in acetic acid to give gossypol dimethyl ether (II), with phenylhydrazine in glacial acetic acid to give a phenylhydrazone of a gossypol tetramethyl ether (III), which on treatment with methanolic or ethanolic hydrogen chloride reverted to gossypol hexamethyl ether (I) or gossypol tetramethyl diethyl ether (IV).[5]

The study of gossypol ethers has now been extended to a variety of others. Gossypol tetramethyl ether (V)[3] has been ethylated to gossypol diethyl tetramethyl ether (VI), isomeric with IV. This same ether (VI) was also prepared by methylation of gossypol diethyl ether (VII).[5]

The new ether (VI) formed a phenylhydrazone of gossypol dimethyl diethyl ether which with methanolic hydrogen chloride gave back VI or

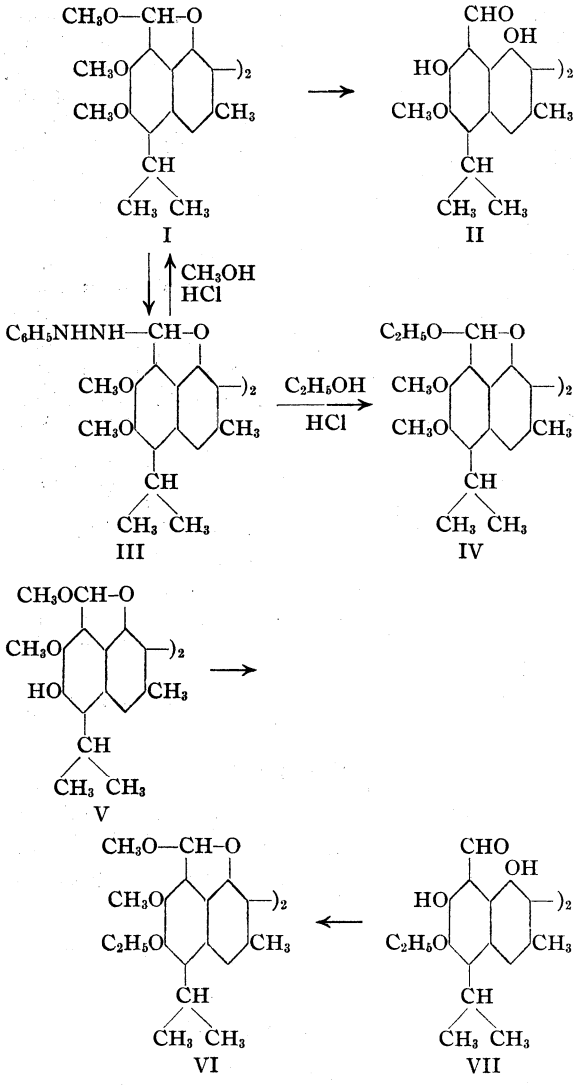
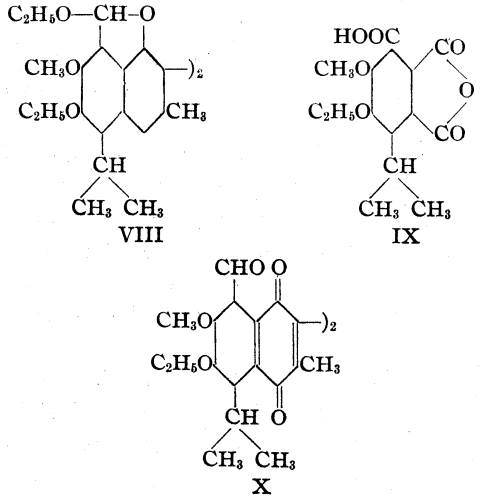
(5) Adams and Geissman, *ibid.*, **60**, 2166 (1938).

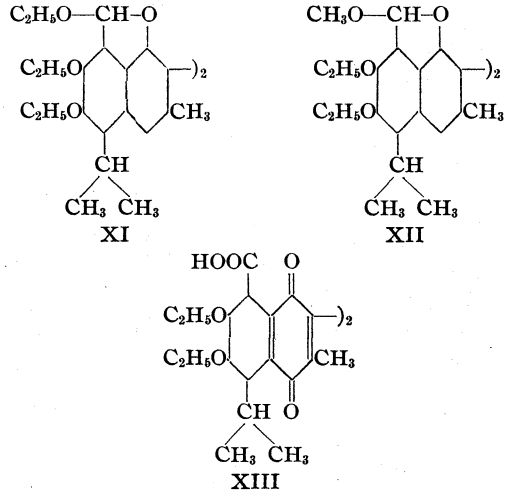


with ethanolic hydrogen chloride gave gossypol tetraethyl dimethyl ether (VIII).

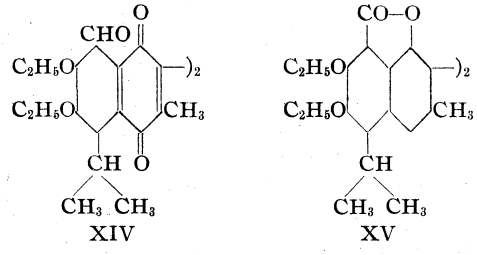


The ether (VI) undergoes reactions similar to gossypol hexamethyl ether. It was dealkylated with a drop of sulfuric in acetic acid[5] to gossypol diethyl ether (VII), and was oxidized with dilute nitric acid to a gossic acid analog (IX)[6] or by chromic acid to a gossypolone derivative (X).

Gossypol hexaethyl ether (XI)[7] was also converted into a phenylhydrazine derivative which on treatment with methanolic hydrogen chloride gave gossypol tetraethyl dimethyl ether (XII) and with ethanolic hydrogen chloride the original ether (XI)



By action of dilute nitric acid on XI, a gossypolonic acid derivative (XIII) resulted[6]; by action of chromic acid XI was converted to gossypolone tetraethyl ether (XIV) and gossylic acid lactone tetraethyl ether (XV).[6]



Gossypol hexamethyl ether was unaffected by hydrogen in the presence of platinum catalyst if ethanol or ethyl acetate was used as a solvent, but in acetic acid it was reduced to a new derivative which has been called desoxygossypol tetramethyl ether and has been assigned formula XVI. Formation of such a derivative may be by direct hydrogenolysis of the two acetal methoxyls in gossypol hexamethyl ether or more likely by hy-

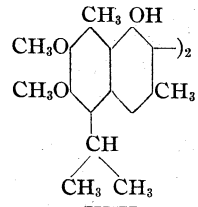
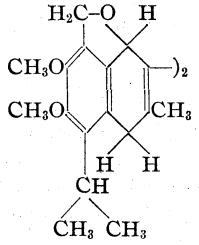
XVI



XVII



XVIII

drolysis of the acetal methoxyls, reduction of the two aldehyde groups and subsequent loss of water.

The analyses for this reduction product were more consistent with formula XVII or XVIII but the chemical reactions excluded the latter two possibilities. This substance may be of the nature of gossypol itself for which consistent analyses for its molecular formula, $C_{30}H_{30}O_8$, were practically impossible to obtain.

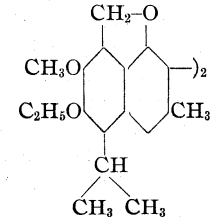
The evidence for structure XVI and against XVII is as follows. The compound gave no color with ferric chloride; it was insoluble in methanolic alkali; it could not be methylated or acetylated; it gave no phenylhydrazine derivative; bromination, nitration, Friedel and Crafts reactions and dealkylation with a drop of sulfuric acid in acetic acid gave no definite products. Neither this product nor gossypol hexamethyl ether with diazotized aniline gave a color; on the other hand, gossylic acid tetramethyl ether which has a free hydroxyl in the same position as is shown in compound XVII did give a color. Diazotized 2,4-dinitroaniline gave a color with all three products. Meyer[8] has shown that diazotized aniline will couple only with phenols and not with phenol ethers whereas diazotized dinitroaniline will couple with both phenols and their ethers. This is evidence for an ether linkage (XVI) in desoxygossypol tetramethyl ether and makes formulas XVII or XVIII unlikely. The infrared absorption spectra[9] of XVI in carbon tetrachloride indicated that no phenolic or alcoholic hydroxyl was present.

(8) Meyer, Isschick and Schlosser, *Ber.*, **47**, 1741 (1914).

(9) The infrared absorption spectra were determined by G. W. McMillan of this Laboratory, to whom we are indebted.

Desoxygossypol tetramethyl ether gave on oxidation with dilute nitric acid gossic acid[6] and with chromic anhydride gossypolone tetramethyl ether. These are the same products as are obtained from gossypol tetramethyl ether with the same reagents.

The gossypol diethyl tetramethyl ether (VI) was reduced under similar conditions with formation of desoxygossypol diethyl dimethyl ether (XIX).



XIX

Gossypol tetramethyl ether (V) was reduced also but no crystalline product was isolated. The crude product must have been the expected desoxy compound for on methylation, crystalline desoxygossypol tetramethyl ether (XVI), and on ethylation, crystalline desoxygossypol diethyl dimethyl ether (XVIII), resulted.

Compounds with this type of ether linkage across the *peri* positions in naphthalene are rare and no very simple compounds of this type have been described with which to compare properties.

Experimental

Gossypol Diethyl Tetramethyl Ether

(a) **Ethylation of Gossypol Tetramethyl Ether.**—A solution of 5.0 g. of recrystallized gossypol tetramethyl ether in a warm mixture of 13 cc. of diethyl sulfate and 22 cc. of benzene was treated with 33 cc. of 20% ethanolic potassium hydroxide added in small portions. The solution was heated for fifteen minutes on the steam-bath and then treated with an additional 13 cc. of diethyl sulfate and 20% ethanolic potassium hydroxide was added until the reaction mixture was alkaline. This was then evaporated to a sludge on the steam-bath with stirring, ethanol being added from time to time until most of the benzene had been removed. The sludge was then cooled and filtered. The solid was washed with ethanol until the filtrates were colorless and then thoroughly with water to remove inorganic salts. The residue (4.0 g.) of gossypol diethyl tetramethyl ether was purified by recrystallizing several times from acetone–methanol mixture and then from benzene–methanol mixture; white microcrystalline powder, m. p. 271–272° (corr.).

Anal. Calcd. for $C_{38}H_{46}O_8$: C, 72.36; H, 7.35. Found: C, 71.99; H, 7.31.

The compound gave an orange color in concentrated sulfuric acid and no color with ferric chloride.

When recrystallized from acetone–methanol mixture alone, the melting point could not be raised above 228–

229° (corr.). The white prisms thus obtained gave *no* melting point depression when mixed in various proportions with the 271–272° form.

Anal. Calcd. for $C_{38}H_{46}O_8$: C, 72.36; H, 7.35. Found: C, 72.47; H, 7.55.

(b) **Methylation of Gossypol Diethyl Ether.**—To a solution of 0.15 g. of gossypol diethyl ether in a mixture of 2 cc. of methanol and 2 cc. of dimethyl sulfate, 3 cc. of 10% methanolic potassium hydroxide was added slowly. The mixture was allowed to stand at room temperature for thirty-six hours and then filtered. The precipitate was filtered and washed with methanol, then with water. The product (0.14 g.) was purified as previously described and gave a crystalline powder, m. p. 271–272° (corr.).

Gossypol Diethyl Ether: Demethylation of Gossypol Diethyl Tetramethyl Ether.—To a solution of 1.0 g. of gossypol diethyl tetramethyl ether (272° form) in 40 cc. of hot glacial acetic acid was added 10 cc. of acetic acid containing ten drops of concentrated sulfuric acid. The solution turned dark red and after heating for fifteen minutes on a steam-bath, it was diluted with 20 cc. of water and cooled. The crude yellow product weighed 0.9 g. It was purified by recrystallization from benzene; yellow needles, m. p. 195–196° (corr.). This product proved to be identical with the diethyl ether of gossypol prepared previously by deëthylation of gossypol hexaethyl ether.[7]

Phenylhydrazone from Gossypol Diethyl Ether.—This was prepared by adding 0.5 cc. of phenylhydrazine to a hot solution of 0.1 g. of gossypol diethyl ether in 3 cc. of glacial acetic acid. After warming for thirty minutes on the steam cone, slender yellow needles of phenylhydrazone separated. These were filtered and washed with methanol; yield, 0.1 g., m. p. 260–261°(corr.). No satisfactory method could be found for the recrystallization of this material.

Anal. Calcd. for $C_{46}H_{50}O_6N_4$: C, 73.22; H, 6.68; N, 7.43. Found: C, 73.07; H, 6.64; N, 7.59.

The same product was obtained from the gossypol diethyl ether formed from gossypol hexaethyl ether.

The phenylhydrazone gives an orange-yellow color in concentrated sulfuric acid and a red color with ferric chloride which changes to orange upon standing. It is insoluble in cold 10% aqueous alkali but soluble in 10% methanolic alkali.

Phenylhydrazone from Gossypol Diethyl Tetramethyl Ether.—A solution of 0.1 g. of the 271–272° form of the above ether in 10 cc. of glacial acetic acid was warmed with 0.8 cc. of phenylhydrazine for thirty minutes on a steam-bath. Upon scratching the side of the flask, 0.95 g. of product separated. After recrystallization from benzene and petroleum ether (b. p. 60–110°), yellow prisms formed, m. p. 268–269° (corr.).

Anal. Calcd. for $C_{48}H_{54}O_6N_4$: C, 73.63; H, 6.95; N, 7.16. Found: C, 73.34; H, 6.71; N, 7.16, 7.25.

The phenylhydrazone gave an orange-yellow color in concentrated sulfuric acid and gave no color with ferric chloride.

The phenylhydrazone prepared in exactly the same manner from the 228–229° form of the ether melted at 268–269° (corr.) and gave no depression when mixed with the phenylhydrazone from the 271–272° form.

The phenylhydrazone can be reconverted to the gossypol diethyl tetramethyl ether by the action of methanolic hydrogen chloride. A suspension of 1.0 g. of the phenylhydrazone in 40 cc. of absolute methanol was treated with dry hydrogen chloride until all of the phenylhydrazone went into solution. The solution was allowed to stand overnight, whereupon the crystalline ether separated. It weighed 0.7 g. and after several recrystallizations from benzene–methanol mixture, melted at 271–272° (corr.) and gave no depression in melting point when mixed with the ether obtained by the ethylation of gossypol tetramethyl ether.

Gossypol Dimethyl Tetraethyl Ether by the Action of Ethanolic Hydrogen Chloride on the Phenylhydrazone from Gossypol Diethyl Tetramethyl Ether.—The same procedure as in the methanolysis was used except for the replacement of methanol by ethanol. After standing overnight 0.75 g. of product separated which was purified by recrystallization from acetone–ethanol mixture; white prisms, m. p. 241–242° (corr.).

Anal. Calcd. for $C_{40}H_{50}O_8$: C, 72.92; H, 7.65. Found: C, 73.19; H, 7.51.

The ether gives an orange color in concentrated sulfuric acid and no color in ferric chloride.

Norgossic Acid Ethyl Methyl Ether: 1-Methoxy-2-ethoxy-3-isopropyl-4,5,6-benzene Tricarboxylic Acid Anhydride-4,5.—Gossypol diethyl tetramethyl ether was treated with dilute nitric acid exactly as was described for the formation of gossic acid from gossypol hexamethyl ether.[5]

The insoluble residue could not be purified but the acid-soluble material amounted to 0.5 g. of crude acid from 2.0 g. of diethyl tetramethyl ether. Purified from toluene, white needles were obtained, m. p. 178–179° (corr.).

Anal. Calcd. for $C_{15}H_{16}O_7$: C, 58.44; H, 5.23. Found: C, 58.39; H, 5.27.

The acid gave no color in concentrated sulfuric acid and no color in ferric chloride.

Gossypolone Diethyl Dimethyl Ether.—To a solution of 2.0 g. of recrystallized gossypol diethyl tetramethyl ether in 50 cc. of boiling glacial acetic acid was added in one portion 10 cc. of a 10% aqueous solution of chromic anhydride. The mixture was allowed to boil for one minute and then poured onto a mixture of 100 g. of ice and 50 cc. of water. The yellow precipitate was filtered with suction, washed with water and air dried. The product was added to 50 cc. of hot methanol and upon cooling yellow platelets separated; yield, 0.8 g. After purification by the recrystallization from methanol, it melted at 185–186° (corr.).

Anal. Calcd. for $C_{36}H_{38}O_{10}$: C, 68.56; H, 6.07. Found: C, 68.20; H, 6.02.

The product gave a brown color in concentrated sulfuric acid which changed to orange upon standing for thirty minutes. It gave no color with ferric chloride.

In this oxidation no evidence of lactone formation was noted.

Phenylhydrazone from Gossypol Hexaethyl Ether.—A solution of 0.1 g. of gossypol hexaethyl ether in 4 cc. of hot glacial acetic acid was treated with 0.5 cc. of phenylhydrazine and the mixture was heated on the steam-bath

for thirty minutes. Upon cooling 0.08 g. of product separated; yellow needles from benzene–petroleum ether (b. p. 60–110°), m. p. 241–242° (corr.).

Anal. Calcd. for $C_{50}H_{58}O_6N_4$: C, 74.05; H, 7.21; N, 6.91. Found: C, 73.91; H, 7.01; N, 6.95.

The product gave an orange color with concentrated sulfuric acid and no color with ferric chloride.

The action of ethanolic hydrogen chloride on this product reconverted it to gossypol hexaethyl ether, m. p. 211–212° (corr.).

Gossypol Tetraethyl Dimethyl Ether.—By treatment of the phenylhydrazone from gossypol hexaethyl ether with methanolic hydrogen chloride in the same manner as described for other phenylhydrazones, 1.5 g. of product was obtained from 2 g. of starting material. It formed white crystals from acetone–methanol, m. p. 206–207° (corr.).

Anal. Calcd. for $C_{40}H_{50}O_8$: C, 72.92; H, 7.65. Found: C, 73.13; H, 7.77.

The product gave an orange color in concentrated sulfuric acid and no color with ferric chloride.

Gossypolonic Acid Tetraethyl Ether.—A suspension of 2.0 g. of gossypol hexaethyl ether in a mixture of 200 cc. of water and 50 cc. of concentrated nitric acid (sp. gr. 1.42) was refluxed for twelve hours. After this time a yellow solid remained in suspension. After cooling the yellow insoluble material was filtered and dissolved in 10% aqueous sodium bicarbonate solution. The bicarbonate solution, after extraction with ether, was filtered and acidified with dilute sulfuric acid. The product weighed 0.5 g. Purified from acetone–methanol mixture, it formed yellow flakes, m. p. 272–273° (corr.).

Anal. Calcd. for $C_{38}H_{42}O_{12}$: C, 66.07; H, 6.13. Found: C, 66.04; H, 6.27.

The product gave a maroon color in concentrated sulfuric acid which changed to brown on standing. It gave no color with ferric chloride. It was soluble in aqueous alkali giving a yellow solution.

The nitric acid filtrate was worked up as described for the dilute nitric acid oxidation of gossypol hexamethyl ether, but no crystalline acid corresponding to gossic acid could be isolated.

Gossypolone Tetraethyl Ether and Gossylic Acid Lactone Tetraethyl Ether.—To a solution of 2.0 g. of gossypol hexaethyl ether in 50 cc. of boiling glacial acetic acid was added 10 cc. of a 10% aqueous solution of chromic anhydride. The mixture was boiled for a minute and then poured onto 100 g. of ice. The insoluble product was filtered and dissolved in 100 cc. of boiling methanol. A yellow insoluble product (0.19 g.) separated almost immediately and proved to be gossylic acid lactone tetraethyl ether. It was purified by dissolving in 8 cc. of boiling acetic anhydride to which was then added slowly a mixture of 3 cc. of glacial acetic acid and 1.5 cc. of water. Upon scratching the walls of the flask, crystals separated. After repetition of this procedure, a white crystalline powder resulted, m. p. 244–245° (corr.).

The methanolic filtrate from the crude gossylic acid lactone tetraethyl ether was concentrated to about 30 cc. and cooled. The precipitate of gossypolone tetraethyl ether (0.5 g.) was purified from methanol; yellow plates, m. p. 146–147° (corr.).

Anal. (Lactone, m. p. 244–245°.) Calcd. for $C_{38}H_{42}O_8$: C, 72.82; H, 6.76. Found: C, 72.54; H, 6.88. (Gossypolone, m. p. 146–147°.) Calcd. for $C_{38}H_{42}O_{10}$: C, 69.28; H, 6.43. Found: C, 69.40; H, 6.55.

The gossypolone gave a brown color in concentrated sulfuric acid and the lactone a yellow color.

The lactone was insoluble in warm aqueous alkali but soluble in warm alcoholic alkali.

Dinitrogossylic Acid Lactone Tetraethyl Ether.—To a solution of 0.08 g. of the gossylic acid lactone tetraethyl ether in 10 cc. of hot glacial acetic acid, 1 cc. of concentrated nitric acid was added. A clear brown solution resulted which was boiled and water added dropwise until crystallization started. After cooling, the product which separated was recrystallized from dilute acetic acid; pale yellow needles, m. p. 266–267° (corr.).

Anal. Calcd. for $C_{38}H_{40}N_2O_6$: N, 3.91. Found: N, 3.72.

Reduction of Gossypol Hexamethyl Ether: Desoxygossypol Tetramethyl Ether.—A solution of 2.0 g. of pure gossypol hexamethyl ether (m. p. 223–225°) in 200 cc. of warm (50°) glacial acetic acid was placed in a reduction bottle together with 0.1 g. of platinum oxide catalyst and shaken with hydrogen at room temperature under three atmospheres pressure. After four hours, the solution was filtered to remove the platinum and the filtrate was poured into 800 cc. of water. The white flocculent precipitate was filtered, washed with water until free of acid and dried in air. The 1.9 g. of white amorphous product was triturated with warm methanol. A gummy mass was at first obtained which became crystalline upon standing for a few minutes. The methanol-insoluble material was filtered and weighed 1.5 g. After recrystallization from acetone–methanol mixture, it melted at 261–263° (corr.), with decomposition.

Anal. Calcd. for $C_{34}H_{38}O_6$: C, 75.28; H, 7.01; 4 OCH_3, 22.8; mol. wt., 542. Calcd. for $C_{34}H_{42}O_6$: C, 74.73; H, 7.69; 4OCH_3, 22.7; mol. wt., 546. Found: C, 74.75, 74.49, 74.31, 75.08, 74.44, 74.90, 74.65; H, 7.49, 7.37, 7.56, 7.46, 7.39, 7.42, 7.29; OCH_3, 26.0, 26.8; mol. wt. (b. p. elev., $CHCl_3$), 529.

The compound is insoluble in alkali (aqueous or alcoholic) and gives no ferric chloride color and no color with Dimroth's pyroboroacetate reagent. It gives a brilliant green color with concentrated sulfuric acid.

The compound is soluble in ether, benzene and acetone. It is slightly soluble in acetic acid or methanol and insoluble in ligroin.

Attempts to reduce gossypol hexamethyl ether in alcohol or ethyl acetate resulted in the recovery of the unchanged ether.

Phenylhydrazine, acetic anhydride and sodium acetate, pyridine and acetic anhydride, methanolic dimethyl sulfate and alkali, all resulted in recovery of unchanged starting material.

Attempted demethylation with glacial acetic acid and a drop of sulfuric acid gave no results.

Nitration with various strengths of nitric acid gave only amorphous products. The same was true of bromine, attempted Friedel and Crafts reactions with acetyl chloride, and of hydriodic acid.

Aniline and 2,4-dinitroaniline were diazotized in glacial acetic acid with butyl nitrite and sulfuric acid according to the method of Meyer.[8]

Each of the solid diazonium sulfates was dissolved in 6 parts of cold glacial acetic acid and 1 cc. of each of these solutions was added to a solution of 15 mg. of the compound to be tested in 5 cc. of glacial acetic acid. Diazotized aniline gave no color with gossypol hexamethyl ether or desoxygossypol tetramethyl ether; it did give a color with gossylic acid tetramethyl ether. Diazotized 2,4-dinitroaniline, on the other hand, gave a color with all three products.

Oxidation of Desoxygossypol Tetramethyl Ether to Gossic Acid—A suspension of 0.18 g. of desoxygossypol tetramethyl ether in a mixture of 15 cc. of water and 5 cc. of concentrated nitric acid (sp. gr. 1.42) was refluxed for fourteen hours whereupon all the material went into solution. After cooling, about 30 mg. of insoluble acidic material was filtered. This could not be purified. The dilute nitric acid filtrate was neutralized with sodium carbonate, then acidified to congo red with sulfuric acid, saturated with sodium chloride and extracted several times with ether. The ether extracts were dried with anhydrous magnesium sulfate and then petroleum ether (b. p. 60–110°) added. The ethyl ether was evaporated whereupon brown needles separated from the petroleum ether. The product was purified from toluene, yield 0.08 g. Upon sublimation (2 mm. at 180°) and then recrystallization from toluene, white needles were obtained, m. p. 185–186° (corr.). Mixed with an authentic sample of gossic acid the melting point was 185–186° (corr.).

Anal. Calcd. for $C_{14}H_{14}O_7$: C, 57.15; H, 4.76. Found: C, 57.27; H, 4.78.

Oxidation of Desoxygossypol Tetramethyl Ether to Gossypolone Tetramethyl Ether.—To a solution of 0.21 g. of desoxygossypol tetramethyl ether in 15 cc. of boiling glacial acetic acid was added rapidly with vigorous stirring 2 cc. of 10% aqueous solution of chromic anhydride and the mixture was allowed to boil for one minute. It was then poured onto a mixture of 30 g. of ice and 10 cc. of water. The product was filtered with suction and the yellow residue was washed with water and air dried. This was added to 10 cc. of warm methanol and the gummy material first formed gradually became crystalline. Recrystallized from methanol, 0.1 g. of yellow plates, m. p. 154–155° (corr.), was obtained. Mixed with an authentic sample of gossypolone tetramethyl ether the melting point was 154–156° (corr.).

Anal. Calcd. for $C_{34}H_{34}O_{10}$: C, 67.77; H, 5.64. Found: C, 67.73; H, 5.81.

Reduction of Gossypol Tetramethyl Diethyl Ether to Desoxygossypol Tetramethyl Ether.—Gossypol tetramethyl diethyl ether[5] which has two acetal ethoxy groups was reduced in the same manner as described for the hexamethyl ether. Upon recrystallization of the product from acetone–methanol, white plates were obtained, m. p. 261–263° (corr.). Mixed with the product obtained by the reduction of gossypol hexamethyl ether, it melted at 261–263° (corr.).

Anal. Calcd. for $C_{34}H_{38}O_6$: C, 75.28; H, 7.01. Found: C, 74.62; H, 7.57.

Reduction of Gossypol Diethyl Tetramethyl Ether: Desoxygossypol Diethyl Dimethyl Ether.—Gossypol diethyl tetramethyl ether[5] which has two methoxy groups as acetal linkages was reduced as previously described for the hexamethyl ether. From 1.2 g. of starting material, 0.6 g. of desoxy compound was obtained; white plates from acetone–methanol mixture, m. p. 240–242° (corr.).

Anal. Calcd. for $C_{36}H_{42}O_6$: C, 75.76; H, 7.42. Found: C, 75.28; H, 7.58.

Reduction of Gossypol Tetramethyl Ether: Desoxygossypol Dimethyl Ether.—Gossypol tetramethyl ether[3] which has two acetal methoxyls was reduced in the same manner as described for the hexamethyl ether but no crystalline material was obtained. The crude tan amorphous desoxygossypol dimethyl ether thus obtained weighed 1.5 g. and had a very indefinite melting point. That this material was a reduction product similar to that obtained by the reduction of gossypol hexamethyl ether was demonstrated by methylation and ethylation.

A solution of 1.5 g. of crude product in 20 cc. of methanol was treated with 5 cc. of dimethyl sulfate. To this mixture was added 16 cc. of a 20% solution of potassium hydroxide in methanol and then heated on a steam-bath for five minutes. Another 5 cc. of methyl sulfate and 16 cc. of 20% methanolic potassium hydroxide was added and the solution evaporated with stirring to a thick sludge. About 20 cc. of methanol was added and the mixture was cooled and filtered. After washing with methanol until the washings were colorless and washing with water to remove potassium salts, 0.5 g. of a cream-colored crystalline material remained on the filter. This after four recrystallizations from acetone–methanol mixture melted at 262–263° (corr.). The white platelets thus obtained proved identical with the desoxygossypol tetramethyl ether already described, mixed m. p. 262–263° (corr.).

Anal. Calcd. for $C_{34}H_{38}O_6$: C, 75.28; H, 7.01. Found: C, 74.67; H, 7.01.

By treatment of the amorphous desoxygossypol dimethyl ether with diethyl sulfate and 20% potassium hydroxide in ethyl alcohol desoxygossypol diethyl dimethyl ether was obtained. It formed white crystals, m. p. 240–242° (corr.) and gave no depression in the melting point when mixed with the sample prepared by the reduction of gossypol diethyl tetramethyl ether.

Summary

1. A number of new ethers of gossypol are described—two gossypol tetraethyl dimethyl ethers and gossypol diethyl tetramethyl ether. These had properties similar to gossypol hexamethyl ether. They could be oxidized to analogous products.

2. Gossypol hexamethyl ether was reduced in glacial acetic acid with hydrogen to desoxygossypol tetramethyl ether and an analogous compound was obtained by the reduction of gossypol diethyl tetramethyl ether. The desoxy compounds oxidize to products similar to those from gossypol hexamethyl ether.

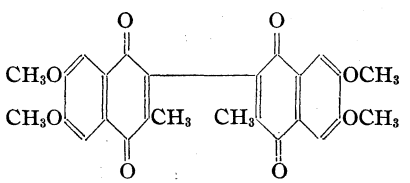
Structure of Gossypol. XXIII. Attempts to Prepare Desapogossypolone Tetramethyl Ether. Condensation of Hexadiene-2,4 with Dibenzoylethylene[1]

BY ROGER ADAMS AND T. A. GEISSMAN

The completion of the verification of the postulated structure for gossypol is dependent either on the degradation of gossypol to a substance of known structure which will establish the positions of the methyl groups and the linkage between the naphthalene nuclei or on the synthesis of one of the supposed β,β-binaphthyl degradation products of gossypol. The former procedure has thus far met with failure. Attempts are now being made to synthesize desapogossypolone tetramethyl ether (I) and the initial series of reactions studied is described in this communication.

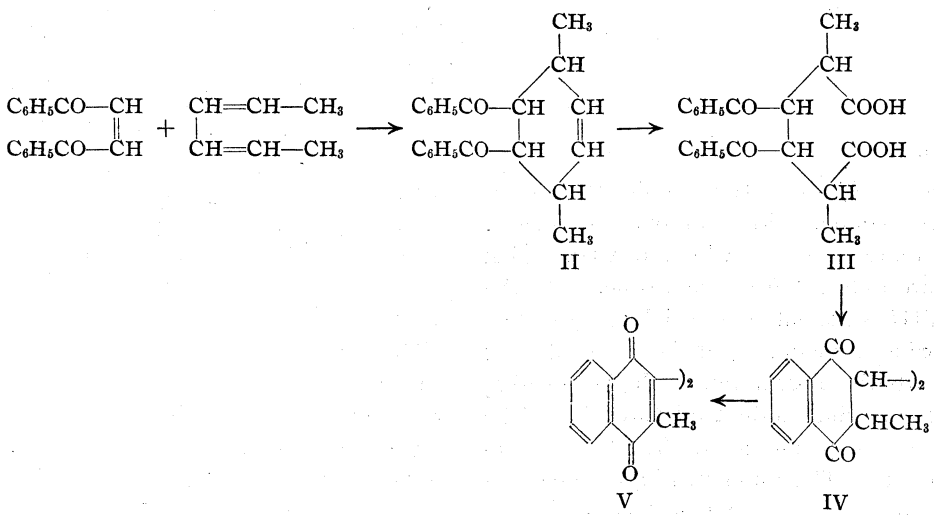


I

In order to test the feasibility of the method, the synthesis of the methoxyl-free analog of desapogossypolone tetramethyl ether was undertaken. *trans*-Dibenzoylethylene and hexadiene-2,4 were condensed to give product II. It was planned to oxidize the double bond in II to give the dibasic acid (III). This, in turn, was to be cyclicized either directly or indirectly to IV which should oxidize to the desired compound (V).

The initial reaction of the dibenzoylethylene and the diene proceeded without difficulty but all the oxidation reactions of II resulted in complete degradation of the molecule or in substances different from the dibasic acid (III) desired. A description of the results actually obtained is given here, along with a description of studies made on the conversion of the adduct (II) by methods which appear to be general for compounds of this type into the fully aromatic derivative (XIX) and the benzofuran (XVI).

The Diels–Alder reaction between hexadiene-2,4 and dibenzoylethylene results in a good yield of a mixture of two products in a ratio of 10:1. These are unquestionably *cis–trans* isomers and each was converted into a dibromide. Merely the higher melting compound, obtained in larger amounts, was further studied. It was oxidized by means of (a) ozone, (b) potassium permanganate, (c) osmium tetroxide and chlorates, and (d) by other specific reagents, such as Prévost's reagent and the action of acetates on the dibromide (XIII), but in no case were satisfactory results obtained. The conclusion drawn from these experiments was that the reactivity of the hydrogen atoms on the carbons *alpha* to the carbonyl groups was so great that these reagents did not confine their action to the double bond.



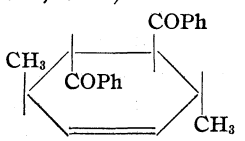
II III IV V

Upon oxidation of the adduct with monoperphthalic acid in an ether–chloroform solution,

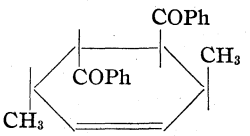
(1) For previous paper in this series see Adams and Dial, THIS JOURNAL, **61**, 2077 (1939).

a smooth consumption of one atom of oxygen was observed and the product was a fairly good yield of a mixture of two isomeric oxido compounds. Of the two oxido compounds, one could be separated easily in a pure state by virtue of its extreme insolubility in methanol, while the other was contaminated with what appeared to be a third substance and was difficult to purify.

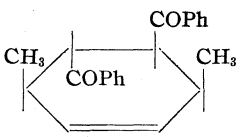
The stereochemical possibilities in these compounds may be deduced with reasonable certainty on the following considerations. Assuming that the benzoyl groups are *trans* in the adducts, the following configurations are to be expected (VI, VII, VIII).



VI

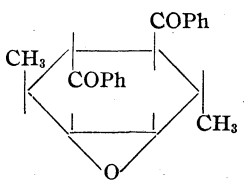


VII

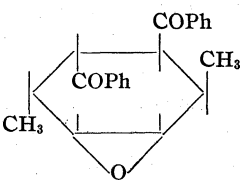


VIII

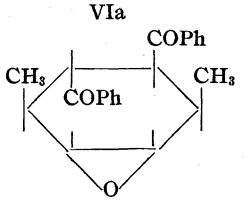
The oxido compounds derived from these three adducts would be



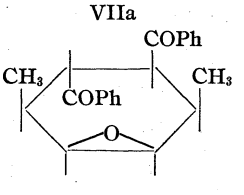
VIa



VIIa



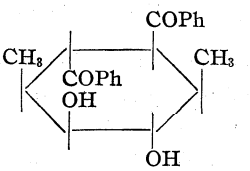
VIIIa



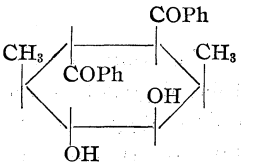
VIIIb

The symmetry of VI or VII precludes the formation of more than one oxido compound from each. These are represented by VIa and VIIa which obviously are different from each other. As the structure VIII is the only one which can give two different oxido compounds, it is assumed that this represents the more abundant higher-melting isomer in the original adduct mixture (II). The lower-melting compound must then have structure VI or VII. The lower-melting oxido compound may be assigned structure VIIIb and the higher-melting VIIIa on the basis of the relationship of the oxido group to the two methyls.

Since the formation of a glycol from an oxide leads to the *trans*-glycol, it would be expected that both VIIIa and VIIIb would give a mixture of the same two glycols (IX and X).



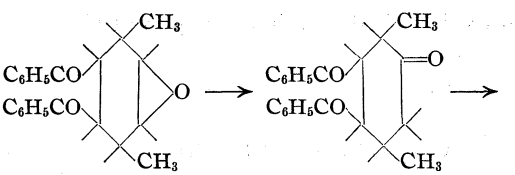
IX

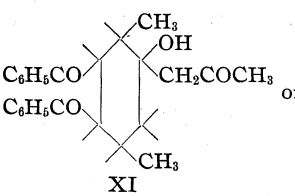


X

Upon hydrolysis of the oxides in acetone solution this was found to be the case, but different proportions of the glycols were obtained from each oxide. From the lower-melting oxide, the higher-melting glycol and from the higher-melting oxide, the lower-melting glycol predominated. The glycols had similar solubility characteristics and were difficult to separate.

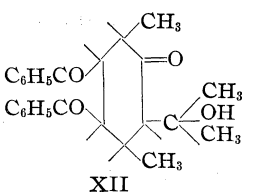
In the preparation of glycol from a low-melting fraction of oxide a third substance was isolated in one run which appeared to be an addition product of one molecule of acetone to the oxide. The structure was not determined but it may possibly be one of the following two, XI and XII, on the assumption that the glycol has rearranged to a ketone and then condensed with acetone. The structure XII is preferred since the compound does not give ketone derivatives (the benzoyl groups in other compounds of the series do not form ketone derivatives) and gives no iodoform on treatment with sodium hypobromite in dioxane solution.





XI

or

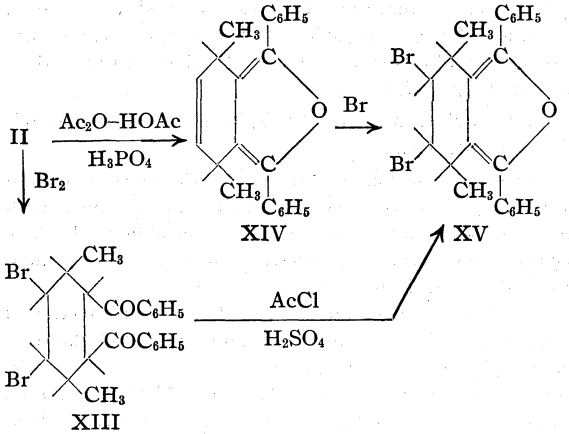


XII

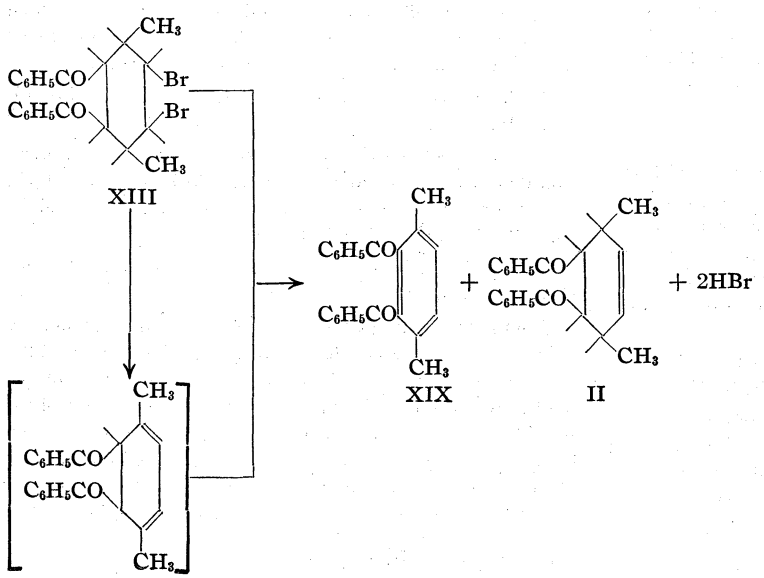
The dibromide (XIII) of the higher-melting adduct of hexadiene-2,4 and dibenzoylethylene upon treatment with sodium acetate rearranged to an isomeric dibromide, probably a stereoisomer of the original compound.

The conversion of the adduct (II) and its dibromide (XIII) into derivatives of isobenzofuran can be accomplished readily by treatment with

dehydrating agents under the proper conditions. When the adduct (II) is treated with a mixture of acetic acid, acetic anhydride and a trace of phosphoric acid it is converted smoothly into the dihydrobenzofuran derivative (XIV). The adduct dibromide (XIII) when treated with acetyl chloride containing sulfuric acid is dehydrated in good yield to the corresponding dibromo derivative (XV). Bromination of XIV under suitable conditions also yields XV.

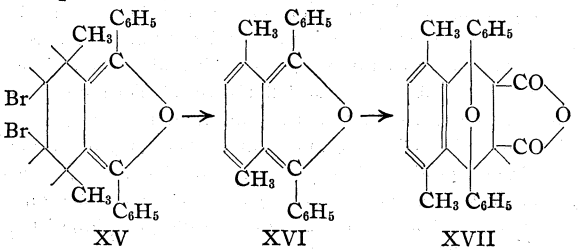


Attempts to convert the adduct (II) into the fully aromatic compound (XIX) by treatment of the dibromide (XIII) with pyridine led to the formation of a mixture of the desired benzene derivative (XIX) and the original adduct. Apparently the dihydrobenzene formed as a direct result of the removal of two molecules of hydrogen bromide from the dibromide (XIII) reacts as shown below to debrominate a molecule of the dibromide and becomes aromatized

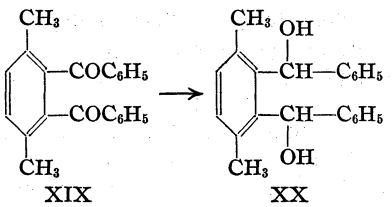


The formation of the benzene derivative (XIX) was accomplished in good yield by treatment of the dihydrobenzofuran (XIV) with two moles of bromine in the presence of sodium acetate.

The dibromotetrahydrobenzofuran (XV) was unchanged by boiling with sodium acetate in acetic acid, but on treatment with dry pyridine it was converted smoothly into the benzofuran (XVI). The latter compound reacted with maleic anhydride instantly in the cold to give the addition product (XVII).



Since other studies in this Laboratory have indicated that certain benzofurans of the type of compound XVI can be obtained by reduction of the dibenzoylbenzenes corresponding to XIX with zinc dust in alcoholic alkali, an attempt was made to form XVI from XIX in this way. None of the benzofuran (XVI) was produced, however, the product being a colorless compound which may be the *o-bis*-(α-oxybenzyl) derivative (XX)



A further study of diene additions to diaroylethylenes and their reaction products is under way.

Experimental

Preparation of Hexene-2-ol-4.—The Grignard reagent prepared from 305 g. of ethyl bromide and 64 g. of magnesium in 1500 cc. of dry ether was cooled in an ice-bath, and 160 g. of crotonaldehyde (in a little ether) was added dropwise with vigorous stirring at such a rate as to keep the solution at 15–20°. After the aldehyde was added stirring was continued for one-half hour while the solution was allowed to come to room temperature. The mixture was decomposed with iced ammonium chloride solution, the ether layer separated, and worked up in the usual manner. There was ob-

tained 188 g. (83%) of hexene-2-ol-4, b. p. 55° (15 mm.). Reiff[2] reports 85–87° (120 mm.) and 133–134° (760 mm.).

Hexadiene-2,4.—A mixture of 75 g. of hexene-2-ol-4 and 5 cc. of 48% hydrobromic acid was distilled slowly through a short column, the outlet temperature of which was maintained by controlling the rate of distillation at 85–95°. The distillate was separated from the water formed and dried over calcium chloride. It boiled at 79–83°; yield, 41 g. (67%).

This method is faster and more convenient than that described by Kyriakides.[3]

3,6-Dimethyl-4,5-dibenzoylcyclohexene-1,2 (II).—A mixture of 60 g. of dibenzoylethylene, 56 cc. (41 g.) of hexadiene-2,4 and 75 cc. of toluene was heated on the steam-bath for eighteen hours (under reflux). The solvent was evaporated in a stream of air and to the residual sirup while still hot was added 150 cc. of methanol. On cooling, the solution set to a crystalline mass. The product was collected by suction and washed with methanol. The crude product was a cream-colored crystalline material weighing 63 g. Recrystallized from acetone–methanol, it formed stout, colorless needles, weighing 53 g., m. p. 136–137°.

Anal. Calcd. for $C_{22}H_{22}O_2$: C, 82.97; H, 6.97. Found: C, 82.66, 83.09; H, 7.00, 6.83.

From the methanol mother liquors from two preparations with a total of 90 g. of dibenzoylethylene there was obtained by concentration 10.5 g. of a low-melting crystalline compound. After repeated recrystallization from methanol there was obtained 6.5 g. of white needles, m. p. 86–88°. This is an isomeric adduct.

Anal. Calcd. for $C_{22}H_{22}O_2$: C, 82.97; H, 6.97. Found: C, 82.73; H, 7.09.

Dibromides of Addition Products

(1) **Of High-Melting Adduct (XIII).**—To a solution of 3.18 g. of adduct (m. p. 136°) in 25 cc. of glacial acetic acid, was added dropwise with cooling a solution of 1.60 g. of bromine in 16 cc. of acetic acid. The bromine was decolorized instantly. The solution was poured into water, the dibromide extracted with chloroform, the chloroform solution concentrated to a small volume, diluted with ethanol, and concentrated again until crystallization began: white crystals, m. p. 169–170°; yield 3.94 g.

Anal. Calcd. for $C_{22}H_{22}O_2Br_2$: C, 55.23; H, 4.60. Found: C, 55.52; H, 4.64.

This dibromide is converted by means of sodium acetate to another dibromide, presumably stereoisomeric with the first. A mixture of 2 g. of the dibromide, 2 g. of anhydrous sodium acetate, 15 cc. of acetic acid, 1 cc. of acetic anhydride was refluxed for five hours. The solution was poured into water. The product crystallized from methanol as white needles, m. p. 202.5–203°, with decomposition; yield, 0.6 g.

Anal. Calcd. for $C_{22}H_{22}O_2Br_2$: C, 55.23; H, 4.65; Br, 33.43. Found: C, 55.66; H, 4.98; Br, 33.15.

(2) **Of Low-Melting Adduct.**—The bromination was carried out essentially as described for the high-melting adduct. The dibromide forms pearly-white leaflets from chloroform–ethanol, m. p. 152°, with decomposition.

Anal. Calcd. for $C_{22}H_{22}O_2Br_2$: Br, 33.43. Found: Br, 33.41.

3,6-Dimethyl-4,5-dibenzoylcyclohexene Oxide-1,2 (VIIIa and VIIIb).—Phthalmonoperacid was prepared according to the directions of Böhme.[4]

To a cold (0°) solution of 31.8 g. of adduct in 100 cc. of chloroform was added a liter of phthalmonoperacid (0.32–0.34 molar in available oxygen), and the solution stored at 0°.

After the oxidation was complete (about five days), as shown by no further drop in titer, a deposit of white prisms was present in the solution. The solution was decanted from this material which was collected, washed with ether, and dried. The oxide (VIIIa) weighed 7.0 g., and after recrystallization from acetone–methanol formed white needles, m. p. 187.5–188°.

Anal. Calcd. for $C_{22}H_{22}O_3$: C, 79.04; H, 6.59. Found: C, 79.28; H, 6.79.

The ether solution was washed with aqueous sodium bisulfite to remove excess oxidizing agent, then with aqueous sodium hydroxide to remove phthalic acid. The solution was dried over sodium sulfate and evaporated under diminished pressure.

The residual solid was recrystallized from methanol and by successive concentrations and removal of the fractions which were, in turn, recrystallized there was obtained the following: 6.6 g., m. p. 148–150°, and 9.7 g., m. p. 146–149°. The first crop after several crystallizations from methanol gave colorless prisms, m. p. 154–155°.

Anal. Calcd. for $C_{22}H_{22}O_3$: C, 79.04; H, 6.59. Found: C, 78.81; H, 6.58.

3,6-Dimethyl-4,5-dibenzoylcyclohexanediol-1,2 (IX and X) from High-melting Oxide.—A solution of 1 g. of the higher melting oxide (m. p. 187°) in 20 cc. of acetone and 5 cc. of 25% sulfuric acid was refluxed for thirty minutes. The solution was poured into water and extracted with chloroform. The oil obtained on evaporation of the chloroform solidified on triturating with ether and petroleum ether; yield 0.62 g.; m. p. about 160°. On crystallization from a mixture of ether–petroleum ether (b. p. 30–60°) first a small amount of product was obtained which separated in colorless prisms. These were recrystallized from dilute methanol, white needles, m. p. 212–213°.

Anal. Calcd. for $C_{22}H_{24}O_4$: C, 74.96; H, 6.87. Found: C, 74.91; H, 6.94.

The filtrates from the ether–petroleum ether crystallization deposited a second product in colorless rosets which, after purification from ethyl acetate–petroleum ether (b. p. 30–60°), melted at 173–175°.

Anal. Calcd. for $C_{22}H_{24}O_4$: C, 74.96; H, 6.87. Found: C, 75.20; H, 6.99.

From Low-Melting Oxide.—In place of pure low-melting oxide, either of the two low-melting fractions, m. p. 148–150° or 146–149°, described under the preparation of the oxides, was used. The procedure followed for hydrolysis was identical with that for the high-melting oxide. From 3.1 g. was obtained as a main product 1.7 g. of high-melting glycol which was purified to its proper melting point of 212–213° with dilute methanol. From the ether–petro-

(2) Reiff, *Ber.*, **39**, 1603 (1906); **41**, 2739 (1908).

(3) Kyriakides, THIS JOURNAL, **36**, 987 (1914).

(4) Böhme, *Ber.*, **70**, 379 (1937).

leum ether filtrates was obtained 0.35 g. of low-melting glycol which on crystallization from the same mixed solvent melted at 173–175°.

From one run of oxide purification was not carried to the extent previously described but merely three fractions were separated, one of high-melting oxide, a second primarily of low-melting, and a third fraction presumably chiefly low-melting oxide. When the last fraction and the mother liquors were hydrolyzed together with sulfuric acid in acetone, a new product (XII) was obtained. It was purified with methanol, white prisms, m. p. 187–188°. A mixed melting point showed it to be different from the high-melting or low-melting oxide.

Anal. Calcd. for $C_{25}H_{28}O_4$: C, 76.53; H, 7.14. Found: C, 76.12; H, 7.19.

The cause of the difference of results in the run just described and the others that were made may be due to the fact that the peracid ether solution was less dry in this experiment. The composition corresponds to a compound from one molecule of oxide and one of acetone.

1 - Hydroxy - 2 - acetoxy - 3,6 - dimethyl - 4,5 - dibenzoylcyclohexane.—In an attempt to cleave the glycol by means of periodic acid, four 1-g. runs of the low-melting oxide were allowed to stand for three hours with various concentrations of one molar periodic acid (1–10 equivalents) in 20 cc. of glacial acetic acid. After pouring into water, extracting with ether, washing, and evaporating the solvent, an oil resulted which crystallized on scratching. It was purified from ether–petroleum ether (b. p. 30–60°), then from dilute methanol; yield, 0.77 g. from the four runs, flat leaflike needles, m. p. 207°.

Anal. Calcd. for $C_{24}H_{26}O_5$: C, 73.06; H, 6.65. Found: C, 72.92; H, 6.58.

Apparently any oxidation products of the oxide or glycol produced from it could not be isolated and merely the monoacetate of the glycol resulted.

The same product could be obtained merely by heating 1 g. of the low-melting oxide, 15 g. of acetic acid and 5 cc. of 25% sulfuric acid on a steam cone for fifteen minutes. Dilution to cloudiness and cooling caused the product to separate. By boiling the compound with 15 cc. of methanol and 15–20 mg. of sodium for fifteen minutes, there was obtained from the reaction mixture 0.2 g. of solid which on purification from dilute methanol melted at 212–213° and proved to be identical with the higher-melting glycol.

Oxidation of Lower-Melting Oxide with Periodic Acid in Acetone Solution.—A solution of 1.0 g. of oxide (low-melting form) in a mixture of 20 cc. of acetone and 5 cc. of 1 *M* periodic acid was refluxed for thirty minutes. The solution was poured into water, extracted with chloroform and the solvent removed under reduced pressure. The residual sirup crystallized on scratching with ethyl acetate–ligroin, and yielded 0.82 g. of crystalline material. After several recrystallizations from benzene, in which the compound is difficultly soluble, the product melted at 177–178° with decomposition.

Anal. Calcd. for $C_{24}H_{26}O_5$: C, 73.06; H, 6.65. Found, C, 73.88, 73.27; H, 6.91, 6.97.

It may also be recrystallized from dilute acetone.

The same product is obtained by oxidizing the glycol with periodic acid in acetone.

Oxidation of the Glycol (M. p. 212°) with Lead Tetraacetate.—A suspension of 1.35 g. of lead tetraacetate in a solution of 1.05 g. of glycol in 10 cc. of acetic acid was shaken at room temperature for four hours and allowed to stand for two days. A crystalline precipitate formed, weight 0.63 g. Upon recrystallization from benzene it formed white needles, m. p. 170–170.5°, with decomposition.

Anal. Found: C, 69.93, 70.69, 69.96; H, 6.42, 6.41, 6.41.

α,α' - Diphenyl - β,β' - (3,6 - dihydro - 3,6 - dimethylbenzo)-furan (XIV).—A solution of 10 g. of the adduct (II) in a mixture of 80 cc. of glacial acetic acid, 40 cc. of acetic anhydride and 0.5 cc. of sirupy (85%) phosphoric acid was refluxed for twenty minutes. The solution was poured into water, extracted with chloroform and the solvent removed under reduced pressure. The residue crystallized on triturating with warm methanol. It weighed 9.0 g. and melted at 100–107°. Recrystallized from methanol it formed silky white needles or stout prisms melting at 114–115°. Occasionally the needle form separated first and changed into the prism form on standing in the solution.

Anal. Calcd. for $C_{22}H_{20}O$: C, 87.95; H, 6.70. Found: (prisms): C, 88.16; H, 6.94; (needles): C, 88.29; H, 6.92.

α,α' - Diphenyl - β,β' - (3,4,5,6 - tetrahydro - 4,5 - dibromo-3,6-dimethylbenzo)-furan (XV).—This compound can be obtained in either of two ways: (a) by bromination of the dihydrobenzofuran (XIV) or (b) by dehydration of the adduct dibromide (XIII).

(a) **Bromination of the Dihydrobenzofuran (XIV).**—To a cold solution of 2.0 g. of the dihydrobenzofuran in 15 cc. of glacial acetic acid was added, slowly and with cooling, a solution of 1.07 g. (1 mol) of bromine in 10 cc. of acetic acid. The bromine was decolorized instantly, and before all was added the addition compound began to separate. After precipitation was complete the product was collected, washed with acetic acid and water and dried. It weighed 2.10 g. and melted at about 165°, with decomposition. Recrystallized from *n*-butanol it formed pale yellow needles, m. p. 168–170°, with decomposition.

Anal. Calcd. for $C_{22}H_{20}OBr_2$: C, 57.39; H, 4.35. Found: C, 57.01; H, 4.50.

(b) **Dehydration of Adduct Dibromide.**—The dibromotetrahydrobenzofuran is most conveniently prepared by this procedure. After preliminary experiments on the pure adduct dibromide, it was found unnecessary to isolate and purify the adduct dibromide and that good results were obtained by dehydration of the crude product obtained by bromination of the adduct.

A solution of 5.0 g. of bromine in 50 cc. of acetic acid was added slowly to a well-cooled solution of 10 g. of the adduct (II) in 50 cc. of acetic acid. The faintly yellow solution was poured into water containing a little sodium bisulfite, extracted with chloroform and the solvent removed under reduced pressure. To the crystalline residue was added 50 cc. of acetyl chloride and five drops of concentrated sulfuric acid and the mixture heated under reflux. The dibromide went into solution rapidly and the solution assumed a brown-red color. After about

ten minutes of refluxing, yellow crystals began to separate and soon a heavy crystalline precipitate filled the liquid. The color of the solution slowly faded and at the end of thirty minutes had become a pale greenish-yellow. The mixture was cooled and filtered and the product washed with acetic acid and with water. There was obtained 11.4 g. of faintly yellow crystals, m. p. about 165°, with decomposition. Recrystallized from *n*-butanol it formed tiny, pale yellow needles, m. p. 168–170°, with decomposition, identical with the material obtained in (a).

α,α′-Diphenyl-β,β′-(3,6-dimethylbenzo)-furan (XVI).—A solution of 2.0 g. of the dibromotetrahydrobenzofuran in 10 cc. of dry pyridine was refluxed for thirty minutes. The solution, almost colorless at the start, became a bright yellow and after ten to fifteen minutes crystals of pyridine hydrobromide separated from solution. The solution was poured into water and the oil which separated soon crystallized. The crude product, which contained a trace of bromine, weighed 1.46 g. and melted at about 115–120°. The benzofuran was separated from unchanged dibromo compound by virtue of its ready solubility in cold ether, in which the dibromo compound is practically insoluble. Removal of the ether and recrystallization of the bright yellow crystalline residue from methanol gave bright yellow needles, m. p. 129–131°.

Anal. Calcd. for $C_{22}H_{18}O$: C, 88.53; H, 6.10. Found: C, 88.26; H, 6.27.

The benzofuran appeared to be somewhat unstable, considerable loss occurring on recrystallization. In the reaction with maleic anhydride described below the first ether extract of the crude product was used, giving a good yield of the addition product based on the original dibromotetrahydrobenzofuran.

1,4 - Endoxo - 1,4 - diphenyl - 5,8 - dimethyl - 1,2,3,4-tetrahydronaphthalene - 2,3 - dicarboxylic Anhydride (XVII).—Treatment of a solution of the benzofuran (XVI) in ether or benzene with a solution of maleic anhydride caused immediate precipitation of the addition product as fine white needles. The compound was best prepared by treating 2.0 g. of the dibromotetrahydrobenzofuran with pyridine as described above, and extracting the crude, dried product with ether. An ether solution containing an excess of the calculated amount of maleic anhydride was added and the addition product began to crystallize immediately. After cooling the solution in ice, the product was collected and washed thoroughly with fresh ether. It formed tiny white needles weighing 1.10 g. (70% over both steps). After recrystallization from glacial acetic acid from which it formed tiny white plates the compound melted at 310–312° with some decomposition.

Anal. Calcd. for $C_{26}H_{20}O_4$: C, 78.79; H, 5.05. Found: C, 78.85; H, 5.04.

The compound dissolves readily in methyl alcoholic potassium hydroxide but only with difficulty in aqueous alkali.

1,2-Dibenzoyl-3,6-dimethylbenzene (XIX).—This compound was obtained (a) by treatment of the adduct dibromide (XIII) with pyridine, (b) by treatment of the adduct (II) with bromine in pyridine solution, (c) by treatment of the dibromotetrahydrofuran (XV) with one mole of bromine in acetic acid containing sodium acetate, and (d) by treatment of the dihydrobenzofuran (XIV) with two moles of bromine in acetic acid containing sodium acetate. Only method (d) gave satisfactory results but method (a) is also described since it involved the unusual reaction mentioned previously which led to the formation of some of the original adduct (II).

(a) A solution of 2.0 g. of the high-melting adduct dibromide (XIII) in 10 cc. of dry pyridine was heated for twenty hours on the steam-bath. Crystalline pyridine hydrobromide separated during the heating. The solution was poured into water and extracted with ether. After washing the ether solution with dilute hydrochloric acid and water and drying, it was evaporated under reduced pressure. The oily residue crystallized on triturating with an ether–petroleum ether mixture and the solid was collected; yield 0.30 g. Upon recrystallization from methanol it formed white, flat prisms, m. p. 144–145°.

Anal. Calcd. for $C_{20}H_{18}O_2$: C, 84.08; H, 5.74. Found: C, 83.82; H, 5.82.

The ether–petroleum ether filtrate yielded on evaporation 0.40 g. of the original adduct (II), bromine-free.

(d) To a solution of 1.0 g. of the dihydrobenzofuran (XIV) and 1.5 g. of anhydrous sodium acetate in 5 cc. of hot acetic acid was added a solution of 1.0 g. of bromine in 10 cc. of acetic acid. The bromine was absorbed instantly and sodium bromide separated. The solution was refluxed for thirty minutes and diluted to cloudiness with water. The product separated on cooling. It weighed 0.83 g., melted at 140–143°, and contained no bromine (Beilstein test). Recrystallized from methanol it formed white prisms, m. p. 143–145°, shown by mixed melting point to be identical with the compound obtained by method (a).

Methods (b) and (c) gave inferior yields of the same compound.

1,2-*bis*-(α-Oxybenzyl)-3,6-dimethylbenzene (XX).—A solution of 1 g. of the benzene derivative (XIX) in a solution of 2 g. of sodium hydroxide in 20 cc. of alcohol was boiled until a deep yellow-brown color appeared. About 0.5 g. of zinc dust was added in portions to the boiling solution and heating was continued for fifteen minutes on the steam-bath.

The nearly colorless solution was poured into water and the gummy precipitate crystallized from dilute methanol. After several recrystallizations from 50% methanol the compound was obtained as tiny white prisms melting at 149–151°. The substance was somewhat unstable and showed a tendency to decompose when dried at 100°.

Anal. Calcd. for $C_{22}H_{22}O_2$: C, 82.97; H, 6.97. Found: C, 83.74; H, 6.68.

Summary

1. The addition of hexadiene-2,4 to *trans*-dibenzoylethylene has been described.

2. An unsuccessful attempt has been made to convert the cyclohexene derivative so obtained into an analog of one of the degradation products of gossypol, namely, desapogossypolone tetramethyl ether.

3. The oxidation of the cyclohexene derivative with perphthalic acid to the corresponding cyclo-

hexene oxides, and the stereochemistry of these oxides and certain of their derivatives, are described.

4. Various transformation products of the cyclohexene derivative have been described, among them the corresponding dibenzoylxylene and α,α'-diphenyl-β,β'-(3,6-dimethylbenzo)-furan. It is believed that the methods described are general for the preparation of compounds of these types.

Structure of the Murexides and the Alloxantines[1]

BY N. M. WINSLOW[2]

The structure of the dye murexide (I) was established independently by Stieglitz,[3] Moehlau,[4] and Piloty.[5] Acid hydrolysis of the dye gives uramil and alloxan in semiquantitative yields. Hydrolysis should, therefore, provide a means of distinguishing isomeric N-substituted murexides of general structures II and III.[6] Hydrolysis of II should give N-substituted uramil and alloxan, while similar treatment of III should give uramil and N-substituted alloxan. However, if II and III exist in tautomeric equilibrium, or if resonance occurs between the two forms, then any preparative procedure calculated to yield either II or III would give the same mixture of the two, and hydrolysis of the product would yield four products: N-substituted uramil, N-substituted alloxan, uramil, and alloxan. The present investigation is concerned with the two isomeric N-phenylmurexides, 1-phenylmurexide (II, X = C_6H_5) and 1′-phenylmurexide (III, X = C_6H_5).

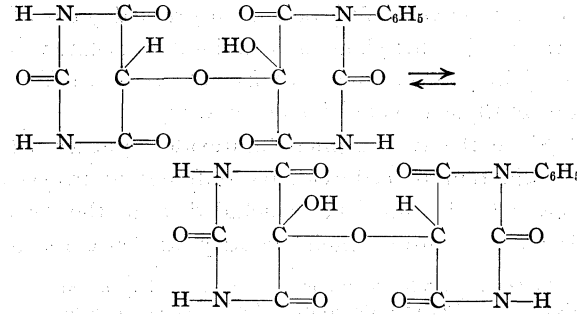
(5) Piloty, *Ann.*, **333**, 22 (1904).

(6) The murexides decompose without melting. A study of absorption spectra should furnish confirmatory evidence.

1-Phenylmurexide was prepared readily from 1-phenyluramil and alloxan in ammonium carbonate solution. When the dye was hydrolyzed within forty-eight hours of its preparation, 1-phenyluramil and alloxan, the latter determined as alloxantine, were recovered in yields representing 70 and 56%, respectively, of the theoretical.

The synthesis of 1′-phenylmurexide in a manner analogous to the method used for the preparation of 1-phenylmurexide was attempted without success, due to the relative insolubility of uramil in ammonium carbonate solution and the instability of the murexide in alkali sufficiently strong to dissolve uramil. There remained the alternative method of preparing the corresponding 1′-phenylalloxantine and treating this compound with ammonia.

Pure 1′-phenylalloxantine was prepared by the condensation of N-phenylalloxan with dialuric acid in hot aqueous solution. But chemical purity, as established by elementary analysis, was not the only requirement of 1′-phenylalloxantine intended for use in the preparation of 1′-phenylmurexide; it must also maintain its tautomeric identity. Quite obviously if a tautomeric equilibrium existed, treatment of the alloxantine with ammonia would give only a mixture of 1-phenylmurexide and 1′-phenylmurexide.



When 1′-phenylalloxantine was hydrolyzed with aqueous potassium acetate, dialuric acid, pre-

cipitated immediately as the potassium salt, was obtained in 98% yields. This quantitative yield of potassium dialurate showed that 1′-phenylalloxantine maintained its identity under the conditions of preparation, a conclusion in entire agreement with the results of Stieglitz and Nightingale,[7] obtained with 1-methylalloxantine and 1′-methylalloxantine.

In this connection it was of interest to study the isomeric 1-phenylalloxantine, prepared by heating 1-phenyluramil with alloxan solution containing hydrochloric acid. Hydrolysis of the pure material with sodium acetate produced 74.5% of the theoretical yield of N-phenyldialuric acid, giving additional confirmation of the views of Stieglitz and Nightingale regarding the asymmetrical structure of alloxantines and the maintenance of identity by isomeric N-substituted alloxantines. One further observation lends strong support to the conclusion of these authors. When 1-phenylalloxantine, which presumably is hydrolyzed to N-phenyldialuric acid and alloxan, was treated with potassium acetate, potassium dialurate was obtained.[8] However, it was precipitated slowly, as contrasted with immediate precipitation when 1′-phenylalloxantine was treated with potassium acetate, and the total amount obtained was approximately 67% of the theoretical. Their explanation of the formation of potassium dialurate from the hydrolysis of the methylalloxantine prepared from alloxan and methyluramil, as the result of a slow inter-(or intra-?)-molecular oxidation and reduction, thus was fully confirmed by our own work with the alloxantine prepared from the alloxan and phenyluramil.

By treatment of 1′-phenylalloxantine, which had been shown to maintain its identity under the conditions of preparation, with ammonia, 1′-phenylmurexide was obtained. Hydrolysis of this dye gave 96.5% of the theoretical yield of uramil. N-Phenylalloxan could not be isolated as a hydrolysis product because of its instability under the acid conditions of hydrolysis.

Since the two N-phenylmurexides synthesized by different procedures gave different hydrolysis products, it must be concluded that the two isomers maintain their identity at least for a limited length of time. Both resonance and rapid tautomerism between the two are ruled out, but this conclusion in no way precludes the probability that each of the dyes will in the course of time be transformed into identical equilibrium mixtures which would give identical hydrolysis products.

Similar results have been obtained with two other pairs of isomeric N-substituted murexides: Stieglitz and Slimmer,[3] later Stieglitz and Eckstein,[9] and finally Stieglitz and Tartar,[10] prepared the two isomers 1,3-dimethylmurexide and 1′,3′-dimethylmurexide; hydrolysis of the former yielded dimethyl uramil and alloxan, while uramil and dimethylalloxan were obtained from the latter as hydrolysis products. More recently,[11] the isomers 1,3-diphenylmurexide and 1′,3′-diphenylmurexide were prepared and similarly shown to yield different hydrolysis products.

These investigations were undertaken in connection with the Stieglitz theory of color production in organic molecules.[12] It is the fundamental concept of this theory that color of organic molecules is due to partial absorption of white light by vibration of electrons held in proper restraint between their own atomic nucleus in a reducing group (the auxochrome) and a nearby strongly positive group (the chromophore). For example, in the structure (I) of the dye murexide, it is, in particular, the pair of electrons indicated by—in $C^{\pm}$, held in loose restraint in the reducing uramil group R, which are attracted both by the positive nucleus of $C^{\pm}$ itself and by the alloxan group Q whose oxidizing power may be considered centered in $C^{\ddagger}$. According to the views of Stieglitz, the color-producing vibrations of these electrons are intra-atomic, that is, between the different energy levels of an atom ($C^{\pm}$), rather than interatomic, that is, between two different atoms ($C^{\ddagger}$ and $C^{\pm}$), leading to tautomeric equilibrium.

While results obtained with the N-substituted murexides discussed above do not establish the source of color in the molecules, they are in complete agreement with the Stieglitz theory. On the other hand, early theories[13] holding that the color of dye molecules is due to electronic movements involved in tautomeric equilibrium are

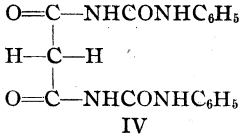
definitely disproved. Resonance involving the valence bonds of the central nitrogen atom in the murexide molecule is also eliminated as the source of color. Nothing is indicated concerning the bonds of other atoms in the molecules.

The results are of more recent interest in connection with the theory of resonance. If the structure (I) of the parent substance is correct, an N-substituted murexide would be expected to exist as a resonance hybrid of II and III. The fact that three different isomeric pairs of N-substituted murexides have been shown to maintain their identity presents an interesting problem.

Experimental

Preparation of Intermediate Compounds.—N-Phenylbarbituric acid was prepared by refluxing a mixture of malonic acid (50 g.), phenylurea[14] (64 g.), acetic anhydride (100 cc.) and dry chloroform (700 cc.) for twenty-four hours. The chloroform was removed by distillation, and from the dry residue a 40% yield of N-phenylbarbituric acid was obtained by extraction with cold aqueous sodium carbonate.

The material undissolved by cold aqueous sodium carbonate contained a small amount of symmetrical acetylphenylurea, but consisted chiefly of malonyl dimonophenylurea (IV):



IV

This compound was obtained in the pure condition by recrystallization from acetone.

Anal. Calcd. for $C_{17}H_{16}O_4N_4$: C, 60.00; H, 4.71; N, 16.20. Found: C, 60.02; H, 5.11; N, 16.21.

The malonyl dimonophenylurea was dissolved in 500 cc. of 0.6 *M* sodium carbonate by digestion for one hour on a steam-bath. Chilling of the solution precipitated about 25% of the phenylurea originally used in the preparation, and the addition of hydrochloric acid gave an additional 20% yield of N-phenylbarbituric acid.

For the purposes of this investigation, N-phenylbarbituric acid prepared as described proved to be sufficiently pure, melting from 254.5 to 258.5°. A pure sample, obtained by recrystallization from dioxane, melted at 262°. The recorded[15] melting point is 262°.

1-Phenyluramil was prepared from a solution of sodium phenylviolurate obtained by digestion at 50° of N-phenylbarbituric acid (5 g.) with 100 cc. of water containing sodium nitrite (1.5 g.). The solution was reduced with hydrogen sulfide, acidified with 50 cc. of concentrated hydrochloric acid, warmed to 45°, and filtered from precipitated sulfur. 1-Phenyluramil crystallized slowly after the addition of four volumes of alcohol; yield 1.7 g.

Anal. Calcd. for $C_{10}H_9O_3N_3$: N, 19.18. Found: N, 19.25.

(14) Davis and Blanchard, THIS JOURNAL, **51**, 1791 (1929).

(15) Macbeth, Nunan and Traill, *J. Chem. Soc.*, **129**, I, 1252 (1926).

N-Phenylalloxan was prepared by oxidation at 0° of 1-phenyluramil (0.50 g.) with 2 cc. of nitric acid (sp. gr. 1.42). The reaction mixture was dried *in vacuo*, and N-phenylalloxan was recovered by extraction with ether and precipitation from the ether solution with four volumes of ligroin. Yields varied from 60 to 90% of the theoretical.

Anal. Calcd. for $C_{10}H_8O_5N_2$: C, 50.95; H, 3.36; N, 11.66. Found: C, 50.65; H, 3.31; N, 11.94.

Preparation of Alloxantines.—1-Phenylalloxantine was prepared by heating at 50° for six hours a suspension of 1-phenyluramil (1 g.) in a solution of alloxan monohydrate (0.9 g.)[16] in 12 cc. of water containing 1 cc. of concentrated hydrochloric acid. The product was collected on a filter, washed with cold water and dried *in vacuo;* yield 1.4 g.

Anal. Calcd. for $C_{14}H_{10}O_8N_4$: N, 15.47. Found: N, 15.50.

A solution of dialuric acid was obtained by reduction of alloxan monohydrate (1.00 g.) dissolved in 12.5 cc. of water with hydrogen sulfide at 98°. When the hot solution, filtered from the precipitated sulfur, was mixed with a hot solution of N-phenylalloxan (0.50 g.) in 6 cc. of water, 1′-phenylalloxantine crystallized over a period of about ten minutes. The product was washed with cold water, alcohol, and ether; yield 0.8 g.

Anal. Calcd. for $C_{14}H_{10}O_8N_4$: N, 15.47. Found: N, 15.42.

Preparation of Murexides.—1-Phenylmurexide was prepared by mixing a solution of alloxan monohydrate (2 g.) in 10 cc. of water with a solution of 1-phenyluramil (2 g.) in 10 cc. of 20% ammonium carbonate solution. The mixture was heated for thirty minutes at 50° in an atmosphere of hydrogen. The product was purified by repeated extraction with 15-cc. portions of 95% alcohol; yield 1.1 g.

Anal. Calcd. for $C_{14}H_{12}O_6N_6$: N, 23.33. Found: N, 23.57.

1′-Phenylalloxantine (1.5 g.) suspended in absolute benzene at 50°, was converted to 1′-phenylmurexide by passing a stream of dry ammonia gas through the suspension for three hours. The murexide was purified by washing with benzene and heating in air for ten hours at 50°; yield 1.5 g.

Anal. Calcd. for $C_{14}H_{12}O_6N_6$: N, 23.33. Found: N, 23.71.

Hydrolysis of Alloxantines and Murexides.—A suspension of 1-phenylalloxantine (0.500 g.) in 19 cc. of water containing sodium acetate (0.35 g.) was heated on a steam-bath until the alloxantine dissolved. From the clear hydrolysate, acidified with 1 cc. of 50% acetic acid, basic lead N-phenyldialurate[17] was precipitated by the addition of 0.600 g. of lead acetate [$Pb(C_2H_3O_2)_2 \cdot 3H_2O$]; yield 0.455 g., theoretical 0.611 g.

Anal. Calcd. for $C_{10}H_8O_6N_2Pb$: N, 6.32; Pb, 46.73. Found: N, 6.67; Pb, 46.50.

1′-Phenylalloxantine was hydrolyzed in the same manner as 1-phenylalloxantine except that potassium acetate was

(16) Biltz and Heyn, *Ann.*, **413**, 60 (1917); *J. Chem. Soc.*, **112**, I, 289 (1917).

(17) This compound was also prepared from N-phenyldialuric acid obtained by reduction of N-phenylalloxan with hydrogen sulfide at 98°.

Anal. Calcd. for $C_{10}H_8O_6N_2Pb$: N, 6.32; Pb, 46.73. Found: N, 6.91; Pb, 46.74.

used instead of sodium acetate. When the hydrolysate was chilled in ice, potassium dialurate was obtained; yield 0.247 g. from 0.500 g. of 1′-phenylalloxantine, theoretical 0.252 g.

Anal. Calcd. for $C_4H_3O_4N_2K$: N, 15.38. Found: N, 15.48.

1-Phenylmurexide (1.000 g.), suspended in 100 cc. of oxygen-free water by the passage of a slow stream of hydrogen, was hydrolyzed with 16 cc. of approximately molar hydrochloric acid added a few drops at a time over a period of forty-five minutes. The solid material remaining when the color of the solution had been completely discharged was brought upon a filter and identified as 1-phenyluramil by its qualitative reactions and nitrogen content; yield 0.427 g., theoretical 0.605 g. From the filtrate from the 1-phenyluramil, concentrated at room temperature to 5 cc., alloxantine was obtained by reduction with stannous chloride; yield 0.205 g., theoretical 0.364 g.

Hydrolysis of 1′-phenylmurexide (1.000 g.) by the procedure used for the hydrolysis of 1-phenylmurexide yielded 0.383 g. of uramil; theoretical 0.397 g. Due to the instability of N-phenylalloxan[18] in acid solution, only traces of 1,1′-diphenylalloxantine could be obtained from the filtrate from the uramil by reduction with stannous chloride.

(18) 1,1′-Diphenylalloxantine was obtained in 73% yields by reduction of a freshly prepared acid solution of N-phenylalloxan with stannous chloride. When the acid solution was allowed to stand for forty-five minutes before reduction, the yield was only 1.5%.

Anal. Calcd. for $C_{20}H_{14}O_8N_4$: N, 12.79. Found: N, 12.87.

Summary

1. The isomers 1-phenylmurexide and 1′-phenylmurexide maintain their identity at least for a limited length of time under certain experimental conditions. 1-Phenylalloxantine and 1′-phenylalloxantine also maintain their isomeric identities.

2. These phenylmurexides constitute the third pair of isomeric N-substituted murexides for which maintenance of identity has been established. The importance of this fact in connection with the theories of color production and resonance in organic molecules has been discussed.

3. The following compounds not described in the literature have been prepared: 1-phenylmurexide, 1′-phenylmurexide, 1-phenylalloxantine, 1′-phenylalloxantine, 1,1′-diphenylalloxantine, 1-phenyluramil, N-phenylalloxan, and malonyl dimonophenylurea.

The Influence of Ionic Strength and *p*H on Electrophoretic Mobility

BY BERNARD D. DAVIS AND EDWIN J. COHN

Electrophoretic mobilities are generally determined in the presence of buffer solutions. It seemed of importance to investigate further the influence of the valence of the buffer and of the ionic strength of the solution. Tiselius has noted[1,2] the effect of ionic strength and of the valence of inorganic cations, and work in this Laboratory had indicated that the ionic strength of the buffer has a very profound influence on electrophoretic mobility. The influence of these variables also has been studied by Abramson[3] and by Smith,[4] who observed the movements of particles of quartz or collodion coated with egg albumin in an electric field. The latter studied especially the dependence of the isoelectric point upon the nature and concentration of neutral salts.

In the present investigation we have used the moving boundary method and have chosen horse carboxyhemoglobin as the protein to be investigated since it is a well characterized protein whose other properties have been investigated extensively.[5–9] Mobility has been determined from *p*H 5.65 to 7.2. Hemoglobin was therefore present as cation in most of these systems, whereas most of the other blood proteins would be present as anions. The ionic strengths vary from 0.02, the concentration often used by Tiselius, to ionic strengths characteristic of physiological systems. Two sets of buffers were employed, namely, phosphates in which monovalent and bivalent anions, and citrates in which bivalent and trivalent anions, are present. The measurements reported demonstrate the great influence

of the type of buffer and of the ionic strength of the solution both upon the observed electrophoretic mobility and upon the apparent isoelectric point of the protein.

Materials and Methods.—The carboxyhemoglobin of the horse employed in these experiments was twice recrystallized from aqueous solution by the method of Ferry and Green.[5,10] The crystals were then repeatedly triturated with distilled water, and centrifuged from the resulting saturated hemoglobin solutions to free them from salt. Solutions saturated with the hemoglobin after the crystals had been washed from three to five times in this manner, were employed in these studies.[11] The desired solutions of hemoglobin in buffer were dialyzed in cellophane bags against identical buffer solutions for from twelve to twenty-four hours at about 3°. This practice, employed by Tiselius,[1] minimizes the disturbances at the protein–buffer interface. The pH and the conductivity of the two solutions were found to be identical within the limits of experimental error.

The phosphate buffer solutions of known ionic strength and pH were those generally employed in this Laboratory.[12,13] Using the data of Hastings and Van Slyke,[14] which give the concentrations of primary, secondary and tertiary citrate at the successive stages in the titration of 0.1 M citric acid with sodium hydroxide, graphs were prepared from which could be read the concentration of citrate necessary to produce a solution of given pH and ionic strength. The pH values of all solutions were checked electrometrically after dialysis, and it is these values that are recorded in the tables.

The apparatus used consists of a U-tube connected through side-arms to large buffer chambers, at the bottom of which Ag–AgCl electrodes, coils of no. 18 wire 1.5 cm. in diameter and 4.5 cm. long, were immersed in reservoirs of 20% potassium chloride. The content of the U-tube below the tops of the stopcocks was about 15 cc.; the potassium chloride reservoir up to a level several mm. above the electrode, 30 cc. on each side; the rest of the buffer chamber and vertical column of the U-tube had a volume of 125 cc. on each side, ample to ensure a run of many hours without contamination by the transport of potassium chloride or electrode products. The diameter of the U-tube was 0.95 cm. The design of the electrode was largely adopted from Tiselius,[1,15] the U-tube was that previously used in investigations in this Laboratory.[16,17] The sharp boundary of the hemoglobin was read directly.

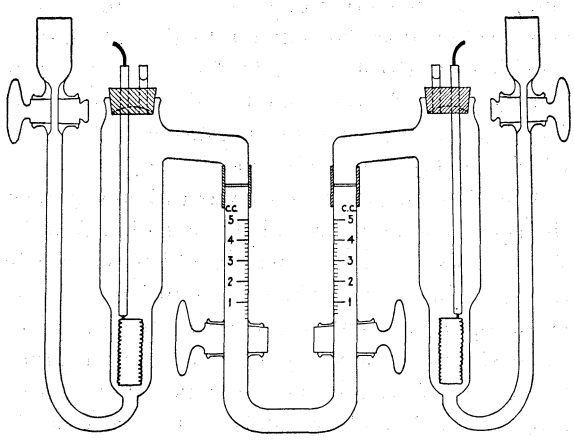

Fig. 1.

The top of each buffer chamber was closed with a two-holed rubber stopper, slightly hollowed on the under side to prevent the trapping of air bubbles. Through one hole of the stopper was passed the glass sealed electrode lead, and through the other a tube for the introduction and leveling of the buffer. The various solutions were evacuated and brought to the temperature of the bath before introduction, in order to remove dissolved air which would later form bubbles injurious to the boundary. When the protein, buffer and hydrochloric acid solutions had been introduced in the proper positions the assembled apparatus was immersed up to the side arms in a glass-walled thermostat at 25 ± 0.1°. The buffer solutions were carefully leveled in the tubes above the buffer chambers by addition of appropriate amounts of solution; the stopcocks were then opened and buffer solution slowly added to one chamber and removed from the other until one hemoglobin column was raised above the optical irregularities of the U-tube near the stopcock. A potential of 110 v. was applied to the electrodes and the movement of the protein in the field directly observed from time to time. The electrodes in successive experiments were alternated in polarity in order to keep them coated with silver chloride.

The determination of the mobility in units of cm.²/volt-sec. involved measurements of the rate of migration in cc./hour, of the conductivity of the buffer, and of the current flow. These quantities are related in the following formulas

$$IR = eq \quad (1)$$

$$M = ueq \times 3600 \quad (2)$$

$$u = M/3600\,IR \quad (3)$$

where M = rate of migration (cc./hour); u =

mobility (cm.²/volt-sec.); I = current (amperes); R = specific resistance of buffer (ohms cm.); e = potential drop in U-tube (volts/cm.); and q = cross section of U-tube (sq. cm.). The cross section does not enter into the calculation, provided the U-tube is calibrated in cc. Current leakage through the joints and stopcocks was found to be negligible by measuring the current while the stopcocks were closed.

The advancing boundary, except when very near the isoelectric point, remained sharp indefinitely, showing less spreading than would be caused in the same interval of time by diffusion. On reversal of the current, the receding boundary became diffuse. Since the difference in conductivity and therefore the difference in potential drop at the boundary interface was very small, the influence of the hemoglobin concentration on its own mobility, whereby velocity increases with concentration, would appear the most probable explanation of the difference in velocity and diffuseness of the advancing and receding boundaries. The measurements reported are for the advancing boundary.

Influence of Hemoglobin Concentration.—The reproducibility of these electrophoretic measurements upon carboxyhemoglobin solutions may be illustrated by a series of experiments in which the hemoglobin concentration was varied systematically, the ionic strength of the buffer and the pH being maintained constant. The hour by hour readings in the seven experiments carried out at pH 5.93 at ionic strength 0.05 and hemoglobin concentrations from 1.67 to 13.3 g. per liter are recorded in Table I. They demonstrate the agreement between duplicate experiments, and the constancy of the rate of electrophoretic migration throughout the experiments. The current, which was always measured with a standardized Weston ammeter, generally increased slightly during the first period. The value when the current flow had become sensibly constant was employed in estimating the mobilities in absolute units recorded in Table I. The current flow, I, varied to be sure with the ionic strength, but the product of the current and the resistance, R—which measures the potential drop—did not vary systematically with pH or ionic strength.

The average mobility at each hemoglobin concentration is given at the bottom of Table I. There would appear to be a definite effect of the hemoglobin concentration upon mobility. This

was not only true at pH 5.93, but in other experiments. Thus at an ionic strength of 0.02 and a pH of 7.11, alkaline to the isoelectric point, when the hemoglobin was moving as an anion, its mobility was -1.6×10^{-5} cm.²/volt-sec. in a solution of 0.3% with respect to hemoglobin (Expt. 81) but -2.3×10^{-5} cm.²/volt-sec. in a 1% hemoglobin solution (Expt. 80).

The observed increase in mobility with increase in hemoglobin concentration may well be associated with interaction of the protein dipolar ions with each other[18] or with buffer ions.[19] Tiselius,[20] working with serum proteins, has explained boundary irregularities at high protein concentration as due to the effect of the protein on the transport of the buffer ions, causing a shift of pH at the boundaries. In the range of hemoglobin concentration here described, all boundaries were sharp and all mobilities reasonably constant. In several experiments with hemoglobin concentrations below 0.1% at ionic strength 0.05, the boundary became convex and then diffuse. The hemoglobin concentration was maintained at 1% in studying the influence of ionic strength.

(19) Smith[4] has found that the mobility of egg albumin decreases with increasing protein concentration. She measured mobility of the protein adsorbed on quartz particles, and her observations may be related to this difference in technique, or to the far smaller effects of egg albumin on the dielectric constant of solvents.[21]

Influence of *p*H and Ionic Strength.—Observations on the influence of *p*H on the mobility of hemoglobin were early reported by Michaelis and Airila.[22] The influence of ionic strength on the mobility of carboxyhemoglobin is shown in Table II. The mobilities in phosphate buffers are graphically represented in Fig. 2, those in citrate buffers in Fig. 3. It will be noted that protein mobility is extremely sensitive not only to *p*H and ionic strength, but also to the valence and nature of the ions present; an effect noted also by others.[1,3,4,23] This sensitivity to the nature and strength of the ionic atmosphere (Fig. 2) would appear to be nearly as important as *p*H in

determining the optimal conditions for the electrophoretic separation of proteins.

The effect of ionic strength[24] and ionic species on the apparent isoelectric point is shown in Fig. 4, the conditions at which there is no mobility being graphically estimated from Figs. 2 and 3. As might be expected on theoretical grounds, mobility in citrate and phosphate buffers appears to approach the same value at low ionic strengths.

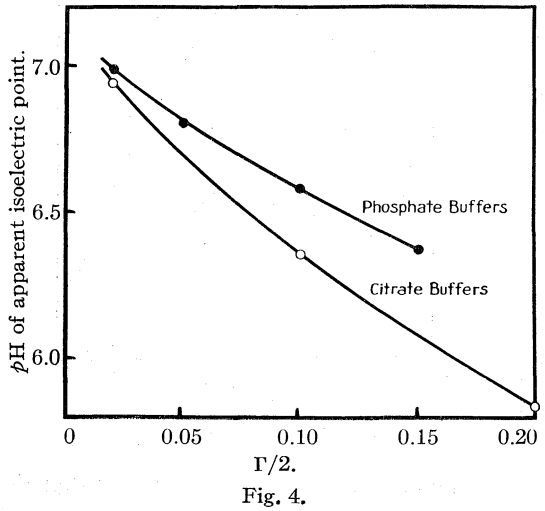

Fig. 4.

In order to analyze further the measurements of electrophoretic mobility that are reported, it seemed desirable first to consider them from the points of view that have been developed for ions of ordinary valence. Two generalizations may first be made: that the greater the valence, the greater the net charge and therefore the greater the mobility. On the other hand, the greater the valence the more the mobility will diminish from that which would obtain in infinitely dilute solution.

The mobility of an ion is given, following Onsager's theory, by an equation of the form

$$u = u_0 - (\alpha u_0 + \beta)\sqrt{\Gamma/2} \qquad (4)$$

in which u is the mobility at ionic strength $\Gamma/2$, u_3 the mobility at infinite dilution and α and β constants depending, respectively, on the relaxation and on the electrophoretic migration of the ionic atmosphere. The former effect is a complicated function of the valence and mobilities at infinite dilution of all ions present.

This equation, valid only in very dilute solution, has been extended by Shedlovsky to the case of more concentrated solutions[25-27] as follows

$$u = u_0 - (\alpha u_0 + \beta)\sqrt{\Gamma/2} + B(\Gamma/2) - \alpha B(\Gamma/2)^{3/2} \qquad (5)$$

The third term is small, in part because of the exponent of the ionic strength, in part because α is small in comparison with β (0.22 and 28.9, respectively, for a univalent ion at 25°). The empirical constant B for simple ions often has been found to be nearly equal to $(\alpha u_0 + \beta)$. Neglecting the third term in the above equation, we may write

$$u = u_0 - A'\sqrt{\Gamma/2} + B'(\Gamma/2) \qquad (6)$$

Values of u_0, A' and B' estimated from the observed mobilities by this equation show no significant variation with ionic strength, and are given in Table III. As in the case of simple ions the values of A' are close to those of B' and it is therefore possible to use for interpolation the still simpler equation for the influence of ionic strength

$$u = u_0 - A'(\sqrt{\Gamma/2} - \Gamma/2) \qquad (7)$$

TABLE III

CONSTANTS DEFINING THE MOBILITY OF CARBOXYHEMOGLOBIN IN PHOSPHATE AND CITRATE BUFFERS VARYING IN pH AND IONIC STRENGTH AT 25° IN TERMS OF EQUATIONS (6) AND (7)

	Three constant equation			Two constant equation	
pH	u_0	A'	B'	u_0	$A' = B'$
		Phosphate Buffers			
5.65	18.5	66.7	66.7	18.5	66.8
5.8	16.6	59.2	56.5	17.1	62.7
6.0	14.5	53.0	49.7	15.0	56.8
6.2	12.6	48.4	45.9	12.9	51.5
6.4	10.2	41.6	38.9	10.6	45.1
6.6	7.9	35.3	31.9	8.4	39.4
6.8	5.6	20.9	29.3	5.9	33.1
		Citrate Buffers			
5.8	9.57	34.7	30.4	10.37	41.2
6.0	8.54	32.4	27.5	9.37	39.4
6.2	7.38	29.3	23.7	8.34	37.3
6.4	6.14	26.1	20.0	7.18	34.8

For the studies in phosphate and citrate buffers, deviations in linearity of u_0 in pH over this pH range are scarcely greater than the experimental error. The straight lines drawn in Fig. 5 for phosphate and citrate, respectively, are given by the equations

$$u_0 - 4.0 = 11.0\ (7.00 - p\text{H}) \qquad (8)$$
$$u_0 - 4.0 = 5.5\ (7.00 - p\text{H}) \qquad (9)$$

It would, however, not be safe to estimate isoelectric points by extrapolation of these equations.

(24) The possibility that the change in mobility with ionic strength might partly be due to differences in heat production was tested in one experiment with high conductivity (acetate) by the introduction in series of a resistance which halved the potential drop, but which did not sensibly influence the mobility.

(25) T. Shedlovsky, THIS JOURNAL, **54**, 1405 (1932).

(26) D. A. MacInnes and T. Shedlovsky, *ibid.*, **54**, 1429 (1932).

(27) T. Shedlovsky and A. S. Brown, *ibid.*, **56**, 1066 (1934).

Indeed their use would imply a higher isoelectric point for hemoglobin in the presence of very small concentrations of citrate than of phosphate ions. Rather linearity would appear to depend on the almost linear combining capacity of carboxyhemoglobin for acid and base over this pH range, one of the reasons for the choice of these particular systems for this study. For the evidence would appear to be conclusive[28-30] that the changes in net charge of the carboxyhemoglobin molecule over this pH range is ascribable to the imidazole ring of histidine. There are 32 or 33 histidine residues in horse hemoglobin on the basis of a molecular weight of 66,800, of which 12 or more dissociate at reactions acid to the isoelectric point. We thus estimate a large number of imidazole groups dissociating over this pH range. The values of A' in Table IV vary only from 20 to approximately treble this value. Moreover, in the systems containing phosphate buffer A' as well as u_0 is linear in pH (Fig. 5) and is given over the range investigated by the relation

$$A' - 27.6 = 29.0\ (7.00 - p\mathrm{H}) \qquad (10)$$

whereas in the systems containing citrate buffer the relation appears more complicated.

Although the above equations are useful for interpolation, their significance is doubtful. If the valence be assumed to reach approximately 12 at the most acid pH investigated, on the basis of the titration curve of hemoglobin,[30] far higher values of u_0 and A' should be expected.

Moyer and Abramson[23] have employed an equation for the electrophoretic mobility of proteins of the form

$$u = u_0[1/(1 + \kappa r)] \qquad (11)$$

Taking the radius of hemoglobin as 27 Å., u_0 may be estimated by this equation as

$$u_0 = u(1 + 9\sqrt{\Gamma/2}) \qquad (12)$$

The values of u_0 calculated by means of our data and equation (12) vary with ionic strength. Thus for the four phosphate ionic strengths investigated at pH 5.65, this equation yields 23.37, 20.78, 15.22 and 12.15; whereas equation (7) yields 18.38, 18.51, 18.45 and 18.54. At other reactions also values of u_0 calculated by equation (7) are essentially independent of ionic strength, whereas those calculated by means of equation (12) show wide variations.

(28) B. German and J. Wyman, Jr., *J. Biol. Chem.*, **117**, 533 (1937).
(29) J. Wyman, Jr., *ibid.*, **127**, 1 (1939).
(30) E. J. Cohn, A. A. Green and M. H. Blanchard, THIS JOURNAL **59**, 509 (1937).

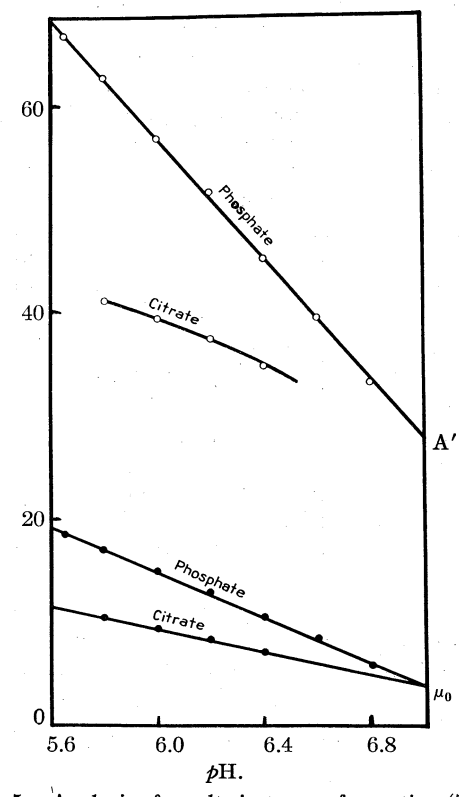

Fig. 5.—Analysis of results in terms of equation (7).

In the electrophoretic term of the Onsager equation, as generally employed, there is omitted a factor of $1/(1 + \kappa r)$, which would take into account as a first approximation the finite size of the ion[31] (p. 325). For dilute solutions of small ions κr is small in comparison with unity, but for proteins this is not the case. Including the above factor but omitting the relaxation term in α. equation (4) becomes

$$u = u_0 - \beta\sqrt{\Gamma/2}/(1 + (r/3)\sqrt{\Gamma/2}) \qquad (13)$$

To use equation (13) for extrapolation to infinite dilution, we have again taken r for carboxyhemoglobin as 27 Å. Values of u_0 and β estimated by means of this equation for the phosphate and citrate systems investigated are recorded in Table IV. These values of u_0 are satisfactorily constant and independent of ionic strength at each pH. They are moreover appreciably greater than the estimates of u_0 derived from either equation (7) or (12).

Not only is u_0 more than half again as great as estimated by means of equation (13) but β is nearly five times as great as A' of equation (7). Whereas A' is approximately of the magnitude

to be expected of a univalent or bivalent ion, the values of β from equation (13) approach those that might be expected for decavalent ions, and this, as we have seen, is approximately the mean valence of the hemoglobin at the greatest acidities studied.

Since the apparent isoelectric point is different for each solvent (Fig. 4), it seemed desirable to consider mobility at fixed *p*H intervals from that *p*H at which there was no mobility in a buffer of the same ionic strength. Applying the same equations to the measurements under these conditions yields the constants in Table V. The values of all the constants are smaller when computed in this way. Moreover, the ratios (A'/u_0) and (β/u_0) would appear to be more nearly independent of the nature of the buffer, as might be expected if both were largely dependent upon the net charge of the protein.

TABLE V

CONSTANTS DEFINING THE MOBILITY OF CARBOXYHEMOGLOBIN IN PHOSPHATE AND CITRATE BUFFERS AT CONSTANT *p*H INTERVALS FROM APPARENT ISOELECTRIC POINTS

The quantity u_0 estimated from measurements in systems containing buffer may well have no significance for salt-free solutions. Indeed values of u_0 independent of the nature of the buffer are not quite realized on the basis of these measurements and of any of the equations considered. Whether this failure depends upon the form of these equations, upon the approximate method of estimating equal net charges for comparison or upon ion association between protein and buffer must await further investigation. The results do not preclude the latter interpretation, especially for buffers with polyvalent anions, and such association, if it occurs, must be taken into account as well as the electrostatic forces between buffer ions, protein ions and protein dipolar ions.

We are indebted to R. M. Ferry and W. C. Morro for certain of the measurements confirming our earlier results with the new Tiselius apparatus, and to J. D. Ferry and G. Scatchard for considering with us implications of the alternative methods of analyzing electrophoretic measurements.

Summary

1. The electrophoretic mobility of carboxyhemoglobin has been studied at 25° in phosphate and citrate buffers, varying in *p*H from 5.65 to 7.2, and in ionic strength from 0.02 to 0.20.

2. Over this range the influence of ionic strength upon mobility is of the same order as that of *p*H. Corrections for the influence of electrostatic forces both in diminishing mobility and in changing the isoelectric point are considered.

3. Whereas the computations attempted on the basis of these results do not preclude ion association, they yield constants for the effect of the buffers at constant *p*H, and at constant *p*H intervals from the isoelectric condition.

4. Carboxyhemoglobin has a net charge due to the dissociation of twelve or more imidazole groups at the most acid reactions investigated.

5. Not only mobility but diminution in mobility due to electrostatic forces is a function of the net charge, and therefore increases with distance from the isoelectric condition.

Thermodynamic Significance of Polarographic Half-Wave Potentials of Simple Metal Ions at the Dropping Mercury Electrode

BY JAMES J. LINGANE[1]

The electrodeposition of simple (hydrated) metal ions at the dropping electrode is a chemically reversible process when the resulting metal is soluble in mercury, and may be represented by

$$M^{n+} + ne + Hg \rightleftharpoons M(Hg) \qquad (1)$$

where M(Hg) represents the amalgam formed on the surface of the mercury drops.[2] Heyrovsky and Ilkovic[3] have pointed out that if the foregoing reaction takes place reversibly the dropping electrode should be subject only to concentration polarization, and accordingly its potential at every point on a discharge wave should be given by

$$E_{d.e.} = E_a^0 - \frac{RT}{nF_y} \ln \frac{C_a \gamma_a}{C_0 \gamma_s} \qquad (2)$$

where C_a is the concentration of the amalgam formed on the surface of the mercury drops, C_0 is the concentration of the metal ions in the depleted layer of solution *at the surface* of the drops, γ_a and γ_s are, respectively, the activity coefficients of the metal in the amalgam and the metal ions in the solution, and E_a^0 is the standard potential of the amalgam, that is, the e. m. f. of the cell: Reference electrode / $M^{n+}(a = 1)$/M(Hg)$(a = 1)$ (I).

When an excess of an indifferent electrolyte is present so that the migration current is eliminated, the reducible metal ions reach the surface of the dropping electrode only by diffusion.[2,4] Representing the concentration of the reducible metal ions in the body of the solution by C, the current at any point on the polarographic wave by i, and the diffusion current by i_d, we have the relations[2,3]

$$i_d = KC \qquad (3)$$
$$i = K(C - C_0)$$

or

$$C_0 = \frac{i_d - i}{K} \qquad (4)$$

and

$$C_a = ki \qquad (5)$$

The validity of eq. 3, in which K is the diffusion current constant, has been amply demonstrated.[2,4] The theoretical significance of K and the factors which influence it have been discussed in detail by Ilkovic[5] and Lingane and Kolthoff.[4] Equation 5 is simply a statement of the fact that the concentration of the amalgam at every point on the wave must be proportional to the current.

By substituting the foregoing relations into eq. 2 we obtain

$$E_{d.e.} = E_a^0 - \frac{RT}{nF_y} \ln \frac{\gamma_a k K}{\gamma_s} - \frac{RT}{nF_y} \ln \frac{i}{i_d - i} \qquad (6)$$

The half-wave potential is defined[3] as the value of $E_{d.e.}$ at the midpoint of the wave, and since the last log term becomes zero when $i = i_d/2$ eq. 6 may be written

$$E_{d.e.} = E_{1/2} - \frac{RT}{nF_y} \ln \frac{i}{i_d - i} \qquad (7)$$

and hence the half-wave potential is given by

$$E_{1/2} = E_a^0 - \frac{RT}{nF_y} \ln \frac{\gamma_a k K}{\gamma_s} \qquad (8)$$

It should be mentioned that the observed value of $E_{d.e.}$ includes a small iR drop in the solution. However, with concentrations of supporting electrolyte greater than about 0.01 M the resistance of a polarographic cell is generally less than 1000 ohms, and hence the iR drop is usually less than 0.001 v. per microampere, which is negligibly small.

When the resulting metal is not soluble in mercury it is simply deposited in the solid state on the surface of the dropping electrode, and in such a case the reduction of the metal ions will be given by

$$M^{n+} + ne \rightleftharpoons M(s) \qquad (9)$$

If this reaction would take place reversibly it readily can be derived that the equation of the polarographic wave should be

$$E_{d.e.} = E_M^0 - \frac{RT}{nF_y} \ln \frac{K}{\gamma_s} + \frac{RT}{nF_y} \ln (i_d - i) \qquad (10)$$

where E_M^0 is the ordinary standard potential of the metal. Quite obviously the curve of this equation is not symmetrical about the half-wave point, and therefore in this case the half-wave potential has no particular thermodynamic significance. The difficulty of obtaining reproduci-

ble electrode potentials in the classical manner with metals that are insoluble in mercury (*e. g.*, metals of group VI in the periodic classification, the iron group, arsenic, vanadium, etc.) is well known, and chemical polarization and passivity phenomena are common in this group. Hence the reduction of such metals according to eq. 9 is in most cases probably not a reversible process. For these reasons the following discussion will be confined to those metals that are soluble in mercury, and whose ions are reduced at the dropping electrode according to eq. 1.

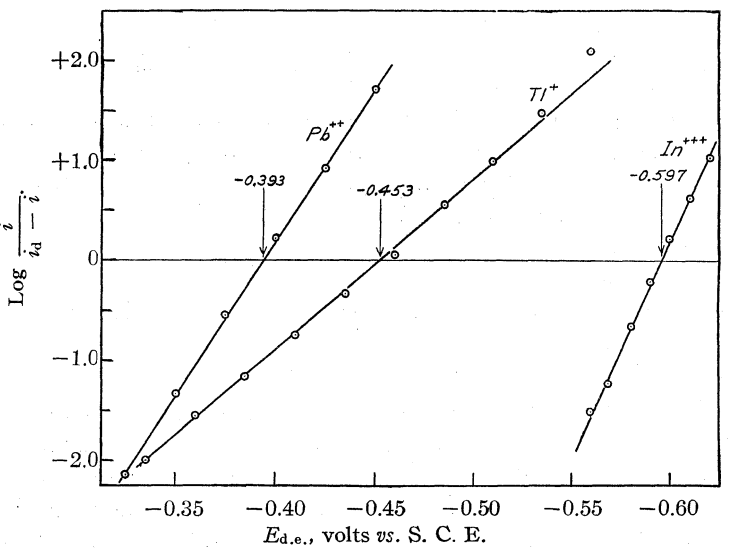

Fig. 1.—Log plots of observed current–voltage curves of thallous and lead ions in 0.1 *N* potassium chloride, and of indium ions in 1 *N* potassium chloride. The slopes of the three lines are Tl^{+} 0.059 v., Pb^{++} 0.033 v., and In^{+++} 0.023 v.

Equation 7 has been verified experimentally by Tomes[6] and Kolthoff and Lingane.[2] By plotting $E_{d.e.}$ against log $i/(i_d - i)$ a straight line results, whose slope is equal to $2.3RT/nF_y$, and the value of $E_{d.e.}$ corresponding to a value of zero for the log term is the half-wave potential. This is demonstrated in Fig. 1, where the plots have been constructed from experimental current–voltage curves obtained by the writer, in the electrolysis of 0.002 *M* solutions of thallous, lead, and indium ions in the presence of an excess of potassium chloride. The current–voltage curves were obtained with the apparatus previously described.[2,4] As predicted by eq. 7, the experimental points fall on straight lines. The observed slopes of the three lines are, respectively, 0.059, 0.033, and 0.023 v. for the thallous, lead, and indium ions, in good agreement with the theoretical values which are 0.059, 0.030, and 0.020 v. for the discharge of uni-, di-, and trivalent ions. It is evident that eq. 7, and the fundamental assumption that the dropping electrode is subject only to concentration polarization in the discharge of metal ions according to eq. 1, are essentially correct.

(6) J. Tomes, *Coll. Czech. Chem. Commun.*, **9**, 12, 81, 150 (1937).

By setting the second differential of eq. 7, *i. e.*

$$\frac{d^2E}{di^2} = \frac{RT}{nF_y}\left(\frac{1}{i^2} - \frac{1}{(i_d - i)^2}\right)$$

equal to zero, it is found that the curve of eq. 7 has a point of inflection when $i = i_d/2$. The polarographic wave is therefore symmetrical about the half-wave point, and $E_{1/2}$ coincides with the true inflection point of the curve.[3]

It has been found experimentally[2,3] that the half-wave potential is entirely independent of the geometrical characteristics of the particular capillary that is used, the rate of flow of mercury, and the drop time. Therefore, it is evident from eq. 8 that the product kK is constant and independent of these factors. Although both k and K are individually dependent on the properties of the capillary, the rate of mercury flow, and the drop time, the effect of these factors on k must be inversely proportional to their effect on K, so that the product kK remains constant. It is also an experimental fact[2,3] that the half-wave potential is constant and independent of the concentration of the reducible metal ions, provided that the composition of the solution with respect to foreign salts, *i. e.*, γ_s, is kept constant. It is evident, therefore, that the half-wave potential is a characteristic property of the reducible ions, and it has definite thermodynamic significance.

Influence of the Concentration of Supporting Electrolyte on the Half-Wave Potential.—Since the activity coefficient, γ_s, of the reducible metal ions decreases with increasing ionic strength, it is to be expected from eq. 8 that $E_{1/2}$ should be shifted somewhat to more negative values with increasing concentration of supporting electrolyte. This is actually observable experimentally, as shown by the data in Table I obtained by the writer.

TABLE I

HALF-WAVE POTENTIALS OF THALLOUS, ZINC, CADMIUM, AND LEAD IONS IN VARIOUS CONCENTRATIONS OF SUPPORTING ELECTROLYTE

Half-wave potentials in volts referred to the saturated calomel electrode at 25°.

Supporting electrolyte	Tl^+	Zn^{++} $E_{1/2}$	Pb^{++}	Cd^{++}
0.02 *N* KNO_3	−0.451	−0.988		−0.572
0.1 *N* KNO_3	.459	0.997	−0.388	.578
1 *N* KNO_3	.477	1.012	.405	.586
0.02 *N* KCl		−0.988	− .377	− .578
0.1 *N* KCl	−0.459	0.995	.396	.599
0.25 *N* KCl	.466		.402	
1 *N* KCl	.480	−1.022	.435	.642

These data were obtained by the manual method of measurement and with the cells that have already been described,[2,4] and $E_{d.e.}$ was measured directly against an external saturated calomel reference electrode during the electrolysis. The concentration of the metal ions was 5×10^{-4} *M* or smaller, the current at the half-wave point was less than 2 microamp., and hence the correction for the *iR* drop in the solution was negligibly small. The $E_{1/2}$ values are reproducible to about ±2 mv.

The negative shift of the $E_{1/2}$ values with increasing ionic strength is of the order of magnitude predicted by eq. 8, when potassium nitrate is used as supporting electrolyte. The half-wave potential of thallous ions is the same in potassium nitrate and potassium chloride media at the same ionic strength, but with the other metal ions the negative shift is considerably greater in potassium chloride than in potassium nitrate solutions, due to complex ion formation between the divalent metal ions and chloride ions. It is well known that the half-wave potentials of metal ions are shifted to more negative values by complex formation.[2,3] In potassium nitrate solutions there is no appreciable complex formation, and only the ionic strength effect is operative.

Thermodynamic Interpretation of the Half-Wave Potential.—In order to interpret the half-wave potentials thermodynamically, it is convenient to compare them with the ordinary standard potentials of the metals. Consider the cell $M(s)/M^{n+}/M(Hg)$ two phase (II), in which the left electrode is the solid metal, and the right electrode is its saturated two-phase amalgam. Let $a_{satd.}$ be the activity of the metal in the saturated liquid amalgam in contact with a solid phase which may be either the pure metal, or a solid compound, or solid solution, of the metal and mercury. The e. m. f. of this cell is given by

$$E_{II} = E^0_a - E^0_M - \frac{RT}{nF_y} \ln a_{satd.} \qquad (11)$$

where E^0_M is the ordinary standard potential of the metal, that is, the e. m. f. of the cell: Reference electrode/$M^{n+}(a = 1)$/M(s) (III).

If we express the composition of the amalgam in terms of mole fraction of the metal, *N*, and designate the *solubility* of the metal in mercury by $N_{satd.}$ and the corresponding activity coefficient by $\gamma_{satd.}$, we obtain from eq. 11

$$E^0_a = E^0 + E_{II} + \frac{RT}{nF_y} \ln N_{satd.}\, \gamma_{satd.} \qquad (12)$$

By substituting this expression for E^0_a into eq. 8 we find that the difference between the half-wave potential of a metal ion and its ordinary standard potential is given by

$$E_{1/2} - E^0_M = E_{II} + \frac{RT}{nF_y} \ln N_{satd.}\, \gamma_{satd.} - \frac{RT}{nF_y} \ln \frac{\gamma_a kK}{\gamma_s} \qquad (13)$$

The first two terms on the right side of this equation are thermodynamic terms, but the last term involves the kinetics of the electroreduction.

In the case of metals which do not form solid compounds or solid solutions with mercury, *e. g.*, zinc, E_{II} is zero. In general, however, when the metal forms a solid compound or solid solution with mercury, E_{II} is equal to $-\Delta F/nF_y$, where ΔF is the free energy increase in the formation of the solid M_xHg_y, according to the reaction

$$xM(s) + yHg(l) \rightleftharpoons M_xHg_y(s) \qquad (14)$$

It is evident, therefore, that the difference between $E_{1/2}$ and E^0_M depends on three distinct factors; the affinity of the metal for mercury (ΔF of reaction 14), the solubility of the metal in mercury, and the kinetic term *kK*.

A comparison of the half-wave potentials and the ordinary standard potentials of several metal ions is given in Table II. The values of $E_{1/2}$ given for the first four metal ions are the values obtained with 0.1 *N* potassium nitrate as the supporting electrolyte (Table I). The $E_{1/2}$ values of sodium and potassium ions were taken from the compilation given by Heyrovsky and Ilkovic[3]; they were obtained by using tetra-substituted alkylammonium salts as the supporting electrolyte.

It will be noted that the difference between $E_{1/2}$ and E^0_M is greatest in the case of the alkali metals, due to their great affinity for mercury. In these cases the difference is due chiefly to the large value of E_{II}, and the second and last terms in eq. 13 are of subordinate importance. On the

other hand, in the case of thallium E_{II} is negligibly small, but the solubility of thallium in mercury is large, so that the difference between $E_{1/2}$ and E^0_M is determined practically entirely by the last two terms in eq. 13.

The solubilities of the various metals in mercury at 25° are listed in the sixth column of the table, in terms of mole fraction, and the corresponding activity coefficients are given in the seventh column. The values of $\gamma_{satd.}$ are based on infinite dilution ($\gamma_a = 1$) as the standard state.

The last column contains approximate values of kK for the various metals calculated by means of eq. 13 from the observed differences between $E_{1/2}$ and E^0_M, and the experimental values of E_{II}, $N_{satd.}$, and $\gamma_{satd.}$ given in the table. In this calculation it was assumed that the activity coefficient of the univalent ions is 0.8, and that of the divalent ions 0.5, at an ionic strength of 0.1 M in potassium nitrate solutions.[7] Since we had no exact knowledge, *a priori*, regarding the concentration of the amalgams formed on the surface of the mercury drops, it was assumed that the concentrations of the amalgams were so small, under the usual conditions of a polarographic experiment, that γ_a was equal to unity. Because of this uncertainty the calculated values of kK can only be considered as approximations, but they are sufficiently accurate to indicate at least the order of magnitude of the constant k.

Although the observed values of $E_{1/2} - E^0_M$, and E_{II}, vary from a few millivolts up to one volt, and the activities of the saturated solutions of the metals in mercury vary widely from 0.01 in the case of lead up to 3.5 in the case of thallium, the calculated values of kK are all of the same order of magnitude. Unfortunately, no independent experimental method for determining k has yet been discovered, so that a more direct test of eq. 13 is not possible at the present time. However, the uniformity of the various calculated values of kK constitutes good indirect evidence of the validity of eq. 13.

The diffusion current constant K for the metal ions in Table II is of the order of magnitude of 5 microamp. per millimole per liter, with capillaries of the usual dimensions.[2,4] Hence the apparent value of k, from the data in Table II, is of the order of 0.005 mole fraction per microamp. for most of the metals. If we express the composition of the amalgams in volume concentration units, the apparent value of k is of the order of 300 mmol. per liter per microamp. This rather large value of k indicates that the deposited metal atoms remain close to the surface of the drop during its life, and that diffusion into the body of the drop is relatively slow. At the present time our knowledge of the diffusion processes in the mercury drops is so meager and incomplete that any attempt at a more detailed interpretation of these results at this time would be pure conjecture.

(7) J. Kielland, THIS JOURNAL, **59**, 1675 (1937).

Summary

The equation of the current–voltage curves in the electrodeposition of metal ions at the dropping mercury electrode has been discussed. When the reduced metal is soluble in mercury the dropping electrode is subject only to concentration polarization.

Experimental data have been presented which demonstrate that the half-wave potentials of metal ions are shifted somewhat to more negative values with increasing ionic strength of the solution.

The characteristics of the half-wave potential have been discussed, and an equation was derived relating the half-wave potentials to the ordinary standard potentials of the metals. The difference between the polarographic half-wave potential of a simple metal ion and the ordinary standard potential of the metal was shown to be a function of three distinct factors: (1) the affinity of the metal for mercury; (2) the solubility of the metal in mercury; and (3) the kinetics of the diffusion processes in the solution and in the mercury drops.

Mutarotation of Tetramethyl-α-d-glucopyranose and Tetramethyl-α-d-mannopyranose

BY B. CLIFFORD HENDRICKS AND ROBERT E. RUNDLE

In a previous paper,[1] a study of the complexity of the mutarotation of *d*-galactopyranose was reported. In this communication a study of the analogous glucose and mannose sugars is presented.

The mutarotation of tetramethyl-α-*d*-glucopyranose has been investigated by Purdie and Irvine,[2] Lowry and co-workers[3-5] and Böeseken and Couvert[6] in water and other solvents. These workers, however, gave direct attention to the reaction order of the sugars' mutarotations at only one temperature. The mutarotation of tetramethyl-α-*d*-mannopyranose has been previously reported,[7] though only incidentally.

A systematic study of the unmethylated α-*d*-glucose[8] does not support the reported[9] complex mutarotation of α-*d*-glucose. The authors proposed to learn whether methylation and mutarotation at or near 0° would give evidence of mutarotation complexity.

Since there is a paucity of data upon tetramethylmannose they prepared and followed the mutarotation of tetramethyl-α-*d*-mannopyranose also.

The two sugars were prepared as indicated in a previous paper.[10] The properties of the tetramethyl-α-*d*-glucopyranose used were: initial rotations, $[\alpha]^0D$ +104.0; $[\alpha]^{25}D$ +104.0; equilibrium rotations: $[\alpha]^0D$ +80.4; $[\alpha]^{25}D$ + 84.8 and m. p. 92.5–93.5°. The constants for the tetramethyl-α-*d*-mannopyranose used were m. p. 49–50°; initial rotations: $[\alpha]^0D$ +11.5; $[\alpha]^{25}D$ +6.3; equilibrium rotations: $[\alpha]^0D$ +2.5 and $[\alpha]^{25}D$ −0.2.

The experimental method followed and technique used were as described in a communication[1] previously cited. In this paper, as there stated, the rotation velocity constant, $k_1 + k_2$, is considered an index of the character of the mutarotation.

Results listed in Tables I, II, III and IV are representative of the results of the numerous experiments made.

The "thermal mutarotation" of tetramethyl-α-d-glucopyranose, using the procedure described previously,[1] was followed over a period of fifteen hours after a temperature change of from 25 to 0°. The calculations from the data for twenty-two observations gave a velocity constant, $(k_1 + k_2) \times 10^3$, of 0.640 ± 0.135. The deviations were random in their distribution with no more indication of trends than that shown in Table II. However, due to smaller changes in specific rotation during mutarotation, the experimental error is larger for methylated sugars. This is especially true for observations for the "thermal mutarotation" of the tetramethylglucose.

Discussion of Results

For purposes of ready comparison the constants of the three methylated sugars are tabulated with their unmethylated analogs in Table V. The data for the latter sugars are taken from the publication of Isbell and Pigman.[8] Those for the methylated galactose are from the paper previously listed.[1]

The mutarotation velocity constants for the methylated glucose show but slightly more variability than do those for the unmethylated sugar, probably due to experimental error. That agreement and the small variation of the velocity of mutarotation constants for the "thermal mutarotation" experiment give no support to the suggested[9] second order type of mutarotation for α-d-glucopyranose. Likewise the mutarotation of tetramethyl-α-d-mannopyranose is as truly of the first order as that of α-d-mannopyranose itself. It should be noted that there is as good an agreement between the heats of activation for the methylated sugars, 16,970 ± 260, as with those of the non-methylated sugars, 17,000 ± 300. These deviations are of about the same order as that introduced by the experimental error.

TABLE V

Sugar	$(k_1 + k_2) \times 10^3$	$(k' + k_2) \times 10^3$	Heat of activation, Q[b]
α-d-Glucopyranose	0.74 ± 0.05 at 0.2°	6.32 ± 0.14 at 20°	17,200
Tetramethyl-α-d-glucopyranose	.72 ± .15 at 1.0°	8.86 ± .34 at 25°	16,963
α-d-Galactopyranose[a]	.93 ± .02 at 0.0°	8.03 ± .04 at 20°	17,100
Tetramethyl-α-d-galactopyranose	.91 ± .06 at .0°	12.1 ± 1.7 at 25°	16,720
α-d-Mannopyranose	2.16 ± .15 at .1°	17.3 ± 0.2 at 20°	16,700
Tetramethyl-α-d-mannopyranose	1.19 ± .20 at .0°	17.1 ± 2.0 at 25°	17,230

[a] The constants for galactose are given only for the second slower phase of its complex mutarotation.

[b] $2.0326 \log \frac{(k_1 + k_2)}{(k_1' + k_2')} = \frac{Q}{1.9864}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$

Summary

The mutarotations of the tetramethylpyranose forms of both α-d-glucose and α-d-mannose have been investigated at the temperatures 0.0 and 25°.

Neither sugar shows a mutarotation of other

than the first order within the precision limits of the experimental technique used.

The heats of activation of these methylated sugars show a marked agreement with the heats of activation of analogous non-methylated sugars.

Sulfophenylarsonic Acids and Certain of their Derivatives. II. *p*-Sulfonamidophenylarsonic Acid

BY J. F. ONETO AND E. L. WAY

In this paper, which is a continuation of our studies of sulfophenylarsonic acids and their derivatives, a number of compounds have been described, two of which (*p*-sulfonamidophenylarsonic acid and *p*-sulfonamidophenylarsine oxide) should be of pharmacological interest.

The preparation of *p*-sulfonamidophenylarsonic acid was effected by application of the Bart reaction to sulfanilamide.

p-Sulfonamidophenylarsine oxide was prepared by two methods: (A) hydrolysis of *p*-sulfonamidophenyldibromoarsine with ammonium hydroxide; (B) interaction between *p*-chlorosulfonylphenyldichloroarsine and ammonium hydroxide. The oxide was converted to *p*-sulfonamidophenylarsonic acid by oxidation with hydrogen peroxide in alkaline solution.

p-Chlorosulfonylphenylarsonic acid, obtained by partial hydrolysis of *p*-chlorosulfonylphenyltetrachloroarsine, reacts with aniline to form *p*-sulfonanilidophenylarsonic acid. This reaction is now being studied in the preparation of substituted anilide and amide derivatives of *p*-sulfophenylarsonic acid.

Experimental Part

***p*-Sulfonamidophenylarsonic Acid.**—This acid was prepared by application of the Bart reaction to sulfanilamide (*p*-aminobenzenesulfonamide). It crystallizes from water in colorless, glistening needles, yield 25%. The acid is somewhat soluble in alcohol and in acetic acid; insoluble in acetone.

Anal. Calcd. for $C_6H_8O_5NAsS$: As, 26.66. Found: As, 26.51.

When heated for two hours under reduced pressure at 185–190°, the acid loses one molecule of water to form the anhydride.

Anal. Calcd. for $C_6H_5O_4NAsS$: As, 28.47. Found: As, 28.36.

The crystalline silver salt of *p*-sulfonamidophenylarsonic acid was obtained when 0.7 g. of the acid dissolved in 10 cc. of boiling water was treated with an excess of 0.25 *N* silver nitrate solution; yield 0.7 g.

Anal. Calcd. for $C_6H_7O_5NAsSAg$: As, 19.31; Ag, 27.81. Found: As, 19.39; Ag, 27.50.

In a second procedure the acid was obtained when 2 g. of *p*-sulfonamidophenylarsine oxide (obtained by treating *p*-chlorosulfonylphenyldichloroarsine with ammonium hydroxide) dissolved in 10 cc. of 10% sodium hydroxide was oxidized with 3 cc. of 30% hydrogen peroxide by heating on the steam-bath for one-half hour. The hot solution was acidified, whereupon the acid crystallized on cooling; yield 0.7 g.

The acid thus obtained was converted to the corresponding dibromoarsine; mixed m. p. 190–191°.

***p*-Sulfonamidophenyldiiodoarsine.**—A hot solution consisting of 1.7 g. of *p*-sulfonamidophenylarsonic acid in 25 cc. of water was treated with 15 cc. of 50% hydriodic acid. The diiodoarsine crystallized on cooling; yield, after recrystallizing from glacial acetic acid, 1.8 g.; m. p. 192–193°.

Anal. Calcd. for $C_6H_6O_2NAsSI_2$: As, 15.45; I, 52.35. Found: As, 15.36; I, 52.70.

***p*-Sulfonamidophenyldibromoarsine.**—A solution prepared from 2 g. of *p*-sulfonamidophenylarsonic acid, 20 cc. of 30% hydrobromic acid and a trace of hydriodic acid was saturated with sulfur dioxide. The resulting crystalline precipitate was recrystallized from glacial acetic acid; yield 2 g.; m. p. 191–192°.

Anal. Calcd. for $C_6H_6O_2NAsSBr_2$: As, 19.16. Found: As, 19.26.

***p*-Sulfonamidophenyldichloroarsine. (A).**—A solution consisting of 2 g. of *p*-sulfonamidophenylarsonic acid, 10 cc. of 37% hydrochloric acid and a trace of hydriodic acid was saturated with sulfur dioxide. The resulting dichloroarsine was recrystallized from glacial acetic acid; yield 1.5 g.; m. p. 176–177°.

Anal. Calcd. for $C_6H_6O_2NAsSCl_2$: As, 24.81. Found: As, 24.85.

(B).—Two grams of *p*-sulfonamidophenylarsonic acid was ground in a mortar with 12 cc. of phosphorus trichloride. After standing for one-half hour, the mixture was treated with ice water and the resulting crude dichloroarsine removed by filtration. The crude dichloroarsine was purified by dissolving in hot 10% hydrochloric acid and precipitating the crystalline substance by the addition of concentrated hydrochloric acid; yield 1.4 g.; mixed m. p. 176–177°.

(C).—One gram of *p*-sulfonamidophenylarsine oxide was dissolved in 10 cc. of hot 10% hydrochloric acid. The crystalline dichloroarsine was precipitated by the

addition of an excess of concentrated hydrochloric acid; yield 0.8 g.; mixed m. p. 176–177°.

p-Sulfonamidophenylarsine Oxide. (A).—Three and one-half grams of *p*-sulfonamidophenyldibromoarsine was boiled with 20 cc. of 27% ammonium hydroxide. The mixture was then chilled in ice and the crude oxide removed by filtration; yield, 1.8 g. after recrystallizing from 2% phosphoric acid.

Anal. Calcd. for $C_6H_6O_3NAsS$: As, 30.32; N, 5.67. Found: As, 30.21; N, 5.67.

(B).—Seven grams of crude *p*-chlorosulfonylphenyldichloroarsine was treated with 20 cc. of concentrated ammonium hydroxide. After standing for one hour the mixture was acidified with dilute sulfuric acid and the resulting oxide purified as above; yield 2.2 g.

One-half gram of the oxide was converted to the corresponding dichloroarsine by method (C) outlined under *p*-sulfonamidophenyldichloroarsine; mixed m. p. 176–177°.

p-Chlorosulfonylphenyldichloroarsine.—This substance was prepared by the method of Barber[1] using phosphorus trichloride and phosphorus pentachloride. The yield from 5 g. of sodium *p*-sulfophenylarsonic acid[2] after several recrystallizations from glacial acetic acid was 1 g.; m. p. 84–85°. This substance is soluble in most organic solvents.

Anal. Calcd. for $C_6H_4O_2AsSCl_3$: As, 23.30; Cl, 33.09. Found: As, 23.42; Cl, 32.87.

(1) Barber, *J. Chem. Soc.*, 2047 (1930).
(2) Oneto, THIS JOURNAL, **60**, 2058 (1938).

p-Chlorosulfonylphenylarsonic Acid.—Five grams of *p*-chlorosulfonylphenyldichloroarsine was dissolved in 10 cc. of warm chloroform and saturated with chlorine. The mixture was chilled in ice and the unstable, crystalline *p*-chlorosulfonylphenylarsine tetrachloride removed by filtration. The tetrachloroarsine was hydrolyzed to the corresponding *p*-chlorosulfonylphenylarsonic acid by treating with ice water. The crude acid was dried in vacuum over calcium chloride and recrystallized from ethyl acetate; yield 1.5 g.

Anal. Calcd. for $C_6H_6O_5AsSCl$: As, 24.93. Found: As, 24.89.

p-Sulfonanilidophenylarsonic Acid.—A mixture consisting of 5.3 g. of *p*-chlorosulfonylphenylarsonic acid and 12 cc. of aniline was heated on a water-bath for one-half hour. The resulting mass was treated with 40 cc. of 5% sodium hydroxide. The alkaline layer, which separated on standing, was treated with concentrated hydrochloric acid until acid to congo red paper, whereupon the *p*-sulfonanilidophenylarsonic acid precipitated in a crystalline form; yield, after recrystallization from water, 5 g.

Anal. Calcd. for $C_{12}H_{12}O_5NAsS$: As, 20.97. Found: As, 20.66.

Summary

The preparation and properties of *p*-sulfonamidophenylarsonic acid and a number of its derivatives have been described.

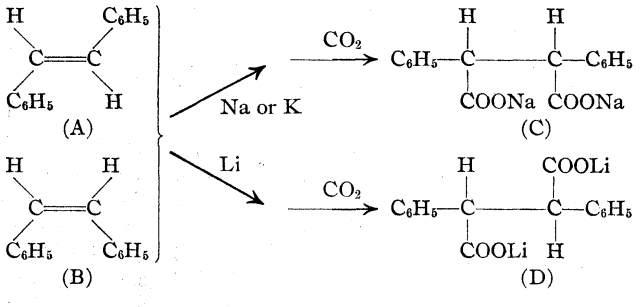
Addition of Alkali Metals to the Stilbenes

BY GEORGE F. WRIGHT

Introduction

In 1928 Schlenk and Bergmann[1] presented evidence to show that when alkali metals were added to ethylenes, the configuration of the adduct depended on the metal added and not upon the geometric isomer which was used. Thus, the addition of sodium or potassium to either stilbene (A) or isostilbene (B) gave, after carboxylation, the salt of *meso*-diphenylsuccinic acid (C), whereas addition of lithium to either geoisomer under similar conditions gave the salt of *dl*-diphenylsuccinic acid (D). They further demonstrated that, under conditions not conducive to the addition reaction, isostilbene was isomerized by sodium to stilbene.



While such a directed addition is not impossible from stereochemical considerations, it would seem improbable that two metals as similar as are sodium and lithium should orient themselves so specifically that mixtures of diastereomers would not be formed. The observations of Schlenk and Bergmann have not been questioned; indeed Bachmann and Pence[2] assumed, on the basis of color, that addition of lithium or sodium to 1,2,3,4-dibenzanthracene yielded each a characteristic diastereomer. However Jeanes and Adams[3]

found that sodium, potassium and lithium all added to phenanthrene to give *trans* dimetalated dihydrophenanthrenes. In contrast, therefore, to the findings concerning stilbene, these latter authors find that the configuration of the adduct is independent of the alkali metal used to form it.

Inspection of the experimental data of Schlenk and Bergmann reveals a contradiction concerning their supposed *dl*-diphenylsuccinic acid. This substance was reported by many workers and was finally resolved by Wren and Still.[4] The resolvable acid melts at 183°, resolidifies and again melts at 222°. The melting point of the carboxylated organolithium compound, which Schlenk and Bergmann designated as the *dl*-isomer, was 241°. It will be shown in the present work that the apparent anomaly is eliminated on the basis that Schlenk and Bergmann never obtained any acid other than the *meso*-diphenylsuccinic acid. Although the latter acid ordinarily melts at 229°, it has been found that melting points of 242,[5] 245,[6] and 252°[7] may be obtained. The variation seems to be dependent on the rate of heating. Since a substance having such an indefinite melting point is obviously unsuited for mixed melting point determination, the fact that Schlenk and Bergmann observed a depression on admixture of their two supposed isomers is of little consequence. Likewise their further identification is unconvincing since, of the two methyl esters which they obtained by diazomethane treatment of the acids, the one derived from their supposed *dl*-isomer melted over a 22° range.[8] The extremely questionable evidence upon which these authors base their specific modes of alkali metal addition to ethylenes made it seem advisable to re-investigate the problem.

The addition of the alkali metals to the stilbenes was therefore reëxamined, giving attention to three variables: 1, configuration of the stilbene; 2, choice of metal and 3, choice of solvent. Table I lists the series of experiments carried out to allocate the effect of each of these factors. The resulting organometallic compound was characterized by conversion to the *s*-diphenylsuccinic acids. In no case was a pure diastereomer isolated, although the presence of both isomers could not be demonstrated when the initial yield was low, owing to the difficulty encountered in isolating the *dl*-acid from a mixture with other impurities. Even under favorable circumstances of high yield the reported percentages of *dl*-isomer must be regarded as questionable; on the other hand, the method employed, that of Anschütz and Bendix[6] involving separation by means of barium salt solubilities, gave reliable yields of pure *meso* acid. Both acids, after separation, were identified by conversion to the methyl esters and by mixed melting point determination of the latter with authentic samples.

Reference to Table I shows that *meso*-diphenylsuccinic acid was always obtained regardless of the geometric isomer, or the metal used. This substantiates the claim of Schlenk and Bergmann that *cis*- and *trans*-stilbene give the same product, but disproves their postulate that sodium and lithium orient differently. Although the table shows only the exception (expt. 2) all other experiments yielded impure *trans*-stilbene as recovered ethylene, regardless of the geoisomer originally used. The solvent medium was found to exert a profound effect. In non-coördinating solvents like petroleum ether and benzene, the organometallic compounds were insoluble; the yields were poor. Much better yields were obtained in coördinating solvents like ethyl ether and glycol dimethyl ether in which the organoalkali compounds were soluble. Of greatest significance is the fact that the ratio of diastereomers varies with the solvent used.

Since isostilbene reacted only slightly, and stilbene not at all in 60–70° petroleum ether, even when the reactive sodium–potassium liquid alloy was used, the addition was studied in benzene. Reaction could not be initiated with sodium or lithium unless a small amount of chlorobenzene was added. This unavoidable contaminant may have contributed to the impurity of the carboxylated product; it was found impossible with the methods at hand to isolate *dl*-diphenylsuccinic acid from the poor yield of comparatively low melting crude substance (Table I, expts. 3–8). It can, however, be stated with certainty that the reddish precipitates, obtained with lithium from stilbene or isostilbene, as well as the brownish-black precipitates of disodium compound from

(8) Although the matter has not been re-investigated in the present study, it should be noted that Schlenk and Bergmann obtained two acids, both melting at 296°, by the action of sodium and lithium on *s*-diphenyldimethylethylene. They claim these acids to be different, but the results obtained in this present work would indicate that the acids are identical.

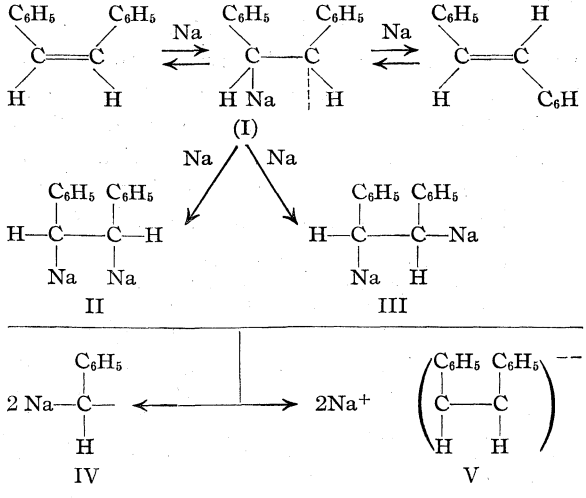
[a] All of these melting points were taken with slow (6°/min.) heating of the bath.

these two geoisomers, all gave *meso*-diphenylsuccinic acid upon treatment with carbon dioxide. Thus in a non-coördinating solvent, from which the organometallic compound precipitates as it is formed, no specific orientation of either sodium or lithium, can be found. Some significance can perhaps be attached to the higher yields from expt. 2 over expt. 1 and expt. 6 over expts. 3, 4 and 5 as indicating that isostilbene is more reactive than stilbene.

Since these results contradicted those of Schlenk and Bergmann, their experiments using lithium and stilbene in diethyl ether were repeated. Instead of an acid melting at 241° as they reported it was found that a mixture of *meso*- and *dl*-diphenylsuccinic acids was obtained when the impure product was subjected to separation through the barium salts. The proportion (55%) of *meso*-diphenylsuccinic acid isolated from the mixture is much more accurate than that of the *dl*-acid. The organometallic compound formed a reddish-brown solution in the ethyl ether. The yield, not reported by Schlenk and Bergmann, was found to be fair, especially over a twenty-four-hour reaction period (expts. 9, 10).

When glycol dimethyl ether[9] was used as a solvent, even better yields were obtained than with ethyl ether, while the reaction period was likewise shorter (expts. 11–16). The solutions of organometallic compounds were so dark that a color difference between organosodium and lithium was difficult to distinguish. The carboxylated product melted higher than that obtained from benzene or ether and, in spite of the careful separation through the barium salts, no *dl*-diphenylsuccinic acid could be isolated until a larger experiment was carried out (expt. 16), wherein 0.3% of the impure *dl*-diphenylsuccinic acid was isolated and identified. The ratio of diastereomers produced is, therefore, found to be different in benzene, ether, and glycol dimethyl ether, although the ratio of isomers is evidently independent of the metal used.

The possible steps in the addition reaction may be outlined according to the following diagram



(9) Scott, Walker and Hansley, THIS JOURNAL, **58**, 2442 (1936).

The first step involves random addition of sodium atoms to the ethylene linkage to give I; if this step were reversible the observed isomerization of isostilbene to stilbene would be expected.[10] The further addition of sodium atoms, with or without Walden inversion to give the pair of diastereomers II and III, is remindful of halogen addition to stilbene, if atomic addition is presumed to cause formation of two dibromostilbenes regardless of the isomer used. The possibility that I → II + III is an equilibrium reaction, or that II and III might dissociate to give a free radical of type IV is exceedingly improbable, but may be discounted further by the fact that the reaction mixture was unaffected by hydrogen, with or without a catalyst (Table I, expts. 13, 15). Finally, a dissociation into sodium cation and organic anion, II and III → V, was suggested by Schlenk and Bergmann, and especially favored by Jeanes and Adams,[3] who considered the sodium ion to be solvated. The ionic hypothesis would explain isomerization in the ethers, though not in benzene, but, unless the ether contributed greatly to anion deformation, it is not clear why different ethers should give different ratios of diastereomers. A better explanation might be afforded if it were assumed that the amorphous ion were subjected to the further influence of the reactant used for characterization. This possibility could not be tested heretofore, because all reactants other than carbon dioxide caused a reversion to stilbene.

Schlenk and Bergmann have shown that the vicinal diorganometallic compound when treated with methyl iodide does not react to give the dimethyl derivative but, instead, reverts to the parent ethylene. In the present investigation it has been found that dimethyl sulfate, unlike methyl iodide, reacts as a methylating agent. The ratio of diastereomers thus obtained is quite different from that produced in the same solvent by the carboxylation reaction. The absolute configuration of the 2,3-diphenylbutanes has not yet been established, but about twice as much low melting isomer as high melting isomer was produced. The ratio of diphenylsuccinic acids in the same solvent, glycol dimethyl ether, was about 300:1. On the basis of two reactions of different type (carboxylation and methylation) it can thus be stated that formation of diastereomeric mixtures is a function of the characterizing reactant. The dependence of stereochemical configuration in the adduct upon the nature of the augend to which the organometallic compound has been added has previously been encountered in the case of geoisomeric Grignard reagents.[11]

(10) Schlenk and Bergmann, *Ann.*, **463**, 1 (1928).

Experimental Part

Addition of Sodium or Lithium in Benzene.—A solution of 1.80 g. (0.01 mole) of stilbene or isostilbene in 25 cc. of benzene was placed in a nitrogen-filled Schlenk tube together with 0.02 mole of sodium or lithium, cut into about 50 pieces. After two sharp glass rods were added the tubes were sealed and shaken for periods of one to ten days. Since no apparent reaction took place, the tube was opened under nitrogen, and 0.02 g. of chlorobenzene was added. Reaction commenced in several hours. The precipitate was reddish-brown when lithium was used and reddish-black with sodium, the supernatant liquid being colorless. The reaction mixture was carboxylated by opening the tube under nitrogen, then by means of a sharp-pointed nichrome rod inserted through the straight arm of the tube breaking the bottom so that the contents dropped into a sidearm Erlenmeyer flask which was attached to the bole of the Schlenk tube by a rubber stopper. The Erlenmeyer flask contained a large excess of crushed dry-ice, which had been freed of water crystals by violent shaking of the flask under water-pump vacuum, atmospheric pressure being eventually restored by carbon dioxide evolution. The excess of sodium was decomposed by adding water to the carbon dioxide-filled flask. The water layer was separated from the benzene layer containing impure stilbene, and, after shaking with charcoal, was filtered and acidified with 12% hydrochloric acid to yield diphenylsuccinic acid.

Addition of Sodium and Lithium in Ethers.—The technique employed heretofore for preparation of organolithium compounds[12] was utilized, a stopcock having been sealed to the bottom of a three-necked flask. When glycol dimethyl ether[13] was used as solvent a conical flask[11] was found unsatisfactory when sodium was employed because the metal agglomerates to a solid lump after the reaction has started and thus interferes with the stirrer. No such difficulty was encountered with lithium. Reaction started immediately upon addition of the stilbene; protection from the air was afforded by a blanket of nitrogen rather than a stream of this gas over the reaction mixture. Upon completion of the reaction the contents of the flask were drained from unused metal through the stopcock into dry-ice. The carboxylated mixture was freed of the ether by evaporation at 70 mm. pressure and the residue processed as before.

Separation and Identification of the Diastereomeric Diphenylsuccinic Acids.—This method of Anschütz and Bendix was checked using equal mixtures of *meso*- and *dl*-diphenylsuccinic acids, the latter having been prepared by isomerization of the *meso* acid with barium hydroxide at 200°. The *meso* acid was recovered in 85% yield, m. p. 229°, while 70% of the *dl*-acid, m. p. 180–222°, was obtained.

In a typical experiment, 1.56 g. of crude diphenylsuccinic acid was dissolved in ammonia, the excess having been boiled off, and treated with 70 cc. of warm barium hydroxide solution saturated at 25°. The solution was then treated with dry-ice until precipitation was complete, the precipitate being then treated with 1:3 hydrochloric acid. The residue, weighing 0.33 g., melted at 160–210°. It was crystallized from hot water to melt at 180–210° (wt. 0.03 g.) and was identified as *dl*-diphenylsuccinic acid by conversion with diazomethane to the dimethyl ester, m. p. 176–177° after two crystallizations from propanol-1. The filtrate from the barium carbonate precipitation was acidified to yield *meso*-diphenylsuccinic acid, m. p. 226°, weight 0.86 g. This was crystallized from acetic acid or propanol-1 to melt at 229–230° (m. p. 238° when placed in bath 10° below this melting point) and was identified by diazomethane treatment in propanol-1 as the dimethyl ester, m. p. 221–222° after crystallization from the same solvent. This ester was hydrolyzed by twelve hours of boiling with a 1:1 mixture of acetic acid and 12% hydrochloric acid. The product, m. p. 232°, was dissolved in ammonia, filtered and re-acidified with hydrochloric acid to melt at 241° (bath initially at 226°). Repeated crystallization failed to raise the melting point. The melting point of the pure *meso*-diphenylsuccinic acid when quickly heated evidently misled Schlenk and Bergmann to assign a diastereomeric configuration to the identical compound.

Methylation of 1,2-Diphenylethanedisodium.—The organodisodium compound prepared over a three-hour period as before from 1.80 g. (0.01 mole) of isostilbene and 0.46 g. (0.02 mole) of sodium in 30 cc. of glycol dimethyl ether was stirred and maintained at 25° while 2.52 g. (0.02 mole) of freshly distilled dimethyl sulfate in 10 cc. of glycol dimethyl ether was added over a twenty-minute period. After the color was completely bleached, the remaining ball of sodium (0.13 g., 0.006 mole) was removed. The reaction mixture was distilled at 40° (10 mm.) to recover the ether; the remainder was mixed with water and the oil which separated was taken up in benzene and treated with an excess of bromine. After evaporation of the benzene at 20 mm., the remainder was steam distilled. The distillate, extracted with ether and the latter evaporated, furnished an oil which was dissolved in hot ethanol. On cooling, 0.46 g. of 2,3-diphenylbutane separated, m. p. 115°. This was identified, after crystallization from 2 cc. of petroleum ether (b. p. 60–70°) m. p. 124°, by mixed melting point with a sample obtained from Dr. C. F. H. Allen and prepared by reduction of 2,3-diphenylbutadiene-1,3.[14] Evaporation of the crystallizing liquors left 0.04 g. more of the solid isomer together with an oil which distilled at 132–134° (6 mm.), wt. 1.14 g. On the basis of the crude products 21% of the solid isomer and 53% of the liquid isomer were obtained.

(14) Allen, Eliot and Bell, *Can. J. Research*, **17**, 75 (1939).

When the experiment was repeated using stilbene, the yields of solid and liquid diastereomers of 2,3-diphenylbutane were 20 and 45%, respectively.

Nitration of the 2,3-Diphenylbutanes.—A stirred suspension of 0.11 g. (0.0005 mole) of 2,3-diphenylbutane (m. p. 124°) in 3 cc. of acetic anhydride was chilled to 0° while a nitrating mixture of 2 cc. of nitric acid (sp. gr. 1.52) and 2 cc. of acetic anhydride was added over a one-minute period. After fourteen hours the precipitate was filtered off, wt. 0.10 g. (65% of theoretical), m. p. 249°. When crystallized from 7 cc. of benzene this melted at 256°, same on recrystallization from benzene.

Anal. Calcd. for $C_{16}H_{16}N_2O_4$: C, 64.0; H, 5.37; N, 9.33. Found: C, 64.5; H, 5.37; N, 9.50.

The experiment was repeated using the liquid isomer. No precipitate appeared following the nitration, so the reaction mixture was poured into ice and water, and alkali was added to *p*H 6. The precipitate was taken up in ether; after evaporation the latter was crystallized from ethanol to yield a crude dinitrodiphenylbutane, m. p. 121–122° in 40% yield. This was recrystallized from ethanol to melt at 133°. None of the much less soluble high melting diastereomer, which is insoluble in the nitrating mixture, was detected in this latter nitration.

Anal. Calcd. for $C_{16}H_{16}N_2O_4$: C, 64.0; H, 5.37; N, 9.33. Found: C, 64.2; H, 5.31; N, 9.42.

Oxidation of the 2,3-Di-(*p*-nitrophenyl)-butanes.—Both of the dinitro compounds were recovered unchanged after boiling with potassium permanganate in acetic acid, but when 0.05 g. (0.00016 mole) of either dinitro compound was boiled in 1.5 cc. of acetic acid with 0.160 g. of chromic anhydride, a 90% yield of *p*-nitrobenzoic acid, m. p. 238–239°, was obtained and identified by mixed melting point.

Thanks are due Miss Joan Romeyn for carrying out the microanalyses reported here.

Summary

1. It has been found, contrary to previous reports, that the addition of alkali metals to stilbene gives a mixture of diasteromers.

2. When *s*-diphenylethanedisodium is treated with dimethyl sulfate a good yield of 2,3-diphenylbutane may be obtained.

3. The isomerization which results in a mixture of diastereomers is thought to occur chiefly when the organoalkali compound is characterized as the derivative and, therefore, the mixture of isomeric products is not indicative regarding configuration of the organometallic compound.

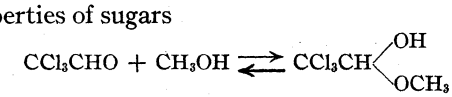
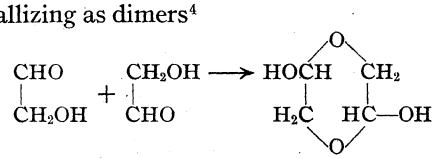
The Chemistry of the Tetrose Sugars. IV.[1] The Structure of a Methyl-*d*-erythroside.[2] The Mutarotation of *d*-Arabinose Oxime

BY ROBERT C. HOCKETT AND CARL W. MAYNARD, JR.[3]

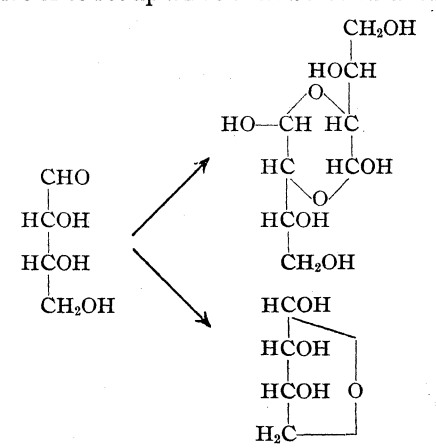
The universal affinity between carbonyl compounds and alcohols, which often impels the reversible formation of hemiacetals, underlies many of the most characteristic physical and chemical properties of sugars



Glycolaldehyde and the trioses manifest this affinity by *inter*molecular hemiacetal formation, crystallizing as dimers[4]



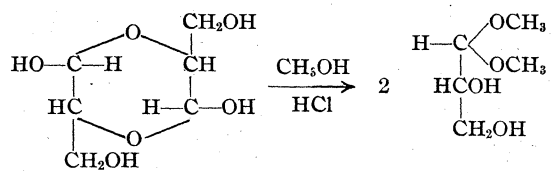
The pentoses and hexoses satisfy similar affinities by *intra*molecular addition of alcohol to aldehyde, yielding cyclic hemiacetals. The predilection in all these cases for a six-membered ring would render difficult a prediction whether the tetroses, on crystallizing, would tend rather to dimerize or to set up a five-membered furanose ring



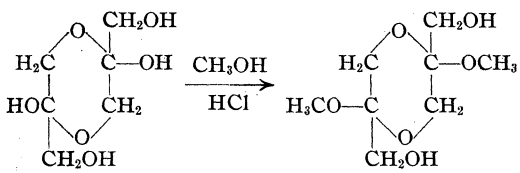
The observation that *l*-erythrose is monomeric in dilute aqueous solution[5] does not solve this question; the trioses are dissociated under like conditions.

On condensation of sugars with methanol containing hydrogen chloride, three types of behavior have been observed.

(1) The dimeric cyclic hemiacetal, glyceraldehyde, is converted into a monomeric open-chain dimethyl acetal



(2) The dimeric hemiacetal, dihydroxyacetone, is converted directly into the dimeric methyl glycoside[6]



(3) Finally, the more stable products obtained by such treatment of the monomeric inner hemiacetal, glucose, are the methyl pyranoside and the methyl furanoside.

Although isolation of a particular type of methyl derivative does not justify any conclusion regarding the preferred structure of the free sugar, it does provide *prima facie* evidence for the existence of the corresponding sugar form and provides some insight into the habits of the compound.

The first objective of the present study was to learn how *d*-erythrose would condense with meth-

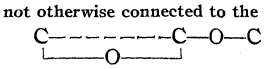
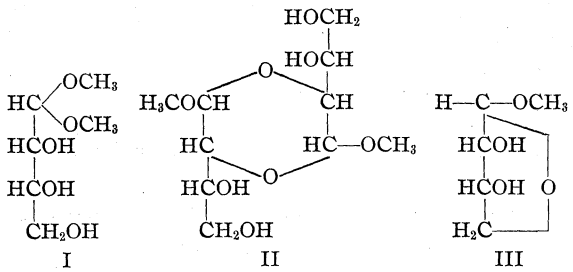
(6) We have not succeeded in finding anywhere an accurate definition of the term glycoside. The definition of Beilstein (Beil., Vol. XXXI, p. 11) is not valid since discovery of the true acetals of the higher sugars [Montgomery, Hann and Hudson, THIS JOURNAL, **59**, 1124 (1937)]. Our concept of a glycoloside provides that within such a compound a carbon atom be joined through oxygen to another carbon which is otherwise linked to the first and also through oxygen to a third carbon not otherwise connected to the first.



More concisely, a glycoside is a monocyclic mixed acetal. This definition includes the methyl glycoloside of Fischer and Baer[4] and analogous derivatives of the three-carbon sugars which are very similar in properties to the prototype, methyl glucoside. It excludes levoglucosan and arabinose dimethyl acetal, which are dicyclic and noncyclic, respectively.

anol containing 1% hydrogen chloride, the possible products being represented as follows[7]



I II III

To determine the structure of the product, both the methylation procedure and the method of cleavage oxidation[8] were employed (Fig. 2).

d-Erythrose diacetamide, obtained from *d*-arabinose by a modification of the Wohl degradation,[9] was hydrolyzed partially with sulfuric acid. The erythrose thus freed was treated with methanol containing about 1% hydrogen chloride and the methyl erythroside obtained was separated from the non-volatile nitrogenous compounds by distillation in a relatively high vacuum. On further methylation and oxidation with nitric acid, inactive dimethoxysuccinic acid was obtained, indicating that the product of condensation with methanol was a methyl-*d*-erythrofuranoside (III).

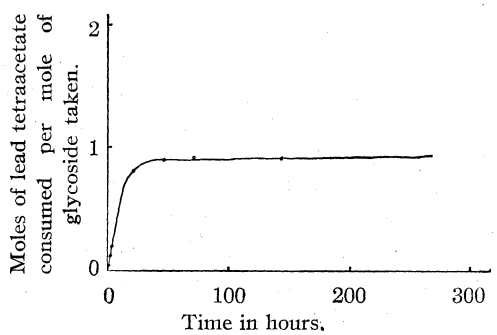


Fig. 1.—Oxidation of methyl-*d*-erythroside by lead tetraacetate.

This methyl-*d*-erythrofuranoside furnished us with a glycoside containing only two free hydroxyl groups, and those of known position and configuration, rendering possible a direct test of certain conclusions drawn by McClenahan and the senior author[8] from relatively indirect evidence, concerning the relative rates of oxidation of *cis* and *trans* glycols by lead tetraacetate. It was found that one mole of the glycoside consumes only one mole of this oxidant and that the rate of the reaction is the relatively rapid one found in the previous study to be characteristic of *cis* glycols (Fig. 1).

Moreover, after lead tetraacetate oxidation of this glycoside, the further action of strontium hypobromite yielded a crystalline salt closely resembling strontium D′-methoxydiglycolate. The latter was reported by Jackson and Hudson[8] and by McClenahan and Hockett[8] as a product of the action either of *excess* periodic acid or of lead tetraacetate (*two* moles) upon alpha-methyl-*d*-pentopyranosides, followed by treatment with strontium hypobromite. The present product showed the same composition and similar crystal habit, but differed optically, showing specific rotation $-8.94°$[13] as compared with a recorded value of $+55.0°$ for the beta and $-56.6°$[13] for the alpha isomer. This was considered evidence that our methyl-*d*-erythrofuranoside was a mixture containing about 58% of the alpha and 42% of the beta form (Fig. 2).

Data are included concerning the mutarotation of *d*-arabinose oxime and the hydrolysis of *d*-erythrose diacetamide by 0.100 *N* sulfuric acid (Table I and Fig. 3).

Experimental Part

***d*-Arabinose.**—This sugar was prepared from calcium gluconate by the procedure of Hockett and Hudson[10] modified for larger scale production.

***d*-Arabinose Oxime.**[5,11]—The method of preparation was almost the same as that described for *d*-xylose oxime.[12] The product crystallized readily from the reaction mixture, on cooling, in a yield of 86%. Recrystallized from about 70% ethanol as thin rectangular plates, washed with absolute ethanol, and dried at 50°, it showed m. p. 136–137° and rotated[13] $-13.5°$ at equilibrium (c, 2.0544; l, 2; H_2O).

The substance showed a mutarotation which was followed quantitatively. The change was found to be very nearly unimolecular.

Tetraacetyl-*d*-arabonic Nitrile.[11]—The *d*-arabinose oxime was acetylated using acetic anhydride and either fused sodium acetate or pyridine as the catalyst. In the former case, the procedure was just as described for *d*-xylose oxime,[12] dry dioxane being used as a diluent to prevent the reaction from becoming too vigorous In the second case 50 g. of pulverized oxime was suspended in 200 cc. of Eastman practical pyridine and 200 cc. of C. P. acetic anhydride

(13) All rotations quoted in this paper represent specific rotations of the D line of sodium at 20°; c is concentration in grams per 100 cc. of solution; and l is the tube length in decimeters.

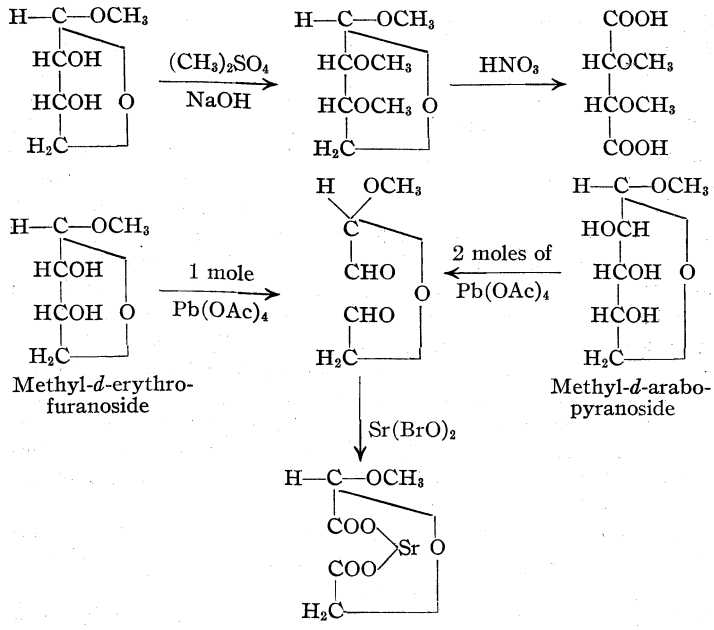

FIG. 2.

was added in three portions with cooling under the tap. The mixture was refrigerated overnight, warmed on a steam-bath for an hour, cooled, and poured upon about 500 g. of cracked ice. After refrigeration overnight, the precipitated gum had become a white solid which was washed free of pyridine with water and dried at 60° *in vacuo;* yield by either procedure, 63%. Recrystallized from absolute ethanol to constant properties, the compound melts 120–121° (corr.) and rotates −3.3° (*c*, 2.824; *l*, 2, $CHCl_3$).

Hydrolysis of *d*-Erythrose Diacetamide.—A sample of 2.0003 g. of purified *d*-erythrose diacetamide was dissolved to a volume of 50.0 cc. with 0.100 *N* sulfuric acid. This solution was poured into a 200-cc. flask submerged in a bath of rapidly boiling water and the time was noted. At noted intervals, the whole solution was cooled rapidly and its rotation read in a 4-dm. polarimeter tube. The results are represented by Fig. 3. The curve corresponds approximately to the unimolecular law; *k* (minutes and logarithms on base 10) = 0.0175. Hydrolysis was not yet complete after the last observation as demonstrated by the isolation of some unchanged *d*-erythrose diacetamide. The data could not be used to calculate a more reliable figure for the specific rotation of *d*-erythrose, owing to lack of a sample of pure sugar with which to standardize a method of estimating *d*-erythrose.[12]

***d*-Erythrose.**—Nine grams of *d*-erythrose diacetamide was heated for seventy-five minutes with 189 cc. of approximately 0.6 *N* sulfuric acid in a boiling water-bath (see Fig. 3). After concentration to about 50 cc., the solution was extracted with ether for eight hours in a continuous extractor to remove acetic acid. The aqueous layer was then treated with barium hydroxide solution to remove sulfuric acid quantitatively, decolorized with carbon, and filtered. The colorless filtrate was concentrated in a vacuum at less than 50°, to a thick sirup which was dried by distilling dry methanol from it.

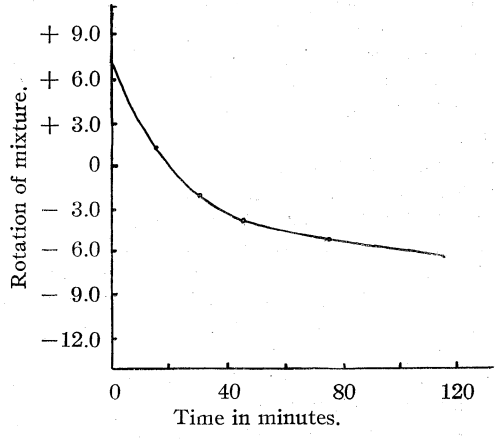

Fig. 3.—Hydrolysis of erythrose diacetamide by 0.1 *N* sulfuric acid.

Methyl-*d*-erythroside.—The erythrose described in the previous paragraph was dissolved in 100 cc. of a 1% solution of hydrogen chloride in dry methanol. The rotation in a 1-dm. tube immediately after homogenizing was −0.08°; this changed to −0.13° in about twenty minutes at room temperature and then remained constant, even though the solution was warmed on a steam-bath. The

power to reduce Fehling's solution disappeared during the same interval. The hydrogen chloride was removed with an excess of silver carbonate, and after filtration the solution was saturated with hydrogen sulfide and refiltered. The filtrate was concentrated under reduced pressure to a thick sirup. On reducing the pressure to 1–2 mm. and heating with an oil-bath, a light yellow liquid came over between 78–98° which showed a rotation[13] of −5.34° in chloroform (*c*, 3.372; *l*, 1), −5.93° in water (*c*, 3.372; *l*, 1), and $n^{20}D$ 1.5318. On another occasion, the distillate was collected in two portions, of which the first rotated −2.25° (*c*, 2.223; *l*, 2; $CHCl_3$) and the second was virtually inactive. The difference is likely due to varying proportions of the alpha and beta forms.

Dimethyl-methyl-*d*-erythroside.—An undistilled sample of methyl-*d*-erythroside weighing between 2 and 3 g. was washed with a little water into a 500-cc. three-necked flask, where, with vigorous mechanical stirring, it was treated first with 18 cc. of freshly distilled dimethyl sulfate and then with 80 cc. of 60% sodium hydroxide added very slowly drop by drop until the vigor of the reaction had slackened and then at an increased rate.[15] The mixture was warmed on a water-bath to 75° and treated with 32 cc. more of dimethyl sulfate added gradually. Finally the water-bath was maintained at boiling for half an hour. The solution was diluted with water, and extracted with 240 cc. of chloroform in four portions which were combined, dried with sodium sulfate, filtered and concentrated free from solvent. The product was distilled at 1–2 mm. with a bath temperature of 135–145°; yield, 0.194 g.

***meso*-Dimethoxysuccinic Acid.**—The 0.194 g. of dimethyl-methyl-*d*-erythroside was treated with 5 cc. of nitric acid (sp. gr. 1.2) at 85–90° for five hours. Freed from most of the nitric acid by distillation under reduced pressure, and redistillation after adding water, the resulting sirup crystallized rapidly on cooling. The large rosets, after recrystallization from a small volume of acetone and drying at 55°, weighed 0.189 g., melted from 146–152°,[16] and were inactive optically (*c*, 3.144; *l*, 2; H_2O).

Anal. Calcd. for $(COOH)_2C_2H_2(OCH_3)_2$: neut. equiv., 178; OCH_3, 34.83. Found: neut. equiv., 180; OCH_3, >31.85.

Strontium D′-Methoxy-diglycolate.—A sample of 0.83 g. (0.0062 mole) of freshly distilled methyl-*d*-erythroside was dissolved in 45 cc. of dried chloroform (calcium chloride) and stirred mechanically in a 250-cc. flask while 3.32 g. (0.0075 mole) of crystalline lead tetraacetate was added. Stirring was continued for one and one-half hours; then the nearly insoluble lead diacetate was removed by filtration and the chloroform was distilled out under reduced pressure. The residue, after solution in water, was treated with hydrogen sulfide to remove lead. After filtration and aeration, the solution was concentrated under reduced pressure to a sirup which was dried and freed from acetic acid by distilling sulfur-free toluene from the flask several times. The product was diluted to 125 cc. with water and treated with 7 g. strontium carbonate and 1 cc. of bromine in the dark at room temperature for twenty-four hours. The mixture was shaken several times during the first hour. The excess bromine was removed by aeration, the excess carbonate was filtered, soluble halides were removed with silver carbonate and, after filtration, silver was removed as the sulfide. After another filtration and aeration, and adjustment of the *p*H slightly to the alkaline side with strontium hydroxide, the solution was concentrated under reduced pressure to 5 cc. Alcohol was added to turbidity (between 2 and 3 cc.) and the solution refrigerated for an hour, whereupon a crop of fine white needles appeared, which were eventually filtered, washed with 50% alcohol and dried in air; yield 0.1085 g. These crystals showed a specific rotation[13] of −8.94° (*c*, 0.447; *l*, 2; H_2O). On addition of one molecular equivalent of 0.1 *N* hydrochloric acid, the rotation became too small to read. Since the beta form of strontium D′-methoxydiglycolate rotates +55.0° and the alpha form −56.6°, and the corresponding free acids, +11.9 and −11.5°, respectively, the particular sample of methyl erythroside employed evidently contained about 58% of the alpha isomer and 42% of the beta.

Anal. Calcd. for $C_5H_6O_6Sr \cdot 3H_2O$; H_2O, 17.8. Found: (loss in wt. at 105° *in vacuo*), 17.1. Calcd. for $C_5H_6O_6Sr$: Sr, 35.1. Found: Sr, 35.9.

Rate of Oxidation of Methyl-*d*-erythroside by Lead Tetraacetate.—A sample of 0.0923 g. (0.00069 mole) of distilled and dried methyl-*d*-erythroside was dissolved in a little less than 50 cc. of aldehyde-free glacial acetic acid in a 100-cc. glass-stoppered volumetric flask, brought to 20°, the time noted and 50.0 cc. of 0.1222 *N* lead tetraacetate solution in acetic acid was added. After making up to 100.0 cc. and mixing, the solution was placed in a 20° room. At intervals, 10-cc. samples were removed and the unconsumed lead tetraacetate estimated by the method of Hockett and McClenahan.[8] The results obtained are shown by Fig. 1. The reaction was very nearly monomolecular, the value of *k* being 0.025 (hours and logarithms on base 10).

Summary

1. *d*-Erythrose sirup has been obtained by the hydrolysis of *d*-erythrose diacetamide prepared from *d*-arabinose by a modification of the Wohl degradation.

2. *d*-Erythrose has been found to condense with methanol containing 1% hydrogen chloride in about twenty minutes at room temperature to give a mixture of α- and β-methyl-*d*-erythrofuranosides.

3. The methyl-*d*-erythrofuranoside mixture has been purified by vacuum distillation.

4. The methyl-*d*-erythrofuranoside mixture has been converted by methylation to dimethyl methyl-*d*-erythrofuranosides which are separated from other substances by high vacuum distillation.

5. Oxidation of the methyl-*d*-erythrofuranoside mixture with nitric acid yielded inactive dimethoxysuccinic acid, proving the presence and nature of the ring.

6. Oxidation of the methyl-*d*-erythrofuranoside

(15) West and Holden, THIS JOURNAL, **56**, 930 (1934).

(16) *Cf.* Purdie, *J. Chem. Soc.*, **79**, 957 (1901).

mixture with lead tetraacetate in chloroform followed by strontium hypobromite, yielded partially racemized strontium D-methoxy-diglycolate, proving independently the presence and nature of the ring and showing the proportion of alpha and beta forms in the mixture used.

7. The rate of oxidation of methyl-*d*-arabinofuranoside by lead tetraacetate, as well as the amount of oxidant consumed, have been found to be in close agreement with the predictions previously made for a substance of this structure.

8. The rate of hydrolysis of *d*-erythrose diacetamide by 0.100 *N* sulfuric acid has been measured.

9. The rate of mutarotation of *d*-arabinose oxime has been measured.

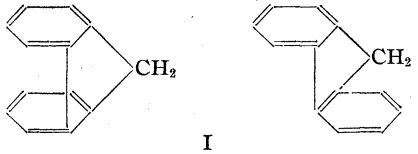
The Structure of Fluorene

BY WARREN C. LOTHROP

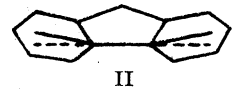
Although fluorene has been a familiar compound for many years, it has not excited the interest which has so enlarged our knowledge of the comparable tricyclic hydrocarbons anthracene and phenanthrene. Indeed a recent review of the chemistry of fluorene[1] indicates how little is known of its reactions and how much uncertainty still attaches to its structure.

Since 1925 when Kuhn and Jacob[2] proposed a space formula for fluorene (I) based on Kaufler's formula for diphenyl, in order to explain



I

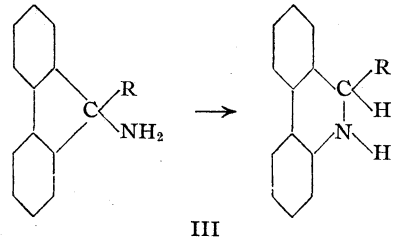
their claimed separation of two forms of 9-aminofluorene, there has been extensive investigation of the possibility of stereoisomerism of 9-substituted fluorenes. All such attempts have failed or been disproved,[3] so that the existence of such extreme forms as pictured in (I) seems unlikely if not impossible. Whether or not the two aromatic rings are inclined at a slight angle to the plane of the five-membered ring[4] cannot be stated with certainty yet, but the evidence does seem to indicate that the rings are bent away from the coaxial diphenyl bond with a distortion of the valence angles from the benzene rings by 12°,[5] to give a planar structure (II) as pictured by Pinck and Hilbert[6] where the five-membered ring is a nearly regular pentagon



II

This formula is probable from dipole measurements[5,7] and X-ray studies[8] and is further supported by the failure of fluorenone-4-carboxylic acid to close a fourth ring,[4a] the distance being too great to be bridged.

That such a planar configuration as (II) would be in a condition of some strain is to be anticipated and has been used[6] to account for the ready enlargement of the five-membered ring in the Stieglitz rearrangement of amines of the type (III) to yield phenanthridines:



III

It has been suggested further[5] that this internal strain could be relieved at least partially by a preferred arrangement of the double bonds according to the argument of Mills and Nixon[9] so that a definitely preferred bond structure (IV) should most nearly represent fluorene

IV

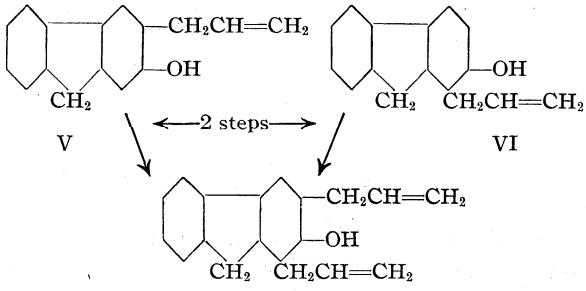
Auwers and co-workers[10] have given the only evidence as to the chemical nature of the double bonds and on the basis of refractive studies they declared that the aromatic rings of fluorene must be classed as similar to naphthalene and anthracene although they do not attempt a quantitative comparison. Others,[11] while not going as far, have distinguished fluorene from diphenyl by considering it as "quasi-aromatic" and more to be compared to dibenzocyclopentadiene. This view is disputed by Ruiz[12] and Mangini[13] with however little evidence aside from the special reactivity of fluorene at positions 2 and 7 which correspond to the active 4,4′-positions in diphenyl.

Evidence favoring formula IV is scant but may be found in the ring closures of γ-2-fluorylbutyric acid[14] and of *o*-(2-fluoryl)-benzoic acid[15] both of which take place into the 3-position. As similar ring closures in the case of 2-substituted naphthalene would be into the 1-position, analogy would seem to indicate that the double bond in fluorene is located entirely between positions 2 and 3 as shown in IV.

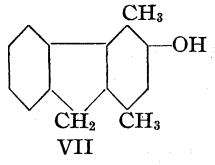
Another reaction indicating preference for position 3 may be found in the reported formation of 2,3-diacetofluorene,[16] while the special reactivity[17] of a bromine atom at 3 must have significance.

From the above discussion it is evident that the problem of the bond structure of fluorene is similar to that of naphthalene, anthracene, hydrindene and tetralin and like them should be susceptible to attack by the methods used by Fieser and Lothrop,[18] which depend on the Claisen rearrangement of allyl ethers and the diazo coupling of hydroxyl derivatives.

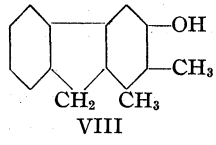
A preliminary investigation of the rearrangement of the allyl ethers of 2-hydroxyfluorene and 3-hydroxyfluorene gave ambiguous results. From the pyrolysis of the former, two isomeric substances were obtained corresponding undoubtedly to compounds V and VI, both of which yielded 1,3-diallyl-2-hydroxyfluorene on pyrolysis of their respective allyl ethers. This indicates apparently that the aromatic ring in fluorene is more benzenoid than naphthoid, for such behavior would be impossible in the latter case. Pyrolysis of the allyl ether of the previously unreported 3-hydroxyfluorene, however, yielded only an unworkable gum.



So that there might be no doubt regarding the chemical activity of a hydroxyl group in position 3, derivatives were synthesized by unambiguous methods in which both ortho positions were successively blocked by methyl groups. The allyl ethers of these test compounds (VII and VIII) rearranged smoothly and the free hydroxyfluorenes coupled readily in alkaline solution with diazotized aniline, proving conclusively that there is little or no fixation of the double bonds in the Mills–Nixon formulation (IV) and that fluorene



VII



VIII

is more like benzene, tetralin and hydrindene, than like naphthalene, anthracene and phenanthrene. The special reactivity of positions 2 and 7 is probably to be ascribed to the greater directive influence of the phenyl group as compared to the benzyl group, and the hydrocarbon is closely related to diphenyl although form IV may be favored slightly.

The preparation of the needed derivatives of 3-hydroxyfluorene was accomplished by the method employed originally by Ullmann and co-workers[19] for the preparation of 3-methoxyfluorenone. This consisted of the internal coupling of diazotized *o*-aminobenzophenone derivatives obtained

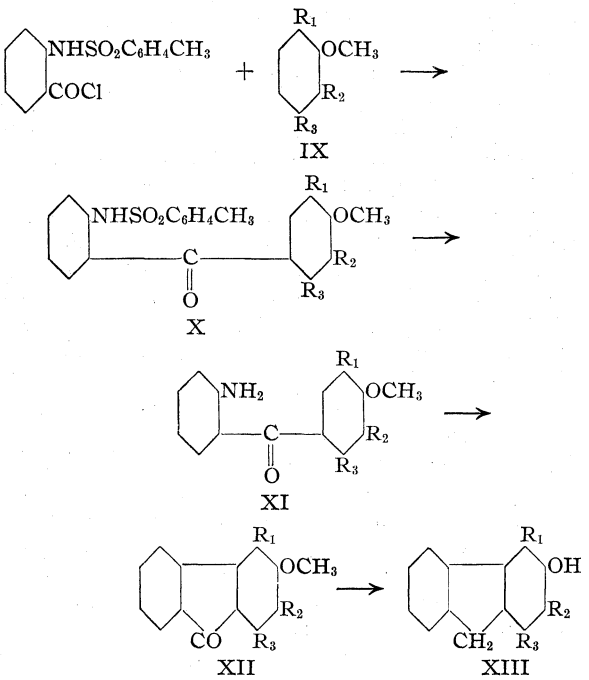
by sulfuric acid hydrolysis of the products formed in the Friedel–Crafts synthesis between the appropriate anisole derivative and the *p*-toluenesulfonamide of anthranilic acid chloride. Refluxing of acetic acid solutions of the resultant methoxyfluorenones with red phosphorus and hydriodic acid gave the desired hydroxyfluorenes directly, since demethylation and reduction were thus effected simultaneously. The general method is indicated below



Experimental Part

2-Hydroxyfluorene.—This compound was obtained in 57% yield from 2-aminofluorene by diazotization and subsequent hydrolysis as described by Ruiz.[12a] After treatment of its alkaline solution with norite and precipitation with acid, it was crystallized in white plates from 50% acetic acid, m. p. 169°.

2-Alloxyfluorene.—A solution of 8.5 g. of 2-hydroxyfluorene in 150 cc. of anhydrous acetone was refluxed for twenty-four hours with 7.7 g. of allyl bromide and 9.25 g. of finely powdered anhydrous potassium carbonate. A white solid product, completely insoluble in 1 *M* sodium hydroxide, was precipitated when the reaction mixture was poured into water; it was crystallized in gleaming white plates from dilute alcohol, m. p. 95–96°. The yield was 10.3 g. or 99%.

Anal. Calcd. for $C_{16}H_{14}O$: C, 86.44; H, 6.34. Found: C, 86.30; H, 6.38.

1-Allyl and 3-Allyl-2-hydroxyfluorene (VI and V).—Pyrolysis of 6.0 g. of 2-alloxyfluorene at 235–238° for five minutes gave a solid product, m. p. 83–84°, which was soluble in alkali but only with great difficulty. It was separated into two products by repeated fractional crystallization from petroleum ether. Compound A crystallized in fine, cream-colored needles, m. p. 87–88°, and represented about 60% of the whole. Compound B crystallized in thick, pale-brown needles, m. p. 111–112°, and represented about 25% of the material recovered.

By analogy with the melting points of pseudo-cumenol (m. p. 70°) and hemi-mellitenol (m. p. 81°) it seemed likely that Compound A was 3-allyl-2-hydroxyfluorene (V) and Compound B was 1-allyl-2-hydroxyfluorene (VI). This is in agreement with the preferred reactivity of position 3 previously cited; however, no proof of structure was attempted.

Anal. Calcd. for $C_{16}H_{14}O$: C, 86.44; H, 6.34. Found for A: C, 86.30; H, 6.18. Found for B: C, 86.16; H, 6.03.

The allyl ethers of both A and B were prepared without difficulty in 70–75% yields and were crystallized from 80% alcohol in nearly colorless plates. The allyl ether of A melted at 44–45° while that of B melted at 82–83°.

Anal. Calcd. for $C_{19}H_{18}O$: C, 87.00; H, 6.90. Found for allyl ether of A: C, 87.30; H, 7.12. Found for allyl ether of B: C, 87.12; H, 7.16.

1,3-Diallyl-2-hydroxyfluorene.—Pyrolysis of the allyl ethers of either A or B gave the same dark oil, which was purified by vacuum distillation, b. p. 170° at 3 mm. The distillate solidified in small clumps of fine yellow needles and crystallized from petroleum ether in fine, cream-colored needles, m. p. 58°.

Anal. Calcd. for $C_{19}H_{18}O$: C, 87.00; H, 6.90. Found: C, 86.96; H, 7.09.

3-Methoxyfluorenone (XII where R_1, R_2 and R_3 are H atoms).—This compound, described by Ullmann and Bleier,[19] was obtained as an orange-yellow solid, m. p. 92–94°, which was not purified further.

3-Hydroxyfluorene (XIII where R_1, R_2 and R_3 are H atoms).—A solution of 8.5 g. of the crude 3-methoxyfluorenone in 75 cc. of glacial acetic acid was refluxed for eighty hours with 1.0 g. of red phosphorus and 60 cc. of constant boiling hydriodic acid. The crude product dissolved in ether and filtered to remove excess phosphorus was extracted with small portions of cold, dilute alkali containing a trace of sodium hydrosulfite to remove iodine and any unreduced hydroxyfluorenone. This method served to eliminate the impurities without apparently effecting any loss of the much less acidic hydroxyfluorene, which was recovered as a white solid. It was crystallized from dilute alcohol in cream-colored plates, m. p. 136–137°. The yield was 4.9 g. or 66%. The **benzoate** crystallized from dilute alcohol in fine plates, m. p. 128°.

Anal. Calcd. for $C_{13}H_{10}O$: C, 85.66; H, 5.54. Found: C, 85.36; H, 6.14. Calcd. for $C_{20}H_{14}O_2$ (benzoate): C, 83.89; H, 4.92. Found: C, 83.52; H, 5.27.

2-(4-Toluenesulfonamido)-benzoyl Chloride.—The acid chloride was prepared from anthranilic acid as described by Miller and Bachman.[17]

2,5 - Dimethyl - 4 - methoxy - 2′ - (4 - toluenesulfonamido)-benzophenone (X where R_1 and R_3 are CH_3 groups and R_2 is a H atom).—To a vigorously stirred mixture of 20.4 g. of powdered aluminum chloride and 45.5 g. of the above acid chloride in 200 cc. of carbon disulfide, 20.0 g. of the methyl ether of *p*-xylene[18c] was added drop-

wise at room temperature, and the resulting dark red complex gradually warmed on the steam-bath. Refluxing was continued for six hours and the reaction allowed to stand overnight. Treatment of the mixture in the usual manner gave 4.2 g. of unchanged methoxyxylene and a white product which crystallized well from 600 cc. of 95% alcohol after treatment with norite. The yield of thick, pale yellow blades, m. p. 140–141°, was 35.0 g. or 71%.

Anal. Calcd. for $C_{23}H_{23}O_4NS$: C, 67.45; H, 5.67; N, 3.42. Found: C, 67.03; H, 5.69; N, 3.52.

The corresponding **methylamine** derivative was prepared in 99% yield by treatment of an alkaline solution of the above compound with dimethyl sulfate. It crystallized in gleaming white plates from alcohol, m. p. 168–169°.

Anal. Calcd. for $C_{24}H_{25}O_4NS$: C, 68.08; H, 5.95; N, 3.31. Found: C, 68.55; H, 6.34; N, 3.16.

2,5-Dimethyl-4-methoxy-2′-aminobenzophenone (XI where R_1 and R_3 are CH_3 groups and R_2 is H).—When 12 g. of the above sulfonamide was mixed with 35 cc. of concentrated sulfuric acid a clear red solution resulted in a few hours but reaction was complete only after three days of standing at room temperature. The mixture was poured into excess ammonia and the product filtered and crystallized from dilute alcohol in bright yellow needles, m. p. 102–104°. The yield was 7.5 g. or 99%.

Anal. Calcd. for $C_{16}H_{17}O_2N$: C, 75.27; H, 6.70; N, 5.48. Found: C, 74.97; H, 6.46; N, 5.46.

1,4-Dimethyl-3-methoxyfluorenone (XII where R_1 and R_3 are CH_3 groups and R_2 is H).—Several trials indicated that while this compound could be obtained in one step by the diazotization of the diluted sulfuric acid hydrolysis solution of the above amine in the manner described by Ullmann and Bleier,[19] the yields were low (36%) and the product difficult to purify. The most satisfactory results were obtained when the crude aminobenzophenone (7.5 g.) was dissolved in 1 liter of cold water containing 260 cc. of concentrated hydrochloric acid and treated with 8.0 g. of sodium nitrite. The clear orange solution was filtered, warmed on the steam-bath for five hours, and the bright yellow product which separated was recovered by filtration. It was three times extracted by suspension at 100° in 50-cc. portions of 3 *N* potassium hydroxide and after thorough washing with water crystallized from dilute alcohol in bright yellow needles, m. p. 140–141°. The yield was 5.85 g. or 84%.

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92. Found: C, 80.78; H, 6.12.

2,5-Dimethyl-4-methoxy-2′-hydroxybenzophenone.—Acidification of the alkaline extracts above gave a substance which crystallized from alcohol in yellow prisms, m. p. 94–95°, and which weighed 0.1 g. Its **acetate** crystallized from alcohol in white prisms, m. p. 81–82°.

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 74.99; H, 6.28. Found: C, 75.17; H, 6.65. Calcd. for $C_{18}H_{18}O_4$(acetate): C, 72.50; H, 6.07. Found: C, 72.45; H, 6.34.

1,4-Dimethyl-3-hydroxyfluorenone.—This compound was a product of incomplete reduction in the reaction described below, or could be obtained directly by the demethylation of its methyl ether with 48% hydrobromic acid. It crystallized from glacial acetic acid in fine, brilliant yellow needles, m. p. 223–224°, and gave an intensely red solution in alkali. The **acetate** separated from dilute acetic acid in pale yellow needles, m. p. 133–134°.

Anal. Calcd. for $C_{15}H_{12}O_2$: C, 80.36; H, 5.40. Found: C, 80.62; H, 5.75. Calcd. for $C_{17}H_{14}O_3$(acetate): C, 76.67; H, 5.29. Found: C, 76.72; H, 5.69.

1,4-Dimethyl-3-hydroxyfluorene (VII).—A solution of 3.9 g. of 1,4-dimethyl-3-methoxyfluorenone in 125 cc. of glacial acetic acid was refluxed for sixteen hours with 30 cc. of hydriodic acid (b. p. 127°) and 0.5 g. of red phosphorus. The product was recovered and purified in the manner already described for 3-hydroxyfluorene, being finally crystallized from ligroin in long, flesh colored needles, m. p. 180–181°. The yield was 2.58 g. or 87%. The acetate crystallized from alcohol in cream-colored plates, m. p. 100°.

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.70; H, 6.71. Found: C, 85.69; H, 6.72. Calcd. for $C_{17}H_{16}O_2$(acetate): C, 80.94; H, 6.38. Found: C, 81.28; H, 6.45.

1,4-Dimethyl-2-benzeneazo-3-hydroxyfluorene.—When an alkaline solution of 0.1 g. of the hydroxyfluorene above in 10 cc. of 2 *N* sodium hydroxide and 5 cc. of water was treated at 0° with a slight excess of a freshly prepared solution of benzene diazonium chloride, an orange-brown precipitate immediately appeared. It was crystallized from glacial acetic acid in fine brown needles, m. p. 183–184°.

Anal. Calcd. for $C_{21}H_{18}ON_2$: C, 80.24; H, 5.76. Found: C, 80.34; H, 5.59.

1,4-Dimethyl-3-alloxyfluorene.—A mixture of 1.1 g. of (VII), 1.0 g. of powdered anhydrous potassium carbonate and 0.7 g. of allyl bromide in 25 cc. of acetone, was refluxed for forty-five hours and poured into water. The oily product was recovered by ether extraction and crystallized from dilute alcohol in fine white needles, m. p. 54–55°. The yield was 1.06 g. or 82%.

Anal. Calcd. for $C_{18}H_{18}O$: C, 86.40; H, 7.23. Found: C, 86.68; H, 7.29.

1,4-Dimethyl-2-allyl-3-hydroxyfluorene.—This compound was obtained in 62% yield by the pyrolysis of the above alloxyfluorene under nitrogen at 215°. It was difficultly soluble in alkali and crystallized from glacial acetic acid in nearly colorless plates, m. p. 150–151°.

Anal. Calcd. for $C_{18}H_{18}O$: C, 86.40; H, 7.23. Found: C, 86.66; H, 7.34.

vic-*o*-Xylenol Methyl Ether (IX where R_1 is H and R_2 and R_3 are CH_3 groups).—Several different attempts showed that this compound may be prepared best from 2-amino-3-methylanisole[20] by its conversion into 2-bromo-3-methylanisole[21] and subsequent treatment of the Grignard reagent of the latter with dimethyl sulfate. The yields for the last two procedures, however, were improved materially. In the Sandmeyer reaction the cuprous bromide solution was added at 0° instead of 60° and the diazonium complex allowed to decompose by standing at room temperature for two hours. The yield of product, b. p. 122–127° at 18 mm., m. p. 37–38°, was 80% compared with the reported 44%.[21]

(21) Short, Stromberg and Wiles, *ibid.*, 319 (1936).

The conversion of the bromide into the desired xylenol methyl ether was effected in 79% yield by the use of two moles of dimethyl sulfate instead of one[21] and subsequent treatment as described elsewhere.[22] The over-all yield from 118 g. of *m*-cresol was 26.3 g. of vic-*o*-xylenol methyl ether.

The preparation of the compounds listed below was accomplished by procedures exactly like those recorded above; therefore repetition of details is omitted.

2,3 - Dimethyl - 4 - methoxy - 2′ - (4 - toluenesulfonamido)-benzophenone (X where R_2 and R_3 are CH_3 groups and R_1 is H).—Was obtained from alcohol in 33% yield as nearly colorless needles, m. p. 136–138°.

Anal. Calcd. for $C_{23}H_{23}O_4NS$: C, 67.45; H, 5.67; N, 3.42. Found: C, 67.43; H, 5.90; N, 3.50.

The corresponding **methylamine** derivative was prepared with difficulty due to the great insolubility of the above sulfonamide in alkali. It crystallized from dilute alcohol in white needles, m. p. 160°.

Anal. Calcd. for $C_{24}H_{25}O_4NS$: C, 68.08; H, 5.95; N, 3.31. Found: C, 68.05; H, 6.25; N, 3.37.

2,3 - Dimethyl - 4 - methoxy - 2′ - aminobenzophenone (XI where R_2 and R_3 are CH_3 groups and R_1 is H).—This was obtained in 95% yield and crystallized from dilute alcohol in pale yellow needles, m. p. 144–145°.

Anal. Calcd. for $C_{16}H_{17}O_2N$: C, 75.27; H, 6.70; N, 5.48. Found: C, 75.58; H, 7.05; N, 5.29.

1,2-Dimethyl-3-methoxyfluorenone (XII where R_2 and R_3 are CH_3 groups and R_1 is H) was obtained in 63% yield by the use of much larger volumes of solutions due to the extreme insolubility of the amine hydrochloride. It crystallized from glacial acetic acid in brilliant yellow needles, m. p. 178–179°.

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.64; H, 5.92. Found: C, 80.90; H, 6.22.

2,3-Dimethyl-4-methoxy-2′-hydroxybenzophenone was formed as a by-product in the above reaction to the extent of 10%. It separated from dilute alcohol in yellow prisms, m. p. 135–136°. Its **acetate** also crystallized from dilute alcohol in white prisms m. p. 97–98°.

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 74.99; H, 6.28. Found: C, 74.79; H, 6.50. Calcd. for $C_{18}H_{18}O_4$(acetate): C, 72.50; H, 6.07. Found: C, 72.80; H, 6.35.

(22) *Org. Syntheses*, **11**, 66 (1931).

1,2 - Dimethyl - 3 - hydroxyfluorenone.—This compound separated from acetic acid in orange needles, m. p. 258–259° dec. The **acetate** was obtained from the same solvent in long yellow needles, m. p. 137–138°.

Anal. Calcd. for $C_{15}H_{12}O_2$: C, 80.36; H, 5.40. Found: C, 80.36; H, 5.59. Calcd. for $C_{17}H_{14}O_3$(acetate): C, 76.67; H, 5.29. Found: C, 76.99; H, 5.48.

1,2-Dimethyl-3-hydroxyfluorene (VIII), formed in 74% yield was obtained in fine white needles from benzene–ligroin, m. p. 212–213° dec. The **acetate** separated from dilute acetic acid in white needles, m. p. 146–147°.

Anal. Calcd. for $C_{15}H_{14}O$: C, 85.70; H, 6.71. Found: C, 85.82; H, 6.98. Calcd. for $C_{17}H_{16}O_2$(acetate): C, 80.94; H, 6.38. Found: C, 81.22; H, 6.68.

1,2 - Dimethyl - 4 - benzeneazo - 3 - hydroxyfluorene.—The extreme insolubility of the hydroxyfluorene in alkali at 0° necessitated the addition of 5 cc. of dioxane. The coupling product crystallized from glacial acetic acid in fine clusters of brown needles, m. p. 201° dec.

Anal. Calcd. for $C_{21}H_{18}ON_2$: C, 80.24; H, 5.76. Found: C, 80.32; H, 6.02.

1,2-Dimethyl-3-alloxyfluorene was obtained in 76% yield from alcohol as white plates, m. p. 102–103°.

Anal. Calcd. for $C_{18}H_{18}O$: C, 86.40; H, 7.23. Found: C, 86.62; H, 7.56.

1,2-Dimethyl-4-allyl-3-hydroxyfluorene.—Pyrolysis of the above allyl ether at 230° gave a yield of 78% of pale yellow needles, m. p. 135–136°, from glacial acetic acid.

Anal. Calcd. for $C_{18}H_{18}O$: C, 86.40; H, 7.23. Found C, 86.44; H, 7.53.

Summary

Methods which have been useful for the location of double bonds in other aromatic hydrocarbons have been applied to fluorene, with the result that the latter may be said to be benzenoid rather than naphthoid. Fluorene has been found to possess no considerable fixation of bonds as might be expected if the Mills–Nixon effect were operating and it is suggested that the special reactivity of positions 2 and 7 may be ascribed to the superior directive properties of the phenyl group.

Native Lignin[1] I. Its Isolation and Methylation

BY F. E. BRAUNS

The experiments reported in the present paper deal with isolated native lignin. Inasmuch as the term "native lignin" has very often been misused in the lignin literature, its meaning in the present investigation is explained briefly. It is a general belief that lignin as it occurs in the plant material is insoluble in organic solvents and cannot be extracted by them without the use of a mineral acid as a catalyst. It is true that it occasionally has been noted that, on extraction of wood with alcohol, some lignin goes into solution. It seems that Klason[2] isolated a product by hot alcohol extraction which he considered to be lignin, but he did not even carry out a test for the presence of methoxyl groups in his product. Moreover, Freudenberg[3] has observed that on extraction of wood with hot alcohol–benzene some low molecular members of the lignin series are removed along with the resins, but the quantity was so small that he discarded the fraction. On the other hand, Hägglund,[4] in his "Holzchemie," says: "The native lignin of the wood is not soluble in organic solvents without the addition of acids." There is little doubt that the principal part of the lignin can be isolated from wood only by the use of strong mineral acid, cuprammonium hydroxide, or by organic solvents in the presence of mineral acids. In the method where alcohols are used without mineral acids,[5] high temperatures (up to 185°) must be applied; the lignin obtained on distillation of the solvent is a black pitchlike product and can no longer be considered identical with native lignin.

Native or unaltered lignin can be obtained only if one can succeed in isolating it by the use of an indifferent solvent and without the application of an elevated temperature. The present investigation deals with the isolation of such a lignin. It has been found during the last fifteen years that a large number of lignin preparations are soluble in methyl or ethyl alcohol and that almost all, except those prepared by extraction of the cellulose with mineral acids, are also soluble in dioxane. If lignin is to be extracted in an unchanged state, these solvents should be the most suitable ones. Furthermore, it has been found possible to extract a small amount (about 2 to 3%) of the lignin present in wood by using such solvents without the application of a high temperature. *The term "native lignin," therefore, means a lignin isolated in such a way that the solvent does not react with the lignin or alter it in any way.*

When sprucewood meal is allowed to stand for three to four days in 96% ethyl alcohol and is then filtered and the clear light brown filtrate evaporated under reduced pressure, a resinous residue is obtained which is washed with distilled water and ether. With the removal of the resins by the ether, the native lignin is obtained as a very finely divided light cream-colored powder, which is precipitated repeatedly from its solution in dioxane into ether until a constant methoxyl content is obtained. This powder gives the typical lignin color reactions: a deep purple with phloroglucinol and hydrochloric acid and a bluish-green with phenol and hydrochloric acid. The native lignin has a methoxyl content of 14.8%. This seems to be low, considering that the methoxyl content of lignin as it occurs in wood has always been assumed to be about 17.3%; furthermore, it is a well-known fact that the methoxyl content of sprucewood lignin, isolated according to Klason, Willstätter, or Freudenberg, varies between 14.5 and 17%, depending upon the conditions of preparation. A methoxyl content of about 17% has been calculated also for spruce lignin by Fuchs[6] from the lignin and the methoxyl contents of the wood, on the obviously incorrect assumption that all the methoxyl in the wood is combined with the lignin. It has been shown by Ritter and his coworkers,[7] and more recently by Hägglund and Sandelin,[8] however, that 0.56% of the total methoxyl content (4.6%) in sprucewood is attached to carbohydrate material. When this part was taken into consideration, Hägglund[4]

(pp. 199, 299) calculated a methoxyl content of 14.8% for lignin. This is exactly the amount found during this investigation.

The first questions to be answered are, of course: "Is this native lignin really lignin, or is it some other methoxyl-containing constituent of the wood, and to what extent is this part of the lignin identical with the principal part of the lignin in wood?" The color reaction with phloroglucinol and hydrochloric acid is not decisive, for there are many other compounds in wood which give the same reaction. In a very recent article Wiechert[9] claims to have shown that this coloration, at least as far as beech lignin is concerned, has no relation to the lignin. Without going into further details, it can be asserted positively that this phloroglucinol color reaction is typical at least of spruce lignin[10]; the mechanism of this reaction is the subject of an investigation now in progress.

There are two other typical lignin reactions—the reactions of lignin with phenol and with thioglycolic acid. The isolated native lignin condenses with phenol in the presence of hydrochloric acid with the formation of a phenol lignin having a methoxyl content of 11.5% which is identical with the same derivative prepared from Willstätter or Freudenberg lignin.[11] Inasmuch as Willstätter lignin is obtained in nearly quantitative yield and the two phenol lignins are apparently identical, it would seem that isolated native lignin has the same chemical properties as the total lignin in the wood. This is further shown by the preparation of the thioglycolic acid derivative of the isolated native lignin with a methoxyl content of 10.5%. This content is in agreement with that found by Holmberg[12] for a tetrathioglycolic acid lignin from sprucewood which is obtained in an almost quantitative yield, but about 1% lower than that found by Ahlm and Brauns.[13] To what extent the phenol and the thioglycolic acid derivatives of the isolated native lignin are identical with corresponding lignin derivatives obtained directly from wood in a quantitative yield will be shown later. If it is possible to prove that this native lignin behaves chemically in a manner similar in every respect to the total lignin, it is obviously an ideal product for a chemical study of the lignin problem.

The first experiment carried out with the isolated native lignin was the action of 42% hydrochloric acid and of 72% sulfuric acid. In preliminary experiments it was found that in both cases about 5 to 8% of the lignin could not be recovered. Native lignin gives with supersaturated hydrochloric acid a bright emerald-green color similar to that observed at the beginning of the preparation of Willstätter spruce lignin; with native lignin the green color is much brighter (purer) and lasts much longer than with wood meal. A part of the lignin dissolves in the hydrochloric acid, and it can be recovered from the filtrate on evaporation.

With 72% sulfuric acid a bluish-green coloration appears at the beginning, lasts only a short time, and soon changes to black. From the clear, colorless filtrate of the sulfuric acid treatment, after removal of the acid with barium carbonate, a white, crystalline product is obtained. The ease with which it crystallizes and the fact that it is optically inactive indicate that it is not a carbohydrate, even though it reduces Fehling solution quite strongly. A further investigation of this crystalline product is in progress. The behavior of the native lignin after treatment with mineral acids resembles that of Willstätter and Klason lignins. The methoxyl contents of these lignins vary from 15.2 to 16%, the same range as that given in the literature for those lignins isolated directly from sprucewood by these methods in a quantitative yield.

The presence of free hydroxyl groups in the native lignin is shown by its acetylation and methylation. With pyridine and acetic anhydride an acetylated native lignin is obtained having a methoxyl content of 11.8%.

Methylation of native lignin with diazomethane in anhydrous dioxane solution gives a partially methylated, nearly white lignin, with a methoxyl content of 21.4%. However, when the methylation with diazomethane is carried out with a suspension of the dry product in anhydrous ether, the methylation seems to stop at about 18.3%, but on further methylation in dioxane solution a final methoxyl content of 21.4% is obtained. The product with 18.3% methoxyl is completely soluble in dilute sodium hydroxide solution, indicating that an acidic hydroxyl group in the lignin molecule is still free; if the lignin were in part completely methylated and in part completely unmethylated, only a portion would be alkali solu-

ble. It should be noted that this partially diazomethane-methylated native lignin still gives the bright purple color reaction with phloroglucinol and hydrochloric acid, whereas on complete methylation with diazomethane this color fails to appear.

A quantitative yield of a lignin with the same methoxyl content (21%) is also obtained when sprucewood meal is methylated with diazomethane and the lignin is isolated according to Klason with 72% sulfuric acid.[10] When the diazomethane-methylated native lignin is treated with 72% sulfuric acid under the same conditions as those used in the Klason method, a partially methylated Klason lignin with a methoxyl content of 21.15% is obtained, which has the same appearance as that isolated directly from diazomethane-methylated sprucewood. The experiment with the methylated native lignin and 72% sulfuric acid has not been followed quantitatively; it is therefore possible, or even probable, that in this case, as in the experiment with the unmethylated native lignin, a small fraction is split off the lignin. A larger amount of the diazomethane-methylated product has been prepared, and an investigation of the fraction split off will soon be started.

A spruce lignin with a methoxyl content of about 21% is also obtained when Willstätter or Freudenberg lignin is methylated in cyclohexanol suspension with diazomethane.[14] As these lignins are isolated in a nearly quantitative yield, it shows that the isolated native lignin, on methylation with diazomethane, behaves in the same way as the lignin which remains in the wood after extraction of the soluble native lignin.

The diazomethane-methylated native lignin still has some free hydroxyl groups, as acetylation with pyridine and acetic anhydride gives an acetylated, partially methylated native lignin with a methoxyl content of 18.9%.

When sprucewood meal is extracted with methanol, using 2% hydrochloric acid as a catalyst, so-called methanol lignin is obtained.[15] By using other alcohols, such as ethyl, butyl, or amyl in the presence of hydrochloric acid, it is found that lignin forms condensation products with these alcohols. In the case of methanol, the reaction could not immediately be established, since the lignin itself contains methoxyl groups. As a matter of fact, when Friedrich[16] first prepared his so-called "primary lignin" by hydrolysis of wood with hydrochloric acid followed by extraction with ethyl alcohol, he believed that native spruce lignin had a methoxyl content of approximately 21%. Hägglund and Urban[15c] later ascertained the presence of ethoxyl groups in Friedrich's "primary lignin."

It was therefore of interest to determine whether isolated native lignin would react with alcohols in the presence of hydrochloric acid. When native lignin is dissolved in methanol, a yellow-brown solution is obtained which, on addition of a solution of anhydrous hydrochloric acid in absolute methanol, immediately turns to a deep wine-red, indicating that a reaction takes place almost instantly. When the concentration of the hydrochloric acid is so chosen that a 2% methanol solution is used and the solution refluxed for four to five hours, about 35% of the lignin separates out as a resin, which is insoluble in dioxane. Its methoxyl content is 20.85%. From the methanol solution a methanol lignin with a methoxyl content of 21.5% is isolated. This methoxyl content agrees exactly with that of methanol lignin prepared under the same conditions directly from sprucewood.[15] The large amount of polymerized methanol lignin formed is undoubtedly due to the relatively high concentration of hydrochloric acid, for when a concentration of only 0.5% is used the same change in color of the solution occurs, but all the lignin remains in solution; the methoxyl content of the isolated methanol lignin in this case is 20.9% and does not change when the treatment with 0.5% methanol–hydrochloric acid is repeated. This observation is in direct contradiction to an experiment recently reported by Hibbert and co-workers,[17] in which it is claimed that "an acetylated, carefully purified oak lignin (8.7% OCH_3, 35% $COCH_3$) [is] reconverted into its primary building units by refluxing it with anhydrous ethanol containing 2% hydrogen chloride." The methoxyl content of this oak lignin, calculated on the acetyl-free lignin, is then about 13.5%, a rather low content for an oak lignin, for which a methoxyl content of 21.8% is given in the literature[4] (p. 229). The discrepancy between the behavior of isolated native spruce lignin and

Hibbert's acetylated oak lignin toward alcohol and hydrogen chloride can be explained only by the fact that the latter was decomposed in its preparation, as is shown by its low methoxyl content. The fact that a part of the native lignin becomes insoluble when treated with a 2% methanol–hydrogen chloride solution may also explain the assumption made by Hägglund[4] (p. 190) that a condensation of the lignin takes place in the solid phase through the mineral acid and for this reason not all the lignin can be extracted in such a way from the wood.

The question now arises as to how methanol and alcohols in general react with lignin in the presence of mineral acids. It has generally been assumed that in this reaction an oxygen ring, such as the furan or pyran ring, is opened with the formation of a new alkoxyl group and a new hydroxyl group. Hägglund and Urban,[15c] using butyl and amyl alcohols, agree with the opinion of Holmberg and Runius[15b] that these so-called alcohol lignins are probably acetals and that, on a basis of a molecular weight of approximately 400 for lignin, a half-acetal is formed[4] (p. 190). It will be pointed out later that, on a basis of a molecular weight of 840, a true acetal is obtained. If the alcohol is bound in an acetal-like manner, it should be possible to split off these groups with acids. When methanol lignin from isolated native lignin is treated with 72% sulfuric acid according to Klason, the methoxyl content decreases from 20.9 to 16.4% (which is the methoxyl content of Klason lignin from sprucewood); in other words, those methoxyl groups introduced by the treatment with methanol and hydrochloric acid are split off again. This is an experimental support for Hägglund's and Holmberg's assumption that in the reaction of alcohols with lignin in the presence of acids acetal-like compounds are formed.

Methanol lignin prepared directly from sprucewood is soluble in sodium hydroxide solution[15b] and can be acetylated or methylated. The same is true of methanol lignin from isolated native lignin. In both cases acetylated or partially methylated methanol lignins, which are insoluble in caustic soda solution, are obtained. The acetylated product has a methoxyl content of 16.9%, the diazomethane-methylated product 25.36%, and the corresponding derivative prepared directly from spruce[15d] 24.9%. A partially methylated lignin with a methoxyl content of 24.4% is obtained when the diazomethane-methylated native lignin is treated with methanol and hydrochloric acid. On remethylation of this product with diazomethane, the methoxyl content increases to 25.45% or to the same value as that of diazomethane-methylated methanol lignin. In other words, isolated native lignin gives partially methylated lignin derivatives with the same methoxyl content regardless of whether it is first methylated with diazomethane and then treated with methanol and hydrochloric acid, or whether this process is reversed.

On further methylation of the diazomethane-methylated native lignin and of the methanol native lignin, two different lignin derivatives fully methylated with regard to dimethyl sulfate are obtained, the first with a methoxyl content of 31.3% and the second with a methoxyl content of 33.0%.

Formulas for Lignin and its Derivatives

The results of these experiments show a far-reaching agreement with those of the corresponding products obtained in an almost quantitative yield directly from sprucewood. Based on these earlier results, an empirical formula (I) for the lignin building unit[18] was proposed.[19] As was later found by Hägglund[19c] and Holmberg,[19d] this formula is in good agreement with the experimental results of other lignin investigators, and the question arises as to how the experimental results obtained from isolated native lignin fit into this formula.

It must be recalled that this formula was developed on the assumption found at that time in the literature, namely, that "native lignin" has a methoxyl content of 17.3% and that one new methoxyl group is formed in the lignin molecule on reaction with methanol and hydrochloric acid; it was also based on the assumption that one methoxyl group was introduced into the lignin building unit on methylation with diazomethane. The assumptions, however, were proved to be in error (this indicates again how cautious one has to be in making assumptions in lignin chemistry) for the methoxyl content of the isolated native lignin is found to be only 14.8%, which is in

(18) The term "lignin building unit" was used by Brauns and Hibbert in 1933 for a unit with a molecular weight of approximately 840. In his recent publications, Hibbert uses the same term for one with a C_9 group only. In order to avoid confusion it would seem to be advisable to use the term "lignin building stone" for the C_9 groups as has already been done by Freudenberg ("Tannin, Cellulose, Lignin," Berlin, 1933, p. 134).

(19) (a) Brauns and Hibbert, THIS JOURNAL, **55**, 4720 (1933); (b) Sarkar, *J. Indian Chem. Soc.*, **12**, 547 (1935); (c) Hägglund, *Svensk Papperstidn.*, **39**, 347 (1936); (d) Holmberg, *Papier-Fabr.*, **36**, 218 (1938); (e) Freudenberg, *ibid.*, **37**, 28 (1939).

agreement with that calculated by Hägglund. In the methylation of the isolated native lignin either with diazomethane or with methanol and hydrochloric acid, two partially methylated lignin derivatives with *almost* the same methoxyl contents are obtained. They differ, however, from each other in that the diazomethane-methylated product is insoluble in sodium hydroxide, whereas the methanol derivative is soluble, and also in that their behaviors toward 72% sulfuric acid are dissimilar. With this reagent the methoxyl content remains unchanged in the case of diazomethane-methylated isolated native lignin (IV), whereas that of methanol lignin is decreased to 16.4%. On the other hand, when diazomethane-methylated isolated native lignin (IV) is treated with methanol and hydrochloric acid (VII) and methanol native lignin is methylated with diazomethane (VI), products with the same methoxyl contents are obtained. It is obvious that with diazomethane an acidic hydroxyl group is methylated which remains free in the methylation with methanol and hydrochloric acid. On the other hand, in both cases one hydroxyl group is methylated either by diazomethane or by methanol and hydrochloric acid. Finally, there is a third hydroxyl group in the native lignin which is only methylated by methanol and hydrochloric acid. In other words, three methoxyl groups are introduced into the lignin molecule when diazomethane and methanol–hydrochloric acid are both used, and two when only one of these reagents is used. The fact that with methanol–hydrochloric acid two methoxyl groups are introduced which are split off again with 72% sulfuric acid indicates that these groups are present in an acetal-like form as proposed by Holmberg. The presence of a carbonyl group in the isolated native lignin is proved by the reaction with phenylhydrazine whereby a hydrazone is formed.

To return now to the development of the empirical formula (I), it is evident that this formula, insofar as methanol lignin is concerned, remains unchanged. With regard to the native lignin, however, all that has to be changed is that one methanol molecule has to be taken out because the calculation was based on the entrance of only one methoxyl group on methylation with methanol and hydrochloric acid, whereas actually two enter the lignin building unit forming a dimethylacetal with the carbonyl group. This carbonyl group is easily enolizable. The empirical formula for native lignin would then be as given in Formula II in its keto form and in formula III in its enol form with a molecular weight of around 840.

In Table I the methoxyl contents of the various derivatives of native lignin and, for comparison,

those calculated on the basis of the formula are given.

It can be seen that in those cases (1, 2, 3, 4, and 11) where neither alkali nor acid is used, the values found for the methoxyl contents agree very well with those calculated, whereas in those cases where the native lignin has come into contact either with alkali, as in 9 and 10, or with acid (HCl), as in 5, 6, 7, and 8, the methoxyl contents vary somewhat. This discrepancy may be explained by the possibility that a methylene oxide group[20] has been split off with the formation of free phenolic hydroxyl groups. Such a reaction seems to be indicated especially in the treatment of diazomethane-methylated native lignin with methanol and hydrochloric acid. When native lignin, completely methylated with regard to diazomethane and containing methoxyl groups which are stable even to 72% sulfuric acid, is treated with methanol–hydrochloric acid, a partially methylated methanol native lignin (VI) is obtained with almost the calculated methoxyl content (24.4 instead of 24.1%). On remethylation of this product with diazomethane, the methoxyl content increases to 25.4% or to the same value as the diazomethane-methylated methanol lignin.

It is a well-known fact that lignin as it occurs in wood is dissolved when heated with a bisulfite solution. When isolated native lignin is heated with sodium bisulfite solution containing 1 g. of sodium oxide and 4.5 g. of sulfur dioxide per liter for twelve to fourteen hours at 125°, it goes completely into solution, giving lignosulfonic acid. In a recent paper[11] it was shown that when sprucewood meal is treated with diazomethane until the lignin has a final methoxyl content of 21%, this wood can no longer be pulped with bisulfite solution. Similar results have been obtained by Hägglund and J. Holmberg[21] and by Klingstedt.[22] This has been explained by the fact that in the lignin molecule a hydroxyl group capable of methylation with diazomethane is present which is essential for rendering the lignin soluble in a bisulfite cook; by blocking this hydroxyl group with methoxyl, this reaction can no longer take place. Freudenberg, on the other hand, showed that, when sprucewood is methylated with diazomethane to a methoxyl content of from 18 to 19% for the lignin, the lignin in this wood can be dissolved completely by a bisulfite cook. How can this discrepancy be explained? It is shown in the present investigation that on methylation of native lignin with diazomethane two methoxyl groups are introduced in the lignin molecule having a molecular weight of 840. Since one of these hydroxyl groups is also methylated by methanol and hydrochloric acid, it is evident that this hydroxyl group is an enolic one and that the

(20) The presence of a methylene oxide group in lignin has been established definitely by Freudenberg, *et al.* [*Ber.*, **72**, 217 (1939)] in contrast to Hibbert and co-workers [*ibid.*, **71**, 734 (1938)], who believe that the formaldehyde obtained in the distillation of lignin with mineral acids is derived from carbohydrate material in the lignin.

(21) Hägglund and Holmberg, unpublished work. See ref. 4, p. 149.

(22) Private communication.

second group is a phenolic one. As already mentioned, on partial methylation of native lignin in ether suspension with diazomethane, only one hydroxyl group in the lignin building unit is methylated, and since the phenolic hydroxyl is more acidic than the enolic, it is very probable that the former is the first to be methylated. Such a partially diazomethane-methylated native lignin has a methoxyl content of 18.3% (that calculated for a native lignin with five methoxyl groups is 18.14%) and with its unchanged carbonyl group it should still be soluble in bisulfite solution. An experimental proof of this statement will be carried out soon. Since Freudenberg methylated his sprucewood to a methoxyl content for the lignin of 18 to 19% only, it is quite understandable how, in his methylated wood, the lignin is dissolved with bisulfite. This would mean that instead of a "phenolic or an enolic hydroxyl" group being responsible for the reaction of the lignin with bisulfite liquor,[10] it is in reality an easily enolizable carbonyl group.

Since a partially methylated lignin with the same methoxyl content is obtained from diazomethane-methylated sprucewood, it follows that in wood the keto form of the lignin is either already present in its enolic form or it is slowly enolized. The long period of time required to reach a final methoxyl content in the diazomethane-methylation of sprucewood may indicate that the keto group is slowly enolized during the methylation.

Experimental[23]

Isolation of Native Spruce Lignin.—Black sprucewood meal (100- to 150-mesh) is extracted first with cold water, then with ether, and finally with alcohol at room temperature in a percolator until the alcohol drains off colorless. The alcohol solution is distilled off under reduced pressure, whereupon a finely divided creamy precipitate separates out in addition to a resinous material. This is washed with water and ether until the material becomes solid and powdery. It is filtered, dissolved in dioxane, and precipitated by pouring the solution into distilled water. Should a colloidal solution be formed, the addition of a few grams of sodium sulfate will coagulate it. The precipitate is filtered again, dried and redissolved in dioxane to give a 10% solution and the centrifuged and filtered dioxane solution dropped slowly into absolute ether with vigorous stirring. The native lignin separates out as a fine powder. This precipitation process is repeated until the methoxyl content remains constant. The product is washed after each purification with ether and finally with petroleum ether. The lignin so obtained is a very light cream-colored powder. It is soluble in 4% sodium hydroxide solution, methanol, ethanol, dioxane, and pyridine, and insoluble in water, ether, benzene, and petroleum ether. It reduces Fehling solution and when dissolved in dioxane with phloroglucinol–hydrochloric acid gives the typical purple color reaction.

Anal. C, 63.62; H, 6.20; MeO, 14.7; after another precipitation from dioxane into benzene, C, 63.89; H, 6.07; MeO, 14.9, 14.6; another preparation gave C, 63.85; H, 6.19; and MeO, 14.8.

Acetylation of Native Lignin.—One gram of native lignin is dissolved in 15 cc. of dry pyridine, 12 cc. of acetic anhydride is added and the mixture allowed to stand at room temperature for two days. It is then poured over cracked ice and the creamy colored precipitate filtered. It is washed well with distilled water and dried in a desiccator over sulfuric acid and sodium hydroxide. It is then dissolved in dioxane, the solution centrifuged and filtered, and the product precipitated as a light cream-colored powder by pouring the solution drop by drop into dry ether. After washing with ether and petroleum ether it is dried. Its solubilities in organic solvents are the same as those of native lignin but it is no longer soluble in cold sodium hydroxide. *Anal.* Found: MeO, 11.9 and 11.7.

Methylation of Native Spruce Lignin with Diazomethane in Dioxane.—Twenty-five grams of native lignin is dissolved in 100 cc. of dioxane, and diazomethane prepared from 20 cc. of nitrosomethylurethan is passed into the solution. A vigorous nitrogen evolution takes place. After standing overnight a sample of the product is precipitated by dropping 5 cc. of the centrifuged solution into dry ether. The product is washed as usual and has a methoxyl content of 20.9%. After two more methylations, each with diazomethane from 10 cc. of nitrosomethylurethan, the methoxyl content is constant. The diazomethane-methylated native lignin is an almost white powder. It still reduces Fehling solution but no longer gives the color reaction with phloroglucinol and hydrochloric acid. It is soluble in alcohol, dioxane, acetone, and pyridine but insoluble in benzene, ether, petroleum ether and alkali solutions. *Anal.* Found: MeO, 21.4, 21.54, and 21.4.

Acetylation of Native Spruce Lignin Premethylated with Diazomethane.—Diazomethane-methylated native lignin is acetylated as described for acetylated native lignin. It is isolated as a cream-colored powder.

Methylation of Native Spruce Lignin Premethylated with Diazomethane with Dimethyl Sulfate and Sodium Hydroxide.—Diazomethane-methylated native spruce lignin (2.5 g.) is dissolved in 25 cc. of acetone and methylated twice at 20° with 25 cc. of dimethyl sulfate and 35 cc. of sodium hydroxide solution (30%) keeping the mixture only slightly alkaline. After eight hours of stirring, the acetone is distilled off under reduced pressure, whereupon the methylated lignin separates as an orange-colored solid material. This is filtered, thoroughly washed with distilled water, and dried in a desiccator. It is then redissolved in dry acetone, centrifuged, and a part of the solution dropped into dry ether with vigorous stirring, whereupon the methylated lignin is precipitated as a cream-colored powder. It is washed with ether and petroleum ether and dried. For the

(23) Many of the analyses were made by Dr. M. A. Buchanan of The Institute of Paper Chemistry.

analysis it is dried in an Abderhalden drier at 100° over phosphorus pentoxide at 10 mm. for several hours. It has a methoxyl content of 30.2%. It is remethylated as before and has then a final methoxyl content of 31.3%. In the final purification the product is precipitated once from its acetone solution into distilled water and twice from its dioxane solution into ether.

Phenylhydrazone from Native Spruce Lignin.—To a solution of 0.5 g. of native spruce lignin in 5 cc. of dioxane, 1 g. of phenylhydrazine is added and the mixture heated for two hours on a water-bath at 80°. It is allowed to stand overnight at room temperature, centrifuged, and the clear deep red solution precipitated into dry ether with vigorous stirring. It separates out as a lemon-yellow product and after another precipitation has a methoxyl content of 13.5%, which remains practically unchanged after a second treatment with phenylhydrazine.

Methanol Spruce Lignin from Isolated Native Lignin.—Ten grams of native spruce lignin is dissolved in 200 cc. of absolute methanol, and 50 cc. of methanol containing 1.25 g. of hydrochloric acid are added. The original yellow-brown color of the solution turns immediately to a cherry-red color. The mixture is refluxed for two and one-half hours, the methanol solution distilled off under reduced pressure, and the reddish-brown residue taken up in 100 cc. of methanol–acetone mixture (1:1). This solution is filtered and dropped into 2 liters of distilled water with vigorous stirring, whereupon the methanol lignin separates as a light brown flaky precipitate. It is filtered, washed well with distilled water, and dried. The yield is almost quantitative. It is twice precipitated from its dioxane solution into dry ether and shows then the same properties as the methanol lignin directly prepared from sprucewood.[15d] The acetylation of methanol spruce lignin from isolated native lignin and its methylation with diazomethane and with dimethyl sulfate and sodium hydroxide are carried out in the same way as that described for the isolated native spruce lignin. The methoxyl contents are given in the table.

Treatment with Methanol and Hydrochloric Acid of Isolated Native Spruce Lignin Premethylated with Diazomethane.—This reaction is carried out under the same conditions as those observed in the preparation of methanol spruce lignin from isolated native lignin. The product so obtained has almost the same methoxyl content (24.4%) as the corresponding derivative prepared directly from sprucewood (24.7%), but on remethylation of the former with diazomethane the methoxyl content increases to 25.4% or the same as the diazomethane-methylated methanol lignin from native lignin.

Summary

1. An unchanged native lignin has been isolated from black spruce by an extraction with indifferent organic solvents without the use of acids or alkali. It has a methoxyl content of 14.8%.

2. Methylation of this lignin with diazomethane indicates that two methoxyl groups are introduced into the lignin building unit of a molecular weight of 840. One of these methoxyl groups is attached to a phenolic hydroxyl group, the second to an enolic hydroxyl group.

3. In the reaction between methanol and native lignin in the presence of 0.5% anhydrous hydrochloric acid, a methanol lignin is formed combining two new methoxyl groups in an acetal-like form to a carbonyl group.

4. The presence of a carbonyl group has been proved by the formation of a phenylhydrazone.

5. A molecular size of the lignin building unit of approximately 840 has been confirmed.[18]

6. The presence of a phenolic hydroxyl group in the lignin building unit has been shown by methylation with diazomethane of the original lignin and of the methanol lignin, and by the solubility of the native lignin and its methanol derivative in sodium hydroxide solution, from which it is reprecipitated by carbon dioxide.

7. The isolated native lignin is completely soluble in bisulfite but it becomes insoluble in this solvent when fully methylated with respect to diazomethane, by which the enolized carbonyl group is methylated.

The Rearrangement of Certain Derivatives of Toluene by the Action of Aluminum Chloride

BY JAMES F. NORRIS AND HOWARD S. TURNER[1]

Many investigations have shown that derivatives of benzene which contain only alkyl groups undergo disproportionation and rearrangement when heated with aluminum chloride. We have not found reports of any study of the rearrangement of alkyl groups in aromatic compounds which contain, in addition to these groups, an atom or group of a different type. The influence of the nature of a substituent on the reactivity of a particular atom or group in a compound has been studied for several years in this Laboratory and it was of interest to extend the study to include the influence of different classes of substituents on the change of position of an alkyl group brought about by the action of aluminum chloride. Further, if rearrangement took place the process might be used as a means of preparing from a readily accessible compound an isomer which is formed to a small extent during nitration, chlorination, etc. For example, if *m*-chlorotoluene or *m*-cresol could be formed from their isomers, the method might make available compounds which are now obtained by indirect methods.

In this paper are described the results of the study of heating with aluminum chloride the following: *o*-, *m*- and *p*-chlorotoluene, *o*-, *m*-, and *p*-nitrotoluene, *p*-cresol, and *p*-dimethylaminotoluene. The effects of change in temperature, time, and the molecular ratio of the aluminum chloride to the second reactant were studied in certain cases. Appreciable rearrangement was observed only with the chlorotoluenes and *p*-cresol. The addition compounds formed from the amines and aluminum chloride were stable at the temperatures used. In the case of the limited number of compounds studied, it appears that the ortho and para orienting groups methyl, hydroxyl, and chlorine produce in a methyl radical sufficient reactivity to permit a change of position of the latter in the molecule. The meta orienting nitro group stabilizes a methyl radical so that it does not migrate under the conditions that affect the other class of compounds.

p-Chlorotoluene was studied first because a preliminary experiment showed that it underwent both rearrangement and disproportionation and resembled *p*-xylene in its behavior. The products resulting from disproportionation indicated that the methyl radical and not the chlorine atom was involved in the change. It has been shown that bromobenzene, when heated at its boiling point with aluminum chloride, yields benzene and *p*-dibromobenzene,[2] but the conditions used in our experiment were much less drastic.

The main difficulty to be overcome in the case of the chlorotoluenes was the quantitative determination of the amount of each isomer in the rearranged product. After the investigation of chemical procedures, which proved to be inadequate, a physico-chemical method was adopted. The amount of the para compound in the mixture, which contained only the isomers, was determined by the freezing point lowering of *p*-chlorotoluene produced by the mixture; this was a measure of the sum of the *o*- and *m*-chlorotoluenes present. A modified form of the Swietoslawski differential ebullioscope[3] was used to determine the percentages of the ortho and of the meta compounds in the mixture. The temperature of the vapor from a rapidly boiling mixture which contained a fixed percentage of the para isomer was determined, and its position on a plot previously prepared was noted. This plot was made by determining the temperature of the vapor of a series of mixtures which contained a definite percentage of the para compound and varying percentages of the other isomers. The change in vapor temperature with change in composition was sufficient to give results accurate within a few per cent. The results are given in the table.

An examination of the table leads to the following conclusions: (a) *p*-chlorotoluene undergoes rapidly both rearrangement and disproportionation when heated with aluminum chloride at 100°; (b) from expts. 1 and 2 it is seen that when heated for half an hour a large change in the molecular

The figures in the column headed "% recovered products other than chlorotoluenes" were calculated from the weights of fractions I, II and III. It is probable that small amounts of the chlorotoluenes were not separated from fractions I and III; for this reason the values of the percentages of recovered products other than chlorotoluenes are presumably too great. The results are comparable, however.

ratio of the chlorotoluene to aluminum chloride has little effect, whereas in four hours the larger proportion of aluminum chloride produced a much greater increase in disproportionation than in rearrangement. This difference also was observed in the case of the xylenes[4]; (c) it is seen from expts. 1, 6 and 3 (mole ratio 1:1) that increase in time results in approximately equivalent increases in the amounts of both rearrangement and disproportion. When less aluminum chloride was used in expts. 2 and 4 (mole ratio 10 to 1) increase in time produced a much larger increase in rearrangement than in disproportionation; (d) increase in temperature (expts. 5 and 7) from 50 to 70° doubled the disproportionation and increased rearrangement 2.8 times; (e) of the three isomers (expts. 10, 11 and 12) the ortho is the most stable under the conditions used; the para is the least stable. Of the original isomer in the rearranged product the ortho compound yielded 78.4%, the meta 49.2% and the para 26.6%. It would be possible to prepare *m*-chlorotoluene from the para compound.

Attempts made to produce rearrangements of the three nitrotoluenes by aluminum chloride and hydrogen chloride were unsuccessful. The temperature used varied from 100 to 150°, the time from half an hour to two hours and the molecular ratios of aluminum chloride to nitro compound were 1 to 1 and 2 to 1. At the lower temperature the nitro compound was recovered unchanged; at the higher temperatures tars were formed.

Since there was such a marked difference between the activating influence of a chlorine atom and a nitro group on a methyl radical joined to a benzene ring, it appeared desirable to study the influence of a dimethylamino group. It has been shown[5] that dimethylaniline is recovered unchanged after being heated at 250° for ten hours. The amine is converted into methyl chloride and aniline hydrochloride when heated with hydrogen chloride.[6] These facts were considered in the experiments with *p*-dimethylaminotoluene. The compound of the latter with aluminum chloride in the absence or presence of hydrogen chloride was so stable that it suffered no appreciable change on heating.

A preliminary experiment has been made with *p*-cresol. When the compound (0.19 mole) was heated at 200° for one and one-half hours with aluminum chloride (0.38 mole), rearrangement took place. The meta isomer which was formed in appreciable quantities was identified by the melting point of the trinitro derivative.

Experimental

Details of an Experiment.—The apparatus used in most of the experiments consisted of a round-bottomed flask provided with an inlet tube through which hydrogen chloride (1 to 2 bubbles per sec.) was passed, a mechanically driven stirrer and a reflux condenser fitted with a calcium chloride tube. The flask containing the reactants was placed in a glycerol bath which was heated by a

(6) Lauth, *Ber.*, **6**, 677 (1873).

refluxing liquid for the desired time. There appeared to be little or no solution of the aluminum chloride in the chlorotoluene. The mixture was treated with ice and hydrochloric acid and distilled with steam. In certain cases the separation of the organic liquid was difficult. If a partial emulsion was formed this was separated, and treated with a little water and calcium chloride. The dense aqueous solution helped in the separation of the two liquids. The product was dried with calcium chloride and distilled very slowly through a 13-turn Davis column.

Compounds Used.—The *p*-chlorotoluene was made from *p*-toluidine and distilled through a 12-turn Davis column; a cooling curve showed that it melted at 7.2° (6.2 to 7.5° in the literature). The ortho and para compounds obtained from the Eastman Kodak Company were fractionated with the Davis column[7]; the ortho isomer was collected at 158.7–158.9° at 754 mm. (literature 159.15 at 760 mm.); the meta compound boiled at 161.8–162° at 768 mm.

The nitrotoluenes were obtained from the Eastman Kodak Company; the para compound melted at 51–53°; the meta at 15–16°; and ortho at −6°. The *p*-dimethylaminotoluene (Kahlbaum) melted at −30.5° (thermometer not calibrated). The *p*-cresol (Eastman Kodak Company) melted at 32.5° (literature 33.5°). Merck pure sublimed aluminum chloride was used.

Methods of Analysis for the Chlorotoluenes.—The amount of the para compound in a mixture containing only the three isomers was found by determining the lowering of the freezing point of pure *p*-chlorotoluene produced by the mixture. The freezing point constant for *p*-chlorotoluene was determined by using *m*-chlorotoluene as solute; two determinations gave 5.92 and 5.97 as the constant. The determinations were made in the apparatus previously described.[4] The method was tested by the analysis of a mixture of known composition, para 50%, meta 33.3%, ortho 16.7%; found 47.8 and 49.8% para.

The determinations of the amounts of the ortho and the para isomers in the mixtures were made in a Swietoslawski differential ebullioscope a drawing of which is included in the reference already given. The apparatus is designed to record the temperature of a boiling liquid and that of the vapor from the liquid, which is condensed and returned to the flask in which the liquid is boiling. Tests of the apparatus designed with a boiling flask of 5-cc. capacity showed that the temperatures of the vapor could be reproduced more accurately than those of the liquid; as a consequence the vapor temperatures were used in the determinations. The apparatus was heavily insulated by cork. In order to operate at a constant and reproducible pressure, the end of the reflux condenser was connected with a 5-gallon (20-liter) bottle which contained 5 lb. (2.5 kg.) of calcium chloride to keep the air at a constant content of moisture. The bottle was placed up to its neck in a large container filled with water. The bottle was connected to a 1-liter flask kept in a thermostat. When a determination was to be made the pressure in the apparatus was adjusted so that the surfaces of the mercury in the two arms of the manometer were at the same level. This arrangement kept the pressure so nearly constant that the temperatures of the vapor during an experiment varied less than 0.005°. In duplicate determinations the temperatures checked within 0.01°.

With this apparatus the temperatures of the vapor from mixtures of varying composition of the three isomers were determined. In each case 11 g. of the mixture which contained 9 g. of the para isomer was used; the amounts of ortho and meta isomers were varied from 2 g. ortho and 0 g. meta to 0 g. ortho—2 g. meta. Determinations on eleven mixtures gave data for a curve that deviated only slightly from a straight line. The difference in the temperatures of the vapors from the two mixtures which varied most in composition was 0.52°. In each case five observations at different time intervals were made of the temperature of the vapor, and the values were averaged. The difference between the several single observations in the case of a particular mixture varied from 0.001 to 0.004°. An analysis was made of a mixture of known composition: calcd., *o* 16.7%, *m* 33.3%, *p* 50%; found, *o* 15.2%, *m* 34.8%, and *p* 48.8%.

In the analyses of the mixtures produced by rearrangement, the product obtained as the result of heating the chlorotoluene with aluminum chloride was distilled with steam and the volatile material was weighed. After drying, the mixture was distilled very slowly through a 12-turn Davis column and separated into three fractions: I up to 158°, II 158–163°, III residue. The percentage of the para isomer in fraction II was next determined. The weight of the mixture that contained 2 g. of the ortho and para compounds was calculated, weighed and taken for analysis. The weight of the para isomer in this sample was calculated and enough of the para compound was added so that the resulting mixture contained 9 g. of para and 2 g. of a mixture of ortho and meta chlorotoluenes. The temperature of the vapor from this mixture when it was boiled in the ebullioscope was determined as before. The position of the temperature on the plot gave the percentages of the ortho and of the meta compounds in the mixture.

An experiment was made with *p*-chlorotoluenes to determine to what extent a more careful fractionation of the mixture before analysis would affect the percentages of the isomer in the fraction boiling at 158–163°. The three fractions obtained with the Davis column were refractionated through a Fenske column[8] (15 theoretical plates). The analyses of the fraction boiling between 158 and 163° showed that the product of the first distillation contained 75.2% of the ortho and meta isomers and after the second distillation 80.6%. As a result of the second distillation the weights of the first and third fractions decreased and the middle fraction increased. As stated in the note in the table the percentages of disproportion given are too great. We were particularly interested in rearrangement and did not carry out the additional fractionation on the experiments reported.

In order to determine what products had been formed as the result of disproportionation, the low boiling fractions from all the experiments were combined and fractionated through a Fenske column equivalent to 13 theoretical plates. About 75% of the material boiled

(7) H. S. Davis, *Ind. Eng. Chem., Anal. Ed.*, **1**, 61 (1929).

(8) M. R. Fenske, Quiggle and Tongberg, *Ind. Eng. Chem.*, **24**, 408 (1932).

between 132.2 and 132.4° and was shown to be chlorobenzene by converting it into *p*-bromochlorobenzene which melted at 65–66°.

The original fractions boiling above 168° were combined and distilled through the Fenske column. There were obtained the following fractions: 2 g. at 170–180°, 6.8 g. at 180–185°, 5.3 g. at 185–187.6°, 8.5 g. at 187.6–192°, 0.9 g. at 192–200° and a small residue. The known chloroxylenes boil from 186.6 to 191.5° and the dichlorotoluenes from 198–206°. It appeared probable that the methyl radical and not the chlorine had migrated. This conclusion was strengthened by the results of the determination of the density of the mixture of the two fractions which boiled between 187.6 and 192°; it was found to be 1.052^{25}_{25}. The density of 2,4-dichlorotoluene is 1.246^{20}_{20} and of 1,2-dimethyl-4-chlorobenzene is 1.069^{15}_{15}. Since the densities of the isomers of these compounds differ but little, it is highly probable that the high-boiling fraction contained chloroxylenes.

Experiments with the Nitrotoluenes.—Equal molecular quantities of aluminum chloride and *o*, *m*, and *p*-nitrotoluenes were heated at 104° for two hours. The chloride dissolved and an oil was formed in each case. After decomposition with water a small amount of tar and the nitrotoluene used was recovered. When *p*-nitrotoluene was heated at 115, 125, and 150° for one hour the amount of tar was increased but no isomers were formed. Similar results were obtained when the meta compound was heated at 115° for one hour. Tests for an amine in the products formed were negative. The result was not changed when 2 molecular quantities of aluminum chloride were used.

Summary

1. It was shown that when the chlorotoluenes are heated with aluminum chloride and hydrogen chloride rearrangement and disproportionation take place.

2. The extent to which these changes occur is determined by the temperature, time of heating and the molecular ratio of aluminum chloride to the chlorotoluene.

3. Under certain fixed conditions the stabilities of the isomers are ortho > meta > para.

4. Under certain conditions the mixture of the isomers obtained from *p*-chlorotoluene consisted of ortho, meta and para in the ratio 1–2–1.

5. Under the conditions used to cause the rearrangement of the chlorotoluenes, the isomeric nitrotoluenes and *p*-dimethylaminotoluene were not affected.

The Rearrangement of the Xylenes by Aluminum Chloride

BY JAMES F. NORRIS AND GORDON T. VAALA[1]

In certain Friedel and Crafts reactions in which a variety of substances are condensed with alkyl derivatives of benzene, the orientation of the alkyl groups in the products obtained is not the same as that in the hydrocarbons from which they were produced. Much work has been done on the rearrangement and disproportionation of such hydrocarbons, but the conditions used have been such that the results cannot be taken as a guide in Friedel and Crafts reactions, when it is desired either to avoid or to take advantage of the rearrangement. The isomeric xylenes were of particular interest because it was found that under certain conditions the chief product of the methylation of benzene was 1,2,4-trimethylbenzene and under other conditions a high yield of 1,3,5-trimethylbenzene was formed.[2] It appeared probable that xylenes were intermediate products. It was important to determine, if possible, whether the change in conditions led primarily to different orientation or to secondary rearrangements. In the earlier work it was shown that the three xylenes underwent appreciable rearrangement when they were heated with aluminum chloride at 55° for ten minutes.

This paper contains the results of a detailed study of the rearrangement of the xylenes. The following factors were investigated: the time, the temperature, the molecular ratio of hydrocarbon to aluminum chloride, the effect of the presence of varying amounts of ferric chloride, and the presence or absence of hydrogen chloride. The results were such that they have been of value in the control of several Friedel and Crafts condensations, which will be described in papers to be published later.

In determining the percentages of the three

(2) Norris and Rubinstein, THIS JOURNAL, 61, 1163 (1939).

isomers in the rearranged product, the freezing point method of Norris and Rubinstein was used for *p*-xylene. An improved apparatus was used, which facilitated the work and has been used in other investigations. The freezing point method when applied to *o*-xylene involved work at inconveniently low temperatures. A method of analysis based on oxidation of the mixture of the xylenes was developed and tested with synthetic mixtures. It was shown that the corresponding dibasic acids could be determined with an accuracy of about 90%.

The results of the experiments are given in the form of tables.

TABLE I

REARRANGEMENT OF *m*-XYLENE AT 50° IN THE PRESENCE OF HYDROGEN CHLORIDE

Mole ratio $1C_6H_4(CH_3)_2$ to $1AlCl_3$. The hydrocarbon used boiled at 139.2–139.5° and was shown by analysis to contain 1% *p*-xylene and less than 1% *o*-xylene.

Time, hours	Weight xylene used, g.	% recovered hydrocarbons	% xylenes in recovered hydrocarbons	% isomers in recovered xylenes Ortho	Meta	Para
0.5	85	92	100	..	..	3
1.5	65	94	100	16	77	7
5	53	95	88	14	74	12
18	85	95	85	16	69	15
30	43	93	84	16	69	15
48	43	87	80	16	67	17
75	43	89	72	16	65	19

TABLE II

REARRANGEMENT OF THE XYLENES IN THE PRESENCE OF HYDROGEN CHLORIDE

Mole Ratio $1C_6H_4(CH_3)_2$ to $1AlCl_3$

Xylene	Temp., °C.	Time	% xylenes in recovered hydrocarbons	% isomers in recovered xylenes Ortho	Meta	Para
Ortho	50	5 hrs.	94	40	55	5
Meta	50	5 hrs.	88	14	74	12
Para	50	5 hrs.	83	14	76	10
Ortho	94	15 min.	84	38	46	16
Meta	94	15 min.	100	18	72	10
Para	94	15 min.	90	16	31	53

A comparison of the results in Table II with those of Norris and Rubinstein shows that at 55° for ten minutes the para isomer gave 3.4 times as much rearranged products as did the ortho; at 50° for five hours 1.5 times, and at 94° for fifteen minutes 0.75 times. The percentage rearrangements of *m*-xylene under the two conditions used were approximately the same.

TABLE III

EFFECT OF MOLECULAR RATIO OF HYDROCARBON TO ALUMINUM CHLORIDE ON REARRANGEMENT OF *m*-XYLENE AT 50° IN THE PRESENCE OF HYDROGEN CHLORIDE

	% xylenes in recovered hydrocarbons	% isomers in recovered xylenes Ortho	Meta	Para
With HCl	80	16	67	17
No HCl	96	14	71	15

The conclusions from the results of the investigation can be used in the preparation of compounds by the Friedel and Crafts reaction and be used as a guide in the discovery of the structure of the compounds obtained. They furnish an explanation of the formation of pseudocumene when benzene is methylated at 0°; the orientation is ortho and para, as might be expected. At 100° the chief product is mesitylene in which the orientation is meta. In the simultaneous acylation and methylation of benzene by esters which is carried out best at about 100°, the orientation of the alkyl groups is largely meta.

A preliminary experiment has been made on the rearrangement of commercial pseudocumene with the thought that the reaction might be used as a convenient and cheap way of preparing mesitylene. A sample of pseudocumene (b. p. 169–171°) which was analyzed by sulfonation and found to contain 8.5% mesitylene, was heated with 2 moles of aluminum chloride at 94° for one hour. The recovered mixture of hydrocarbons contained 18% of mesitylene.

The fact that aluminum chloride produced a rearrangement of the xylenes led to a study of the condensation of methyl alcohol with pure *m*-xylene. The molecular ratios were 1.25 hydrocarbon, 0.25 methyl alcohol, and 0.75 aluminum chloride, the time five hours and temperature 110°; the yield of mesitylene boiling at 163.8° to 165.2° was 84%. After sulfonation and hydrolysis the yield was 80% of mesitylene which boiled

at 164–164.8° and gave a yield of 99.5% of the tribromo derivative which melted at 224–225° before crystallization.

A similar experiment was carried out but the time of heating was reduced to one and one-half hours and dry air was passed through the reacting mixture to remove the hydrogen chloride. In this case the yield of mesitylene boiling at 164.2–164.8° after sulfonation was 90% of the theoretical. With technical xylene at 90° for five hours, the yield of mesitylene was 34% and that of pseudocumene 37%.

Experimental

Details of an Experiment.—The aluminum chloride was placed in a 500-cc. round-bottomed flask fitted with a spiral return condenser, a motor-driven stirrer and a tube, leading to the bottom of the flask, through which dry hydrogen chloride was passed (1 bubble in two seconds). This tube contained a T through which the hydrocarbon could be introduced from an attached separatory funnel. The flask was heated in an oil-bath at the desired temperature, and the hydrocarbon, previously heated, was introduced. At the end of the desired time the product was cooled rapidly, decomposed by ice and hydrochloric acid in a flask, and distilled with steam. In certain experiments hydrogen chloride was not passed through the reactants.

Merck reagent anhydrous aluminum chloride was used in all experiments. The *m*-xylene was furnished by the du Pont Company. All temperatures are corrected; they were determined with a calibrated thermometer graduated in 0.2°.

Analytical Methods.—After the hydrocarbon had been heated with aluminum chloride the product was decomposed by ice and hydrochloric acid and distilled with steam. The weights of hydrocarbon used and of the mixture which distilled gave data for the percentage of hydrocarbon recovered.

The product was dried, distilled slowly through a 13-turn Davis column,[3] and the temperature observed on a calibrated Anschütz thermometer with graduations of 0.2°. The material was collected in three fractions: I up to 137°; II 137–144°; III above 144°. The residue in the flask was redistilled in a 10-cc. flask and any material boiling at 137–144° was added to fraction II and higher boiling material, to fraction III. The sum of the weights of fractions I and III and the weight of fraction II were used in calculating percentage recovered xylenes.

Quantitative Determination of *p*-Xylene.—The lowering of the freezing point of pure *p*-xylene produced by a sample of the mixture gave data for calculating the percentage of compounds other than *p*-xylene in the mixture. The solvent was prepared from Eastman Kodak Co. pure *p*-xylene by distillation through a 13-turn Davis column; the fraction used boiled at 137.5–137.6° and melted at 13.0°. The freezing point constant was determined with toluene (b. p. 110.4–110.5°) and found to be 42.5 (value in literature, 43). The method was tested by analyzing two known mixtures which contained I 8% para, 10% ortho, and 82% meta xylenes, and II 20% para and 80% meta xylenes. Mixture I was found to contain 8.3% and mixture II 20.4% *p*-xylene.

In determining freezing points, a very convenient modification of the Hortvet cryoscope[4] was used. The apparatus consisted of a tall 1-liter vacuum bottle, insulated with a metal case and covered with a tightly fitting cork with a central opening for a metal tube 4 cm. in diameter and 20 cm. long. This tube served as an air jacket for a test-tube (18 × 2.5 cm.) which was fitted to it by a cork. The cooling was accomplished by passing dry air through a 4-mm. metal tube which extended to the bottom of the vacuum bottle where 500 cc. of ether had been placed. The tube ended in a loop which was pierced with pin holes to permit the formation of a stream of air bubbles. The evaporation of the ether produced by drawing air through it caused a lowering of the temperature which could be held within 0.10° at temperatures from 20 to −10°. In making the freezing point determinations the bath was held at 8 ± 0.1°, and the solution was supercooled about 0.3°. Determinations checked within 2%.

Quantitative Determination of *o*-Xylene.—A method was developed for the oxidation of the three xylenes to the corresponding phthalic acids, which gave sufficiently high yields to make the method useful for quantitative determinations. *o*-Xylene gave 89.4% of an acid which was shown by titration to be 98.6% dibasic; the corresponding figures with *p*-xylene were 88.3 and 97.4% and with *m*-xylene 91.3 and 98%.

The method was as follows: 4 cc. of the xylene, measured in a calibrated pipet, was placed in a 500-cc. flask fitted with a motor-driven stirrer through a mercury seal, a reflux spiral condenser, and a dropping funnel. The flask was heated to 120° and 3.8 cc. of bromine added drop by drop. Next, 10 cc. of a saturated solution of sodium hydroxide diluted with an equal volume of water was added. After the solution was refluxed for one hour, 100 cc. of a 5% solution of potassium permanganate (one-third the theoretical amount) was added. After heating for fifteen minutes, another 100 cc. was added and after one hour, 130 cc. The total time of refluxing was six hours. The cooled solution was treated with sulfur dioxide and filtered. The filtrate and washings from manganese dioxide were concentrated to about 150 cc. and poured into a 25% excess of concentrated hydrochloric acid. In a few minutes the hot solution was filtered; the precipitated isophthalic and terephthalic acids were washed with cold water, dried, and weighed. The filtrate and washings were evaporated to dryness, the residue powdered and transferred to a 500-cc. round flask with a long neck. Into the latter was placed a test-tube through which water flowed. The flask, surrounded and covered by asbestos, was placed on an iron gauze and asbestos and heated by a flame to such a temperature that a thermometer placed in the jacket just above the gauze registered 180–190°; the phthalic anhydride sublimed slowly. At the end of from two to three hours the anhydride collected as a compact crystalline mass on the cooled test-tube. The latter was withdrawn, the

(3) H. S. Davis, *Ind. Eng. Chem., Anal. Ed.*, **1**, 61 (1929).

(4) Hortvet, *J. Ind. Eng. Chem.*, **13**, 203 (1921).

anhydride dissolved in 200 cc. of neutral alcohol and titrated with 0.1 *N* sodium hydroxide solution. To test the purity of the acid it was recovered and converted into phthalic anhydride. The quantitative isolation of the anhydride in this way was tested with a weighed sample which was converted into the salt, liberated and sublimed, and titrated. The recovery was 95.7%. In a second test a mixture of 1 g. each of the three phthalic acids gave a recovery of *o*-phthalic acid of 97%.

We were unable to find a quantitative method for the separation of isophthalic and terephthalic acids. As a consequence, the percentage of *m*-xylenes in the mixtures analyzed was considered to be the difference between the weights of the mixed xylenes and the sum of the ortho and para isomers. In several experiments the weight of *m*-xylene was calculated from the weights of the *p*-xylene and of the isophthalic and terephthalic acids obtained. The result checked within less than 1% the value obtained.

Summary

1. The effect of aluminum chloride on the three xylenes was studied under different conditions.

2. It was found that (1) change in temperature affects the relative proportions in which the isomers are formed; (2) rearrangement takes place much more rapidly than the decomposition of the hydrocarbons and yields a mixture approaching that present in commercial xylene; (3) decrease in the molecular ratio of aluminum chloride decreases the rate of rearrangement and the percentage decomposition; (4) the presence of ferric chloride had little or no effect and (5) hydrogen chloride did not affect rearrangement but appeared to increase decomposition.

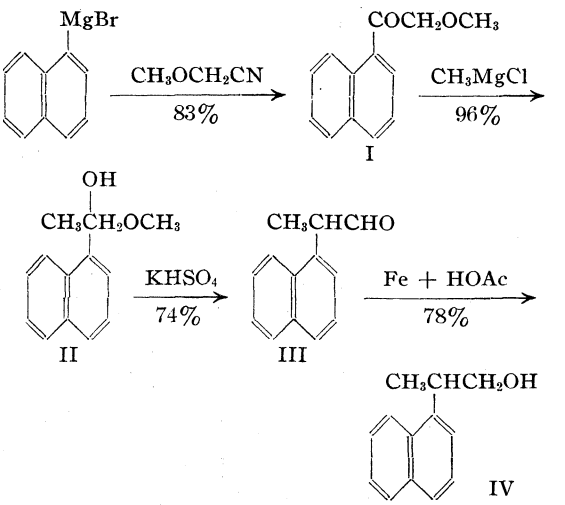
Synthetic Experiments in the Chrysene Series

BY LOUIS F. FIESER, LLOYD M. JOSHEL[1] AND ARNOLD M. SELIGMAN[2,3]

The goal of the present work was the development of a synthesis of 5-methylchrysene which would be capable of application as well to the synthesis of 4,5-dimethylchrysene, both hydrocarbons being desired as possible models of the carcinogenic 3,4-benzpyrene.[4] The scheme selected for investigation required 2-(α-naphthyl)-propionaldehyde (III) as an essential intermediate, and a method for the preparation of the aldehyde was found which is very satisfactory for the case at hand and which should be capable of other applications. The remainder of the plan could not be realized, for a rearrangement was encountered in the final stages of the synthesis.

In the most satisfactory procedure for preparing the intermediate aldehyde, α-naphthylmagnesium bromide was condensed with methoxyacetonitrile to give the keto ether I and this by interaction with methylmagnesium chloride was converted into the carbinol ether II in over-all yield of 80%. It is not practical to reverse the order of the two Grignard reactions, for when methylmagnesium chloride was added to methoxyacetonitrile ac-



cording to Gauthier[5] and the resulting methoxyacetone condensed with α-naphthyl Grignard reagent, the over-all yield of II was only 12%. Carbinol ethers analogous to II have been synthesized similarly by Bradsher and Schneider[6] from 2-iodobiphenyl and cyclized with acids to phenanthrene derivatives. Our methyl-methoxymethyl-α-naphthylcarbinol (II) in the next step was distilled over potassium bisulfate, when methyl alcohol was liberated and the chief product was 2-(α-naphthyl)-propionaldehyde (III). This

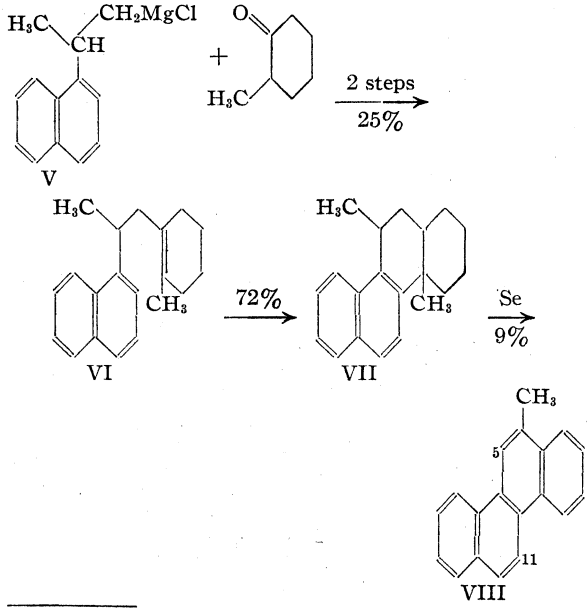
is probably formed by dehydration of II to the enol ether, $Ar(CH_3)C{=}CHOCH_3$, and acid hydrolysis to the enol form of the aldehyde. A small amount of the enol ether indeed escaped hydrolysis under the conditions used and was isolated as a by-product on purifying the aldehyde through the bisulfite compound. It is convertible into the aldehyde in good yield by hydrolysis with dilute hydrochloric acid.

2-(α-Naphthyl)-propionaldehyde, a liquid substance characterized as the crystalline semicarbazone, was reduced in good yield with iron powder and dilute acetic acid to the alcohol IV. Certain of the standard methods for conversion to the chloride or bromide gave mixtures of wide boiling range, but treatment of the alcohol with phosphorus pentachloride in benzene afforded a homogeneous chloride in fair yield. The chloride seems to have the expected normal structure, for carbonation of the magnesium derivative gave a substance corresponding in properties to the known β-(α'-naphthyl)-butyric acid.[7]

In one attempt to obtain 5-methylchrysene use was made of the Bogert–Cook synthesis and Cook's device of introducing a 2-methyl group in the alicyclic ring to suppress spiran formation, for this has been shown to give good results in the synthesis of chrysene itself.[8] The Grignard reagent (V) from 2-(α-naphthyl)-chloropropane was condensed with 2-methylcyclohexanone and the carbinol (oil) was dehydrated with potassium bisulfate. This gave an unsaturated hydrocarbon of composition corresponding to VI, which was cyclized with aluminum chloride in carbon bisulfide solution at 0° to the dimethyloctahydrochrysene VII. Dehydrogenation with sulfur gave no pure product, but with either selenium or palladium charcoal there was obtained an oily product from which a homogeneous hydrocarbon was isolated in low yield through the trinitrobenzene derivative. The hydrocarbon, m. p. 159–159.8°, corr., has the expected composition but corresponds in properties to 6-methylchrysene (VIII), recently synthesized by Newman.[9] A direct comparison of the hydrocarbon, picrate (m. p. 170–170.6°, corr.), and trinitrobenzene derivative (m. p. 189.8–190.6°, corr.) with samples kindly made available by Dr. Newman established the identity of the substances, for the melting points are the same and there is no depression on mixing.



While it is not likely that Newman's synthesis could give anything but the expected 6-methylchrysene, there is analogy for the occurrence of a rearrangement in the dehydrogenation of a substance of the structural type involved in the present synthesis. Haworth[10] observed the para migration of a methyl group in the dehydrogenation of a 4-methyl-1,2,3,4-tetrahydrophenanthrene, but noted that rearrangement occurs only if the methylated ring is completely saturated. The nuclear methyl group of our hydrocarbon VII occupies a similar position in a saturated ring, and the case differs from that studied by Haworth only in that the para position is blocked. The most plausible interpretation of the present observation is that the methyl group migrates from C_5 to the ortho position 6. W. E. Jones and Ramage[11] recently investigated the dehydrogenation of certain decahydrochrysenes which normally should give 5-methylchrysene and 5,11-dimethylchrysene. They found the methyl groups to be largely eliminated from these positions with the formation of chrysene, but obtained from both starting materials small amounts of a methylchrysene, m. p. 151° (uncorr.?) which they tentatively regard as the 5-isomer. The apparently uncorrected melting points of their hydrocarbon, its picrate, and trinitrobenzene derivative are from 4 to 10° below the corrected melting points for corresponding compounds of the 6-methylchrysene series.

Before the above experiments were completed

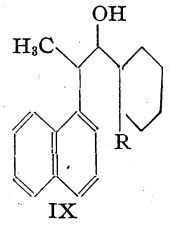
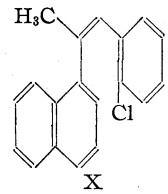
other possible synthetic routes were explored. 2-(α-Naphthyl)-propionaldehyde (III) was condensed with cyclohexylmagnesium chloride and the resulting carbinol IX (R = H) was submitted



IX

to cyclodehydration, both with phosphorus pentoxide and with potassium bisulfate, followed by aluminum chloride. In a closely analogous case, Perlman, Davidson and Bogert[12] obtained from benzylcyclohexylcarbinol a mixture of *as*-octahydrophenanthrene and the isomeric spiran. In our experiments the crude cyclization product on dehydrogenation with selenium afforded a hydrocarbon mixture from which there were separated as the trinitrobenzene derivatives small amounts of substances having the composition of a methylchrysene and of a spiran, respectively. Neither substance was obtained in large enough amounts for satisfactory purification and identification. Spiran formation was effectively suppressed by employing 2-methylcyclohexylmagnesium chloride in the synthesis, but the homologous carbinol (IX, R = CH_3) on cyclodehydration and selenium dehydrogenation gave a mixture containing chrysene and, in one experiment, a small amount of a substance which was not fully purified but which appeared from the analysis to be a methylchrysene. The partial loss of the methyl group corresponds to the experiences of W. E. Jones and Ramage,[11] and this synthesis clearly is not practical.

Another trial was inspired by Hewett's[13] successful utilization of a general synthetic method described in the patent literature.[14] 2-(α-Naphthyl)-propionaldehyde was condensed with the Grignard reagent from *o*-chlorobromobenzene and the crude carbinol was dehydrated by distillation over potassium bisulfate. The product was a liquid of the expected composition but boiled over a considerable range, and it presumably consisted of a mixture of the geometrical isomers of the structure X. Attempts to cyclize this sub-



X

stance by fusion with potassium hydroxide alone[13] or in quinoline solution[14] gave only tars. The Grignard reagent from *o*-bromoiodobenzene was tried in the synthesis in the hope of obtaining a halide which would undergo cyclization more readily, but the carbinol was low in halogen content and no hydrocarbon was obtained on putting the crude material through the remaining steps of the above process.

Experimental Part[15]

Methoxymethyl α-Naphthyl Ketone (I).—The **methoxyacetonitrile** required was conveniently prepared by the action of cuprous cyanide on chloromethyl ether according to Gauthier.[16] Previous reports give the yield as 60–70%[16] and 74%[17]; by using a fused salt-bath to distil completely the product from the reaction mixture we obtained a yield of 81.6% of redistilled product, b. p. 120–120.6°.

A solution of 68 g. of methoxyacetonitrile in 300 cc. of benzene was dropped with stirring into a Grignard solution from 230 g. of α-naphthyl bromide and 27.5 g. of magnesium in 500 cc. of ether and 150 cc. of benzene. The mixture was refluxed for one-half hour and allowed to stand overnight. After decomposition with dilute hydrochloric acid the mixture was steam distilled for one hour and the residue taken up in ether, dried, and distilled. The ketone distilled as a viscous yellow oil, b. p. 144–146° (1 mm.) or 172° (4 mm.); yield 159.5 g. (83%).

Anal. Calcd. for $C_{15}H_{12}O_2$: C, 77.98; H, 6.04. Found: C, 77.77; H, 6.47.

The **semicarbazone,** prepared by refluxing a solution in alcohol with semicarbazide hydrochloride and sodium acetate, was crystallized from benzene and then from alcohol and formed colorless needles, m. p. 166.4–167.8°.

Anal. Calcd. for $C_{14}H_{15}O_2N_3$: N, 16.33. Found: N, 15.87, 15.94.

Methyl-methoxymethyl-α-naphthylcarbinol (II). (a) From the Ketone I.—A solution of 244 g. of the ketone in 500 cc. of ether was added during one hour to the Grignard reagent from 35 g. of magnesium and excess methyl chloride. The mixture was refluxed for one and one-half hours, allowed to stand overnight, and decomposed with acid. The ether layer was washed and dried and the product distilled, giving 254 g. (96.4%) of carbinol, b. p. 138–142° at 1.5 mm. The distillate partially crystallized in the receiver; a sample crystallized from petroleum ether in colorless prisms, m. p. 56.4–60.4°. The material analyzed was purified merely by distillation.

*Anal.** Calcd. for $C_{14}H_{16}O_2$: C, 77.70; H, 7.46. Found: C, 77.69; H, 7.70.

(b) From Methoxyacetone.—In one trial the yield of **methoxyacetone**[5,17] from methoxyacetonitrile (67 g.) and methylmagnesium halide was 31% (b. p. 114°). Twenty-six grams of this reagent was added to a stirred Grignard solution from 70 g. of α-naphthylmagnesium bromide, and on proceeding as above there was obtained 26 g. (41%) of distilled carbinol.

2-(α-Naphthyl)-propionaldehyde (III).—A mixture of 160 g. of the carbinol II and 15 g. of fused potassium bisulfate was heated in a Claisen flask at 165–180° for one-half hour, allowing the volatile products to escape, and the residue was distilled at 2–4 mm. pressure. The clear distillate was stirred mechanically or shaken with 250 cc. of saturated sodium bisulfite solution, when a white precipitate of the addition product soon formed. After cooling, this was collected and washed with alcohol and ether. The aldehyde is conveniently stored in the form of this derivative; it is best liberated by shaking the bisulfite compound with aqueous sodium carbonate solution and extraction with ether. In the experiment cited there was obtained 83.5 g. (61%) of colorless aldehyde, b. p. 130–132° (2 mm.).

The **semicarbazone** formed colorless needles from alcohol, m. p. 203–204°.

*Anal.** Calcd. for $C_{14}H_{15}ON_3$: C, 69.72; H, 6.27. Found: C, 69.95; H, 6.09.

On recovering the material in the alcohol–ether washings of the bisulfite compound there was obtained 23.4 g. (16%) of the **enol methyl ether** of the aldehyde as a pale yellow, unsaturated oil, b. p. 120–122° (1.5 mm.).

Anal. Calcd. for $C_{14}H_{14}O$: C, 84.81; H, 7.12. Found: C, 84.49; H, 7.19.

A 5.6-g. portion of this ether was refluxed with 50 cc. of 20% hydrochloric acid for three and one-half hours and the oil was extracted with benzene, washed, dried and distilled, giving 4.8 g. of crude aldehyde, b. p. 116–119° (1.5 mm.). On purification through the bisulfite compound and redistillation, 4.2 g. (81%) of pale yellow aldehyde, b. p. 117–119° (1.5 mm.), resulted. On this basis the total yield of pure aldehyde obtainable from the carbinol is 74%.

2-(α-Naphthyl)-propanol-1 (IV).—A mixture of 83.5 g. of the pure aldehyde III, 300 cc. of acetic acid, 300 cc. of water, and 200 g. of iron powder was heated with stirring on the steam-bath for seven hours. The solution was filtered hot and the filter cake was washed well with water and then with ether. The filtrate and washings were diluted with water and extracted with ether, and after evaporation of the solvent the remaining oil was refluxed for one-half hour with 15 g. of sodium hydroxide in 30 cc. of water and 50 cc. of alcohol to hydrolyze any acetate. The alcohol was then washed and dried in ether and distilled; it was obtained as a yellowish, viscous oil, b. p. 144–147° (3 mm.); yield 66.3 g. (78.5%).

The **3,5-dinitrobenzoate,** prepared by warming the alcohol with dinitrobenzoyl chloride, crystallized from alcohol in small, colorless needles, m. p. 125.5–126.5°.

*Anal.** Calcd. for $C_{20}H_{16}O_6N_2$: C, 63.17; H, 4.24. Found: C, 63.16; H, 4.22.

Attempts to obtain a homogeneous halide from the alcohol II by the use of hydrobromic acid, phosphorus tribromide, thionyl chloride with pyridine or with dimethylaniline, or by the action of phosphorus pentachloride or tribromide on the acetate, all failed. Also unsuccessful were attempts to prepare the chloride by the condensation of naphthalene with allyl chloride[18] in the presence of sulfuric acid or anhydrous hydrogen fluoride; with the latter condensing agent (five hours at room temperature) there was obtained 13% of a halogen containing compound, but this had a wide boiling range (110–130° at 1 mm.). A satisfactory transformation of the alcohol was accomplished as follows.

2-(α-Naphthyl)-1-chloropropane.—A solution of 94 g. of the alcohol IV in 500 cc. of dry benzene was treated with 125 g. of phosphorus pentachloride, the vigorous reaction ensuing being controlled by external cooling. After refluxing for two hours the solution was cooled, water was added, and the benzene layer was washed, dried, concentrated, and treated with phosphorus pentoxide. Three distillations gave a mobile, yellowish liquid, b. p. 114–116° (1 mm.); yield 58 g. (56%). A sample shaken with 90% sulfuric acid and distilled was obtained in an almost colorless condition.

Anal. Calcd. for $C_{13}H_{13}Cl$: C, 76.28; H, 6.40. Found: C, 76.45; H, 6.41.

On preparing the Grignard reagent from 2.9 g. of the chloride and 0.4 g. of magnesium the reaction started promptly but about half of the metal remained unattacked after refluxing for several hours. On adding solid carbon dioxide and recovering the product in the usual way the acidic fraction afforded 1.1 g. (36%) of crude acid, m. p. 80–95°, on crystallization from benzene–ligroin. The recrystallized material formed colorless prisms, m. p. 108–108.6°, corresponding to the description of β-(α'-naphthyl)-butyric acid reported by Radcliffe, Sherwood and Short[7] (m. p. 108°).

2-(α-Naphthyl)-1-(2'-methylcyclohexenyl)-propane (VI).—Difficulty was again experienced in effecting the conversion of 2-(α-naphthyl)-1-chloropropane (31.8 g.) into the Grignard reagent (with 4 g. of magnesium in ether–benzene), and titration showed only 40% active reagent. No better results were obtained on forming the reagent in the presence of 1 mole of ethyl bromide. The cooled solution was treated with 21 g. of 2-methylcyclohexanone, kept at room temperature for one hour, refluxed for three hours, stirred overnight, and then decomposed with ammonium chloride solution. The neutral portion was distilled, and after a large fore-run, 11.8 g. (27%) of a yellow, viscous oil was obtained at a bath temperature of about 250° (2 mm.). The carbinol could not be obtained crystalline.

For dehydration, 16.1 g. of the carbinol was heated with 25 g. of potassium bisulfate at 200° for one and one-quarter hours. After two distillations the hydrocarbon was obtained as a yellow, viscous oil boiling at about 200–225° (2 mm.); yield 14.2 g. (94%). The substance crystallized readily when triturated with methanol at −70° but melted below room temperature.

Anal. Calcd. for $C_{20}H_{24}$: C, 90.85; H, 9.15. Found: C, 90.59; H, 9.53.

(18) Truffault, *Compt. rend.*, **202**, 1286 (1936); **207**, 676 (1938).

5,10a-Dimethyl-*as*-octahydrochrysene (VII).—A solution of 13.5 g. of the olefin VI in 135 cc. of carbon bisulfide was treated at 0° with 15 g. of aluminum chloride in portions and stirred at 0° for twenty-one hours. The solution was decanted, washed with water, dried and evaporated, and the residue was distilled from a little sodium. Redistillation gave 9.7 g. (72%) of a viscous, almost colorless oil, b. p. about 220–240° (2 mm.). Tests with bromine and alkaline permanganate indicated that some unsaturated material was still present, but the tests were still positive after a further treatment with aluminum chloride as above at room temperature.

Anal.† Calcd. for $C_{20}H_{24}$: C, 90.85; H, 9.15. Found: C, 91.37; H, 8.94.

6-Methylchrysene (VIII).—The octahydride (2 g.) was heated with selenium (4.8 g.) at 320° for twenty-four hours and the product extracted with benzene, distilled, treated with norite in benzene, and distilled over sodium. The resulting oil yielded a crude but crystalline trinitrobenzene derivative from benzene, and after passing a benzene solution of this material through a tower of alumina the recovered hydrocarbon crystallized from benzene–alcohol as colorless plates, m. p. 141–148° (167 mg.). The combined product from two such runs was crystallized several times from ethyl acetate–alcohol and gave 165 mg. of colorless, fluorescent needles, m. p. 159–159.8°.

Anal. Calcd. for $C_{19}H_{14}$: C, 94.18; H, 5.82. Found: C, 94.19; H, 5.90.

The melting point of the hydrocarbon was not depressed by admixture with a sample of 6-methylchrysene synthesized by Newman.[9] This was true as well of the **picrate,** which crystallized from benzene–alcohol in orange needles, m. p. 169.8–170.2°, with previous softening, and of the **trinitrobenzene derivative.** The latter derivative, which has not been described before, was obtained from our hydrocarbon as yellow needles, m. p. 188.5–189.5°, from benzene–alcohol, and from Newman's sample of hydrocarbon as yellow needles, m. p. 189.8–190.6°.

Anal. Calcd. for $C_{25}H_{17}O_6N_3$: C, 65.93; H, 3.76. Found: C, 65.83; H, 4.02.

On heating 0.5 g. of the octahydride with 50 mg. of 30% palladium charcoal for sixteen hours at 310°, with the addition of 150 mg. more catalyst at intervals, the gas evolution was only 25% of the theoretical amount. The mixture was extracted with benzene and the hydrocarbon precipitated as the trinitrobenzene derivative. After recovery as before, one crystallization from benzene–ligroin gave 17 mg. of colorless needles, m. p. 145–150°; on recrystallization the substance melted at 154–158° and gave no depression when mixed with the above sample.

1-Cyclohexyl-2-(α-naphthyl)-propanol (IX, R = H).—A solution of 7.3 g. of freshly distilled 2-(α-naphthyl)-propionaldehyde in 40 cc. of ether was added to the ice-cold Grignard reagent from 5.8 g. of cyclohexyl chloride and 1.3 g. of magnesium. After one hour in the ice-bath, and one and one-half hours at room temperature, the mixture was refluxed for one hour and decomposed with ammonium chloride solution. The ether solution was washed and dried and the solvent displaced with petroleum ether, from which the carbinol crystallized in two crops as colorless needles, m. p. 55–58°; yield 6.5 g. (61%). On recrystallization the substance melted constantly at 59–61°.

Anal. Calcd. for $C_{19}H_{24}O$: C, 85.03; H, 9.00. Found: C, 84.64; H, 9.69.

Cyclodehydration of IX and Dehydrogenation.—For dehydration and ring closure the above carbinol (IX, R = H) was either heated with phosphorus pentoxide at 150° for thirty minutes or heated with potassium bisulfate at 160–180° for one hour, followed by treatment of the resulting oil with aluminum chloride in carbon bisulfide at 0° for twenty-four hours. In either case the oil was then heated with selenium at 320° for twenty-four hours and the product isolated as the trinitrobenzene derivative. The crude derivative from 2 g. of carbinol amounted to 363 mg. and melted at 90–100°. Fractional crystallization from alcohol gave 50 mg. of an orange substance, m. p. 232–235° with previous softening, having the composition of a **methylchrysene–trinitrobenzene.**

Anal.† Calcd. for $C_{25}H_{17}O_6N_3$: N, 9.23. Found: N, 9.27.

A yellow substance was also separated in small amounts from the mixture; this melted at 107–109° and the nitrogen content is that of a derivative of the **spiran** (or octahydride).

Anal.† Calcd. for $C_{25}H_{25}O_6N_3$: N, 9.07. Found: N, 9.09.

The preparation of **1-(2′-methylcyclohexyl)-2-(α-naphthyl)-propanol-1 (IX, R = CH_3)** from 2-methylcyclohexyl chloride[19] (6.6 g.) and the aldehyde III (7 g.) was conducted as before, the product remaining after evaporation of the washed and dried ether extract being a viscous yellow oil which failed to crystallize (stereoisomerism?); yield 8.3 g. (77%). In one trial 3 g. of the crude carbinol was dropped slowly with stirring and ice cooling into 6 cc. of 90% sulfuric acid and the dark, viscous mass was extracted with benzene. After washing with 85% sulfuric acid and water, and removing the solvent, a yellow, viscous oil (1.4 g.) distilled at a bath temperature of about 240° (2 mm.). This was heated with selenium as above and the purified product afforded 239 mg. of an orange mixture of trinitrobenzene derivatives, m. p. 155–162°, which could not be separated by crystallization. After decomposing the complex (alumina tower), crystallization from benzene–methanol afforded 42 mg. of **chrysene,** m. p. 242–248°, which gave no depression when mixed with an authentic sample, and, from the more soluble fraction, 36 mg. of another substance as colorless needles, m. p. 98–100°. After two recrystallizations this largely fused at 105.5–106.5°, but the melt became clear only at 165°. The trinitrobenzene derivative formed orange needles, m. p. 165–167°, from alcohol. The composition of the hydrocarbon is that of a methylchrysene.

Anal. Calcd. for $C_{19}H_{14}$: C, 94.18; H, 5.82. Found: C, 94.11; H, 5.88.

In another experiment 2.95 g. of the carbinol IX (R = CH_3) was dehydrated with potassium bisulfate at 180° and the oil (2 g.) treated at 0° with aluminum chloride in carbon bisulfide (nineteen hours). The material (1.35 g.) was then dehydrogenated and a crystalline trinitrobenzene derivative was separated and reconverted to the

(19) Sabatier and Mailhe, *Compt. rend.*, **140**, 841 (1905); von Auwers and Dersch, *J. prakt. Chem.*, **124**, 232 (1930).

hydrocarbon, giving 22 mg. of chrysene as the sole homogeneous product.

1 - (*o* - Chlorophenyl) - 2 - (α - naphthyl) - propene (X).—An ethereal solution of 3.2 g. of the aldehyde III was added at 0° to the reagent from 4.2 g. of *o*-chlorobromobenzene and 0.6 g. of magnesium and the temperature was slowly raised from 0° to the boiling point. The product was collected as a viscous oil (5.3 g.) which was heated with 7.5 g. of potassium bisulfate at 170–180° for one hour and distilled twice, giving a light yellow oil, b. p. 150–180° (1 mm.); yield 3.1 g. (64%).

Anal. Calcd. for $C_{19}H_{15}Cl$: C, 81.86; H, 5.42. Found: C, 81.27; H, 5.66.

In various experiments this olefin was refluxed with potassium hydroxide in quinoline for three hours, stirred with potassium hydroxide at 250–260° for seven minutes, or at 250–300° for twenty minutes, but this resulted only in tars or in oils from which no crystalline trinitrobenzene derivative could be isolated. The carbinol was also fused with potassium hydroxide under various conditions without successful result.

When *o*-bromoiodobenzene was used in the synthesis the distilled carbinol contained only 13.0% of halogen, as compared with the theoretical value of 23.4%. No satisfactory product was obtained on dehydration and alkali fusion.

Summary

A convenient method of preparing 2-(α-naphthyl)-propionaldehyde has been found in the condensation of α-naphthylmagnesium bromide with methoxyacetonitrile followed by a methyl Grignard reaction on the resulting methoxymethyl α-naphthyl ketone and acid dehydration of the carbinol. The aldehyde can be reduced smoothly to the alcohol and the latter converted into the chloride.

With these intermediates readily available, an attempt was first made to synthesize 5-methylchrysene by the Bogert–Cook method, but there was obtained instead a hydrocarbon identical with Newman's 6-methylchrysene. Apparently in analogy with the para migration of a methyl group attached to a saturated ring observed by Haworth, an ortho methyl migration occurs in the dehydrogenation.

Various other possible methods of utilizing the same intermediates for the synthesis of 5-methylchrysene were explored without success, the difficulty being associated in part with the ready loss of methyl from the 5-position, as observed by W. E. Jones and Ramage.

The Oxygen Effect in the Reaction of Cyclopropane with Bromine and with Hydrogen Bromide

BY M. S. KHARASCH, M. Z. FINEMAN AND F. R. MAYO

Previous papers from this Laboratory[1–3] have shown that the brominations of toluene and phenanthrene are markedly accelerated by traces of oxygen and peroxides. These and similar observations with other hydrocarbons[4] have led us to reëxamine the reactions of cyclopropane with bromine and with hydrogen bromide.

Previous Work

The literature on the reaction of cyclopropane with bromine and hydrogen bromide is meager, although a great deal of work has been done with substituted cyclopropanes.[5] Gustavson[6] states that at ordinary temperatures cyclopropane reacts with bromine quite slowly in the dark, and rapidly in sunlight. He noted that propyl bromide, more highly brominated products, and large quantities of hydrogen bromide were formed in addition to trimethylene bromide. Ogg and Priest[7] have investigated several vapor phase reactions of cyclopropane. At 250° iodine yielded 1,3-diiodopropane and light had no effect on the reaction. At room temperature under intense illumination, bromine added to give mostly 1,3-dibromopropane and a little hydrogen bromide. At 220° in the dark, large proportions of hydrogen bromide were formed. Hydrogen bromide gave little indication of reaction at 300°.

Experimental Part

The cyclopropane used in this work was obtained from the Ohio Chemical Company. It boiled at −33.5 to

−33° and was completely absorbed by concentrated sulfuric acid. The method of preparation excluded the possibility of the presence of propylene and similar impurities.[8] Analytical reagent grade bromine was used. It was dried with anhydrous calcium bromide and distilled in an all-glass apparatus. Only the middle fraction which boiled at 58.7° at 751 mm. was used.

Difficulty was experienced in obtaining consistent results in the study of the addition of bromine and hydrogen bromide to cyclopropane until the apparatus shown in Fig. 1 was devised for eliminating dust and water from the reaction.

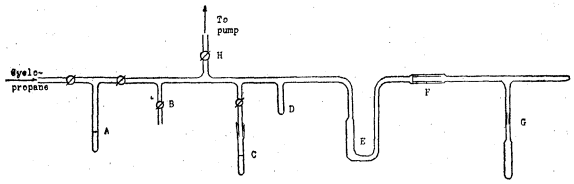

Fig. 1.

A was calibrated to contain 1.56 g. of liquid cyclopropane at the temperature of a solid carbon dioxide–acetone bath. The tube C was calibrated (by titration) to contain 0.288 or 2.62 g. of liquid hydrogen bromide at a similar temperature and was attached to the system through a ground glass connection. To avoid contact of bromine with stopcock and joint lubricant, bromine was weighed out in a tube which was then sealed onto the line at D. After the tube containing hydrogen bromide or bromine was attached to the system, the tube was cooled in liquid nitrogen and the whole system was evacuated to about 10^{-5} mm. through the line H. By suitable manipulations of stopcocks, cyclopropane was introduced into A, any excess hydrogen bromide or cyclopropane was removed from the calibrated tubes by cautious evacuation, and the reactants were degassed.[3] They were then distilled successively through phosphorus pentoxide and a glass wool plug in tube E, and finally through glass filter cloth in tube F, into the reaction tube G. Any added substances had been previously placed in G before it was sealed onto the system and kept cold during the above procedures. For experiments in the absence of oxygen (indicated by − in the oxygen column of the tables), the system was then evacuated once more to remove traces of uncondensed gases and tube G was sealed off at the constriction. For experiments in the presence of oxygen, the degassing operation was omitted and oxygen was admitted through stopcock B until its pressure in the line was 22 cm. before tube G was sealed off. Since this tube was at the temperature of liquid nitrogen it was estimated that the oxygen pressure would increase to about one atmosphere at room temperature.

For the dark reaction, the bomb tubes were allowed to stand in an iron pipe at room temperature. In the photochemical studies (indicated by + in the "light" column in the tables) the reaction tubes were immersed in water kept at 20 ± 5° and only the liquid phase was exposed to light from a 300-watt incandescent lamp at a distance of approximately ten centimeters.

(8) Hass, McBee, Hinds and Gluesenkamp, *Ind. Eng. Chem.*, **28**, 1178 (1936).

After reaction, the bomb tube was immersed in liquid nitrogen and opened. A tube was then sealed on so that the low-boiling contents would distil into water or aqueous potassium iodide solution at room temperature. The remainder was washed into the same solution. Unreacted bromine or hydrogen bromide was then determined by titration.

Reaction of Cyclopropane with Bromine.—In Table I are summarized the experiments which demonstrate the effect of various substances on the interaction of bromine and cyclopropane. The first two experiments show that the reaction of cyclopropane and bromine in the dark is very slow, and that oxygen has an accelerating effect on the reaction. It is remarkable, however, that in the absence of oxygen the photochemical reaction is extremely slow (47% reaction in two hundred hours), while in the presence of oxygen the reaction is complete in about two hours. Peroxides exert an effect similar to that of oxygen. Another striking observation is the inhibition of the photochemical oxygen-catalyzed reaction by ethyl alcohol and isoamyl nitrite.

[a] In all cases the mole ratio of bromine to cyclopropane was 1:10, except the one marked with an asterisk when it was 1:2. Experiments in concentrated solution were not carried out because bromine seems to act as an inhibitor for chain reactions under such conditions. [b] Quantities expressed in moles per mole of bromine used. [c] Complete reaction was assumed when color faded to a faint yellow tinge.

Because of the small quantities of materials used in our study, we were unable to isolate any reaction product other than 1,3-dibromopropane. That other materials are formed was indicated by the formation of hydrogen bromide and small quantities of a material boiling lower than 1,3-dibromopropane.

Reaction of Cyclopropane with Hydrogen Bromide.—Two distinct types of reaction mix-

tures were used in the study of the reaction of cyclopropane and hydrogen bromide. In one group of experiments, equimolecular quantities of the reactants were used, in the second, a tenfold excess of cyclopropane. These procedures yielded strikingly different results as shown in Table II.

TABLE II

THE ADDITION OF HYDROGEN BROMIDE TO CYCLOPROPANE

Added substances[a]	Conditions Oxygen	Light	% reaction	Remarks
None[b]	−	−	8	
None[b]	−	+	11, 12	
None[b]	+	−	81	
None[b]	+	+	99, 99

None[d]	+	+	74, 76[e]	
Thiocresol, 0.03[d]	−	+	90	Mixture became warm in a few minutes
Catechol, 0.03[d]	−	−	97[b]	
Water, 0.03[d]	−	−	94	
Acetic acid, 0.03[d]	−	−	87	

[a] Quantities expressed in moles per mole of hydrogen bromide used. [b] Mole ratio of hydrogen bromide to cyclopropane was 1:10; the reaction time was two hours. [c] Odor of product indicated formation of propyl ether of catechol. [d] Mole ratio of hydrogen bromide to cyclopropane was 1:1; the reaction time was four hours. [e] Addition products combined and found to be *n*-propyl bromide.

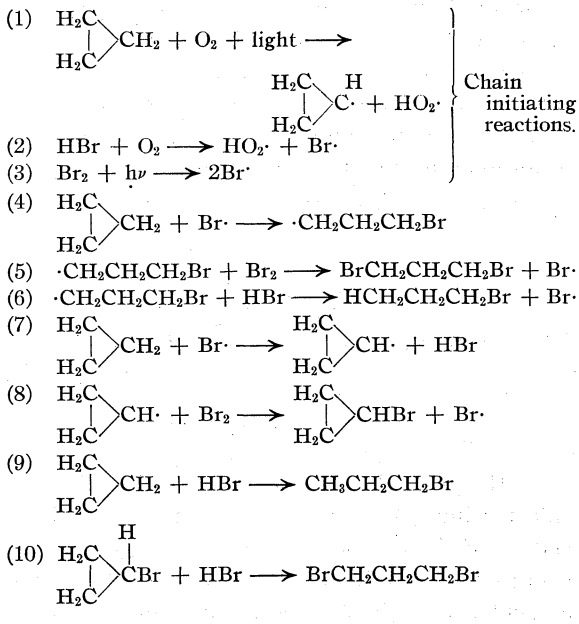
Thus, when excess cyclopropane was used, and oxygen was removed from the system, a slow reaction took place in the dark (8% in two hours), and only a slight increase was observed upon illumination (11% in two hours). However, in the presence of oxygen a tremendous increase in the reaction velocity was noted. Thus, in two hours a yield of 81% of normal propyl bromide was obtained in the dark and nearly 100% in the light. The effect of benzoyl peroxide on the rate of reaction was similar to that of oxygen. Antioxidants appear to overcome partially the accelerating effect of oxygen, but duplicate experiments show that in illuminated reactions in the absence of oxygen, catechol accelerates the reaction. Since water has the same effect (in the dark), it seems likely that catechol may accelerate the reaction by one mechanism while inhibiting it by a second.

On the other hand, when equimolecular quantities of cyclopropane and hydrogen bromide are used, oxygen and illumination have no significant effect on the rate of reaction. Water, acetic acid, thiophenol and catechol accelerate the addition reactions in the absence of oxygen.

Discussion

It is evident from our experiments that pure cyclopropane and pure bromine do not react appreciably in the dark, and only very slowly in the light. The observations recorded in the literature regarding the ring cleavage by bromine must therefore apply to an oxygen-catalyzed photochemical reaction. A careful study of our data indicates that we are dealing with a chain reaction similar to the oxygen-catalyzed photochemical brominations of phenanthrene[2] and toluene.[1,3] In support of this one may cite the following facts: (1) minute amounts of oxygen or peroxides are effective in bringing about a rapid reaction; (2) traces of inhibitors markedly retard the reaction.

The following schematic representation is suggested for the bromination of cyclopropane (a dot is used to represent an unpaired electron)



The low-boiling materials observed by us could have been formed in reactions 6, 8 and 9. Reaction 7 readily explains the formation of hydrogen bromide. The relative ineffectiveness of light in the absence of oxygen is surprising for one might expect a fairly large concentration of

bromine atoms from equation 3. This suggests that the active entity responsible for the chain reaction may not be the bromine atom but a free radical of the type $\cdot BrO_2$. The latter is a possibility which we are keeping in mind.

From the standpoint of the thesis developed in this paper, an attractive explanation is at once available to account for the fact that cyclopropylamine does not react with bromine, although the ring is easily cloven by nitrous acid.[9] The amino group is an inhibitor in reactions involving bromine atoms. The stability of the ring, therefore, is to be ascribed to the chain-breaking mechanism of the amino group, rather than to the inherently greater stability of the ring in cyclopropylamine. The same explanation applies to the resistance toward cleavage of cyclopropyl cyanide.[5c] The effect of groups on the stability of the cyclopropane ring is, therefore, not necessarily related to ease of cleavage of the ring with bromine.

The oxygen effect in the reaction of hydrogen bromide and cyclopropane, when the latter is used in large excess, is readily correlated with our bromine atom chain mechanism. The free bromine atoms are formed by equations 1 or 2. The formation of normal propyl bromide by the chain mechanism is indicated by equations 4 and 6, by a different mechanism in equation 9.

The ineffectiveness of light and oxygen on the rate of reaction of equimolecular quantities of hydrogen bromide and cyclopropane is suggestive of an ionic mechanism different from an atom or free-radical chain reaction. Furthermore, the fact that substances such as thiocresol, catechol, acetic acid, and water have an accelerating effect lends some support to the idea that the mechanism is ionic in character. These substances are all capable of combining with a proton and thereby causing dissociation of the hydrogen bromide molecule into a bromide ion and a positively charged fragment. The cleavage of the cyclopropane ring by ions would not be expected to be photochemical. The accelerating effect of hydroxylic compounds indicates that the contribution of an atom mechanism to the rate of reaction is insignificant in concentrated hydrogen bromide solutions.

(9) Kishner, *Chem. Zentr.*, **72**, II, 579 (1901); **76**, I, 1703 (1905).

Summary

1. The reaction of bromine with a ten-fold excess of cyclopropane is greatly accelerated by the combined effect of oxygen and light.

2. The reaction of hydrogen bromide with a ten-fold excess of cyclopropane is greatly accelerated by oxygen and only slightly accelerated by light.

3. Organic peroxides have an effect similar to that of oxygen.

4. A chain mechanism involving bromine atoms is suggested for each addition reaction.

5. The addition of hydrogen bromide to an equivalent quantity of cyclopropane is not significantly affected by oxygen or light, but is accelerated by hydroxylic compounds. For this effect a competing non-atomic mechanism is suggested.

Chlorinations with Sulfuryl Chloride. I. The Peroxide-Catalyzed Chlorination of Hydrocarbons

BY M. S. KHARASCH AND HERBERT C. BROWN[1]

In the past the use of sulfuryl chloride as a chlorinating agent has depended upon the dissociation of the compound, under the experimental conditions, into its components—sulfur dioxide and chlorine. That is, the sulfuryl chloride served as a source of *molecular* chlorine, and it has been used almost exclusively for the chlorination of aromatic nuclei in the presence of halogen carriers.[2] The utilization of sulfuryl chloride in this way offers little advantage over the use of gaseous chlorine; for this reason sulfuryl chloride has not been generally adopted in the laboratory for carrying out such chlorinations.

In the course of investigations on the chemical properties of free radicals in solution, which are now being carried out in this Laboratory, it was found that in the presence of certain catalysts (such as organic peroxides) sulfuryl chloride can serve as a source of chlorine *atoms*. Using this procedure,

(2) (a) Tohl and Eberhard, *Ber.*, **26**, 2940 (1893); (b) Silberrad, *J. Chem. Soc.*, **119**, 2029 (1921); (c) **121**, 1015 (1922); (d) Silberrad, Silberrad and Parke, *ibid.*, **127**, 1724 (1925).

it is possible to chlorinate *in the dark* many types of compounds (paraffin hydrocarbons, side-chains of aromatic hydrocarbons, aliphatic acids, aldehydes, and ketones, etc.) far more rapidly and conveniently than is possible by the use of elementary chlorine and light.[3]

General Procedure

$$RH + SO_2Cl_2 \xrightarrow[\text{peroxide}]{\Delta} RCl + SO_2\uparrow + HCl\uparrow$$

The sulfuryl chloride is mixed with the compound to be chlorinated (Note 1) in a round-bottomed flask, and a small amount of benzoyl peroxide (Note 2) is added (0.001 to 0.005 mole of peroxide per mole of sulfuryl chloride). The flask is connected to an efficient reflux condenser (Note 3), preferably by a ground-glass joint, and the entire mixture is refluxed gently. Evolution of gases (hydrogen chloride and sulfur dioxide) begins at once. When these gases are no longer given off, the reaction is complete (Note 4). The reaction mixture is fractionated without further treatment (Note 5).

As previously stated (Note 3), the yields obtainable by this method vary with the efficiency of the reflux condenser. Without using any particular precautions, yields of 80% (based on the available chlorine utilized) are obtained easily. If a trap kept at $-10°$ is connected to the condenser, and the trapped material is returned to the reaction flask periodically, the yields can be made quantitative.

Notes

(1) The molar ratio of sulfuryl chloride to organic compound which is used depends upon the same factors that operate in ordinary chlorinations: relative cost of materials, ease of separation of the higher chlorinated products, etc. In this work, we have usually used a large excess of hydrocarbon in carrying out the chlorination because in most of the preparations we were interested primarily in observing the point of attack of the reagent, not in obtaining the maximum possible yield.

(2) Benzoyl peroxide was used in most of this work. Most other peroxides tested (*e. g.*, lauroyl peroxide) act similarly. On the other hand, ascaridole gives poor results. Apparently, it decomposes far too rapidly to be used as a catalyst in this reaction.

(3) In this paper the chlorination of hydrocarbons is discussed. The chlorination of many types of oxygen derivatives by this method is under investigation, and the results will be reported shortly.

(3) The yield of product depends upon the efficiency of the reflux condenser. An inefficient condenser permits the gases evolved to carry off an appreciable quantity of the volatile reactants.

(4) The progress of the reaction is followed easily if the gases evolved are led through a gas wash bottle connected by tubing to the top of the reflux condenser. The time required to carry out a reaction varies with the compound to be chlorinated, the rate of heating, and the amount of peroxide added; however, in most cases, the reaction can be completed in from one to two hours for reaction mixtures which contain one mole of sulfuryl chloride, one to three moles of hydrocarbon, and 0.002 mole of peroxide.

(5) The results reported in this paper were obtained with the use of a short fractionating column, 25 cm. in length, the inner tube of which (9 mm.) was packed with a spiral of no. 18 silver wire coiled to two turns per centimeter.

Chlorination of Paraffin Hydrocarbons

The study of the action of sulfuryl chloride on paraffin hydrocarbons and their halogen derivatives has been neglected almost completely. The only report in the literature dealing with this subject is a patent covering the chlorination of methane with sulfuryl chloride at 300° in the presence of a catalyst such as carbon.[4]

In the absence of catalysts and light, sulfuryl chloride does not react with **cyclohexane**[5] to an appreciable extent at temperatures as high as its boiling point. Even in the presence of light, the chlorination of the hydrocarbon with sulfuryl chloride is very slow. For example, a mixture of the two compounds, strongly illuminated[6] and refluxed, reacts no more than 25% in six hours.

Most of the materials whose catalytic activity was investigated affect the rate of chlorination but slightly. In contrast, the effect of a trace of peroxide is amazing. The addition of 0.001 mole of benzoyl peroxide to the reaction mixture causes *complete reaction in from fifteen to thirty minutes in the dark*. The results of these studies are listed in Table I.

In these experiments, 0.6 mole of the hydrocarbon and 0.2 mole of sulfuryl chloride were refluxed, usually for six hours unless the reaction was complete before that time.

(4) McKee and Salls, U. S. Patent 1,765,601 (1930).

(5) Cyclohexane was selected because of its simple structure and availability, and its reactions with sulfuryl chloride under various conditions were studied intensively.

(6) A 300-watt lamp, placed 10 cm. from the flask, was used to illuminate the reaction mixture.

The extent of reaction was calculated from the amount of chlorocyclohexane isolated upon fractionation of the reaction mixture. Except where stated otherwise, the reaction was carried out with complete exclusion of light.

TABLE I

CHLORINATION OF CYCLOHEXANE WITH SULFURYL CHLORIDE

Catalyst	Reaction time, hours	Yield, %
CuCl, 0.2 mole	6	20
S, 0.01 mole	6	0
I, 0.01 mole	6	0
PCl_5, 0.01 mole	6	5
Slow stream HCl	3	0
Slow stream SO_2	3	0
Slow stream O_2	3	0
No catalyst	6	0
Animal carbon, 5 g.	6	30
No catalyst, light[a]	6	25
Animal carbon, 5 g., light	6	75[b]
Benzoyl peroxide, 0.001 mole	1/2	80
Lauroyl peroxide, 0.001 mole	1/4	80

[a] For intensity of light, see footnote 6. [b] Reaction was not complete in less than six hours.

The study of the chlorination of a number of paraffin hydrocarbons and their halogen derivatives was undertaken to determine the generality of this method of chlorination and to compare the results thus obtained with those reported for the photochemical chlorination of these compounds with chlorine gas.

In general, the results are similar. Secondary hydrogen atoms are substituted by chlorine more readily than primary, and the presence of a halogen substituent increases the difficulty of further substitution. This deactivating effect is especially strong upon the carbon atom holding the substituent,[7] and decreases with increasing distance from it.

The experimental results are summarized in Table II.

Chlorination of Side-Chains in Aromatic Hydrocarbons

As stated previously, the use of sulfuryl chloride as a chlorinating agent has been restricted largely to the chlorination of aromatic nuclei in the presence of halogen carriers.[2] However, the isolation of benzyl chloride from the chlorination of toluene has been reported several times. Dubois[8] reports that toluene and sulfuryl chloride react slowly at 115° to form benzyl chloride and chlorotoluene, and Wohl[9] patented the preparation of benzyl chloride in 50% yield by the action of sulfuryl chloride on toluene at 130°. Tohl and Eberhard[2a] state that a refluxing mixture of toluene and sulfuryl chloride does not react. More recently, this statement has been questioned, and it has been reported that toluene and sulfuryl chloride do react in the dark at the temperature of reflux.[2d]

We find that pure peroxide-free **toluene** shows no sign of reaction with sulfuryl chloride after six hours of refluxing in the dark. In the light,[6] however, a slow reaction takes place which is not complete in less than seven hours.[10] Benzyl chloride is formed. In the presence of a small amount of added peroxide, a vigorous reaction occurs in the dark and nearly quantitative yields of benzyl chloride can be obtained in fifteen minutes. In the presence of excess sulfuryl chloride further chlorination of the side-chain occurs and benzal chloride is formed. The introduction of a third chlorine atom into the side-chain either does not take place or occurs so slowly that for all practical purposes the reaction may be neglected. For example, a mixture of **benzal chloride,** sulfuryl chloride, and benzoyl peroxide was refluxed for twenty hours without any reaction being observed. This result is a confirmation of the conclusion previously drawn from the inertness of *sym*-tetrachloroethane and chloroform: the accumulation of two chlorine atoms upon a carbon atom prevents further substitution upon that atom (by this method of chlorination).

Derivatives and homologs of toluene are chlorinated readily by sulfuryl chloride and peroxide with but few exceptions. Thus ***p*-chlorotoluene, ethylbenzene, isopropylbenzene,** etc., are easily and smoothly chlorinated in the side chain. On the other hand, neither ***o*-nitrotoluene** nor ***p*-nitrotoluene** can be chlorinated in this way.

Diphenylmethane is another compound which does not undergo the peroxide-catalyzed chlorination with sulfuryl chloride. Furthermore, this compound strongly inhibits the reaction between sulfuryl chloride and cyclohexane. This inhibitory ability must be a property of the substance itself; careful purification of the hydrocarbon does not alter its behavior.

(7) The presence of two or more chlorine atoms upon a carbon atom completely prevents further substitution on that carbon atom by this method. Thus, neither chloroform nor *sym*-tetrachloroethylene could be chlorinated. That this inactivity is not due to the presence of inhibitors is shown by the fact that these compounds can be used as solvents in the chlorination of other substances.

[a] The total yield was calculated from the chlorinated reaction mixture before separation into the individual components. [b] Yields are calculated from the rectification graphs.

This method of chlorination with sulfuryl chloride promises to be of special value in the chlorination of side-chains of aromatic hydrocarbons containing reactive nuclei. The photochemical chlorination of the side-chains of such molecules usually leads to impure products due to simultaneous nuclear substitution. By the use of sulfuryl chloride and a peroxide, however, it is possible, in some cases, to prevent entirely the chlorination of the nucleus and obtain a pure product, containing halogen in the side-chain only.

For example, the chlorination of the side-chain of ***m*-xylene** with chlorine gas and sunlight to form *m*-xylyl chloride is accompanied by the formation of at least 10% of 4-chloro-*m*-xylene under the most favorable conditions.[11] The separation of the two products by fractionation is difficult. Chlorination of *m*-xylene with sulfuryl chloride and peroxides yields only *m*-xylyl chloride. The purity of the product was ascertained from the refractive index, and a comparison of the analytical data for side-chain and total halogen. In spite of reports to the contrary,[2a] pure sulfuryl chloride and *m*-xylene do not react at the reflux temperature[12] of the mixture.

***t*-Butylbenzene** is another compound whose chlorination is better effected by the use of sulfuryl chloride than by the ordinary photochemical method. As a matter of fact, the side-chain of this hydrocarbon is so unreactive toward the halogens that it is impossible to obtain the halogen derivatives directly. Conditions under which reaction occurs with the halogens lead only to nuclear substitution products.[13] However, by the use of a peroxide and sulfuryl chloride, the side-chain can be chlorinated with ease.

On the other hand, the nuclei of **fluorene** and **β-methylnaphthalene** are extremely reactive, and the reaction, to produce nuclear substitution products,[14] occurs so readily that the method cannot be used for the chlorination of the side-chains of these molecules.

The experimental results are summarized in Table III.

Experimental Part

Materials.—The sulfuryl chloride was obtained in large quantities from the Hooker Electrochemical Company. The other materials used in this work were chiefly Eastman Kodak Co. chemicals or commercial products. Several of the substances used were prepared by standard methods.

(11) King and Merriam, *Proc. Nova Scotian Inst. Sci.*, **18**, 276 (1933–34); *C. A.*, **29**, 6214 (1935).

(12) The difficulties encountered in proving this fact illustrate the extreme caution needed in working with peroxide-catalyzed reactions. A test run which was made in the dark with *m*-xylene and sulfuryl chloride in the absence of added peroxides showed a vigorous reaction. The product formed, however, was *m*-xylyl chloride, not the 4-chloro-*m*-xylene which nuclear chlorination would have produced. The reagents were tested and found to be peroxide free. Further investigation disclosed that the solvent (acetone) which had been used to rinse the reaction flask, was the source of the peroxide impurity.

(13) Salibil, *Chem. Ztg.*, **35**, 97 (1911); *Chem. Zentr.*, I, 1581 (1911).

(14) The products formed in the reaction between sulfuryl chloride and such reactive hydrocarbons will be reported in a later communication.

[a,b] See notes on Table II. [c] Added in three equal portions at one-hour intervals.

n-Propyl bromide and *n*-butyl chloride were synthesized according to the general procedures described in "Organic Syntheses." Diphenylmethane was prepared by the action of aluminum amalgam on benzyl chloride and benzene.[15] *t*-Butylbenzene was prepared conveniently by the treatment of a mixture of 40 moles of benzene and 4 moles of *t*-butyl chloride with 10–15 g. of aluminum chloride for four hours at room temperature. The yield of purified product was 80%.

Although in the experiments reported in this paper the materials were purified by distillation or recrystallization before use, such purification is not necessary: the commercial products undergo this peroxide-catalyzed chlorination readily. In some cases in which impure materials were used, an inhibition period of from fifteen to thirty minutes was observed. However, no noticeable diminution of the yield occurred. It appears that the impurities which cause the inhibition are removed or deactivated by continued refluxing with sulfuryl chloride and peroxides.

Solvents.—The use of a solvent or a diluent is advantageous in a few cases, as in the chlorination of solid materials and in lowering the reaction temperature,[16] so the applicability of a number of solvents was tested.

A mixture containing 0.3 mole of toluene, 0.2 mole of sulfuryl chloride, and 0.3 mole of the solvent (diluent in this case) was treated with 0.001 mole of benzoyl peroxide and refluxed. The course of the reaction was followed by the rate of evolution of the gases, and by the loss in weight of the reaction flask.

The following solvents were found applicable: methylene chloride (40°), chloroform (61°), carbon tetrachloride (77°), benzene (80°), chlorobenzene (132°), and *o*-dichlorobenzene (180°).

Carbon tetrachloride was used in the chlorination of a number of aromatic hydrocarbons (Table III).

Chlorination of Aliphatic Hydrocarbons.—The chlorination of the aliphatic hydrocarbons and their halogen derivatives when treated with sulfuryl chloride and peroxides according to the general procedure outlined, proceeds smoothly, and the experimental conditions in the individual cases need not be described. However, it may be worthwhile to call attention to the following observation. The chlorination of volatile compounds (*e. g.*, *n*-propyl chloride, b. p. 46.8°) is rather slow, due to the slow rate of decomposition of the benzoyl peroxide at the temperature of reflux. This rate can be increased in two ways—by using a less stable peroxide (*e. g.*, lauroyl peroxide) or by raising the boiling point of the reaction mixture. The latter can be accomplished most conveniently in the laboratory by adding a suitable diluent of relatively high boiling point (chlorobenzene or *o*-dichlorobenzene).

(15) *Org. Syntheses*, **15**, 34 (1934).

(16) The solution must be kept refluxing throughout the reaction so that the vapors of the boiling solution may keep the oxygen of the air, which strongly inhibits the reaction, away from the reaction mixture. By using a low-boiling solvent, it is possible to accomplish this at a lower temperature and thus minimize the possibilities of secondary reactions of sulfuryl chloride with the compound.

Chlorination of Side-Chains.—The chlorination of the side-chains of aromatic hydrocarbons according to the general procedure also proceeds smoothly in most cases. However, certain of the preparations require special techniques or raise points of interest, and therefore should be discussed further.

Toluene reacts readily when an excess of the hydrocarbon is treated with benzoyl peroxide and sulfuryl chloride. The identity of the chief product was established as benzyl chloride by preparing the quaternary ammonium salt with dimethylaniline (m. p. 115–116°). On the other hand, when the hydrocarbon is treated with an excess (1:4) of sulfuryl chloride, the reaction does not go to completion, but ceases after only two parts of the sulfuryl chloride have been utilized to form benzal chloride. In order to determine the cause of this inactivity the following experiments were carried out.

In a 200-cc. round-bottomed flask were placed 36.8 g. of toluene (0.4 mole), 54.0 g. of sulfuryl chloride (0.4 mole), and 0.5 g. of benzoyl peroxide (0.002 mole). Upon refluxing this mixture a vigorous reaction took place, complete in less than half an hour. Another portion of sulfuryl chloride (0.4 mole) and benzoyl peroxide (0.002 mole) was added, and the refluxing was continued. In this case, the reaction required three hours to reach completion. No further reaction was observed after a third portion of sulfuryl chloride and peroxide was added and the treatment was repeated. The product isolated was benzal chloride.

Benzal chloride (Eastman Kodak Co.) was distilled under reduced pressure, and a fraction boiling between 104–105° at 30 mm. was collected. A reaction mixture made up of 32.2 g. of this material (0.2 mole), 54.0 g. of sulfuryl chloride (0.4 mole), and 0.5 g. of benzoyl peroxide (0.002 mole) was refluxed for twenty hours. The loss in weight of the flask was less than 10% of the theoretical. The reaction mixture was fractionated, but beyond the fact that the last portion of the reaction mixture distilled up to 108° (30 mm.), no evidence of reaction was observed.

In a flask were placed 18.4 g. of toluene (0.2 mole), 16.1 g. of benzal chloride (0.1 mole), and 27.0 g. of sulfuryl chloride (0.2 mole). Benzoyl peroxide was added (0.002 mole), and the mixture was refluxed. Reaction began at once, and was complete in twenty minutes.

These experiments indicate that the inability of sulfuryl chloride to chlorinate toluene completely to benzotrichloride must be due to the inactivity of benzal chloride toward the reagent, and not to any chain-breaking property of the molecule.

The chlorination of **ethylbenzene** yields the α-chloro derivative as shown by the ease of hydrolysis of the compound isolated, and by the formation of acetophenone by the action of cupric nitrate upon the compound.[17] A small amount of β-chloroethylbenzene is probably formed also, but its presence could not be demonstrated by the method used.[18]

In a sealed tube were placed 14.0 g. of chloroethylbenzene (0.1 mole), and 20 g. of pyridine (0.25 mole). The mixture was heated at 115–120° for six hours. The tube was then opened, and the styrene and excess pyridine were removed under reduced pressure. The residue was extracted twice with an alcohol–ether mixture. However, the quaternary ammonium salt of β-chloroethylbenzene could not be isolated.

The chlorination of **isopropylbenzene** also indicates that the substitution of chlorine in the side-chain takes place predominantly at the α-position. In this case, the analysis of the reaction mixture is simplified by the fact that the α-chloro derivative is a tertiary chloride, readily decomposed by heating into an olefin and hydrogen chloride.

The reaction was carried out according to the general procedure. In order to minimize disubstitution, a 5:1 ratio of hydrocarbon to sulfuryl chloride was used (1.5 mole cumene, 0.3 mole sulfuryl chloride). Benzene was used as a solvent to keep the temperature moderate throughout the reaction. After the reaction was complete, the benzene and excess isopropylbenzene were carefully removed under reduced pressure (21 mm.). The weight of the residual liquid indicated a yield of 95%. This material was refluxed under reduced pressure until hydrogen chloride was no longer given off, and was then fractionated. β-Phenylpropylene passed over between 59 and 62° (21 mm.). Between 95 and 100°, 2.5 g. of β-chloroisopropylbenzene was collected. This represents approximately 10% of the total product.

***t*-Butylbenzene** was prepared by the Friedel–Crafts synthesis. The measurement of the refractive index of the product ($n^{20}D$ 1.4927) and its unreactivity toward bromine demonstrate the absence of alpha hydrogen atoms, and establish the purity of the product.

The hydrocarbon, 5.0 g., was treated with 1 cc. of a 5% solution of bromine in carbon tetrachloride. The mixture was illuminated by a 300-watt lamp for twenty-four hours. No reaction was evident.

In another experiment, the hydrocarbon was treated with bromine and ascaridole,[19] but no reaction occurred.

Chlorination of the hydrocarbon with sulfuryl chloride proceeded with a rapidity that is especially surprising in view of the general unreac-

(17) Fischer and Schmitz, *Ber.*, **39**, 2210 (1906). The acetophenone was identified in the form of its phenylhydrazone.

(18) α- and β-chloroethylbenzene cannot be separated by fractionation.

(19) Kharasch, Margolis, White and Mayo, THIS JOURNAL, **59**, 1405 (1937).

tivity of the side-chain toward other reagents. A product was isolated by fractionation (b. p. 119–120° at 30 mm., $n^{20}D$ 1.5253) which was identified as β-chloro-*t*-butylbenzene by the preparation of the anilide of β,β-dimethylhydrocinnamic acid,[20] m. p. 122–123°.

The action of **diphenylmethane** toward sulfuryl chloride is different from that of any of the other hydrocarbons whose chlorinations have been described. Not only is this compound incapable of undergoing the usual peroxide-catalyzed reaction with sulfuryl chloride, but it is capable of inhibiting the chlorination of other hydrocarbons by this method.

It is probable that this peculiar action is not due to the hydrocarbon itself, but to some product formed by a reaction of sulfuryl chloride with the compound. When diphenylmethane is mixed with sulfuryl chloride (no peroxide added), and the mixture is permitted to stand at room temperature, the originally clear solution becomes cloudy within a few minutes, reddening upon longer standing. After some time (one to three days), a red oil separates.

In a round-bottomed flask were placed 33.6 g. of diphenylmethane (0.2 mole), 30 g. of sulfuryl chloride (0.22 mole), and 0.5 g. of benzoyl peroxide (0.002 mole). The mixture was refluxed. No evolution of gas occurred during the first thirty minutes, but the solution became red in color. Upon continued refluxing, a slow reaction occurred, as was shown by the gas given off. Examination disclosed that this gas contained free chlorine, indicating decomposition of the sulfuryl chloride. After three hours, reaction had ceased. The reaction mixture was fractionated under reduced pressure. It consisted chiefly of unchanged diphenylmethane. Less than 20% of the product distilled in the temperature range of benzhydryl chloride (156–162 at 13 mm.). No sulfuryl chloride was recovered; it was probably completely dissociated into sulfur dioxide and chlorine.

A number of other experiments were carried out in which the conditions (temperature, solvents, peroxide, ratio of reagents, etc.) were altered, but with the same result. Since sulfuryl chloride is ordinarily stable under the conditions used in these experiments, the dissociation of the reagent must be due to the catalytic action of some substance formed in the reaction mixture.

The following experiment illustrates the inhibiting effect of diphenylmethane on the chlorination of other hydrocarbons.

(20) The general procedure recommended by Underwood and Gale, THIS JOURNAL, **56**, 2117 (1934), was followed with one exception. The Grignard reagent could not be prepared with the usual commercial magnesium activated according to the procedure recommended. Using sublimed magnesium and a crystal of iodine, the reaction occurred without difficulty.

Two reaction mixtures were made up. Both contained 5 g. of sulfuryl chloride and 5 g. of toluene plus a few grains of benzoyl peroxide. To one was added 5 cc. of chlorobenzene; to the other, 5 cc. of diphenylmethane. The flasks containing the mixture were placed in a hot-water bath simultaneously. The first mixture reacted vigorously while the second showed no signs of reaction after two hours.

Triphenylmethane, however, is chlorinated without difficulty.

In a reaction flask were placed 8.4 g. of triphenylmethane (0.033 mole), 13.5 g. of sulfuryl chloride (0.1 mole), and 0.1 g. of lauroyl peroxide (0.0005 mole). The mixture was refluxed for thirty minutes. The excess sulfuryl chloride was removed, and the reaction product was twice recrystallized from ligroin (90–100°). There was isolated 5.7 g. of material, m. p. 111–112°, which was identified as triphenylmethyl chloride by the fact that the melting point of a mixture with a known sample of triphenylmethyl chloride was not depressed.

The **nitrotoluenes** do not undergo the peroxide-catalyzed reaction with sulfuryl chloride. This inactivity is probably due to inhibitory (chain-breaking) properties of the nitro groups. For example, the chlorination of cyclohexane is slowed down markedly by the addition of a small amount of *p*-nitrotoluene.

Inhibition of the Reaction.—It has been pointed out that the reaction between sulfuryl chloride and hydrocarbons is markedly catalyzed by small amounts of peroxides.[21] The reaction is equally sensitive to small quantities of other substances. For example, the addition of iodine or sulfur, in moderate excess over the amount of peroxide added, will completely inhibit the reaction. A slow stream of oxygen through the reaction mixture also inhibits the reaction.[16] A number of substances were tested for their effect on the reaction.

A mixture of 168 g. of cyclohexane (2.0 moles) and 270 g. of sulfuryl chloride (2.0 moles) was made up. To 21.9 g. of this mixture (containing 0.1 mole each of cyclohexane and sulfuryl chloride) there was added 0.001 mole of benzoyl peroxide and 0.01 mole of the substance whose inhibitory properties were being tested. The mixture was refluxed for one hour (unless the reaction was complete before that time), and the extent of the reaction was estimated from the loss in weight of the reaction flask.

Under these conditions, the following substances inhibit the reaction: iodine, sulfur, *p*-nitrotoluene, thionyl chloride, phosphorus trichloride, and isoamyl nitrite. A slow stream of oxygen passing

(21) We have not made any attempt as yet to measure the smallest quantity of peroxide capable of completely chlorinating one mole of hydrocarbon. In one experiment, however, 0.0003 mole of benzoyl peroxide was sufficient catalyst to chlorinate completely one mole of toluene.

through the reaction mixture also prevents reaction.

On the other hand, the addition of acetyl chloride, acetic acid, and benzophenone has no noticeable effect upon the rate of the reaction.

Reaction of Benzoyl Peroxide with Sulfuryl Chloride.—In developing the mechanism of this reaction between sulfuryl chloride and hydrocarbons to be described later in this paper, it became of interest to study the action of benzoyl peroxide on sulfuryl chloride itself. It was found that at 70–80° benzoyl peroxide reacts slowly with sulfuryl chloride to form chlorobenzene, according to the equation

$$(C_6H_5CO)_2O_2 + SO_2Cl_2 \xrightarrow{\Delta} 2C_6H_5Cl + SO_2 + 2CO_2$$

Sulfuryl chloride (0.4 mole) and benzoyl peroxide (12.1 g., 0.05 mole) were placed in a round-bottomed flask, and 0.4 mole of benzene was added as a diluent. The mixture was refluxed for twenty-four hours, and then fractionated; chlorobenzene, 8.0 g., was isolated (b. p. 128–131°), and identified by means of its nitration product, 2,4-dinitrochlorobenzene (m. p. 50–51°). Since the amount of chlorobenzene isolated represents 70% of the theoretical yield, it is evident that the equation above represents the main reaction. A few grams of higher-boiling material was also formed. This was fractionated under reduced pressure and the presence of benzoic acid and diphenyl demonstrated. These are the usual products of the decomposition of benzoyl peroxide in benzene.[22]

Mechanism of the Reaction

It is evident that this reaction between sulfuryl chloride and hydrocarbons has those characteristics which are commonly ascribed to chain reactions. Among these properties, the most significant is probably the sensitivity of the reaction to small traces of other substances—the rate is increased tremendously by small amounts of peroxides, and completely inhibited by small quantities of sulfur, iodine, and oxygen. Furthermore, the similarity of the results obtained in this reaction with those obtained by photochemical chlorination is also significant, and points to an identical reactive intermediate—the chlorine atom.

The decomposition of peroxides to form free radicals appears to be well established.[23] These free phenyl radicals are known to remove halogen from molecules containing reactive halogen. Based upon these facts, the following chain mechanism for this reaction is advanced tentatively.

$$C_6H_5CO{-}OO{-}COC_6H_5 \longrightarrow 2C_6H_5- + 2CO_2 \quad (1)$$
$$C_6H_5- + SO_2Cl_2 \longrightarrow -SO_2Cl + C_6H_5Cl \quad (2)$$
$$-SO_2Cl \longrightarrow SO_2\uparrow + Cl- \quad (3)$$
$$Cl- + RH \longrightarrow R- + HCl\uparrow \quad (4)$$
$$R- + SO_2Cl_2 \longrightarrow RCl + -SO_2Cl \quad (5)$$

It may be that the reaction proceeds through an alternative mechanism involving a direct attack of the chlorine atom upon the hydrocarbon, forming the alkyl chloride and liberating a *hydrogen atom* to carry on the chain. This mechanism, which we consider very unlikely, may be indicated as follows:

$$Cl- + RH \longrightarrow RCl + H- \quad (4')$$
$$H- + SO_2Cl_2 \longrightarrow HCl\uparrow + -SO_2Cl, \text{ etc.} \quad (5')$$

The chain could be broken by the following steps

$$R- + R- \longrightarrow R{-}R \quad (6)$$
$$R- + Cl- \longrightarrow R{-}Cl, \text{ etc.} \quad (7)$$
$$H- + H- \longrightarrow H_2 \quad (6')$$
$$H- + Cl- \longrightarrow HCl, \text{ etc.} \quad (7')$$

In addition, traces of impurities could break the chain by combining with the reactive intermediates, the atoms or free radicals. Those substances which have been shown capable of inhibiting the reaction probably operate in this manner.

These considerations indicate why peroxides are effective catalysts in this reaction. Furthermore, they suggest that any substance capable of removing a chlorine atom from sulfuryl chloride should also catalyze the reaction between sulfuryl chloride and organic compounds. This conclusion has been verified in a number of cases.[24] However, benzoyl peroxide remains the most convenient catalyst for general use in this reaction.

Summary

1. A trace of an organic peroxide induces a reaction between sulfuryl chloride and organic compounds

$$RH + SO_2Cl_2 \xrightarrow[\text{peroxide}]{\Delta} RCl + SO_2\uparrow + HCl\uparrow$$

By the use of this procedure, it is possible to chlorinate *in the dark* many types of organic compounds more rapidly and conveniently than can be done by the use of elementary chlorine and light.

2. The study of the chlorination by this method of cyclohexane, *n*-heptane, *n*-propyl chloride, *n*-butyl chloride, ethylene chloride, propylene chloride, *sym*-tetrachloroethylene, chloroform, and *n*-propyl bromide leads to the following generalization: (a) Substitution takes place on a secondary carbon atom in preference to a primary. (b) A second chlorine atom tends to substitute as

(22) Lippmann, *Monatsh.*, **7**, 522 (1886).

(23) Hey and Waters, *Chem. Rev.*, **21**, 186 (1937).

(24) These results will be reported in a later communication.

far from the first chlorine atom as possible. (c) Substitution of a second chlorine atom upon a carbon atom already holding a halogen substituent is difficult; a third chlorine atom cannot be introduced. (d) A bromine substituent is not displaced.

3. The chlorination of side-chains of aromatic hydrocarbons proceeds readily as shown by a study of the chlorination of toluene, *p*-chlorotoluene, ethylbenzene, isopropylbenzene, *t*-butylbenzene, *m*-xylene, and triphenylmethane. The study of the chlorination of toluene, with an excess of sulfuryl chloride, reveals that in this case also the substitution of chlorine upon a carbon atom ceases with the introduction of the second chlorine atom. Both ethylbenzene and isopropylbenzene chlorinate chiefly in the alpha position of the side-chain. Diphenylmethane and the nitrotoluenes cannot be chlorinated by this method.

4. This method of chlorination is of particular value for the chlorination of side-chains in molecules containing reactive nuclei. Thus, *m*-xylene is chlorinated in the side-chain without the simultaneous formation of any nuclear-substituted products; and *t*-butylbenzene reacts readily to form β-chloro-*t*-butylbenzene, a compound which cannot be prepared by the direct action of chlorine upon the hydrocarbon.

5. The characteristics of the reaction indicate that the slow decomposition of the peroxide at the reaction temperature initiates a chain reaction involving chlorine *atoms*.

The Magnetic Properties of Myoglobin and Ferrimyoglobin, and their Bearing on the Problem of the Existence of Magnetic Interactions in Hemoglobin

BY DONALD S. TAYLOR

Myoglobin, or muscle hemoglobin, was first isolated in crystalline form by Theorell,[1a] who showed that it is very similar to hemoglobin but that it has certain important differences. The minimum molecular weight calculated from the iron analysis is 17,000,[1a] a value agreeing with that calculated from hemoglobin analyses. Theorell[1b] investigated the sedimentation velocity of crystallized myoglobin, and found two components, with molecular weights of 34,000 for the principal one and 68,000 for the secondary one. A redetermination by Polson[2] in the same laboratory gave the value 17,000, leading to the conclusion that there is only one iron atom, and therefore only one heme group per molecule. The oxygen saturation curve found for myoglobin[1e] is a rectangular hyperbola rather than a sigmoid curve as is found for hemoglobin. It has a much higher affinity for oxygen than hemoglobin has[1e] and thus acts as an oxygen reservoir for the muscle. Its oxygen equilibrium is much less affected by change in acidity than is that of hemoglobin.[1e] Myoglobin forms compounds analogous to those of hemoglobin, and is very easily oxidized to brown ferrimyoglobin[3] (metamyoglobin). The absorption spectra[1c] of myoglobin and its derivatives are very similar to those of the analogous hemoglobin substances, but the band positions are slightly shifted.

The magnetic studies of myoglobin are then of interest for the information they give about the structural chemistry of the myoglobin series, and also for the opportunity offered to make a comparison between this series in which the hemes are located on individual molecules (or at least are physico-chemically independent as judged by the oxygen equilibrium study[1e]) and the hemoglobin series in which there are four hemes per molecule with a large physico-chemical interaction effect (calculated to be about 6000 calories per mole according to the theoretical analysis of the oxygen equilibrium by Pauling[4]). In particular this comparison should shed light on the question as to

(1) H. Theorell, *Biochem. Z.*, (a) **252**, 1 (1932); (b) **268**, 47 (1934); (c) **268**, 55 (1934); (d) **268**, 64 (1934); (e) **268**, 73 (1934).

(2) T. Svedberg, *Nature*, **139**, 1051 (1937). Note added in proof: Dr. Theorell has informed us in a private communication that Polson worked with cow myoglobin, so that the reported differences from values obtained by Theorell on horse myoglobin may be real. However, the discussion or conclusions given here are not changed by this new information.

(3) The nomenclature adopted here is analogous to that proposed by Pauling and Coryell[5] for hemoglobin substances.

(4) L. Pauling, *Proc. Natl. Acad. Sci.*, **21**, 186 (1935).

whether magnetic interactions occur between the hemes in hemoglobin. The postulate of interaction was advanced by Pauling and Coryell[5] because the magnetic moment of ferrohemoglobin (calculated from the magnetic susceptibility assuming no interaction) is somewhat higher than expected for ferrous ion. It was thought that this might be caused by a slight tendency for the magnetic moments of the four hemes in a molecule to orient together when a magnetic field is applied. In myoglobin we have the hemes on separate molecules, so that no magnetic interaction can occur in dilute solution. The magnetic moment calculated for myoglobin from the susceptibility must then be the true magnetic moment of the heme group conjugated to globin, a value different from that found for hemoglobin if magnetic interaction does occur.

In the work that is to be described it will be shown that the magnetic properties of the iron in myoglobin (from horse heart muscle) in both the ferrous and ferric forms are to within the limits of experimental error equal to those of the corresponding hemoglobin substances.

Experimental Part

Preparation of Myoglobin Solutions.—Three myoglobin preparations were made, which will be designated as myoglobins I, II, and III. The first preparation was a pioneer preparation using the material from one heart. The last two yielded sufficient quantities for magnetic measurements. The method used in the preparations is essentially that described by Theorell[1a] with modifications as suggested by Morgan.[6] The procedure will be described here, as some variations were introduced.

Horse hearts were obtained from the animals less than two hours after death and placed in ice for the trip to the laboratory. They were then washed well with water and freed from fat as thoroughly as possible, and the meat was finely ground. An amount of water about equal to half the weight of the meat was added and the mixture allowed to stand about twenty hours in the cold room. A reddish extract was then obtained by squeezing out the liquid in a large press. It was found that additional myoglobin solution was obtained if the meat was again extracted in the same way.

The red liquid which was obtained rapidly darkened due to auto-oxidation to ferrimyoglobin when the reducing action of the tissues was no longer effective.

The *p*H was adjusted to 7.00 by addition of 1 *N* potassium hydroxide with rapid stirring. The solution was mixed at room temperature with one-fourth its volume of a saturated solution of basic lead acetate. This substance caused precipitation of the globulins in the form of a dense white glutinous mass which was easily removed by centrifuging. The *p*H was again adjusted to 7.00 by addition of 1 *N* potassium hydroxide, and 210 g. of potassium dihydrogen phosphate and 300 g. of potassium monohydrogen phosphate were added to each liter of solution, this being enough to give a solution approximately 3 molar in phosphate and buffered at about *p*H 6.6. The precipitate of lead phosphate and hemoglobin which then formed was filtered off. The myoglobin was obtained by repeatedly dialyzing this solution against saturated neutral ammonium sulfate solution. The first nearly colorless precipitate (albumins) was filtered off and discarded. The myoglobin finally precipitated as a brownish solid mixed with considerable albuminous material. Dialysis was carried out in cellophane casings in the cold room.

The crude myoglobin precipitate thus obtained was purified somewhat by several treatments involving redissolution in water and dialysis against saturated neutral ammonium sulfate until precipitation took place. No effort was made to get absolutely pure crystals since the only requirement for this work was the preparation of a hemoglobin free solution of sufficiently high myoglobin concentration.

All processes were carried out in the cold room or in the refrigerator except for the short periods for filtration and handling. Chemically pure reagents were used throughout except for some impure ammonium sulfate used in preparation II, it being thought that the inorganic iron present would not be carried through the purification process. Some seemed to have been carried through, however, and this rendered certain measurements on this solution valueless, as will be pointed out later.

For preparation II eleven hearts were obtained and the final step yielded 130 ml. of dark brown solution concentrated enough for magnetic measurements. In preparation III twelve hearts (45 pounds, 20 kg.) were used but only about 100 ml. of solution of slightly lower concentration was obtained. (From concentrations given later it can be calculated that in all about 15 g. of myoglobin was obtained.) The solutions were adjusted to *p*H 7.0 and kept in the refrigerator until used.

Standardization of Solutions.—Spectroscopic examination of solutions obtained in the manner described above indicated that all of the myoglobin was in the form of ferrimyoglobin. A Van Slyke–Neill[7] oxygen-capacity determination on solution III gave zero oxygen capacity, which also indicated the substance to be entirely in the ferric form, as Theorell[1c] has pointed out.

The concentration of the solutions was determined in the following manner. To 10 ml. of solution 0.15 g. of sodium hydrosulfite ($Na_2S_2O_4$) was added to reduce the ferrimyoglobin completely. The carbon monoxide capacity of the solution so obtained was then determined by the method of Van Slyke and Hiller[8] using the Van Slyke–Neill blood gas apparatus. Calculations from equilibrium data showed that the carbon monoxide affinity of myoglobin is not enough different from that of hemoglobin to affect the completeness of saturation when carried out in the manner recommended for hemoglobin. One-ml. solution samples were used, corrections being

made for retention on the walls of the transfer pipet and for change in the meniscus level on standing. The Van Slyke gas pipet had been calibrated previously. A volume of 0.25 ml. of acid ferricyanide reagent was used and correction for solubility of carbon monoxide in the sample and dissolved gases in the reagent was determined as is customary by analysis carried out on 1 ml. of water.

From the amount of carbon monoxide chemically bound as determined in this way the concentration of myoglobin was calculated in terms of moles of heme iron per liter. The gasometric determinations were carried out at least three times, and the agreement was thoroughly satisfactory.

Measurement of Magnetic Properties of Solutions.—The general technique used in the magnetic measurements by the differential Gouy method has been described elsewhere.[9] The standardized tube was surrounded by an air thermostat at 25°. The Δw values which are given below represent the mean of two determinations of the observed force in milligrams on the tube containing the sample when in a standard magnetic field. The two determinations were made in fields of different strengths and converted to a common basis by an empirically determined factor.

Each sample of myoglobin solution was treated in the following way. Twenty-five ml. of solution was placed in the tube and the value of Δw of the ferrimyoglobin ($\Delta w_{\mathrm{Mgb}^+}$) was measured. The solution was then reduced by the addition of 0.3 g. of sodium hydrosulfite and the Δw measured, which on the addition of an experimentally determined correction of +0.09 mg. for the diamagnetism of the added hydrosulfite gives the Δw for ferromyoglobin (Δw_{Mgb}). This solution was then removed from the tube, treated with 0.1 g. of sodium hydrosulfite and saturated with carbon monoxide by stirring in a dark stoppered flask with pure carbon monoxide. The solution so obtained was returned to the tube in the dark or diffuse daylight, and the Δw was measured, which on addition of a total correction of +0.12 mg. for diamagnetism of hydrosulfite gives Δw for carbonmonoxymyoglobin ($\Delta w_{\mathrm{MgbCO}}$). Enough of solution II was available to run four sets of measurements as described above and enough of solution III to run three sets of measurements. Averages of the values obtained were used in calculations.

Calculations.—The molal susceptibilities (χ_m) of the paramagnetic iron atoms in any compound x were calculated by means of the following equation, which holds for determinations made in the manner described.

$$\chi_m \times 10^6 = \frac{(\Delta w_x - \Delta w_{\mathrm{MgbCO}})}{m} 18.60 \qquad (1)$$

Here m is the molar concn. of heme iron and 18.60 is the apparatus constant determined by standardization with air and water.

In using Equation (1) we are assuming that the iron in carbonmonoxymyoglobin is in a diamagnetic state, and that therefore $\Delta w_{\mathrm{MgbCO}}$ may be used to correct for the diamagnetism of the solutions. This assumption is partially justified by the very close chemical similarity between carbonmonoxyhemoglobin and carbonmonoxymyoglobin. The magnetic results obtained by making this assumption agree so well with results for hemoglobin that we do not hesitate to accept them. If carbonmonoxymyoglobin were paramagnetic its magnetic moment would be due to unpaired electrons, of which there would necessarily be at least two. These two unpaired electrons would give a magnetic moment of at least 2.83 Bohr magnetons, an amount which would certainly cause a large difference in the calculated results for the free ferrous and ferric forms from results for the corresponding hemoglobin compounds arrived at in the same manner.

Magnetic moments μ in Bohr magnetons were calculated assuming Curie's law in the form

$$\mu = 2.84 \sqrt{\chi_m T} \qquad (2)$$

Experimental Results

All important experimental and calculated values are collected in Table I. It is to be noticed that the value of $\Delta w_{\mathrm{Mgb}^+} - \Delta w_{\mathrm{MgbCO}}$ for solution II is noticeably low. We ascribe this to the presence of inorganic iron in some form which undergoes increase in susceptibility on reduction. However, the value for solution III compares favorably with hemoglobin values, and since in this case care was taken to avoid contamination with inorganic iron we use this value to calculate the susceptibility of ferrimyoglobin. For ferromyoglobin measurements inorganic iron can have no effect, since the change in going from ferromyoglobin to carbonmonoxymyoglobin, the addition of carbon monoxide, would not change the susceptibility of the inorganic iron, but only that of the heme iron. In taking the difference we calculate the paramagnetic susceptibility of the heme iron independently of the other constituents of the solution. The close check between results for the two solutions indicates the precision that was obtained for even these rather dilute solutions.

The mean value of the molal susceptibility (χ_m) of ferromyoglobin is accordingly found to be $12{,}400 \times 10^{-6}$, corresponding to a magnetic moment of 5.46 Bohr magnetons; the value of the molal susceptibility of ferrimyoglobin (solution III) is found to be $14{,}200 \times 10^{-6}$, corresponding to a magnetic moment of 5.85 Bohr magnetons.

Experiments made on a very dilute solution of

ferrimyoglobin recovered from carbonmonoxymyoglobin III indicated that the formation of ferrimyoglobin hydroxide is accompanied by a decrease of magnetic susceptibility to approximately 8000×10^{-6}, very much like that attending the formation of ferrihemoglobin hydroxide.[9] These experiments were not of sufficient accuracy to allow quantitative conclusions to be made. A similar experiment also indicated that ferrimyoglobin fluoride has a susceptibility somewhat greater than that of ferrimyoglobin itself.

Discussion

The value $12{,}400 \times 10^{-6}$ for the molal magnetic susceptibility found for ferromyoglobin is to within experimental error equal to that of $12{,}290 \times 10^{-6}$ reported by Taylor and Coryell[10] for ferrohemoglobin. The susceptibility found for ferrimyoglobin is also to within the experimental error equal to that of ferrihemoglobin reported by Coryell, Stitt and Pauling.[9]

The values of the magnetic moments obtained for ferromyoglobin and ferrimyoglobin may be interpreted in the same manner as for ferrohemoglobin[5] and ferrihemoglobin,[9] leading to the conclusion that the iron atoms are held to the porphyrin by essentially ionic bonds.

Since myoglobin has one (or possibly two chemically independent) hemes per molecule as contrasted with the four of hemoglobin, the existence of interaction between the hemes of hemoglobin might lead to some difference in the magnetic moments observed for the two substances. That no difference greater than the experimental error is observed for either the ferrous or ferric forms of these substances is a strong indication that there is little or no magnetic interaction between the hemes in hemoglobin. We believe, therefore, that 5.44 Bohr magnetons is the magnetic moment of ferroheme conjugated with globin, and that 5.80 Bohr magnetons is the magnetic moment of ferriheme conjugated with globin. Magnetic titrations carried out by Coryell, Pauling, and Dodson[11] on systems involving the transformation of ferrohemoglobin to oxyhemoglobin and to nitric oxide hemoglobin also failed to give evidence for magnetic interactions between the hemes in ferrohemoglobin. These measurements would not be expected to be so sensitive as those described in this study.

That the observed moment of ferromyoglobin and ferrohemoglobin is considerably higher than that calculated for spin alone (4.92 for ferrous ions) may possibly be explained by assuming that the difference is due to orbital contribution to the moment. This contribution seems to be greater than that usually found for ferrous ions (0.2–0.3 Bohr magnetons). However, it should be remembered that the ferrous ion in the heme compounds is surrounded by the nitrogen atoms of the rigid planar heme group, and the closeness of approach of the nitrogen atoms to the iron atom is so restricted by the porphyrin structure that the separations may be greater than they would be

if the groups were free to move radially; and hence the orbital moment might not be quenched so much as it is in simpler compounds. A large amount of orbital contribution to the moment is also observed in the case of ferrihemoglobin cyanide and hydrosulfide,[9] which, however, have only one unpaired electron per iron atom.

Summary

The magnetic moments of the iron atoms in ferromyoglobin and ferrimyoglobin have been determined to be 5.46 and 5.85 Bohr magnetons, respectively. The magnetic moments indicate that the iron atoms are held by essentially ionic bonds in ferromyoglobin and ferrimyoglobin. The agreement of the magnetic moments with those calculated for the analogous hemoglobin compounds leads to the conclusion that magnetic interactions do not occur between the four hemes of hemoglobin.

Activity Coefficients of Barium and Strontium Carbonates in Aqueous Solutions of Alkali Chlorides

BY ERNEST HOGGE AND HERRICK L. JOHNSTON

Townley, Whitney and Felsing[1] have computed activity coefficients of strontium and barium carbonates in alkali chloride solutions from solubility measurements in carbon dioxide-free, aqueous solutions at 25 and at 40°. We have been unable to check the calculations recorded in their tables and, while details of their computations are not given, it appears that they incorrectly computed the mean ion molality and have misinterpreted (K_2')'s taken from tables of MacInnes and Belcher[2] as stoichiometric second dissociation constants of carbonic acid in salt solutions whereas these K's are in reality the products of the stoichiometric constants by the square of the mean activity coefficients of hydrochloric acid in the same solutions.[3] Correction for the activity coefficients of hydrochloric acid is important in the higher concentrations of the salt solutions employed by Felsing and co-workers.

We have accordingly recalculated the activity coefficients and obtained results that differ from those of T., W. and F. by as much as 100% in the higher salt concentrations. We employed the same equation used by T., W. and F. to correct for hydrolysis of carbonate ion, namely

$$\frac{x^2}{C - x} = \frac{k_w}{k_m'} \qquad (1)$$

with C set equal to *total* carbonate concentration in solution (equal as well to divalent metal ion concentration); x, to the concentration of bicarbonate ion; $(C - x)$ to that of carbonate ion; k_w to the stoichiometric ionization constant of water in the salt solutions and k_m' to the correct stoichiometric second ionization constant of carbonic acid in the solutions. The latter is computed from MacInnes and Belcher's tabulations of pK_2' [2] by the relationship

$$\log k_m' = -pK_2' - 2 \log \gamma_{HCl} \qquad (2)$$

In solving equation (1) for x, necessary in the eventual computation of the mean molality of barium (or strontium) and carbonate ions and the evaluation of the activity coefficients of barium (or strontium) carbonate, we employed the following sources of data.

Values of C are taken from Tables I and II of Townley, Whitney and Felsing. These are smoothed values of their solubility measurements in potassium, sodium and lithium chloride solutions, respectively.

The values of k_w are taken from the data of Harned and co-workers[4] who have determined the

(1) Townley, Whitney and Felsing, THIS JOURNAL, **59**, 631 (1937).

(2) (a) MacInnes and Belcher, *ibid.*, **55**, 2630 (1933); (b) **57**, 1683 (1935).

(3) The above misinterpretation is easily made for MacInnes and Belcher refer to their (K_2')'s as "apparent second ionization constants" and use them, without correction, as the stoichiometric constants in constructing their Tables V and VI. For their own purpose this use was justified for they were employed in computing a small correction term in solutions of relatively low ionic strength and neglect of the factor γ^2_{HCl} was without significance. The correct interpretation was further clouded by a misprint in equation (12) of MacInnes and Belcher's first paper (ref. 2a) which is, however, given in correct form as equation (3) of their second paper (ref. 2b). The latter equation shows clearly the dependence on γ^2_{HCl} in relating (K_2') to the stoichiometric constant

$$\left(K_2 \frac{\gamma_{HCO_3^-}}{\gamma_{H^+}\,\gamma_{CO_3^=}}\right)$$

(4) (a) Harned and Hamer, THIS JOURNAL, **55**, 2194 (1933); (b) Harned and Copson, *ibid.*, **55**, 2206 (1933); (c) Harned and Mannweiler, *ibid.*, **57**, 1874 (1935); (d) Harned and Cook, *ibid.*, **59**, 2304 (1937).

degree of water dissociation in each of the three chlorides and at, or near, both 25 and 40°.

Values of k'_m were computed, for potassium chloride solutions, by use of equation (2) with pK'_2 taken from the tables of MacInnes and Belcher[2a,b] and γ_{HCl} from Table IV of Harned and Hamer.[4a] Interpolations were made by graphical methods. MacInnes and Belcher's measurements at 38° were assumed valid at 40°.

For sodium and lithium chlorides evaluation of k'_m is, of necessity, less exact. Reliable values of γ_{HCl} in these solutions are available[4b,c] but MacInnes and Belcher's determinations of pK'_2 are limited to potassium chloride solutions and no determinations of similar accuracy are available for sodium and lithium chlorides. We corrected for this as follows

$$k'_m \text{ equals } \left(K_2 \frac{\gamma_{HCO_3^-}}{\gamma_{H^+}\ \gamma_{CO_3^-}}\right)$$

where K_2 is the true thermodynamic dissociation constant, whence

$$\log (k'_m)_{NaCl} - \log (k'_m)_{KCl} = \log \left(\frac{\gamma_{HCO_3^-}}{\gamma_{H^+}\ \gamma_{CO_3^-}}\right)_{NaCl} - \log \left(\frac{\gamma_{HCO_3^-}}{\gamma_{H^+}\ \gamma_{CO_3^-}}\right)_{KCl}$$

and a similar relationship holds for the ratio of $(k'_m)_{LiCl}$ to $(k'_m)_{KCl}$. Further, $\gamma_{CO_3^-}$ can be set equal to $\gamma^4_{HCO_3^-}$ as an approximation.[5,6] A similar relationship has held in other solutions of similarly related mono-, di- and trivalent ions.[7]

We may therefore write

$$\log (k'_m)_{NaCl} = \log (k'_m)_{KCl} + \log (\gamma_{H^+}\ \gamma^3_{HCO_3^-})_{KCl} - \log (\gamma_{H^+}\ \gamma^3_{HCO_3^-})_{NaCl}$$

and reduce this to the form

$$\log (k'_m)_{NaCl} = \log (k'_m)_{KCl} + 4 \log \frac{(\gamma_{HCO_3^-})_{KCl}}{(\gamma_{HCO_3^-})_{NaCl}} \quad (11)$$

by the not unreasonable assumption that $(\gamma_{H^+})_{KCl}$ bears to $(\gamma_{H^+})_{NaCl}$ very nearly the same ratio as $(\gamma_{HCO_3^-})_{KCl}$ to $(\gamma_{HCO_3^-})_{NaCl}$.

The final term in equation (3) is evaluated from Table XII of Walker, Bray and Johnston,[6] and is considered to be the same at 25 and at 40°. The influence of this correction alone affects the activity coefficients of the carbonates to the extent of about 10% at the higher ionic strengths in aqueous lithium chloride.[8]

Finally, the values of x obtained from equation (1) were employed to yield values of $(1/m_\pm)$, by the relationship $m_\pm = \sqrt{C(C-x)}$, and a plot was made of log $(1/m_\pm)$ *vs.* $\sqrt{\mu}$ for the several solutions. Extrapolation to $(\mu = 0)$ gave the limiting values listed in Table I.

(5) This approximation should be quite good at low ionic strengths (to 0.1 or 0.2 μ) where the mean activity coefficient of the alkali bicarbonate should be given rather accurately by an expression of the type

$$\log \gamma_{25°} = \frac{-0.504\sqrt{\mu}}{1 + A\sqrt{\mu}} \quad (3)$$

[Debye and Hückel, *Physik. Z.*, **24**, 185 (1923)], where A is a constant related to the "mean ion size," and that of the alkali carbonate by the expression

$$\log \gamma_{25°} = \frac{-1.008\sqrt{\mu}}{1 + A\sqrt{\mu}} \quad (4)$$

Since it is fair to conclude that carbonate and bicarbonate ions will differ little in size (Ref. 6) the A's can be set equal and it follows that

$$\log \gamma_{M_2CO_3} = 2 \log \gamma_{MHCO_3} \quad (5)$$

and

$$\log \gamma_{CO_3^-} = 4 \log \gamma_{HCO_3^-}$$

At ionic strengths above 0.1 or 0.2 the mean activity coefficients of the electrolytes require the addition of a linear term in μ, to correct for the influence of the ions on the dielectric constant of the medium. This leads to equations of the type

$$\log \gamma_{MHCO_3} = \frac{-0.504\sqrt{\mu}}{1 + A\sqrt{\mu}} + B_{MHCO_3}\mu \quad (6)$$

$$\log \gamma_{M_2CO_3} = \frac{-1.008\sqrt{\mu}}{1 + A\sqrt{\mu}} + B_{M_2CO_3}\mu \quad (7)$$

[Hückel, *ibid.*, **26**, 93 (1925), also cf. Harned, THIS JOURNAL, **48**, 326 (1926), and Åkerlöf, *ibid.*, **48**, 1160 (1926)], whence

$$\log \gamma_{M_2CO_3} = 2 \log \gamma_{MHCO_3} + (B_{M_2CO_3} - 2B_{MHCO_3})\mu \quad (8)$$

and the extent to which the approximation we use is in error is determined by the magnitude of the term in μ.

Walker, Bray and Johnston (ref. 6) claim to have shown that log $\gamma_{CO_3^-} = 4 \log \gamma_{HCO_3^-}$ for several of the alkali carbonate–bicarbonate mixtures in alkali chloride solutions but the proof that they offer appears rather to confirm only the experimental accuracy of their determinations of ϕ/ϕ_0 (defined as $\gamma_{CO_3^-}/\gamma^2_{HCO_3^-}$) arrived at both from equilibrium and cell measurements. However, their data for the potassium salts can be shown to confirm the above simple relationship in the following manner.

Combination of equations (6) and (7) with the definition of (ϕ/ϕ_0), and the introduction of activity coefficient of the metal ion leads correctly to the result

$$\log \phi/\phi_0 = \frac{-\sqrt{\mu}}{1 + A\sqrt{\mu}} + 4B_{MHCO_3}\mu + (6B_{M_2CO_3} - 12B_{MHCO_3})\mu \quad (9)$$

$$= 2 \log \gamma_{MHCO_3} + (6B_{M_2CO_3} - 12B_{MHCO_3})\mu \quad (10)$$

Disappearance of the last term in (10) leads to the assumed relationship $\gamma_{M_2CO_3} = \gamma^2_{MHCO_3}$ or $\gamma_{CO_3^-} = \gamma^4_{HCO_3^-}$. Walker, Bray and Johnston's data for the potassium salts are quite accurately reproduced by the equation

$$\log \phi/\phi_0 = \frac{-\sqrt{\mu}}{1 + 1.72\sqrt{\mu}}$$

over the *whole* concentration range (*i. e.*, to $\mu = 2.5$) which is equivalent to equation (9) with *both* of the terms in μ removed (*i. e.*, implies that equations (3) and (4) yield the correct activity coefficients for the potassium salts in chloride solutions even to μ greater than 2). A similar experimental simplification does not hold for their measurements on *sodium* salts which may mean only that B_{MHCO_3} is not negligible in the *sodium* salt solution. Accurately, this would permit us to use the simplification log $\gamma_{CO_3^-} = 4 \log \gamma_{HCO_3^-}$, with full confidence above $\mu = 0.1$ or 0.2 only within the potassium chloride parentheses of our equation (11). However, it does not appear to us reasonable that sensible error is introduced by using the simplifications for sodium chloride as well.

(6) Walker, Bray and Johnston, THIS JOURNAL, **49**, 1235 (1927).

(7) McDowell and Johnston, *ibid.*, **58**, 2009 (1936); Johnston and Leland, *ibid.*, **60**, 1439 (1938).

(8) In the treatment by Townley, Whitney and Felsing this correction for sodium and lithium salt solutions was neglected—*i. e.*, they considered the change of the stoichiometric ionization of *water* with the variation in salt solutions but not the change in the stoichiometric ionization of carbonic acid.

TABLE I

LIMITING VALUES OF $(1/m_{\pm})$ AT $\mu = 0$

Carbonate	Temp., °C.	$(1/m_{\pm})_{\mu=0}$
$SrCO_3$	25	43,680
$SrCO_3$	40	44,170
$BaCO_3$	25	22,180
$BaCO_3$	40	19,110

Values of $(1/m_{\pm})$ were read from the curve for convenient values of μ and used to obtain γ by the relationship

$$\gamma = \left(\frac{1}{m_{\pm}}\right)_{\mu=m} \Big/ \left(\frac{1}{m_{\pm}}\right)_{\mu=0} \qquad (12)$$

Values of γ so computed are listed in Tables II and III.

The absolute accuracy of these values is probably not better than $\pm 2\%$, but the relative values for each salt at a given temperature should be somewhat more accurate than this figure, and for this reason the third figure as given in the values of γ is included.

Summary

The mean activity coefficients of barium and strontium carbonates in aqueous solutions of the alkali chlorides, published originally by Townley, Whitney and Felsing,[1] have been recomputed. The recomputations correct for: (1) improper evaluation of the mean molalities; (2) misinterpretation of constants published by MacInnes and Belcher[2] and (3) differences in the degree of carbonic acid dissociation in the several alkali halides. The latter correction was made with the aid of Walker, Bray and Johnston's[6] observations concerning the activity coefficient ratio of carbonate and bicarbonate ions in alkali chloride solutions. The influence of the above corrections affects barium carbonate activity by some 40% at unit ionic strength, and about doubles the values for strontium carbonate.

Tables of the corrected values are given, for 25 and 40°.

Phase Equilibrium Relations in the System, Na_2SiO_3–Li_2SiO_3

BY F. C. KRACEK

The experimental investigation reported upon in this article is a continuation of the work of this Laboratory on phase equilibrium relations in silicate systems involving one or more alkalies. The system described is a binary section within the ternary system, Na_2O–Li_2O–SiO_2, which is now under investigation, in preparation for a study of the mineralogically more interesting relationships of the sodium and lithium aluminosilicates.

The two metasilicates, Na_2SiO_3 and Li_2SiO_3, cocrystallize in two series of solid solutions with intermediate compound formation, one series extending from Na_2SiO_3 to $NaLiSiO_3$, while the other, a limited series, is at the Li_2SiO_3 end of the system, with Na partially replacing Li in crystalline Li_2SiO_3.

The freezing point relations in this and several other binary systems of silicates were investigated by Wallace[1] in Tammann's laboratory, by the method of cooling curves, supported by microscopic examination. It is now well realized that the results of cooling curve thermal analysis must be interpreted with care, even with rapidly crystallizing substances; with silicates, the arrest temperatures are always found to be too low in comparison with the equilibrium values as determined by quenching.[2] The reason for this lies in the reluctance with which most silicates crystallize. Although, in the system under discussion, the crystallization is comparatively rapid, the temperatures as determined by cooling curves are below the equilibrium values by as much as 72° for mixtures at the Na_2SiO_3 end of the system.

Wallace concluded from his data that mixtures of the two components crystallize together in a complete series of solid solutions with a minimum on the freezing curve between 40 and 50% Li_2SiO_3, and noted that, under the microscope, the crystalline phase changed at about 20 to 30% Li_2SiO_3 from Na_2SiO_3-like to Li_2SiO_3-like aspect. As no measurements of the refractive indices are presented, these observations have only qualitative value at the present time.

Experimental Details

The mixtures of sodium and lithium metasilicates employed in this work were synthesized by fusing together pure silica, sodium and lithium carbonates in the required proportions. The fusions were made in platinum crucibles. The reagents used were: (1) purified quartz, first converted to cristobalite by heating in a gas furnace at about 1500° to enhance its reactivity in the fusions. It left a residue of 0.03% after evaporation with hydrogen fluoride and sulfuric acid. (2) Reagent grade $Na_2CO_3 \cdot H_2O$, converted to sodium carbonate by drying at about 250° in an atmosphere containing carbon dioxide. Analysis by E. G. Zies gave 0.001% of $Fe_2O_3 + Al_2O_3$, 0.001% of CaO, and negligible amounts of other impurities. (3) Reagent grade lithium carbonate, stated to contain 0.003% $Fe_2O_3 + Al_2O_3$ and only a trace of Na.

A standardized method of fusing the mixtures was employed for the reason that, unless special precautions are taken, the lithium carbonate present, on melting in air, corrodes platinum with the formation of a greenish to black deposit which tends to crawl over the surface of the crucible. Experiments show that the attack is not caused by the lithium carbonate itself, as fusions of this carbonate in a carbon dioxide atmosphere have no appreciable action on platinum. Another reason for exercising special care in making the fusions is that mixtures of sodium carbonate and lithium carbonate begin to melt as low as 510°,[3] and when silica is present, vigorous bubbling and mechanical losses may occur at very low temperatures.

The procedure adopted is to heat the mixtures in covered crucibles over a small Méker burner to incipient fusion until a large part of the carbon dioxide in the charge is driven off. The temperature is then raised slowly to complete the fusion. The carbon dioxide from the burner provides a sufficiently inert atmosphere to prevent the corrosion of the crucibles. In order to expel the carbon dioxide completely, the charges must be heated finally in a carbon dioxide-free atmosphere, such as that of an electric furnace; access of oxygen to the charges at this stage is no longer harmful because the alkali is now well incorporated in the melt. Precaution must, however, be taken to avoid excessive volatilization of the alkali. Instead of heating to a high temperature, and allowing the carbon dioxide to escape by diffusion and bubbling, the desired result may be accomplished more safely by crystallizing the melt, which causes the carbon dioxide to be forced out during the last stages of the crystallization. For this purpose the crucibles are alternated between two electric furnaces, one kept at a temperature high enough to produce complete melting, the other at a temperature sufficiently lower to allow the melt to crystallize. About five successive crystallizations and remeltings suffice to expel the carbon dioxide completely from the mixtures in this system.

[a] All preparations were pre-crystallized for quenching. Under the headings "Liquidus" and "Solidus" the letter "c" denotes crystals alone, and "g" glass alone, in the quenched samples. "c + g" or "g + c" denotes the presence of both glass and crystals; "h" denotes determinations by heating curve thermal analysis.

Slight losses of alkali by volatilization occur in spite of the precautions, particularly from mixtures of more than 70% lithium metasilicate. These losses, which may be as much as 0.1% of the total weight of the charge, appear to be mainly due to lithium oxide. To compensate for them a small excess of lithium carbonate is weighed out in preparing the mixtures, in accordance with a previously determined estimate. This method of compensating for the losses was found to be preferable to the alternative one of adding a small amount of the desired constituent after the mixture had been prepared, as it avoids a number of additional reheatings.

The compositions of the mixtures are known from the initial and final weights during the synthesis. They were in all cases within 0.10% of the desired values. Any departure toward ternary compositions could have been detected under the microscope by the presence of more than traces of residual glass in quenches from temperatures which are below the lowest point on the solidus in the binary system, but above the eutectics in the ternary system.

The liquidus and solidus relations were determined mainly by quenching in mercury. It was found, however, that in compositions of more than 60% lithium metasilicate, the equilibrium at the liquidus cannot be satisfactorily quenched, because of rapid crystallization of lithium metasilicate. The quenching determinations in this region were supplemented by heating curves, where use was made of a special technique which was described in an earlier paper,[4] and in which a thimble crucible with a centrally reëntrant sheath for a differential thermocouple provides an accurately centralized location of the junction in the melting charge.

The temperatures were measured by calibrated Pt *vs.* 90 Pt–10 Rh thermocouples connected to a shielded potenti-

(4) F. C. Kracek, N. L. Bowen and G. W. Morey, *J. Phys. Chem.*, **41**, 1183 (1937).

ometer system. The conversion of the thermocouple readings to degrees was made with the aid of standard tables.[5] The furnaces used in the quenching work were thermostatically controlled with a precision of ±0.3 to 0.5° at the various required temperatures. In short runs (up to three hours) the precision was somewhat closer, but in long runs it approached the value given.

Equilibrium in the various charges was reached in approximately one hour, but two hours were usually allowed in the study of the liquidus relations. For the solidus the runs lasted a day or more in testing certain questions that arose during the course of the work.

Experimental Results

The essential thermal measurements are presented in Table I, as determined by quenching, and, for a few of the preparations, by heating-curve thermal analysis. The latter determinations are distinguished by the letter "h." The quenching results are presented by listing the two nearest temperatures determined above and below the transformation point in question for each composition, rather than by giving a detailed abstract of the experimental record.

The Phase Equilibrium Diagram

Figures 1 and 2 represent the phase equilibrium relations in the system (at atmospheric pressure). Instead of a complete series of solid solutions with a minimum on the liquidus, as outlined by Wallace,[1] there is an incongruently melting intermediate compound, $NaLiSiO_3$, and two series of solid solutions. One of these series extends from Na_2SiO_3 to $NaLiSiO_3$; the other is a Li_2SiO_3-rich solid solution, the composition limits of which lie between 83 ± 3 and 100% Li_2SiO_3.

The compound, $NaLiSiO_3$ (42.43% Li_2SiO_3), at its incongruent melting point of 847 ± 1°, decomposes into a melt, containing 39.3 ± 0.2% of Li_2SiO_3, and the above-mentioned Li_2SiO_3-rich solid solution. The extent of the peritectic line giving the compositions of these phases is determined by the measurements on the liquidus, on the one hand, and by a search with the microscope, on the other hand, for the presence of two kinds of crystals in quenches from below the peritectic, in compositions near the Li_2SiO_3 end of the system. At 85% Li_2SiO_3, only Li_2SiO_3-like crystals were found; at 80%, in addition to these, there was present a small quantity of $NaLiSiO_3$. The position of the solidus curve for the Li_2SiO_3-rich solid solutions, as determined by quenching, must be regarded as only approximate, because of the difficulty of quenching the interstitial glass.

Above the peritectic, the liquidus for the Li_2SiO_3-rich solid solutions rises smoothly to the melting point of Li_2SiO_3 at 1201 ± 1°.[6]

Between Na_2SiO_3 and the end of the peritectic line the liquidus and solidus relations are as illustrated in Figs. 1 and 2, the crystalline phase being

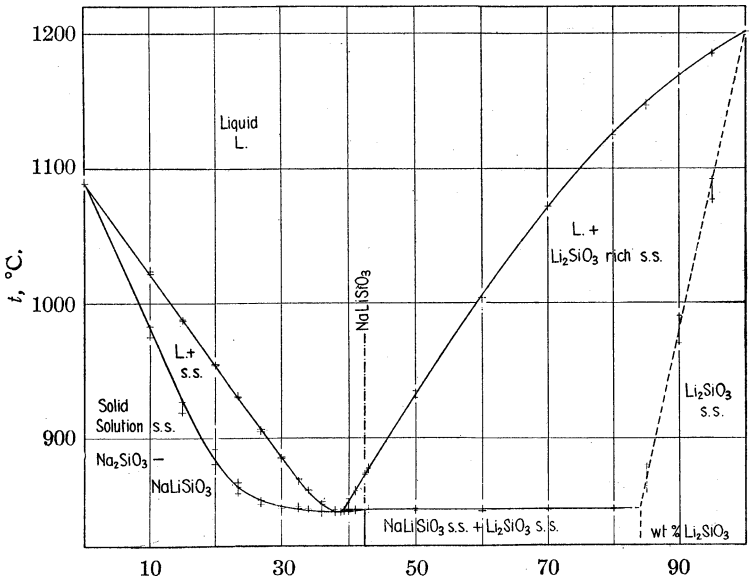

Fig. 1.—Equilibrium diagram for the system, Na_2SiO_3–Li_2SiO_3. Liquidus determinations, 60.0 to 100.0% Li_2SiO_3 by heating curve thermal analysis. All other determinations by quenching.

a continuous series of solid solutions whose composition varies from Na_2SiO_3 to $NaLiSiO_3$. Beginning at the melting point of Na_2SiO_3, 1089 ± 1°,[7] the liquidus and the solidus curves first drop, and follow their courses separately to meet again at the minimum point, 38.5 ± 0.2% Li_2SiO_3, 845 ± 1°. From the minimum point the liquidus curve rises to the end of the peritectic line, 39.3% Li_2SiO_3, 847 ± 1°. The solidus also rises to the peritectic, but meets it at the composition of the compound, $NaLiSiO_3$. The solid solution series becomes saturated at this composition, or, at the

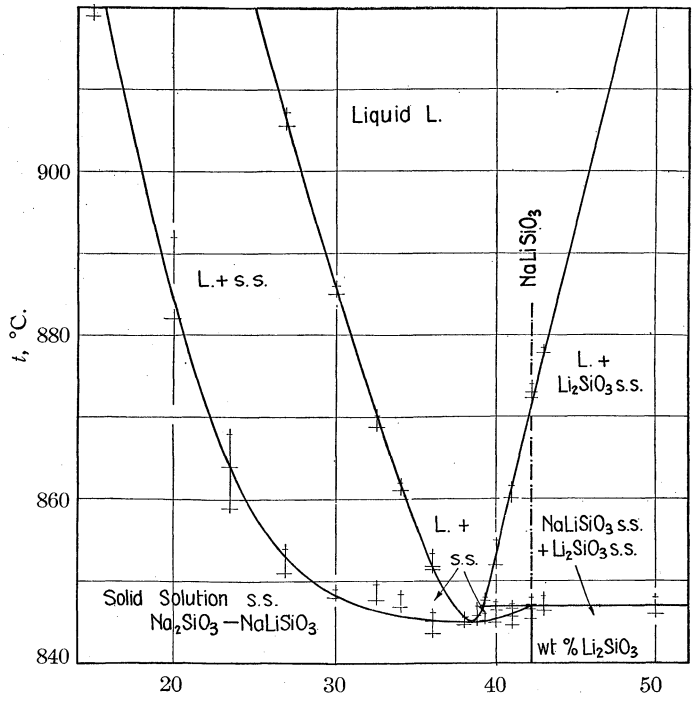

Fig. 2.—Portion of the equilibrium diagram for the system, Na_2SiO_3–Li_2SiO_3, enlarged to demonstrate the phase relations in the neighborhood of the minimum on the liquidus.

most, only a few tenths of a per cent. beyond, since quenches of this composition from below the peritectic contained only the one kind of homogeneous crystals, while those of 43.0% Li_2SiO_3 contained, in addition, a definite quantity of the Li_2SiO_3-like crystals of the other series of solid solutions.

To establish the properties of the crystalline phase (or phases) in this region, we have examined, microscopically, quenched samples of the various compositions, first completely crystallized, and then brought to equilibrium by long annealing at temperatures both above and below the solidus.[8] Only one equilibrium crystalline phase could be found. Its refractive indices were found to vary continuously with the composition, as would be expected for a continuous series of solid solutions. This is illustrated in Fig. 3. The results of these optical measurements agree with the thermal data on the liquidus and solidus, and exclude from consideration the possibility of any type of eutectic relations in the system.

Optical Properties of the Various Phases

During the course of the work we have measured the refractive indices of the glasses and the crystals in the quenched samples. The data for the glasses are listed in Table I. No measurements could be made on annealed glasses, since all the vitreous preparations within the system devitrify rapidly at annealing temperatures. The value for Na_2SiO_3 glass, 1.517, is interpolated from the data of Morey and Merwin.[9]

The refractive indices of the various phases are plotted against the composition in Fig. 3.

The optical properties of crystalline Na_2SiO_3 and Li_2SiO_3 are already known.[10]

The properties of $NaLiSiO_3$, end-member of the Na_2SiO_3–$NaLiSiO_3$ series of solid solutions, as measured by H. E. Merwin, are:

Orthorhombic prisms with two good lengthwise cleavages; elongation || to γ; near endwise sections crystals show acute bisectrix or an optic axis, 2V very large. Refractive indices for Na light: γ 1.571, β 1.557, α 1.552, all within about 0.002.

In cleavage splinters, crystals of this compound bear a superficial resemblance

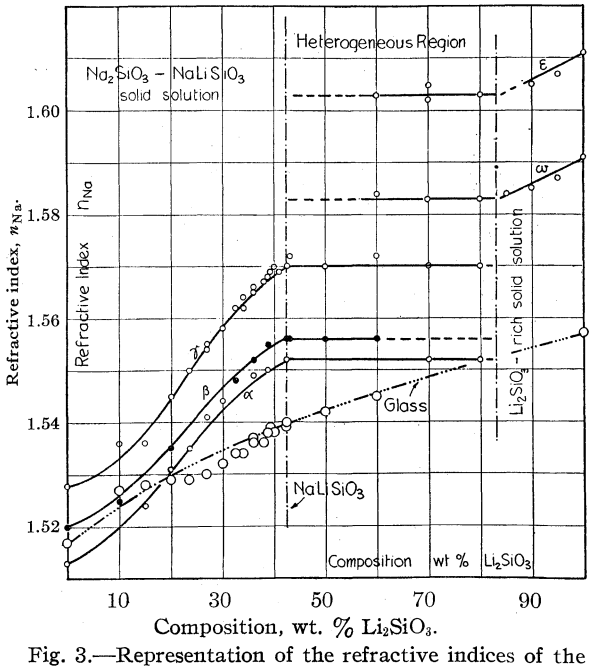

Fig. 3.—Representation of the refractive indices of the various phases in the system, Na_2SiO_3–Li_2SiO_3, as a function of the composition.

(8) I am indebted to my colleague H. E. Merwin for much valuable help on this question.

(9) G. W. Morey and H. E. Merwin, *J. Optical Soc. Am.*, **22**, 632 (1932).

(10) Na_2SiO_3: G. W. Morey and N. L. Bowen, *J. Phys. Chem.*, **28**, 1167 (1924). Li_2SiO_3: F. M. Jaeger, *Proc. K. Akad. Wet. Amsterdam*, **16**, 857 (1914); measurements by H. E. Merwin, in F. C. Kracek, *J. Phys. Chem.*, **34**, 2647 (1930).

to Li_2SiO_3, in spite of their lower indices of refraction. This resemblance is due to (1) a similarity of the cleavage habit, (2) similarity in the orientation with respect to the indices of refraction, and (3) comparable magnitudes of the birefringence, that of $NaLiSiO_3$ being somewhat smaller. It explains, at least in part, why Wallace[1] found crystals resembling Li_2SiO_3 in compositions as low as 30% Li_2SiO_3. However, crystals of the Li_2SiO_3-rich solid solutions sometimes are formed from the melt in mixtures of Li_2SiO_3 content lower than 39.3%, the equilibrium termination of the liquidus for this phase at the peritectic (see Fig. 2). Such crystals are metastable, and are formed occasionally when a melt is cooled rapidly to a temperature below the metastable extension of this liquidus. In the completely crystallized preparation they remain as inclusions within crystals of the stable Na_2SiO_3–$NaLiSiO_3$ solid solution. On reheating they redissolve before the solidus temperature is reached, and the preparation recrystallizes to the stable solid solution phase.

Acknowledgment.—I am indebted to my colleague H. E. Merwin for measurements of the optical properties of the compound, $NaLiSiO_3$, and for help in various other parts of this work.

Summary

The binary system, Na_2SiO_3–Li_2SiO_3, a binary section within the ternary system, Na_2O–Li_2O–SiO_2, contains an intermediate compound, $NaLiSiO_3$, which melts incongruently at 847 ± 1°. The liquidus consists of two branches. One of these begins at the melting point of Na_2SiO_3, 1089 ± 1°, falls to a minimum at 38.5 ± 0.2% Li_2SiO_3, 845 ± 1°, and then rises to its junction with the other branch at the peritectic point 39.3 ± 0.2% Li_2SiO_3, 847 ± 1°. The second branch of the liquidus rises from the peritectic point to the melting point of Li_2SiO_3, 1201 ± 1°. The primary phases in equilibrium with the liquid are two series of solid solutions. The first series extends from Na_2SiO_3 to $NaLiSiO_3$; the second series is a limited one, and ranges in composition from 83 ± 3 to 100% Li_2SiO_3. The optical properties of the various phases have been measured, and are reproduced graphically in a diagram giving the variation of the refractive indices with the composition.

"Effective Electron Density" and Chemical Behavior[1]

BY HEOU-FEO TSEOU

In a previous exposition a theory was proposed by us for the explanation of various types of organic reactions.[2] The purpose of the present paper is to show the concordance which it bears to the chemistry of other elements than carbon.

The essential idea of the theory was that as concerned with chemical properties an element may be imagined not to occupy a fixed position in the periodic table but it changes as the position of a part of the outer electrons is affected by certain adjoined atoms or groups of atoms; an inward shift causes a displacement of the element to the right side in the periodic series, while an outward shift displaces it toward the left side. The change as stated should be most conspicuously reflected in a change of its effective atomic radius which corresponds to what we call a compact or open octet.[3] If this statement is universally true, then it would follow as a logical sequence that, in passing through a periodic series, a constant decrease in atomic radius will be observed as the atomic number of the elements increases. To testify to the validity of the statement the atomic dimensions of the first three short periods are collected in Table I.

A glance at the table will show immediately that these values arranged in the descending order fit in nicely with our postulate. Note should be taken that these are the dimensions of covalent linkages, which are what we have uniquely dealt with in organic reactions. These measurements

(1) This article has been edited, with the author's consent, by a member of the Editorial Board. Except insofar as a few examples have been retained to clarify the principles formulated, the author's applications of his theory have been omitted. It seems better to leave the applications to the reader's imagination than to attempt what must be a too limited discussion.—THE EDITOR.

(2) Tseou, "A New Electronic Theory of Organic Reactions," 1937.

(3) The change of atomic radius of the carbon atom in different organic compounds as shown to be complying with the author's postulation rules is given in a table in the chapter "Evidence of Physical Measurements."

TABLE I

Element	H^4						
r	0.375						
Element	Li^5	Be^5	B^4	C^6 aliph.	N^4	O^4	F^4

Element	K^5	Ca^5	Sc	Ti^5	V^5	Cr^5	Mn^5
r	2.31	1.97	..	1.45	1.30	1.25	1.18

r = effective atomic radius in Å.

offer actually a most suitable means for comparing the chemical behavior of the different elements, which, as shown in our previous article, is dependent on the compactness of the outermost electronic shell of the atoms. A closer observation shows that the compactness of an octet is concerned with two factors: (a) the effective atomic radius r and (b) the number of outermost electrons n properly allocated to the particular atom. The oxygen atom linked by a semi-polar bond to sulfur in sulfoxides or sulfones, for example, may be considered to contain seven outer electrons instead of six. We propose to use a new term "effective electron density" as a determining quantity of the chemical behavior and denote its relative magnitude by the empirical formula n/r. To state it in other words, the effect of each outer electron to be displaced toward the atomic center during the formation of a link is a linear function of its distance from the nucleus $(1/r)$, and the total relative effect of all the outermost electrons is expressed by the term n/r.

TABLE II

Element	H						
n/r	2.70						
Element	Li	Be	B	C, aliph.	N	O	F
n/r	0.66	1.78	3.37	5.19	7.14	9.09	10.9

Triple Bonds

Element	C	N
r	0.60	0.55
n/r	6.66	9.09

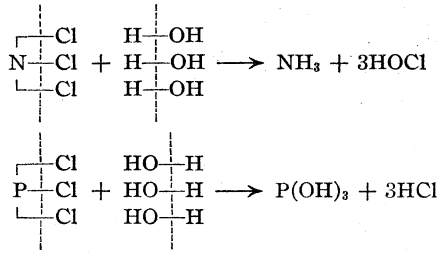
[a] Aromatic resonance between single and double bonds.

In reading over the elements listed above it will be remarked that potassium and sodium stand foremost among the electropositive elements, while trebly linked nitrogen and doubly linked oxygen are the most electronegative ones, the latter, being joined to other elements by two or three electron pairs each exercising an effect comparable with that of fluorine, possessing the greatest capacity of displacing electrons away from the multiply bonded atoms. Trebly linked carbon possesses an "effective electron density" nearly as high as the singly linked nitrogen, a fact which complies with the formation of stable metallic acetylides, the metal being joined to the carbon by a single bond. The position of hydrogen is peculiar. It has long been taken as electrodual in character; for, although univalent, it exhibits no property of the alkali metals or of the halogens. Its abased position in the electrochemical series together with its characteristic behavior revealed in organic and other non-dissociated compounds point to the conclusion that it should occupy a particular position in the periodic table. As indicated in Table II it is more electronegative than beryllium and aluminum, although somewhat more positive than boron and carbon. This estimation coincides with its behavior revealed in different types of organic reactions described in our previous treatise.

In the table the effective electron density of chlorine is shown to be remarkably low in comparison with fluorine and oxygen. This accounts for the relative electropositivity of the atom in many covalently linked compounds. One conspicuous example is the chlorine atom in hypochlorous acid and metallic and alkyl hypochlorites. Chlorine atoms in chloric and perchloric acids are really comparable with boron and carbon in boric and carbonic acids. Hypofluorous, fluoric and perfluoric acids are for example unknown (see below). The small orientation capacity of chlorine in chlorobenzene vis-à-vis the hydroxyl and amino groups in phenols and aniline and the comparative inertness of alkyl and aryl halides also point in the same direction. Indeed, numerous reactions, especially organic ones, become interpretable only when chlorine atoms in certain compounds are regarded as electropositive

(4) Pauling, *Proc. Natl. Acad. Sci. Wash.*, **18**, 293 (1932).
(5) Neuburger, "Gitterkonstanten," Leipzig, 1931.
(6) Wierl, *Ann. Physik*, **8**, 521 (1931).

in nature, although in electrovalency the element is invariably negative. As one of the most simple and convincing examples showing the electron density relationships among chlorine, nitrogen and phosphorus can be cited the hydrolysis of nitrogen and phosphorus chlorides.



It is obvious that the different courses taken by the two halides in hydrolysis are simply due to the fact that the e. e. d. (effective electron density) of chlorine is just situated intermediate between those of nitrogen and phosphorus.

It is a remarkable fact that carbon is the most prominent element capable of forming stable polyatomic compounds. The explanation formulated by us has been that its position is right in the vicinity of the equilibrium point, which condition entails little strain in its atomic linkings[2] (p. 141). The element which comes next appears to be sulfur. This can be well predicted from the data in Table II. In polysulfides, which are compounds very easily formed, many sulfur atoms are connected in series or in ring forms, and elementary sulfur itself is shown to be a very stable octa-atomic ring which can be scarcely attacked by common reagents. On the other hand, an element with an effective electron density very different from that of carbon does not form stable and inert polyatomic chains. Thus the linkages between oxygen atoms (e. e. d. = 9.09) are so unstable that peroxides and ozonides are generally explosive. The equilibrium point of effective electron density is probably nearer to that of aromatic carbon (5.71) than to that of aliphatic carbon (5.19).

Covalent linkages between atoms having very different effective electron densities degenerate to ionic linkages. Thus the stepped line dividing the electrovalent and covalent chlorides shown in Table IV is a line separating elements with effective electron densities greater than 1.7 from those with smaller values.

TABLE IV

H			
Li	Be	B	C
Na	Mg	Al	Si
K	Ca	Sc	Ti

The expansion of a valence shell should be considered as a mechanism for the increase of an effective electron density to a value that permits the formation of covalent bonds.

Summary

It is pointed out that many properties of an element depend on the density of its valence electrons in a covalent compound.

This characteristic is called the effective electron density, and is determined from the number of valence electrons and the covalent atomic radii of the metals.

In doubly and triply bonded atoms the radii are smaller and the effective electron densities are higher than in singly bonded atoms.

High effective electron densities are associated with high electronegativity. Stable polyatomic chains are associated with elements that have intermediate effective electron densities. Covalent bonds between atoms of high and low effective electron densities degenerate to ionic linkages.

Some Studies in the System Zinc Acetate–Hydrogen Chloride–Acetic Acid

BY ARTHUR W. DAVIDSON AND WILBERT CHAPPELL

In previous papers from this Laboratory and elsewhere, numerous similarities have been pointed out between solutions of acids, bases and salts in anhydrous acetic acid on the one hand, and familiar aqueous systems on the other. As yet, however, few acetic acid systems containing analogs of so-called acid or basic salts have been described. It is obvious that the anhydrous ternary systems zinc chloride–zinc acetate–acetic acid and zinc chloride–hydrogen chloride–acetic acid might be regarded as analogous, respectively, to zinc chloride–zinc oxide–water and zinc chloride–hydrogen chloride–water; and that in the former case basic salts might be expected to occur, in the latter case, acid salts.

The study of equilibria between solid and liquid phases in binary solutions of zinc chloride in acetic acid presents extraordinary difficulties because of the extremely high viscosity of the concentrated solutions, which, as previously noted by Reddelien,[1] form thick sirups at ordinary temperatures. The same difficulty arises also in ternary solutions containing hydrogen chloride. Hence, except for a rough determination of the solubility of zinc chloride, the quantitative data obtained for these "neutral" and "acid" systems are limited to solutions from which acetic acid separates as solid phase. It was found possible, however, to investigate the "basic" system over a considerable concentration range at 30°, and to isolate two "basic" salts in the solid state.

Method

Preparation of Materials.—Pure anhydrous acetic acid and zinc acetate were prepared as described in previous papers of this series.[2]

Because of the difficulty of preparing and handling anhydrous zinc chloride, no attempt was made to use the solid salt, except in preliminary qualitative experiments. It was found, however, that a solution of zinc chloride in acetic acid might be obtained readily by the passage of dry hydrogen chloride over dry zinc acetate; a metathetic reaction takes place, which may be regarded as a neutralization

$$Zn(C_2H_3O_2)_2 + 2HCl = 2HC_2H_3O_2 + Zn^{++} + 2Cl^-$$

Gaseous hydrogen chloride, prepared in the usual manner, was dried by passage through two towers filled with glass wool which had been moistened with anhydrous sulfuric acid. The gas was then passed into a flask containing zinc acetate (suitably protected from atmospheric moisture), and the mixture was warmed, with gentle agitation; gradual liquefaction resulted, in accordance with the above equation. After all the solid had disappeared, the solution, which contained at this stage a slight excess of hydrogen chloride, was analyzed both for chlorine and for zinc; the former was determined gravimetrically, the latter by titration against potassium ferrocyanide solution, with uranyl nitrate solution as an external indicator. From these data the amount of excess hydrogen chloride was calculated, and zinc acetate was added to the solution in quantity just sufficient to react with this excess. Thus a mixture containing 1 mole of zinc chloride to 2 of acetic acid was obtained; this was used as a stock solution, from which more dilute solutions were prepared by the addition of acetic acid.

Binary System $ZnCl_2$–$HC_2H_3O_2$.—Cryoscopic determinations were made, as described in previous papers, on samples of known composition prepared by dilution of the stock solution. The freezing points reported, except for concentrations of above 16 mole % of solute, are believed to be correct to within 0.1°. Up to a concentration of 22 mole %, only acetic acid was obtained as solid phase. Beyond this point the solutions became so viscous that they yielded no solid phase on cooling.

Reddelien[1] gave the solubility of zinc chloride in glacial acetic acid at 15° as 47.8 g. per 100 cc. of solution. While this figure, in the absence of density data, cannot be exactly interpreted, it appears to be much too low, for even our 33.33 mole % solution proved to be still unsaturated at 30°. Some of this solution was warmed with an excess of solid zinc chloride and then maintained in contact with the solid at 30°, with occasional agitation, for three months. Before the end of this period, additional crystals were observed to have separated out. Samples of the extremely viscous solution, upon analysis, showed 40.1 mole % of zinc chloride. Since the solid used may not have been absolutely anhydrous and since equilibrium was approached from supersaturation, this figure may be regarded only as a maximum value for the solubility of zinc chloride at 30°.

Ternary System $ZnCl_2$–HCl–$HC_2H_3O_2$.—Solutions containing zinc chloride in proportions up to 33.33 mole %, and saturated with hydrogen chloride, yielded, on cooling, no solid phase other than acetic acid. In many cases such solutions, even on being cooled to liquid air temperatures, showed no tendency to crystallize, but merely set to glassy solids. A few cryoscopic determinations were made, however, upon dilute solutions containing both zinc chloride and hydrogen chloride, in the following manner. Freezing point measurements were first made on solutions of hydrogen chloride, the composition of which had been determined by analysis. Then small weighed quantities of concentrated zinc chloride solution were added, and the freezing points were again determined. Because of the

(2) Davidson and McAllister, THIS JOURNAL, **52**, 512, 519 (1930).

relatively high vapor pressure of hydrogen chloride from dilute solutions in acetic acid,[3] no great accuracy is claimed for these results.

Ternary System $ZnCl_2$–$Zn(C_2H_3O_2)_2$–$HC_2H_3O_2$.—Equilibrium in this system at 30° was studied by the analytical method; because of the high viscosity of many of the solutions, seeding was necessary in order that equilibrium might be attained in a reasonable time. Portions of the stock solution referred to above were diluted to the desired extent with acetic acid, and varying quantities of zinc acetate were added. The mixtures were placed in glass-stoppered bottles, heated until all of the solid had dissolved, cooled to about 40° and seeded with the appropriate solid phase, as determined from preliminary experiments. The bottles were then sealed, placed in a thermostat maintained at 30°, and agitated mechanically for about two weeks. (Preliminary experiments had shown this time to be sufficient for the attainment of equilibrium, even in the most viscous of the solutions.) The solutions were then allowed to stand for a day in order to allow complete settling of the solid phase, portions of the liquid were withdrawn, and their zinc and chlorine contents were determined as described above. The proportions of zinc chloride and of zinc acetate were calculated from these analyses, and that of acetic acid was determined by difference. It was found possible to investigate this system up to concentrations of almost 30 mole % (48% by weight) of zinc chloride, beyond which point the solutions were too viscous to permit reliable results to be obtained.

The composition of solid phases was determined both by direct analysis of crystals which had been freed from mother liquor by means of filtration and pressure between porous tiles, and by the Schreinemakers method of analysis of wet residues.

Results

1. Freezing Point Data.—In Table I, S denotes the mole percentage of zinc chloride in the binary solution, and T is the temperature at which the solution is in equilibrium with solid acetic acid.

TABLE I

ZINC CHLORIDE–ACETIC ACID

S	T	S	T
0	16.60	12.88	8.55
1.77	15.75	14.14	7.30
3.46	14.95	16.16	4.80
4.31	14.45	17.80	2.8
7.31	12.85	18.45	2.0
9.67	11.45	22.07	−4.0
10.99	10.35		

In Table II, S_1 and S_2 denote the mole percentages of zinc chloride and of hydrogen chloride, respectively, in the mixed solution, and Δ_1 and Δ_2 are the freezing point depressions corresponding to these mole percentages of solute in the respective binary systems.[4] R is the ratio of the number of moles of zinc chloride to the number of moles of hydrogen chloride, and Δ_3 is the observed freezing point depression in the mixed solution.

TABLE II

ZINC CHLORIDE–HYDROGEN CHLORIDE–ACETIC ACID

S_1	Δ_1	S_2	Δ_2	R	$\Delta_1 + \Delta_2$	Δ
2.53	1.22	0.74	0.44	3.42	1.66	1.05
1.60	0.78	1.50	1.03	1.07	1.81	0.75
0.57	.30	1.51	1.04	0.38	1.34	.95

It will be noted that, in each case, Δ_3 is much less than the sum of Δ_1 and Δ_2.

2. System $ZnCl_2$–$Zn(C_2H_3O_2)_2$–$HC_2H_3O_2$.—In Table III, S_1 and S_2 represent the mole percentages of zinc chloride and of zinc acetate, respectively, in the ternary solution which is in equilibrium, at 30°, with the solid phase indicated. These data are also represented graphically in Fig. 1.

TABLE III

4.99	1.17	28.91	1.07
6.18	1.43	29.36	0.828

[a] Ref. 2, p. 522.

The mean of four analyses on dried samples of the solid phase B, from solutions of different composition, gave Zn, 41.3%; Cl, 22.5% (calcd. for $Zn(C_2H_3O_2)Cl$: Zn, 40.9%; Cl, 22.2%). Because of the hygroscopic nature of this compound, and the difficulty of completely removing the very viscous mother liquor from it, it seemed desirable to supplement these analyses by determinations made by the Schreinemakers method. Accordingly, tie-lines through six pairs of corresponding compositions of solution and wet residue were plotted on a triangular diagram (not reproduced here), and were found to intersect the $Zn(C_2H_3O_2)_2$–$ZnCl_2$ axis at a point corresponding to 49.88 mole % $Zn(C_2H_3O_2)_2$, 50.12 mole % $ZnCl_2$. This result confirms the analysis of the dried salt, and

(4) The values for Δ_1 and Δ_2 were determined by interpolation, from plots which for space considerations are not reproduced here.

shows the solid phase to be a compound of the composition $Zn(C_2H_3O_2)_2 \cdot ZnCl_2$, or $Zn(C_2H_3O_2)Cl$, which may be regarded as a basic salt of the acetic acid system.

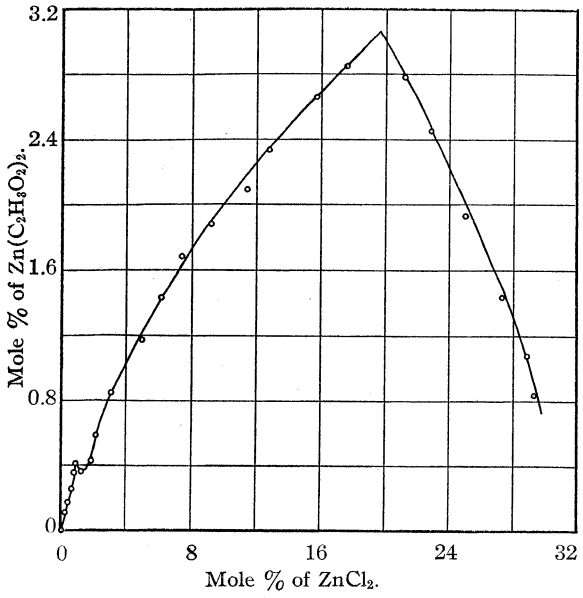

Fig. 1.—System $ZnCl_2$–$Zn(C_2H_3O_2)_2$–$HC_2H_3O_2$ at 30°.

The mean of two analyses of solid phase C (which was very sticky when moist and could be dried only with difficulty) gave Zn, 43.4%; Cl, 35.5% (calcd. for $Zn(C_2H_3O_2)Cl \cdot ZnCl_2$: Zn, 44.1%; Cl, 35.9%). Again these results were checked by the method of wet residues; tie-lines through four pairs of corresponding compositions of solution and wet solid intersected the $Zn(C_2H_3O_2)_2$–$ZnCl_2$ axis of the triangular diagram at a point corresponding to 23.72 mole % $Zn(C_2H_3O_2)_2$, 76.28 mole % $ZnCl_2$. These results prove the compound to be a second basic salt of the composition $Zn(C_2H_3O_2)_2 \cdot 3ZnCl_2$, or $Zn(C_2H_3O_2)Cl \cdot ZnCl_2$.

The composition of solid phase A was determined by means of wet residues only. Wet residues from this portion of the system contain only very small amounts of chlorine, and hence the tie-lines lie very close to the $Zn(C_2H_3O_2)_2$–$HC_2H_3O_2$ axis, and are almost parallel to it. Since it has been found in previous work[2,5] that zinc acetate forms no solvates with acetic acid, it may be safely concluded that this solid phase consists of unsolvated zinc acetate.

It may be seen from Fig. 1 that at 30° the solubility of zinc acetate increases from 0.0025 mole % in pure acetic acid to a maximum of about 0.41 mole % in a solution containing about 0.93 mole % of zinc chloride. With the appearance of a new solid phase, the proportion of zinc acetate in the saturated solution at first falls off slightly with increasing concentration of zinc chloride, then rises to a maximum of about 3% at approximately 20% of zinc chloride. Here another new phase appears, and thereafter the proportion of zinc acetate again declines sharply with increasing concentration of chloride.

(5) Davidson and Griswold, THIS JOURNAL, **57**, 423 (1935).

Discussion

Zinc chloride is found to be by far the most soluble in acetic acid of any salt so far studied, its saturated solution at 30° containing more than 11 moles per 1000 g. of solvent.

Freezing point data for this salt show that the value of j, the freezing point divergence function, remains practically constant at 0.74 for molalities from 0.3 to 1.3. Such constancy in the value of j, while quite contrary to the behavior of aqueous solutions, appears to be characteristic of most salt solutions in acetic acid.[6]

With regard to the system $ZnCl_2$–HCl–$HC_2H_3O_2$, although it would be unwarranted to attempt to draw quantitative conclusions as to the molecular complexity of ionizable solutes from cryoscopic data, yet the relatively small freezing point depressions in solutions containing both zinc chloride and hydrogen chloride point strongly toward the formation of some sort of addition compound between the two solutes. Hildebrand and Bowers[7] have presented evidence of the existence of a complex acid, of the composition $HZnCl_3$, in dilute aqueous solution, and hydrates of this acid and of HZn_2Cl_5 have been obtained in the solid state[8]; no such complex has as yet been isolated from acetic acid solutions, however.

The system $ZnCl_2$–$Zn(C_2H_3O_2)_2$–$HC_2H_3O_2$, as has been stated previously, may be regarded as analogous to the system $ZnCl_2$–ZnO–H_2O, which has been studied recently by Feitknecht[9] and by Holland.[10] It is of interest to note that both of these observers isolated the compound $ZnCl_2 \cdot ZnO \cdot H_2O$, or Zn(OH)Cl, of which the exact analog, $Zn(C_2H_3O_2)Cl$, was found to be stable over a considerable range of concentrations in the present work. The other "basic" salt found here, Zn-

$(C_2H_3O_2)Cl \cdot ZnCl_2$, is analogous to the compound $Zn(OH)_2 \cdot 3ZnCl_2$, or $Zn(OH)Cl \cdot ZnCl_2$, earlier described by Ephraim.[11] Neither of these aquobasic salts can be dissolved in water without decomposition, but, like their acetic acid analogs, they are stable in contact with solutions containing a large excess of zinc chloride.

Summary

1. A convenient method of preparing anhydrous zinc chloride–acetic acid solutions has been devised, and the freezing points of such solutions, over a wide concentration range, have been determined.

2. Evidence for the presence of an addition compound of zinc chloride and hydrogen chloride, even in dilute solution in acetic acid, has been obtained.

3. The system $ZnCl_2$–$Zn(C_2H_3O_2)_2$–$HC_2H_3O_2$ has been studied at 30°. Two new double salts, $Zn(C_2H_3O_2)Cl$ and $Zn(C_2H_3O_2)Cl \cdot ZnCl_2$, have been isolated and analyzed.

Effect of Polar Groups upon Esterification Velocities of Substituted Benzoic Acids with Cyclohexanol

BY R. J. HARTMAN, L. B. STORMS[1] AND A. G. GASSMANN

The effect of substituents on the reaction velocity of various compounds has long been of interest. There have been attempts made to group the effect of substituents under a single theory. Williams[2] classifies reactions into three groups according to the effect of polar substituents on reaction rates as follows: (A) those favored by accession of electrons to the point of reaction; (B) those favored by recession of electrons from the point of reaction; and (C) those in which the data available are insufficient to classify in either group A or B. Of the three esterification studies cited by Williams, two, those by Goldschmidt[3] and Kailan[4] are in group C. The third, by Michael and Oeschlin[5] is placed in group B, *i. e.*, the esterification reaction was accelerated by a substituent such as the nitro group. Hammett[6] has expressed the effect of a substituent in the meta or para position on the benzene ring upon the rate of a side chain reaction by the equation

$$\log k = \log k_0 + \sigma\rho$$

where k is the velocity constant for the substituted reactant, k_0 the constant for the unsubstituted reactant, σ a constant depending upon the substituent, and ρ a constant depending on the reaction, medium, and temperature. Hammett found a probable error for log k of less than 0.1 in thirty-three of thirty-nine reactions, including equilibrium as well as velocity constants. The equation was applied to the esterification work of Goldschmidt.[3] The probable error found was 0.118. Hartman and Borders[7] applied the equation to the esterification of substituted benzoic acids with methanol. They found an average error of 0.058. The values of σ used in the work of Hartman and Borders as well as those used in this work were taken from Hammett[6] and were determined by him from the data of Dippy[8] for the dissociation constants in water of substituted benzoic acids.

The object of this investigation was to determine the velocity constants of hydrion-catalyzed esterification of substituted benzoic acids with cyclohexanol. Using the data thus obtained, the energies of activation are determined in order to analyze the data from the point of view of the Arrhenius equation. Hammett's equation is tested for its applicability to the esterification of the cyclic alcohol, cyclohexanol.

Experimental

Materials.—Pure cyclohexanol was first dried by the method of Bjerrum and Lund[9] and then by refluxing over calcium oxide. The acids were

(1) This paper is constructed from a dissertation presented by Lee B. Storms to the Faculty of the Graduate School of Indiana University in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry.

purchased from the Eastman Kodak Co. They were dried carefully over phosphorus pentoxide.

Procedure.—The experimental procedure was the same as that followed by Hartman and Borders.[7] The concentration of hydrogen chloride used was 0.1 normal. The thermostats were maintained at 55.00, 60.00, 70.00 and 75.00 ± 0.01°.

Calculations.—The velocity constants were calculated using the formula developed by Goldschmidt[10] which corrects for the retardation of esterification caused by the water formed in the course of the reaction

$$k = \frac{[(a + r) \ln a/a - x] - x}{rct}$$

where a is the original acid concentration, x the amount of acid esterified at time t, and c the H^+ concentration. The units are g. mole/liter/sec. The constant r allows for the retardation of the hydrion-catalyzed esterification by water. The values used in this investigation were calculated by the method of Williamson and Hinshelwood,[11] and were

t	55	60	70	75
r	0.10	0.19	0.31	0.40

The average value of k at each temperature is reported for the determination in which k varied the least. The values of the energy of activation were calculated in the usual way by means of the Arrhenius equation.

Results and Discussion

TABLE I

VELOCITY CONSTANTS AND ENERGIES OF ACTIVATION FOR HYDRION-CATALYZED ESTERIFICATION OF AROMATIC ACIDS WITH CYCLOHEXANOL

Acid	$k \times 10^5$ 55°	60°	70°	75°	Energy of activation, E
o-Nitrobenzoic	...	0.625	1.44	2.20	20,000
o-Toluic	0.889	1.34	2.52	4.26	17,800
o-Bromobenzoic	1.21	1.72	3.92	5.59	17,400
p-Toluic	1.45	2.16	5.03	7.81	19,500
o-Chlorobenzoic	1.61	2.35	5.26	7.31	17,500
m-Toluic	2.03	2.94	6.26	9.08	16,900
Benzoic	2.21	3.25	7.19	10.88	17,700
p-Chlorobenzoic	2.41	3.71	7.60	11.14	17,100
m-Bromobenzoic	2.83	4.26	8.77	12.47	17,000
m-Chlorobenzoic	2.96	4.07	8.55	12.14	15,900
m-Nitrobenzoic	3.05	4.30	10.57	15.91	18,300

Table II gives the values of log k_{55} obtained in this investigation for the esterification of the meta and para substituted benzoic acids and the corresponding values as calculated from Hammett's equation. The value of ρ adopted, 0.262, was obtained by the least squares method (see Hammett[6]).

TABLE II

COMPARISON OF LOG k_{55} OBSERVED WITH LOG k CALCULATED WITH THE EQUATION: LOG $k = -4.656 + \sigma$ (0.262)

Acid	Log k, obsd.	Log k, calcd.	Error
m-Toluic	−4.692	−4.674	0.018
p-Toluic	−4.839	−4.701	.138
p-Chlorobenzoic	−4.618	−4.596	.022
m-Bromobenzoic	−4.548	−4.554	.006
m-Chlorobenzoic	−4.529	−4.558	.029
m-Nitrobenzoic	−4.516	−4.470	.046
		Av.	.043

The average error of log k for the work of this investigation was 0.043. This compares favorably with the mean of probable errors of less than 0.1 found by Hammett[6] for a series of thirty-nine reactions, and of 0.122 for the data of Goldschmidt.[3] Hartman and Borders[7] report an average error of 0.054. The authors recalculated the value of ρ from the data of Hartman and Borders and found it to be − 0.53 instead of − 0.58 which they reported. Using this corrected value of ρ together with the values of σ given by Hammett,[6] their average error is found to be 0.049 instead of 0.054 as reported.[7] The results presented here indicate that the equation of Hammett can be applied to the esterification of cyclic alcohols.

Ortho substituted acids are not included in Hammett's theory. Since the effect of a substituent in the ortho position upon the velocity of side chain reactions is of an entirely different mechanism from that of the meta and para substituted acids, the velocity of the ortho substituted acids is not discussed here.

The outstanding difference in the order of the esterification of substituted acids with cyclohexanol and with methanol is that the order is practically reversed. Hartman and Borders[7] found that the order of decreasing speed of esterification with methyl alcohol is *m*-CH_3 > *p*-CH_3 > *m*-Br > *m*-Cl > *p*-Cl > *p*-NO_2. The order found by the authors for cyclohexanol is *m*-NO_2 > *m*-Cl > *m*-Br > *p*-Cl > *m*-CH_3 > *p*-CH_3. It should be noted that the value of ρ for methanol reported by Hartman and Borders is negative, whereas that found in this investigation for cyclohexanol is positive. This change in sign probably accounts for the reversal of the order of the esterification with cyclohexanol

(10) Goldschmidt, *Ber.*, **39**, 711 (1906).

(11) Williamson and Hinshelwood, *Trans. Faraday Soc.*, **30**, 1145 (1934).

Evans, Morgan, and Watson[12] found in the bromination of substituted acetophenones what they considered to be a significant variation in the non-exponential factor, P, of the Arrhenius equation: $k = PZe^{-E/RT}$. Nathan and Ingold[13] criticized this conclusion because the range of velocities was not sufficient for accurate separation of the factors E and P. This criticism of these factors might also apply to the present work because the ratio of the velocity of the fastest to the slowest acid is only 3.4 to 1.

The change in the various factors of the Arrhenius equation may be analyzed at least qualitatively by plotting the values of E for the various acids against log k_{55}. This relationship is shown in Fig. 1. If the change in the velocity of esterification of the acids produced by the substituents were entirely dependent upon changes in E, a straight line having a slope of $2.303RT$ would be obtained. The solid line in Fig. 1 represents an approximate graphical average obtained from plotting the data of this investigation. The broken line represents the theoretical line having a slope of $2.303RT$. If the experimental line can be considered to be approximately correct, it is apparent that the two lines have nearly identical slopes. The scattered points obtained from the data, however, indicate that such a conclusion cannot be drawn with certainty. If the line can be regarded as nearly true, it could be concluded that the steric factor, P, does not undergo an appreciable change in the Arrhenius equation. As has been pointed out already, however, the small range of velocities studied and the effect of large experimental error at high temperatures upon the values of E, precludes the possibility of a positive statement of this point.

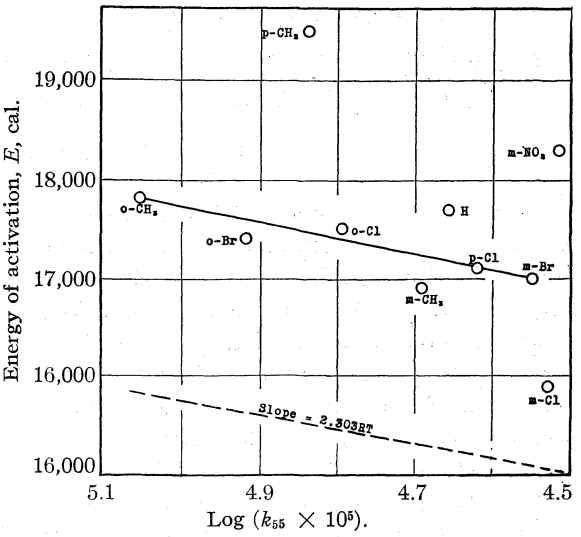

Fig. 1.—Relationship between speed of reaction and activation energy.

Summary

1. The investigation of the effect of polar substituents on the reaction velocity of hydrion-catalyzed esterification of substituted benzoic acids with cyclohexanol shows that the velocity is decreased by the displacement of electrons toward the carboxyl group.

2. Excellent agreement was found between the experimental values of log k for the esterification reactions and the values calculated from Hammett's equation. This equation is therefore applicable to the esterification of cyclohexanol.

3. It appears that the value of E in the Arrhenius equation is the chief factor in determining the velocity of esterification.

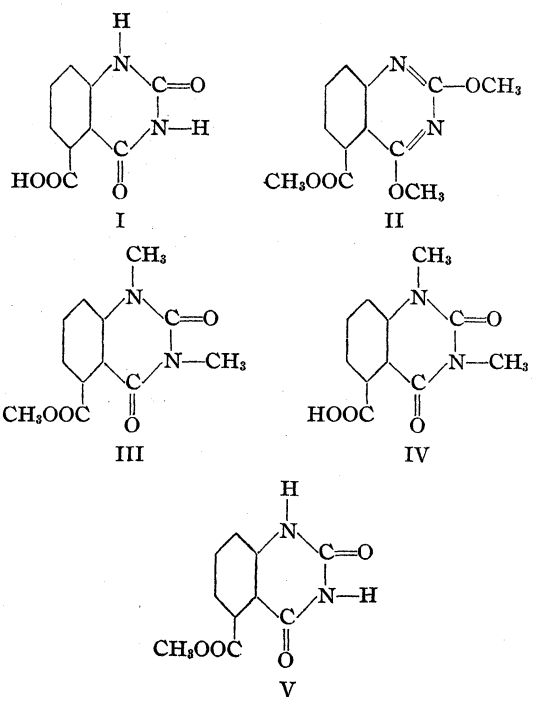
Quinazolines. VIII. The Methyl Esters of 1,3-Dimethylbenzoylene-urea-5-carboxylic Acid and 2,4-Dimethoxyquinazoline-5-carboxylic Acid

BY N. A. LANGE, DOUGLAS C. CHISHOLM[1] AND J. LESTER SZABO

Scott and Cohen[2] prepared benzoylene-urea-5-carboxylic acid (2,4-diketo-1,2,3,4-tetrahydroquinazoline-5-carboxylic acid) (I). In reaction with dimethyl sulfate in alkaline solution, it yielded a product to which they assigned structure II. In previous studies of this method of alkylation of compounds of type I, it has been found that —NCH_3CO— derivatives invariably are formed and not —N=$COCH_3$— derivatives.[3-5]

A reinvestigation by the authors of the work of Scott and Cohen shows conclusively that their product is actually methyl 1,3-dimethylbenzoylene-urea-5-carboxylate (III). In confirmation of this claim, methyl 2,4-dimethoxyquinazoline-5-carboxylate (II) was prepared from I by the reaction with phosphorus pentachloride to yield the chloride of 2,4-dichloroquinazoline-5-carboxylic acid, followed by replacement of the halogen with three methoxy groups through the use of sodium methoxide.



I II III IV V

As was to be expected, it has been found that the quinazoline in question reacts tautomerically to yield either O,O- or N,N-dimethyl derivatives and Zeisel determinations have shown that the Scott–Cohen product conforms to structure III and ours to structure II.

Experimental Part

Benzoylene-urea-5-carboxylic acid (2,4-diketo-1,2,3,4-tetrahydroquinazoline-5-carboxylic acid) (I) was prepared by the method of Scott and Cohen.[2] It forms colorless, shining, micro crystals, m. p. 346° (copper block, uncorr.). Scott and Cohen reported that this compound does not melt below 320° but sublimes slowly above 280°. The *p*H of a saturated aqueous solution of this acid was found to be 2.9 (quinhydrone electrode).

1,3-Dimethylbenzoylene-urea-5-carboxylic acid (1,3-dimethyl-2,4-diketo-1,2,3,4-tetrahydroquinazoline-5-carboxylic acid) (IV), prepared by the method of Scott and Cohen,[2] from I in alkaline solution and dimethyl sulfate, crystallized from dilute alcohol in minute needles, m. p. 318° (uncorr.). It is sparingly soluble in water or alcohol but dissolves in alkalies, from which it is precipitated unchanged on the addition of acids, even after prolonged boiling of the alkaline solution.

Methyl Benzoylene-urea-5-carboxylate (Methyl 2,4-diketo-1,2,3,4-tetrahydroquinazoline-5-carboxylate) (V).—Since the method described by Scott and Cohen for the preparation of III was found to proceed much slower than claimed and invariably resulted in a mixture of III and IV, experiments were made in the hope of improving their method of preparation. More satisfactory results were obtained by first esterifying the carboxyl group of I and then alkylating the two nitrogen atoms. Two grams of benzoylene-urea-5-carboxylic acid (I) was placed in a flask equipped with reflux condenser, 40 cc. of anhydrous methyl alcohol was added, and dry hydrogen chloride passed into the gently boiling mixture for four hours. The solution was allowed to cool while still passing in hydrogen chloride until it was completely saturated at room temperature; after standing overnight it was heated to boiling and more hydrogen chloride was passed in. On cooling, fine, colorless needles separated which were collected, washed with water, and dried; m. p. 318° (uncorr.). An extraction of this product with dilute sodium carbonate solution to remove any unreacted I, followed by crystallization of the undissolved residue from ethyl alcohol gave fine colorless needles of methyl benzoylene-urea-5-carboxylate (V), m. p. 307–309° (uncorr.). Scott and Cohen reported that this compound turns yellow at 180° and melts at 310–312°.

This ester (V) is best prepared by treating the acid (I)

with thionyl chloride to form the carboxylic acid chloride, thus avoiding the introduction of halogen into the ring at the 2,4-positions, which occurs when phosphorus pentachloride is used.[6] The acid chloride on treatment with anhydrous methyl alcohol gave the desired ester (V). To 8 g. of the quinazoline carboxylic acid (I) 100 cc. of thionyl chloride was added and the mixture refluxed for three and one-half hours, after which it was allowed to stand overnight. The excess thionyl chloride was decanted from residual solids and the latter placed in a desiccator containing calcium chloride and alkali. This crude material formed colorless clusters of thin plates and micro prisms which darkened when heated to 300° and melted at 331–332° (uncorr.) with decomposition. Attempts to recrystallize this material were not successful because of its insolubility in hot or cold chloroform, carbon tetrachloride, benzene, xylene, anisole or thionyl chloride. On titration with standard silver nitrate solution the chlorine content indicated a purity of 90% acid chloride. Refluxing this product with various anhydrous alcohols and with ammonia gave products which were purified by recrystallization but not analyzed and which are most likely the following derivatives: methyl ester, colorless, thin, micro, needle-like plates, m. p. 318°; ethyl ester, colorless, thin, micro, needle-like plates, m. p. 297–299°; benzyl ester, colorless, shining, thin, irregular plates, m. p. 257–261°; amide, colorless, cotton-like, micro needles, m. p. 359°, this last, when mixed with the carboxylic acid (I) gave a melting point of 338°. These melting points are uncorrected.

Methyl 1,3-Dimethylbenzoylene-urea-5-carboxylate (Methyl 1,3-Dimethyl-2,4-diketo-1,2,3,4-tetrahydroquinazoline-5-carboxylate) (III).—Four grams of the crude acid chloride and 150 cc. of anhydrous methyl alcohol were refluxed several hours, a part of the material remaining undissolved. The mixture was placed in a refrigerator overnight and the undissolved solids filtered off and partially dried. The 4.6 g. of crude ester (V) obtained in this way was dissolved in a solution of 4 g. of potassium hydroxide in 30 cc. of water, and 4.5 g. of dimethyl sulfate added with vigorous shaking. This mixture was allowed to stand overnight at room temperature and then placed in a refrigerator. The crystalline material which separated was filtered off, washed with water and dried; yield about 1 g. Crystallization from a small amount of methyl alcohol gave a product which is not volatile with steam and which forms very long (sometimes 3–4 cm.), colorless needles, m. p. 144.4–145.5° (corr.). Scott and Cohen[2] reported a melting point of 144° for this product. It is unaffected by boiling for a short time with hydrochloric acid; prolonged boiling, however, causes gradual hydrolysis of the ester group.

Anal. Calcd. for $C_{11}H_9O_3N_2(OCH_3)$: CH_3O, 12.50. Found: CH_3O, 12.38, 12.61.

Methyl 2,4-Dimethoxyquinazoline-5-carboxylate (II).—One gram of pure benzoylene-urea-5-carboxylic acid (I), 5 g. of phosphorus pentachloride, and 1.4 cc. of phosphorus oxychloride in an acetylating flask were refluxed in an oil-bath until all of the carboxylic acid had dissolved. The excess of phosphorus halides was removed under reduced pressure and the dark brown liquid residue became viscous on cooling. To this residue a solution of 0.4 g. of metallic sodium in 8 cc. of anhydrous methyl alcohol was added gradually with shaking and cooling in running water. The viscous material dissolved slowly and sodium chloride gradually precipitated. The undissolved material was removed by filtration, and from the filtrate small, pale yellow plates began to separate. The mixture was cooled thoroughly and the separated material collected. A single crystallization of this product from methyl alcohol gave 1 g. of colorless plates, m. p. 134.5–135.5° (corr.). The cautious addition of water to the alcoholic solution increases the amount which separates on crystallization. This compound is not volatile with steam. It is partially demethylated on boiling with dilute hydrochloric acid with the formation of the benzoylene-ureacarboxylic methyl ester (V), identified by determining the melting point of a mixture with a known sample of the ester.

Anal. Calcd. for $C_9H_3ON_2(OCH_3)_3$: C, 58.05; H, 4.87; CH_3O, 37.51. Found: C, 58.40; H, 4.97; CH_3O, 37.40.

Summary

Methyl 2,4-dimethoxyquinazoline-5-carboxylate has been synthesized and found to possess properties expected for a compound of this structure. It also has been shown that a compound previously assigned this constitution is actually the isomeric methyl 1,3-dimethylbenzoylene-urea-5-carboxylate.

The Molecular Size of Starch by the Mercaptalation Method[1]

BY M. L. WOLFROM, D. R. MYERS AND E. N. LASSETTRE

In a previous publication from this Laboratory[2] we have reported an estimate of the molecular size of methylated cellulose (from acetone-soluble cellulose acetate) made by a mathematical extrapolation to zero time of the data obtained by subjecting the polysaccharide to hydrolysis at 0° with fuming hydrochloric acid under conditions of continuous mercaptalation and determining the amount of combined sulfur at stated time intervals. We wish now to report the extension of this procedure to a sample of high grade commercial potato starch.

Shortly after the publication of the work of Willstätter and Zechmeister[3] on the action of fuming hydrochloric acid (d. 1.20) on cellulose, Daish[4] reported a careful study of the mutarotation of a sample of "soluble" starch at 20° in the same reagent and in ordinary concentrated hydrochloric acid (d. 1.16). He showed that the mutarotation was a continuous function and that the specific rotation changed from an initial value of approximately +200° to a value very close to that of *d*-glucose in the same solvent. He found that under the same conditions maltose yielded mutarotation data from which a first order specific rate constant could be calculated but that this was not true for starch.

Our sample of commercial potato starch gave a clear solution in hydrochloric acid, showed no detectable Fehling's reduction, and gave a very low alkali number by the Schoch and Jensen[5] procedure.

For the mercaptalation work the starch was suspended in water at 0° (undercooled) and to this was added fuming hydrochloric acid (d. 1.21) so that the resultant mixture was a 5% solution of starch in hydrochloric acid containing 37.5 g. of hydrogen chloride per 100 cc. of solution. An excess of ethyl mercaptan was then added and samples were withdrawn from the hydrolysis mixture and neutralized at various time intervals during the first twenty-six hours. Since no water-insoluble products were obtained, acetylation was employed in order to effect a separation from inorganic salts. The neutralization mixtures were concentrated to dryness and the mercaptalated hydrolyzed starches converted to their acetates by acetylation with acetic anhydride in pyridine. The acetate mixtures were isolated, dried and precisely analyzed for sulfur. The average chain lengths indicated by the analytical data varied from two to seventeen glucose units. The results are recorded in Table I.

The course of the hydrolysis was followed polarimetrically at 0° by means of a separate sample of the hydrolysis mixture, withdrawn for this purpose before the addition of the ethyl mercaptan. The specific rotations for various time intervals are recorded in Table I. Figure 1 represents the change in rotation with increasing time of hydrolysis. Extrapolation of this curve to zero time (time of addition of the acid to the starch) indicates an initial specific rotation of approximately +203° for the original starch.

Figure 2 represents the degree of polymerization as calculated from the analytical data, plotted against the time of hydrolysis, initial time being taken as the time of addition of the acid. A smooth curve may be drawn through the points but the initial curvature is such that a graphic extrapolation to zero time is uncertain. The data were then subjected to a graphic analysis by application of the equation (2) previously developed for methylated cellulose

$$\frac{d-1}{d} = \frac{d_0-1}{d}e^{-kt}$$

where d is the average degree of polymerization in glucose units at time t as defined by the expression

$$d = \frac{\text{total number of glucose units}}{\text{number of polymers}}$$

d_0 is the initial degree of polymerization or the number of glucose units initially present in each polymer; k is the specific rate constant.

When the above equation is satisfied a plot of $\log_e (d-1)/d$ against t will give a straight line,

(1) The experimental data herein reported were presented before the Division of Organic Chemistry at the 96th Meeting of the American Chemical Society, Milwaukee, Wisconsin, September 8, 1938. Original manuscript received December 27, 1938.

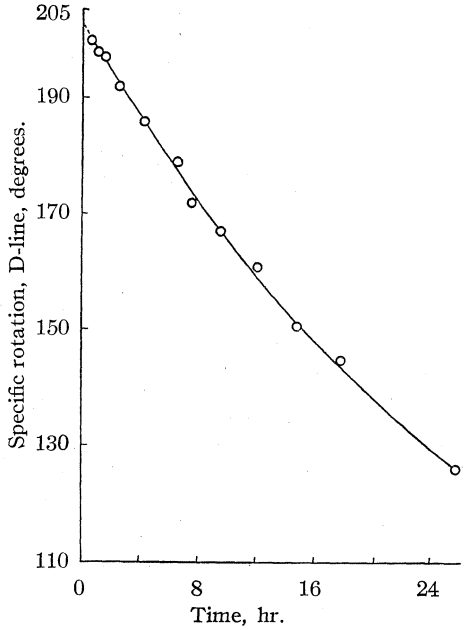

Fig. 1.—Mutarotation of potato starch (c, 4.84) in hydrochloric acid (37.5 g. HCl per 100 cc. soln.) at 0°.

the slope of which is $-k$ and from the intercept of which d_0 can be calculated. The experimental results are shown graphically in Fig. 3. A straight line is obtained and the closely approximate validity of the equation as applied to starch is accordingly confirmed. The points do show a slight tendency to oscillate about the line but this is of no significance as the polarimetric data (Fig. 1) show no discontinuities. The extrapolated points lie close to the axis. The degree of polymerization reaches such a low value that deviations from linearity might well be expected. However, the accuracy of the present experimental results is such that further refinement of the calculations is not required. The value of the specific rate constant k (hours^{-1}) at 0° is 2.66×10^{-2}. The average degree of polymerization, d_0, for the original starch is 20 ± 4, the uncertainty being estimated graphically.

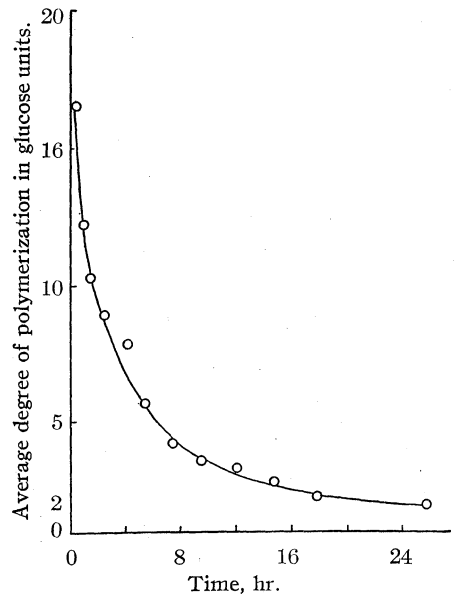

Fig. 2.—Relationship between time of hydrolysis of potato starch and average degree of polymerization as calculated from sulfur content of mercaptalated products.

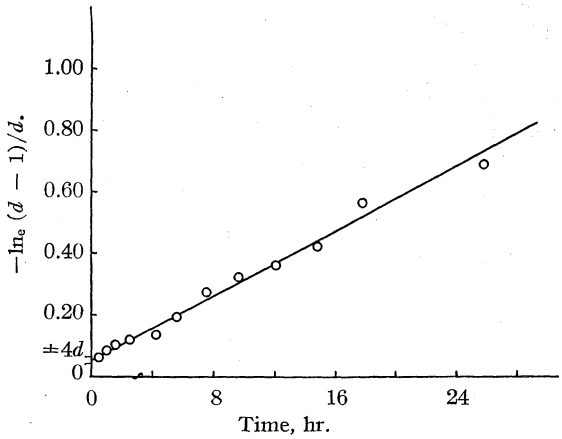

Fig. 3.—Potato starch in hydrochloric acid at 0°.

The value which we have obtained for our sample of potato starch lies within the range of the value of 23–24 glucose units (5% tetramethylglucopyranose in final hydrolysis mixture) found by Hirst, Plant and Wilkinson[6] for both the amylose and amylopectin fractions of potato starch. Hirst and co-workers employed the tetramethylglucopyranose end-group assay method developed by Haworth and Machemer.[7] Application of this end-group assay method to other samples of starch from several plant sources have all yielded values within the range of 25–30 glucose units.[8] Hassid and Dore employed an extraction technique for the tetramethylglucopyranose isolation instead of the distillation technique of Haworth and Machemer.

Neumann and Hess[9] have developed a method

(6) E. L. Hirst, M. M. T. Plant and M. D. Wilkinson, *J. Chem. Soc.*, 2375 (1932).

(9) F. Neumann and K. Hess, *Ber.*, **70B**, 721 (1937).

for tetramethylglucopyranose end-group assay which is different from that of Haworth and Machemer[7] and for which a high degree of accuracy is cited. Application of this procedure to potato starch by Hess and Lung[10] yielded a value of 52.0–52.4 glucose units. It is rather surprising that a refinement in the end-group assay method should yield a higher rather than a lower value. The results of Hess and Lung are not directly comparable with other values on potato starch as these workers isolated the starch from the plant source by their own method. The end-group assay of Neumann and Hess[9] has been criticized by Hirst and Young[11] and by Averill and Peat.[12]

Evidence that the starch particle in dilute solution is a molecular aggregate rather than a single molecule has been presented frequently.[13] The ultracentrifuge results so far obtained[14] show a wide distribution of particle size ranging from an apparent molecular weight of 60,000 to 1,000,000. The Staudinger viscosity methods yield a value of more than 1000 glucose units for starch.[15]

This discrepancy between values for molecular size by the viscosity and chemical methods is explained by Staudinger by postulating a branched chain structure for the starch molecule. One of the arguments for such a structure is the isolation of dimethyl glucose from the hydrolysis products of methylated starch by Irvine.[16]

Hess[10] claims that the amount of dimethylglucose isolated corresponds to the degree to which the methylation of the original starch is incomplete.

It is interesting to point out that a branched structure would not affect the value for molecular size obtained in the present work. In order for this value from the mercaptalation technique to represent the true molecular size, it is only necessary that a reducing group be produced whenever a bond is broken by hydrolysis.

Experimental

Characterization of Starch.—The sample of starch used in this work was a high grade commercial (J. L. Hopkins Co., New York) potato starch. It showed no detectable Fehling's reduction. According to Schoch and Jensen,[5] Fehling's solution procedures are not reliable when applied to starch and they have devised a measure which they term "alkali number." This value is determined by heating the starch under controlled conditions with 0.1 *N* sodium hydroxide for one hour at the temperature of boiling water. The amount of alkali consumed is then determined and the "alkali number" is expressed as the number of cc. of 0.1 *N* alkali consumed by one gram of starch during one hour of digestion. Dr. Schoch has kindly determined the alkali number of our sample of potato starch in comparison with those of several other starches and reports as follows:

	Alkali number
Your sample	5.7
Imported potato starch	6.6
Domestic potato starch	6.9
Corn starch	9.8

Dr. Schoch states that "these results indicate that your material is of exceptionally high quality, and that manufacturing processes have produced little or no hydrolytic degradation."

Hydrolysis and Mercaptalation.—The starch (71 g., moisture content 12.22%) was placed in a 2-liter, 3-necked flask at 0°, equipped for rapid mechanical stirring and for rapid removal of samples through a delivery tube, and was treated with water (100 cc.) previously undercooled to 0°. The starch was suspended by rapid stirring and then fuming hydrochloric acid (1150 cc., d^0_4 1.212), previously cooled to 0°, was added. As soon as solution (d^0_4 1.214, 4.84 g. starch (moisture free) per 100 cc. soln. at 0°) was complete, polarimeter and density samples were withdrawn and maintained at 0°. Well-purified ethyl mercaptan (200 g.), previously cooled to 0°, was then added and the stirring continued at 0°. Samples of 50 cc. were withdrawn after the time intervals recorded in Table I, and immediately poured, with stirring, into mixtures of sodium bicarbonate (54 g.) and water (185 cc.). The neutralization mixtures were then concentrated to dryness under reduced pressure at 37–40°, and the resulting mixtures of salt and hydrolyzed starch mercaptals were dried in the vacuum oven at 40°.

Acetylation of Mercaptalated Products.—The mixtures of salt and mercaptalated products were individually acetylated for four days with acetic anhydride (20 cc.) and pyridine (40 cc.). The resulting pyridine solutions were poured into ice and water (1000 cc.) and the insoluble acetates extracted with chloroform. The chloroform extracts were washed successively with hydrochloric acid (5%), saturated sodium bicarbonate solution, and water. Concentration of the dried extracts under reduced pressure at 37–40° produced the acetates, usually as amorphous solids, but as sirups in a few instances. Several of these products were analyzed for acetyl content by the Kunz procedure. The results are tabulated in Table I.

Optical Rotation of Potato Starch in Hydrochloric Acid at 0°.—The polarimeter sample from the hydrolysis mixture was maintained at 0° and its optical rotation observed at various time intervals as the hydrolysis progressed. The concentration of starch in the solution was 4.84 g. per 100 cc. and the concentration of hydrogen chloride, 37.5 g. per 100 cc. The hydrolysis solution had a density of

[a] Initial time taken as time of addition of the acid to the starch. [b] By extrapolation. [c] Average degree of polymerization in glucose units, assuming complete acetylation.

Sulfur Analyses of Acetylated Mercaptalated Products.—The sulfur analyses were performed by the Parr bomb method, employing total samples of approximately 1 g., on a moisture-free basis, in the manner described previously.[2] In Table I are recorded the sulfur analytical data and the corresponding average degrees of polymerization calculated from them. The degree of polymerization (D. P.) may be calculated from the sulfur content by the equation

$$\text{D. P.} = 2 + \left[\frac{6412}{\%S + C_{12}H_{16}O_8}\right] - 2\left[\frac{C_{14}H_{19}O_9 + C_2H_5S}{C_{12}H_{16}O_8}\right]$$

where $C_{14}H_{19}O_9$ is the molecular weight of the end structural units and $C_{12}H_{16}O_8$ is the molecular weight of the intervening units.

Summary

1. Potato starch has been hydrolyzed with a concentrated solution of hydrochloric acid at 0° in the presence of an excess of ethyl mercaptan. The resulting mercaptalated mixtures of hydrolyzed products were isolated as their acetates at various time intervals, during the first twenty-six hours of the hydrolysis.

2. Sulfur analytical data indicated that the average degree of polymerization of the mercaptalated products varied from 17 glucose units after one-half hour to 2 glucose units after twenty-six hours.

3. The course of the hydrolytic reaction (without mercaptalation) at 0° was followed by optical rotation measurements.

4. A graphic analysis of the data yields a value of 2.66×10^{-2} for the specific rate constant (hours^{-1}) of the rate of change of the degree of polymerization in concentrated hydrochloric acid at 0°.

5. By graphic analysis the value 20 ± 4 glucose units is obtained for the initial average degree of polymerization of the potato starch.

The Action of Isobutylmagnesium Bromide on 3,4,5-Trimethoxybenzonitrile

BY H. L. HALLER AND P. S. SCHAFFER[1]

A recent communication by Suter and Weston[2] describes the preparation of some 5-alkylresorcinols. As work along similar lines has been under way for some time in this Laboratory, occasion is taken to present some of the results that are closely related to the studies of Suter and Weston. This work had for its object the preparation of 5-isoamylresorcinol[3] in order that its properties might be compared with those of 4-isoamylresorcinol[4] and 2-isoamylresorcinol.[5]

4-Isoamylresorcinol was first prepared by Dohme[4] in connection with his studies on the bactericidal action of 4-alkylresorcinols, and 2-isoamylresorcinol was first synthesized by Haller[5] and shown to be identical with tetrahydrobutanol,[6] a degradation product of rotenone.[7]

The reaction of 3,5-dimethoxybenzonitrile with

isobutylmagnesium bromide according to the procedure described by Haller[5] in his work on 2,6-dimethoxyphenyl isobutyl ketone was first studied. The yield of the resulting ketone was 45 to 50% based on the nitrile.

Several methods for the reduction of the ketone were investigated, with results similar to those described by Suter and Weston[2] in the reduction of their ketones.

Reduction with sodium and alcohol, as described by Asahina[8] for the 3,4,5-trimethoxyphenyl alkyl ketone, yielded mixtures which were difficult to separate. When the ketone was shaken in an atmosphere of hydrogen with palladium charcoal as described by Hartung and Crossley,[9] no hydrogen was absorbed and the unchanged starting material was recovered. The Clemmensen method likewise failed to yield a satisfactory reduction product.

Owing to the high cost of 3,5-dimethoxybenzonitrile, a study of the reaction between 3,4,5-trimethoxybenzonitrile and isobutylmagnesium bromide was undertaken, as it has been shown[10] that the methoxyl group in the 4-position of trimethylpyrogallol derivatives can be replaced by hydrogen. The reaction of this nitrile and the Grignard reagent yielded, after hydrolysis, in addition to the expected 3,4,5-trimethoxyphenyl isobutyl ketone, two other products. One of these products is soluble in aqueous alkali and forms a semicarbazone, an oxime, and an acetyl and a benzoyl derivative. With ferric chloride in alcohol it gives a faint green color. On the basis of these reactions, analytical data, and the known reactivity of the methoxyl group in the 4-position of trimethylpyrogallol derivatives, it is suggested that the compound is 3,5-dimethoxy-4-hydroxyphenyl isobutyl ketone. The other compound forms a crystalline semicarbazone, possesses two methoxyl groups, and is insoluble in aqueous alkali. Analyses of the compound and of its semicarbazone indicate the empirical formula $C_{17}H_{26}O_3$. It is suggested that this compound possesses a butyl group in the 4-position of the benzene ring and that the compound is probably a 3,5-dimethoxybutylphenyl isobutyl ketone.

Several attempts were made to reduce the trimethoxyphenyl isobutyl ketone. In some cases a reduction was accomplished, but it could not be repeated and further studies are desirable.

Experimental

3,5-Dimethoxybenzonitrile.—This compound was obtained on dehydration of the corresponding amide[11] with phosphorus pentoxide.

Five-tenths of a gram of 3,5-dimethoxybenzamide was mixed intimately with 0.4 g. of phosphorus pentoxide, and the mixture heated in a sand-bath. After the vigorous reaction had subsided, the mixture was treated with ice and water, filtered, thoroughly washed with water, and then dried. The product was recrystallized from 60% ethanol. It melted at 87–88°.

Anal. Calcd. for $C_9H_9NO_2$: N, 8.6. Found: N, 8.58.

In attempts to prepare the nitrile from the amide and phosphorus pentachloride according to the procedure of Kauffmann,[12] dehydration took place, but the product also contained chlorine.

A mixture of 0.4 g. of 3,5-dimethoxybenzamide and 0.65 g. of phosphorus pentachloride was heated in a sand-bath to initiate reaction. After the vigorous reaction had subsided and the mixture had cooled, ice and water were added. The reaction product was thoroughly washed with water and dried. After recrystallization from ethanol it melted at 124–125°.

Anal. Calcd. for $C_9H_8ClNO_2$: N, 7.1. Found: N, 7.18.

3,5-Dimethoxyphenyl Isobutyl Ketone.—A Grignard reagent was prepared in the usual manner from 2.4 g. (0.1 mole) of magnesium suspended in 40 cc. of ether and 13.0 g. (0.095 mole) of isobutyl bromide dissolved in 25 cc. of ether. To this ether solution was added, in the course of five minutes and with constant stirring, 3.2 g. (0.02 mole) of 3,5-dimethoxybenzonitrile dissolved in 50 cc. of ether. The reaction mixture was then refluxed for one hour, cooled, and poured into ice and concentrated hydrochloric acid. The aqueous solution, after separation from the ether solution, was extracted twice with ether, placed in an open beaker, and heated on the steam-bath to remove the dissolved ether. Finally the solution was boiled vigorously under reflux for one hour. The separated oil was extracted from the cooled solution with ether; the ether extract was washed with water and dried over sodium sulfate. The oil remaining after the ether had been removed was distilled. It boiled at 143–145° (2.0 mm.). The yield was 3.6 g. When treated with semicarbazide hydrochloride and sodium acetate, according to the procedure described by Shriner and Turner,[13] 3.6 g. of the oil yielded 4.0 g. of a crystalline semicarbazone. The product after recrystallization from ethanol melted at 195–196°.

Anal. Calcd. for $C_{14}H_{21}N_3O_3$: C, 60.21; H, 7.53. Found: C, 59.86; H, 7.70.

3,4,5-Trimethoxybenzonitrile.—Gallic acid was methylated with dimethyl sulfate according to the directions in "Organic Syntheses."[14] The methylated acid on treatment with thionyl chloride yielded the acid chloride, which was converted to the amide[15] by treatment with concen-

(15) Harding, *J. Chem. Soc.*, **99**, 1585 (1911).

trated aqueous ammonia. The amide, on being heated in benzene solution with phosphorus pentachloride, yielded the nitrile.[16]

Reaction of 3,4,5-Trimethoxybenzonitrile with Isobutylmagnesium Bromide.—To the Grignard reagent prepared from 34.2 g. (0.25 mole) of isobutyl bromide in 65 cc. of ether and 6.07 g. (0.25 mole) of magnesium turnings suspended in 200 cc. of dry ether was added, in the course of twenty minutes and with constant stirring, 19.3 g. (0.1 mole) of 3,4,5-trimethoxybenzonitrile dissolved in 200 cc. of dry toluene. The reaction mixture was then heated in an oil-bath and the ether removed by distillation, toluene being added gradually to maintain the original volume.[17] After all of the ether had been replaced with toluene, the mixture was refluxed for three hours with constant stirring. The reaction mixture was then poured onto ice containing 30 cc. of concentrated hydrochloric acid. The aqueous layer, after separation of the toluene, was washed twice with ether, placed in an open beaker, and heated on the steam-bath until all the dissolved ether was removed. It was then boiled for two hours under reflux and cooled, and the oil that separated was removed by extraction with ether. The combined ether extracts were washed with 5% sodium hydroxide and with water, and then dried over sodium sulfate. The oil (A) remaining after removal of the ether was distilled under reduced pressure. It boiled at 147–150° (1 mm.). The yield was 6.5 g. Analysis indicated the compound to be trimethoxyphenyl isobutyl ketone.

Anal. Calcd. for $C_{14}H_{20}O_4$: C, 66.66; H, 7.93; OCH_3 (3), 36.9. Found: C, 66.43; H, 7.88; OCH_3, 36.4.

A crystalline semicarbazone was obtained readily when 0.5 g. of the distilled oil (A) in 5 cc. of ethanol was treated with 2 cc. of pyridine and 0.5 g. of semicarbazide hydrochloride dissolved in a small quantity of hot water. The yield was 0.6 g. The product, after crystallization from ethanol, melted at 205°.

Anal. Calcd. for $C_{15}H_{23}N_3O_4$: C, 58.3; H, 7.44; OCH_3 (3), 30.1. Found: C, 58.45; H, 7.81; OCH_3, 30.0.

The alkali-soluble fraction (B) obtained on extraction of the ether solution was acidified with dilute sulfuric acid and the separated product removed by extraction with ether. The ethereal solution was washed with water and dried with sodium sulfate. On removal of the ether a colorless crystalline product was obtained. The yield was 6.0 g. When recrystallized from 50% ethanol, it melted at 94°. Analyses indicate it to be a dimethoxyhydroxyphenyl isobutyl ketone.

Anal. Calcd. for $C_{13}H_{18}O_4$: C, 65.54; H, 7.56; OCH_3 (2), 26.05. Found: C, 66.04; H, 7.80; OCH_3, 26.09.

A crystalline semicarbazone was obtained readily when the product (B) was treated with semicarbazide hydrochloride as described above for the trimethoxyphenyl isobutyl ketone. After recrystallization it melted at 162.5°.

Anal. Calcd. for $C_{14}H_{21}N_3O_4$: C, 56.9; H, 7.12; OCH_3(2), 21.0. Found: C, 57.75; H, 7.67; OCH_3, 21.2.

With hydroxylamine the alkali-soluble product yielded an oxime. A solution of 1.2 g. of the oil (B), 0.35 g. of hydroxylamine hydrochloride, and 0.45 g. of anhydrous sodium acetate in 10 cc. of absolute ethanol was refluxed for two hours. The solution was filtered and concentrated to a small volume, and water was added. The separated product was filtered and dried. The yield was 1.0 g. After recrystallization from dilute ethanol it melted at 110°.

Anal. Calcd. for $C_{13}H_{19}NO_4$: OCH_3(2), 24.5. Found: OCH_3, 24.4.

Fraction B with benzoyl chloride yielded a benzoyl derivative.

One gram of the oil (B), 1 g. of benzoyl chloride, and 1 cc. of pyridine in 7 cc. of benzene were heated in a boiling water-bath for one hour. To the cooled reaction mixture dilute hydrochloric acid was added and the solution was extracted with ether. The ether–benzene solution was washed with dilute sodium carbonate solution, with water, and then dried over anhydrous sodium sulfate. After removal of the solvent the remaining product crystallized readily. It was recrystallized from methanol. The yield was 1 g. It melted at 111°.

Anal. Calcd. for $C_{20}H_{22}O_5$: OCH_3(2), 18.15. Found: OCH_3, 18.0.

The toluene solution obtained after separation of the aqueous acid solution was washed with water, dried over sodium sulfate, and the toluene removed by distillation. The residue was distilled and 2.0 g. of an oil that boiled at 140–145° (1 mm.) was obtained. It yielded 0.2 g. of alkali-soluble material on treatment in ether solution with 5% sodium hydroxide. The alkali-insoluble fraction distilled at 128–130° (0.35 mm.).

Anal. Calcd. for $C_{17}H_{26}O_3$: C, 73.4; H, 9.35; OCH_3(2), 22.3. Found: C, 72.8; H, 9.14; OCH_3, 23.0.

When treated in ethanol with semicarbazide hydrochloride and pyridine, the oil yielded a crystalline semicarbazone. When recrystallized from methyl alcohol it melted at 184°.

Anal. Calcd. for $C_{18}H_{29}O_3N_3$: C, 64.5; H, 8.66; OCH_3(2), 18.5. Found: C, 64.53; H, 8.82; OCH_3 18.5.

Summary

Reaction of 3,5-dimethoxybenzonitrile and isobutylmagnesium bromide yields 3,5-dimethoxyphenyl isobutyl ketone.

Interaction of 3,4,5-trimethoxybenzonitrile and isobutylmagnesium bromide yields, in addition to the expected 3,4,5-trimethoxyphenyl isobutyl ketone, two other products. The one has the empirical formula $C_{14}H_{20}O_4$, is soluble in alkali, and forms both carbonyl and hydroxyl derivatives. It is probably 3,5-dimethoxy-4-hydroxyphenyl isobutyl ketone. The other product has the empirical formula $C_{17}H_{26}O_3$, is insoluble in alkali, and forms a semicarbazone. It is suggested that the compound is probably a 3,5-dimethoxy-4-butylphenyl isobutyl ketone.

WASHINGTON, D C. RECEIVED MAY 17, 1939

(16) Harding, *J. Chem. Soc.*, **105**, 2790 (1914).

(17) When the reaction was carried out in ether only, in which the nitrile is slightly soluble, about two-thirds of the starting material was recovered unchanged.

Studies on Melanins.[1] III. X-Ray Diffraction Patterns of Photosynthetic and Genuine Melanins

BY MONA SPIEGEL-ADOLF AND GEORGE C. HENNY

Although ultra-spectrographical investigations[2] have made it possible to distinguish several groups of melanins, no clues are as yet available as to the structure of the melanin molecule. X-Ray diffraction patterns of melanins have been made in an attempt to fill this gap.

Method.—X-Rays are provided by a gas type, self-rectifying X-ray tube[3] used with a copper target and operated at 35 kv. peak at an average current of 15 m. a. Aluminum foil windows (0.013 mm.) and lead diaphragm 1 mm. in diameter and 47 mm. effective length are used. With this arrangement, a fairly monochromatic beam of X-rays of average wave length of 1.54 Å. is secured. The finely ground specimen is pressed into a hole drilled in a microscope slide.[4] The specimen is at a distance of 88 mm. from the focal spot and of 37.7 mm. from the film (Eastman X-ray); the rigid construction of the cameras and of their attachment to the tube assures a correct alignment. The necessary time of exposure was found to be one hour. The table of Katz[5] (corrected for our cameras) was used for the conversion of the diffraction rings into the plane distances in Ångström units.

Material.—The preparation and some properties of the three so-called photosynthetic melanins, *i. e.*, melanin-like products derived from phenylalanine, tryptophan, and tyrosine through the influence of ultraviolet light have been described before.[6] The chemical as well as the ultraspectrographical properties of the samples of human tumor melanins as well as of two samples of sepia and a sample of mouse melanin have been given in a former paper.[2] All the preparations have been kept in powder form at room temperature.

Experimental Results.—All melanins show an X-ray diffraction pattern consisting of either one or two diffuse rings. The diameter of these rings as well as the corresponding planar separations are summarized in Tables I and II. Table I contains besides comparable data for phenylalanine, tryptophan and tyrosines, which were used as sources of photosynthetic melanins.

TABLE I[a]

	Diameter, mm.[b]	Plan. Sep., Å.
Phenylalanine melanin	24 (6)	6.89
Tryptophan melanin	30 (5)	4.10
Tyrosine melanin	30 (4)	4.10
dl-β-Phenylalanine	16, 24, 30, 35, 38, 41, 53	
l-Tryptophan	6.5, 13, 21, 25, 32 (1.5),* 47, 55, 64	
l-Tyrosine	13, 18, 21, 25, 28, 36,* 41, 45, 50,* 54, 57, 62, 69, 76, 84	

[a] The three photosynthetic melanins show besides evidence on an inner ring less than 9 mm. in diameter.

[b] The figures in parentheses indicate the width of the ring, * indicates a band instead of a sharp line.

TABLE II[a]

Melanins	Outer ring Mm.	Outer ring Å.	Inner ring Mm.	Inner ring Å.	Log *E* Å. = 3000
Sepia gen.	32 (8)	3.86	12	9.8	2.62
Sepia digest.	31	3.98	11	10.6	2.42
Hum. tumor F_2	30	4.10	11	10.6	2.38
Hum. tumor F_1	28	4.35	12	9.8	2.34
Hum. tumor P	28	4.35	11	9.8	2.30
Hum. tumor F_3	27	4.5	11	9.8	..
Mouse melanoma	26 (4)	4.66	11	9.8	1.94

[a] Melanins P and F_1 are chemically identical; F_3 shows only slight differences; F_2 larger differences.

Conclusions

1. The three photosynthetic melanins show a similar diffraction pattern which is very different from the elaborate sharp line pattern of their mother substances. Only tryptophan contains one diffuse ring similar to the one of tryptophan and tyrosine melanin. These findings confirm former observations of Spiegel-Adolf[2] according to which only irradiated tyrosine, but not phenylalanine, solutions gave a positive Hopkins–Cole reaction.

2. The diffraction pattern of the tumor melanins and of sepia although of greater intensity are similar to the ones of the photosynthetic melanins. There exist certain differences in the diameters of the various genuine melanins. These differences seem to run parallel to differences in chemical and optical properties of the genuine melanins.

3. The planar separations of the genuine melanins vary between 9.8–10.6 Å. and 3.86–4.66 Å. These values are close to the ones found by Astbury and his co-workers in proteins. (All our melanins were free from any protein contamina-

tion.) The interpretation of these results ought therefore to follow lines similar to the interpretation of the protein diffraction pattern. Either melanins must be considered as "anisotropic amorphous solid substances" according to Freundlich[7] or as non-amorphous crystalline substances according to Astbury.[4]

Acknowledgments.—We are indebted to Drs. H. K. Barrenscheen (Vienna) and B. Gruskin (Philadelphia) for some of the melanin material, to Dr. R. W. G. Wyckoff for helpful suggestions facilitating the construction of the X-ray tube and to the National Research Council Committee on Radiation, whose grant to one of us (Sp.-A.) has made these investigations possible.

Summary

X-Ray diffraction patterns of photosynthetic melanins as well as of the corresponding amino acids and of various tumor melanins and sepia are described. Slight differences observed in the diffraction patterns of the genuine melanins (from 9.8–10.6 Å. and from 3.86–4.66 Å.) run parallel with observed differences in the optical absorption power of the same substances.

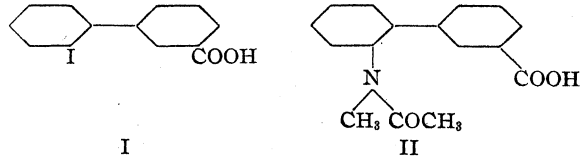
Stereochemistry of Biphenyls. XLVI.[1] 2-Substituted Biphenyls

BY ROGER ADAMS AND T. L. CAIRNS[2]

The prediction of restricted rotation in biphenyls by means of calculated interferences based on atomic radii has proved very helpful. In 2,2′-disubstituted biphenyls, however, the actual stability of the optically active forms is less than would be anticipated from the stability of closely related 2,2′,6- and 2,2′,6,6′-tri- and tetrasubstituted compounds. On these grounds, biphenyls monosubstituted in the 2-position should show even greater instability than atomic radii calculations would indicate. The published results of Meisenheimer[3] and Lesslie and Turner[4] confirm this. These latter investigators found it impossible to resolve the 3′-bromobiphenyl-2-tetramethylammonium iodide but obtained the corresponding tetramethylarsonium iodide as a mutarotating compound. In the same paper they mention that 2-iodo-3′-carboxybiphenyl was prepared and could not be resolved. However, this latter compound and its method of preparation were not described. The fact that 2,2′-diiodo-4,4′-dicarboxybiphenyl has been separated into two optically active forms[5] indicates beyond a doubt that an iodine atom is sufficiently large to interfere with a hydrogen and consequently that, unless some mobility greater than that found in 2,2′-disubstituted biphenyls is present in monosubstituted compounds, 2-iodo-3′-carboxybiphenyl should be resolvable.

The syntheses of biphenyls with a substituent in the 2-position and, in addition, a salt-forming group are difficult. 2-Amino-3′-carbethoxybiphenyl offers an attractive starting point for the preparation of such biphenyls since the amino group should be converted readily into or replaced by groups of large radii without difficulty. The details have now been determined by which this compound can be made from the condensation of *o*-bromonitrobenzene and ethyl *m*-iodobenzoate followed by reduction of the nitro group. This synthesis, which appears simple, required much experimentation before a satisfactory procedure was found.

In this communication the preparation of 2-iodo-3′-carboxybiphenyl (I) and N-acetyl-N-methyl-2-amino-3′-carboxybiphenyl (II) from 2-amino-3′-carbethoxybiphenyl is described. The



I II

work of Lesslie and Turner was confirmed in that the iodo compound could not be resolved.

resolving N-acetyl-N-methyl-2-amino-8-naphthalene sulfonic acid and N-acetyl-N-methyl-2-amino-4-methylbenzene sulfonic acid, the N-acetylmethylamino group was introduced into the 2-position as shown in compound II. The sphere of influence assumed by Mills for this group should result in restricted rotation in molecule II. This might occur not only between the phenyl groups but also between the nitrogen atom and the carbon atom of the ring. If in both places, two diastereoisomeric forms should result. Careful fractionation of this product from methanol indicated the presence merely of a single compound.

When resolution of II was attempted through the quinine salt by fractionation from acetone, two salt fractions were obtained. They had different specific rotations (−125 and −140°) and different solubilities. They were not interconvertible, however, and did not mutarotate. Upon hydrolysis, both gave the original acid in the inactive form. Although the explanation of the two salt fractions is not clear, the results indicate that resolution was not accomplished.

The replacement of the amino group in 2-amino-3′-carboxybiphenyl by other groups of large radius is now being studied.

Experimental

2-Nitro-3′-carboxybiphenyl.—A mixture of 25.8 g. of *o*-bromonitrobenzene and 28 g. of ethyl *m*-iodobenzoate was heated under reflux, with mechanical stirring, to a temperature of 215°. In small quantities at a time, 48 g. of activated copper-bronze[7] was added. The temperature was then raised to 235–250° and maintained for forty-five minutes. After cooling, the mixture was extracted with acetone (500–600 cc.) and the copper and copper salts removed by filtration. The acetone solution was concentrated to about 50 cc., 100 cc. of ethanol was added, and the distillation continued until all the acetone was removed. A mixture of 500 cc. of ethanol and 160 cc. of 10% aqueous sodium hydroxide was then added and the solution refluxed for one hour. The alcohol was removed by distillation and 500 cc. of water added to the residue. After filtration, the filtrate was cooled and was extracted with ether to remove alkali-insoluble products. After warming the aqueous solution to evaporate the residual ether it was cooled in an ice-bath and acidified with dilute hydrochloric acid. The brownish mass which separated became hard on standing. This was dissolved in a minimum quantity of glacial acetic acid (150–200 cc.) and on cooling a crystalline product separated. It was recrystallized from ethanol with the use of norite: yellow crystals, m. p. 207–208° (corr.); yield, 7.6 g. (31%).

Anal. Calcd. for $C_{13}H_9O_4N$: C, 64.19; H, 3.70. Found: C, 64.46; H, 3.97.

(7) Kleiderer and Adams, THIS JOURNAL, **55**, 4219 (1933).

2-Nitro-3′-carbethoxybiphenyl.—A mixture of 7.5 g. of 2-nitro-3′-carboxybiphenyl and 30 cc. of thionyl chloride was refluxed gently for twenty to thirty minutes. The excess thionyl chloride was removed under reduced pressure and 50 cc. of ethanol was added drop by drop at first and then faster after the exothermic reaction subsided. The mixture was then refluxed until all the ester was in solution, cooled and poured onto 200 cc. of cracked ice. The pale yellow oil which separated solidified on standing. It was purified by distillation *in vacuo*, b. p. 215° (11 mm.), and then recrystallization from ethanol: white crystals, m. p. 63–65° (corr.); yield, 8 g. (84%).

Anal. Calcd. for $C_{15}H_{13}O_4N$: C, 66.42; H, 4.80. Found: C, 66.90; H, 4.78.

2-Amino-3′-carbethoxybiphenyl.—A solution of 16.5 g. of 2-nitro-3′-carbethoxybiphenyl in 150 cc. of 95% ethanol was refluxed for one hour and fifteen minutes with a teaspoonful of Raney nickel. This procedure was used to remove impurities which interfered with the normal reduction of the nitro to the amino group. After filtration, 0.22 g. of platinum oxide was added and reduction was carried out at 3–3.5 atmospheres (about thirty minutes). After filtration of the platinum, the solution was concentrated to 50 cc. and then poured into 400 cc. of ice water. The pale yellow oil which separated was extracted with 300 cc. of ether and the ether solution, in turn, extracted several times with dilute hydrochloric acid. The hydrochloric acid extract was warmed to remove the ether, filtered, cooled, and neutralized with a slight excess of aqueous ammonia. The oil which separated, rapidly solidified and was recrystallized from ethanol: white crystals, m. p. 75–76° (corr.); yield, 11.5 g. (80%).

Anal. Calcd. for $C_{15}H_{15}O_2N$: N, 5.81. Found: N, 5.86.

2-Iodo-3′-carboxybiphenyl.—In the replacement of the amino group by the iodine, crude 2-amino-3′-carbethoxybiphenyl was often used. Consequently, it was desirable to add 1 g. of the amino compound to a boiling mixture of 100 cc. of concentrated hydrochloric acid and 25 cc. of water and any insoluble material removed by filtration through glass wool. The solution was then cooled to below 5° and, over a period of two hours, 6 cc. of aqueous 10% sodium nitrite solution was added drop by drop. A saturated aqueous solution of 0.5 g. of potassium iodide was added and the mixture allowed to stand overnight at room temperature. The temperature was then raised to 80–85° and sufficient sodium bisulfite added to remove the free iodine. After cooling to room temperature and filtering, the product was washed and recrystallized from dilute dioxane (3:1 water to dioxane, by volume). Very pale pink crystals were obtained, m. p. 168–170° (corr.); yield, 0.9 g. (69%).

Anal. Calcd. for $C_{13}H_9O_2I$: C, 48.14; H, 2.78. Found: C, 48.05; H, 2.80.

Attempted Resolution of 2-Iodo-3′-carboxybiphenyl.—A solution of 0.504 g. of quinine in 25 cc. of anhydrous acetone was added to a solution of 0.504 g. of 2-iodo-3′-carboxybiphenyl in 10 cc. of anhydrous acetone. About 5 cc. of acetone was used to wash out the flask. The mixture was brought to boiling, filtered and the filter paper washed with 5 cc. more of acetone. After standing

overnight, 0.64 g. of pinkish crystals separated, m. p. 184–187° (corr.).

Upon concentration of the filtrate, other fractions were obtained which gave essentially the same melting point as the first fraction. Upon recrystallization of the various fractions from dilute methanol (5:1 methanol to water, by volume), the samples of salt obtained in every instance appeared to be identical, and within experimental error to give a constant rotation and no mutarotation.

Rotation. 0.0488 g. made up to 10 cc. in methanol, $\alpha^{0-2}D$ −0.516; $l = 1$; $[\alpha]^{0-2}D$ −106.

Anal. Calcd. for $C_{33}H_{33}O_4N_2I$: N, 4.32. Found: N, 4.11.

N-Acetyl-2-amino-3′-carbethoxybiphenyl.—A solution of 6 g. of 2-amino-3′-carbethoxybiphenyl in 40 cc. of glacial acetic acid was warmed almost to boiling and 2.4 g. of acetic anhydride and one drop of concentrated sulfuric acid were added. After heating for thirty minutes, the mixture was allowed to stand at room temperature for one hour and was then poured into 500 cc. of ice water. The oil which separated rapidly solidified and was purified by crystallization from petroleum ether (b. p. 60–110°): white crystals, m. p. 111–111.5° (corr.); yield, 6.5 g. (90%).

Anal. Calcd. for $C_{17}H_{17}O_3N$: C, 72.10; H, 6.01. Found: C, 71.87; H, 6.05.

N-Acetyl-N-methyl-2-amino-3′-carboxybiphenyl.—The general procedure followed was that described by Mills and Kelham.[6] To a solution of 4.5 g. of N-acetyl-2-amino-3′-carbethoxybiphenyl in 100 cc. of dry benzene was added 0.5 g. of powdered sodium and the mixture was refluxed for five hours. A solution of 3 g. of dimethyl sulfate in 20 cc. of dry benzene was now added and refluxing was continued for one hour and thirty minutes. The remaining sodium was decomposed by the addition of a small amount of ethanol and then a solution of 5 g. of potassium hydroxide in 100 cc. of 50% ethanol was added. After steam distillation to remove all the benzene, the alkaline solution was refluxed for two hours, treated with norite, filtered and, while still hot, acidified with dilute hydrochloric acid. The yellow precipitate was filtered and purified by solution in essentially the calculated amount of 1–2% aqueous potassium hydroxide, treatment with norite, filtration and acidification. It may be recrystallized from methanol: white crystals, m. p. 228–239° (corr.); yield, 3 g. (70%).

Anal. Calcd. for $C_{16}H_{15}O_3N$: C, 71.36; H, 5.57. Found: C, 71.46; H, 5.62.

From the filtrate a small quantity of N-acetyl-2-amino-3′-carboxybiphenyl was isolated. This was purified by recrystallization from water; white crystals, m. p. 183–188° (corr.).

Anal. Calcd. for $C_{15}H_{13}O_3N$: C, 70.60; H, 5.10. Found: C, 70.52; H, 4.85.

Fractionation of N-Acetyl-N-methyl-2-amino-3′-carboxybiphenyl.—A careful fractionation of the N-acetyl-N-methyl-2-amino compound from methanol gave no indication of the presence of more than a single compound. Practically every fraction had similar melting points and solubilities.

Attempted Resolution of N-Acetyl-N-methyl-2-amino-3′-carboxybiphenyl.—A solution of 0.94 g. of quinine in 20 cc. of methanol was added to a solution of 0.83 g. of N-acetyl-N-methyl-2-amino-3′-carboxybiphenyl in 60 cc. of methanol. The mixture was boiled and filtered and the filter washed with 20 cc. of methanol. The solution thus obtained deposited no crystals after many hours at 5°. It was evaporated, therefore, to dryness at room temperature and a pale yellow oil resulted. This was dissolved in 40 cc. of boiling dilute acetone (4:1 water to acetone, by volume) and after standing for thirty-six hours at 5–7°, 1.2 g. of white crystals separated, m. p. 170.5–173.5° (corr.).

Rotation. 0.0733 g. made up to 10 cc. in chloroform. $\alpha^{26}D$ −1.031; $l = 1$; $[\alpha]^{26}D$ −140.

This product was dissolved in 120 cc. of dry boiling acetone and filtered. After standing for four hours at 5–7°, 0.77 g. of white crystals separated: (Fraction A) m. p. 173–182° (corr.).

Rotation. 0.0691 made up to 10 cc. in chloroform. $\alpha^{27}D$ −0.89; $l = 1$; $[\alpha]^{27}D$ −129.

Anal. Calcd. for $C_{36}H_{39}O_5N_3$: C, 72.85; H, 6.58; N, 7.08. Found: C, 72.46; H, 6.86; N, 6.90.

The filtrate from this material was evaporated to dryness and yielded a pale yellow oil. This was dissolved in boiling water (about 50 cc.), filtered and cooled. About 0.2 g. of white crystals (Fraction B), m. p. 172.5–173.5° (corr.).

Rotation. 0.0778 g. made up to 10 cc. in chloroform. $\alpha^{28}D$ −1.088; $l = 1$; $[\alpha]^{28}D$ −140.

Anal. Calcd. for $C_{36}H_{39}O_5N_3$: C, 72.85; H, 6.58; N, 7.08. Found: C, 73.17; H, 6.81; N, 6.90.

Fraction A was recrystallized from acetone and fraction B from water. In the case of fraction B cooling must be carried out slowly to avoid separation as an oil. The melting points and rotations of the fractions were essentially unchanged.

Upon decomposition of these two fractions with hydrochloric acid at 0°, the free acids were obtained which showed no optical activity.

The two fractions also showed no mutarotation upon heating in chloroform solution.

Summary

1. A satisfactory method for the preparation of 2-amino-3′-carbethoxybiphenyl has been developed.

2. 2-Iodo-3′-carboxybiphenyl and N-acetyl-N-methyl-2-amino-3′-carboxybiphenyl could not be resolved by fractionation of the quinine salts.

URBANA, ILLINOIS RECEIVED JUNE 5, 1939

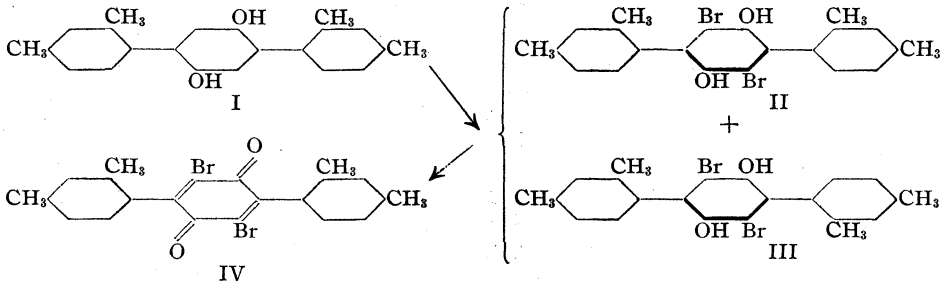
Stereochemistry of Biphenyls. XLVII.[1] Certain 3,6-Di-(2,4-dimethylphenyl)-hydroquinones and their Derivatives

BY ROGER ADAMS AND G. C. FINGER[2]

Browning and Adams[3] condensed *m*-xylene with *p*-benzoquinone to give 3,6-di-(2,4-dimethylphenyl)-hydroquinone (I). Upon bromination of this compound, two diastereoisomeric 3,6-di-(2,4-dimethylphenyl)-2,5-dibromohydroquinones (II and III) were readily formed and separated from each other by their different solubilities.

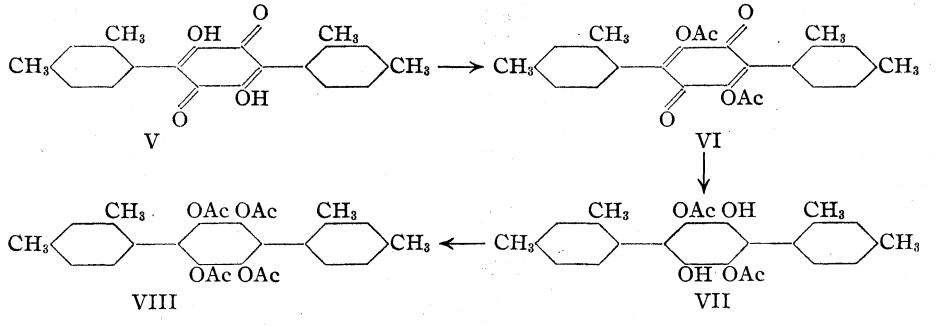


The two dibromohydroquinones (II and III) formed their own characteristic diacetates and tetranitrodiacetates. On the other hand, the oxidation of II or III gave the same 3,6-di-(2,4-dimethylphenyl)-2,5-dibromoquinone (IV). Reduction of IV gave a mixture of II and III. From this it is evident that a methyl, bromine, hydroxyl, and hydrogen in the 2,2′,6,6′-positions of a biphenyl are sufficient to cause restricted rotation. However, in a phenylquinone, a bromine, methyl and hydrogen in addition to the carbonyl will not cause restricted rotation.

The investigation has now been extended to analogous derivatives. The dibromoquinone (IV) upon treatment with alkali gave 3,6-di-(2,4-dimethylphenyl)-2,5-dihydroxyquinone (V) which formed the diacetyl derivative (VI). This in turn was reduced to the diacetoxy hydroquinone (VII) which upon acetylation gave 3,6-di-(2,4-dimethylphenyl)-1,2,4,5-tetraacetoxybenzene (VIII).

In none of these derivatives was the presence of diasteroisomeric forms observed. It may thus be deduced that in a biphenyl, two acetoxyls, a methyl and a hydrogen or one acetoxyl, a hydroxyl, a methyl and a hydrogen in the 2,2′,6,6′-positions will not cause restricted rotation.

On the basis of atomic radii, two hydroxyls, a methyl, and a hydrogen in the 2,2′,6,6′-positions of a biphenyl should result in a slightly restricted rotation, provided a rather rigid coaxial formula is assumed. Since greater mobility is always observed in 2,2′,6-trisubstituted biphenyls, to which group the products studied belong, than in 2,2′,-6,6′-tetrasubstituted compounds, it is not surprising that the substances described show absence of restricted rotation. Apparently, the acetoxy groups are not sufficiently larger than the hydroxyl to modify the results.



Experimental

3,6 - Di - (2,4 - dimethylphenyl) - hydroquinone (I) and 3,6 - Di - (2,4 - dimethylphenyl) - 2,5 - dibromo-

(1) For previous paper see Adams and Cairns, THIS JOURNAL, **61**, 2179 (1939).

(2) An abstract of a thesis submitted in partial fulfilment of the requirements for the degree of Doctor of Philosophy in chemistry.

(3) Browning and Adams, THIS JOURNAL, **52**, 4098 (1930).

hydroquinones (II and III).—The procedures used for the preparation of these compounds were those described by Browning and Adams.[3] The preparation of the former was modified in that the original reaction mixture was not allowed to stand overnight but worked up after the addition of the quinone was complete and the mixture had been stirred for two hours. The yield by these former authors was miscalculated as it should have been about 15% as obtained in this investigation.

3,6 - Di - (2,4 - dimethylphenyl) - 2,5 - dihydroxyquinone (V).—To a cold solution of 21 g. of 3,6-di-(2,4-dimethylphenyl)-2,5-dibromoquinone (m. p. 192–193°) in 1200 cc. of ethanol was added with stirring a cold solution of 180 g. of sodium hydroxide in 720 cc. of water. The rate of addition was controlled so that no appreciable rise in temperature took place. The mixture was allowed to come to room temperature and stirred continuously for twenty-four hours. It was then poured with stirring into ice and concentrated hydrochloric acid was added until the mixture was just acid to litmus. During this neutralization the temperature was maintained at 25° by the addition of ice. The dihydroxyquinone separated as a red precipitate which was coagulated by heating on a steam-bath and allowing to stand for several hours. The crude product weighed 14.5 g. (94%). No satisfactory solvent was found for this product and the sample for analysis was obtained by hydrolysis of the pure diacetate. When obtained in this manner it recrystallized from hot benzene as small red needles (m. p. 282–284°).

Anal. Calcd. for $C_{22}H_{20}O_4$: C, 75.82; H, 5.79. Found: C, 75.52; H, 5.86.

3,6 - Di - (2,4 - dimethylphenyl) - 2,5 - diacetoxyquinone (VI).—To a solution of 14.5 g. of crude 3,6-di-(2,4-dimethylphenyl)-2,5-dihydroxyquinone in 50 cc. of hot pyridine was added 50 cc. of acetic anhydride and the mixture was then refluxed for fifteen minutes. Upon cooling the diacetate precipitated. After filtering, washing with a little acetic anhydride, then with water containing a small amount of hydrochloric acid the crude product was dried and purified from ethanol or butanol. It crystallized in bright yellow needles, m. p. 186–188°.

Anal. Calcd. for $C_{26}H_{24}O_6$: C, 72.19; H, 5.59. Found: C, 72.57; H, 5.8.

The filtrate from the original reaction mixture of diacetate upon dilution with a liter of water resulted in the separation of unreacted dihydroxyquinone.

A solution of 0.52 g. of pure diacetoxyquinone in 10 cc. of hot glacial acetic acid and 2 cc. of dilute hydrochloric acid was refluxed for a few minutes. Hydrolysis took place rapidly and small red needles of the dihydroxyquinone separated which were readily purified from benzene, m. p. 282–284°.

3,6 - Di - (2,4 - dimethylphenyl) - 2,5 - diacetoxyhydroquinone (VII).—A solution of 2 g. of 3,6-di-(2,4-dimethylphenyl)-2,5-diacetoxyquinone (m. p. 186–188°) in 270 cc. of hot ethanol was heated with 1 g. of stannous chloride and the mixture refluxed for fifteen minutes. The deep color of the original solution changed to faint yellow. The mixture was poured into a liter of 4 *N* hydrochloric acid, stirred and allowed to stand until coagulation took place. The crude product weighed 1.5 g. (75%). It was purified best from hot butanol forming white crystals, m. p. 213–215°.

Anal. Calcd. for $C_{26}H_{26}O_6$: C, 71.85; H, 6.03. Found: C, 71.99; H, 5.73.

3,6 - Di - (2,4 - dimethylphenyl) - 1,2,4,5 - tetraacetoxybenzene (VIII).—Acetylation was carried out on crude diacetoxyhydroquinone, either in acetone or in pyridine; the latter proved to be the better procedure. A solution of 1.9 g. of diacetoxyhydroquinone in 20 cc. of hot acetic anhydride, 3–5 cc. of pyridine and a pinch of stannous chloride was refluxed. In the course of a few minutes a heavy precipitate of the tetraacetoxy compound formed. The reaction mixture was poured into 100 cc. of water and 20 cc. of concentrated hydrochloric acid. The crude product weighed 1.9 g. (84%). It was purified from butanol, forming large flake-like crystals, m. p .276–278°.

Anal. Calcd. for $C_{30}H_{30}O_8$: C, 69.46; H, 5.83. Found: C, 69.26; H, 6.01.

The tetraacetoxy compound just described was taken in the crude state and crystallized from four different solvents, acetic anhydride, acetone, methanol, and butanol. In no case was it possible to obtain more than a single individual compound.

Summary

3,6 - Di - (2,4 - dimethylphenyl) - 2,5 - dibromoquinone was converted by the action of alkali to 3,6 - di - (2,4 - dimethylphenyl) - 2,5 - dihydroxyquinone. This was acetylated to the diacetoxyquinone which was reduced to 3,6-di-(2,4-dimethylphenyl) - 2,5 - diacetoxyhydroquinone. Acetylation of this last product gave 3,6-di-(2,4-dimethylphenyl)-1,2,4,5-tetraacetoxybenzene.

In no case were diastereoisomeric forms obtained. It is thus concluded that two acetoxyls, a methyl, and a hydrogen or one acetoxyl, one hydroxyl, a methyl, and a hydrogen in the 2,2′,-6,6′-positions of a biphenyl will not cause restricted rotation.

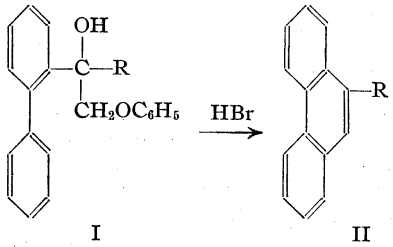
Synthesis of Phenanthrene Derivatives. III.[1] 9-Methylphenanthrene

BY CHARLES K. BRADSHER[2,3] AND ROY W. H. TESS

It has been demonstrated that 1-aryl-1-(2-biphenyl)-2-phenoxyethanols (I, R = aryl) readily undergo cyclization to give 9-arylphenanthrenes.[4]

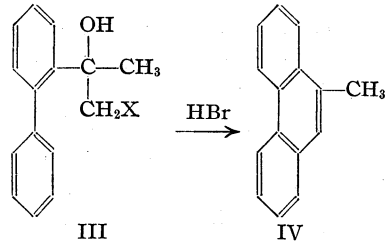


I II

In view of this, it seemed not improbable that the corresponding 1-alkylethanols (I, R = alkyl) might be made to undergo a similar reaction.

We have found that in the case of the methylethanol (I, R = CH_3) such a reaction does take place. When 2-biphenylmagnesium iodide was treated with phenoxyacetone, and the crude carbinol (I, R = CH_3) cyclized by refluxing in a mixture of hydrobromic and acetic acids, 9-methylphenanthrene was obtained in a yield of 32%.

In an effort to find a more satisfactory route to the desired hydrocarbon, the cyclization of a series of carbinols of type III was studied. The



III IV

(X = OCH_3, OC_6H_5, $OC_{10}H_7(\beta)$, $N(C_2H_5)_2$ or Cl)

methods by which the carbinols were prepared together with the over-all yields of methylphenanthrene (IV) are recorded in Table I.

Although all of the carbinols investigated afforded some methylphenanthrene, the yields varied widely. Since these are the over-all yields for both the Grignard reaction and the cyclization, they may not be interpreted as indicative of the tendency of the several carbinols to cyclize. They do, however, afford us a means for the evaluation of the methods of synthesis studied.

TABLE I

Carbinol III, X =	Method of preparing carbinol: Grignard reagent	Ketone	% yield[a] of hydrocarbon
OCH_3	CH_3MgI	o-$C_{12}H_9COCH_2OCH_3$	50
OC_6H_5	o-$C_{12}H_9MgI$	$CH_3COCH_2OC_6H_5$	32
$OC_{10}H_7(\beta)$	o-$C_{12}H_9MgI$	$CH_3COCH_2OC_{10}H_7(\beta)$	23
$N(C_2H_5)_2$	o-$C_{12}H_9MgI$	$CH_3COCH_2N(C_2H_5)_2$	10
Cl	o-$C_{12}H_9MgI$	CH_3COCH_2Cl	< 1

[a] In each case the percentage yield is calculated from the amount of ketone taken.

Calculated from the amount of *ketone* used, the route through the methoxyethanol (III, X = OCH_3) gave the highest yield of the desired hydrocarbon. This carbinol, however, was prepared from 2-(ω-methoxy)-acetobiphenyl which was itself prepared from 2-iodobiphenyl in a yield of 60%. Thus the average over-all yield from the halide was about 30% whether the route was through the methoxy- or phenoxy-ethanol (III, X = OCH_3 or OC_6H_5) although the latter is more direct. The other routes studied lack the preparative value of these two, but are of interest in illustrating the generality of the cyclization reaction.

Our methods for the synthesis of 9-methylphenanthrene, though more convenient than those of Windaus[5] and of Haworth,[6] cannot compare with the method of Bachmann[7] which involves only the action of methyl iodide on 9-phenanthrylmagnesium bromide. If our synthesis finds application, it will be in the preparation of derivatives rather than of the hydrocarbon itself.

One further observation of interest is that 1-methyl-1-(2-biphenyl)-2-phenoxyethanol-1 (III, X = OC_6H_5) can be cyclized to 9-methylphenanthrene in 10% yield by the action of aluminum chloride. This constitutes a new type of Friedel and Crafts reaction.

Experimental

Phenoxyacetone.[8]—This ketone was prepared by a modification of the general procedure of Bradsher and

(7) Bachmann, THIS JOURNAL, **56**, 1363 (1934).

(8) Previously prepared in unstated yields by the addition of sodium to a phenol solution of chloroacetone, Stoermer, *Ber.*, **28**, 1253 (1895). Since the completion of this problem, a more satisfactory method has been reported using bromoacetone, Calaway and Henze, THIS JOURNAL, **61**, 1355 (1939).

Rosher[1] for the preparation of α-phenoxy ketones. Phenol (51.7 g.), anhydrous potassium carbonate (76 g.) and acetone (300 cc.) were placed in a 3-necked flask and mechanically stirred while a solution of chloroacetone (46.8 g.) in acetone (50 cc.) was added slowly over the period of a half hour. Sufficient heat was evolved to cause refluxing of the acetone. Stirring was continued for twenty-four hours. The inorganic salts were then filtered off, the solution concentrated, poured into water and extracted with ether. The ethereal solution was washed with dilute alkali, dried, concentrated and the residue distilled under reduced pressure. The product was a nearly colorless liquid, b. p. 117–124° (19 mm.); yield 17.7 g. (23%). If the mixture is refluxed for three hours instead of being stirred at room temperature for twenty-four hours, the yield is 21%.

1-Methyl-1-(2-biphenyl)-2-phenoxyethanol-1 (III, X = OC_6H_5).—A Grignard reagent was prepared from 20 g. of 2-iodobiphenyl. To this was added a solution of 10 g. of phenoxyacetone in dry ether. After refluxing for forty-five minutes, the mixture was decomposed with a 20% solution of ammonium chloride. Upon concentration of the ethereal extract, the carbinol was obtained as a brown oil. This was not purified further.

Cyclization of 1-Methyl-1-(2-biphenyl)-2-phenoxyethanol-1.—The crude carbinol obtained above was dissolved in 110 cc. of acetic acid, and 60 cc. of 40% hydrobromic acid added. The mixture was refluxed for twenty-four hours. It was then neutralized, steam-distilled from some tarry material and the product collected by filtration. Once recrystallized from methanol, this product gave 3.1 g. (32%) of **9-methylphenanthrene** as white needles, m. p. 91–92.5°. An analytical sample obtained by repeated crystallization melted at 91.5–92.5°.

Anal. Calcd. for $C_{15}H_{12}$: C, 93.69; H, 6.31. Found: C, 93.68; H, 6.31.

The picrate, recrystallized from alcohol, was obtained as fine orange needles, m. p. 153–154°.

1-Methyl-1-(2-biphenyl)-2-methoxyethanol-1 (III, X = OCH_3).—A Grignard reagent was prepared from 2.8 g. of methyl iodide and an ether solution of 2.1 g. of 2-(ω-methoxy)-acetobiphenyl[4] was added. The mixture was decomposed with ammonium chloride solution, and the crude carbinol obtained by evaporation of the ethereal solution.

Cyclization of 1-Methyl-1-(2-biphenyl)-2-methoxyethanol-1.—The crude carbinol obtained above was refluxed for twenty-four hours with a mixture of 20 cc. of acetic acid and 10 cc. of 40% hydrobromic acid. There was little evidence of tar formation, and upon cooling the 9-methylphenanthrene crystallized from the solution. Twice crystallized from methanol, the hydrocarbon was obtained in a yield of 1.78 g. (50%); m. p. 88–91°.

1-(2-Naphthoxy)-acetone[9] was prepared by refluxing a mixture of 46.8 g. of chloroacetone, 79.2 g. of β-naphthol, and 76 g. of anhydrous potassium carbonate in 500 cc. of acetone. The product was worked up as in the case of phenoxyacetone except that the crude material was purified by crystallization from methanol rather than by distillation. Twice crystallized, the product was obtained as small irregular white crystals, m. p. 69–72°; yield 21 g. (21%).

(9) This ketone has been prepared previously in unstated yields by Stoermer, *Ann.*, **312**, 237 (1900).

1-Methyl-1-(2-biphenyl)-2-(2-naphthoxy)-ethanol-1 (III, X = $OC_{10}H_7(\beta)$).—A Grignard reagent was prepared from 15.4 g. of 2-iodobiphenyl and to it was added a solution of 10 g. of 1-(2-naphthoxy)-acetone in 50 cc. of dry benzene. The crude carbinol was isolated as in the case of the corresponding phenoxy carbinol (III, X = OC_6H_5).

Cyclization of 1-Methyl-1-(2-biphenyl)-2-(2-naphthoxy)-ethanol-1.—The crude carbinol was cyclized by refluxing for sixteen hours in a mixture containing 50 cc. of acetic acid and 50 cc. of 34% hydrobromic acid. The product was worked up as in the cyclization of the phenoxy carbinol (III, X = OC_6H_5). The yield was 2.24 g. (32%); m. p. 91–92°.

1-Methyl-1-(2-biphenyl)-2-diethylaminoethanol-1 (III, X = $N(C_2H_5)_2$).—A Grignard reagent was prepared from 28 g. of 2-iodobiphenyl and 12.9 g. of diethylaminoacetone[10] added in ether solution. The mixture was refluxed for thirty minutes and then decomposed with ammonium chloride solution. The crude carbinol was obtained in ether solution.

Cyclization of 1-Methyl-1-(2-biphenyl)-2-diethylaminoethanol-1.—The ether solution obtained above was extracted with 2 *N* hydrochloric acid and the acid extract concentrated to a small volume under reduced pressure. To the residue was added 125 cc. of 34% hydrobromic acid and the mixture refluxed for forty-eight hours. The solution was extracted with ether, the ether evaporated and the residue crystallized from methyl alcohol; yield 2.0 g. (10%), m. p. 92–93°.

1-Methyl-1-(2-biphenyl)-2-chloroethanol-1 (III, X = Cl) was prepared in a manner analogous to that employed in the synthesis of the corresponding phenoxyethanol (III, X = OC_6H_5). A Grignard reagent was prepared from 19.9 g. of 2-iodobiphenyl and treated with 6.55 g. of chloroacetone. The crude carbinol, obtained as in the preceding cases, was a viscous brown liquid.

Cyclization of 1-Methyl-1-(2-biphenyl)-2-chloroethanol-1.—The crude carbinol obtained above was cyclized as in the case of the corresponding phenoxyethanol. The resinous product, after vacuum distillation, yielded a few crystals of 9-methylphenanthrene, m. p. 90–92°. Attempts to cyclize the carbinol with 85% sulfuric acid or aluminum chloride were unsuccessful.

Cyclization of 1-Methyl-1-(2-biphenyl)-2-phenoxyethanol-1 by the Action of Aluminum Chloride.—The crude carbinol, obtained from 10 g. of phenoxyacetone by the method previously described, was dissolved in 240 cc. of carbon bisulfide and 10 g. of aluminum chloride added. The reaction was allowed to proceed overnight. The mixture was treated in the usual way and the 9-methylphenanthrene isolated as the picrate, yield 2.8 g. (10%).

Summary

The new type of ring closure has been extended to the synthesis of 9-methylphenanthrene. Several variations of the ring closure have been studied.

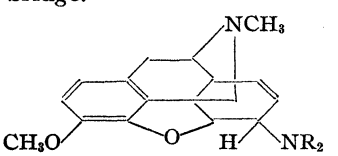
The Aminomorphides and Aminocodides[1]

BY LYNDON SMALL AND FRED S. PALMER[2]

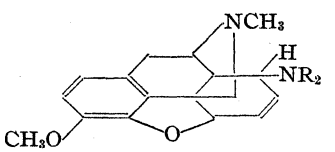
The investigation of compounds derived from the morphine series and carrying basic groups in ring III was begun in the Virginia Laboratory in 1934, with the object of determining the effect of such basic radicals upon physiological action. As early as 1903, Vongerichten and Müller[3] found that α-chlorocodide entered into reaction with piperidine to yield a dibasic compound in which the piperidino group was assumed to have taken the place of the chlorine atom of α-chlorocodide. Some years later, Wieland and Kappelmeier[4] carried out the parallel reaction between α-chloromorphide and diethylamine (diethylaminomorphide), as did von Braun and Kindler[5] with α-chlorocodide and dimethylamine and diethylamine.

As is now well known, replacement of the halogen atom in the halogenomorphides or halogenocodides by other groups may involve both configurational and positional changes, as exemplified in the hydrolysis of these halogeno compounds to α-, β- and γ-isomorphines, or to the corresponding codeine isomers. Before significant conclusions concerning structure and physiological action can be drawn, it is therefore necessary to scrutinize the structural evidence for any derivative originating from replacement of a halogen atom (or perhaps other groups) in ring III of the morphine series.

There exist, to our knowledge, no distinctive physical or chemical criteria that may be applied to the determination of the configuration of groups at C-6 or C-8 relative to any arbitrarily chosen standard. We have, in the past, classified certain derivatives as having the codeine or isocodeine, the pseudocodeine or allopseudocodeine configuration, on the basis of similarities in pharmacological action,[6] with full realization, however, of the limitations and weaknesses of such deductions. In respect to positional differences, between the unsaturated 6- and 8-substituted types, we possess, in catalytic hydrogenation, a determinative method that has been in agreement with so many compounds of proved structure that it probably may be considered reliable as far as the morphine series is concerned. Namely, for all those derivatives having the substituent (or hydrogen) in the 8-position, and a double bond at the 6,7-position, the usual course taken by hydrogenation results in opening the oxygen bridge simultaneously with, or before, saturation of the double bond. The derivatives with the 6-substituent (halogen excepted) and the 7,8-double bond undergo hydrogenation normally, without involving the oxygen bridge.



6-Aminocodides



8-Aminocodides

As would be expected from observations already reported in the thiocodide and other series, two of the examples cited, reactions of α-chlorocodide with piperidine and of α-chloromorphide with diethylamine, result, respectively, in 8-piperidocodide and 8-diethylaminomorphide. There can be little doubt that the dimethylaminocodide of von Braun and Kindler also carries the new basic group in the 8-position. The reaction product from α-chlorocodide and piperidine, 8-piperidocodide, under the ordinary conditions of hydrogenation, takes up two moles of hydrogen, to give the tetrahydro derivative, in which not only has the alicyclic double bond been saturated, but the

(1) The work reported in this paper is part of a unification of effort by a number of agencies having responsibility for the solution of the problem of drug addiction. cyclic ether group been opened reductively as well. As with other examples of 6,7-unsaturated morphine types,[7] 8-piperidocodide, under special hydrogenation conditions, can be converted in part to the non-phenolic "normal" dihydro derivative. The latter, no longer possessing the pseudocodeine type of unsaturated system, is indifferent toward further reduction.

By the reaction of α-chloromorphide with piperidine, the analogous 8-piperidomorphide is obtained, whose relationship to the known 8-piperidocodide can be shown by methylation. 8-Piperidomorphide, like its methyl ether, absorbs two moles of hydrogen readily, to yield the corresponding diphenolic tetrahydro derivative. Although reduction of the hydrochloride in glacial acetic acid resulted in diminished hydrogen absorption, the desired dihydro derivative was not isolated in pure form.

We have verified the Wieland and Kappelmeier reaction of diethylamine with α-chloromorphide, to form a diethylaminomorphide, but because of the more favorable solubility of the codides, and their greater stability toward oxidation, turned our attention to the 8-diethylaminocodide of von Braun and Kindler. As a pseudocodeine type, this undergoes reduction with additon of two moles of hydrogen, to give tetrahydro-8-diethylaminocodide, so that the 8-position for the basic group seems assured.

α-Chlorocodide also reacts with liquid ammonia at about 50°, with substitution of an amino group at the 8-position and loss of the 6-halogen atom. 8-Aminocodide, as a primary amine, undergoes acetylation readily with cold acetic anhydride to yield 8-diacetylaminocodide. 8-Aminocodide behaves in a typical way toward catalytic reduction. As hydrochloride, in glacial acetic acid, it can be reduced to a non-phenolic dihydro derivative. As base, in alcohol, on the other hand, it takes up two moles of hydrogen, giving the phenolic tetrahydro-8-aminocodide.

All of the products that we have examined derived from amination of α-chloromorphide or α-chlorocodide, appear to have resulted from an α,γ-shift, and carry the basic group in the 8-position. The halogeno compounds of the morphine series that are generally believed to carry the halogen atom at the 8-position, namely, bromocodide and bromomorphide, and β-chlorocodide and β-chloromorphide, seem to react with amino compounds with the reverse α,γ-shift, to yield the 6-amino derivatives. Bromomorphide and piperidine, at 100°, give 6-piperidomorphide. We believe the assignment of the 6-position to the substituent to be justified from the fact that the compound cannot be induced to take up more than one mole of hydrogen, and yields only a dihydro derivative. 6-Piperidomorphide undergoes methylation to give 6-piperidocodide, a compound that also results from the action of piperidine with either bromocodide or β-chlorocodide. 6-Piperidocodide likewise is saturated by addition of one mole of hydrogen, although the reduction product was so difficult to purify that analytical data cannot be advanced.

The identity of the amination products from bromocodide and β-chlorocodide lends additional support to the conception that both of these compounds carry the halogen atom in the 8-position. It is remarkable that while the reactions of the α-halogeno types, and of β-chlorocodide and bromocodide, with piperidine seemed to proceed with equal facility, bromocodide was regained quite unchanged from attempted reaction with liquid ammonia. 6-Aminocodide will perhaps be obtained when facilities for working at higher temperatures and pressures are available. The failure with bromocodide is the more unexpected in view of the fact that the bromo base seems to enter into replacement reactions with hydriodic acid and with mercaptans as readily as does α-chlorocodide, in contrast to the inactive β-chloro series.

The aminocodides and aminomorphides are outstanding exceptions to the general rule that replacement of the alcoholic hydroxyl of the morphine types by other groups leads to increased physiological activity. Introduction of the basic group usually reduced toxicity, and greatly decreased analgesic action.[8] We have observed that the substitution of a basic group in the aromatic ring of morphine (2-aminomorphine[4,9]) also results in a great diminution of physiological action. The intramolecular acidic and basic relationship in the morphine types appears to be intimately associated with biological effect.

Experimental

8-Diethylaminomorphide.—This base was prepared essentially according to the procedure of Wieland and Kap-

pelmeier. After three sublimations in a high vacuum, it had the melting point 201–204° (evac. tube) and $(\alpha)^{21}D$ +49.1° (methanol, *c*, 0.87) (W. and K. observed the melting point 203°).

Anal. Calcd. for $C_{21}H_{28}N_2O_2$: N, 8.2. Found: N, 8.1.

On treatment with diazomethane it yielded 8-diethylaminocodide. 8-Diethylaminomorphide dihydriodide was prepared in the usual way and purified from water; m. p. 87–93° (evac. tube), $(\alpha)^{25}D$ +2.6° (water, *c*, 0.38). The salt appears to be a sesquihydrate.

Anal. Calcd. for $C_{21}H_{30}I_2N_2O_2 + 1.5H_2O$: I, 40.8; H_2O, 4.3. Found: I, 41.1; H_2O, 4.6.

The diperchlorate was crystallized from water, m. p. 114–116° (evac. tube), $(\alpha)^{19}D$ +4.4° (water, *c*, 0.91).

Anal. Calcd. for $C_{21}H_{30}Cl_2N_2O_{10}$: Cl, 13.1. Found: Cl, 13.5.

8-Piperidomorphide.—Ten grams of α-chloromorphide with 10 g. of piperidine was heated in an evacuated sealed tube at 100° for thirty minutes. The product was dissolved in 3 *N* hydrochloric acid, precipitated with excess of sodium carbonate and the precipitate extracted into ether. The yield of crystalline product was 9.2 g. It was purified from alcohol and sublimed in a high vacuum at 200°; m. p. 222–224° (evac. tube), $(\alpha)^{24}D$ +28.7° (methanol, *c*, 1.15).

Anal. Calcd. for $C_{22}H_{28}N_2O_2$: C, 74.9; H, 8.0; N, 7.9. Found: C, 74.9; H, 7.8; N, 8.2.

The dihydriodide was prepared in 10% acetic acid with potassium iodide, redissolved in dilute acetic acid and again precipitated with potassium iodide. It was purified from water and had $(\alpha)^{23}D$ +14.9° (water, *c*, 0.37), m. p. 208–214° (evac. tube).

Anal. Calcd. for $C_{22}H_{30}I_2N_2O_2$: I, 41.7. Found: I, 42.3.

The monomethiodide was prepared in methanol solution, and purified from water; m. p. 243–245° (evac. tube), $(\alpha)^{23}D$ +23.7° (50 vol. % alcohol, *c*, 1.14).

Anal. Calcd. for $C_{23}H_{31}IN_2O_2$: I, 26.4. Found: I, 25.8.

Tetrahydro-8-piperidomorphide.—Two grams of 8-piperidomorphide in 30 cc. of 5% acetic acid with 50 mg. of platinum oxide absorbed two moles of hydrogen rapidly. The new base was isolated with sodium carbonate and ether and was sublimed three times in a high vacuum. It had the m. p. 270–280° (evac. tube, dec.) and $(\alpha)^{26}D$ +45.1° (10% acetic acid, *c*, 0.63). The ferric chloride test was moss-green. No crystalline salts could be obtained.

Anal. Calcd. for $C_{22}H_{32}N_2O_2$: C, 74.1; H, 9.0; N, 7.9. Found: C, 73.8; H, 8.9; N, 8.1.

Acetylation with acetic anhydride resulted in a base of m. p. 172–178°.

8-Diethylaminocodide.—This compound, prepared according to von Braun and Kindler and sublimed three times in a high vacuum, had the m. p. 101–103° (von B. and K., 102°) and $(\alpha)^{23}D$ +42.6° (methanol, *c*, 1.0). The same compound was obtained from the methylation of the 8-diethylaminomorphide described above.

The diperchlorate was prepared in dilute perchloric acid in the presence of a little alcohol, and purified from water or alcohol; $(\alpha)^{19}D$ +3.3° (water, *c*, 0.92), m. p. 180.5–183°.

Anal. Calcd. for $C_{22}H_{32}Cl_2N_2O_{10}$: Cl, 12.8. Found: Cl, 12.7.

The dihydriodide was prepared in the usual way and recrystallized from water or alcohol to constant rotation, $(\alpha)^{26}D$ +22.9° (absolute alcohol, *c*, 0.39); m. p. 179–182°.

Anal. Calcd. for $C_{22}H_{32}I_2N_2O_2$: I, 41.6. Found: 1, 41.0, 42.3.

Tetrahydro-8-diethylaminocodide.—Two grams of 8-diethylaminocodide in 50 cc. of ethanol with 80 mg. of platinum oxide absorbed two moles of hydrogen in five hours. The residue from evaporation of the alcohol was washed with a little cold ether. This material melted at 116–119° with gas evolution and was probably hydrated. It was sublimed four times in a high vacuum at 130°; m. p. 154–157°, rotation constant at $(\alpha)^{25}D$ +31.5° (methanol, *c*, 0.75).

Anal. Calcd. for $C_{22}H_{34}N_2O_2$: C, 73.7; H, 9.6. Found: C, 73.6; H, 9.5.

The monoperchlorate was prepared in dilute perchloric acid and crystallized by cooling the solution after addition of a drop of alcohol. It was purified from water, $(\alpha)^{26}D$ +18.3° (water, *c*, 0.30); m. p. 234–238° (evac. tube).

Anal. Calcd. for $C_{22}H_{35}ClN_2O_6$: Cl, 7.7. Found: Cl, 8.0.

8-Piperidocodide.—This base, prepared according to Vongerichten and Müller, was purified from methanol and had the m. p. 116–117° (V. and M. observed m. p. 118°). After four sublimations in a high vacuum, the rotation was constant, $(\alpha)^{22}D$ +25.8° (methanol, *c*, 0.89). The same base was obtained by methylation of 8-piperidomorphide with diazomethane.

Anal. Calcd. for $C_{23}H_{30}N_2O_2$: N, 7.7. Found: N, 7.7.

The di-acid sulfate dihydrate was prepared by dissolving the base in 10% sulfuric acid, from which the salt crystallized immediately. It was crystallized twice from 10% sulfuric acid and twice from alcohol, $(\alpha)^{26}D$ +19.8° (water, *c*, 1.46); m. p. 161–163.5° (evac. tube).

Anal. Calcd. for $C_{23}H_{38}N_2O_2S_2 = C_{23}H_{30}O_2N_2 \cdot 2H_2SO_4 \cdot 2H_2O$: SO_4, 32.1; H_2O, 6.0. Found: SO_4, 32.5; H_2O, 5.4.

The monohydriodide was prepared in the usual way and purified from water. It has $(\alpha)^{24}D$ +13.3° (water, *c*, 0.337); m. p. 234–237° (corr., evac. tube).

Anal. Calcd. for $C_{23}H_{31}IN_2O_2$: I, 25.7. Found: I, 27.3.

A homogeneous salt is very difficult to obtain. Other preparations consisted mostly of the dihydriodide (Calcd.: I, 40.8. Found: I, 38.4, 38.6).

For the monomethiodide of V. and M. we observed the value $(\alpha)^{25}D$ +22.0° (water, *c*, 0.86).

The diperchlorate, purified from water, has the m. p. 181–183° and $(\alpha)^{23}D$ +13.2° (50 vol. % alcohol, *c*, 1.02).

Anal. Calcd. for $C_{23}H_{32}Cl_2N_2O_{10}$: Cl, 12.5. Found: Cl, 12.3.

Tetrahydro-8-piperidocodide.—A solution of 2 g. of 8-piperidocodide in 60 cc. of ethanol with 50 mg. of platinum oxide absorbed 2 moles of hydrogen rapidly. The residue from evaporation of the alcohol was washed with

a little cold ether, and the crystals sublimed twice in a high vacuum; m. p. unsharp at about 125°, rotation constant at $(\alpha)^{25}D$ +36.7° (methanol, *c*, 1.07); ferric chloride test, deep emerald-green.

Anal. Calcd. for $C_{23}H_{34}N_2O_2$: C, 74.5; H, 9.3; N, 7.6. Found: C, 74.7; H, 9.1; N, 7.5.

Dihydro-8-piperidocodide.—Three grams of the amorphous powdery hydrochloride, obtained by treating an ethereal solution of 8-piperidocodide with ethereal hydrogen chloride, was dissolved in 50 cc. of glacial acetic acid and hydrogenated in the presence of 150 mg. of platinum oxide. The absorption of hydrogen stopped at 1.6 moles. The filtered solution was diluted with an equal volume of water, made alkaline with ammonia, and the precipitate extracted into ether. The crystalline residue from evaporation of the ether was recrystallized from alcohol, yield 0.95 g., m. p. 164–167°. Two crystallizations from alcohol and two sublimations in a high vacuum yielded a product of melting point 167–169°, $(\alpha)^{23}D$ −1.2° (methanol, *c* 1.68). The ferric chloride test was negative.

Anal. Calcd. for $C_{23}H_{32}N_2O_2$: C, 74.9; H, 8.8; N, 7.6. Found: C, 75.0; H, 9.1; N, 8.0.

From the alcohol mother liquors, 0.46 g. of pure tetrahydro-8-piperidocodide could be isolated.

8-Aminocodide.—Ten grams of α-chlorocodide in 180 g. of liquid ammonia was held at 50° for twenty-four hours. After excess ammonia had evaporated, the residue was dissolved in dilute hydrochloric acid, and the base was precipitated with sodium hydroxide and brought into ether. The amorphous product was dissolved in warm alcohol and the crystalline base precipitated by slow addition of ether. It was converted to the hydrochloride with alcoholic hydrogen chloride, yield 11 g.[10] A solution of the hydrochloride was treated with alkali and extracted rapidly with a large volume of ether. The ether solution quickly deposited star-shaped crystalline aggregates of the base. It was recrystallized from ether and sublimed in a high vacuum at 130°. It has the melting point 128.5–129°, $(\alpha)^{21}D$ −79.2° (alcohol, *c*, 0.48).

Anal. Calcd. for $C_{18}H_{22}N_2O_2$: C, 72.4; H, 7.4; N, 9.4. Found: C, 72.3; H, 7.4; N, 9.8.

The dihydrochloride, purified from 95% alcohol, has the melting point 300–305° (corr., evac. tube) and $(\alpha)^{24}D$ −40.7° (water, *c*, 0.88).

Anal. Calcd. for $C_{18}H_{24}Cl_2N_2O_2 + H_2O$: Cl, 18.2; H_2O, 4.6. Found: Cl, 18.2; H_2O, 3.6.

8-Diacetylaminocodide was prepared by allowing 0.5 g. of 8-aminocodide in 5 cc. of acetic anhydride to react for eighteen hours at room temperature. Neutralization with sodium carbonate yielded 0.6 g. of crystalline base, which was purified from ethyl acetate. It crystallizes with a molecule of ethyl acetate, which could not be determined directly because of the tendency of the base to sublime; the m. p. is 218–220° (decomp.); in an evacuated tube, 165–175°, solidifying and remelting at 205°; $(\alpha)^{24}D$ −83.1° (alcohol, *c*, 1.04).

Anal. Calcd. for $C_{26}H_{34}N_2O_6$: C, 66.4; H, 7.3. Found: C, 66.5, 66.4; H, 7.0, 7.1.

(10) We are indebted to Dr. B. F. Faris, Experimental Station of E. I. du Pont de Nemours and Co., for this preparation.

Tetrahydro-8-aminocodide.—A solution of 8-aminocodide in methanol, with platinum oxide, absorbed two moles of hydrogen in fifteen minutes. The base could not be obtained crystalline from solvents, but sublimed onto a cold finger in a high vacuum at 130° in large white crystals; m. p. 138.5–140°, $(\alpha)^{24}D$ −9.7° (alcohol, *c*, 1.13). It is soluble in alkali; ferric chloride test, intense blue-green.

Anal. Calcd. for $C_{18}H_{26}N_2O_2$: C, 71.5; H, 8.7. Found: C, 71.7; H, 8.6.

The dihydrochloride was prepared with alcoholic hydrogen chloride and purified from absolute alcohol; $(\alpha)^{24}D$ +6.6° (water, *c*, 0.91).

Anal. Calcd. for $C_{18}H_{28}Cl_2N_2O_2$: Cl, 18.9. Found: Cl, 18.2.

Dihydro-8-aminocodide.—A suspension of 2.3 g. of 8-aminocodide dihydrochloride in 20 cc. of glacial acetic acid with 50 mg. of platinum oxide absorbed about 1.7 moles of hydrogen in thirty minutes. The product was precipitated with excess dilute sodium hydroxide, brought into ether, and the ethereal solution was extracted several times with dilute alkali. The dihydro compound could not be obtained crystalline, and was distilled twice in a high vacuum at 170°. It consisted of a colorless, glassy solid having $(\alpha)^{21}D$ −28.7° (alcohol, *c*, 1.08). The base is so soluble in water (like 8-aminocodide itself) that the absence of a phenolic group cannot be demonstrated with alkali. It gives a faint green ferric chloride test, and may contain a little of the tetrahydro derivative.

Anal. Calcd. for $C_{18}H_{24}N_2O_2$: C, 71.9; H, 8.0. Found: C, 71.7; H, 8.0.

The dihydrochloride, prepared with alcoholic hydrogen chloride and purified from a mixture of 1 part of absolute alcohol with 2 parts of 95% alcohol, has the m. p. 274–277° (evac. tube) and $(\alpha)^{24}D$ −14.7° (water, *c*, 1.08).

Anal. Calcd. for $C_{18}H_{26}Cl_2N_2O_2 + H_2O$: Cl, 18.1; H_2O, 4.6. Found: Cl, 17.8; H_2O, 4.6.

6-Piperidomorphide.—A mixture of 20 g. of bromomorphide and 20 g. of piperidine in a sealed evacuated tube was heated for thirty minutes in the boiling water-bath. The product was dissolved in 3 *N* hydrochloric acid, from which the base was precipitated with sodium carbonate and extracted into ether. The crystalline residue from the ether had the melting point 213–215°, yield 14.6 g. It was crystallized from ethyl acetate and sublimed four times in a high vacuum at 200°; m. p. 216–217° (evac. tube), $(\alpha)^{23}D$ −234.8° (methanol, *c*, 0.871). No other crystalline product could be isolated from the reaction.

Anal. Calcd. for $C_{22}H_{28}N_2O_2$: C, 74.9; H, 8.0; N, 7.9. Found: C, 75.2; H, 8.0; N, 8.2.

By methylation with diazomethane, 6-piperidomorphide was converted to 6-piperidocodide.

The methiodide was prepared in methanol, and separated crystalline when absolute ether was added cautiously. It crystallized as long needles from water; m. p. 236–241° (corr., evac. tube), $(\alpha)^{23}D$ −145.8° (50 vol. % alcohol, *c*, 1.05).

Anal. Calcd. for $C_{21}H_{31}IN_2O_2$: C, 53.6; H, 6.6. Found: C, 54.8, 54.3; H, 6.3, 6.2.

Dihydro-6-piperidomorphide.—A solution of 5 g. of 6-piperidomorphide in 80 cc. of ethanol with 0.2 g. of plat-

inum oxide absorbed 1 mole of hydrogen in twenty-two hours. After removal of the alcohol under diminished pressure, the oily residue was crystallized by addition of ether; yield 3.6 g., m. p. 203–210°. After four crystallizations from ethyl acetate it had the m. p. 215–217° and $(\alpha)^{24}D$ −155.9° (methanol, *c*, 0.76).

Anal. Calcd. for $C_{22}H_{36}N_2O_2$: C, 74.6; H, 8.5; N, 7.9. Found: C, 74.2; H, 8.8; N, 7.8.

6-Piperidocodide.—A mixture of 10 g. of bromocodide and 10 g. of piperidine in an evacuated sealed tube was heated in the boiling water-bath for forty-five minutes. The product was dissolved in acid, precipitated with sodium carbonate, and extracted into ether. The residue from the ether was again put through this procedure to remove piperidine. The oily product (10 g.) was treated with 6 cc. of 60% perchloric acid and diluted with 75 cc. of water, warming into solution. When the solution cooled, oily material began to separate, and was brought just into solution with alcohol. After twelve hours, the solution had deposited 6.5 g. of crystalline diperchlorate, which was purified from water to constant rotation $(\alpha)^{23}D$ −113.4° (water, *c*, 0.44); m. p. 172–175°.

Anal. Calcd. for $C_{23}H_{52}Cl_2N_2O_{10}$: Cl, 12.5. Found: Cl, 12.1.

The perchlorate was converted to the base, extracted with ether, and the residue from the ether was washed with cold 30–60° ligroin. The base was sublimed four times in a high vacuum at 130° (to constant rotation); melting point, 75–80°, $(\alpha)^{25}D$ −233.9° (methanol, *c*, 0.87).

Anal. Calcd. for $C_{23}H_{30}N_2O_2$: C, 75.4; H, 8.2; N, 7.6. Found: C, 75.1; H, 8.2; N, 7.6.

The same base and perchlorate were obtained by treatment of 6-piperidomorphide with diazomethane, likewise by heating β-chlorocodide with piperidine for six hours at 130°. Hydrogenation of 6-piperidocodide resulted in absorption of 1 mole of hydrogen, but the product was a viscous liquid from which no crystalline derivatives could be prepared. A similar substance was obtained when dihydro-6-piperidomorphide was methylated with diazomethane.

Treatment of 50 g. of bromocodide with liquid ammonia at 50° for twenty-four hours resulted in recovery of 40 g. of unchanged material. No halogen-free product could be isolated.

Summary

The reaction of α-chloromorphide and α-chlorocodide with secondary amines or ammonia proceeds with a rearrangement such that the new basic groups appear at the 8-position. The morphine derivatives that are believed to have the halogen atom in the 8-position, as bromomorphide, bromocodide, and β-chlorocodide, react with a rearrangement in the reverse sense, to give 6-aminomorphide and 6-aminocodide derivatives. The introduction of basic groups into the morphine or codeine molecule results in a considerable diminution of physiological action, especially analgesic effect.

Studies on Lignin and Related Compounds. XLI. The Detection, Isolation and Estimation of the Syringyl Radical in Plant Products[1]

BY M. J. HUNTER AND HAROLD HIBBERT

The syringyl group was first identified in natural products as a unit in the glucoside, syringin,[2] and later in the anthocyanidin, malvin chloride.[3] Although its presence in hard wood lignin occasionally had been inferred from indirect evidence of various kinds,[4] the first isolation of syringyl components from this source was accomplished in these Laboratories.[5] More recently, it was shown that the ethanolysis of hard woods gave much higher yields[6a] than previous methods, and α-ethoxypropiovanillone and α-ethoxypropiosyringone were successfully isolated in almost equal amounts.[6b] The far-reaching implications which the corresponding hydroxy compounds (I) and (II) have for the theory of lignin structure have already been discussed exhaustively,[6,7] and it will suffice to emphasize our view that hard wood lignin is a condensation product of the unit structures (I) and (II) in equal

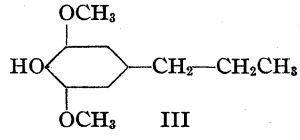
amounts, while in soft wood lignin the syringyl nucleus is lacking. Unpublished results[8] indicate that both the extracted lignins and the individual units give C_6–C–C–C derivatives, in practically quantitative yield, on hydrogenation at high pressure. The methoxyl content of spruce lignin, 15–17%, is in accord with that of α-hydroxypropiovanillone (I), 15.8%. An equimolecular mixture of (I) and (II) has a calculated value of 21.6%, in comparison with an observed methoxyl content of 20–21.5% for maple and other hard wood lignins.[4a,9] Ethanol lignin from maple wood[6b] contains 27–28% alkoxyl calculated as methoxyl. Of this, 10% is ethoxyl, equivalent to one ethoxyl group per molecular weight of 450 and identical with that of an equimolecular mixture of the ethoxy derivatives from (I) and (II). As a result of improvements in the separation of syringyl from guaiacyl derivatives, we are now able to show that 53% of the phenol fraction from ethanol maple lignin consists of α-ethoxypropiosyringone. All these observations support our view as to the nature of hard wood lignins. On the other hand, the presence of the very small amounts (a fraction of 1%) of syringyl derivatives reported in a soft wood lignin[10] (spruce) could not be confirmed, due possibly to the fact that less than 3–5% of syringyl in presence of 95–97% of guaiacyl derivatives cannot be detected by our method.

Separation of Syringyl and Guaiacyl Derivatives.—The recent discovery[6b] of the presence of both of these type substances in hard woods has necessitated the development of practical methods for their isolation and quantitative separation. In this communication[6b] a separation of syringyl from guaiacyl derivatives by formation of their *p*-nitrobenzoates was given, and, while this procedure served for the characterization of the former, the method was unsuitable, quantitatively, and the original compounds were difficult to reclaim. The following new method does away with these disadvantages. It rests on the discovery that addition of an anhydrous ethanol solution of potassium acetate to an ethanol solution of a mixture of guaiacyl and syringyl derivatives brings about precipitation of the latter in the form of a crystalline potassium salt, usually in high yield; the potassium salt of the guaiacyl-containing product is more soluble and remains in solution. The efficiency of the method when applied to a number of different syringyl compounds is shown in Table I.

The fact that 3,5-dimethoxy-4-hydroxyphenylpropane-1 (III) is not precipitated by potassium



acetate would seem to indicate that precipitability with this reagent apparently is limited to syringyl compounds having a carbonyl group in the para position. This is in harmony with the evidence presented by Lock,[11] indicating a direct relationship between the 1,4-hydroxycarbonyl groups in the benzene nucleus. The much lower value obtained with α-acetoxypropiosyringone (Table I, no. 5) is possibly the result of an intramolecular effect exerted between the acetate and the carbonyl groups.

The reaction appears to be a general one, although trinitrophenol, which contains a strongly acidic hydroxyl group, is also precipitated readily with potassium acetate under the same conditions. Apparently phenols with both ortho hydrogen atoms substituted, and also having a strongly negative group in the para position, are precipitated by potassium acetate in absolute ethanol.

The quantitative efficiency of the method is shown in Table II.

The actual process of separation may be varied greatly, depending on the nature of the products under investigation. Addition of one to three volumes of dry ether to the potassium acetate solution, in the case of the more difficultly precipitable syringyl derivatives, was found greatly to increase the yield of potassium salts. Other reagents such as dry ammonia, and potassium and sodium hydroxides in ethanol, were found effective in bringing about a practical separation

in dilute solution in many cases, although they are not entirely specific, since most of the guaiacyl analogs are precipitated, to some extent, when *concentrated* ethanol solutions are used.

Sodium acetate, apparently because of its low solubility in ethanol, does not precipitate syringyl compounds, while ammonia, *in anhydrous ether*, precipitates both guaiacyl and syringyl compounds containing a carbonyl group in the para position to the hydroxyl group.

In Table III a survey of the conditions necessary for the qualitative precipitation of syringyl and guaiacyl derivatives is given.

The progressive order (1 to 5) in which the reagents are tabulated is that of their increasing relative value as precipitating media for phenolic derivatives. Thus compounds precipitated by reagent no. 1 will be precipitated more readily by each subsequent reagent, nos. 2, 3, 4 and 5, in the order named, and the conditions for separating a given mixture of syringyl and guaiacyl components will be determined by the relative ease with which they are precipitated in the form of their potassium or ammonium salts. Both potassium and ammonium derivatives of syringyl compounds separate in a microcrystalline form; the former on heating do not melt, while the latter do, with evolution of ammonia, over a wide range depending on the rate of temperature increase.

Application of the above methods to the distilled phenol fraction obtained in the ethanolysis of maple wood[6b] showed that 53% consisted of α-ethoxypropiosyringone.

While these results are in harmony with the assumption of the presence of a mixed dimeric

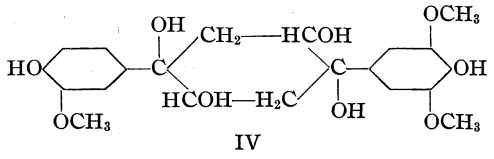
lignin building unit in hard woods of type IV derived from one mole each of α-hydroxypropiovanillone and α-hydroxypropiosyringone, it should be emphasized that up to the present no experimental evidence has been obtained of its actual existence.



IV

Experimental

Quantitative Precipitation of Syringyl Derivatives.—The syringyl compound (0.1000 g.) is dissolved in 2 cc. of absolute ethanol and then a saturated solution (3 cc.) of anhydrous potassium acetate in absolute ethanol (3 cc.) added. The potassium salt generally separates out very rapidly as a microcrystalline product, the color varying in shade from colorless to deep orange. After standing at room temperature (25°) for thirty minutes, the mixture is filtered, washed with absolute ethanol (5 cc.) and dry ether (5 cc.) and dried for one hour at 100° (760 mm.) before weighing. Prior to analysis the precipitate is dried over phosphorus pentoxide at 56° (14 mm.). The results are given in Table I.

Quantitative Separation of Guaiacyl and Syringyl Derivatives.—To the mixture in anhydrous ethanol (2 cc.) of 0.1000 g. of the guaiacyl derivative and varying quantities of the syringyl product, as indicated, was added a saturated anhydrous ethanol solution of potassium acetate (3 cc.), and the precipitated potassium salt of the syringyl derivative filtered, washed and weighed. The results are shown in Table II.

Separation of the Syringyl and Guaiacyl Components in the Phenol Fraction Obtained in the Ethanolysis of Maple Wood.[6b]—The distilled phenol fraction (9.6 g.) was added to a solution of anhydrous potassium acetate (10 g.) dissolved in absolute ethanol (75 cc.) and the mixture well shaken. To this was added dry ether (175 cc.) and the yellow precipitate filtered, washed with ethanol, then with ether and dried (wt. 4.7 g.). The filtrate was shaken with 500 cc. of water and the aqueous layer then extracted thoroughly with benzene. The combined ether and benzene solutions were then concentrated and the residual oil distilled as usual under reduced pressure. The total distillate (4.96 g.) was dissolved in 40 cc. of *anhydrous ethanol* and dry ammonia gas passed into the solution for a few minutes. The yellow crystalline ammonium salt (1.1 g.) was filtered off, washed with ethanol and ether and dried under reduced pressure at room temperature. Both the ammonium and potassium salts when treated with an equivalent of *p*-nitrobenzoyl chloride in dry pyridine yielded the *p*-nitrobenzoate of α-ethoxypropiosyringone.[6b] The combined weights of the two crystalline fractions are equivalent to 5.07 g. of α-ethoxypropiosyringone or 53% of the original mixed phenol fraction.

Synthesis of 3,5-Dimethoxy-4-hydroxyphenylpropane-1.—This derivative was prepared by Mauthner[12] by a molecular rearrangement of the allyl ether of pyrogallol 1,3-dimethyl ether followed by hydrogenation of the acetate of the resulting phenol with a palladium catalyst. The material used in these experiments was prepared by a Clemmensen[13] reduction of propiosyringone[6b] obtained by demethylating 3,4,5-trimethoxypropiophenone with concentrated sulfuric acid.

From 2.0 g. of propiosyringone there was obtained 0.9 g. of product. Distillation of this gave a colorless, mobile oil (0.50 g., 26.6%) which solidified at −5 to 0°; b. p. 123–126° (0.004 mm.), 279–281° (749 mm.); reported by Mauthner[12] 285° (760 mm.). The product could not be purified further.

Anal. Calcd. for $C_9H_{10}O(OCH_3)_2$: OCH_3, 31.6. Found: OCH_3, 30.3.

Synthesis of α-Hydroxypropiosyringone.—The method used was similar to that developed by Robinson[14] for an analogous compound.

α-Acetoxypropiosyringone[6b] (12.5 g.) was dissolved in boiling anhydrous methanol (120 cc.) and mixed with a warm methanol solution of potassium hydroxide (12.0 g.). There was a vigorous reaction, the solution darkened and in a few seconds a yellow crystalline material was precipitated. After filtration, washing first with methanol, then with ether, it was dried in a vacuum desiccator; yield, 12.0 g. (98% calculated as potassium salt of α-hydroxypropiosyringone).

This potassium salt (11.1 g.) was dissolved in a dilute acetic acid solution (50 cc. of water and 7.2 cc. of glacial acetic acid), the solution inoculated with crystals of α-hydroxypropiosyringone and allowed to stand at room temperature for twenty-four hours, the crystalline product removed by filtration, the filtrate carefully extracted with chloroform and the chloroform solution dried with anhydrous sodium sulfate and concentrated, under reduced pressure, to a thick sirup. To this was added the previous crystalline material and the combined product dissolved in a minimum amount of hot benzene. After filtration and cooling, 8.6 g. of crystalline precipitate (90%) was obtained. Three recrystallizations from benzene gave a pure white product in the form of square-shaped crystals, m. p. 126–127°.

Anal. Calcd. for $C_9H_8O_3(OCH_3)_2$: C, 58.4; H, 6.20; OCH_3, 27.4. Found: C, 58.3; H, 6.38; OCH_3, 27.1.

The authors desire to express to the Dow Chemical Company their best thanks for the assistance rendered in the form of a Scholarship granted to one of them (M. J. H.).

Summary

1. A simple method for the quantitative separation of syringyl from guaiacyl derivatives is given.

2. A characteristic difference between hard and soft woods is shown to consist in the presence in the lignin derived from the former of an equal amount of guaiacyl and syringyl analogs;

(12) Mauthner, *J. prakt. Chem.*, **102**, 36 (1921).

(13) (a) Clemmensen, *Ber.*, **46**, 1837 (1913); (b) Hurd and Fowler, THIS JOURNAL, **61**, 252 (1939).

(14) Robinson, *J. Chem. Soc.*, 2701 (1931).

in the latter only the corresponding guaiacyl components are present.

3. It is suggested that in hard woods the lignin building unit may be a mixed dimer, derived, for example, from one mole each of α-hydroxypropiovanillone and α-hydroxypropiosyringone.

4. A method for the synthesis of α-hydroxypropiosyringone (possibly a building unit of hard wood lignins) is described.

Studies on Lignin and Related Compounds. XLII. The Isolation of a Bisulfite Soluble "Extracted Lignin"

BY WILLIAM H. STEEVES[1] AND HAROLD HIBBERT

The fact that "extracted lignins," isolated for example by the use of acids and of organic solvents in presence of a catalyst (hydrochloric acid, etc.), are insoluble on heating with bisulfite solution points to their having undergone deep-seated changes in structure during their isolation, since "protolignin" as present in the wood is readily bisulfite soluble.

In a recent investigation[2] it was shown that an acetylated oak lignin isolated by the acetylation procedure developed by Suida and Titsch[3] (use of a mixture of acetic anhydride, glacial acetic acid and a small amount of concentrated sulfuric acid) gave, on deacetylation, and for the first time, an extracted lignin completely soluble in hot bisulfite solution at 110°. As shown in another communication[4] the oak lignin sulfonic acid thus formed, on heating with alkali, gave a mixture of vanillin and syringaldehyde in approximately equal amounts.

Under the same conditions of acetylation, the reactive sugar, fructose,[5] and its dehydration product, hydroxymethylfurfural,[6] yield crystalline acetates and no appreciable amounts of acetylated lignin-like materials.

These results thus serve to indicate that lignin is not formed during isolation from carbohydrate material as postulated by Hilpert.[7]

This method of lignin isolation, through acetylation, evidently gives a relatively unchanged, and only slightly polymerized, form of "protolignin." This recently has been confirmed by the partial reconversion of an acetylated lignin, isolated in this manner, to simple lignin building units by treatment with hydrogen chloride and ethanol.[8]

More recently it has been shown that after deacetylation the recovered oak lignin can also be depolymerized in the same manner.[9]

Experimental

Extraction with Alkali.—The procedure followed was that used by Suida and Titsch.[3] Alcohol–benzene and hot water extracted red oak meal (600 g.) was stirred for forty-eight hours at room temperature with 12 liters of 5% sodium hydroxide solution. The wood meal was then removed by filtration, washed with water at 60°, and the extraction repeated in an identical manner three times to ensure complete removal of soluble hemicelluloses. An atmosphere of nitrogen was maintained during the alkali treatments. The extracted wood meal was finally washed with distilled water, 1% acetic acid, water and methyl alcohol, in the order named, and dried (50° at 15 mm.). The pale yellow residual wood meal represented about 80% of the original wood.

Anal. Found: methoxyl, 6.8; lignin, 31.0; cellulose, 66.6; pentosan, 13.3.

Acetylation of the Extracted Wood Meal and Isolation of Acetylated Oak Lignin.—The dried, alkali-extracted oak wood meal (50 g.) was acetylated with a mixture of acetic anhydride (450 g.), glacial acetic acid (250 g.), and concentrated sulfuric acid (3.5 g.), the reaction being carried out in a bronze Werner–Pfleiderer mixer provided with a water cooling system. The temperature was allowed to rise gradually from 15 to 30°, as follows: two and one-half hours at 15°, one-half hour at 15–20°, two hours at 20–25°, and two hours at 25–30°. The highly viscous, dark brown solution was allowed to stand overnight in an atmosphere of nitrogen without stirring. It was then poured into 2 liters of a vigorously stirred 20% sodium acetate solution. The resulting solid, acetylated product

was collected in a cotton sack and washed for forty-eight hours with running water and dried; yield approximately 80 g.

The dried acetylated wood meal was then mixed with a liter of chloroform, stirred for two hours, and allowed to stand for twelve hours at room temperature. The viscous solution was then filtered through finely powdered, anhydrous sodium sulfate, leaving an insoluble residue amounting to about 10 g. The clear chloroform solution was concentrated under reduced pressure and the residual solvent allowed to evaporate in air at room temperature. The resulting hard, glassy solid was crushed, pulverized, and extracted with acetone for five days in a Soxhlet apparatus. The acetone extract was concentrated to 200 cc., filtered, and poured into two liters of water. The acetylated lignin product was collected on a filter, washed with water, and dried; yield 27 g.

Purification of the Fully Acetylated Crude Oak Lignin.—The dry, acetylated product (10 g.) was dissolved in acetone (50 cc.), filtered, and precipitated by pouring in a fine stream into anhydrous ether (500 cc.). A very light-colored precipitate was obtained which was collected on a filter, washed with ether, then with petroleum ether, and dried.

Anal. Found: OCH_3, 11.0; $COCH_3$, 35.4; Klason lignin, 75.2.

The acetylated oak lignin was fractionated further by precipitating from dioxane solution into anhydrous ether. After three such precipitations, the methoxyl content remained unchanged (11.1%). Apparently, either the non-ligneous materials present are chemically bound to the acetylated lignin or the acetylated carbohydrates have solubility characteristics very similar to those of the acetylated lignin. The purified product contained about 10% pentosan which could be completely removed by deacetylation of the material with dilute alkali.

Deacetylation and Isolation of Native Oak Lignin.—Thirty grams of crude acetylated oak lignin (OCH_3, 11.1%) was dissolved in 1 liter of acetone, and 1 liter of 20% sodium hydroxide was slowly added with stirring. The mixture was allowed to stand for twenty-four hours at room temperature, the acetone removed under reduced pressure, and water added to maintain the volume at 2 liters. After two weeks' standing, the mixture was filtered to remove the alkali insoluble material (about 5 g.). After washing with water and drying, this was found to contain 4.1% methoxyl. The alkaline filtrate was acidified with 5% sulfuric acid and the resulting buff-colored precipitate collected, washed free from sulfate and dried; yield 15 g. The product was purified by dissolving in 50 cc. of dioxane and precipitating into anhydrous ether. The precipitate was collected in a centrifuge, washed with ether followed by petroleum ether, and dried. Found: OCH_3, 20.8.

The alkali insoluble material apparently is composed of methoxyl-containing substances still chemically bound to polysaccharides. It was found to be insoluble in all common organic solvents.

The alkali soluble, deacetylated native oak lignin, after purification by precipitation from dioxane solution into ether, could be fractionated into a chloroform soluble and a chloroform insoluble fraction. Chloroform soluble fraction: OCH_3, 23.4. Chloroform insoluble fraction: OCH_3, 20.6; C, 64.0; H, 6.2.

On methylation with diazomethane in dioxane solution both of the above fractions gave, after three treatments, products having the same constant methoxyl value of 26.6%.

Acetylation of the Native Oak Lignin.—Ten grams of the unfractionated native oak lignin (OCH_3, 20.6%) was acetylated at room temperature with a mixture of 50 cc. of acetic anhydride and 100 cc. of pyridine. After standing for twelve hours, the solution was poured into a liter of ice water and the precipitate removed by filtration, washed, dried, and reprecipitated from acetone into ether. Found: OCH_3, 18.2. Ten grams of the acetylated product was reacetylated by dissolving in a mixture of acetic anhydride (100 g.), glacial acetic acid (50.0 g.) and concentrated sulfuric acid (0.7 g.). The mixture was held at 20–25° for twenty-four hours and then poured into a liter of 20% sodium acetate. The product was filtered, washed, dried, and purified by precipitation from acetone into ether followed by a reprecipitation from dioxane into ether. Found: C, 62.3; H, 5.9; OCH_3, 16.8; $COCH_3$, 22.9.

Solubility of Native Oak Lignin in Bisulfite Solution.—A sample of the chloroform soluble fraction of native oak lignin (OCH_3, 23.4%) was heated in a sealed tube with a bisulfite solution containing 6.0% "total" and 1.4% "combined" sulfur dioxide. Solution was complete on heating for twelve hours at 110°.

Preparation of 5-Acetoxymethylfurfurylidene Diacetate.—The method of Blanksma[6] was used. A higher yield (75%) was obtained by adding the sulfuric acid to the acetic anhydride and keeping the temperature below 0°. This mixture was added slowly to the hydroxymethylfurfural. The acetate was isolated in the manner outlined by Blanksma; m. p. 73°.

Acknowledgment.—The authors are indebted to Dr. Saul M. Trister for the preparation of the 5-acetoxymethylfurfurylidene diacetate.

Summary

1. A description is given of a simple method for the isolation of a lignin from oak wood which retains the reactive character of "protolignin," namely, solubility in hot bisulfite solution.

2. Under the same conditions of acetylation used in the isolation of the above "native oak lignin," fructose and hydroxymethylfurfural yield crystalline acetylated products with practically no formation of material resembling lignin. This is considered an argument against Hilpert's theory[7] of lignin formation as a change arising during the extraction process from the action of the extractant on a sensitive carbohydrate.

3. It has been found possible to reacetylate "native oak lignin" to give a product soluble in acetone or dioxane and containing 22.9% acetyl.

Studies on Lignin and Related Compounds. XLIII. The Absence of the Piperonyl Group in the Lignin Structure

BY M. J. HUNTER[1] AND HAROLD HIBBERT

Formaldehyde was first isolated from lignin materials by Freudenberg and Harder,[2] a discovery confirmed by Sarkar,[3] the yields amounting to 0.5–2.0% calculated on the weight of (Klason) lignin present. Freudenberg[4] as well as Sarkar[3] regards the isolation of formaldehyde as direct proof of a piperonyl radical in the lignin complex and the former uses the formaldehyde values to calculate the size of the lignin building unit.[4] Phillips and Goss[5] have objected to this interpretation. Formaldehyde yields from various lignins were given recently[6] and it was shown that these are dependent on the method of extraction of the lignin from the wood. The improbability of the existence of the dioxymethylene group in lignin as part of a piperonyl radical was indicated.

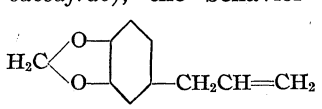
Recently, Freudenberg[7] has found additional support for the presence of the piperonyl group in new experimental technique involving acridane formation by the action on lignin and related products of a mixture of aniline and concentrated hydrochloric acid at a high temperature and pressure. The use of such a drastic procedure with a highly sensitive complex such as lignin would seem open to serious objection as a criterion for distinguishing between formaldehyde formation from piperonyl groups and other sources, respectively.

It was shown recently[6] that the dioxymethylene group in the piperonyl radical, when subjected to various reagents and procedures used in lignin extraction, is decomposed to the extent of only 25%, so that if present in "protolignin" it also should be found to a correspondingly large extent in the extracted lignin. However, the wide variation in formaldehyde yields from various lignins[6b] may be considered as indirect evidence against the view of the piperonyl group as the formaldehyde precursor. The approximate relationship found in certain acetic acid lignins between the amounts of furfural and formaldehyde cleavage products indicated the possibility of both being formed simultaneously from certain hexoses, adsorbed by, or combined with, the extracted lignins. Hexoses[6] gave traces of formaldehyde and furfural in most cases on treatment with mineral acids, but the yields were much too low to account for the amounts obtained from isolated lignins; also certain lignins which gave the highest amounts of formaldehyde yielded only traces of furfural.

The outstanding relationship noted[6] was that extracted lignins when refluxed with 95% formic acid gave a very low yield of formaldehyde. The stability of the piperonyl group to formic acid and the action of the latter reagent on ethanol lignin, both with respect to removal of this group and to the suppression of the formaldehyde-yielding constituent, have now been investigated.

Piperonal on refluxing with formic acid (95%) for sixteen hours was decomposed to the extent of only 15%, while treatment of ethanol lignins removed 90–95% of the formaldehyde-producing component.

Klason[8] regarded lignin as related to coniferyl alcohol, present as a glucoside in coniferin, the latter being found in the cambium sap of a wide variety of woods. Since safrole (I) is found in the cambium sap of the roots of the sassafras tree (*Sassafras sassafras*), the behavior of ethanol



I

sassafras lignin toward hot dilute acids was investigated. This lignin was prepared by the usual procedure[9] and the yields of formaldehyde obtained from it and maple and spruce ethanol lignins are shown in Table I.

TABLE I

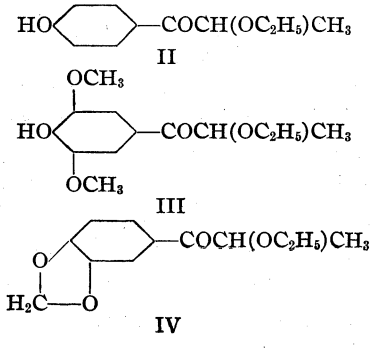
YIELDS OF FORMALDEHYDE FROM SASSAFRAS, MAPLE AND SPRUCE ETHANOL LIGNINS

	Wood species	Method of isolation	Hrs.	Secondary treatment, refluxed with	Alkoxyl content calcd. as methoxyl, %	Formaldehyde analyses: Sample, g.	Dimedone deriv., g.	Formaldehyde, %
1	Maple	Ethanol–2% HCl	20	.....	27.1	1.000	0.0490	0.50
2	Maple	Ethanol–0.3% HCl	100	.....	28.4	1.000	.1229	1.26
3	Maple	Ethanol–0.3% HCl	100	95% formic acid for 16 hrs.	23.6	1.000	.0064	0.066
4	Sassafras	Ethanol–2.0% HCl	24	.....	26.4	1.000	.0392	.40
5	Sassafras	Ethanol–2.0% HCl	24	95% formic acid for 16 hrs.	23.2	1.000	.0032	.033
6	Spruce	Ethanol–3.0% HCl	40	.....	19.2	1.000	.0244	.25

The analyses show that boiling 95% formic acid removes the component responsible for formaldehyde formation from maple and sassafras ethanol lignins with equal ease, and, since the piperonyl group in various derivatives is decomposed to the extent of only 15% under identical conditions, the results provide conclusive evidence against the existence of the piperonyl group in lignin.

Also piperonal when refluxed for twenty-four hours with absolute ethanol containing 3% hydrogen chloride can be recovered in 90% yield, while, from the data given in Table I, it would appear that a large percentage of the original formaldehyde-producing constituent is removed, or transformed, even by the action of the (2%) ethanol–hydrochloric acid during the lignin extraction, since an extracted lignin prepared from maple wood meal by heating with ethanol, containing only 0.3% hydrogen chloride, for one hundred hours, showed a much higher formaldehyde content.

The water-soluble oils obtained in the ethanolysis of sassafras wood[9] gave no formaldehyde on treatment with hot dilute acids by the customary procedure. If sassafras lignin contained a piperonyl group, this should be present as α-ethoxypropiopiperonylone (IV) in the neutral water-soluble ethanolysis fraction[9] as an analog of the guaiacyl (II) and syringyl (III) compounds[9] obtained from the ethanolysis of spruce and maple woods, respectively, but not the slightest trace of formaldehyde could be obtained.



Regarding the origin of the formaldehyde from extracted lignins, Freudenberg[10] has shown recently that cinnamyl alcohol when distilled with 28% sulfuric acid gives about 2% formaldehyde. He concludes[10] that this configuration, if present in lignin, is not responsible for the formaldehyde formation since no acridane formation[7] takes place with cinnamyl alcohol under conditions whereby it is formed both from lignins and piperonyl derivatives. The drastic conditions employed, namely, heating with aniline and concentrated hydrochloric acid under pressure at 270–290° for thirty-four hours, would seem to preclude application of this method to such a highly reactive substance as the lignin aggregate.

Whilst the more unstable methylals and cyclic acetals[11] would yield formaldehyde readily under the conditions employed, no evidence has been found, as yet, indicating the presence of such groupings in wood.

According to Kohler[12] vinyl phenyl ketone loses formaldehyde spontaneously at room temperature and the possible relation of this type of structure to that of α-hydroxypropiosyringone and α-hydroxypropiovanillone should not be overlooked.

The amount, if any, of piperonyl-containing constituent present in lignin would seem to be so small that it cannot be regarded as an essential part of the lignin structure, and the evidence obtained thus far appears to indicate that the formaldehyde (1–4%) is formed from an aromatic side-chain, possibly one existing as part of a complex present in lignin condensation polymers[13] and similar to cinnamyl alcohol.

Experimental

Determination of the Formaldehyde Liberated by the Action of Acids on Extracted Lignins and Related Substances.—This was carried out as described in the previous communication.[6]

Stability of Piperonal toward Boiling Formic Acid (95%).—Piperonal (2.000 g.) was refluxed with 95% formic acid (20 cc.) for sixteen hours following the method of Wright and Hibbert.[14] After removing the formic acid under reduced pressure, the residue was dissolved in ether and the ether solution extracted with cold 1% sodium hydroxide solution. The ether extract was dried over anhydrous calcium chloride, concentrated, and the residue distilled under reduced pressure. The distillate (1.696 g., equivalent to 84.8%) crystallized at room temperature, m. p. 36–38°. A mixed melting point with the original product showed no depression.

Stability of Piperonal to Hot Ethanol Containing 3% Hydrogen Chloride.—Piperonal (2.000 g.) was refluxed for twenty-four hours with absolute ethanol containing 3% hydrogen chloride. These conditions were somewhat more drastic than those used for the ethanolysis of maple and sassafras woods. The ethanol was removed under reduced pressure, the residue dissolved in ether, and the piperonal isolated as above: weight of recovered piperonal, 1.827 g. (91.3%).

Behavior of Lignins toward Boiling Formic Acid (95%).—The various ethanol lignins (3.0 g.) were each refluxed with 95% formic acid (30 cc.) for sixteen hours. The solution was then poured with stirring into 300 cc. of distilled water and the precipitated lignins washed free from acid. The precipitates were vacuum dried over calcium chloride at room temperature and then over phosphorus pentoxide at 56° (14 mm.). The products were analyzed for methoxyl and the formaldehyde yield determined. The results are shown in Table I.

Preparation of Sassafras Ethanol Lignin.—Sassafras woodmeal (450 g.) previously extracted with (i) alcohol–benzene, (ii) benzene and (iii) water, after drying was refluxed for twenty-four hours with 3 liters of absolute ethanol containing 2% hydrogen chloride, as previously described.[9] This gave 52.0 g. of sassafras ethanol lignin and 36.3 g. of crude ether soluble oils, as compared with 44.6 g. of lignin and 36.7 g. of crude oils from a similar run with maple wood. From the sassafras crude oils there was obtained a neutral fraction of 2.2 g. Distillation of this latter with 28% sulfuric acid gave no formaldehyde.

Summary

The absence of the piperonyl group in the structure of lignin is indicated by (a) the inability of workers in this field to isolate from an extracted lignin a piperonyl-containing derivative; (b) the pronounced instability toward formic acid of the formaldehyde-producing constituent in lignin as compared with the very much greater stability of the piperonyl radical present in known compounds; (c) the liberation of formaldehyde from such derivatives as cinnamyl alcohol, and the probability of the presence of this type of grouping in extracted lignins; (d) the behavior of ethanol sassafras lignin and the water-soluble ethanolysis products from sassafras wood toward hot dilute acids, whereby yields of formaldehyde similar in amount to those found with other woods are obtained from the former, and none from the latter.

Studies on Lignin and Related Compounds. XLIV. The Ethanolysis of Maple Wood; Separation and Identification of the Water-Soluble Aldehyde Constituents[1]

BY JAMES J. PYLE, LEO BRICKMAN AND HAROLD HIBBERT

In two recent communications[2] of this series, a description was given of the isolation, in considerable amount, of water-soluble aromatic constituents formed in the ethanolysis of spruce and maple woods. The crude oils were shown to consist of a phenolic, aldehydic, acidic and neutral fraction. In a later paper,[3] a revised method for their isolation was given by which much improved yields were obtained. The phenol fraction from spruce wood[2a] has been shown to consist in large part of α-ethoxypropiovanillone and that from maple wood[2b] of a mixture, in approximately equal amounts, of this and α-ethoxypropiosyringone.

In the present communication an account is given of the separation and identification of the

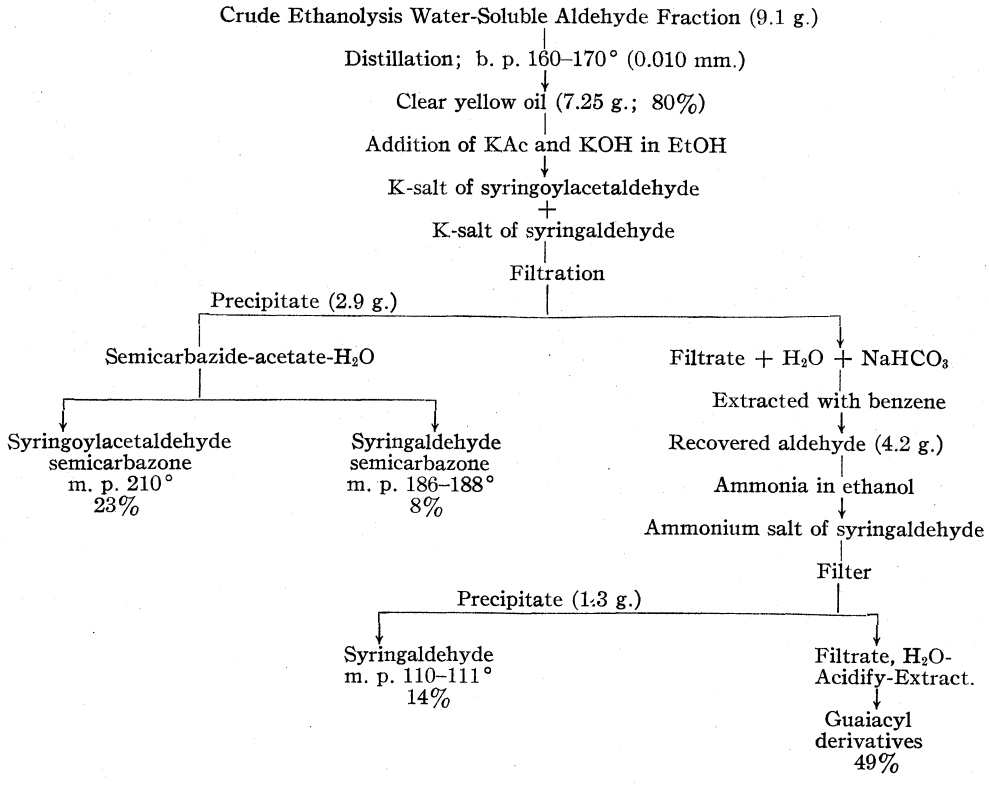
METHODS OF SEPARATION OF SYRINGYL AND GUAIACYL COMPONENTS IN THE WATER-SOLUBLE ALDEHYDE FRACTION FROM MAPLE WOOD



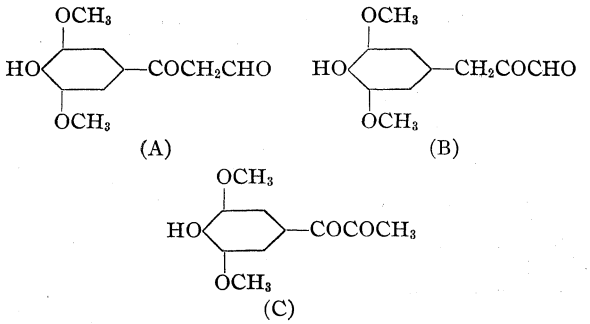
aldehydic constituents present in the ethanolysis fraction from maple wood. It has been found that this consists of a mixture of syringoylacetaldehyde, syringaldehyde, vanilloylacetaldehyde and vanillin in approximately equal amounts, thus providing a further significant proof of this characteristic difference between soft and hard woods emphasized repeatedly by Hibbert and co-workers.[4] The total syringyl and guaiacyl fractions amount to 8.2% calculated on the weight of (Klason) lignin present in the wood.

The method used in separating these two types was that outlined in a previous communication,[4d] namely, precipitation of the syringyl, but not the guaiacyl, components by the addition of potassium acetate in anhydrous ethanol. Advantage was taken of an improvement on this method, found in the use of a solution of anhydrous ammonia in ethanol, whereby a quantitative precipitation of the syringyl derivatives is effected. Use of both reagents with the corresponding aldehydic fraction from spruce, and in which only the guaiacyl derivatives (vanilloylacetaldehyde and vanillin in equal amounts) are present, gave no precipitate. The use of potassium acetate in ethanol brought about a practically complete precipitation of the syringoylacetaldehyde and a partial precipitation of the syringaldehyde. The remaining portion was recovered by treatment with anhydrous ammonia in ethanol as a yellow, crystalline precipitate. The filtrate from this latter treatment contained the whole of the guaiacyl components (vanilloylacetaldehyde and vanillin) the details of the separation and identification of which are to appear in a later communication.

The method of separation is outlined in the flow-sheet.

The analysis of the syringoylacetaldehyde and the preparation and analysis of its mono- and disemicarbazones established its empirical formula as $C_{11}H_{12}O_5$, and showed the presence of two carbonyl groups. Oxidation with hydrogen peroxide yielded syringic acid, thus establishing definitely the presence of the syringyl nucleus. Its structure must, therefore, correspond to one of three products

(4) (a) Hawkins, Wright and Hibbert, THIS JOURNAL, **59**, 2447 (1937); (b) Leger and Hibbert, *Can. J. Research*, **B16**, 151 (1938); (c) Leger and Hibbert, THIS JOURNAL, **60**, 565 (1938); (d) Hunter and Hibbert, *ibid.*, **61**, 2190 (1939).



Formula C may be eliminated on the basis of the following results:

(a) Syringoylacetaldehyde gave a negative iodoform test, indicating the absence of the (—CO—CH_3) group; (b) it reduces ammoniacal silver nitrate indicating presence of an aldehydic group; and (c) it reacts *almost immediately* with semicarbazide hydrochloride in 3 *N* hydrochloric acid. Michael[5] has shown that ketones do not react under these acidic conditions.

In view of these facts structure (C) was eliminated and a decision between (A) and (B) was reached on the basis of the following experimental facts.

(a) Syringoylacetaldehyde gave a negative test with *o*-phenylenediamine, indicating absence of a 1,2-diketone.

(b) On oxidation with hydrogen peroxide a 65% yield of syringic acid was obtained, insufficient hydrogen peroxide being added to effect complete degradative oxidation of the side-chain.

Mechanism of Formation of Syringic Acid.—This will vary in the case of structures (A) and (B) as shown

$$\text{R—COCH}_2\text{CHO} \longrightarrow \text{R—C(OH)=CHCHO} \xrightarrow{H_2O_2} \text{R—COOH}$$

$$\text{R—CH}_2\text{COCHO} \longrightarrow \text{R—CH=C(OH)CHO} \xrightarrow{H_2O_2}$$

$$\text{R—CHO} \xrightarrow{H_2O_2} \text{R—COOH}$$

where R = syringyl

It is evident that with formula (B) oxidation to the acid proceeds through the intermediate compound, syringaldehyde. Syringaldehyde was therefore treated with hydrogen peroxide under the same experimental conditions and was *recovered unchanged*, indicating that it could not be an intermediate in the formation of the syringic acid.

(c) The similarity between formula (A) and compounds of the acetoacetic ester type, that is, with an active methylene group between two carbonyls, is evident. Thus under the influence of strong alkali, syringoylacetaldehyde would be expected to cleave to give syringic acid in the same manner that acetoacetic ester yields acetic acid. Karrer and Widmer[6] heated syringidin with 20% sodium hydroxide in a stream of hydrogen, and obtained a 30% yield of syringic acid. Isolation of syringic acid from syringoylacetaldehyde, also in yields of approximately 30% of the theoretical, under conditions in which no oxidizing medium is present, definitely establishes the position of the second carbonyl as adjacent to the nucleus.

On the basis of these results, this new aldehyde isolated from the ethanolysis products of maple wood must have formula (A).

Further evidence in support of this conclusion was obtained when the syringoylacetaldehyde was subjected to the action of aqueous bisulfite followed by alkaline cleavage. This experiment was one of a series[7] on the mechanism of sulfite pulp manufacture to determine whether any of the products isolated by ethanolysis would give rise to vanillin or syringaldehyde when heated with aqueous bisulfite followed by alkaline cleavage.

Instead of syringaldehyde the products isolated were acetosyringone and syringic acid. This result apparently is due to the incomplete removal of oxygen from the nitrogen used during the experiment to provide an inert atmosphere. Some of the syringoylacetaldehyde evidently was oxidized to syringoylacetic acid which latter, being a β-keto acid, underwent decarboxylation in the presence of the alkali, to give acetosyringone.

$$\text{RCOCH}_2\text{CHO} \xrightarrow{[O]} \text{RCOCH}_2\text{COOH} \xrightarrow{[-CO_2]} \text{RCOCH}_3$$

R = syringyl

The accompanying syringic acid probably is formed from some unoxidized syringoylacetaldehyde. Unfortunately it was not found possible to duplicate this experiment.

Recovery of Syringaldehyde.—As indicated in the flow-sheet, the monosemicarbazone of syringoylacetaldehyde was obtained directly from the potassium salt of the mixture of the two aldehydes. The filtrate from this contained the semicarbazone of syringaldehyde, which precipitated out from the solution on boiling and was identified as such.

The crystalline ammonium salt of the syringal-

(5) Michael, THIS JOURNAL, **41**, 393 (1919).

(6) Karrer and Widmer, *Helv. Chim. Acta*, **10**, 5 (1927).

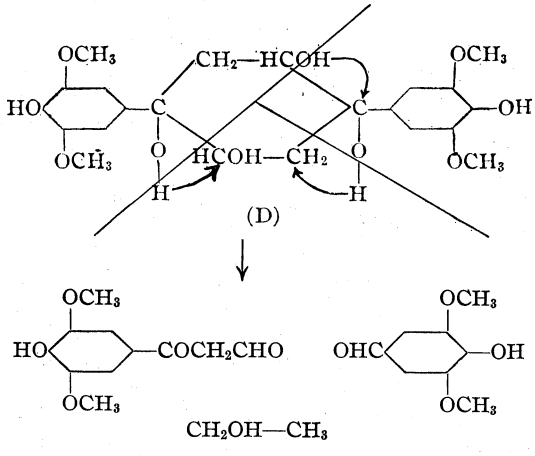
(7) Under investigation in these Laboratories by Dr. Rodger Dorland.

dehyde (see flow-sheet) gave with 2,4-dinitrophenylhydrazine the hydrazone of syringaldehyde, the yield indicating that the ammonium salt was practically pure syringaldehyde.

On the basis of the yields of the semicarbazones and 2,4-dinitrophenylhydrazone and those obtained using known quantities of the pure aldehydes under the same experimental conditions, the syringoylacetaldehyde and syringaldehyde amount to 23 and 22%, respectively, of the total aldehyde fraction. Analysis of the guaiacyl fraction indicates that approximately the same ratio holds for the vanilloylacetaldehyde and vanillin.

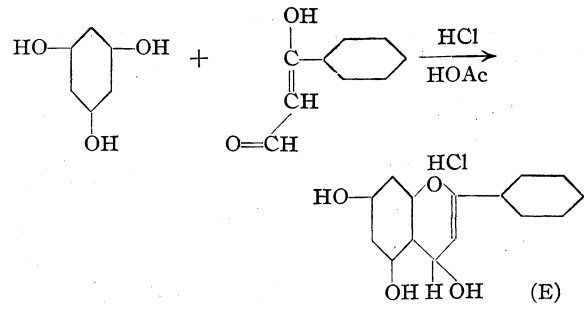
The relationship of the various ethanolysis products to the structure of "protolignin" has been discussed by Hibbert[8] in a previous communication. He suggests that lignin is probably derived from the condensation of an aldehyde (methyl glyoxal) with a phenol (guaiacol or 1,3-pyrogallol dimethyl ether). Such a dimeric building unit (D) can, theoretically, undergo ring fission by hydrogen migration in a number of ways. Cleavage may thus give rise, as pointed out by him, to (a) two moles of a hydroxy ketone (α-hydroxypropiovanillone and α-hydroxypropiosyringone), or (b) to aldehydic constituents.

It is thus of considerable interest that the aldehydes obtained in the present investigation can be visualized as cleavage products formed by a specialized type of reversed aldol formation, from Hibbert's hypothetical dimer (D).

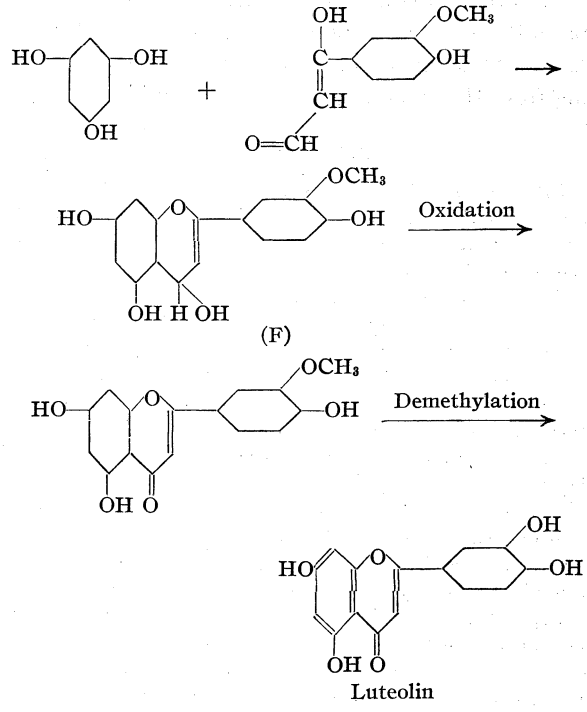


to give products of the type (E) shown

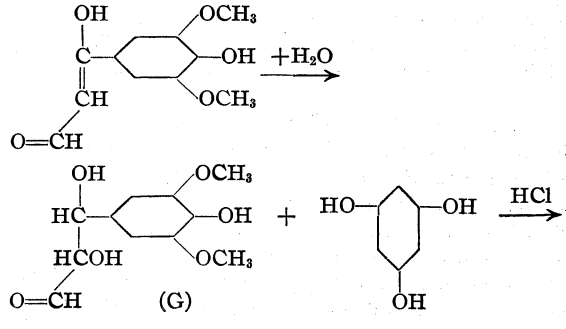
(8) Hibbert, THIS JOURNAL, **61**, 725 (1939). Due to a printer's error, p. 729, the structure of the aldehyde isolated from maple wood was incorrectly given as corresponding to Formula IV instead of Formula VI.

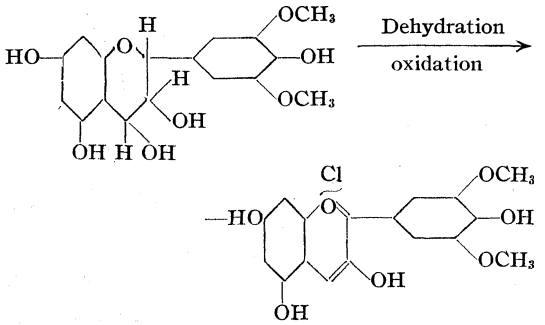


It is to be anticipated that vanillylacetaldehyde would undergo a similar condensation to give (F). The latter on oxidation and loss of methoxyl would yield a typical flavone, namely, luteolin.



On the other hand, hydration of syringoylacetaldehyde could give rise to formation of (G) which on condensation with phloroglucinol followed by loss of water and accompanying oxidation would give a typical anthocyanidin, namely, syringidin





Experiments with a view to effecting such typical syntheses are to be carried out.

It is thus of considerable interest that such apparently unrelated plant constituents as lignin and plant pigments may be visualized as originating from the same type of building unit.

Experimental

Ethanolysis of Maple Wood.—A complete and detailed account of the ethanolysis procedure and fractionation of water soluble oils is given in a recent communication,[3] so that only a brief summary is necessary.

A solvent-extracted maple wood meal was refluxed with ethanol containing anhydrous hydrogen chloride in an inert atmosphere (carbon dioxide) and the reaction mixture filtered. The ethanol filtrate was brought almost to neutrality by addition of a solution of sodium ethylate in ethanol, then concentrated, and precipitated into water. The filtrate was concentrated, and continuously extracted with benzene.

The benzene extract was shaken with aqueous bisulfite solution, the solution acidified and back-extracted with benzene. The benzene solution of the crude aldehyde fraction was used for the following investigation.

Separation of Guaiacyl and Syringyl Components.—A portion of the benzene solution was concentrated under reduced pressure, leaving 9.1 g. of a brownish-colored, very viscous residue. This on distillation gave two fractions (88% yield): (1) b. p. 160–170° (0.010 mm.), 7.25 g., clear yellow oil; (2) b. p. 250–350° (0.025 mm.), 0.73 g., red resin.

To a solution of the distilled aldehyde (Fraction 1, 7.25 g.) dissolved in ethanol (60 cc.) was added a saturated ethanolic solution of potassium acetate (60 cc.) followed by 18 cc. of 2% potassium hydroxide in ethanol to neutralize the acetic acid formed, and the mixture shaken well. The red crystalline precipitate was filtered, washed with ethanol and dried; yield, 2.9 g., or 34.6% on the basis of free aldehyde.

The filtrate was diluted with 2–3 volumes of water, made slightly alkaline with sodium bicarbonate, and continuously extracted with benzene in an atmosphere of carbon dioxide. The amount of recovered aldehyde was 4.2 g. or 90% of the theoretical. This recovered aldehyde gave no precipitate with potassium acetate in ethanol solution.

The recovered aldehyde mixture (4.2 g.) was now dissolved in 25 cc. of anhydrous ethanol and 0.7 g. of anhydrous ammonia dissolved in 10 cc. of ethanol added. A yellow crystalline precipitate formed immediately. This was filtered and dried; wt. 1.3 g., or 16.8% calculated as the free aldehyde.

The guaiacyl derivatives were recovered from the filtrate by diluting again with several volumes of water, acidifying with sulfuric acid and continuously extracting with benzene in an atmosphere of carbon dioxide.

Isolation of Syringoylacetaldehyde.—The red crystalline potassium salt (11.3 g.) obtained above was dissolved in 100 cc. of water and 1 cc. of concentrated sulfuric acid added. The solution was extracted with benzene leaving after removal of the solvent 9.3 g. of a yellow oil, which crystallized almost completely on standing. Recrystallization first from low-boiling (60–70°), and then from high-boiling petroleum ether (100–110°) gave 4.0 g. of crude syringoylacetaldehyde, m. p. 64–68°. After several recrystallizations a constant melting point, 74.0–74.5°, was reached.

Concentration of the mother liquors yielded an oil which on treatment with semicarbazide acetate gave, as shown later, a mixture of the semicarbazones of syringoylacetaldehyde and syringaldehyde.

Analysis of Syringoylacetaldehyde.—Calcd. for $C_{11}H_{12}O_5$: C, 58.9; H, 5.4: OCH_3, 27.9. Found: C, 58.8; H, 5.6; OCH_3, 27.9.

Syringoylacetaldehyde is soluble in almost all organic solvents and also relatively soluble in water. When crystallized very slowly from petroleum ether (b. p. 100–110°), it separates in the form of colorless, hexagonal crystals.

Proof of Presence of the Syringyl Nucleus.—The aldehyde (0.050 g.) was dissolved in 5 cc. of water and 0.2 cc. of 3% hydrogen peroxide added. The reaction mixture was allowed to stand at room temperature for four hours, and then at 0° for a further two hours. Long colorless needles crystallized from the aqueous solution, m. p. (crude) 198–200°. After recrystallization from water the melting point rose to 204–205° and a mixed melting point with an authentic sample of syringic acid showed no depression.

Proof of the Dicarbonyl Structure by Preparation of a Mono- and Disemicarbazone. (a) Monosemicarbazone.—The isolated syringoylacetaldehyde (0.050 g.), semicarbazide hydrochloride (0.030 g.) and potassium acetate (0.035 g.) were dissolved in 5 cc. of water. Long, colorless needles crystallized from the solution on standing for several hours and were recrystallized from hot water; yield, 0.045 g., 71.5%; m. p. 210–210.5°.

This derivative was also prepared in 1 and 3 *N* hydrochloric acid solution. It could be obtained directly from the crystalline mixture of the potassium salt of syringoylacetaldehyde and syringaldehyde (see flow-sheet) by dissolving the mixture in an aqueous solution of semicarbazide acetate and removing the crystalline monosemicarbazone after a period of two hours in order to avoid admixture with the semicarbazone of syringaldehyde.

Analysis of Monosemicarbazone of Syringoylacetaldehyde.—Calcd. for $C_{12}H_{15}O_5N_3$: C, 51.2; H, 5.59; N, 14.9; OCH_3, 22.0. Found: C, 51.6; H, 5.61; N, 14.8; OCH_3, 22.0.

(b) Preparation of the Disemicarbazone.—The monosemicarbazone (0.090 g.) was mixed with a solution of 0.050 g. of freshly-prepared, free semicarbazide in 10 cc. of eth-

anol and refluxed for five hours. The hot ethanol solution containing the insoluble disemicarbazone was filtered and the product recrystallized from hot water; short, colorless needles, insoluble in all common organic solvents; yield, 0.080 g., 75%; m. p. 239.0°.

Anal. Calcd. for $C_{13}H_{18}O_5N_6$: C, 46.2; H, 5.3; N, 24.9; OCH_3, 18.4. Found: C, 46.5; H, 5.6; N, 24.9; OCH_3, 18.4.

Alkaline Cleavage of Syringoylacetaldehyde.—Syringoylacetaldehyde (0.100 g.) dissolved in 5 cc. of water was placed in a small distilling flask, fitted with a reflux condenser ("cold finger") and then a stream of nitrogen, from which all traces of oxygen had been removed, was passed into the flask through the side-arm. When all of the oxygen had been removed, 1.2 g. of sodium hydroxide was added and the reaction mixture heated to 130–140° for twelve hours, a nitrogen atmosphere being maintained throughout. The solution was cooled, acidified with dilute sulfuric acid and extracted continuously with benzene. The benzene was removed and the residue sublimed at 117–125° (2 mm.). The white, crystalline sublimate was recrystallized from water; melting point 203–205°, a mixed melting point with authentic syringic acid showed no depression; yield, 0.026 g., 30%.

Action of Bisulfite Followed by Alkaline Cleavage.—A solution of 0.050 g. of syringoylacetaldehyde in 2 cc. of "sulfite cooking liquor" (containing 6% free sulfur dioxide and 1.1% combined sulfur dioxide) was placed in a small sealed tube and heated to 110° for twelve hours.

The sealed tube was cooled, opened, and the contents transferred by use of 3 cc. of water into a small distilling flask, fitted as in the preceding experiment. Sodium hydroxide (1.2 g.) was added as before, but inadvertently the oxygen was incompletely removed from the stream of nitrogen. The alkaline solution was heated to 135° for twelve hours, cooled, acidified and continuously extracted with benzene. The benzene solution was shaken with aqueous bisulfite (5%) and the bisulfite solution acidified and extracted with ether. The benzene solution left after the bisulfite treatment was evaporated to dryness and the residual dark brown solid sublimed at 115–120° (2 mm.). The sublimate was washed with cold petroleum ether (30–50°) and resublimed, m. p. 117–118°; a mixed melting point with authentic acetosyringone showed no depression; yield, 0.015 g., 34%.

The ether solution was treated in the same manner and yielded 0.008 g. of a white, crystalline sublimate which was shown by melting point (202–204°) and mixed melting point to be syringic acid.

Isolation and Identification of Syringaldehyde

(1) From the Crystalline Potassium Salt.—The mixture of the reddish-colored crystalline potassium salts (0.45 g.) was dissolved in 15 cc. of water and semicarbazide hydrochloride (0.30 g.) and potassium acetate (0.40 g.) added. The homogeneous reaction mixture was allowed to stand at room temperature for an hour, cooled to 0° and filtered. The crystalline precipitate was the monosemicarbazone of syringoylacetaldehyde obtained above; yield 0.22 g.

The filtrate was heated to 100° and then kept at 0° for several days. Clusters of short, colorless needles slowly formed throughout the solution. These were filtered off and dried. Recrystallization from water and methanol raised the melting point to 186–188° and a mixed melting point with an authentic sample of syringaldehyde semicarbazone showed no depression.

Anal. Calcd. for $C_{10}H_{13}O_4N_3$: OCH_3, 25.9. Found: OCH_3, 26.1.

(2) From the Crystalline Ammonium Salt.—To a solution of 0.10 g. of the ammonium salt, dissolved in 7 cc. of ethanol containing a few drops of concentrated hydrochloric acid, was added 0.085 g. of 2,4-dinitrophenylhydrazine, also dissolved in 5 cc. of ethanol–hydrochloric acid. The solution was allowed to stand at room temperature for four to six hours, during which period a voluminous red crystalline precipitate formed. The product was filtered off and recrystallized from ethyl acetate; yield, 0.165 g., 82%; m. p. 235–235.5°.

The 2,4-dinitrophenylhydrazone of an authentic sample of syringaldehyde was prepared in the same manner, m. p. 235.5–236.5°. A mixed melting point showed no depression.

Anal. Calcd. for $C_{15}H_{15}O_7N_4$: OCH_3, 17.2. Found: OCH_3, 17.3.

Acknowledgment.—The authors wish to thank the Carnegie Corporation of New York, the Canadian Pulp and Paper Association and the Spruce Falls Power and Paper Company for their kind financial assistance.

Summary

1. The water soluble "aldehyde fraction" obtained in the ethanolysis of maple wood has been shown to consist of a mixture of syringyl and guaiacyl derivatives, present in approximately equal amounts.

2. A method has been devised for the complete separation of syringyl constituents by precipitation of their insoluble potassium and ammonium salts.

3. The syringyl fraction has been shown to consist of syringoylacetaldehyde and syringaldehyde, present in approximately equal amounts.

4. Syringoylacetaldehyde has been isolated and completely characterized by analysis, preparation of derivatives, and degradation to known compounds.

5. The significance of the presence of syringaldehyde and syringoylacetaldehyde among the ethanolysis products from maple wood with regard to the structure of "protolignin" and their relation to the synthesis of plant pigments has been pointed out.

Studies on Lignin and Related Compounds. XLV. Synthesis and Properties of α-Hydroxypropiovanillone

BY A. B. CRAMER[1] AND HAROLD HIBBERT

In a previous communication the isolation of α-ethoxypropiovanillone from the ethanolysis products of spruce[2] and of maple woods[3] was described. The relation of these to the corresponding hydroxy derivatives in connection with the role of the latter as the possible precursors of lignin has been discussed in a comprehensive manner by Hibbert[4] in a recent paper.

The present communication deals with the synthesis and properties of α-hydroxypropiovanillone.

This synthesis was carried out by the following series of reactions

(1) Veratrole + α-bromopropionyl bromide $\xrightarrow{AlCl_3}$ α-bromopropiovanillone

α-bromopropiovanillone $\xrightarrow[\text{acetic anhydride}]{\text{sodium acetate}}$ α-acetoxypropiovanillone acetate

α-acetoxypropiovanillone acetate $\xrightarrow{\text{alcoholic potash}}$ α-hydroxypropiovanillone

Reaction (1), which is based on the synthesis of α-bromoacetovanillone,[5] is of interest in that condensation and demethylation occur simultaneously.

α-Bromopropiovanillone is a colorless, crystalline product (m. p. 105–106°), which on prolonged heating with organic solvents (such as petroleum ether), in which it is only slightly soluble, undergoes conversion to tarry materials. This did not occur with solvents such as ethanol in which it is readily soluble, so that its purification entailed considerable experimentation; yield 35%. Its conversion into the crystalline diacetate (m. p. 122–123°) in yield of 84% takes place quite smoothly. This acetate, on treatment with alcoholic potassium hydroxide, gives almost the theoretical yield (92%) of crystalline α-hydroxypropiovanillone, m. p. 109–110°.

Properties of α-Hydroxypropiovanillone.—The secondary hydroxyl group present in the side chain has certain rather remarkable properties. Thus it is etherified, as in the case of benzoin,[6] by ethanol–hydrogen chloride, but does not react with diazomethane. The carbonyl group, due to its location *para* to the phenol group, shows similar abnormal properties to those possessed by related substances,[7] such as *p*-oxybenzaldehyde, vanillin and certain syringyl derivatives. Thus in the Grignard machine[8] the amounts of active hydrogen and carbonyl addition, 1.75 and 0.75 moles, respectively (based on a molecular weight of 196), are much smaller than the theoretical values 2.0 and 1.0, respectively.

Action of Acids.—α-Hydroxypropiovanillone exhibits a similar, reactive behavior, on treatment with acids, to that shown by various benzoins.[9] When it is refluxed with dilute sulfuric acid (5%), methanol–hydrochloric acid or formic acid, amorphous lignin-like products are formed. The carbon content of these derivatives is high, namely, 70–70.3% as compared with values of 63.6–67% found for "extracted lignins."[10] Whether this is due to the presence of carbohydrate condensation products in the customarily "extracted" lignins or to a different type of polymerization–condensation reaction taking place in the plant, as compared with that brought about by acids,[10] can only be decided after considerable further experimentation.

It is of interest, however, that the analytical values for a condensation, furan trimer (A) of α-hydroxypropiovanillone, of the type shown below, are in agreement with the theoretical figures for the formic acid polymer. No great significance can, however, be attached to this until a more complete investigation (now in progress) has been completed.

The similarity, however, between (A) and the furan trimer (B) obtained by Japp and Meldrum[11]

(B)

Experimental Part

I. Synthesis of α-Hydroxypropiovanillone

Step I. Preparation of α-Bromopropiovanillone.—Aluminum chloride (Merck) (40 g.) was added to carbon disulfide (150 cc.) in a 3-necked flask fitted with stirrer, dropping funnel and condenser. Veratrole (40 g.) was added rapidly at room temperature through the dropping funnel over a period of twenty-five minutes, the solution being stirred vigorously. When the reaction had subsided, α-bromopropionyl bromide (66 g.) was added slowly (during sixty minutes) to the mixture, and a further 40 g. of aluminum chloride then added in small portions (during sixty minutes). After stirring vigorously for a further thirty minutes the mixture was allowed to stand overnight. The carbon disulfide was decanted, and the product decomposed with ice and concentrated hydrochloric acid. The crude, oily bromo compound was washed by stirring repeatedly with dilute hydrochloric acid followed by water, dilute sodium bicarbonate, and finally water. This crude moist product was dissolved in ether, and the solvent removed slowly from the solution, in an open dish, by drawing a stream of air over the surface. Crystals formed around the edges of the dish and were stirred into the main body of the product. The thick sirup on standing for a short time changed to a sticky granular mass. This was filtered and washed with a small amount of petroleum ether, leaving a comparatively pure bromo derivative. The filtrate was concentrated similarly by slow evaporation and again filtered, giving a second crop of crude α-bromopropiovanillone; yield of relatively pure α-bromopropiovanillone obtained from three crops of crystals was 35%.

A small amount was purified for analysis by recrystallization from a chloroform–petroleum ether mixture (1:3); m. p. 105–106°.

Anal. Calcd. for $C_9H_8O_2Br(OCH_3)$: C, 46.4; H, 4.24; Br, 30.9; OCH_3, 11.9. Found: C, 46.3; H, 4.40; Br, 31.2; OCH_3, 12.1.

Step 2. Preparation of α-Acetoxypropiovanillone Acetate.—Crude α-bromopropiovanillone (70 g.), anhydrous sodium acetate (140 g.) and acetic anhydride (490 cc.) were mixed in a one-liter flask and heated on the steam-bath for four hours. The mixture was then poured into five liters of water and stirred vigorously for four hours. The resulting oil crystallized rapidly and was filtered off, washed thoroughly with water, pressed dry on the Büchner funnel, and recrystallized from alcohol; yield 60 g. (84%); m. p. 122–123°.

Anal. Calcd. for $C_{12}H_{13}O_5(OCH_3)$: C, 60.0; H, 5.72; OCH_3, 11.05. Found: C, 59.8; H, 5.90; OCH_3, 11.08.

Step 3. Hydrolysis of α-Hydroxypropiovanillone Acetate.—The diacetate (54 g.) was dissolved in hot methanol (500 cc.) and a solution of potassium hydroxide (54 g.) in hot methanol (540 cc.) added. The mixture was warmed on the steam-bath for fifteen minutes and then cooled. On allowing to stand several hours the crystalline potassium salt of α-hydroxypropiovanillone settled out and was filtered off. Concentration of the filtrate gave a further crop of crystals.

The combined potassium salts were dissolved in 125 cc. of warm water and a slight excess of sulfuric acid (30–40%) added. The heavy oil which separated from the warm solution crystallized completely on scratching the sides of the flask. The reaction mixture was cooled to about 0° and filtered. The crystalline mass was washed several times with ice water, filtered, and dried in a vacuum desiccator; yield 34 g. (92%); m. p. 101°; recrystallized from benzene, m. p. 109–110°.

Anal. Calcd. for $C_9H_9O_3(OCH_3)$: C, 61.2; H, 6.12; OCH_3, 15.8. Found: C, 61.0; H, 6.21; OCH_3, 15.7.

II. Properties of α-Hydroxypropiovanillone

(1) **Etherification.**—α-Hydroxypropiovanillone (2 g.) was dissolved in absolute ethanol (50 cc.) containing 0.5% dry hydrogen chloride. The solution was allowed to stand at room temperature for seventy-two hours during which time it became dark brown in color. It was then refluxed for six hours and the solvent removed, leaving a black tarry residue. An attempt to isolate a pure ethoxy derivative from this by solvent extraction with boiling petroleum ether (60–70°) was unsuccessful. The product was therefore freed from the last traces of solvent at 100° (30 mm.) and distilled at 125–140° (0.005 mm.). There were obtained a clear, yellow, non-crystallizable sirup (0.6 g.) and a black tarry undistillable residue. Analysis indicated the former product to be α-ethoxypropiovanillone. The slightly lower alkoxyl, carbon and hydrogen values are due presumably to the presence of a small amount of unetherified product which it was not found possible to remove by a subsequent distillation or crystallization.

Anal. Calcd. for $C_{12}H_{16}O_4$: C, 69.3; H, 7.79; alkoxyl calculated as methoxyl, 29.8. Found: C, 68.5; H, 7.20; alkoxyl calculated as methoxyl, 28.9.

(2) **Methylation with Diazomethane.**—α-Hydroxypropiovanillone (1 g.) was dissolved in ether (100 cc.) and to this an ethereal solution containing two equivalents of diazomethane was then added. The mixture was allowed to stand overnight, filtered from the diazomethane polymer and the ether removed. The product on distillation (130–150° (0.010 mm.)) yielded a clear yellowish-colored, highly viscous sirup which could not be caused to crystallize. Calcd. for $C_9H_8O_2(OCH_3)_2$: OCH_3, 28.5. Found: OCH_3, 28.1.

(3) **Grignard Analysis.**—Calcd. for α-hydroxypropiovanillone: active hydrogen 2.0 moles; carbonyl addition

1.0 moles, per molecular weight of 196. Found: 1.75 and 0.75, respectively.

(4) Action of Acids on α-Hydroxypropiovanillone

(a) Sulfuric Acid (5%).—α-Hydroxypropiovanillone (1 g.) was refluxed with 50 cc. of sulfuric acid (5%) for twenty-four hours. The resulting dark brown insoluble material was filtered, washed with water, dissolved in acetone (10 cc.) and precipitated into water (200 cc.). The flocculent precipitate was centrifuged, the liquors discarded and the product dried in the vacuum desiccator. It was redissolved in chloroform (10 cc.) and reprecipitated into petroleum ether (b. p. 60–70°) (200 cc.). The centrifuged material was stirred with petroleum ether (b. p. 30–50°), centrifuged and dried in the vacuum desiccator; yield 0.25 g. (25%). The light brown amorphous product was soluble in alkali. *Anal.* Found: C, 70.0; H, 4.94; OCH_3, 17.1.

(b) Methanolic Hydrogen Chloride.—α-Hydroxypropiovanillone (1 g.) treated similarly with a 5% solution of anhydrous hydrogen chloride in methanol (20 cc.) gave a similar dark colored, alkali-soluble, amorphous product; yield, 31%. *Anal.* Found: C, 70.3; H, 4.96; OCH_3, 20.6.

(c) Formic Acid (95%).—α-Hydroxypropiovanillone (1 g.) was treated in the same manner with 95% formic acid (20 cc.). The dark colored, alkali-soluble reaction product was purified similarly. *Anal.* Found: C, 70.0; H, 5.86; OCH_3, 17.3. A condensation trimer of type (A), $C_{27}H_{21}O_5(OCH_3)_3$ (mol. wt. 518) requires C, 69.5; H, 5.8; OCH_3, 17.9.

Acknowledgment.—The authors wish to thank the Carnegie Corporation of New York for kind financial assistance.

Summary

1. A description is given of the synthesis of α-hydroxypropiovanillone, a possible precursor of lignin, and of its behavior toward diazomethane and the Grignard reagent.

2. Hot dilute sulfuric acid, methanol–hydrochloric acid and formic acid (95%) convert it into alkali-soluble, lignin-like products.

Synthesis of Quinones Related to Vitamins K_1 and K_2

BY LOUIS F. FIESER, WILLIAM P. CAMPBELL[1] AND EDWARD M. FRY[2,3]

In a recent Communication[4] we advanced structural formulas for the antihemorrhagic vitamins which Doisy and co-workers[5] isolated in a condition of demonstrated purity, and there are now further indications that our conception of the structures is essentially correct. Of particular importance is the degradative work on vitamin K_1 by the Doisy group,[6] reported in a Communication submitted about the same time as ours.

Since the evidence from the degradations is still incomplete and in some points uncertain, we shall include in the present paper a fuller account of the previous deductions and report certain observations of significance made in a study of synthetic model substances.

Following Doisy's report of the quinonoid character of vitamins K_1 and K_2, Dr. R. N. Jones pointed out to us that in absorption spectra[5,7] the substances resemble 1,4-naphthoquinones more closely than quinones of other series. Such a structure would account for the known lability to light,[8,9] heat,[5a] and alkali,[7] for the yellow color and for the sensitivity of the hydroquinones to air oxidation.[5b] Anthraquinones possess the last-named property but are far more stable substances. The next clue was the resistance of the dihydro vitamin diacetates to alkaline hydrolysis,[5b] which suggested the presence of hindering substituents in the 2 and 3 positions adjacent to the acetoxyl groups, and an entirely analogous behavior has been encountered in 2,3-diallyl-1,4-naphthohydroquinone diacetate. Hindering substituents are also indicated by the failure of vitamin K_1 concentrates to react with carbonyl reagents.[10,11] From these considerations it seemed

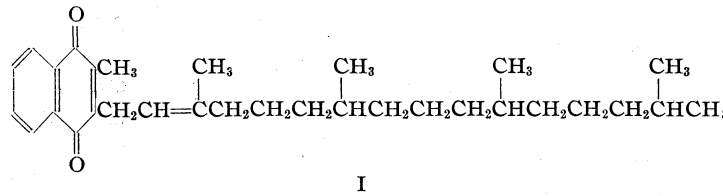
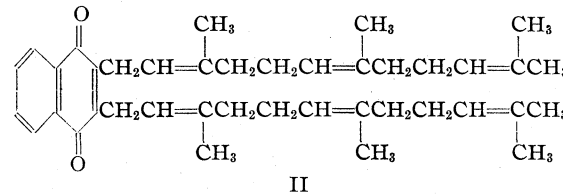
(10) Klose, Almquist and Mecchi, *J. Biol. Chem.*, **125**, 681 (1938). These investigators observed that the antihemorrhagic activity is not destroyed by reduction and concluded that the vitamin is inert to reducing agents, but it is now evident that reoxidation could have occurred before the test was made.

(11) Riegel, Schweitzer and Smith, in press (personal communication from Dr. Riegel).

likely that both vitamins are 2,3-dialkyl-1,4-naphthoquinones, and this was further supported by preliminary data on the oxidation–reduction potential of alfalfa concentrates of which Dr. Byron Riegel kindly informed us.[4]



I



II

If the vitamins are 1,4-naphthoquinones they must, according to Doisy's analyses,[5] have one or more long side chains containing a certain number of double bonds. If the values for the hydrogen absorption observed by Doisy[5a] in microhydrogenation experiments were due entirely to saturation of such linkages, vitamin K_1 would have three side chain double bonds and vitamin K_2 would have eight, but in the naphthoquinone series such a formulation would not be compatible with the analytical figures. We therefore assumed that under the as yet unreported conditions of the hydrogenation the reaction proceeded beyond the first possible stopping point and resulted in saturation of the oxygen-free ring of the naphthalene nucleus, giving a 5,6,7,8-tetrahydro-1,4-naphthohydroquinone which could revert to a quinone on air oxidation,[5a] an interpretation also reached by Doisy.[6] This would mean that vitamins K_1 and K_2 have 1 and 6 lateral double bonds, respectively.

It then occurred to us that the presence of a phytyl group in vitamin K_1 and of two farnesyl groups in vitamin K_2 not only would satisfy these unsaturation requirements but also would give structures of the observed carbon content, interpreted by Doisy[5a] in terms of C_{32} and C_{40} formulas, respectively. It was postulated that vitamin K_1 has the basic structure of 2-methyl-3-phytyl-1,4-naphthoquinone (I), with or without a second methyl group in the benzenoid ring, and that vitamin K_2 is 2,3-difarnesyl-1,4-naphthoquinone (II). There is a certain amount of coincidental circumstance to lend appeal to the hypothesis, considered as a whole. It is striking that among the radicals of the known naturally occurring alcohols those two which give the correct degree of unsaturation are also those which provide the proper number of carbon atoms in the side chains. Naphthoquinone and methylnaphthoquinone derivatives are widely distributed in nature, and it is perhaps significant that the vitamin regarded as a phytyl derivative occurs along with the phytol-containing chlorophyll in green leaves.[12]

According to formula I an interesting relationship exists to another type of vitamin (E). α-Tocopherol apparently arises in nature by the nuclear substitution of a phytyl group into trimethylhydroquinone, followed by ring closure between a hydroxyl group and the double bond in the side chain; vitamin K may arise by a similar condensation of phytol with a 2-alkyl-1,4-naphthohydroquinone, followed by oxidation. The occurrence of vitamin K_2 in putrefied fish meal (Doisy[5a]) is also suggestive of a significant relationship, for the farnesyl group postulated to be present in this substance is associated structually with squalene, a known constituent of fish liver oils, which has the structure di-farnesyl.

According to the suggested structures the vitamins are further related to the natural products lapachol and lomatiol, for these substances are 1,4-naphthoquinones having β-unsaturated, isoprenoid side chains. It is to be noted that the yellow color of the vitamins rules out alternate formulas with double bonds adjacent to the quinonoid nucleus, for such substances are all red or orange.[13] Also of significance is the fact that the spectrum of the highly unsaturated vitamin K_2 is very similar to that of vitamin K_1 and gives no indication of conjugation in the side chains. The distribution of the six double bonds according to the farnesyl pattern is one of a very limited number of ways possible which avoid both conjugation and α-unsaturation.

As mentioned above, Doisy[5] interpreted the analytical results with carefully purified vitamin K_1 in terms of the empirical formula $C_{32}H_{48}O_2$ or $C_{32}H_{50}O_2$. In accordance with the first formula we originally considered the possibility that the substance has a structure similar to I but with a second methyl group in the benzenoid nucleus,

(13) Hooker, THIS JOURNAL, **58**, 1163, 1174 (1936).

for example at position 6. Our observation[14] that the model substance 2,6-dimethyl-3-allyl-1,4-naphthoquinone has an absorption curve very similar to that of vitamin K_1 but shifted to a considerable extent in the direction of longer wave length led us recently to question the presence of this second nuclear substituent, and Doisy's isolation of phthalic acid as an oxidation product of the vitamin[6] now proves definitely that the benzenoid ring is not substituted. Doisy also has obtained evidence from ozonization experiments which already provides a strong indication of the presence of the phytyl group. In accordance with the C_{32}-formulation, and on the basis of the isolation of an as yet unidentified oxidation product having the composition of 2-ethyl-1,4-naphthoquinone-3-acetic acid, Doisy has suggested the structure of 2-ethyl-3-phytyl-1,4-naphthoquinone. Until the evidence is complete there is little choice between this structure and that of the lower homolog I. We may point out that the C_{31}-formulation is entirely admissible on the basis of the available analytical data, as shown in the table, and that the occurrence of methylnaphthoquinones is common while ethyl derivatives have not previously been encountered.

TABLE I

ANALYSES BY DOISY AND CO-WORKERS

	C, %		H, %	
Calcd. for $C_{31}H_{46}O_2$	82.61		10.29

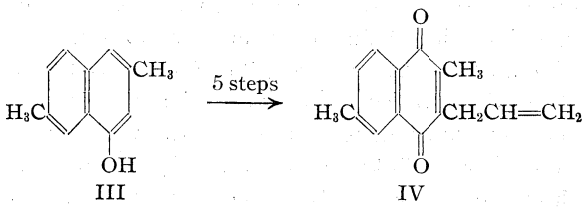
Calcd. for $C_{35}H_{52}O_4$	78.31		9.77	
Dihydro K_1 Diacetate[5b]	78.21	78.01	10.07	10.03

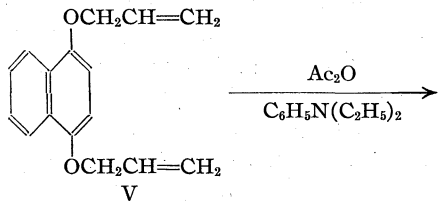
Methods of Synthesis.—In undertaking synthetic work on the problem we thought it of importance first of all to investigate the properties of reasonably accessible allyl derivatives of α-naphthoquinone even though the methods of preparation might not be directly applicable to the synthesis of the vitamins. Thus the allyl group is introduced into phenols more conveniently by the Claisen rearrangement than by direct allylation of the sodium salt, while the introduction of higher β-unsaturated groups of the desired structure from the available primary halides would require the use of the second method (which is now under investigation).

2-Allyl-1,4-naphthoquinone was obtained from the known 2-allyl-1-naphthol by the standard procedure of coupling with diazotized sulfanilic acid, reduction with hydrosulfite, and oxidation employed previously on numerous occasions in this Laboratory. Hydrogenation, followed by reoxidation of the hydroquinone, gave the 2-*n*-propyl derivative, which was obtained as well from the intermediate allylaminonaphthol. In the same way 2,6-dimethyl-8-naphthol (III) was

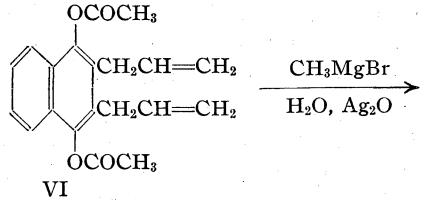


III IV

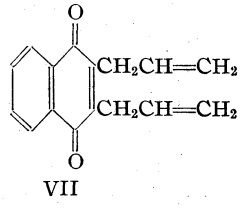
converted through the allyl ether to the 3-allyl derivative and thence to 2,6-dimethyl-3-allyl-1,4-naphthoquinone, IV, which presents an interesting analogy to the structure I. In one of two routes developed for the synthesis of a simple model for structure II, α-naphthohydroquinone was first allylated by Claisen's allyl bromide–potassium carbonate–acetone procedure. The yield was poor, possibly because of appreciable C-allylation,



V



VI



VII

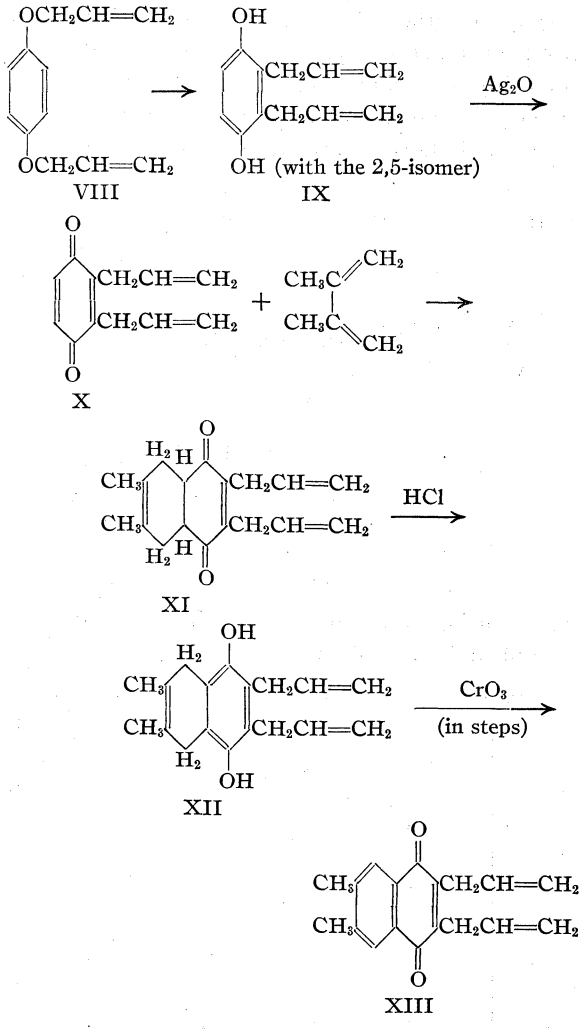
and the crystalline ether V could not be rearranged satisfactorily by the usual methods because of the sensitivity of the product. Good use was made, however, of the device employed on a previous occasion[15] of heating the allyl ether with acetic anhydride in diethylaniline solution. The sensitive hydroquinone is protected as formed by

(14) Fieser, Bowen, Campbell, Fry and Gates, THIS JOURNAL, **61**, 1926 (1939).

(15) Fieser and Lothrop, *ibid.*, **58**, 749 (1936).

acetylation and the diacetate VI is obtained in excellent yield. The hindered character of the acetoxyl groups of this compound and its analogy to the corresponding vitamin derivatives already has been mentioned. The best method found for effecting hydrolysis is exactly that employed in the vitamin series by Doisy,[5b] namely, interaction with a methyl Grignard reagent and oxidation in ethereal solution with either air or silver oxide. The resulting 2,3-diallyl-1,4-naphthoquinone (VII) is a low melting yellow solid (m. p. 29–30°) resembling the vitamins in general properties. When the diacetate VI was refluxed for prolonged periods with ethyl or *n*-butylmagnesium bromide the reagent apparently exerted a reducing action, for there was isolated a small amount of a quinone having two hydrogen atoms more than the normal product VII. The spectrum[4] is very similar to that of 2,3-dimethyl-1,4-naphthoquinone, showing that the naphthoquinone nucleus is intact and that the reduction occurs in the side chain or chains, possibly with condensation to give a third ring.

Another route to 2,3-diallyl derivatives of 1,4-naphthoquinones was found starting with hydroquinone diallyl ether. This method was based upon preliminary observations of H. B. Dunkle.[16] The diallyl ether VIII rearranges smoothly when heated in kerosene solution, from which the phenolic product crystallizes, giving a mixture of two isomers. The higher melting substance presumably is 2,5-diallylhydroquinone, but the structure was not established; the other compound is identified as the 2,3-isomer IX by the successful outcome of the following synthesis. The corresponding quinone X, employed as an unpurified oil, was condensed with 2,3-dimethylbutadiene and the product (XI) isomerized with acid to the dihydronaphthohydroquinone XII. As with simpler examples reported in the patent literature,[17] it was found that treatment of this with chromic acid under rather mild conditions gives a yellow crystalline complex intermediate in composition between the desired naphthoquinone and its dihydride. Further oxidation with excess reagent at 90–100° gave the unsaturated naphthoquinone derivative XIII in a pure condition and in reasonably good yield; probably a portion of the quinone is exhaustively oxidized to easily



eliminated products. Similar intermediate complexes were isolated in syntheses of 6,7-dimethyl-1,4-naphthoquinone and 2,3-diallyl-1,4-naphthoquinone involving the same type of oxidation. The substances do not have the deep color characteristic of quinhydrones and their nature is still obscure.

The above diene synthesis makes possible the introduction of substituents in the benzenoid nucleus of the naphthoquinone. By reversing the sequence of the Claisen rearrangement and the diene addition a practical method was found which permits variation in the nature of the unsaturated side chain. The product XIV of the addition of butadiene to quinone is known to be isomerized easily by acids or bases to 5,8-dihydro-1,4-naphthohydroquinone,[18] and it was found that the change occurs in the presence of potassium carbonate, allyl bromide, and acetone, for the

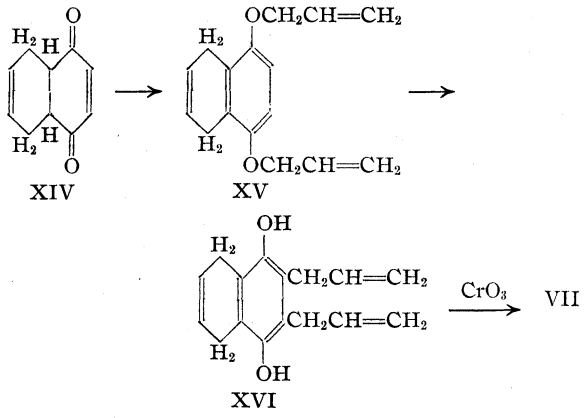
crystalline ether XV was obtained satisfactorily from this reaction mixture. The ether rearranged smoothly in boiling kerosene to XVI, and the latter on stepwise oxidation with chromic acid gave 2,3-diallyl-1,4-naphthoquinone, identical



with the material obtained by the synthesis from α-naphthohydroquinone.

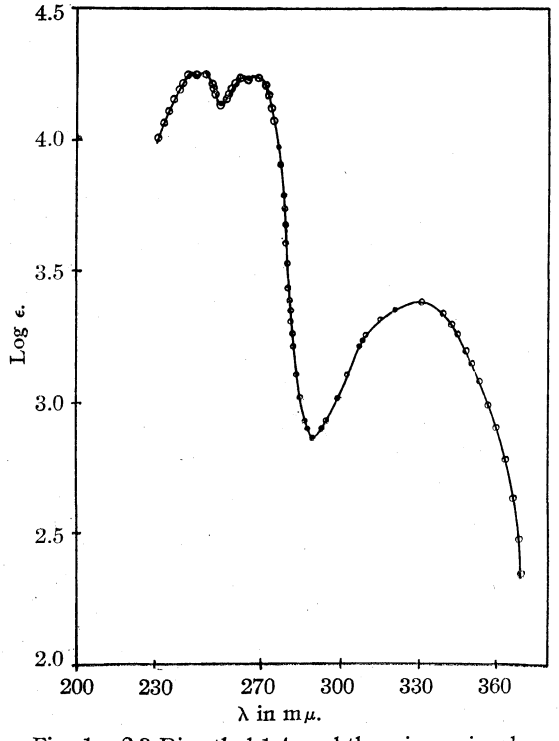


Fig. 1.—2,3-Dimethyl-1,4-naphthoquinone in absolute alcohol. Maxima in mμ (with log ε values in parentheses): 243, 249 (4.26); 262, 267 (4.24); 330 (3.38).

Absorption Spectra.—Table II of our second Communication[14] summarizes the spectrographic data on most of the above synthetic naphthoquinones except the 2,3-diallyl derivative, and the

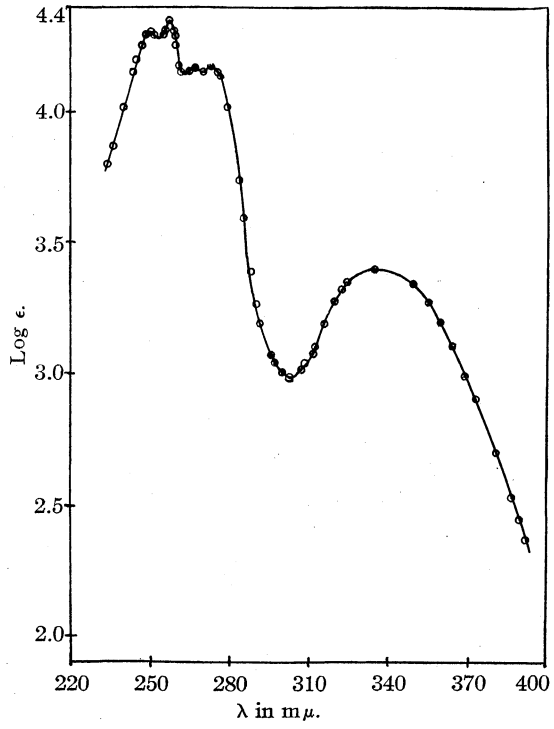

Fig. 2.—2,6-Dimethyl-3-allyl-1,4-naphthoquinone in absolute alcohol. Maxima in mμ: 249 (4.30), 256 (4.35); 265, 272 (4.17); 335 (3.39).

absorption curves for this and other compounds of interest are given in Figs. 1–4. The only set of complete data for comparison consists in the curve published by Dam, Karrer, *et al.*,[7] for a purified preparation from alfalfa consisting largely of vitamin K_1, but the positions of the maxima are very close to those reported by Doisy[5] for pure K_1. According to Doisy vitamins K_1 and K_2 are spectrographically almost identical. As the chief characteristics the spectra show two intense bands, centering in the neighborhood of 245 and 265 mμ, and a broader band of low intensity at about 324 mμ. The first intense band shows some evidence of resolution, with maxima at 243 and 248 mμ (Doisy, K_1) while the second one has definite fine structure with peaks at 261 and 270 mμ (K_1 and K_2). In comparing the synthetic compounds with the vitamins it is significant that naphthoquinones which depart appreciably from the suggested structures I and II of 2,3-dialkyl derivatives diverge considerably in spectrographic characteristics. Thus the 2,6-dimethyl compound has only one intense absorption band and the 2-methyl derivative has two such bands but both are lacking in fine structure. 2,3-Dimethyl-1,4-naphthoquinone, however, gives

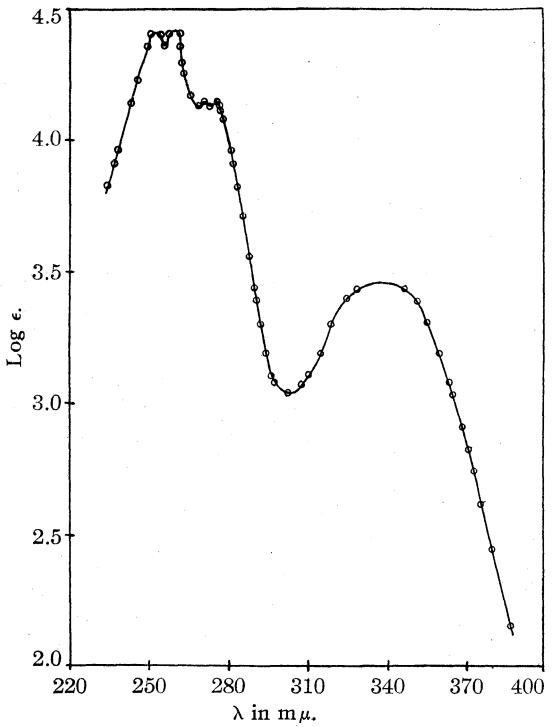

Fig. 3.—6,7-Dimethyl-2,3-diallyl-1,4-naphthoquinone in hexane. Maxima in mμ: 253, 260 (4.41); 271, 276 (4.14); 338 (3.46).

indications of resolution in the first intense band and the second one is definitely resolvable. This fine structure was first pointed out to us by Dr. T. J. Webb of the Merck Research Laboratories, and decisive evidence on the question has been obtained through the kind coöperation of Dr. H. H. Darby, Columbia University. Dr. Darby examined the plates prepared by D. M. Bowen using the Krüss densitometer at the Bartol Institute and found unquestioned resolution of the second band, as shown in Fig. 1, and probable resolution of the first band. In both the positions and the special characteristics of all three principal absorption bands this 2,3-dialkyl-1,4-naphthoquinone corresponds very closely with the natural vitamins, and the only difference is that in the Dam–Karrer curve the second intense band is somewhat less intense than the first. This same characteristic is met with in 2,6-dimethyl-3-allyl-1,4-naphthoquinone (Fig. 2), and indeed the form of the curve throughout almost duplicates that given by Dam, Karrer, *et al.* The reading of the plates in this case was verified by Dr. Darby with the densitometer and the more accurate values for the maxima are recorded in the legend of Fig. 2. The whole curve for the 2,6-dimethyl-3-allyl compound, however, is shifted about 5 mμ toward the red end of the spectrum, and we interpret this difference as due to the presence of a 6-methyl group in the model substance and not in the vitamins. A smilar and even more pronounced shift (av. 11 mμ) is observable in the 6,7-dimethyl-2,3-diallyl compound (Fig. 3) as compared with 2,3-diallyl-1,4-naphthoquinone (Fig. 4). Examination of the previously reported[14] data for 2-allyl-1,4-naphthoquinone will show that a second band of high intensity is clearly resolvable only when hexane is used as the solvent and that this is relatively closer to the first band than in the case of the synthetic 2,3-dialkyl derivatives and the natural vitamins; the 2-allyl compound indeed seems related more closely to the 2-methyl quinone than to these substances.

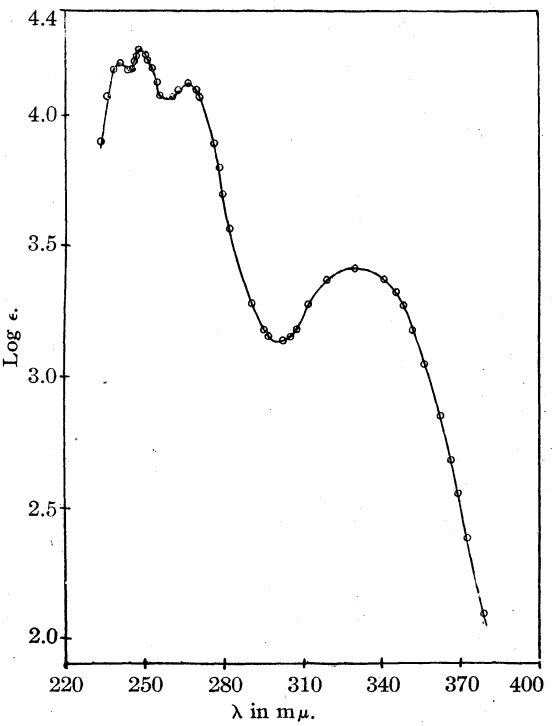

Fig. 4.—2,3-Diallyl-1,4-naphthoquinone in absolute alcohol. Maxima in mμ: 240 (4.20); 249 (4.24); 267 (4.12); 330 (3.42).

The spectrographic evidence as a whole provides convincing evidence for the proposed formulations I and II. From the form of the curves and the positions of the maxima it is evident that 2,3-dimethyl and 2,3-diallyl-1,4-naphthoquinone constitute very close optical models for the vitamins, whereas nuclear homologs and compounds lacking the feature of 2,3-disubstitution depart signifi-

cantly from the natural pattern. An alteration in the size of the alkyl substituents in the quinonoid ring clearly does not influence the spectrum, and 2-methyl and 2-ethyl-3-phytyl-1,4-naphthoquinone would of course be spectrographically equivalent.

Bio-assays.—We had hoped to gain an insight into the nature of the antihemorrhagic vitamins from a knowledge of the biological properties of synthetic models, and we are of course also interested in producing synthetic vitamins or synthetic substitutes. Indeed Doisy's isolation[5a] of two antihemorrhagically active substances differing by as much as eight or nine carbon atoms and containing from one to six lateral double bonds adequately demonstrates that vitamin K activity is not specific to a single structure. Our new compounds, as well as various known substances, have been examined in exploratory assays by Dr. W. L. Sampson of the Merck Institute, through the courtesy of Dr. R. T. Major, and most of the results have been reported in our two Communications.[4,14] These assays by the rapid Ansbacher procedure[19] were recognized as preliminary and now seem rather uncertain. Thus 2-allyl-1,4-naphthoquinone gave evidence of high vitamin K potency in an assay with one series of chicks[14] but in a subsequent test it appeared to be inactive even at a higher dosage level. A similar inconsistency appears in recent reports concerning 2-methyl-1,4-naphthoquinone. The Doisy group[20] find the 2-methyl compound to be only slightly more potent than phthiocol, which various workers have described as greatly inferior to the natural vitamins in activity.[20,21,22] Ansbacher and Fernholz,[22] on the other hand, state that 2-methyl-1,4-naphthoquinone is practically as active as vitamin K. Evidently the rapid assay procedures require considerable further investigation for application to the testing of pure compounds, and for the present it is necessary to reserve judgment on the preliminary results.

Dr. Sampson has tested three compounds from our Laboratory by the Almquist procedure.[23] Lapachol, tested at a level of 8 mg. and 15 mg. per kilogram of diet was entirely inactive, as was lomatiol at the 5-mg. and 10-mg. levels. Almquist and Klose obtained similar results at still higher levels. 2,3-Dimethyl-1,4-naphthoquinone was dosed at 8 mg., 3 mg., and 0.5 mg. The 8 mg. level was about as effective as 2 g. of the Walker–Gordon standard, giving an average blood clotting time of 7.5 minutes for 8 birds (two prolonged). The birds on the two lower doses were but slightly different from the controls.

Color Reaction with Sodium Ethylate.—Dam, Karrer, *et al.*,[7] reported that their highly purified vitamin K_1 preparation gave with sodium ethylate in alcohol a transient purple color changing to reddish-brown, and Almquist and Klose[24] have published an extensive comparison of the color reactions and bio-assays of concentrates which strongly indicates that the color is due to the vitamin. Fernholz, Ansbacher and Moore,[25] however, question this conclusion and the matter is still unsettled; unfortunately the behavior of pure vitamins K_1 and K_2 in the color reaction has not been reported.

The response of our synthetic models to treatment with alcoholic alkalies presents certain points of special interest. All of the above 1,4-naphthoquinones containing at least one allyl group in the quinonoid ring give strikingly beautiful purple or blue solutions changing in a minute or two to dull brown-red, whereas naphthoquinones containing saturated alkyl groups show no purple or blue phase. The contrast between 2-allyl and 2-*n*-propyl-1,4-naphthoquinone is so marked that the color test was used to determine when traces of the former substance had been removed completely from a preparation of the latter.

Speculating on the nature of the changes involved, we were impressed by a similarity to observations on the behavior of 2-hydroxy-3-alkenyl-1,4-naphthoquinones on treatment with sodium acetate and acetic anhydride. Lapachol gives an unusual reaction product referred to in the early literature as Paternò's isolapachone, and the structure of this substance was fully established in the later researches of Hooker.[26] In connection with a recent study of the tautomerism of certain alkylated β-naphthoquinones in this Laboratory,[27] the abnormal reaction was interpreted as involving in the essential step a tautomeric shift of hydrogen from the activated methylene group between the unsaturated quinone ring and the external double bond and it was noted that similar

abnormal acylations occur with the 3-allyl[28] and 3-benzyl derivatives of 2-hydroxy-1,4-naphthoquinone, but not with substances having no activating double bond or phenyl group attached to the α-carbon atom of the side chain.

Applied to the case at hand, these inferences suggested that the color reaction of 2,3-diallyl-1,4-naphthoquinone, for example, may be due to a similar tautomeric shift to the hydroxyquinonemethane XVII, the intense color being due to the orthoquinonoid group and salt formation with the acidic hydroxyl substituent. Such an intermediate might well be subject to fission by hydrolysis, or by some process involving disproportionation and cleavage, and we consequently sought to isolate the pigment from the dull red end solution by a procedure adapted to the properties of a 2-hydroxy-3-alkyl-1,4-naphthoquinone. These substances are strongly acidic and give cherry-red or orange-red solutions in aqueous sodium carbonate, and indeed soda extraction of the pigment from the 2,3-diallyl compound gave an easily purified yellow substance identified as 2-hydroxy-3-allyl-1,4-naphthoquinone by analysis and by direct comparison with a sample available from a previous synthesis.[28] The color reaction with alcoholic alkali, which in the above case goes to completion at room temperature in less than ten minutes, thus involves the cleavage of one allyl group and its replacement by hydroxyl. 2-Allyl-1,4-naphthoquinone similarly gives a substance very probably identical with 2-hydroxy-1,4-naphthoquinone.

(28) Fieser, THIS JOURNAL, **48**, 3201 (1926).

This observation probably is of considerable significance to the vitamin K problem although application of the information must remain somewhat uncertain until more is known of the behavior of the vitamins. If the pure substances K_1 and K_2 are found to give the color test, the present experiments will afford a good indication of the presence of a β-unsaturated side chain. Furthermore, it should be possible to degrade vitamin K_1 to phthiocol or to the ethyl homolog, and to convert K_2 to a 2-hydroxy-3-alkyl(farnesyl ?)-1,4-naphthoquinone which should be obtainable by a known process of synthesis.[28,29]

Of considerable interest is the observation of Almquist and Klose[21] that the pigment resulting as the end-product of the action of sodium methylate on vitamin K concentrates gives color changes and tests very similar to those exhibited by phthiocol and its homologs. This provides at least a preliminary confirmation of the above prediction and encourages us to mention tentatively a further speculation. Almquist and co-workers[30] have demonstrated that various bacteria are capable of producing vitamin K, including *Mycobacterium tuberculosis*, from which Anderson and Newman[31] isolated phthiocol. Since their isolation procedure involved saponification with alcoholic potassium hydroxide, it is conceivable that the phthiocol was not a true natural constituent of the organism but arose as a product of the alkaline cleavage of vitamin K_1 or a homolog.

Experimental Part[32]

2-Allyl- and 2-*n*-Propyl-1,4-naphthoquinone (W. P. C.).—2-Allyl-1-naphthol was prepared from α-naphthol by allylation in acetone and rearrangement of the ether according to Claisen and Eisleb[33]; over-all yield 67%, b. p. 144° at 4 mm. The coupling of this substance (2.02 g.) with diazotized sulfanilic acid and reduction of the dye was conducted by exactly the procedure given for α-naphthol[34] except that more water was required in dissolving the amine hydrochloride, which is rather sparingly soluble. After one recrystallization from a solution containing excess hydrochloric acid and a trace of stannous chloride, **2-allyl-4-amino-1-naphthol hydrochloride** was obtained as colorless needles; yield 1.60 g. (62%). The sample for analysis was dried at 110° and 15 mm.

2-Allyl-1,4-naphthoquinone.—On adding a solution of 2.7 g. of ferric chloride crystals and 1 cc. of concentrated hydrochloric acid in 5 cc. of water to a solution of 1 g. of the above hydrochloride and 0.5 cc. of concentrated hydrochloric acid in 90 cc. of warm water the solution turned deep orange and deposited a greenish-black solid. After cooling, this was collected and extracted while moist with ether and the solution was clarified with Norite and evaporated. The yellow residue was obtained crystalline from ether–petroleum ether and afforded 0.65 g. (76%) of product in the form of yellow needles melting constantly at 36–36.5°.

Anal. Calcd. for $C_{13}H_{10}O_2$: C, 78.77; H, 5.09. Found: C, 78.82; H, 5.14.

The quinone darkens rapidly in direct sunlight. It reacts with acetic anhydride–sulfuric acid in the cold to give an apparently colorless substance very soluble in organic solvents. It is very readily soluble in ether or alcohol, less so in petroleum ether, and sparingly soluble in water. On adding 0.5 cc. of a solution prepared from 0.5 g. of sodium and 25 cc. of alcohol (95%) to a solution of 1–2 mg. of the quinone in 1 cc. of alcohol the solution at once acquires an intense, vivid purple color, and after about one minute this changes to dull red. The color changes were similar when 2 cc. of 10% aqueous potassium hydroxide was added to 0.2 g. of the quinone in 5 cc. of alcohol (L. F. F.); on diluting and acidifying the red solution a gelatinous precipitate separated which yielded only a trace of a yellow hydroxyquinone on extraction with ether or hot water. In repeating the experiment two drops of 30% hydrogen peroxide was added to the alcoholic solution and after dilution of the final red solution this was extracted with ether and the acidic material separated with soda solution, taken into ether, crystallized from dilute alcohol, and sublimed. There was obtained 5 mg. of yellow material giving the color reactions of hydroxynaphthoquinone and melting at 178–180°, dec. Mixed with an authentic sample, m. p. 186–188°, dec., the m. p. was 180–181°. The purple phase in the color test is seen best in a dilute solution with a very small amount of alkali. With one drop of 10% methyl alcoholic potassium hydroxide added to 1–2 mg. of the quinone in 25 cc. of alcohol the solution becomes so strongly purple that it is not transparent when viewed lengthwise in a 2 × 15-cm. test-tube and the purple phase persists for about thirty minutes before fading.

2-*n*-Propyl-1,4-naphthoquinone.—On shaking a solution of 2 g. of the allylaminonaphthol hydrochloride in 200 cc. of water with 0.1 g. of Adams catalyst and hydrogen, one mole of gas was absorbed in about twenty-four hours. After removing the catalyst, hydrochloric acid was added to turbidity at the boiling point and the reduction product was obtained as nearly colorless needles. The material was dissolved while still moist in 175 cc. of hot water and a solution of 6 g. of ferric chloride crystals and 2 cc. of concentrated hydrochloric acid in 15 cc. of water added. The quinone separating as a red oil was extracted with ether and the solution was washed, dried, clarified with Norite, and concentrated. Crystallization from ether–petroleum ether gave 1 g. (59%) of crude product sintering at 36° and melting at 38–39.5°. This gave a purple color in the test with alcoholic potassium hydroxide, indicating contamination with allylnaphthoquinone. Several recrystallizations from petroleum ether gave pure material crystallizing in clusters of pale yellow needles, m. p. 39–39.5° (no previous sintering). This gave an immediate red color with alcoholic alkali, with no blue or purple phase.

Anal. Calcd. for $C_{13}H_{12}O_2$: C, 77.97; H, 6.07. Found: C, 78.06; H, 6.21.

The allylnaphthoquinone was also hydrogenated (1 g. in 25 cc. of absolute alcohol), 2 moles of gas being absorbed in about three minutes. After oxidation in ether with silver oxide, the propylnaphthoquinone was obtained pure in 70% yield.

2,6-Dimethyl-3-allyl-1,4-naphthoquinone (M. D. G., W. P. C.).—2,6-Dimethyl-8-naphthol[35] was converted into the allyl ether by heating a mixture of 5 g. of the material with 3 g. of allyl bromide, 8 g. of finely powdered potassium carbonate, and 75 cc. of purified acetone for fifteen hours on the steam-bath with mechanical stirring. The mixture was diluted with water, extracted with ether, and, after extraction of a trace of phenolic material with 10% potassium hydroxide containing sodium hydrosulfite, the ethereal solution was dried and evaporated. The oily residue of the crude ether was heated with 30 cc. of freshly distilled dimethylaniline in an atmosphere of nitrogen for two and three-quarters hours in a salt-bath maintained at 240°, and the cooled solution taken up in ether and extracted with dilute hydrochloric acid. For separation of the **2,6-dimethyl-3-allyl-8-naphthol** the ethereal solution was extracted several times with 10% potassium hydroxide, which removed successive small amounts, and then with Claisen's aqueous alkali–methanol mixture. The combined extracts were acidified and extracted with ether. The product distilled at 152–157° (2 mm.) as a rather dark oil (3 g., 49%) which was used directly without further purification.

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.86; H, 7.60. Found: C, 84.20; H, 7.74.

In an early experiment using crude starting material containing 2,6-dimethyl-3-naphthol the rearrangement gave a small amount of a crystalline product which forms long fibrous needles, m. p. 109–110°, from ligroin (b. p. 70–90°). The substance fails to couple with diazotized amines and evidently is **2,6-dimethyl-4-allyl-3-naphthol.**

Anal. Calcd. for $C_{15}H_{16}O$: C, 84.86; H, 7.60. Found: C, 84.69; H, 7.67.

The introduction of an amino group into the liquid isomer was conducted as above and the crude **2,6-dimethyl-7-allyl-5-amino-8-naphthol** collected as a nearly colorless precipitate; yield 2.3 g. (72%). The substance is very sparingly soluble in the usual solvents and dissolves to only a slight extent in a large volume of boiling, dilute hydrochloric acid. The filtered solution on cooling deposits very fine, colorless needles of the **hydrochloride,** which apparently forms a stable trihydrate.

Anal. Calcd. for $C_{15}H_{18}ONCl\cdot 3H_2O$: N, 4.41. Found: N, 4.32 (Kjeldahl), 4.39 (Dumas).

Conversion to the Quinone.—For oxidation, 1.3 g. of the free amine was suspended in 50 cc. of acetone and treated

(35) Weissgerber and Kruber, *Ber.*, **52**, 360 (1919).

with 30 cc. of a solution of 27 g. of ferric chloride crystals and 10 cc. of concentrated hydrochloric acid diluted to 245 cc. On warming and stirring the solid dissolved (ten minutes) and the cooled solution was diluted and extracted with ether. After clarification and drying the solvent was removed in vacuum and the residual oil taken up in petroleum ether. On cooling, the quinone separated as yellow needles, m. p. 42–42.5°, and the melting point was not raised on recrystallization; yield 0.75 g. (57%).

Anal. Calcd. for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24. Found: C, 79.82; H, 6.36.

In the color test with sodium ethylate in alcohol the quinone gives first a deep blue solution, changing to purple and then brown. Treated with 5% methyl alcoholic potassium hydroxide, the quinone gives a deep blue solution which changes in one to two minutes to a dull greenish-brown and then to a dull red; the diluted solution gives a gelatinous precipitate on acidification. Intense coloration does not develop if much water is present; the addition of 10% aqueous potassium hydroxide to a solution in alcohol gave a faint dull green color changing to weak purplish-red and then to a dull, weak red.

2,3-Diallyl-1,4-naphthoquinone from α-Naphthoquinone (M. F.)

α-Naphthohydroquinone Diallyl Ether.—The α-naphthohydroquinone required as starting material was prepared by dissolving 10 g. of the quinone in 50–75 cc. of hot alcohol and adding gradually a solution of 20 g. of stannous chloride crystals and 20 cc. of concentrated hydrochloric acid in 50 cc. of water. After heating gently until the color faded to pale yellow, and filtering if necessary, the solution was diluted with water and cooled in an ice-bath. The product separated as colorless or gray needles; yield 8.2–8.8 g.

For allylation, 6.1 g. of α-naphthohydroquinone was refluxed for ten to fifteen hours with 6.5 cc. of allyl bromide, 10.4 g. of potassium carbonate, and 20 cc. of acetone. The mixture usually became very dark, even in an atmosphere of nitrogen, and when the ether extract was shaken with alkali containing hydrosulfite considerable phenolic material was removed. After drying with magnesium sulfate the ethereal solution was cooled in a solid carbon dioxide bath, when the diallyl ether separated as a pasty solid. After adding petroleum ether, the crystalline material was collected, and an additional quantity was obtained by diluting the mother liquor with petroleum ether, filtering the solution through a tower of activated alumina, concentrating, and cooling as before. The yield of satisfactory material was 2–3.5 g. (22–38%). Repeated crystallization from petroleum ether containing a trace of ether gave colorless plates, m. p. 49.5–50°.

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 79.96; H, 6.72. Found: C, 80.09; H, 6.74.

2,3-Diallyl-1,4-naphthohydroquinone Diacetate.—Attempted rearrangement of the ether in kerosene in an atmosphere of nitrogen gave only dark tars, but the expedient of acetylating the reaction product as produced[15] gave satisfactory results. A mixture of 3 g. of the diallyl ether, 3 cc. of acetic anhydride, and 3 cc. of diethylaniline was heated under reflux in a stream of hydrogen at 200–210° for five hours. The cooled mixture was taken into ether and the solution extracted with dilute hydrochloric acid, dried, and evaporated to a small volume. On slow cooling the diacetate separated as large hexagonal prisms; yield 3.2 g. (79%). The substance is very readily soluble in benzene or alcohol and moderately soluble in ligroin. Recrystallized from ether–petroleum ether or from ligroin (b. p. 70–90°) it formed large, colorless prisms, m. p. 92.5–93°.

Anal. Calcd. for $C_{20}H_{20}O_4$: C, 74.05; H, 6.22. Found: C, 74.18; H, 6.33.

2,3-Diallyl-1,4-naphthoquinone (M. D. G.).—The diacetate is resistant to hydrolysis by alkalies, and considerable material was recovered unchanged after boiling for two hours with 12% sodium hydroxide solution. Hydrolysis occurs with mixtures of alcohol and 25% alkali on warming, but the isolation of a satisfactory reaction product is not easily accomplished. For best results the diacetate is cleaved with a Grignard reagent having little reducing action.

To the Grignard solution prepared under nitrogen from 3 g. of magnesium, 100 cc. of absolute ether and sufficient methyl bromide to give complete reaction, was added 2.86 g. of 2,3-diallyl-1,4-naphthohydroquinone diacetate. The solution was refluxed for forty-five minutes, the ether was largely replaced with dry benzene, and after refluxing for one-half hour longer the mixture was decomposed with 25% ammonium chloride solution and a little acid. The organic layer was washed and dried and stirred mechanically with 2.05 g. of silver oxide and 10 g. of Drierite for fifteen minutes (oxidation can be accomplished also by shaking with air). The filtered, yellow solution was concentrated, eventually under vacuum, and the residual, dark yellow oil was cooled well and caused to solidify. After two crystallizations from alcohol (collecting the crystals in the cold room) the substance formed glistening yellow blades, m. p. 29–30°. It gave no depression when mixed with the analyzed sample prepared by the synthesis described below. The total yield of pure material was 1.05 g. (50%). The quinone is very readily soluble in ether or petroleum ether, sparingly soluble in water. It gives a yellow or brown solution in concentrated sulfuric acid.

Alkaline Cleavage of the Quinone (L. F. F.).—2,3-Diallyl-1,4-naphthoquinone gives a characteristic, intense color reaction with alcoholic alkali. When one drop of 10% aqueous alkali is added to a dilute solution of the substance in 1–2 cc. of alcohol, the solution becomes pale greenish-blue, then deep blue, slowly fading to a dull, weak green. With a larger amount of aqueous or alcoholic alkali the green phase is not observed and at the end the solution is red. In one experiment a solution of 0.1 g. of the quinone in 5 cc. of alcohol was treated with 1 cc. of 10% aqueous potassium hydroxide. The solution became deep indigo blue (ten seconds), purplish blue (forty seconds), intense purple (about one minute); a small amount of a cloudy gray precipitate then separated (two minutes) and the solution soon became dull red (two to three minutes) and underwent no further change on standing or heating. After dilution with water, which caused more of the gray material to separate, the mixture was acidified and shaken with ether, when all of the precipitated ma-

terial dissolved. Extraction of the ether solution with sodium carbonate gave a cherry-red aqueous layer and left a dark brown ether layer which gave on evaporation a resin showing no blue color with alcoholic alkali. After washing the red aqueous extract once with ether it gave on acidification a yellow emulsion of crude **2-hydroxy-3-allyl-1,4-naphthoquinone.** This was taken into ether and the solution dried and evaporated. The glassy residue largely dissolved in boiling ligroin (b. p. 70–90°) and after clarification and cooling the hydroxyquinone separated as bright yellow prism clusters, m. p. 115–116°; yield 5 mg. This was combined with material from two other experiments and recrystallized from dilute alcohol–acetic acid, giving fine yellow needles, m. p. 115.5–116°.

Anal. Calcd. for $C_{13}H_{10}O_3$: C, 72.88; H, 4.71. Found: C, 73.19; H, 5.02.

Mixed with synthetic 2-hydroxy-3-allyl-1,4-naphthoquinone,[28] m. p. 115.5–116°, the above sample gave no depression; other preparations were compared with similar results. In a further experiment the hydroxyquinone was purified by sublimation at 2 mm. pressure and the product dissolved in concentrated sulfuric acid. The red solution was poured into water and the product extracted and dried in ether and crystallized from ligroin (b. p. 70–90°), giving ball-like clusters of red microcrystals, m. p. 130–131.5°. A mixture with a synthetic sample of 1-methyl-3,4-benzo-5,6-coumaranequinone[28] (m. p. 134.5–135°, purified with bisulfite) melted at 131–132°.

Reducing Action of the Grignard Reagent (L. F. F.).—On cleavage of 2,3-diallyl-1,4-naphthohydroquinone diacetate by refluxing overnight with excess ethyl or *n*-butylmagnesium bromide in ether and working up the reaction mixture as before, small amounts of a quinone much less soluble than the main reaction product separated in a crystalline condition on concentrating the final ethereal solution to a small volume. Washed free of adhering oil with ether, the substance was obtained as bright yellow prisms, m. p. 127–128°. It was purified by crystallization from dilute alcohol and sublimation at 1 mm. pressure (about 125°), giving bright yellow needles, m. p. 129–130°.

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71. Found: C, 79.93, 80.32, 80.06; H, 6.76, 6.91, 6.78.

The absorption spectrum is very similar to that of 2,3-dimethyl-1,4-naphthoquinone. The addition of dilute alkali to an alcoholic solution of the quinone gives a weak purplish-pink color which develops rather slowly and gradually changes to red.

Preparation of the Diallylbenzoquinones (E. M. F.)

Hydroquinone diallyl ether was prepared more satisfactorily by the following method than by that described by Hahn and Stenner.[36] A mixture of 44 g. of hydroquinone, 200 cc. of acetone, 96.8 g. of allyl bromide, and 112 g. of potassium carbonate was refluxed for nine hours, water was added to dissolve the inorganic salts, and the reaction product was extracted with ether. Phenolic material was removed by extraction with 1 *N* sodium hydroxide and the solution was washed well with water, dried and evaporated. The orange-yellow residue was induced to crystallize from a cooled solution in dilute alcohol, giving 52 g. of colorless, lustrous plates, m. p. 33–34°; 5 g. of yellowish material was obtained in a second crop, making the total yield 75%.

Rearrangement.—A solution of 53 g. of hydroquinone diallyl ether in 330 cc. of kerosene (b. p. 210–215°) was refluxed vigorously under a stream of nitrogen for two and one-quarter hours. The phenolic reaction product largely crystallized on cooling, and a small additional quantity was obtained on concentrating the mother liquor. The combined, almost colorless material was washed with petroleum ether to remove most of the kerosene and dried at 50°; yield 57.5 g.

2,5-Diallylhydroquinone was separated from this mixture by crystallization from water and the 2,3-isomer subsequently was isolated from the aqueous liquors. The crude rearrangement product was heated to boiling with 2 l. of water containing a little sodium hydrosulfite and steam distilled to remove kerosene still present. A considerable amount of material remained undissolved as an oily solid and the hot solution was decanted from this and filtered. On cooling the colorless filtrate a large crop of 2,5-diallylhydroquinone crystallized, and after collecting this the mother liquor was used to extract a further quantity of material from the semi-solid residue. After heating to boiling, the solution was filtered from a small amount of dark brown oil and cooled, giving another crop of colorless crystals. The total yield of crude 2,5-isomer was 25 g.; recrystallization from 2 l. of water gave 15.2 g. (29%) of pure product in the form of broad, flat needles, m. p. 129.5–131°.

Anal. Calcd. for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42. Found (H. B. Dunkle): C, 75.80; H, 7.40.

The **diacetate** was prepared by adding 1.5 cc. of pyridine to a supension of 1.5 g. of the hydroquinone in 3 cc. of acetic anhydride. The mixture became warm, the solid dissolved, and on cooling the product crystallized. It separated from dilute alcohol as colorless needles, m. p. 111–112° (1.8 g.).

Anal. Calcd. for $C_{16}H_{18}O_4$: C, 70.05; H, 6.62. Found: C, 70.25; H, 6.70.

The dimethyl ether was prepared by the action of dimethyl sulfate in alkali containing hydrosulfite and the chief fraction boiled at 132–135° (1.5 mm.) and melted at about 40°. On oxidation with alkaline permanganate at 30–40° the ether gave a high yield of oxalic acid as the only observed product.

2,3-Diallylhydroquinone.—The combined aqueous mother liquors remaining from the above experiment after removal of the 2,5-isomer on extraction with ether gave 22.2 g. of colorless, crystalline material consisting largely of 2,3-diallylhydroquinone. This is very soluble in hot water but crystallizes satisfactorily from this solvent in fine, colorless needles, m. p. 87–90°.

Anal. Calcd. for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42. Found: C, 76.17; H, 7.60.

2,5-Diallyl-1,4-benzoquinone.—A solution of 2.5 g. of the hydroquinone in 150 cc. of dry ether was stirred mechanically for two hours with 6.3 g. of silver oxide and 6.5 g. of anhydrous sodium sulfate with exclusion of air. The course of the oxidation can be followed by transfer-

(36) Hahn and Stenner, *Z. physiol. Chem.*, **181**, 88 (1929).

ring a drop of the solution to a watch glass; a violet color appears if hydroquinone is still present, otherwise the spot is completely yellow. The yellow solution was filtered and evaporated, leaving the quinone as a dark orange-yellow oil. It was purified by careful distillation from a salt-bath, b. p. 105–106° (1 mm.), which gave 1.6 g. of a clear yellow oil. Local overheating or distillation at a higher pressure results in decomposition, as evidenced by darkening or by the appearance of a green coloration. The yellow distillate crystallized on cooling in rectangular tablets, m. p. 16°.

Anal. Calcd. for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43. Found: C, 76.71; H, 6.75.

2,3-Diallyl-1,4-benzoquinone was prepared from the corresponding hydroquinone (2.5 g.) in an analogous manner and the dark reddish-yellow oil (2.4 g.) remaining after evaporation of the ether was used directly in the synthesis and not purified further.

Diene Synthesis of Naphthoquinones (E. M. F.)

6,7-Dimethyl-1,4-naphthoquinone was prepared essentially as described in the patent literature.[17] A solution of 1 g. each of benzoquinone and 2,3-dimethylbutadiene in 2 cc. of benzene was refluxed for five hours and the addition product which crystallized on cooling (1.9 g.) was purified from dilute alcohol and thus separated from a little high melting material. The substance (m. p. 113–115°) was isomerized with 1 *N* alkali under nitrogen and acidification, or by adding dilute hydrochloric acid to a warm solution of the addition product in alcohol (nearly quantitative). The once crystallized (alcohol) dihydronaphthohydroquinone derivative (0.4 g.), m. p. 232–238°, was dissolved in glacial acetic acid (2 cc.) and treated with 0.3 g. of chromic anhydride, when a sharp temperature rise was noted. After a short period water was added and the yellow precipitate purified from alcohol (0.37 g.). It formed somewhat dull yellow crystals, m. p. 120–126°, dec. (blackening). The substance is intermediate in composition between the naphthoquinone and its dihydride and appears to be a complex.

Anal. Calcd. for $(C_{12}H_{11}O_2)_x$: C, 76.98; H, 5.92. Found: C, 77.19, 76.98; H, 6.14, 6.08.

Further treatment of the intermediate with chromic anhydride gave 6,7-dimethyl-1,4-naphthoquinone, which crystallized from alcohol in bright yellow needles of constant m. p. 118–119°.

Anal. Calcd. for $C_{12}H_{10}O_2$: C, 77.40; H, 5.41. Found: C, 77.43; H, 5.61.

6,7-Dimethyl-2,3-diallyl-1,4-naphthoquinone.—The addition product which separated after refluxing 2.4 g. of 2,3-diallyl-1,4-benzoquinone and 3.4 cc. of 2,3-dimethylbutadiene in 3 cc. of benzene for twenty hours was isomerized by short boiling with dilute alcoholic hydrochloric acid to **6,7-dimethyl-2,3-diallyl-5,8-dihydro-1,4-naphthohydroquinone,** which formed somewhat brownish crystals from alcohol, m. p. 156.5–159° (2.3 g.).

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20. Found: C, 80.27; H, 8.15.

A solution of 0.5 g. of this material in acetic acid was treated at room temperature with 0.25 g. of chromic anhydride in glacial acetic acid. A rapid reaction ensued with rise in temperature (40°). After heating to 60° the solution was cooled and a dull yellow intermediate precipitated with water. This formed rectangular plates from alcohol, m. p. 54–56° with previous sintering; yield 0.4 g.

Anal. Calcd. for $(C_{18}H_{19}O_2)_x$: C, 80.87; H, 7.16. Found: C, 80.80; H, 7.17.

For further oxidation to the naphthoquinone 1 g. of the intermediate in 20 cc. of solvent was heated with 0.3 g. of chromic anhydride to 80°, when the solution warmed spontaneously to 90°, and then to 100°. The product then crystallized from alcohol in long flat needles or rectangular plates; both forms are bright yellow and melt at 69.5–70.7°.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81. Found: C, 81.46; H, 6.96.

The color changes in the reaction with sodium ethylate are similar to those of 2,3-diallyl-1,4-naphthoquinone.

2,3-Diallyl-1,4-naphthoquinone from Butadiene-benzoquinone (L. F. F.)

5,8-Dihydro-1,4-naphthohydroquinone Diallyl Ether.—A mixture of 7 g. of monobutadiene-*p*-benzoquinone,[18] 10 cc. of allyl bromide, 23.8 g. of finely powdered potassium carbonate, and 150 cc. of purified acetone was refluxed overnight, diluted with water and extracted with ether. After washing with alkali–hydrosulfite and water the light yellow ethereal solution was dried and evaporated, eventually with suction. The residue was taken up in warm methanol and on cooling the ether crystallized in colorless, pearly plates, m. p. 63–64°; yield 5.6 g. (54%). Recrystallized twice from methanol it melted at 64–65°.

Anal. Calcd. for $C_{16}H_{18}O_2$: C, 79.30; H, 7.49. Found: C, 79.51; H, 7.55.

2,3-Diallyl-5,8-dihydro-1,4-naphthohydroquinone.—A solution of 5.6 g. of the diallyl ether in 34 cc. of kerosene was heated under nitrogen in a bath maintained at 240–250° for two hours, and on cooling (under nitrogen) the rearrangement product separated as a crystalline paste. It was collected, washed well with petroleum ether in which it is sparingly soluble, and obtained as completely colorless plates, m. p. 107–108.5°; yield 4.9 g. (88%). The substance is moderately soluble in ligroin (b. p. 70–90°) and crystallizes from this solvent in clusters of microcrystals, m. p. 108–109°. The solution turns slightly yellow in the air and the crystals acquire a pale tan color.

Anal. Calcd. for $C_{16}H_{18}O_2$: C, 79.30; H, 7.49. Found: C, 79.36; H, 7.78.

Oxidation (E. M. F.).—This was conducted in stages as above, first using 4.35 g. of the dihydronaphthohydroquinone in 25 cc. of acetic acid and 4.3 g. of chromic anhydride and warming to 50° to start the reaction. The initial reaction was controlled to 70° and after heating to 100°, cooling and diluting, the oily intermediate product was extracted with ether. Seed was obtained by cooling in alcohol to −78° and the product then crystallized from alcohol in bright yellow, rectangular tablets, m. p. 19.5–21° (previous sintering).

Anal. Calcd. for $(C_{16}H_{15}O_2)_x$: C, 80.31; H, 6.32. Found: C, 80.11; H, 6.30.

Further oxidation of 3.2 g. of the intermediate in 10 cc. of solvent was conducted with 1 g. of chromic anhydride at 60–90°, and the collected product (2 g.), being part liquid and part solid, was oxidized again as before, when an exothermic reaction was noted at 80–90°. The material recovered by ether extraction as a yellow oil crystallized readily from alcohol after obtaining seed and formed long, rectangular, bright yellow plates, m. p. 28–29.5°, identical with the sample described above.

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.65; H, 5.92. Found: C, 80.53; H, 6.02.

Summary

Details are given of observations summarized in two recent Communications. The chemical properties and absorption spectra of synthetic model compounds and the marked antihemorrhagic activity of at least one of these substances (2,3-dimethyl-1,4-naphthoquinone, assayed by the Almquist procedure) lends support to the formulation of vitamin K_1 as 2-methyl- (or ethyl)-3-phytyl-1,4-naphthoquinone and of vitamin K_2 as 2,3-difarnesyl-1,4-naphthoquinone.

A theoretical interpretation is given of the purple-blue color reaction of β-unsaturated alkyl naphthoquinones with sodium ethylate and it is shown that the reaction involves the replacement of the unsaturated side chain by hydroxyl. This accounts for the formation of a phthiocol-like pigment as the end-product of the color reaction with vitamin K concentrates, and the pigment probably is phthiocol or the ethyl homolog. The phthiocol isolated from human tubercle bacilli may have arisen from the alkaline cleavage of a K-type vitamin.

A Study of Some Derivatives of Phthalyl Urea

BY CLAYTON S. SMITH AND CHESTER J. CAVALLITO

Many types of derivatives of urea have been prepared, most of them in the search for compounds possessing hypnotic activity. A large number of substituted ureas possess some degree of hypnotic activity.[1] The most active hypnotics are found among the cyclic ureas, especially the ureides of substituted malonic acid.

The object of the present work was to synthesize derivatives of phthalyl urea, the cyclic ureide of phthalic acid, and to study them for hypnotic activity.

Phthalyl urea was first described by A. Piutti.[2] He prepared the compound by heating equimolecular quantities of phthalic anhydride and urea to 120–125°, forming first the intermediate acyclic ureide of phthalic acid, 
which when treated with phosphorus oxychloride yielded the closed ring structure.

In the present work, the general method of Piutti was used for the synthesis.

(2) A. Piutti, *Ann.*, **214**, 17 (1882); *Gazz. chim. ital.*, **12**, 169 (1882).

Experimental Procedure

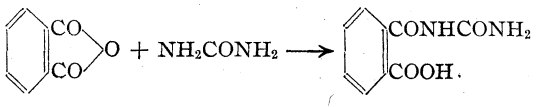
Preparation of Phthalyl Urea and Phthalyl Thiourea.—Equimolecular quantities of phthalic anhydride and urea were ground together in a mortar, then transferred to a round-bottomed flask. The mixture was heated at about 124° on a sulfuric acid bath until the reaction mixture became pasty and finally solidified to a hard mass. The melt should not be heated to such a temperature as to cause the evolution of gas bubbles. The product was pulverized, washed several times with cold water and ether, then recrystallized from hot water (about 35% yield).

Ring closure was brought about by treating the acyclic ureide with enough phosphorus oxychloride to form a thin paste and warming slowly on a water-bath. The reaction was considered complete when hydrogen chloride fumes were no longer liberated. Ether was then added to the reaction mixture, and the product filtered, washed with ether, and recrystallized from hot water.

Phthalyl urea decomposes at 185 to 190° leaving a residue which melts partly at about 230°, and completely above 300° with decomposition. Phthalimide and cyanuric acid $(CONH)_3$ are present as decomposition products.[2]

Phthalyl thiourea was prepared by the same general procedure as described above. The intermediate acyclic ureide did not form as rapidly in the case of thiourea as with urea.

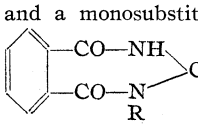
Attempts to prepare the cyclic ureides by treating phthalic anhydride and urea directly with phosphorus oxychloride were unsuccessful. It appears necessary first to bring about the combination



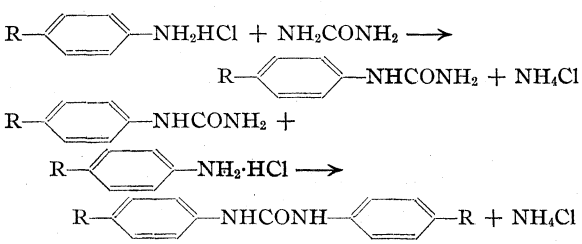
by fusing the two components.

Δ^2-Tetrahydrophthalyl Urea.—This compound was prepared from urea and Δ^2-tetrahydrophthalic anhydride. Tetrahydrophthalic acid was prepared by reducing phthalic acid with sodium amalgam in a strongly alkaline solution.[3] The acid was purified and treated with acetyl chloride to form the anhydride. Δ^2-Tetrahydrophthalic anhydride combined with the urea less readily than did phthalic anhydride, as measured by the time necessary for the fused mixture to solidify. Ring closure was brought about by treatment with phosphorus oxychloride as described above.

N-Substituted Phthalyl Ureas.—This type of derivative was prepared by starting with phthalic anhydride and a monosubstituted urea. Compounds of the type



were prepared, where R consisted of the following groups: methyl, allyl, phenyl, *o*-tolyl, *m*-tolyl, *p*-tolyl, *o*-phenetyl, *p*-phenetyl, *o*-anisyl, and *p*-anisyl. The aromatic substituted ureas used were prepared by heating an aqueous solution of urea with the corresponding aromatic amine hydrochloride.[4]

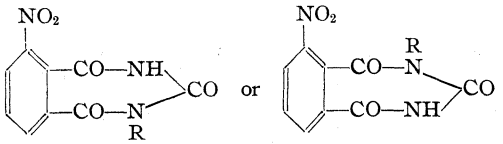


The monosubstituted urea formed by the above reaction in about 50% yield was separated from the disubstituted urea by solution of the former in hot water. The alkyl substituted ureas were purchased from the Eastman Kodak Company.

The monosubstituted ureas combined with phthalic anhydride more slowly than did urea. Attempts to combine phthalic anhydride with N,N^1-disubstituted ureas by the fusion method were unsuccessful. It may be that the high temperature necessary to fuse this mixture is above the decomposition temperature of the expected product.

Nitrophthalyl Ureas.—3-Nitrophthalyl urea and 4-nitrophthalyl urea were prepared from urea and the corresponding 3- and 4-nitrophthalic anhydrides. The nitro acids were prepared by direct nitration of phthalic anhydride[4] (p. 399),[3] (p. 828). The nitro anhydrides were prepared by treating the acids with acetic anhydride. 3-Nitrophthalyl derivatives of *p*-tolyl urea and of *p*-phenetyl urea were also prepared. The nitro anhydrides reacted with the ureas more rapidly upon fusion than did phthalic anhydride.

These last two compounds may possess either of two structures



It has not yet been determined whether both or just one of the above types are formed.

The compounds prepared are listed in Table I, together with some of their physical constants and properties. These compounds generally decompose before melting, and the decomposition points are not sharp. Phthalyl urea when heated slowly decomposes between 185–190° into phthalimide and cyanuric acid, and this mixture softens again at about 230°. If, however, the melting point is determined by lowering the temperature of the melting point apparatus from some high point, to the lowest point which will produce complete liquefaction of freshly added phthalyl urea, it will be found to melt at 207°. The melting points of the compounds were determined in this manner.

The derivatives of phthalyl urea are all relatively insoluble in cold water, but are more soluble in hot water or in hot alcohol. The solubility in hot water is greatly diminished with increase in the molecular weight of the compounds. The above phthalyl ureas are fairly soluble in alkali. This can be explained on the basis of enol formation. The alkali solubility of the nitro phthalyl ureas is greater than that of the phthalyl ureas without a nitro group.

With the exception of phthalyl allyl urea, the compounds prepared appear quite stable. The allyl derivative was observed to liberate formaldehyde in the presence of air and moisture at room temperatures, and its melting point also dropped about 10° in a few months. It is fairly stable in the absence of moisture.

The yields in the synthesis of these compounds are rather low. Practically all the loss of material takes place in the first step of the reaction. The ring closure takes place with little loss.

In order to purify some of the more insoluble substituted phthalyl ureas, several washings were made with water containing a few drops of ammonium hydroxide, and then with several portions of warm water. This procedure, when carried out after the ether washings, removed any phthalimide or non-cyclic acid ureide present.

Pharmacological Procedure

Preliminary tests for pharmacological activity of the phthalyl ureas were conducted on rats.

In order to facilitate rapid absorption of the compounds, it was decided to inject them by the intraperitoneal route. Since the *p*H necessary to dissolve the compounds in the concentrations desired was too high for animal administration, the compounds were pulverized to pass through a 100-mesh sieve, then suspended in an aqueous solution of glycerol and glucose (20 g. glucose, 20 g. glycerol per 100 cc. solution). About 2 cc. of fluid was injected into each rat, with the amount of compound to be tested in suspension. The glycerol–glucose solution alone produced a little irritation for about five minutes as evidenced by the behavior of the rat, but if the rat were killed the next day and examined, the internal organs appeared normal.

The pharmacological tests were made to determine whether the compounds possessed hypnotic activity, and to study the effect of various chemical groups upon the activity. For the sake of comparison, all the compounds were tested in doses of 500 mg. per kilogram body weight. It was observed that if the compounds possessed any activity it would be evident with this dose. Larger doses did not produce greater degrees of depression, and the absorption of larger quantities was not always complete. This was probably due to the limited solubility of these compounds. Most of the compounds did not produce complete anesthesia; therefore, some criterion for judging the degree of depression was necessary. It was observed that a rat deeply depressed but not completely anesthetized would remain on his back when so placed, and would not turn over ($^{++++}$ in Table II). A rat showing somewhat less depression would turn over if placed on his back but would remain lying on his side if so placed ($^{+++}$ in Table II). One still less depressed would not remain lying on his side but would not struggle if held in the hand in the inverted position ($^{++}$ in Table II). A normal rat (0 in Table II) or one but very slightly depressed ($^{+}$ in Table II) would struggle if held in this fashion. The above criteria merely served to compare the hypnotic activities of the compounds with one another. Table II shows the results obtained.

TABLE II

Phthalyl urea deriv.	Relative order of hypnotic activity
3-Nitro	+ + + +
N-*p*-Tolyl	+ + +
3-Nitro-, N-*p*-Tolyl	+ + +
N-*p*-Anisyl	+ +
N-*p*-Phenetyl	+ +

N-*o*-Anisyl	+
N-Phenyl	+
N-*o*-Tolyl	+
N-*o*-Phenetyl	+
N-Methyl	0
Δ^2-Tetrahydro	0
Phthalyl urea	0

The induction period for depression ranged from five to fifteen minutes, after which the effects of the more active compounds lasted for three to four hours.

Degrees of depression simulating natural sleep are very often observed in rats under the influence

of these compounds. Doses of 150–200 mg./kg. of the more active compounds induce sleep, from which, however, the animals may be aroused rather easily.

The compounds 4-nitrophthalyl urea, phthalyl allyl urea, and phthalyl thiourea are not included in the above table, as they are toxic with the doses required to produce depression. The minimum fatal dose for the 4-nitrophthalyl urea is between 100 and 250 mg./kg.; phthalyl allyl urea and phthalyl thiourea are fatal with a dose of about 500 mg./kg. The 3-nitrophthalyl urea is toxic with a dose of about 1000 mg./kg.

It may be observed from the above table that phthalyl urea itself is practically inactive as a hypnotic. The introduction of a nitro group in the 3-position of the aromatic nucleus increases the activity without increasing the toxicity, while a 4-nitro group increases the toxicity considerably. The introduction of a thio group in the urea molecule also increases toxicity. The partial hydrogenation of the aromatic nucleus has practically no effect in increasing hypnotic activity of phthalyl urea. The introduction of a methyl group on a nitrogen does not enhance the activity. However, if an allyl group is substituted, the activity increases. A phenyl group on the nitrogen produces greater activity than does a methyl, but less than does the allyl. A *p*-tolyl group on a nitrogen increases the activity almost as much as does the allyl group, and the former is much less toxic. If a *p*-phenetyl or *p*-anisyl group is introduced on a nitrogen, the activity is increased but not as much as by the *p*-tolyl group. The ortho compounds and the meta tolyl derivative are relatively inert.

Since 3-nitrophthalyl urea and phthalyl *p*-tolyl urea were found to produce the greatest depression, together with the least toxicity, the compound 3-nitro phthalyl *p*-tolyl urea was prepared. It proved to be, if anything, slightly less active than the phthalyl *p*-tolyl urea. 3-Nitrophthalyl *p*-phenetyl urea was also prepared and found to differ little in activity from phthalyl *p*-phenetyl urea. If chemical structure were the only deciding factor in hypnotic activity, the nitro substituted phthalyl *p*-tolyl and *p*-phenetyl ureas should be very much more active. This apparently is not the case.

Summary and Conclusions

The synthesis and properties of a series of seventeen phthalyl urea derivatives have been described.

The hypnotic activity of the compounds was tested on rats by intraperitoneal injections of suspensions of the compounds in an aqueous solution of glucose and glycerol. The derivatives of phthalyl urea prepared do not appear to be very active as hypnotics. This is of theoretical interest, since several other types of cyclic ureides such as the barbiturates are quite active as hypnotics. The low solubility of the phthalyl ureas may be a limiting factor preventing the compounds from reaching their site of action in effective concentrations.

The combination in a molecule of two groups, each of which separately increases activity, does not necessarily lead to a compound more potent than one with either of the active groups alone, as in the case of 3-nitrophthalyl urea, phthalyl *p*-tolyl urea, and 3-nitrophthalyl *p*-tolyl urea.

Arrangement of Substituents in Cellulose Derivatives[1]

BY H. M. SPURLIN

In the course of our consideration of published work and our own results on cellulose derivatives, members of our organization frequently have had occasion to take account of the method of arrangement of the substituents on partially substituted cellulose derivatives. In order to visualize as well as possible the differences that might exist between cellulose derivatives in which the manner of arrangement of the substituents is determined by different influences, several series of calculations have been carried out and the results plotted. While there is nothing original in the considerations on which these calculations were made, they are contributed in order to save others working on the same subject the labor involved, and possibly to bring to the attention of those who have not given the matter much thought the rather interesting conclusions that may be drawn from this study.

The necessity for considering cellulose as having large units of structure in which the substituents are distributed among the available positions according to the laws of chance seems to have been brought out first by Cross and Bevan.[2] Since that time, this conception of a statistical distribution seems to have been before most cellulose investigators at all times. However, a quantitative treatment of the subject was not possible until Denham and Woodhouse's[3] demonstration that substitution on cellulose occurs only on the 2,3- and 6-positions of the glucose units of which cellulose is composed (Fig. 1). This treatment does not seem to have been made, although Thiersch[4] has shown the behavior of the somewhat similar case of coupled reactions.

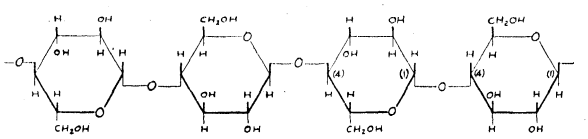

Fig. 1.—Theoretical configuration of a portion of a cellulose molecule.

(4) Fr. Thiersch, *Z. physik. Chem.*, **111**, 175 (1924).

Basis of the Calculations.—Before beginning the calculations, it is necessary to decide what simplifying assumptions may be made. To begin with, cellulose is considered as a chain of glucose units sufficiently long for the end-groups to be neglected. Other disturbances in the structure, such as partial oxidation of some of the glucose units, may be neglected or may be considered as a form of substitution.

The most important assumption that we make is that the ratio of the reactivities of the three sorts of hydroxyl groups is independent of the degree of substitution of the cellulose chain as a whole or of the state of substitution of neighbor hydroxyls. Of these two influences, we may surmise that the degree of substitution of the chain as a whole will influence more the solubility of the chain, and thereby its rate of reaction, than it will influence the ratios of the reactivities of its hydroxyls. Of course, we know that the influence of substitution on the absolute value of the rate of reaction may be very large. Lorand[5] has shown that this is the case with etherification in the presence of dilute alkali. It must, therefore, be emphasized that all that is assumed in the present work is that the rates of reaction of the three sorts of hydroxyls maintain the same ratios of reactivity constants (*i. e.*, equilibrium constants and reaction rate constants) to one another throughout the course of the reaction, however much the reactivity as a whole may vary.

It is not possible to justify on the basis of any quantitative data the assumption that the substitution of one hydroxyl, in, say, the 2-position, will not influence the reactivity of its neighbor, in the 3-position. However, from what is known of action at a distance in a molecule, it appears that so long as neither group bears an electric charge there will be little influence of the 2- and 3-hydroxyls on one another (they are *trans* to one another). There should be no interaction between the secondary and the primary hydroxyls.

Briefly, then, what has been done is as follows. A certain reactivity has been assigned to each sort of hydroxyl, the fraction of each sort that has reacted calculated for a given degree of substitution,

(5) E. J. Lorand, *Ind. Eng. Chem.*, **31**, 891 (1939).

and the probability that two hydroxyls on the same glucose unit are substituted is set equal to the product of the reacted fractions of those two hydroxyls. In the same manner, the fraction of the glucose units that contains all three hydroxyls in the substituted state is equal to the product of the fractions reacted of the three individual hydroxyls. Obviously, the fraction reacted in the 2- and 3-positions only is equal to the total fraction with substituents on the 2- and 3-positions minus the 2,3,6-trisubstituted fraction. In the same manner, the fraction substituted only in the 2-position is obtained by subtracting the 2,3-, the 2,6- and the 2,3,6-portions from the fraction that contains substituents in the 2-position. Analogous methods are used for the other possible manners of reaction.

Extent of Reaction Governed by an Equilibrium.—The following symbols will be employed in the general discussion: x_2, x_3, x_6 are the fractions of the glucose units that contain substituents in the 2, 3 and 6 positions, respectively; s_2, s_3 and s_6, the fractions with substituents *only* in the positions named. In the same manner, $s_{2,6}$ indicates the fraction of the glucose units containing substituents only in the two and six positions. To indicate the fraction of the glucose units that are unsubstituted, c_0 is employed; monosubstituted, c_1; disubstituted, c_2; trisubstituted, c_3. The average number of substituents per glucose unit, S, is obviously equal to the sum of x_2, x_3 and x_6.

If the extent of the reaction is determined by an equilibrium between some substituting medium and the hydroxyl groups, as in nitration, we may write (considering only reaction of one of the hydroxyls, say that in the 2-position, while those in the 3- and 6-position may or may not be reacting at the same time)

$$C_6H_{10}O_5 + RX \rightleftarrows C_6H_9O_5R + HX$$

$$\frac{(C_6H_9O_5R)}{(C_6H_{10}O_5)} = \frac{(RX)}{(HX)} K$$

or

$$x_2/(1 - x_2) = AK_2;\ x_2 = AK_2/(1 + AK_2)$$

Similarly

$$x_3 = AK_3/(1 + AK_3) \qquad (1)$$
$$x_6 = AK_6/(1 + AK_6)$$

A is a constant denoting the substituting power of the reaction mixture, while K_2, K_3 and K_6 are the equilibrium constants for the substitution reactions of the three sorts of hydroxyls

$$c_3 = s_{2,3,6} = x_2x_3x_6 = \frac{A^3K_2K_3K_6}{(1 + AK_2)(1 + AK_3)(1 + AK_6)} = \frac{A^3K_2K_3K_6}{D} \qquad (2)$$

setting D equal to the denominator of the above expression. Also

$$s_{2,3} = x_2 \cdot x_3 - s_{2,3,6} = A^2K_2K_3/D$$
$$s_{2,6} = A^2K_2K_6/D \qquad (3)$$
$$s_{3,6} = A^2K_3K_6/D$$

$$s_2 = x_2 - s_{2,3} - s_{2,6} - s_{2,3,6} = AK_2/D$$
$$s_3 = AK_3/D \qquad (4)$$
$$s_6 = AK_6/D$$

Collecting the equations for the fractions of unsubstituted, mono-, di- and trisubstituted glucose, we have

$$c_0 = 1 - s_2 - s_3 - s_6 - s_{2,3} - s_{2,6} - s_{3,6} - s_{2,3,6} = 1/D \qquad (5)$$

$$c_1 = A(K_2 + K_3 + K_6)/D \qquad (6)$$

$$c_2 = A^2(K_2K_3 + K_2K_6 + K_3K_6)/D \qquad (7)$$

$$c_3 = A^3K_2K_3K_6/D \qquad (2)$$

The substitution S, equal to $x_2 + x_3 + x_6$, is calculated most easily from the relationship

$$S = 3 - 3c_0 - 2c_1 - c_2 \qquad (8)$$

Extent of Substitution Governed by Rates of Reaction.—Many reactions of cellulose, and in particular acylation with an acid anhydride and etherification, are characterized by the fact that they do not stop until complete substitution is reached, the reagent is exhausted, or the reaction is interrupted; there is no back reaction.

For these types of reactions, if the concentration of reagents in the reaction medium were kept constant, the rate of disappearance of the three hydroxyls would be given by an equation of the type

$$dx_2/dt = k_2'(1 - x_2)$$
$$x_2 = 1 - e^{-k_2't} \qquad (9)$$

We are not restricting ourselves to the case where the rates remain constant. However, if the rates of the three reactions retain a constant ratio to one another at all times, the ratios of the substituted fractions will bear the same ratio to one another as if the above equation had been followed. In order to avoid confusion, the exponent in equation (9) has been changed from $-k_2't$ to $-Bk_2$, and we have (k_2 and k_2' are reaction rate constants

$$x_2 = 1 - e^{-Bk_2},\ x_3 = 1 - e^{-Bk_3},\ x_6 = 1 - e^{-Bk_6} \qquad (10)$$

$$c_3 = s_{2,3,6} = (1 - e^{-Bk_2})(1 - e^{-Bk_3})(1 - e^{-Bk_6}) \qquad (11A)$$

$$s_{2,3} = (1 - e^{-Bk_2})(1 - e^{-Bk_3})\, e^{-Bk_6}$$
$$s_{2,6} = (1 - e^{-Bk_2})(1 - e^{-Bk_6})\, e^{-Bk_3}$$
$$s_{3,6} = (1 - e^{-Bk_3})(1 - e^{-Bk_6})\, e^{-Bk_2} \qquad (12)$$

$$s_2 = (1 - e^{-Bk_2})e^{-B(k_3 + k_6)}$$
$$s_3 = (1 - e^{-Bk_3})e^{-B(k_2 + k_6)}$$
$$s_6 = (1 - e^{-Bk_6})e^{-B(k_2 + k_3)} \qquad (13)$$

$$c_0 = e^{-B(k_2 + k_3 + k_6)} \qquad (14)$$

$$S = 3 - e^{-Bk_2} - e^{-Bk_3} - e^{-Bk_6} \qquad (15)$$

Grouping the equations for the fraction of the glucose units that are unsubstituted, mono-, di- and trisubstituted, and putting in a form suitable for easy calculation from a table of exponentials, we have

$$c_0 = e^{-B(k_2+k_3+k_6)} \quad (14)$$

$$c_1 = e^{-B(k_2+k_3)} + e^{-B(k_2+k_6)} + e^{-B(k_3+k_6)} - 3e^{-B(k_2+k_3+k_6)} \quad (16)$$

$$c_2 = e^{-Bk_2} + e^{-Bk_3} + e^{-Bk_6} - 2e^{-B(k_2+k_3)} - 2e^{-B(k_2+k_6)} - 2e^{-B(k_3+k_6)} + 3e^{-B(k_2+k_3+k_6)} + e^{-B(k_2+k_6)} \quad (17)$$

$$c_3 = 1 - e^{Bk_2} - e^{Bk_3} - e^{-Bk_6} + e^{-B(k_2+k_3)} + e^{-B(k_3+k_6)} - e^{-B(k_2+k_3+k_6)} \quad (11B)$$

Choice of Constants in the Equations.—In order to plot the above equations, it is necessary to assume ratios of $k_2:k_3:k_6$ or $K_2:K_3:K_6$, and calculate corresponding values of S and the other quantities for a sufficient number of values of A or B to determine the course of the curves. An explicit solution of the c's and s's in terms of S is very difficult in the general case. It will be noted that these curves will not depend on the absolute value of the K's and k's but only on their ratios.

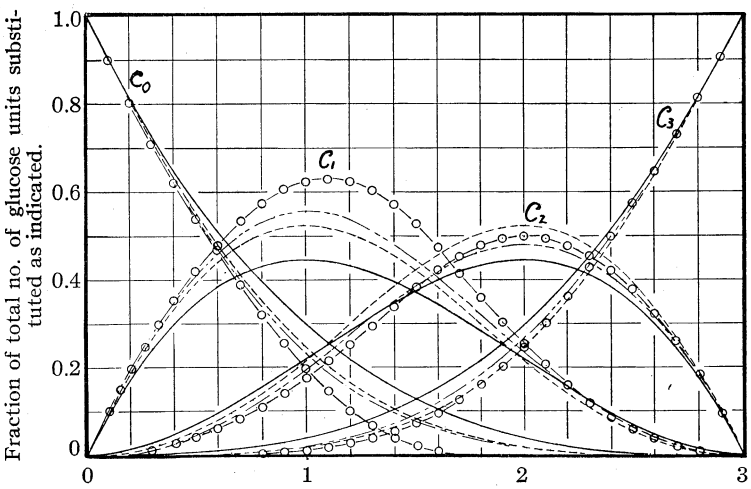

Fig. 2.

The equilibrium controlled condition will be realized only in the case of addition compounds and esters of cellulose. The data of Hatch and Adkins[6] indicate that there is little difference in the esterification equilibria for primary and secondary hydroxyls. Lieser[7] has abandoned his contention[8] that cellulose xanthogenate is exclusively substituted in the 2-position. From all that we know, it appears likely that the primary hydroxyl has an esterification equilibrium constant less than twice that of the secondary hydroxyls, and we might assume $K_2:K_3:K_6 = 1:1:2$. However, the curves so obtained would not depart noticeably from those with a ratio of 1:1:1, if the content of unsubstituted, mono-, di- and trisubstituted glucose units were plotted against the average substitution, in the manner of Fig. 2. Therefore, curves have been plotted with ratios of the constants of 1:1:1, 1:4:16 and 1:1:10 (Fig. 2). Curves for s_2, $s_{2,3}$, etc., have not been plotted, as these quantities always bear a constant ratio to c_1 and c_2, easily derivable from Equations (3) and (4). For example

$$\frac{s_2}{c_1} = \frac{K_2}{K_2 + K_3 + K_6} \quad (18)$$

$$\frac{s_{2,3}}{c_2} = \frac{K_2K_3}{K_2K_3 + K_2K_6 + K_3K_6} \quad (19)$$

While this relationship shows that the disubstituted glucose unit derived from the two hydroxyls with the smallest constants is present in relatively small quantity, it will always hold its own. This is not the case with the rate controlled distribution, as will be shown later.

Curves.—The curves of Fig. 2 show that, within the usual limits of error in working with such substances, the amounts of unsubstituted, mono-, di- and trisubstituted glucose units will be the same for the three sets of ratios of constants for the equilibrium controlled case. Detection of differences of reactivity of the three hydroxyls will always be possible if it is possible to determine the ratios of the three possible mono- or disubstituted glucose units to one another. For this purpose, it is recommended that attention be directed to products of either very low or very high substitution in order to avoid the difficulties of separating mono- and disubstituted glucoses from one another.

In the case of the rate controlled substitution, we have even fewer data for estimating the ratios of the constants. A survey of the data in Landolt–Börnstein leads to the conclusion that esterification reactions of primary alcohols proceed at about ten times the rate of esterification of sec-

ondary alcohols. Some old data on etherification[9] indicate even slighter differences. Not too much confidence can be given the application of these results to carbohydrates, but a rate ratio of 1:1:10 has been selected as a probable limit, with a ratio of 1:1:1 as the other limit. The curves in the latter case are identical with the similar curves for the equilibrium controlled substitution. The fourth set of curves of Fig. 2 gives the distribution of mono-, di-, tri-, and unsubstituted glucose units for the ratio of rate constants 1:1:10. These curves are much less symmetrical than in the case of the equilibrium curves. However, all four sets of curves are so close together that careful experimental work would be required to distinguish between actual cases with the constants used for these curves.

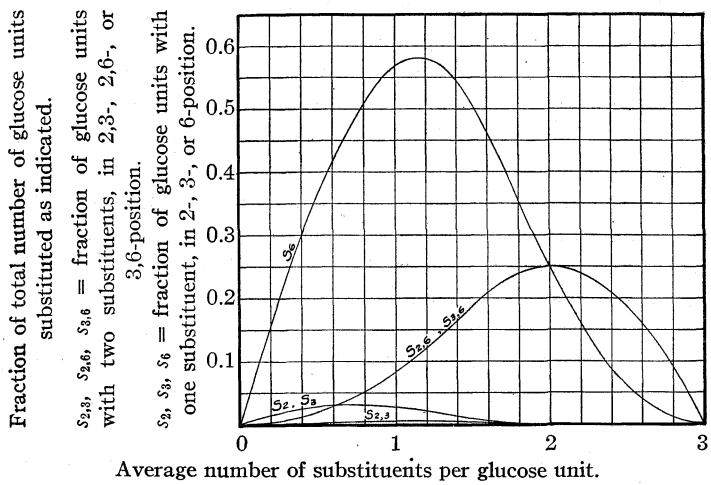

Fig. 3.—Proportions of the six different mono- or disubstituted glucoses, if the nature of substitution is determined by rates of reaction of the three hydroxyls in the ratio 1:1:10.

Again, as in the case of the equilibrium curves, an examination of the proportions of the individual monosubstituted or disubstituted glucose units gives us much more information. As no simple ratio exists between these, they have been plotted for the case $k_2:k_3:k_6$ = 1:1:10 in Fig. 3. It is evident that with this ratio of constants, practically all of the groups that are substituted at all are substituted in the 6-position after the early stages of the reaction. Conversely, if examination of a cellulose derivative of substitution above 2, whose degree of substitution is governed by the reaction time, shows that more than one sort of monosubstituted glucose is present, it is obvious that the two highest reaction rate constants must be close to one another. In order to form an idea of the relative size of the two smallest constants, the relative amounts of the three monosubstituted glucoses at the beginning of the reaction or of the two disubstituted glucoses chiefly present at some intermediate stage would have to be determined.

As the recent data of Heddle and Percival[9a] on the monomethyl glucoses from a methyl cellulose of substitution 0.5–0.6 indicate that the 2- and 3-positions are much more readily methylated than position 6, and are approximately equal in reactivity, the curves for a ratio of reaction rate constants of 1:10:10 were plotted (Fig. 4). It is evident that the proportions of mono-, di- and unsubstituted glucose for substitutions less than 1.2 are similar to those for the types of reaction plotted in Fig. 2. In this case, as well as in those previously considered, mere determination of the amount of unsubsti-

tuted and mono- and disubstituted glucose in a derivative of substitution less than one will not give any information about the relative reactivity of the three hydroxyls. Only determination of the relative percentages of the three monosubstituted glucoses, as attempted by Heddle and Percival, will give this information.[10]

It may be a surprise to some to note that a monosubstituted cellulose derivative may contain less than 45% of monosubstituted glucose units and still be perfectly uniform, in the sense that each cellulose molecule has the same degree of substitution.

Variation of Substitution with Time.—As pointed out above, the constant B in the equations for the rate controlled substitution is of the nature of a time. In order to enable a picture of the relative times required for a given degree of reaction when the constants have differing ratios, Table I is given.

TABLE I

Substitution, S	Relative time, B: $k_2:k_3:k_6$ = 1:1:1	$k_2:k_3:k_6$ = 1:1:10	$k_2:k_3:k_6$ = 1:10:10
0.1	0.034	0.010	...
.5	.18	.050	0.027
1.0	.40	.14	.064
1.5	.69	.34	.12
2.0	1.1	.69	.23
2.5	1.8	1.4	.70
2.7	2.3	1.9	1.25
2.8	2.7	2.3	1.7
2.9	3.4	3.0	2.4

The time for reaching a high degree of substitution depends mainly on the rate of reaction of the slowest hydroxyl. It will be noted from Table I that the time required to reach a substitution of 2.5 is from four to ten times the time required to reach a substitution of 1.0, even if the concentration of reagents remains constant. The rate of etherification of cellulose seems to be some high power of the concentration of alkali, which of course drops during the reaction if it is not replenished. It is evident from this why so many investigators have had difficulty in reaching a high degree of substitution on etherification. Actually this is not difficult if the alkali concentration is kept high.

Comparison with the Literature.—A few papers have appeared bearing on the distribution of substituents in cellulose. Of these, the most informative are those of Compton,[11] Traube, Piwonka and Funk[12] and Schenck.[13] In Compton's paper, the yield of unsubstituted glucose from an apparently very uniform methyl cellulose with an average substitution of about 0.9 was given as 30–35%. The highest curve of Fig. 2 indicates 34%, the lowest 25%, for this substitution. From the other data in Compton's article, it would appear that the contents of mono-, di- and trisubstituted glucose were substantially as indicated in Fig. 2 or 4. It is evident that these data are in agreement with the calculations for a statistical grouping of the substituents and a low ratio of the reactivities of the most and the least reactive hydroxyl group.

Traube and his co-workers[12,13] have attempted to calculate the content of mono-, di- and trisubstituted glucose from the alkoxyl content of fractions obtained on distilling the hydrolysis products of partially alkylated cellulose. This is, of course, only justified if very good fractionation is obtained. As there is no evidence that any sort of a column was used, it appears doubtful that this separation was very good. The results reported therefore possess only qualitative value. They are sufficiently extensive, however, to justify discussion of the point whether the copper present in the reaction mixtures exerted a directive influence on the position of substitution.

The first section of Table II gives the results of Traube, Piwonka and Funk on methyl celluloses. The first four samples represent materials obtained by methylating alkaline copper complexes of cellulose, the fifth sample is a commercial methyl cellulose, and the sixth is a remethylated sample. The second section of the table gives calculated results for equal reactivities of the hydroxyls, while the third section gives the calculated results if one hydroxyl has ten times the reactivity of the other two. Table III is arranged similarly and based on Schenck's values for ethyl cellulose.[13]

It is apparent that the experimental results in Table II, third, fourth and sixth columns, are close checks of the calculated values for ratios of 1:1:10 for the reactivities of the hydroxyls. The values in the first two columns show a higher content of monosubstituted glucose than calculated. This indicates that under the conditions of these

(10) Destruction of the 6-monosubstituted glucose units of the cellulose by selective oxidation at the 2,3-position with periodic acid or lead tetraacetate should be a powerful tool for detecting the presence of other modes of monosubstitution in a highly substituted product.

experiments, the reactivity of one of the hydroxyls was more than ten times that of the next most reactive hydroxyl. These five samples were all made in the presence of copper oxide. The sample in column five, with 1.44 substitution, had a manner of substitution closer to the calculated values for reactivity ratios 1:1:1. This sample, therefore, does not show the same tendency for one hydroxyl to be more reactive than the others. This is undoubtedly connected with the fact that a sodium–copper derivative was not used in the preparation of Sample 5. It appears from the data of Table II that Traube and his co-workers are justified in their belief that the sodium–copper complex of cellulose is especially reactive in one of the three positions. However, examination of the data of Table III throws doubt on this conclusion, as all three of the reported results fall fairly near the calculated values for equal reactivities of the three hydroxyls.

There is no evidence to indicate that any of the products made from sodium–copper cellulose is composed of a mixture of higher and lower substitution products. However, it is interesting to observe that the composition of the product of substitution 1.44 (Table II) may be calculated fairly exactly if a mixture of products of substitution 1.2 to 1.6 is assumed, with the 2- and 3-positions about twice as reactive as position 6.

Sakurada[14] and Shorygin[15] have attempted to determine the ratio of primary to total free hydroxyls in cellulose acetates of substitution 2.3, with substantial agreement that this ratio is about 0.3. Secondary cellulose acetate probably occupies an intermediate position between the rate controlled and the equilibrium controlled distributions considered in this paper. This would lead us to believe that in the hydrolysis reaction leading to secondary acetate, the three hydroxyls are losing their acetate at very nearly the same rates.

The work of Piwonka[16] would tend to indicate that in his special conditions the 3-hydroxyl reacts preferentially. The work of Heddle and Percival[9a] indicates that both 2 and 3 hydroxyls react under these conditions, but that the 6 position does not react.

Conclusions

The available experimental evidence is entirely in harmony with the viewpoint developed in this paper: namely, that the substituents in a cellulose derivative are distributed among the hydroxyls according to the laws of chance, and the three sorts of hydroxyls are substituted to an extent relative to one another that is determined by the relative reactivities of the hydroxyls (determined by their inherent properties as well as by the reaction medium) and the nature of the reaction (proceeding to an equilibrium at a partially substituted state, or with a tendency to proceed to complete substitution, but stopped at a partially substituted state).

The Adsorption of *cis*- and *trans*-Azobenzene

BY HERBERT FREUNDLICH AND WILFRIED HELLER

G. Spencer Hartley[1] has shown that commercial azobenzene mainly consisting of the *trans* isomer can be converted partly into the *cis* isomer, when exposed to daylight in dilute solution. He succeeded in separating the two isomers and in preparing them in a pure form. A. H. Cook[2] and L. Zechmeister[3] found that separation could be effected by adsorption, using the chromatographic method (aluminum oxide as adsorbent, petroleum ether as solvent); *cis*-azobenzene was adsorbed more strongly than the *trans* isomer.

The stronger adsorption of the *cis* compound on aluminum oxide as it is emphasized in the latter papers might lead to the presumption that *cis* isomers generally are adsorbed more strongly than *trans* isomers. Freundlich and Schikorr[4] have found, however, that maleic acid, a *cis* compound, is adsorbed far less than the *trans* isomer, fumaric acid, in aqueous solution on charcoal. This seems to indicate that it depends on the affinity of the solute to the adsorbent and to the molecules of the solvent, whether the *cis* or the *trans* isomer is adsorbed more strongly. Taking water as a standard, as it were, one could say that the more hydrophilic or more hydrophobic nature of the adsorbent (case 1) and of the solvent (case 2) are decisive for the difference in adsorbabilities of the solutes in question. That influences of this kind have to be taken into account is shown most clearly by the adsorption of methyl violet by charcoal or silica gel in water and tetralin, respectively, investigated by E. Berl and E. Wachendorff.[5] Dissolved in "hydrophobic" tetralin, methyl violet is adsorbed more strongly by the hydrophilic silica gel; in an aqueous solution, on the contrary, by the hydrophobic charcoal. Here we are dealing with case 2. From the outset, case 1 appears to be just as likely. In any case, the strongest contrast to the behavior of aluminum oxide in petroleum ether was to be expected with a hydrophobic adsorbent like charcoal and a hydrophilic solvent.

We prepared *cis*-azobenzene by somewhat modifying Hartley's method. We avoided vacuum distillation and the tedious fractionating by crystallization; instead of that, we separated the two isomers by the differences in their solubilities in water and purified the *cis* compound by crystallization from petroleum ether at low temperatures (−15 to −35°). The m. p. of our crystals was 71.7°, determined by quick plunging; Hartley's value is 71.4°, Cook's 71°.

trans-Azobenzene was prepared following Hartley's method.

Methyl alcohol was chosen as hydrophilic medium, petroleum ether as the hydrophobic one; aluminum oxide was the hydrophilic adsorbent, charcoal (Norit) the hydrophobic one. The adsorption experiments were done at 20°. Five cc. of solution was shaken with different amounts of adsorbent for a few minutes, until the final state of adsorption was reached. The adsorbent was then separated from the solution by centrifuging; this lasted five to ten minutes in solutions of petroleum ether (b. p. 55 to 65°), fifteen to twenty minutes with methyl alcohol. We started with a 0.5% solution and reached different final concentrations by varying the amount of adsorbent. This procedure may lead to irregularities in adsorption, when small amounts of adsorbent (below 0.1 g.) are used (this refers to two measurements at higher concentrations of the *trans* isomer not taken into account in Fig. 2; *cf.* also H. Morawitz[6]).

The concentration after adsorption was determined with a colorimeter, using standard solutions of the same isomer as comparison. In the experiments with the *cis* isomer both standard solutions and those used for adsorption were freshly prepared every thirty minutes. Light-filters were used. A small amount of adsorbent, remaining in suspension, then became noticeable by a change in absorption, when passing from blue to red, namely, by requiring different values of the layer thickness for which equality of the half-shades was observed. Samples behaving in this way were rejected.

All operations were carried out in the dark or in indirect red light. The light intensity of the

(6) H. Morawitz, *Kolloid-Beihefte*, **1**, 301 (1910).

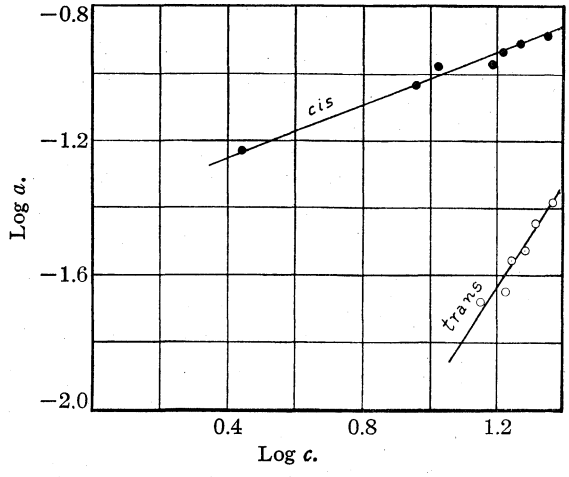

Fig. 1.—Adsorption of *cis*- and *trans*-azobenzene by aluminum oxide in petroleum ether: c in millimoles per liter, a in millimoles per 1 g. of adsorbent.

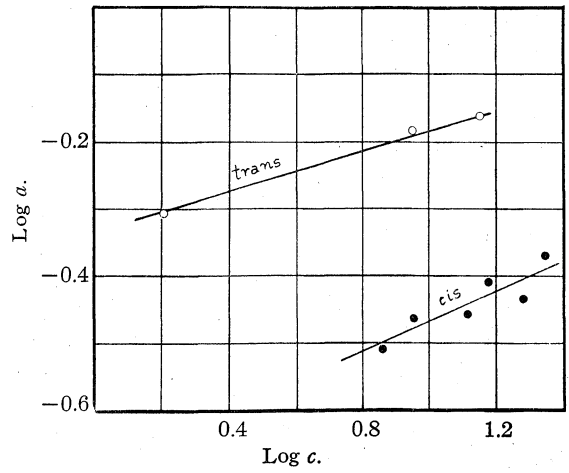

Fig. 2.—Adsorption of *cis*- and *trans*-azobenzene by charcoal in methyl alcohol: c in millimoles per liter, a in millimoles per 1 g. of adsorbent.

colorimeter was kept weak enough to prevent a noticeable *cis–trans* transformation during two minutes of illumination; the actual illumination lasted 8 times five seconds during one experiment.

The results obtained with aluminum oxide in petroleum ether and with charcoal in methyl alcohol are given in Figs. 1 and 2. c is the equilibrium concentration in millimoles per liter, a is the amount adsorbed in millimoles per 1 g. of adsorbent. The adsorption isotherms are represented in a logarithmic diagram showing that the empirical equation $a = \alpha c^{1/n}$ holds fairly well. In the case of the weak adsorption of the *trans* isomer by aluminum oxide in petroleum ether $1/n$ is practically about 1; in the other cases it lies between 0.30 and 0.45, *i. e.*, it agrees with the values generally found.

In agreement with Cook's chromatographic experiments, Fig. 1 proves that the *cis* isomer is adsorbed much more strongly than the *trans* isomer by aluminum oxide in petroleum ether. In agreement with our expectations, the behavior is reversed with charcoal as adsorbent in methyl alcohol (*cf.* Fig. 2). On comparing the values of a for an equilibrium concentration of 10 millimoles per liter, we find

a (*cis;* aluminum oxide, petroleum ether) = 0.093
a (*trans;* aluminum oxide, petroleum ether) = 0.012
a (*cis;* charcoal, methyl alcohol) = 0.34
a (*trans;* charcoal, methyl alcohol) = 0.65

Some adsorption experiments were done with aluminum oxide in methyl alcohol and with charcoal in petroleum ether. As was to be expected, the difference in the behavior of the azobenzene isomers was somewhat less pronounced. Again comparing the a-values for an equilibrium concentration of 10 millimoles per liter, we found

a (*cis;* aluminum oxide, methyl alcohol) about 0.004
a (*trans;* aluminum oxide, methyl alcohol) about 0.002
a (*cis;* charcoal, petroleum ether) = 0.43
a (*trans;* charcoal, petroleum ether) = 0.58

It was always observed that $1/n$ was larger for the solute which is adsorbed less, independent of the nature of the solvent; this is seen from the two figures and it was also very marked in the adsorption by charcoal in petroleum ether. At higher concentrations the lines of the adsorption isotherms (in the logarithmic diagram) would intersect, provided that the whole behavior is not changed by the occurrence of saturation.

In our experiments the influence of the more hydrophilic or more hydrophobic nature of the adsorbent prevails (case 1), the succession of the adsorbents is the same in both media, in contrast to the experiments with methyl violet, mentioned above. But there is also in our case an influence of the solvents in the same direction, as is shown when the differences in the amounts adsorbed are compared.

Adsorption experiments with another hydrophilic adsorbent, namely, powdered silica gel, again showed that *cis*-azobenzene is more strongly adsorbed in petroleum ether than the *trans* isomer. The difference is markedly smaller than with aluminum oxide.

Our results agree with the fact, mentioned above, that fumaric acid, the *trans* isomer, is adsorbed more strongly than maleic acid by char-

coal in water; for an equilibrium concentration of 10 millimoles per liter we have (Freundlich and Schikorr): a (maleic acid) = 0.992; a (fumaric acid) = 1.56.

The more hydrophilic nature of *cis*-azobenzene compared with the *trans* compound also is indicated in the differences of solubilities. According to Hartley the solubility (at 25°) of the *cis* isomer in water is 0.65 millimole per liter, that of the *trans* isomer 0.02 millimole per liter in petroleum ether (b. p. 40 to 60°); on the other hand, the *cis* isomer is less soluble (at 0°), 49.4 millimoles per liter, compared to a value of 192 for the *trans* isomer. We determined colorimetrically the solubilities in methyl alcohol at 0° and found a succession as in water: 410 millimoles per liter for *cis*-azobenzene, 164 for the *trans* isomer.

It is quite probable that the *cis* isomers are generally more hydrophilic than the *trans* isomers. Perhaps it is due to a *cis–trans* difference in structure that maltose is more hydrophilic than cellobiose—as it appears to be—and accordingly starch so much more hydrophilic than cellulose.

Summary

The adsorptions of pure *cis*- and *trans*-azobenzene by aluminum oxide and by charcoal in solutions of petroleum ether and of methyl alcohol were measured and compared. The *cis* isomer is adsorbed more strongly by aluminum oxide, particularly in petroleum ether, less in methyl alcohol; the *trans* isomer is adsorbed more strongly by charcoal, particularly in methyl alcohol, less in petroleum ether. This is in agreement with other experimental results, according to which the more hydrophilic solute, here the *cis* isomer, is adsorbed more strongly by a hydrophilic adsorbent, here aluminum oxide, in a more hydrophobic medium, here petroleum ether, than by a more hydrophobic adsorbent, here charcoal, in a more hydrophilic medium, here methyl alcohol.

That *cis*-azobenzene is more hydrophilic than *trans*-azobenzene is also shown by the *cis* isomer being more strongly soluble in water and methyl alcohol and less soluble in petroleum ether than the *trans* isomer.

Homogeneous Catalytic Hydrogenation

BY M. CALVIN

Last year it was announced[1] that quinone in quinoline solution could be hydrogenated using dissolved cuprous acetate as homogeneous catalyst. This is a report of further study of the kinetics of this reaction in the attempt to discover precisely what structure has this important property of bringing the highly inert hydrogen molecule into reaction.

Experimental

The apparatus was essentially the same as already has been mentioned,[1] and the experiments consisted of following the rate at which hydrogen was absorbed by a given solution varying the conditions of concentration, solvent, temperature, and reactants. The detail of the reaction vessel is shown in Fig. 1. The internal condenser was removed and weighed amounts of the catalyst and substrate introduced. The vessel was then mounted in the shaker and connected to the vacuum system through the ground joint J. The solvent was run in from a pipet and the condenser quickly replaced and the tap to the vacuum system opened. But before the air could be removed some oxidation had taken place, so that blank runs without substrate were made on a given catalyst to determine the correction to be applied to the amount of hydrogen absorbed. The heating was then commenced and pumping was continued until the McLeod gage at the other end of the system showed a pressure of 10^{-4} mm. or less. This degassing sometimes took as long as thirty minutes after the thermostating liquid had reached its boiling point. For runs at 100° water was used and for 117.7° *n*-butyl alcohol was used as thermostating liquid. In all the runs the shaker speed was about 325 vibrations per minute. In the course of one run the shaker speed was increased to 530 vibrations per minute for a time and then decreased to 325 again and no appreciable break in the rate curve was observed, showing that the rate of solution of the gas was sufficiently fast not to be a disturbing factor.

Materials

Quinoline.—Eastman Kodak Co. synthetic quinoline was purified by (1) initial fractionation at atmospheric pressure to within 1°, (2) treatment with benzoyl chloride for several days and then washed with sodium hydroxide solutions followed by distilled water, (3) fractionation at atmospheric pressure to remove water, (4) final fractionation in a 1-foot (30-cm.) Widmer column at 50–60 mm. pressure. The quinoline so obtained remains water white for months when kept in a glass-stoppered uncolored glass bottle.

(1) M. Calvin, *Trans. Faraday Soc.*, **34**, 1181 (1938).

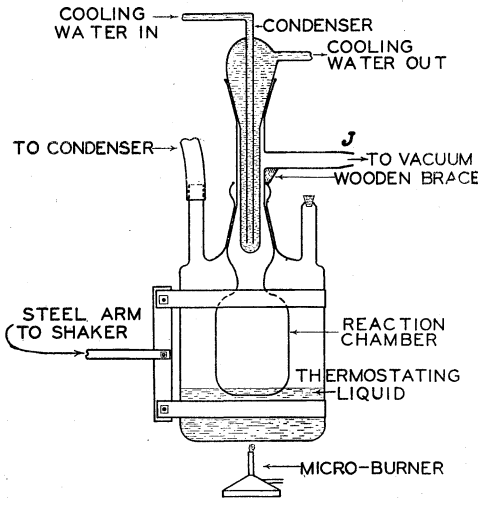

Fig. 1.

Quinone.—Eastman Kodak Co. quinone was purified by high vacuum sublimation and alternatively by recrystallization from alcohol. The two products gave the same results.

Cuprous Acetate.—Cuprous oxide (Baker) was extracted with glacial acetic acid containing 2–5% acetic anhydride, in a stream of hydrogen. The white cuprous acetate crystallized out and was filtered rapidly and washed with dry ether. The white cuprous acetate must be kept in a vacuum desiccator since moisture will hydrolyze it and oxygen oxidize it appreciably in as short a time as twenty-four hours. It was very difficult to prepare large quantities (10 g.) of absolutely pure cuprous acetate. It always contained some cupric salt. But since the method of starting the hydrogenation reaction involved some oxidation a large sample containing traces of cupric salt (pale greenish color) was standardized with respect to its catalytic power and this remained constant throughout a comparable series of experiments. The differences in individual samples were small in any case. The different samples of cuprous acetate are indicated by different letters in the tables.

α-Chloronaphthalene was fractionated in the Widmer column at 50–60 mm. pressure. The identified impurity was only naphthalene.

Hydrogen.—Normal hydrogen was prepared by collecting the gas as it evaporated from liquid hydrogen. Parahydrogen was prepared by passing *n*-hydrogen through charcoal immersed in liquid hydrogen. Deuterium was obtained from the Stuart Oxygen Company. The thermal conductivity measurements indicated that all three hydrogens were sufficiently pure.

Results

A typical run is shown in Fig. 2. All the others are identical in form and differ only in the slope of the straight line, *i. e.*, the rate of the hydrogenation. The effect in pure quinoline solution, of variation of concentration of catalyst, substrate, and hydrogen are shown in Table I. This is for one catalyst preparation. Identical results have been obtained on other preparations.

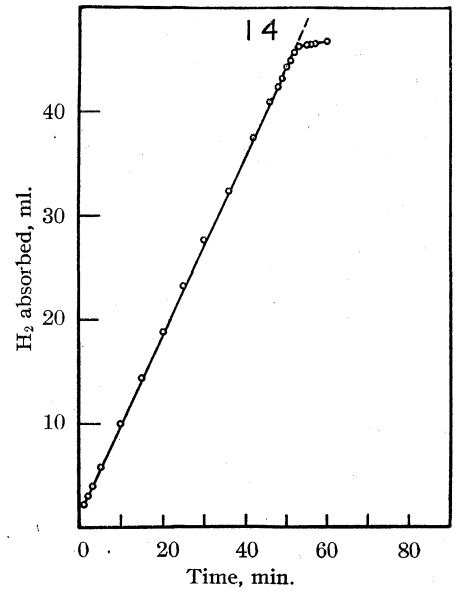

Fig. 2.—Expt. 2 in Table I.

TABLE I

Temperature, 100°; 50 cc. quinoline; catalyst preparation G.

Expt.	Catalyst, mmol.	Substrate, mmol.	Press. H_2, mm.	Rate, cc./min.	Rate per mmol. Cu^I	H_2 abs. mmol.
1	1.02	0.51	395	0.325	0.32	0.28
2	2.04	1.02	395	0.775	.39	0.57
3	4.08	2.04	395	1.81	.45	1.02
4	2.04	2.04	395	0.718	.36	1.05
5	2.04	1.02	595	.776	.39	0.60

The four points which emerge from this tabulation are: (1) the rate is strictly proportional to the concentration of hydrogen in solution (compare expts. 2 and 5; in expt. 5 the concentration of hydrogen in the gas phase and in solution has been increased by the ratio 595/395, so that when the rate in cc./min. remains the same, the rate in moles/min. has increased in precisely the same ratio); (2) the rate is somewhat more than proportional to the amount of cuprous acetate in solution, *i. e.*, when the concentration of cuprous acetate is doubled the rate is somewhat more than doubled; (3) the quinone has a small depressing effect on the rate (expts. 2 and 4); (4) the amount of hydrogen absorbed corresponds rather closely to half reduction of the quinone, *i. e.*, reduction to quinhydrone.

In Table II are shown the rates for the different kinds of hydrogen and the temperature coefficient for normal hydrogen all in quinoline solution.

It should be noted in connection with the at-

TABLE II

6	100	2.04(C)	1.0 chloranil	387 *n*-H_2	0.0
8	100	2.04(C)	1.02 quinone	387 *n*-H_2	.86
9	100	2.04(C)	1.02 quinone	387 *p*-H_2(95%*p*)	.86
10	100	2.04(C)	1.02 quinone	387 D_2(100%D)	.80
14	100	2.04(F)	1.02 quinone	387 *n*-H_2	.87
15	117.7	2.04(F)	1.02 quinone	387 *n*-H_2	2.07

50 ml. quinoline

tempted reduction of chloranil that not only was the hydrogenation completely stopped but the subsequent oxidation of the cuprous complex by oxygen was very markedly slower in the presence of the chloranil than in its absence or with quinone present. The difference between hydrogen and deuterium is surprisingly small though quite real, and whether this difference is a variation in activation energy or temperature independent factor still remains to be seen. Para hydrogen reacts at the same rate as *n*-hydrogen (expts. 8, 9 and 10). The apparent activation energy for the normal hydrogen reaction is 14,300 cal. and if the temperature coefficient of the solubility of hydrogen (given in Table III) is taken into account this activation energy is reduced to 13,000 cal.

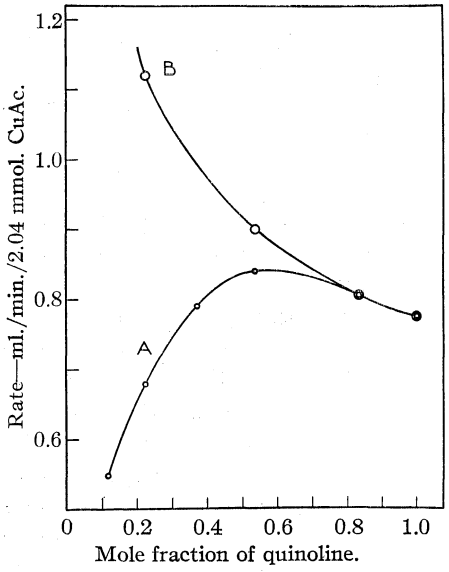

Fig. 3.—2.04 millimoles CuAc; 1.02 millimoles quinone; run at 100°; 50 ml. solvent measured at 20°; press. H_2, 395 mm. at 20°. Curve A, experimentally observed rate; Curve B, rate corrected for the solubility of CuAc.

The accuracy of these solubility measurements did not disclose any difference in the solubilities of deuterium and para hydrogen from that of normal hydrogen.

TABLE III

SOLUBILITY OF HYDROGEN

Temp., °C.	Solvent	Ml. H_2 (press. 380 mm.; temp. 20°)
100	54.5 g. quinoline,	2.1
20	(50 cc. at 20°)	1.35
117.7		2.30
100	54.5 g. quinoline + 1	2.05
20	mmol. quinone	1.4
100	54.5 g. quinoline + 2	2.2
20	mmols. CuAc	1.4
100	59.5 g. α-chloronaphthalene	
	(50 ml. at 20°)	2.15

A series of runs in quinoline–α-chloronaphthalene mixtures was made and the results are given in curve A, Fig. 3. Since the solubility of the cuprous acetate decreased as the mole fraction of the quinoline decreased, all the cuprous acetate which was added to the reaction mixture did not dissolve when the mole fraction of the quinoline dropped below about 0.55. Curve B, Fig. 3, gives the rate, calculated from the observed rate (curve A) and an independently measured solubility (Table IV), corresponding to the condition that all of the cuprous acetate added was completely dissolved.

TABLE IV

SOLUBILITY OF CUPROUS ACETATE IN QUINOLINE–α-CHLORONAPHTHALENE MIXTURES AT 100°[a]

N_Q (mole fraction quinoline)	Soly. (g. CuAc in 50 ml. solvent measured at 20°)
1	0.53
0.537	.23
.223	.14

[a] Since the solid phase was apparently different in the different solvents and in the absence of quinone, these solubilities can only be taken as an indication of what the concentration of cuprous acetate in the solution is.

Discussion

The mechanism that has been proposed previously,[1] namely, that the rate-determining step in the reduction of cupric copper or quinone is an activation of molecular hydrogen by a cuprous quinoline complex followed by a rapid reduction of the substrate, still holds. The succeeding slow absorption of hydrogen after the reduction of substrate is complete is the reduction of cuprous to free copper. There is at least one important addition to be made to this mechanism, which is that the catalytically active species is a dimer of cuprous acetate. This is based primarily on the fact that the rate increases more than linearly with the concentration of cuprous acetate, taken

together with the following line of argument. There exist no data on the molecular weight of cuprous acetate in quinoline solution but the work of Beckmann[2] on other cuprous salts, especially the chloride, indicate just such a polymerization. From the data of Beckmann one can calculate an association constant for the reaction

$$2CuCl(solution) \rightleftarrows Cu_2Cl_2(solution)$$

in quinoline solution in the neighborhood of 238° to be about 5 to 10, expressing the concentrations in moles per liter. If it is assumed that the rate of hydrogenation is proportional to the concentration of dimeric cuprous acetate one can calculate a similar constant of about 700 to 800 for the cuprous acetate in quinoline at 100°. This is entirely reasonable considering the lower temperature and the more favorable conditions afforded by the carboxyl group for polymerization. The heat of dissociation of these dimers in solution can be estimated by assuming an entropy decrease on association of about 15 cal./deg. and using the above equilibrium constants. The dissociation heat for the acetate is then about 10 kcal. and that of the chloride about 8 kcal., both not unreasonable values. Although the molecular structure of a solute as derived from its crystal structure is no proof of the state of the solute in solution, it is a good indication of the tendency of the solute as the solution approaches saturation. Just such binuclear bridged structures as the one here proposed for cuprous acetate–quinoline have been found in crystals of other cuprous and palladous compounds.[3] The function of the quinoline is first of all to bring the cuprous salt into solution by virtue of its coördinating property and second to furnish in this coördinated compound the electrons which seem to be necessary for the catalytic activity. A correlation with the basic strength or aromatic character of the coördinated molecule awaits further investigation. Whether one or two quinoline molecules per copper atom are required is still not known and in the structures written here Q will be used to represent the quinoline in the complex without implying any number. An analysis of the corresponding chloride gave (CuCl–quinoline) although from the work of Mann[3a] it would seem that two quinolines per copper atom would be more likely. In any case the considerations as far as they go at present are unaffected by whether there are one or two quinolines per copper atom or whether, if the cuprous center is four-covalent, these four covalences are planar or tetrahedral. The fact that the rate increases as the mole fraction of the quinoline decreases in the quinoline–chloronaphthalene mixtures can be attributed to the shifting of the polymerization equilibrium toward the side of the dimer and thus increasing the amount of the catalyst, specified for the same concentration of cuprous acetate. However, it seems that the actual increase in going only to solutions which are 10 mole per cent. quinoline is too large to be accounted for on this basis alone since the association constant in pure quinoline is already 700. Any attempt at a quantitative correlation between the solubility (activity) and the rates has so far been futile and should so be, since the solid phase (standard state) does not remain constant (see footnote to Table IV).

The precise path by which the quinone is reduced is still very much in the dark. In any given run the rate is independent of the state of reduction of the quinone but the total amount of quinone present does have an effect on the rate (Table I). The only plausible explanation at the moment is that the quinone forms a complex with the cuprous acetate in competition with the hydrogen and that the reduction product (quinhydrone) is about equally effective in occupying the cuprous acetate and diminishing its availability in the hydrogen activating process. That such a complex is possible is evidenced by the fact that when quinone and white cuprous acetate are kept in the same vacuum desiccator the quinone sublimes over onto the cuprous acetate and forms a very dark blue-black compound. The case of the tetrachloroquinone also is illuminating. Here it seems that the complex formation with the cuprous acetate is so strong and so complete that not only is the hydrogenation prevented but the oxidation by oxygen of the cuprous acetate is inhibited very markedly. In writing out the following mechanism the condition of the quinone is left unspecified. All that can be said is that it is not involved in the rate determining step.

The previously proposed mechanism is essentially correct and is here rewritten with the aforementioned revisions. The notation is identical with that previously used.

(3) (a) Mann, *et al.*, *J. Chem. Soc.*, 873, 1503 (1936). (b) Burawoy, *et al.*, *ibid.*, 1690 (1937). (c) A. F. Wells, *Proc. Roy. Soc.* (London), **167**, 169 (1938).

$$Cu^{I} + Q \rightleftarrows Cu^{I}Q \quad (a)$$

$$2Cu^{I}Q \rightleftarrows (Cu^{I}Q)_2 \quad (a_2)$$

$$(Cu^{I}Q)_2 + H_2 \underset{k_1'}{\overset{k_1}{\rightleftarrows}} (Cu^{I}Q)_2H_2 \quad (b)$$

$$(Cu^{I}Q)_2H_2 + 2Su \xrightarrow{k_2} (Cu^{I}Q)_2 + 2HSu \quad (c)$$

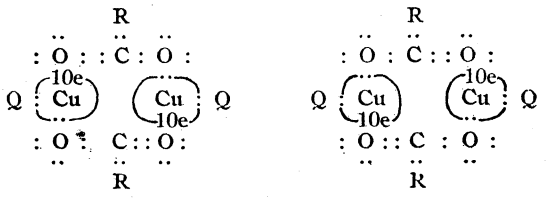
$$(Cu^{I}Q)_2H_2 \xrightarrow{k_3} 2Cu^{\circ} + 2Q + 2HAc \quad (d)$$

with $k_2 > k_1' > k_1 > k_3$

k_1' is set larger than k_1 since the equilibrium of (b) must be far to the left as evidenced by the only very small effect of cuprous acetate on the solubility of hydrogen in quinoline.

The temperature coefficient of the hydrogenation includes the shift of the equilibrium (a_2) as well as the change of the rate k_1. This shift of equilibrium affects the rate in the opposite direction from the change in k_1. If one makes a correction for this shift in equilibrium using the heat of dissociation of 10 kcal. previously calculated, one finds that the activation energy of k_1 is increased only slightly and probably is very close to 14,000 cal.

Thus it seems quite reasonable that the cuprous acetate is at least partially dimeric in solution, although the possibility of a higher polymer is not eliminated. The structure of this dimer analogous to that of other carboxylate dimers can be represented by a number of valence formulas containing chelated copper.



Any further speculation concerning the properties of such a dimer awaits an independent demonstration of its existence.

Summary

It has been shown that probably a dimer of a cuprous acetate–quinoline complex is responsible for the activation of molecular hydrogen in the homogeneous catalytic hydrogenation of quinone in solution.

The Composition of the Colloidal Platinum Micelle

BY S. W. PENNYCUICK

Evidence brought forward by the author[1,2] has shown that the particles of colloidal platinum are composite in nature, containing platinum, platinic oxide and hexahydroxyplatinic acid.

This has now been confirmed by the microchemical analysis of the coagulated particles; and the relative amounts of the three constituents have been determined. The composition of the micelle in an average Bredig preparation is given by the formula $[3.9\ Pt, 1.16\ PtO_2, 1.0\ H_2Pt(OH)_6]_n$.

Isolation of the Micelle.—The sols were prepared from conductivity water by the Bredig method,[3] and the particles were isolated by coagulating the sol by freezing and then thawing the mixture.[4] In the preparation of the sol and in the isolation of the micelle no foreign electrolyte was added, nor was any foreign matter allowed to enter. The micelle was thus obtained in as pure a form as possible.

The particles in the frozen coagulum were sufficiently compact to settle readily; they were therefore washed free from the mother liquor by decantation, and allowed to drain and dry. Filtering was avoided.

Preliminary Observations.—In the previous work[1,2] it was not possible to decide whether the self-formed acid which acted as stabilizing electrolyte was hexahydroxyplatinic acid or one of its dehydration products. Now, however, the indications are fairly clear that the acid in the micelle is in its most highly hydrated form, namely, $PtO_2 \cdot 4H_2O$ or $H_2Pt(OH)_6$. This is based on the following observations.

First, the weight of any one sample of the air-dried micelle varies slightly from day to day. The changes are not in one direction, but appear to follow variations in the atmospheric vapor pres-

sure. This is in keeping with the behavior of the highest hydrate, $PtO_2 \cdot 4H_2O$; for Wöhler[5] and Bellucci[6] have shown that it is the only hydrate of PtO_2 which suffers partial dehydration at low temperatures.

Second, when a sample of the micelle is placed in a desiccator over sulfuric acid there is a steady loss in weight, which after some weeks attains a maximum of 2.6% (see Table IA). Analysis (detailed later) shows that this loss is equal to approximately one-half the total water content. This again indicates that the highest hydrate is present in the micelle; for Wöhler[5] has shown that $PtO_2 \cdot 4H_2O$, when dehydrated by sulfuric acid, yields $PtO_2 \cdot 2H_2O$, thereby losing half its water.

TABLE I

Loss in weight of the platinum micelle, (A) on standing in desiccator, (B) on heating.

(A) In desiccator			(B) On heating Treatment			
Time	Wt., mg.	% loss	°C.	Time	Wt., mg.	% loss
....	34,445	..	...	...	34,194	..
4 hours	33,890	1.61	100	10 min.	33,714	1.40
2 days	33,700	2.17	110	4 hrs.	33,291	2.60
6 days	33,625	2.38	160	4 hrs.	33,033	3.40
20 days	33,570	2.54	400	1 hr.	32,538	4.84
23 days	33,550	2.60	Ignited		31,130	8.96

Third, when the micelle is strongly heated, all the water is driven out. Actually it appears to come out in fractions (see Table IB). Approximately one quarter comes out readily at 100°; the next quarter less readily after heating at 110° for four hours; the third quarter requires a temperature of 160° for four hours; whilst the final quarter is difficult to remove, requiring to be kept for an hour at a temperature of 400°. (Analysis, details of which are given later, shows that the further loss on ignition which appears in the last line of the table is due to the decomposition of the oxide. All the water is given up at 400°.)

This fractional decomposition is in agreement with the behavior of $PtO_2 \cdot 4H_2O$ as recorded by Wöhler, who has shown that under the action of heat the dehydration becomes progressively more difficult as the hydrate moves from $4H_2O$ to $3H_2O$ to $2H_2O$ to $1H_2O$, the last hydrate being very resistant to heat.

These three results taken together indicate that all the water in the micelle is in the form of the hydrate $PtO_2 \cdot 4H_2O$.

Analysis of the Micelle.—The air-dried micelle was used in all cases. The slight variations in initial weight were smoothed out by taking a series of analyses over several days. Constancy in weight could not be secured except at the cost of dehydrating the particles.

It proved desirable to separate the water estimation from that of the oxygen, since a quick heating was necessary to determine the former, and a slow ignition to obtain the latter.

In the water estimation, about 30 mg. of the air-dried micelle was heated rapidly to a temperature well over 400°, and the water quickly and completely expelled. The heating was carried out in a platinum boat in a shortened combustion tube using an adaptation of the microchemical combustion chain. A stream of purified nitrogen was passed continuously through the apparatus at the rate of one bubble every two seconds, and the expelled water was collected and weighed in a calcium chloride tube with the usual microchemical precautions. Two blank tests preceded each estimate, followed by a final blank.

In the oxygen estimation, on the other hand, a fresh sample of the micelle, from 10 to 15 mg., was heated very slowly to 600°, at which temperature, apart from the water being driven out, all the platinic oxide was completely decomposed into platinum and oxygen. The sudden decomposition of the oxide at about 550° was characteristic and rather striking. The micelle, with or without the water, was brown-black in color, but as the oxygen was expelled it changed almost instantaneously to light gray.

The heating was carried out slowly in order to avoid loss of weight by spluttering. The sample was then reweighed, the total loss in weight being made up of the water expelled together with that of the oxygen. As the former already had been determined, the oxygen content was at once obtained by difference. The micelle was finally ignited, but it seldom showed any further loss in weight.

A preliminary method in which the oxygen was determined as water after reduction with a stream of hydrogen was abandoned as it proved to be unreliable. The present method, however, has proved satisfactory and accurate.

The analyses of a number of different preparations are set out in Table II (i). From these it is seen that the micelle suffers a total loss in weight (at 600° or on ignition) of from 10.2 to 12.1%. Approximately one-half of this is due to the water given up by the complete dehydration of the hexahydroxy acid, and the remainder to the oxygen expelled by the decomposition of the platinic oxide.

Numerous freshly made sols (all prepared by the Bredig method) were analyzed. Four characteristic analyses (A, B, C and D in Table II (i)) are set out. Two very old samples of micelles that had been isolated ten years previously were also analyzed. One of these (F) had been kept under water, and the other (G) had been stored in the dry state. The analysis shows that over the ten-year period, although each suffered some slight variation, neither showed any abnormal change.

Calculation of the Formula.—A representative formula is quite sufficient. This can be obtained by using the average results for the micelles from the four freshly made sols, all of which were made under exactly the same conditions. These four sols (A, B, C and D in Table II) show an average water content of 5.4%, and an oxygen content of

5.2%. One thousand parts by weight of the colloid micelles thus contain 894 parts of platinum, 52 of oxygen and 54 of water.

Writing the constitution of the micelle as $[x\text{Pt}, y\text{PtO}_2, z\text{H}_2\text{Pt(OH)}_6]_n$, a simple calculation gives the values of x, y and z as 576, 199 and 225 g., respectively. Converting the values into gram molecules, the formula becomes $[3.9\ \text{Pt}, 1.16\ \text{PtO}_2, 1.0\ \text{H}_2\text{Pt(OH)}_6]_n$.

The Free Hexahydroxyplatinic Acid.—Quite apart from the hexahydroxy acid in the micelle, there is a further quantity which exists in solution as free electrolyte and which is responsible for practically the whole of the conductivity of the sol. The amount so present can be calculated directly from the specific conductivity.

For example, the freshly prepared sols (A, B, C and D in Table II) have an average specific conductivity (after boiling) of 12.2 gemmhos measured at 25°. Using 349 and 43 as the respective mobilities of the hydrogen ion and the hexa acid anion (and assuming complete ionization), the concentration of the hexa acid is calculated as 0.0046 g. per liter.

One liter of the above sol is found (by analysis) to contain 97 mg. of the micelle. The free hexa acid is thus 4.7% of the weight of the micelle, whereas the combined acid (from the figures already given) is 22.5% of the micelle weight. There is thus five times as much hexahydroxyplatinic acid bound up in the micelle as there is in the free state.

On continued boiling, or even on aging, some of the combined acid passes into solution. The relative amounts can be calculated at any time from the conductivity figures and from the micelle analysis. These have been determined in various cases and are set out in Table III.

TABLE III

DISTRIBUTION OF THE HEXAHYDROXYPLATINIC ACID BETWEEN THE PARTICLES AND SOLUTION

Total acid present is 27.2% of the weight of the particles.

Treatment	Acid combined in micelle, %	Acid free in solution, %	Spec. conduc. in gemmhos.
Freshly made	25.4	1.8	4.7
Boiled 0.5 hour	22.5	4.7	12.0
Boiled 30 hours	20.2	7.0	17.8 (max.)
Boiled 45 hours	(Unstable)		13.2

The results show that in the freshly made sol (before boiling) 1.8% of the acid is in solution, while 25.4% is in the micelle. After thirty minutes of boiling, the free acid content increases to 4.7%, leaving 22.4% in the micelle. After boiling for thirty hours in a reflux condenser, the free acid rises to a maximum of 7.0%, leaving 20.2% in the micelle. On further boiling, the sol becomes unstable. The fact that the greater part of the acid remains always in the micelle seems to indicate that some at least of the acid is in the interior of the particles from whence it is incapable of passing into solution.

Analysis of the Precipitate Formed on Boiling or on Aging.—When the sol is boiled or allowed to stand for some time a soft flocculate is thrown down. This can be isolated by drawing off most of the sol, then freezing and thawing the residue.

The analysis of this early precipitate is shown in Table II (ii), whence it is seen that both the oxygen and water content are low, being roughly one-half of the corresponding figures for the stable micelle. These low values are not unexpected seeing that the early precipitate would consist of the less stable particles, that is, those which contain less of the stabilizing material.

Analysis of the Residue in the Bredig Vessel.—During the arcing process there is a moderate amount of wastage which collects in the bottom of the Bredig vessel. Part of this is light gray in color, and has the appearance of the ignited micelle. Analysis of this gray matter (Table II (iii)) shows that it is practically pure platinum. Evidently it consists of the metallic particles which for some reason have failed to collect any appreciable amount of stabilizing material during the arcing process.

The author is indebted to the Trustees of the Endowment Fund of the Council for Scientific and Industrial Research of the Commonwealth of Australia for grants toward the purchase of platinum used in this work.

Summary

The colloidal platinum micelle, after isolation by freezing from Bredig preparations, has been analyzed by microchemical methods. The composition of the micelle of an average preparation can be given by the formula $[3.9Pt, 1.16PtO_2, 1.0H_2Pt(OH)_6]_n$.

There is evidence that the whole of the water in the micelle is present in the form of the highest hydrate, $PtO_2 \cdot 4H_2O$, which is hexahydroxyplatinic acid.

The total amount of this acid (in the micelle and in solution) is 27.2% of the gross weight of the particles. On continued boiling the greater part of this remains in the micelle, where some appears to be in the interior.

The precipitate formed on aging is less rich in stabilizing material than is the ordinary micelle.

The light-gray wastage in the Bredig vessel is practically pure platinum.

The Use of the Concentration Cell in Quantitative Analysis. II. The Determination of Fluoride[1]

BY GEORGE W. LOW, JR.,[2] AND EVERETT H. PRYDE

The first paper in this series[3] described in detail the procedure which may be used for the determination of traces of chloride by employing a simple concentration cell. It was pointed out that the technique involved should be perfectly general and should be applicable to the determination of any substance for which a suitable reversible electrode could be found. In the present paper is given a discussion of the application of this technique to the determination of fluoride. Detailed reviews of the literature on the subject of fluoride determination recently have been given[4] and therefore need not be considered here.

Preliminary Measurements

Our first concern was to find an electrode which would behave reversibly toward fluoride ions. Allen and Furman[5] have reviewed this subject in developing a potentiometric titration method for fluorine. Treadwell and Köhl[6] showed that the system Fe^{+++}/Fe^{++}–Pt functions as a good fluoride electrode because of the formation of the complex iron cryolite, Na_3FeF_6. This system seemed to offer the best possibilities for use in the concentration cell. Accordingly preliminary titrations were performed using the electrode pair, Pt–satd. calomel, in order to determine, if possible, the conditions of acidity and salt concentration which would be most suitable for the final concentration cell measurements and for what range of fluoride concentration the electrode would be expected to function. These titrations, the results of which are shown in Figs. 1, 2 and 3, give information, of a qualitative nature, which is of particular value to anyone who wishes to carry out concentration cell measurements under different conditions from those described in this paper.

Figure 1 shows typical curves for the titration of pure ferric chloride solutions of different concentrations with solutions of sodium fluoride, in the presence of a small amount of ferrous iron, potassium chloride of concentration 0.5 *M*, and hydrochloric acid 0.01 *M*. Under these condi-

electrode to fluoride ions is markedly decreased. On the other hand, the acidity should not be too low, because even in 0.001 *M* hydrochloric acid solutions hydrolysis of ferric chloride is quite rapid.[7]

Preliminary titrations of this type also give important information of a qualitative nature, with regard to the effect of impurities on the e. m. f. of the system. Anything which reacts with ferric ion, ferrous ion, or fluoride ion, would be expected to interfere with a determination of this sort.

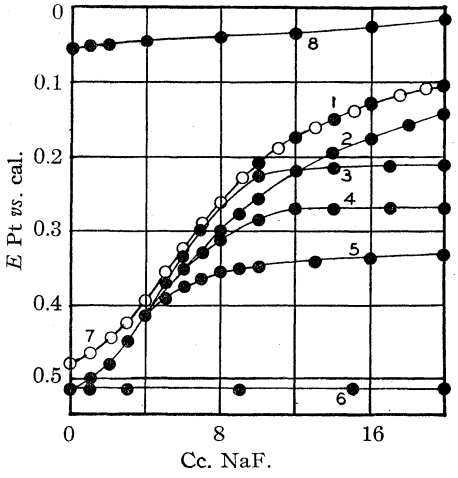

Fig. 3.—Effect of foreign salts: Fe^{+++}, 0.01; NaF, 0.1; Fe^{+++}/Fe^{++}, 2/1; KCl, 0.5; HCl, 0.01; foreign salt, 0.1: 1, none, KNO_3, NaCl, NH_4Cl, KBr, $ZnCl_2$; 2, $MgCl_2$; 3, $HgCl_2$; 4, $CuCl_2$; 5, $CaCl_2$; 6, $AlCl_3$; 7, K_2SO_4; 8, tartrate.

Figure 3 shows the effects of a number of foreign salts on curve 1 of Fig. 1. The fact that aluminum ions interfere so completely can be interpreted as evidence that the Al–F complex is more stable than the Fe–F complex. A number of bivalent metals also affect the curve (but only after about 4 cc. of the sodium fluoride solution is added) owing, presumably, to the formation of the insoluble MF_2. It is interesting to note that these curves give a measure of the relative insolubilities of the several fluorides involved. Interference by these ions is not encountered at the start of the titration, when the ferric ion concentration is relatively high; *i. e.*, we would expect calcium fluoride to dissolve in ferric chloride if the latter is present in great excess. Sulfate, citrate and tartrate interfere because of reaction with the ferric ion, and special means must be taken to eliminate this effect, as well as those mentioned

(7) Lamb and Jacques, THIS JOURNAL, **60**, 973, 1215 (1938).

above, when determining fluoride with the concentration cell.

All of the above qualitative information is valuable in considering the best conditions for determining fluoride with the concentration cell. Consideration of these curves showed that the following cell would serve as a suitable test of the concentration cell technique over the range of fluoride concentration, a, from 1–20 mg. per liter.

Cell 1

(1)		(2)	
Fe^{+++}	= 0.0005	Fe^{+++}	= 0.0005
Fe^{++}	= .0002	Fe^{++}	= .0002
Pt, KCl	= .5	KCl	= .5, Pt
HCl	= .01	HCl	= .01
F^-	=	F^-	= a

All concentrations are expressed in moles per liter.

It is a simple matter to calculate what the e. m. f. of cell 1 should be if we know the reaction which takes place between ferric and fluoride ions. The following relationship would be valid at 30°

$$E = 0.0601 \log \frac{f_1' Fe_1^{+++}}{f_1 Fe_1^{++}} \Big/ \frac{f_2' Fe_2^{+++}}{f_2 Fe_2^{++}} \qquad (1)$$

where the subscripts refer to sides 1 and 2 of cell 1, f is the activity coefficient, Fe^{+++} and Fe^{++} refer to the molar concentrations of the two ions, and E is the difference of potential between the two platinum wires. Since Fe^{++} does not enter into the reaction with fluoride, and since $f_1' = f_2'$ and $f_1 = f_2$ because of the high and essentially uniform ionic strength throughout, the equation may be simplified to

$$E = 0.0601 \log \frac{Fe_1^{+++}}{Fe_2^{+++}} \qquad (2)$$

If the reaction between ferric and fluoride ions is:

$$xF^- + Fe^{+++} = (FeF_x)^{-(x-3)}$$

then

$$Fe_2^{+++} = 0.0005 - \frac{1}{x} a$$

and

$$Fe_1^{+++} = 0.0005$$

where a is the molar concentration of fluoride and $x - 3$ represents the number of charges on the complex ion. Thus it is possible to calculate x from the e. m. f. of the cell if we work with known concentrations of fluoride. In Table I is given a summary of measurements made using cell 1. It is seen that x is not 6, as we might reasonably expect it to be, nor is it a constant. If a constant value for x is used in the Nernst equation, a curve (curve 1, Fig. 4) is obtained, whereas the experimental data fit a straight line

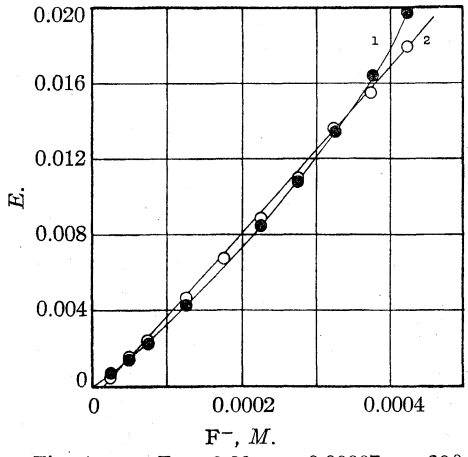

Fig. 4.—○, $E = 2.29a_2 - 0.00067$, at 30°; ●, $E = 0.0601 \log (0.0005/(0.0005 - 0.61a_1))$.

(curve 2, Fig. 4) which is described by the following empirical equation

$$E = 2.29\ a_2 - 0.00067 \text{ at } 30°$$

where E is the observed e. m. f. of the cell when the fluoride concentration, a_2, is expressed as mg. of fluoride per liter.

TABLE I

RESULTS WITH CELL 1

.000500	9.5	.0213	.000220	1.81

The preliminary measurements described above lead us to the conclusion that an empirical but reproducible relationship, suitable for analytical determinations, exists between the e. m. f. of a given cell and the fluoride concentration. Thus if it is desired to use a concentration cell for measurements of unknown fluoride concentrations it is necessary to determine experimentally the empirical curve for the particular ferric reagent being used.

Results with the Concentration Cell

Apparatus.—The glass concentration cell has been described in detail by Furman and Low.[3] All e. m. f. measurements were made by means of a Leeds and Northrup type K2 potentiometer in conjunction with a Leeds and Northrup lamp and scale galvanometer No. 2420c. For most measurements the ordinary Students type potentiometer with a sensitive galvanometer should be satisfactory.

Platinum wires sealed into soft glass tubing were used as electrodes, and it is very important that they be cleaned frequently by dipping into chromic acid cleaning solution. All measurements were made after the cell had reached constant temperature in a water-bath designed to maintain the temperature constant within ±0.02°.

Cell Used.—Since sulfate is likely to be encountered with fluoride in waters or in distillates resulting from the separation of fluoride from other materials, it was decided to modify cell 1 for our final series of measurements by adding sulfate to each side. In this way, the effect of small amounts of sulfate on the e. m. f. of the system is masked. This addition of sulfate merely changes the slope of the straight line of Fig. 4, and offers no inconvenience, since the empirical relationship must be determined anyway. The following cell was used for all measurements described in this paper, with the exception of a few which will be indicated specifically:

Cell 2

	$FeCl_3$ = 0.000497 ± 0.000002		$FeCl_3$ = 0.000497 ± 0.000002
	Fe^{++} = any value (0.0002)		Fe^{++} = any value (0.0002)
Pt,	KCl = 0.5 ± 0.1		KCl = 0.5 ± 0.1
	Na_2SO_4 = 0.15 ± 0.01		Na_2SO_4 = 0.15 ± 0.01, Pt
	HCl = 0.0094 ± 0.0001		HCl = 0.0094 ± 0.0001
	F^- = 0		F^- = 0.000025 to 0.0016 (0.5 to 30 mg./l.)

Measurements showed that the concentrations (all expressed as molarities) must be within the limits indicated in order that the e. m. f. values fit the data presented in this paper. However, it is an easy matter for any worker to determine his own empirical curve (with known amounts of fluoride) for any given ferric ion concentration. Variation of any of the concentrations outside of the above limits results in a change of the slope of the straight line. A careful study of the preliminary titrations, shown in Figs. 1, 2, and 3, was necessary in order to decide upon the various concentrations shown in cell 2, for the determination of fluoride concentrations of from 0.5 to 30 mg. per liter. For much higher concentrations of fluoride, or lower, a different concentration of ferric ion in the cell would be necessary.

Reagents and Chemicals.—It was found convenient to prepare the following reagents. All concentrations indicated need be only approximate, standardization of solutions being unnecessary since an empirical curve must be determined. Our ferric reagents were standardized, and the final ferric ion concentration is indicated in cell 2, but only because we had hoped to find that our data would fit the Nernst equation in some way.

Hydrochloric acid: one liter of 3 *M* stock solution.

Reagent 1: one liter of ferric stock solution containing 0.16 *M* $FeCl_3$ and 0.3 *M* HCl.

Reagent 2: ferric solution containing 0.0016 *M* $FeCl_3$, 0.03 *M* HCl, 1.67 *M* KCl and 0.50 *M* Na_2SO_4. One liter of this reagent can be prepared conveniently by pipetting exactly, 10 ml. of Reagent 1 and 10 ml. of hydrochloric acid stock solution (3 *M*) into a liter volumetric flask, adding the proper amounts of C. P. potassium chloride and sodium sulfate decahydrate (weighed roughly) and diluting to one liter. It is best to dissolve the potassium chloride and sodium sulfate in boiling water before adding to the volumetric flask.

$(NH_4)_2SO_4 \cdot FeSO_4 \cdot 6H_2O$, C. P.: a stock solution of this is not prepared because of the ease of oxidation by air. Solutions are made freshly as needed.

NaF, C. P., or other material containing a known amount of fluoride: a stock solution of this is convenient, but should be kept in a paraffin lined bottle.

Procedure.—In order to make a measurement of the amount of fluoride in a given solution, the following procedure is used. Two solutions are prepared:

Solution 1		Solution 2	
Reagent 2	3 cc.	Reagent 2	3 cc.
Fe^{++} soln.	2 cc.	Fe^{++} soln.	2 cc.
Water	5 cc.	F^- soln.	5 cc.

(The ferrous ion solution is made freshly from C. P. Mohr salt and should be roughly 0.001 *M* in Fe^{++} and 0.001 *M* in hydrochloric acid. The actual concentration of Fe^{++} may vary a hundred-fold, as shown below, provided the same solution is used for both solutions 1 and 2.)

Pipets are used to measure out the quantities of solutions needed above. Solution 1 is then transferred to one side of the concentration cell, solution 2 to the other, care being taken not to make the junction between the two sides, in order to avoid mixing. A platinum electrode is inserted in each side of the cell and it is then placed in the thermostat. After five minutes have elapsed, in order for the solutions to reach temperature equilibrium, the junction is made between the sides of the cell (as described by Furman and Low[3]) and the e. m. f. measured. The e. m. f. remains constant for at least a half hour under ordinary circumstances. Drifting of the potentials indicates that the solutions are mixing or that the electrodes are not clean and the measurement is of no value. From the e. m. f. can be calculated the amount of fluoride present by means of the empirical equation obtained below from measurements of known fluoride solutions.

Results with Pure Fluoride Solutions.—In order to determine the empirical relationship between e. m. f. of the cell and amount of fluoride present, a series of measurements was made using solutions of fluoride made from C. P. sodium fluoride. Table II shows the results obtained. In the two columns at the right the data are expressed as gamma in the 5-cc. sample taken for analysis, which is diluted to 10 cc. (see procedure) to become the "final concentration" shown in the two left columns and expressed as mg. per liter. It can be seen that the method is satisfactory for amounts of fluoride, in the 5-cc. sample taken for analysis, as small as 1

gamma. That these data fit a straight line is shown in Fig. 5. The equation for the straight line was found from a series of measurements made at different temperatures, as described below, under *effect of temperature*. If more than 30 mg. per liter of fluoride is present in the final solution, the relationship is no longer linear, and therefore the fluoride sample should be adjusted so that the amount of fluoride in the final solution falls within the range indicated. As shown below larger amounts of fluoride could also be determined using a reagent in which the ferric ion concentration is higher.

TABLE II

[a] Calculated from the following equation, g. F^-/l. = (0.490 + 0.002t) E + 0.0001 in which E is the observed e. m. f. of the cell and t is the centigrade temperature.

Results with Known Fluoride Samples.—A series of measurements was also made using other sources of fluoride than C. P. sodium fluoride, specifically synthetic sodium fluoride made by the method suggested by Allen and Furman[8] from C. P. sodium carbonate and hydrofluoric acid, C. P. calcium fluoride, C. P. sodium fluosilicate, and Bureau of Standards fluorspar of known purity. The sodium fluoride was dissolved in water, but the others, being insoluble in water, were treated by a special procedure which was predicted on the basis of the preliminary titrations. To an accurately weighed sample, not over 0.1 g., was added 30 cc. of water and 30 cc. of Reagent 1 (measured by pipet). The mixture was stirred on the hot-plate (80–90°) for one hour, cooled and diluted to 100 cc. in a volumetric flask. This solution was then diluted to the proper concentration for measurement in the concentration cell, with a solution of potassium chloride, hydrochloric acid and sodium sulfate. The reference side of the cell was made in exactly the same way except that no fluoride was put into it. Prolonged heating on the hot-plate was found to be necessary only for the fluorspar; the calcium fluoride and sodium fluosilicate dissolved readily in fifteen minutes of stirring at room temperature. The results obtained using a number of samples of these materials are given in Table III.

[a] Calculated from the equation: g. F^-/l. = (0.490 + 0.002t) E + 0.0001.

Effect of Ferric Ion Concentration.—It was pointed out above that the ferric ion concentration determines the slope of the straight line of Fig. 5. Quantitative data concerning the magnitude of this effect are shown in Fig. 6 and Table IV.

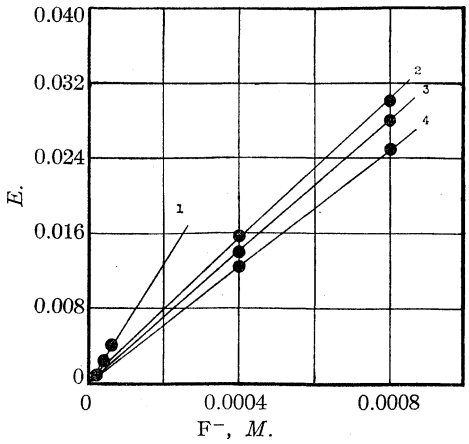

Fig. 6.—Curve 1, Fe^{+++} = 0.0000993 *M*; 2, Fe^{+++} = 0.000398; 3, Fe^{+++} = 0.000497; 4, Fe^{+++} = 0.000597.

TABLE IV

EFFECT OF CHANGE IN FERRIC ION CONCENTRATION

Fe^{+++} = 0.0000993, Reagent 3. Fe^{+++} = 0.000497, Reagent 2.

F^- present, mg./l.	E. m. f., reagent 3	E. m. f., reagent 2
0.19	0.0003	0.00017
.38	.0009	.00052
.76	.0026	.00122
1.14	.0040	.00194

In each case the reagent differs from Reagent 2 only with respect to the ferric ion concentration; all other concentrations are the same. Thus it can be seen that if we were working with very small amounts of fluoride (under 1 mg. per liter), it would be to our advantage to use a reagent whose ferric ion concentration is lower than that of Reagent 2. This reasoning cannot be carried too far, however, because if the concentration is much lower than that indicated for Reagent 3 there is so little iron present that the e. m. f. cannot be read to as many decimal places; the system is then insensitive. On the other hand, if it is desired to measure amounts of fluoride greater than 30 mg. per liter, a reagent whose ferric ion concentration is greater than that of Reagent 2 can be used, which will again cause a different slope to the line.

Effect of Ferrous Ion Concentration.—It was assumed in the preliminary discussion that the concentration of ferrous ion in the cell should not be critical since it does not enter into the reaction with fluoride. It seemed advisable, however, to obtain quantitative data showing this assumption to be valid. Table V gives the results obtained using cell 2, with the exception that the ferrous ion concentration was varied a hundredfold. This table shows definitely that the ferrous ion concentration may be any value within reasonable limits. It is important to note, however, that the concentration must be the same on each side of the cell in any given measurement. One other factor also must be considered: namely, that the ferrous ion concentration must be kept fairly low in order to make sure that no appreciable amount of ferric ion, which is always present as an impurity, is added to the cell.

TABLE V

EFFECT OF CHANGE IN FERROUS ION CONCENTRATION

Ferrous concn. in each side, *M*	E. m. f., v.	F^- found mg./l.
0.00002	0.0047	2.64
.0002	.00470	2.64
.002	.00475	2.67

Effect of Temperature.—It was expected that the e. m. f. value would, of course, be higher if the temperature were higher, for any particular cell. Accordingly, it was somewhat surprising to find exactly the opposite effect; *i. e.*, the e. m. f. of a given cell was lower at 30° than at 25°. Measurements were made, using cell 2, at a series of temperatures, allowing time for temperature equilibrium to be reached between readings. The temperature in the thermostat in which the cell was placed was raised from 15 to 35° and then lowered again to 15°. The same e. m. f. value, at any temperature, was obtained when approached from above or below the given temperature. In Table VI is given a summary of data showing this unexpected effect.

TABLE VI

EFFECT OF TEMPERATURE

Temp., °C.	F^-, 0.0004 *M* Obsd. e. m. f.	F^-, 0.0004 *M* Calcd. e. m. f.[a]	F^-, 0.0008 *M* Obsd. e. m. f.	F^-, 0.0008 *M* Calcd. e. m. f.[a]
15	0.0143	0.0143	0.0289	0.0289
20	.0141	.0145	.0284	.0294
25	.0139	.0148	.0280	.0299
30	.0137	.0150	.0275	.0304
35	.0134	.0153	.0269	.0309

[a] Calculated assuming the value at 15° to be correct; *i. e.*, the e. m. f. at 20° should be 293/288 × the value at 15°.

These results are shown graphically in Fig. 7.

This unexpected phenomenon can be explained on the basis that the degree of hydrolysis of the ferric chloride is greater at the higher temperatures. A measurement carried out at 100° supports this view, inasmuch as at this temperature a precipitate was formed, presumably of ferric hy-

droxide. That the effect is due to hydrolysis rather than to a change of the extent of dissociation of the Fe–F complex was shown by a measurement made on a similar cell put together without any fluoride present in either side. The same anomalous effect was observed with this latter cell.

If consideration is taken of this observed effect of temperature on the slope of the line of Fig. 5, equation 3 is found to be the empirical equation which fits our data at any temperature between 15 and 35°. E is the observed e. m. f. of the cell, and t the centigrade temperature.

$$\text{g. } F^-/\text{l.} = (0.490 + 0.002t)\,E + 0.0001 \quad (3)$$

This hydrolysis in no way affects the usefulness of the method, since the fact that our reagents remained perfectly stable over a period of many months shows that this partial hydrolysis of the ferric chloride is completely reversible and not progressive. It is interesting to note that a means here suggests itself for measuring the degree of hydrolysis of salts of this type by e. m. f. measurements.

Effect of Impurities.—In order that the method may be of value for the determination of fluoride, it must function, of course, in the presence of certain impurities. Consequently, a series of measurements was performed which was designed to study this effect. Different foreign salts were added with the fluoride to the concentration cell, and the effect of these salts, if any, on the e. m. f. was determined. Table VII summarizes the data obtained in this series. A study of this table shows that most of the common ions cause no trouble, but that high results are obtained if phosphate, citrate or tartrate is present (because of reaction with ferric ion), and low results if aluminum or thorium is present (because of reaction with fluoride). As was predicted on the basis of the preliminary titrations, calcium and other bivalent metal ions do not interfere if present in moderate amounts. It can be seen that appreciable amounts of sulfate, perchlorate or silicate, cause no trouble. This is very important, inasmuch as it means that the distillate obtained by separation of fluoride by the usual methods contains no ions which would interfere with the determination of the fluoride. It also should be noted that if the total concentration of impurity is greater than 0.01 M, fictitious e. m. f. values will be encountered because of a liquid junction potential.

Means of eliminating trouble due to impurities will be given below.

Distillation of Fluoride.—A very satisfactory method for the separation of fluoride from other substances has been developed by Willard and Winter.[8a] They recommend the separation of fluoride by distillation from a perchloric acid solution. The determination of fluoride in the distillate can then be made by a number of standard methods. That our concentration cell method is satisfactory for the determination of fluoride in this distillate is shown in Table VIII. A 30-cc. sample of pure sodium fluoride solution, of the concentration shown in the table, was distilled according to the Willard and Winter procedure and the amount of fluoride in the distillate measured by the technique described here.

TABLE VIII

DISTILLATION OF FLUORIDE BY WILLARD–WINTER PROCEDURE

75 cc. of distillate

Concn. of 30-cc. sample, mg./l.		Mg. of fluoride	
Added	Found	Added	Found
4.7	4.7	1.4	1.4
16.7	15.3	5.0	4.6
30	29	9.0	8.7
62	61	18.6	18.3

Another procedure commonly employed is distillation from sulfuric acid solution. This offers the advantage that the temperature can be taken much higher without the danger of explosion which is attendant upon the use of perchloric acid. It is often quite difficult to separate fluoride from a sample by a single perchloric acid distillation, and it is frequently the practice to distil twice, first from sulfuric acid and then from perchloric acid.[9] This second distillation is for the purpose of removing small amounts of sulfate which interfere with some methods of determining the fluoride. Distillation from sulfuric acid has been described in detail by Hoffman and Lundell[10] and is used by them in the determination of fluoride in phosphate rock. Their determination of fluoride in the distillate is then done by a gravimetric process, precipitation as lead chlorofluoride. The concentration cell technique is applicable to the determination of fluoride in such rocks, where the percentage of fluoride is low. Table IX shows the results obtained in determining the fluoride in Bureau of Standards sample No. 56a, by means of our technique. The distillation was carried out as described by Hoffman and Lundell, with the exception that we employed no preliminary fusion and collected the distillate in air rather than under sodium hydroxide solution. Three hundred cc. of distillate was collected, the solution made faintly alkaline to phenolphthalein, then very slightly acidic with 0.01 *M* hydrochloric acid, and diluted to 500 cc. in a volumetric flask. Five cc. of this was then taken for analysis in the concentration cell according to the procedure already described. The whole procedure, after the distillation, takes about fifteen minutes, whereas the gravimetric procedure usually employed takes much longer.

TABLE IX

ANALYSIS OF PHOSPHATE ROCK

Bureau of Standards Sample No. 56a

Sample, g.	% F^- present (certificate)	% F^- found			
0.3650	3.56		3.56		
.1988	3.56	3.61	3.57[a]	3.57[b]	

[a] A 50-cc. sample of the distillate from sample 2 was evaporated to dryness after making slightly alkaline with sodium hydroxide. It was then taken up with water, made slightly acidic with hydrochloric acid and diluted to 25 cc. Five cc. of this solution was then taken for analysis. The evaporation was carried out in Pyrex glass. [b] Same as [a] except that the evaporation was carried out in platinum.

These results show that distillates may be concentrated, if desired, by evaporation in either glass or platinum. Since our experiments concerning the effect of impurities showed that small amounts of silicate do not interfere, this was to be expected.

Elimination of Error Due to Phosphate.—The preceding section described the procedure which may be used for the separation of fluoride from any or all impurities, by distillation. It is possible to determine fluoride in the presence of phosphate by means of a procedure which involves no distillation. If phosphate is present with the fluoride, fictitiously high values for fluoride would be found by the usual concentration cell technique, because of the fact that phosphate reacts with ferric ions in much the same way as does fluoride. This difficulty can be eliminated in the following manner. First the "apparent fluoride" is measured in the usual way by the direct procedure. The measurement is then repeated on a different sample, with a small amount of aluminum ion in each side of the concentration cell. Thus the two solutions would be made as follows.

(8a) Willard and Winter, *Ind. Eng. Chem., Anal. Ed.*, **5**, 7 (1933).
(9) Churchill, Bridges and Rowley, *ibid.*, **9**, 222 (1937).
(10) Hoffman and Lundell, *J. Research Natl. Bur. Standards*, **20**, 607 (1938).

Solution 1	Solution 2
3 cc. reagent 2	3 cc. reagent 2
1 cc. Fe^{++} solution	1 cc. Fe^{++} solution
1 cc. Al^{+++} sol. (0.015 *M*)	1 cc. Al^{+++} sol. (0.015 *M*)
5 cc. H_2O	5 cc. F^- ($+PO_4$) solution

In this second cell the aluminum ions tie up the fluoride so that it cannot react with the ferric ions, whereas the phosphate does not react with aluminum ions if ferric ions are also present. The e. m. f., therefore, is due to the phosphate alone, whereas the e. m. f. of the first cell is due to both the phosphate and the fluoride. The difference between the two values gives the e. m. f. due to the fluoride. Table X shows results obtained by this procedure. The results show that the method yields only approximate values and that distillation should be resorted to if accurate values are required.

TABLE X

DETERMINATION OF FLUORIDE IN THE PRESENCE OF PHOSPHATE

		Direct procedure		Aluminum procedure		
			Apparent		E. m. f. due	
PO_4 present mg./l.	F^- present mg./l.	E. m. f.	F^- found mg./l.	E. m. f. due to phosphate	to F^- (by diff.)	F^- found mg./l.
10	1.6	0.0054	3.0	0.0024	0.0030	1.7
20	1.6	.0092	5.1	.0054	.0038	2.2
30	1.6	.0124	6.8	.0087	.0037	2.1

Analysis of Water Samples.—The technique was tested on Arizona water samples, which were kindly furnished by Professor H. V. Smith of the University of Arizona, who recently has compared[11] a number of standard methods used for the determination of fluoride in water. These samples had been analyzed in his laboratories, and his results are given with ours in Table XI as a means of comparison. Samples 4 and 5 had been passed through a bone filter devised by Smith and Smith[12] to remove fluoride from water; the original content of these samples was quite high in fluoride.

TABLE XI

ARIZONA WATER SAMPLES

	Fluoride found, mg./l.		
Sample no.	Direct proc.	Aluminum proc.	H. V. Smith Sanchis method
1	3.5	3.5	4.0
2	6.8	6.3	6.0
3	0.7	0.2	0.3
4	.9	.6	.3
5	.4	.1	.0
6	4.1	3.8	3.5

The table indicates that there was a small amount of phosphate in the water also, the effect of which was removed by means of the "aluminum procedure" already described.

(11) Smith, *Ind. Eng. Chem., Anal. Ed.*, **7**, 23 (1935).
(12) Smith and Smith, *Water Works Eng.*, Nov. 10, 1937.

Discussion of Results

Advantages of the Technique

1. *Wide range of applicability.*—The procedure should be applicable to the determination of fluoride in any substance, since it may be applied to the filtrate obtained by distilling fluoride from impurities, from either a perchloric or sulfuric acid medium.

2. *Rapidity.*—A single measurement takes about fifteen minutes, if the fluoride is present in solution. If a solid material is being analyzed, or if many impurities are present, the time to carry out the distillation to separate the fluoride must be added to this. It is very convenient to make a number of measurements at the same time, using three or four concentration cells.

3. *Simplicity.*—Since the procedure involves only the use of a pipet and the ability to read a potentiometer, it is extremely simple. In addition, no personal error enters, as it does in certain titration methods where the end-point is difficult to distinguish.

4. *Accuracy.*—For small amounts of fluoride the accuracy of the method is satisfactory, particularly if the size of sample can be so regulated that the amount of fluoride in the final cell is above 10 mg. per liter.

5. *Application to micro determination.*—As indicated in the tables, the method is suitable for quantitative determination of as little as 1 gamma of fluoride in 5 cc. of solution taken for analysis.

Disadvantages of the Technique

1. *Necessity for an empirical curve.*—Unfortunately it is impossible to relate the e. m. f. of the concentration cell to the amount of fluoride in any way except by an empirical equation. Fortunately, however, it is a straight line relationship in the range studied. Thus for all practical purposes this is no serious disadvantage. All of the measurements given in this paper, using cell 2, were made using the same empirical curve. Since the reagents are perfectly stable, a curve once determined is satisfactory for a year or more if sufficient reagent is made. The amounts suggested in this paper are sufficient for about 15,000 determinations.

2. *Limited to small amounts.*—Because of the very nature of the technique, our procedure is

limited to the determination of small amounts of fluoride. A detailed study has not been made of the application of this technique to larger amounts using a much higher concentration of ferric ion in the reagent. The preliminary titrations indicate that such an application could be made, but the range we have chosen to study should be satisfactory for most of the fluoride determinations necessary.

3. *Accuracy.*—Although, as pointed out above, the accuracy is very good for the small amounts of fluoride determined, it should also be mentioned that the method would not be satisfactory for the accurate determination of fluoride in a substance whose fluoride content is greater than 10%, because in that case a 1% error would be appreciable, whereas for very small amounts of fluoride a 1% error is not important.

4. *Liquid junction.*—It is important to keep the total impurity molarity of the unknown fluoride solution below 0.01 *M*, else an appreciable liquid junction potential will cause fictitious results. In practice this is very easily done, by distilling the sample from impurities if in no other way. The distillate is much lower than 0.01 *M* in foreign ions.

It should be pointed out that the size of sample of an unknown should be adjusted so that the amount of fluoride in the final concentration cell is between 0.1 and 30 mg. per liter, preferably greater than 10 mg. per liter, since the percentage error is smaller for larger amounts of fluoride.

The procedure we have described corresponds to the "Standard Solution" method for chloride used by Furman and Low.[3] An attempt was made to apply the "small excess" method[3] to the determination of fluoride, but with no success. The e. m. f. of the cell, with fluoride in both sides, seemed to be dependent upon the difference in fluoride concentration between the two sides rather than the ratio of the two concentrations. Because this "small excess" method offered no promising results, we abandoned a further study of it in favor of the procedure we have given.

The material presented in this paper gives indication that the technique described should be applicable to the determination of a number of other substances, such as aluminum, phosphate, sulfate, citrate or tartrate, by slight modifications of the procedure. It is hoped that further study will confirm this prediction.

Summary

A technique has been described for the determination of fluoride rapidly and accurately by means of a simple concentration cell. Interference of other ions can be eliminated entirely, since the procedure is applicable to the determination of fluoride in the distillate obtained in separating fluoride from all impurities. The range over which the method has been applied is 0.2 to 60 mg. per liter in a 5-cc. sample which is taken for analysis. Results are given showing the method's applicability to water analysis and to the determination of fluoride in phosphate rock.

NOTES

Dibenzyl Sebacate

BY R. E. BURNETT AND J. J. RUSSELL

The new compound dibenzyl sebacate was synthesized recently in this Laboratory for use in another investigation.[1] Sebacic acid was esterified with benzyl alcohol, the crude ester then distilled at 0.5 mm. pressure, and the middle fraction recrystallized several times from its melt. The following are properties of the pure dibenzyl sebacate.

Temp., °C.	Refractive index n_D (Abbe)	Density d_4^t
30.0	1.5171	1.055(6)
35.0	1.5152	1.051(9)
40.0	1.5133	1.048(1)

Colorless plates, practically odorless; melting point (from cooling curve), 28.3°; boiling point (in Claisen flask), 257° (uncorr.) at 4 mm.

On the Conversion of *l*-Abietic Acid into a *d*-Abietic Acid

BY TORSTEN HASSELSTROM AND JOHN D. MCPHERSON

The addition of hydrogen chloride to abietic acid produces dichlorodihydroabietic acid which is crystalline and easily purified.[1] We have found that dichlorodihydroabietic acid may be obtained directly from rosin and in apparently equal purity as when Steele's abietic acid[2] is used as a starting material. On splitting off of hydrogen chloride from dichlorodihydroabietic acid with sodium ethoxide, we have been able to obtain an abietic acid with the positive sign of rotation. This seemingly new abietic acid was characterized through its di-*n*-amylamine salt. According to Levy,[1] the dichlorodihydroabietic acid produces an abietic acid with the negative sign of rotation when heated at its melting point, and when treated with quinoline.

Experimental

Dichlorodihydroabietic Acid.—This compound was prepared substantially according to the directions given by Levy.[1] Ninety-five grams of "X" grade gum rosin was dissolved in 70 cc. of glacial acetic acid and boiled for four hours. The solution was then cooled to about 0°. The semi-solid mixture was saturated with dry hydrogen chloride, the bottle sealed and the mixture left standing at room temperature for two weeks. It was then filtered and the solid collected; yield 26 g. It was recrystallized from acetone and then from ethyl acetate, m. p. 190.5° dec. (corr.); $(\alpha)_D$ −10° (in ethanol).

Anal. Calcd. for $C_{20}H_{32}O_2Cl_2$: C, 63.97; H, 8.59. Found: C, 63.76; H, 8.60.

The dichlorodihydroabietic acid prepared from Steele's abietic acid,[2] m. p. 163.5–165° (corr.); $(\alpha)_D$ −76° (in ethanol) showed the following constants: m. p. 190.5° dec. (corr.); $(\alpha)_D$ −8.1 (in ethanol). Found: C, 63.96; H, 9.16.

***d*-Abietic Acid.**—Ten grams of dichlorodihydroabietic acid (m. p. 190.5° dec. (corr.); $(\alpha)_D$ −10°), was added in portions over a period of five to ten minutes to a boiling solution of sodium ethoxide (17.5 g. of sodium and 175 cc. of absolute ethanol). The mixture was refluxed for one hour. Water was then added and the excess of alcohol was distilled off. As much of the liquid as possible was poured off the remaining solid. The soapy residue was then dissolved in 3 liters of water. The solution was filtered and the filtrate acidified with dilute hydrochloric acid. The white precipitate was filtered off and crystallized from methanol, yield 3.5 g. (40%), m. p. 137–139°; $(\alpha)_D$ +27° (in ethanol), which on successive crystallization yielded an abietic acid melting at 142–143° (corr.); $(\alpha)_D$ +20° (in ethanol). Calcd. for $C_{20}H_{30}O_2$: C, 79.40; H, 10.05. Found: C, 79.33; H, 10.08; C, 79.57; H, 10.32.

(2) Steele, THIS JOURNAL, **44**, 1333 (1922).

The mother liquor from this separation yielded small quantities of an acid melting at 207–212° (corr.), probably identical with the dihydroabietic acid of melting point 217.5–218.5° (corr.), previously described by us.[3]

A solution of 6 g. of *d*-abietic acid of m. p. 139–143° (corr.) was treated with 4 g. of di-*n*-amylamine (Eastman Kodak Company) in acetone. The solution was boiled for about ten minutes and filtered. On standing 10.6 g. of crude di-*n*-amylamine salt was obtained, m. p. 117.5–119° (corr.). The compound was recrystallized four times, the melting point remaining constant after the third crystallization, being 119–119.5° (corr.), $(\alpha)_D$ +3.3° (in ethanol). The amounts of recovered di-*n*-amylamine salt were too small to be converted into the original acid.

Anal. Calcd. for $C_{30}H_{53}O_2N$: C, 78.35; H, 11.62. Found: C, 78.61; H, 11.76.

The di-*n*-amylamine salt of *l*-abietic acid shows the following constants: m. p. 141–142°; $(\alpha)_D$ −74.5°.[4]

This investigation is being continued.

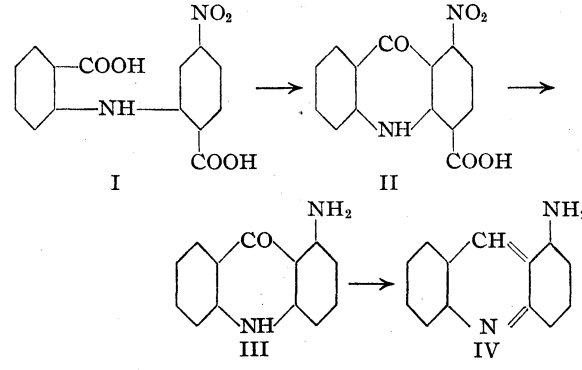
The Identification of 1-Nitroacridone-4-carboxylic Acid as 1-Aminoacridine

BY KONOMU MATSUMURA

In a previous paper,[1] it was stated that the nitroacridone-carboxylic acid (m. p. 333° dec.) which was obtained from 5-nitrodiphenylamine-2,2′-dicarboxylic acid (I) by ring closure should have the constitution of 1-nitroacridone-4-carboxylic acid (II) in consideration of the observations that the fluorescence and solubility of the aminoacridone (III), which was converted from the nitroacridonecarboxylic acid in question, exactly coincided with those of 1-aminoacridone but were widely different from those of the 3-isomer.



The present paper indicates the previous interpretation to be altogether correct, but not in harmony with the Lehmstedt conclusion,[2] on

TABLE I

COMPARISON OF THE PROPERTIES OF SUBSTITUTED ACRIDINES

Substituent		1-Amino-	3-Amino-
Fluorescence in alc. soln.		None	Intense green
M. p., °C.		178 (uncorr.) 182.3 (corr.)[a]	218 (uncorr.)[b] 223.5 (corr.)
Hydrochloride	Cryst. color	Blue-black	Orange-red
	Aq. soln.	Violet-red color with no fluores.	Orange-yellow color with green fluores.
	M. p., °C. (uncorr.)	285 (dec.)[c]	328–329 (dec.)

[a] Albert and Linnell [*J. Chem. Soc.*, 22 (1938)] give m. p. 181° (corr.), and Lehmstedt [*Ber.*, **71**, 808 (1938)] gives m. p. 165–170°. [b] Albert and Linnell [*J. Chem. Soc.*, 1618 (1936)] give m. p. 219° (corr.) and Scherlin [*Ann.*, **516**, 218 (1935)] m. p. 221–222° for their products, respectively. [c] Lehmstedt (*loc. cit.*) gives m. p. 286° (dec.) for his product.

the basis of further investigations as follows. The aminoacridine (IV) which was obtained from the aminoacridone in question (III), on admixture with synthesized 3-aminoacridine, showed a great depression of the melting point, while with synthetic 1-aminoacridine it showed no depression; moreover, its other properties were in good agreement with those of 1-aminoacridine shown in Table I.

The nitroacridone-carboxylic acid must, therefore, be 1-nitroacridone-4-carboxylic acid.

Experimental

1-Aminoacridine.—Four-tenths gram of the aminoacridone in question (m. p. 289–290°) and 5 g. of sodium amalgam (5%) in 30 cc. of dilute alcohol (33%) were heated on a water-bath for three hours with frequent shaking. The solution was decanted from mercury, acidified with hydrochloric acid and oxidized with 2 g. of ferric chloride. The base (yield, 0.25 g.) which was set free from the hydrochloride, crystallized from alcohol (33%) into gold-yellow prismatic needles, melting at 178° alone or on admixture with a sample of 1-aminoacridine (m. p. 178°), whereas a mixture (7:3) of this compound with an authentic specimen of 3-aminoacridine (m. p. 218°) melted at 135–140°.

Anal. Calcd. for $C_{13}H_{10}N_2$: C, 80.41; H, 5.15. Found: C, 80.22; H, 5.28.

The hydrochloride gives blue-black prismatic needles from dilute hydrochloric acid (5%), m. p. 285° (dec.). The aqueous solution assumes a violet-red color, while an alcoholic solution has a violet-blue color, both showing no fluorescence in any dilution.

Synthesis of Aldehydes by Stephen's Method[1]

BY JONATHAN W. WILLIAMS

The application of Stephen's[2] procedure to the preparation of several aldehydes has led to the conclusion that the method is not as general as claimed. Stephen states, "the method is applicable to aliphatic and aromatic nitriles, and the yields are usually almost quantitative." Exceptions are made by Stephen only in the cases of *o*-tolualdehyde and α-naphthaldehyde, where "steric hindrance" is offered as an explanation for poor yields.

The method has been tried in this Laboratory with good results in the preparation of benzaldehyde, *p*-tolualdehyde and β-naphthaldehyde, and with only fair results in the preparation of phenylacetaldehyde and isocapraldehyde. Stephen's poor yields with α-naphthaldehyde and *o*-tolualdehyde have been verified, and the method has been found completely unsatisfactory for the preparation of β-hydroxypropionaldehyde.

Experimental

Preparation of Phenylacetaldehyde.—Eleven runs were made, each different, and the following was found to give the highest yield.

A mixture of anhydrous stannous chloride (57 g., 0.3 mole, prepared by heating the hydrated salt for one hour in a 200° bath, cooling and pulverizing the resulting solid mass) and dry ether (400 ml., twice distilled from sodium) was placed in a 2-liter three-necked round-bottomed flask, provided with a mechanical stirrer and a reflux condenser fitted with a calcium chloride drying tube. The mixture was saturated with dry hydrogen chloride,[3] using slow stirring to agitate the stannous chloride. Within two hours all of the solid stannous chloride had dissolved, forming a separate lower viscous layer.

The source of hydrogen chloride was then disconnected and phenylacetonitrile (16 g., 0.136 mole, freshly distilled) was added rapidly by means of a dropping funnel. The mixture was stirred vigorously for one hour and then allowed to stand for eighteen hours. The aldimine hydrochloride–stannic chloride complex began to separate after five hours.

The ethereal hydrogen chloride was removed by decantation and the residue washed twice with 100-ml. portions of dry ether to remove hydrogen chloride. To the residue were added 800 ml. of water and sufficient solid sodium bicarbonate to render the solution neutral to congo red.

(1) Presented before the Division of Organic Chemistry at the Baltimore meeting of the American Chemical Society, April, 1939.

(2) Stephen, *J. Chem. Soc.*, **127**, 1874 (1925).

(3) "Organic Syntheses," Coll. Vol. I, p. 287 (1932).

The mixture was then brought to boiling and live steam passed through it until the total volume of distillate was 250 ml.

The steam distillate was extracted with two 75-ml. portions of ether and the ethereal extract dried over sodium sulfate. The ether was removed on the steam-bath and the residue vacuum-distilled: yield of phenylacetaldehyde, b. p. 87–88° (18 mm.), 5.4 g., 0.045 mole, 33%.

The other aldehydes studied were prepared by much the same procedure. The results are summarized in the table.

Aldehyde prepared	Time allowed for pptn. of addn. complex	Yield, %
Benzaldehyde[4]	5 hours	97
β-Naphthaldehyde[5]	12 hours	91
p-Tolualdehyde[4]	12 hours	77
Phenylacetaldehyde[4]	18 hours	33
Isocapraldehyde	7 days	31
o-Tolualdehyde[7,8]	8 days	9
α-Naphthaldehyde[7]	7 days	7
β-Hydroxypropionaldehyde[6]	7 days	0

(4) Reported by Stephen[2] in almost quantitative yields.

(5) One liter of hot water was added to the residue and live steam passed through the mixture as long as any solid came over in the steam distillate. The solid was recrystallized from 50% aqueous alcohol. Fulton and Robinson, *J. Chem. Soc.*, **152**, 200 (1939), reported the preparation of β-naphthaldehyde by the Stephen technique in 75% yield. Their work was published after the preparation had been completed at the University of Maryland.

(6) Removal of the aldehyde by steam distillation was not attempted; 500 ml. of water was added to the addition complex, the mixture warmed on the steam-bath for one hour, allowed to cool and extracted with ether. The product was a thick, tarry liquid which gave negative tests with Schiff and Tollens reagents.

(7) Reported by Stephen[2] in poor yield.

(8) There was no precipitate after seven days so one-half of the ether was removed and the reaction mixture allowed to stand another twenty-four hours.

Crystalline Lead Orthophosphate

BY EDWARD J. ROEHL

In the preparation of crystalline metathetical reaction products where the solubility of the reaction product is very low, it is often difficult to obtain crystals large enough for microscopic examination, and a number of methods have been employed for maintaining the necessary slight supersaturation. The writer has successfully employed a cellophane membrane for a number of such cases.

By treating a solution of lead acetate with sodium hydrophosphate, Aiders and Stähler[1] succeeded in preparing lead orthophosphate, but without any signs of microscopically recognizable crystals. In fact, it appears from the literature that the only method of preparing this salt is the rather cumbersome one of Zambonini,[2] who fused and slowly cooled the white powder. In our experiments, a cellophane membrane was tied over the mouth of a test-tube (an open tube could of course be used) containing a 1% solution of Na_2HPO_4 and the tube inverted in a slightly acidified 0.2% solution of $Pb(C_2H_3O_2)\cdot 3H_2O$. At once an almost amorphous precipitate of lead orthophosphate appeared on the under side of the membrane and in about a minute crystals of the white salt started to fall.

The crystals (some of which were 2 mm. in length) were uniaxial hexagonal prisms exhibiting strong birefringence and showing an optically negative character. The values of $\omega = 1.970$ and $\epsilon = 1.936$ check the data in the literature for the refractive indices of lead orthophosphate. Analysis of the crystals gave a value of 17.4% as compared with the calculated value of 17.5% for $Pb_3(PO_4)_2$.

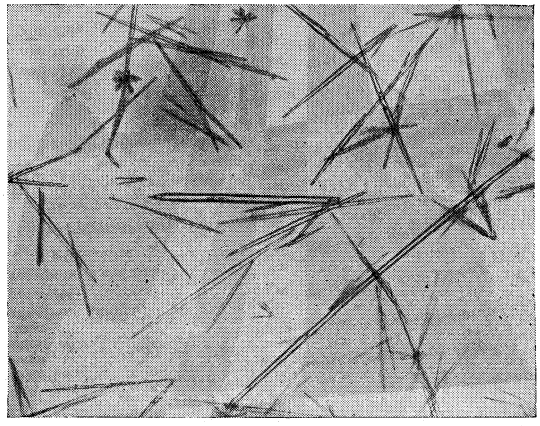

Fig. 1.

The accompanying photomicrograph at (50 ×) shows some of the crystals obtained.

α-Furfuryl Bromide (2-Bromomethylfuran)

BY J. E. ZANETTI AND J. T. BASHOUR

In 1927 one of us[1] prepared an ether solution of α-furfuryl bromide by acting on furfuryl alcohol with phosphorus tribromide. The solution proved satisfactory in the synthesis of various furfuryl ethers but the pure bromide was not separated as its decomposition was rapid once the solvent was evaporated. Von Braun and Kohler[2] had

(1) Zanetti, THIS JOURNAL, **49**, 1065 (1927).

(2) Von Braun and Kohler, *Ber.*, **51B**, 86 (1918).

had a similar experience when they synthesized the bromide by acting on α-furfurylmethylethylamine with cyanogen bromide in ether solutions; they were unable to obtain the pure compound from the ether solution. Recently the ether solution of the bromide has been used by Paul[3] in the synthesis of alkyl furans with the Grignard reagent and by Paul and Normant[4] in a study of the preparation of phenyl-α-furfuryl ether and its rearrangement.

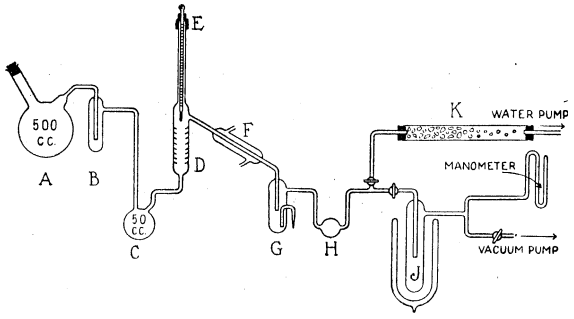

Fig. 1.

The work herein presented was undertaken with the object of obtaining the pure bromide and in this we have succeeded as far as the very unstable nature of the compound would permit. By distilling the dry ether solution under the reduced pressure of a water pump, then lowering the pressure to 2 mm. with a vacuum pump and distilling rapidly, we succeeded in obtaining a colorless product boiling at 32.5 to 34.5°. The apparatus employed is described in the Experimental Part. Though the bromide distils over as a colorless liquid, in a few minutes it begins to color yellow and then brown. Its rate of decomposition seems to be a function of the concentration of hydrobromic acid, which is one of the decomposition products. Hence it must never be kept long in a confined space as the rapidity of the decomposition reaches explosive violence. During a specific gravity determination a pycnometer containing 3 cc. of the bromide exploded a few minutes after being taken out of the balance case. The operator fortunately had moved far enough away so that he was not injured, but no trace of the pycnometer could be found except one of the caps closing the capillaries. Even when kept in loosely stoppered containers the decomposition is rapid the vessels becoming coated with tough graphitic films similar to those described in the preparation of the α-furfuryl iodide.[5]

The bromide is slightly lachrymatory and a distinct lung irritant, the irritation not appearing for some hours after inhaling the vapor.

Density determinations gave d^{20}_{20} 1.560 and the index of refraction with the Abbe refractometer was n^{20} 1.5380. Chemically the compound was identified by condensing it with furfuryl alcohol to di-α-furfuryl ether, b. p. 100–102° at 2 mm.

Because of the short life and dangerous nature of this compound and the fact that the ether solution in which it is prepared is satisfactory for synthetic work, it did not appear of importance to carry this investigation any further.

Experimental

Preparation of the α-Furfuryl Bromide.—This was carried out as described by Zanetti[1] using smaller quantities (20 g. of furfuryl alcohol and 20 g. of phosphorus tribromide). The solutions stood from twenty to forty hours over granulated sodium hydroxide. The solutions were then rapidly filtered and distilled in the apparatus shown in Fig. 1.

Apparatus.—The apparatus consisted of a 500-cc. bulb (A) connected through a trap (B) with a smaller bulb (50 cc.) C. This was connected through a 5-cm. reflux column (D) with thermometer attachment (E) and a condenser (F) with another trap (G) provided with a siphon side-tube ending in a capillary. A small bulb (H) of 50-cc. capacity was inserted before trap (J) which was immersed in "dry-ice"–ethylene trichloride mixture and used to protect the vacuum pump. (K) was a drying tube to prevent water vapor from entering the apparatus. The entire apparatus was made of Pyrex glass. The only points where the compound might come in contact with organic material were at the side tube of (A) and at the thermometer holder (E) where a piece of rubber vacuum tube was used to hold the thermometer in place. The side-tube of (A) and the thermometer holder were made of 8-mm. tubing, the stoppered ends far removed from the warm vapors so that contamination from these sources was unappreciable.

Operation of the Apparatus.—The apparatus was first exhausted to 2 mm. and warmed to take out all moisture. Air was slowly let in through (J) till atmospheric pressure was reached. The filtered ether solution was then placed in (A) and the side-tube closed with a small cork thoroughly covered with collodion. The connection leading to the vacuum pump was closed and that leading to the water pump opened. When the water pump was started the boiling of the ether solution was rapid and the temperature dropped fast. In order to keep the ether boiling it was necessary to immerse (A) in water kept at about 30°. When no more ether came over, the vacuum pump was started and the pressure in the apparatus brought down to 2 mm. A small amount of ether col-

(5) Zanetti, THIS JOURNAL, **49**, 1061 (1927).

lected in (J). Ice water-baths were then placed around (B) and (C) and a hot water-bath around (A). Distillation of the bromide began accompanied by darkening and film formation in (A). The distillate collected mostly in (B). When distillation was finished, the bath around (B) was heated almost to boiling and an ice water-bath placed around (G). When this distillation was over, the bath around (C) was raised to boiling and an ice-bath placed under (H). This was the final distillation, the colorless bromide distilling into (G) while the temperature remained at 32.5 to 34.5°. A very small amount of distillate passed into the bulb (H). When the distillation was complete, the apparatus was brought back to atmospheric pressure by slowly letting air through (J). The side-tube capillary was then broken and the liquid siphoned off into a small flask by gently sucking out the air from the flask.

The residues in (A), (B) and (C) were black and tarry but the distillate in (G) was colorless throughout the distillation, though shortly after it began to color. Five runs were made, each with a new apparatus as it was found easier to discard the one used than to attempt to remove the graphitic films formed in it from the bromide decomposition.

The yields were about 50% of the theoretical.

Properties of the Compound.—As mentioned, the compound is a colorless liquid which decomposes rapidly, turning yellow then brown and ending in a tarry mass which adheres tightly to the container. Attempts to keep the compound for more than a few hours proved futile. Moisture doubtless plays an important role in initiating the decomposition. Phosphorus pentoxide or anhydrous sodium sulfate, however, proved useless in stabilizing the compound. Solid potassium hydroxide, though unable to prevent blackening, delays total decomposition for a much longer time. This points to the possibility that the hydrobromic acid formed by the decomposition may act as an accelerator. The compound thus prepared and dissolved in ether remains undecomposed for days.

Identification.—Analyses gave for bromine 50.3 and 49.0%, calculated, 49.66%.

Four and one-half grams of the bromide was condensed with excess of furfuryl alcohol and potassium hydroxide and the product distilled at 2 mm. The di-α-furfuryl ether came over at 100–102°; yield 85%.

COMMUNICATIONS TO THE EDITOR

HOMOGENEITY OF GONADOTROPIC HORMONE PREPARATIONS ISOLATED FROM PREGNANCY URINE

Sir:

We have reported the preparation from pregnancy urine of gonadotropic fractions containing 4000 minimal ovulating doses per milligram when assayed in the post-partum rabbit [*J. Biol. Chem.*, **128**, 525 (1939)]. Two such samples have recently been examined on the ultracentrifuge,[1] and appear to be homogeneous with respect to sedimentation. In each case, in the concentrations employed, a single sharply defined band was observed at approximately 250,000 times gravity.

In addition, electrochemical homogeneity of one of these preparations was demonstrated as a result of studies with the electrophoresis apparatus of Tiselius.[2] Evidence for the presence of only a single component (which previous analysis had shown to be a polypeptide-polysaccharide complex), was indicated by the appearance of a single migrating band having sharp boundaries in a phosphate buffer of ionic strength 0.1 (*p*H 7.0). The mobility was 4.85×10^{-5} cm.^{2}, sec.$^{-1}$, volt^{-1}.

Isoelectric point determinations, made by adsorbing the hormone upon collodion particles, and determining migration in a microelectrophoresis cell, showed an isoelectric point of *p*H 3.2–3.3.

Since such preparations appear to be identical with regard to biological activity and chemical composition, we feel that the evidence obtained with the ultracentrifuge and Tiselius apparatus demonstrates the homogeneity of our preparations.

Further detailed data bearing upon the physical and chemical properties of these and similar preparations of the hormone will be reported shortly.

THE STABILITY OF THE KETO ACID FROM METHIONINE[1]

Sir:

The metabolic path of most amino acids seems to be preponderantly through the corresponding keto acids. Hence a thorough knowledge of the behavior of these keto acids is essential for the understanding of amino acid metabolism. In a study of the mechanism of methylation processes in the animal organism we were interested, therefore, in the behavior of the keto acid from methionine. This amino acid is one of the few physiological substances which may yield methyl groups. According to the prevailing view methionine is demethylated to homocysteine during metabolism. We have obtained evidence by studying the behavior of the corresponding keto acid that a second reaction—splitting off of the —SCH_3 group—is also possible.

Since the keto acid from methionine has as yet not been synthesized, we prepared it biologically by the deamination of methionine in the presence of kidney slices according to the technique developed by Krebs.[2] A dinitrophenylhydrazone of the keto acid melting at 149° was obtained in about 20% yield.[3]

Anal. Calcd. for $C_{11}H_{12}O_6N_4S$: C, 40.24; H, 3.68; N, 17.07; S, 9.77. Found: C, 40.40; H, 3.81; N, 16.57; S, 9.80.

Solutions of methionine which had been similarly incubated with kidney slices were deproteinized and the filtrates containing the free keto acid and unchanged methionine were digested with acid and with alkali. Under both conditions methyl mercaptan was produced copiously. The liberated methyl mercaptan was identified by its yellow silver compound and by the melting point and analysis of the mercury mercaptide. In one experiment 400 mg. of *dl*-methionine was metabolized by kidney slices. After deproteinization the keto acid was determined in an aliquot of the solution as the dinitrophenylhydrazone (yield, calculated to the total sample, 210 mg. of the hydrazone). To another aliquot sufficient 10 *N* sodium hydroxide was added to make the solution 2 *N*. The solution was refluxed under nitrogen for one hour and the liberated mercaptan was absorbed in a solution of mercuric cyanide. Most of the methyl mercaptan was liberated during the first twenty minutes. The mercaptan weighed as mercury mercaptide corresponded to 72% of the keto acid in the solution (68 mg. $Hg(SCH_3)_2$). Since the original solution contained negligible amounts of mercaptan and as methionine does not yield mercaptan under these conditions, the reaction is ascribed to the decomposition of the keto acid. This finding may be explained on the basis of the instability of β-keto sulfides investigated by Nicolet.[4]

To establish the possible physiological significance of our findings we are continuing our studies with other sulfur-containing compounds.

THE VERATRINE ALKALOIDS. VI. THE OXIDATION OF CEVINE

Sir:

In previous work on the degradation of cevine, high temperature pyrolytic procedures (soda lime distillation or selenium dehydrogenation) have been rewarding in the search for degradation products. These, however, have been limited in number and their nature has made them difficult to relate to the parent substance with the exception of those derived from its basic portion. More recently it has been possible, for the first time, to achieve a crystalline oxidation product. Chromic acid in dilute sulfuric acid has given a mixture from which an acid fraction in good yield has been separated. This fraction, still a mixture, could not be directly crystallized. However, when heated to 180° evolution of carbon dioxide occurred, with production in good yield of a crystalline product which was non-nitrogenous (m. p. 273–278°), $[\alpha]^{25}D$ +47.6° (c = 0.925 in pyridine). Analysis indicated a formula $C_{14}H_{14}O_6$. Calculated: C, 60.41; H, 5.07. Found: C, 60.51; H, 5.20.

Diazomethane gave a product which crystallized readily from acetone (m. p. 165–166°). Analysis indicated 2 methoxyl groups. Calcd. for $C_{16}H_{18}O_6$: C, 62.75; H, 5.92; OCH_3, 20.26. Found: C, 62.96; H, 6.07; OCH_3, 19.90. The

molecular weight by the Rast method was found to be 326. Calculated for $C_{16}H_{18}O_6$, 306.14.

15.06 mg. of the acid in 2.5 cc. of alcohol was titrated against phenolphthalein. Found 1.014 cc. of 0.1 *N* NaOH; calculated for 2 equivalents, 1.082 cc. No additional alkali was consumed after boiling with excess 0.1 *N* sodium hydroxide.

14.96 mg. of the ester required 0.478 cc. of 0.1 *N* NaOH for direct titration in the cold. Calculated for one equivalent: 0.488 cc. After boiling for two hours an additional 0.437 cc. of alkali was consumed.

From these data it appears likely that the substance contained a labile lactone group and that one of the two methyl groups introduced with diazomethane involved a phenolic or enolic hydroxyl. Presence of a phenolic or enolic group was indicated by a prompt, deep red-purple color obtained with ferric chloride. The acid as well as the ester coupled with diazotized sulfanilic acid. On hydrogenation with platinum approximately 3 moles of hydrogen was absorbed, but the product could not be crystallized. It no longer gave the original color reactions.

These properties suggest that the substance contained a benzene ring and is possibly the lactone of a substituted tetrahydronaphthalene. However, the substance when treated with alkali gave a solution from which carbon dioxide was liberated on acidification. From this solution crystalline degradation products could be isolated which suggested that the original acid is capable of undergoing decomposition similar to that of β-ketonic acids. The phenolic or enolic character may therefore be due to such a grouping and thus the unsaturation of the substance to the presence of ketonic linkages rather than to a benzene ring. The details of this further degradation must be left to a later communication.

Our previous studies [*J. Biol. Chem.*, **119,** 141 (1937); **120,** 447 (1937)] have indicated that the basic portion of the cevine molecule is a substituted octahydropyridocholine. The substance, $C_{14}H_{14}O_6$, must be derived from that portion of the molecule all or in part distinct from the basic portion.

NEW BOOKS

The Principles of Electrochemistry. BY DUNCAN A. MACINNES, Associate Member, Rockefeller Institute for Medical Research. Reinhold Publishing Corporation, 330 West 42d Street, New York, N. Y., 1939. 478 pp. Price, $6.00.

This book treats the conductive and thermodynamic properties of electrolytic solutions and is not concerned with metallic and gaseous conduction, which the author considers a branch of electrophysics. After a brief historical introduction, there follows an excellent treatment of transference phenomena embodying the masterly researches of the author and his collaborators on the moving boundary method and precision conductance determinations; several well written chapters on the thermodynamics of galvanic cells, standard electrode potentials and the ramifications of Debye–Hückel theory. The vexing problem of liquid junction potentials receives a critical and modern treatment. The practical determination and meaning of *p*H, conductance methods, oxidation potentials, potentiometric titrations with the glass and other electrodes which have found wide application, are adequately presented. Conductance in non-aqueous and mixed solvents is treated in an up-to-date fashion. The book closes with chapters on ionization constants and structure, effects of centrifugal forces, dielectric constants, passivity and overvoltage, and the latest accepted developments in electrokinetic phenomena.

A comparison of the tables with those of previous texts gives ample evidence of the discrimination that has been exercised in assembling these data. The expert will notice the omission or correction of many of the time-honored values of the pioneers but he will be gratified to learn that these omissions and corrections are the result of painstaking recomputation and critical evaluation of the data from the original sources. Misprints and errors of statement are rare. On page 142, eq. 19, "extremely dilute" instead of "infinitely dilute" would be a more concrete expression. On page 143, *kappa* is to be held constant in the Güntelberg–Müller charging process. The reviewer has not found a single meaningless sentence. The format and printing are in keeping with the high standard of presentation.

Readers interested in locating the very latest theoretical contributions or commercial applications will be disappointed. The author consistently refrains from including theories which have not been adequately verified by experiment, and makes no pretense of dealing with the patent literature.

The artifice of eliminating both liquid junction potentials and activity coefficient corrections in concentration cells by "swamping" with an inert electrolyte deserved mention by the author at least as a simple practical device for determining ionic concentrations. It is unfortunate that the author, in presenting Güntelberg's data (pp. 170–171), did not seize the opportunity to demonstrate the excellent agreement of these data in each case with the specific osmotic properties of the solvent. By introducing the Gibbs–Duhem equation, electrochemistry, instead of appearing as a separate subject, can be correlated with general solution theory in a comprehensive manner. However, like Donnan membrane potentials, some important topics had to be eliminated to keep the book within reasonable compass. The book should prove to be an excellent treatise in Theoretical Electrochemistry.

VICTOR K. LA MER

An Introduction to the Principles of Physical Chemistry. By O. MAASS, Macdonald Professor of Physical Chemistry, and E. W. R. STEACIE, Associate Professor of Chemistry, McGill University. Second edition. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1939. ix + 395 pp. 102 figs. 15.5 × 23.5 cm. Price, $3.00.

The second edition of this text is considerably larger and more complete than the first edition. Many matters which were passed over too rapidly and superficially have now been elucidated in more detail. The discussions are clear and understandable, being particularly adapted to those students who have not had any mathematics beyond algebra. The discussion of electrolytic solutions has now been brought up to date although it is a little unfortunate to begin with the laws of osmotic pressure.

The treatment of reaction rates is now much more rigorous than formerly. While on page 291 the statement is made that "the chemical equation, therefore, does not necessarily represent the true course of reaction," the student might obtain an erroneous idea from the previous two pages. The statement is made on page 290 that the initial rate of a reaction

$$A + B + C + \ldots \longrightarrow \text{(Products)}$$

is given in its initial stages by

$$\text{Rate} = kC_AC_BC_C \ldots$$

The discussion on this and the next page creates, therefore, a rather unfortunate impression which may not be completely eradicated by the more correct statements on the following pages.

On the whole, however, the book is exceedingly well and clearly written and is admirably adapted to give an introduction in physical chemistry to those students who have not had much previous experience with physics and mathematics.

Baron Joji Sakurai

JOURNAL OF THE
AMERICAN CHEMICAL SOCIETY

VOLUME 61 SEPTEMBER 8, 1939 NUMBER 9

BARON JOJI SAKURAI*

1858–1939

BY KOICHI MATSUBARA

Joji Sakurai was born in Kanazawa, Ishikawa Prefecture, on August 18, 1858. Coming to Tokyo in 1871, he entered Daigaku Nanko, the forerunner of the Tokyo Imperial University, where he received general education in modern sciences, specifying himself, later, in chemistry. In 1876, he was sent to England by the government to study under Professor A. W. Williamson in University College, London. Soon Sakurai distinguished himself by carrying off the gold medal in chemistry at the end of the first year, and secured the Clothworker Scholarship for two following years. In 1879, he was elected a Fellow of the Chemical Society, London, of which he has been a life member, and elected an Honorary Fellow in 1931.

Returning home in 1881, Dr. Sakurai was appointed lecturer in the newly established Tokyo University and, in the following year, promoted to a full professorship which he held until 1919, when he reached the traditional age limit and retired from the University, after serving the cause of science and education for nearly forty years, not only as a teacher but also as a University Councillor, Dean of the Faculty of Science and Acting President of the University. The title of Honorary Professor of the Tokyo Imperial University was conferred on him soon after.

The Degree of Rigakuhakusi (D.Sc.) was conferred upon Prof. Sakurai in 1888. In 1901, the Honorary Degree of Doctor of Laws was conferred upon him by the University of Glasgow, when he attended the celebration of the Ninth Jubilee of the University as a representative of the Tokyo Imperial University. He was elected a member of the Imperial Academy of Tokyo in 1898, in which he was elected the President in 1926, after assiduous service as Secretary during the preceding thirteen years. He was reëlected several times and remained in the post until his death.

Professor Sakurai was, in brief, the founder of Scientific Chemistry in Japan. He worked at first in the field of organic chemistry, but his natural bent of mind was in the direction of theoretical and physical chemistry. When the brilliant researches of van't Hoff, Ostwald, Arrhenius, Nernst and a host of others were published in succession, he recognized at once their immense importance, and endeavored to take up the new

(*) This Obituary is based on a note left by Professor Sakurai himself. A notice nearly the same as this was contributed by Professor Yukichi Osaka to the *Proceedings of the Imperial Academy, Tokyo*, **15**, No. 2, February (1939). Here my name is affixed both as one of those who were pupils of Professor Sakurai in the last decade of the nineteenth century and were near him ever since, and as a present member of the American Chemical Society.—K. M.

principles and introduce them in all stages of chemical education. Among the scientific contributions of Prof. Sakurai, special mention may be made of his modification of Beckmann's ebullition method for the determination of molecular weight, published in 1892. To avoid superheating, he passed the vapor of the solvent through the solution, and succeeded in overcoming the difficulty. This idea was followed by several other investigators.

Professor Sakurai was one of the most active members of the Chemical Society of Japan almost since its foundation as the Tokyo Chemical Society in 1878, and served as its president for several terms of office. When he completed twenty-five years of his professorship in 1907, the occasion was celebrated by his friends and former pupils. On this occasion, a respectable sum of money was raised to be used as a fund in association with his name under the direction of the Chemical Society.

Important as were the contributions to chemistry and chemical education in the earlier years of his career, Prof. Sakurai was destined to be an outstanding promoter of research activities in Japan and her international cultural relations. Indeed, he left imperishable footprints in both of these fields.

The bitter experience in the World War, which deprived Japan of several necessities, which had been imported from Germany, taught the nation a valuable lesson in the importance of self-supply. Professor Sakurai and his colleagues lost no time in embarking upon a movement with the object of realizing an independent research organization. This movement, strongly backed by influential men of business, succeeded in raising an ample fund, including a subsidy from the government, and in consequence Rikwagaku Kenkyusho (Institute of Physical and Chemical Research) was established in 1917. At the same time, H. M. The Emperor graciously made a contribution to the fund of the Institute. The Institute is now, as is well known, one of the most important and active centers of research in Japan, in the field of exact sciences and their applications.

When the International Research Council, renamed afterwards International Council of Scientific Unions, was organized as the result of the conferences held in London and Paris in 1918, in which Prof. Sakurai was a representative of the Imperial Academy, that Academy proceeded at once to organize a National Research Council. It was Prof. Sakurai who drafted the Constitution and actively promoted its organization. He was elected the President of the National Research Council shortly after its foundation, and remained in the position until his death.

Professor Sakurai was always looking to another sort of organization of a much wider scope, namely, an organization having for its main object the general promotion of research in all branches of science, pure and applied, by giving aids in research funds to competent scholars. The movement for its realization was started in 1931 by convening a meeting of the representatives of all the Universities, important research organizations and other like bodies. As the most important effect of the meeting, two Houses of the Imperial Diet soon adopted by a unanimous vote a resolution aiming at the speedy promotion of scientific research. Those directly concerned in the movement were deeply moved when, in August, 1932, it was officially announced that H. M. The Emperor was graciously pleased to make a magnificent gift toward the fund of the proposed organization for the encouragement of scientific research. The government was now determined to take definite steps to help the organization with an ample subsidy, and the Nippon Gakujutu Shinkokwai (Japan Society for the Promotion of Scientific Research) came into existence with H. I. H. Prince Chichibu as Patron and Viscount Saito, then Premier, as President. Professor Sakurai was elected Chairman of the Board of Directors, and the Society started its work from the fiscal year commencing April 1, 1933. At its seventh general meeting on January 19, 1939, Prof. Sakurai gave an eloquent official address to the meeting. On the next day he took cold, suffered pneumonia and passed away after eight days.

His long stay in London and his attendance at many international scientific meetings, combined with his extended tours in the world gave him splendid opportunities of studying men and world affairs, of which his knowledge was both deep and wide. This knowledge and his love of mankind, besides his being President of the Imperial Academy and of the National Research Council for so many years, made him a figure particularly suited to promoting Japan's international cultural relations.

In recognition of the valuable services rendered to the State, Prof. Sakurai was, in 1920, appointed by the Throne a member of the House of Peers

and, six years later, Privy Councillor, this being the first occasion on which a man of purely scientific career has been raised to the high post of supreme adviser to the Throne. Further, in 1916, the Order of the First Class of the Sacred Treasure was conferred upon him and in addition, in 1929, that of the Grand Cordon of the Rising Sun. Shortly before his death, Prof. Sakurai was decorated with the Order of the Grand Cordon of the Rising Sun and Paulownia and was created a Baron in recognition of his meritorious services to the State.

Professor Sakurai's work was also widely recognized abroad. In addition to his election as an Honorary Member of the American Chemical Society in 1926, he received the Honorary Degree of LL.D. from the University of Glasgow in 1901, was elected an Honorary Member of the Chemical Society of France in 1923, the Society of Chemical Industry (of London) also in 1923, the Royal Institution of Great Britain in 1925, the Academy of Sciences of U. S. S. R. in 1927, the Chemical Society of Poland in 1929 and the Chemical Society (of London) in 1931. On the occasion of his last visit to London in 1937, he was elected by his *alma mater* an Honorary Member of University College, London, an honor which had never before been bestowed upon a foreigner.

The Polyhydric Alcohol–Polybasic Acid Reaction. III. Further Studies of the Glycerol–Phthalic Anhydride Reaction[1]

BY R. H. KIENLE,[1] P. A. VAN DER MEULEN AND F. E. PETKE

Since the appearance of the first paper of this series,[2] the polyhydric alcohol–polybasic acid reaction has become the basis for a large number of industrial products. Several excellent scientific treatments have been published covering the simple bi-bi functional or non-convertible type polyester polymerides, that is, those obtained from dihydric alcohols and dibasic acids.[3] The glyceryl phthalate reaction,[4] however, still remains the only convertible or higher functional saturated polyester polymeride to which scientific attention has been directed in spite of the clarification that a study of other similar systems should have offered to the problem of resin formation.

In the previous paper on glyceryl phthalate, the data seemed to indicate that the reaction was simple esterification. Such being the case, it followed that all polyester polymerides might be studied by carefully determining the rate and amount of water formed as the reaction proceeded, then directly calculating acid values and percentage esterifications therefrom. Several of the recent investigations on glyceryl phthalate,[5] however, raised some doubt as to the validity of this deduction that only esterification was involved. It was decided, therefore, prior to investigating other polyester systems, to reinvestigate thoroughly the glyceryl phthalate reaction under more rigidly controlled conditions than was done previously, to collect continuously all the products evolved, and to examine in detail resin samples representative of the progress of the reaction.

Recently several kinetic treatments, particularly for the non-convertible polyester polymerides, have been presented principally by Chalmers,[6] Dostal, Mark and Raff,[7] Alatman and Kedrinski,[8] Flory,[9] and Davies.[10] These treatments, with the exception of that by Davies, have all been made on fairly limited experimental data. Very little has been done kinetically, however, with the convertible polyester polymerides, especially when the reaction is carried out under conditions as usually encountered in practice, that is, where the condensation products are removed as formed. In obtaining our experimental data an attempt was made so that sufficient evidence would be available to allow subsequent presentation of a kinetic treatment.

Experimental

Apparatus and Procedure.—After considerable experimentation and many changes, during which time a number of physical factors governing polyester reactions were examined and placed under control, an apparatus was finally developed wherein polyester formation could be carried out under carefully controlled and exactly reproducible conditions and in which the water formed could be instantly and accurately determined. Because this apparatus will be referred to in later papers of this series, it will be described at this time in some detail. The apparatus is illustrated in Fig. 1.

In the experiments on glyceryl phthalate the charge used was such as to theoretically produce $^1/_4$ mole of resin calculated as glyceryl triphthalate, *i. e.*, $^1/_2$ mole or 46.0 g. of glycerol, $^3/_4$ mole or 111.0 g. of phthalic anhydride. In the relating experiments with other polybasic anhydrides, the charges were adjusted to yield an equivalent volume. Whenever polybasic acids were employed, because of the limitation effected by the size of the water-collecting chamber (E) and the increased volume of water evolved, a charge approximately one-half that employed for the anhydride experiments was used.

The water evolved could, of course, have been determined gravimetrically by using a suitable absorbent medium in an absorbent train attached to the outlet of the reaction flask. This would, however, have required continual weighings which would have made rapid readings very difficult. Therefore, a volumetric method was employed. It was essential in the design of the water-collecting chamber that immediately any water was evolved in the reaction flask (A) it was condensed and appeared

in (E). The calibrated tube used to read the water evolved in (E) had, therefore, to be as close to the reaction flask as possible and the condensation in (E) had to occur with little or no time lag. Furthermore, many of the polybasic acids, particularly in the early stages, possessed subliming tendencies. It was therefore necessary that (E) be filled with a liquid which would dissolve and remove any of such sublimate that might be formed and carried over by the inert gas. It was also recognized that whatever liquid was used in (E), water must be insoluble therein and readily form a sharp distinct meniscus. After considerable experimentation, it was found that a mixture of three parts by volume of toluene to one part by volume of acetophenone was a suitable liquid to use.

It was realized that the gas flow and speed of stirring might have an important effect on the rate of the polyester reaction. These factors were therefore investigated and both were found to be important. In order to obtain reproducible results, a certain optimum definite gas flow and speed of stirring had to be used.

The gas flow was adjusted by observing the rate at which the gas bubbled through the sulfuric acid drying bottle (H). It was found that a rate of three bubbles per second was the optimum for use. With this gas flow, a stirring rate of 400 r. p. m. for stirrer (S) was found to be satisfactory.

The experimental technique was first carefully to weigh out the acid or anhydride into the reaction flask (A). The apparatus was then assembled and the proper amount of polyhydric alcohol carefully introduced into the dropping funnel. In order to prevent any contamination from the exterior and in order thoroughly to seal the apparatus, all the ground glass joints on assembling were lubricated with a small amount of glycerol. The apparatus, once assembled, was placed in the constant temperature bath (D) and with gas very slowly flowing through, heated until the polybasic acid or anhydride was at the temperature at which it was intended to carry out the reaction. The polyhydric alcohol in the dropping funnel, in the meanwhile, was brought to this same temperature by means of a free flame played on the outside thereof. When both the polybasic acid or anhydride and the polyhydric alcohol were at the reaction temperature, the gas was stopped momentarily and the polyhydric alcohol run into the flask. This addition was taken as the zero time for the reaction. Upon the completion of the addition of the polyhydric alcohol, which rarely took more than fifteen seconds, the glass stopper of the dropping funnel was closed and the gas flow adjusted to the proper rate.

When phthalic anhydride was used, because of its subliming tendency, a small amount was transferred by the gas stream to the toluene–acetophenone in the water-collecting chamber. The actual amount thus carried over was determined at the end of any run by analyzing the toluene–acetophenone mixture.

As water was evolved, it was transferred immediately into the water-collecting chamber where it was condensed, dropping to the bottom of the collecting tube where the amount given off could be accurately read as a function of the time of reaction. The small amount of water vapor carried in the gas stream was trapped by means of the anhydrone, the increase in weight of the anhydrone being determined for each run, at regular intervals, by removing the absorption bottle (G_2) and weighing it. In order to eliminate any possibility of loss during the weighing operation, a second pre-weighed (G_2) absorption bottle was used as a replacement, while the first absorption bottle was out of the system. The increase in weight of the anhydrone was thus plotted as a function of time, from which curve corrections were made to the amount of water evolved as read in the collecting tube, giving the true water evolved.

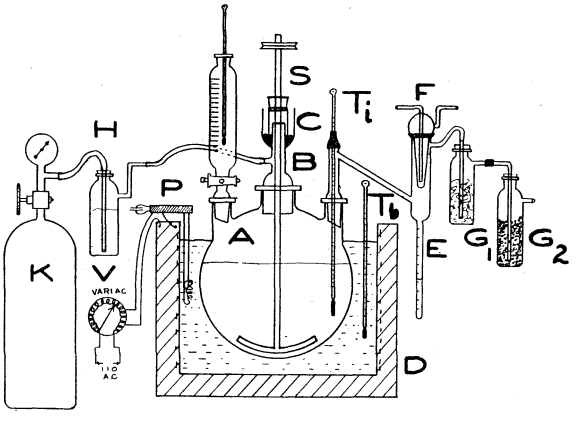

Fig. 1.—Apparatus for preparation of glyceryl phthalate. A, Pyrex reaction flask (500 cc.); B, adapter with side-arm; C, mercury seal stirrer (S); D, constant temperature wax bath; E, 10-ml. water-collecting chamber; F, condenser; G_1, absorption bottle (glass wool); G_2, absorption bottle (anhydrone); H, gas drier (sulfuric acid); K, gas cylinder (nitrogen or carbon dioxide); P, de Khotinsky thermo-regulator; V, variac (General Radio Company).

In order to prevent any condensation of moisture in the upper part of the reaction flask, adapter (B), or that part of the water-collecting chamber connected to the reaction flask, all these parts were heated during a run by continually playing a Bunsen burner thereon.

It was thus possible to carry out reproducible polyester formation reactions accurately and determine the rate at which the water was evolved. It was also possible to carry out these reactions so that samples could be taken out at regular intervals and the reactions studied by subsequently studying the composition of these samples at the various stages. And, finally, it was possible to carry any of the desired polyester resin-forming reactions along to some particular predetermined end-point and to be reasonably assured that the rate at which that end-point was achieved was, to all purposes, the same as passed through in carrying out the complete reaction.

Materials.—The phthalic anhydride for this investigation was resublimed C. P. phthalic anhydride obtained from the Selden Division, American Cyanamid Company, which material itself had already been sublimed in its preparation.

The glycerol was obtained by twice distilling Procter and Gamble C. P. water-white glycerin at 6 mm. pressure in an atmosphere of nitrogen. A small portion was then frozen rapidly in carbon dioxide and alcohol with continual

stirring until small crystals were obtained. These crystals were used to seed the specially distilled glycerol and the entire product crystallized by maintaining in a sealed container and a thermostat set at 17°. This crystallized glycerol was then brought to room temperature and the first portion melted, decanted and discarded. The remaining portion was used in the experiments. Its constants were: specific gravity at 20°, pycnometer corrected for vacuum, 1.2631; index of refraction at d_{20} 1.4741. This compared with the data given by Bozart and Snoddy[11] for 100% glycerol: specific gravity at 20° 1.2633; index of refraction at d_{20} 1.4740.

The Reaction at 200°

The glycerol–phthalic anhydride reaction was studied in detail at 200°. This temperature was chosen because experience showed that at 200° the reaction progressed at a rapid rate but not at such a rapid rate that it could not be followed accurately; also, it represented an average temperature at which alkyd resins are prepared commercially.

[a] Calculated at each point from the water evolved–acid value curve, which curve was established carefully by a large number of individual determinations.

Studies were made to determine whether the reaction could be carried out quantitatively. A large number of experiments revealed that the loss in weight obtained after the reaction had been completed equalled the sum of the amount of water evolved and collected in the water-collecting chamber, plus such correction as it was necessary to make for the water carried off by the inert gas, and the amount of phthalic anhydride that had been carried over into the toluene–acetophenone mixture.

In order to determine whether or not the liquid which was collected and measured in the water-collecting chamber was actually water, at the end of one of the runs the entire contents of the water-collecting chamber was placed in a separatory

(11) Bozart and Snoddy, *Ind. Eng. Chem.*, **19**, 506 (1927).

funnel. After allowing sufficient time for complete separation, the lower layer was then removed and examined. It was neutral to litmus and tasteless. The index of refraction was determined in an Abbe refractometer and found to be $n^{22}D$ 1.333 which agrees very well with the value for pure water as given in the "International Critical Tables."

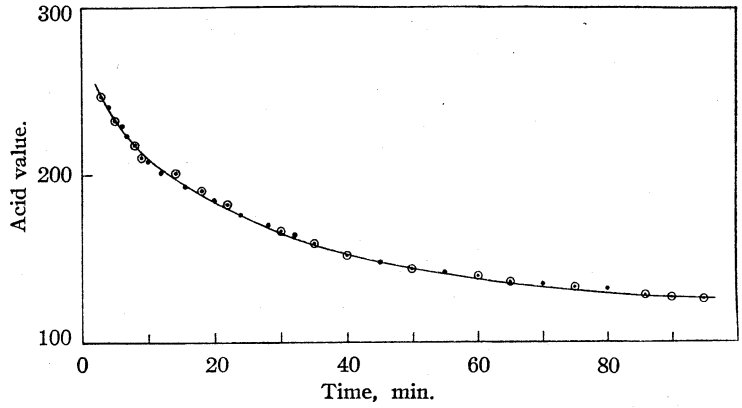

Fig. 2.—Glyceryl phthalate: variation of acid value with time at T = 200°; ●, expt. 39; ⊙, expt. 40.

It was observed, as in previous studies of this reaction, that when the reactants were brought together at 200°, an almost instantaneous exothermic interaction occurred, the temprature rising approximately 35°. In this interaction, no evolution of water was obtained, but the acid value dropped from an initial one of 535.7 to approximately 267. In other words, an initial 50% esterification occurred.

A detailed study of the water evolved–acid value relationship was undertaken. In order accurately to establish this relationship, it was necessary to make individual experimental runs to certain water evolved values and, on the resulting samples, to determine the acid values, having previously established the fact that experimental runs carried to the same water evolved values gave substantially identical acid values. This gave a series of samples of sufficiently large size that such properties as ultimate composition, molecular weight, viscosity characteristics, etc., could then be determined readily as a function of the progress of the reaction. But it was necessary to be certain that no change occurred in the samples on standing. A study was therefore made of what effect aging for several weeks had on the samples from various stages of the reaction. Except for a slight change in the early stages, the samples were apparently unaffected.

The complete water evolved–time data for the reaction at 200° are given in Table I. The corresponding acid values attained are included. As the reaction proceeded, the bath temperature (T_b), the temperature of the reaction itself (T_i), and the amount of water collected in the water-collecting chamber (V_0), were recorded carefully at every time interval that readings were taken. From the water–correction curve, V_0 was corrected to give V_a, the actual amount of water evolved. It is obvious that at the temperature of 200° very little correction in V_0 is necessary.

The change in acid value as a function of time, T, 200°, is plotted in Fig. 2, the complete data for experiments 39 and 40 being included. It is evident that both runs give exactly the same curve, showing that the reaction is accurately reproducible. In Fig. 3, the water evolved–time curve is plotted similarly.

From these two curves, Fig. 4 has been constructed which shows the water evolved–acid value relationship. In addition, the experimentally determined values of a number of individual runs also have been given. It will be seen that these individual values quite accurately fit the curve obtained by combining Figs. 2 and 3, showing that the water evolved–acid value relationship

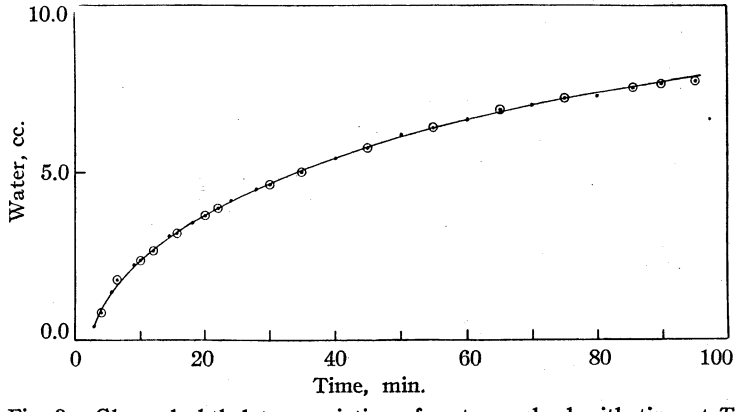

Fig. 3.—Glyceryl phthalate: variation of water evolved with time at T = 200°; ●, expt. 39; ⊙, expt. 40.

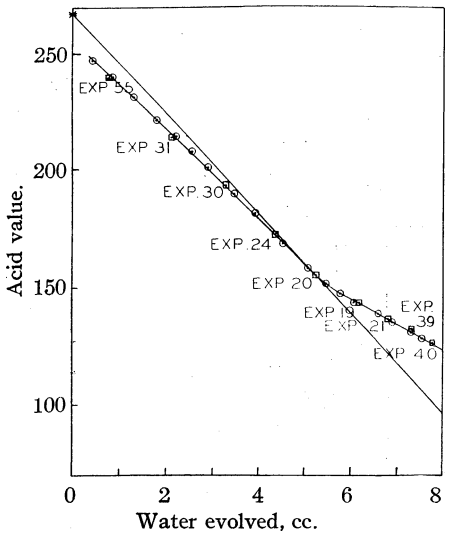

Fig. 4.—Glyceryl phthalate (anhydride): water evolved—acid value relationship.

is the same whether obtained by the method of individual runs or by the graphical method of combining the complete acid value–time run with the water evolved–time run. In Fig. 4 there is shown also the theoretical relationship between the volume of water evolved and the acid number on the assumption that, immediately after 50% esterification had been attained without loss of water, subsequent resinification occurred with evolution of water and with only esterification occurring at all times. The equation representing this theoretical relationship is

$$A = 378.9\frac{P - P_c}{W - P_c} - 3110\frac{V}{W - T} \qquad (1)$$

wherein A is acid number; P, weight of phthalic anhydride used; W, the total weight of ingredients; T, total weight loss in experiment; V, cc. of water evolved; and P_c, weight of phthalic anhydride lost in the experiment.

It is evident, when Fig. 4 is examined, that in the early stages of a glyceryl phthalate reaction there is less water evolved than is required on the assumption that only esterification has taken place. In the later stages of the reaction, more water is evolved which suggests that over this portion of the reaction some anhydride formation occurs.

Numerous attempts were made to treat water evolved and acid value data for glyceryl phthalate kinetically. It is sufficient to indicate at this point that no simple kinetic relationship was found applicable to the entire data.

In order to get some idea of the "beyond the gel" state, an experiment was made in which the rate of water evolution was followed well beyond the gel state. That portion of the data which covers the portion of the reaction just prior to and beyond gelation, is shown in Fig. 5. The point at which gelation occurred is indicated clearly by an arrow. It is evident from this curve that condensation continues beyond gelation with such change of rate as takes place seemingly resulting from the physical limitations of intercontact of the molecules brought about by the state of arrested motion that occurred at gelation.

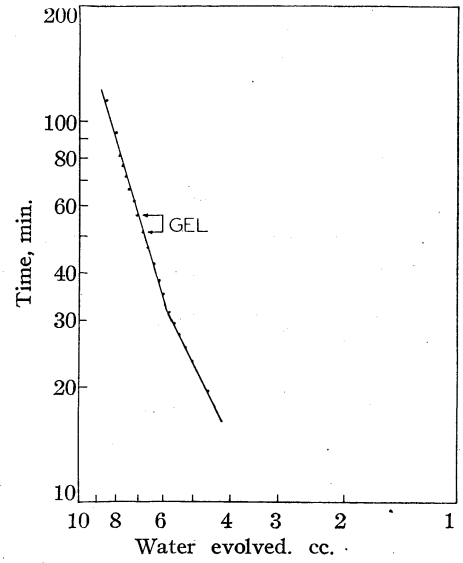

Fig. 5.—Glyceryl phthalate: water evolved, V_0, before and after gelation.

Effect of Temperature

The reaction was studied over the temperature range 160–215°. A number of individual experiments revealed that over this temperature range the same acid value is attained for any given water loss independent of the temperature. This having been established, detailed quantitative water evolved–acid value–time runs were carried out at 160, 185 and 215°. The data obtained, as well as those given in Table I, are plotted as a log acid value–log time relationship in Fig. 6.

In Table II are summarized for the various temperatures, the time for gelation to occur and the water evolved. It will be noted that the amount of water evolved at gelation appears to be independent of the temperature. Using the gel point, therefore, as a common reference state for the reaction, the heat of activation has been calculated and found to be 21,600 cal. per g. mole.

TABLE II

EFFECT OF TEMPERATURE

Temp., °C.	Time, min. gelation	Water evolved, cc.
160	860	7.98
185	255	7.99
200	105	7.99
215	50	7.98

Physical and Chemical Variations as Reaction Progresses

Analytical.—In Table III are summarized the analytical data of the various glyceryl phthalate samples prepared in the 200° temperature studies. The methods used in determining the acid value and saponification value already have been described[2]; carbon and hydrogen were determined by the standard micro-chemical methods now in use for these elements.[12] The values given for the sample marked "gel" are only approximate. The sample marked "degelled" was prepared by taking a portion of the gelled resin, placing in a Pyrex tube, sealing the tube and heating in an oven overnight at a temperature of approximately 150°. A fusible, amber, resinous product resulted which was now soluble in acetone and which cured only very, very slowly when a small portion was placed on a hot-plate at 200°. Data on the degelled sample are included for whatever bearing such data might have on the later theoretical speculations.

Infrared Spectra.—Infrared spectra on the samples described in Table III and covering the range from 1–15 μ have been measured. The details of this investigation will be reported elsewhere.[13] The spectra showed that the glyceryl phthalate samples for the various acid values fell into groups rather than varying continuously, the spectra of the several samples in a given group being quite similar one with another.

Of special interest in the infrared investigation were the spectra of the degelled samples. These were found to be similar to the corresponding polymeride of the same acid value obtained when approaching gelation, making the assumption that gelation is the result of the formation of a gigantic molecule very questionable.

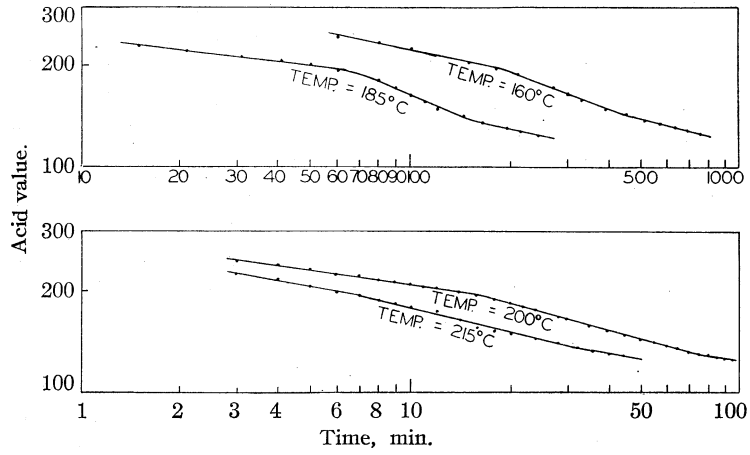

Fig. 6.—Glyceryl phthalate: acid value–time isotherms.

Molecular Weight.—For the determination of the average molecular weights, a cryoscopic solvent was sought in which the polyesters were all very soluble, in which water was immiscible, and in which duplicate values, unaffected by moderate changes in concentration of resin used, could be obtained. Acetophenone (K = 5650) was found to answer these requisites. In the experimental data presented, carefully distilled acetophenone was employed throughout, its suitability being checked with specially purified naphthalene.

The average molecular weights found for the various glyceryl phthalate samples are given in Table IV together with the concentrations at which the measurements were made and the depressions observed. In Fig. 7, these average molecular weights are plotted against the corresponding acid values.

How the molecular weight would vary with the acid value if any ideal (2,3) continuous interesterification alone occurred is shown as the so-called theoretical curve in Fig. 7. The deviation of the

(12) Acknowledgment is made to Dr. G. L. Royer for carrying out these determinations.

Degel	142	3.98	.227	680

actual data from the theoretical shows that other molecular species in variance with simple interesterification must be forming. The fact that the experimental curve falls below the theoretical, and in keeping with the general evidence that the reaction is essentially esterification, strongly suggests intraesterification. These average molecular weights must be dovetailed with the other data such as acid value, water loss, etc., in modifying the reaction and structural consideration.

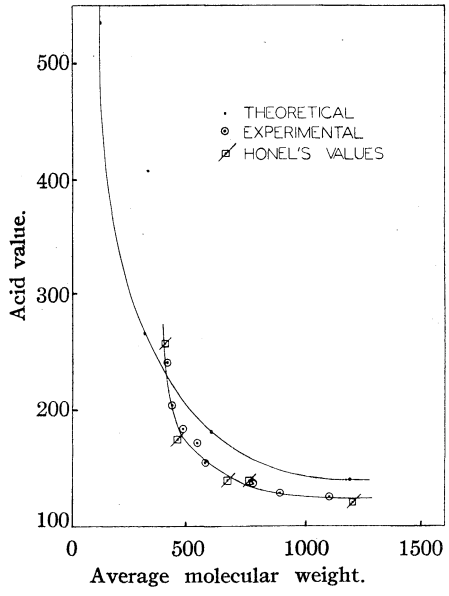

Fig. 7.—Glyceryl phthalate.

Viscosity Studies.—As a further possible adjunct to information concerning the molecular changes in the glyceryl phthalate reaction, viscosity measurements were undertaken.

Working in dioxane, Kienle and Race[14] reported the viscosity characteristics of a series of glyceryl phthalate samples at various acid values. A similar investigation was later made by Houwink and Klaassens.[4] There is a fair agreement between the values reported in both these papers for the samples taken at the early stages of the reaction. Houwink and Klaassens, however, were not able to obtain the high value reported by Kienle and Race for the very last stages. But Houwink and Klaassens, in their measurements, used as a final sample one which was a considerable time period away from gelation, while Kienle and Race used a sample just prior to gelation. All of these values reported, however, were low as compared with numerous specific viscosity values given by Staudinger for other synthetic polymerides, such as polystyrene. If the contention of Staudinger, that specific viscosity bears relation to the molecular size, has the importance he attributes thereto, this would indicate that glyceryl phthalate is definitely a small polymeric molecule.

The present measurements were made using C. P. acetone (A. V. = 0) as a solvent at a concentration of 15.0% by weight. The measurements were made in a vacuum capillary type viscometer described by Gregory, Ressweiler and Lampert,[15] and were carried out at 35°. The average values of several determinations have been corrected for the density of the solution in each case. The values obtained for the different glyceryl phthalate samples are given in Table V. It will be noted that until an acid value of less than 137 is reached, only a small steady increase in the specific viscosity is observed. From then on, the increase is rapid in line with Kienle and Race's original observations. The rather rapid increase in specific viscosity that begins at an acid value of approximately 137 indicates that a change in molecular complexity occurs when this acid value is reached. Up to this time, the molecules probably were of such small size that they had some, although little,

effect on the viscosity. Beyond this point, the reaction started to produce large enough molecules to be effective in causing a pronounced increase in viscosity.

Monomolecular Films.—It was found that the various glyceryl phthalate samples readily formed monomolecular films. These have been studied in detail and will be reported upon later. Although Moss[16] and Harkins[17] investigated some of the linear polymerides in this manner, as far as is known, no measurements have been reported on convertible polymerides.

By means of the usual method of intercepts, it was possible to determine an area which represented the area per molecule of the average molecular species, A_{max}, present in any given sample. The values of A_{max} and the corresponding acid values are given in Table VI and are shown in curve form in Fig. 8.

TABLE VI

AREA PER AVERAGE MOLECULE, A_{max}, OF SEVERAL GLYCERYL PHTHALATES AS MONOMOLECULAR FILMS ON 0.001 *N* HCl

Acid value	Area/molecule, A_{max} (Å.)²
240	31.1
204	35.5
184	52.0
155	74.0
137	129.2
126	138.8

Fractionation.—While studying the various glyceryl phthalate samples in glacial acetic acid solution, it was observed that when this solution was drowned in a large volume of water, white amorphous precipitates frequently resulted. It was found that if the water was made slightly acid with hydrochloric acid, the precipitate obtained was readily filterable and often granular in nature. Undoubtedly low molecular weight portions were separated from the larger molecules by this treatment. Thus some idea of obtaining the size of the latter seemed a possibility. A fractionation was therefore made, using glyceryl phthalate, A. V. 130.

Fifteen grams of the resin was dissolved in 150 g. of glacial acetic acid. This solution was added slowly to 1500 cc. of water which had been acidified with hydrochloric acid. The resulting precipitate was reslurried in distilled water, washed several times by decantation, filtered, and dried at 60°. The acid value was found to be 92.2, and

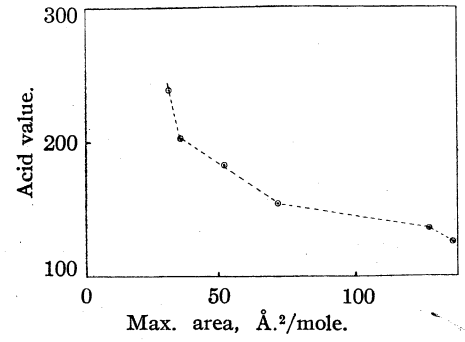

Fig. 8.—Glyceryl phthalate: monomolecular area per average molecule as function of acid value.

the molecular weight in acetophenone was 2580. It is interesting to compare these values with the theoretical values calculated if only interesterification were involved. On the assumption that a condition of interesterification equivalent to tetramer formation has occurred, which is required by the molecular weight and other data, the acid value resulting would be 117 and the molecular weight 2384. If intraesterification occurred at one position on the molecule along with the interesterification, the acid value would be 94.5 and the molecular weight 2366. These latter values are in fair agreement with the values found experimentally.

It has been known for some time that if polyester resins are dissolved in acetone, water can be added slowly and, at a certain point, precipitation or turbidity occurs. The amount of water that can be added to any given solution and the character of the precipitate obtained seemingly depend on the extent to which the resin has been carried in its preparation. Thus a solution of a partially formed resin will tolerate a large amount of water and will give a very gummy precipitate while a resin near the gel point will tolerate little water and will yield a precipitate quite granular in character.

TABLE VII

PRECIPITATION STUDIES OF GLYCERYL PHTHALATE (ANHYDRIDE) AT 20–21°

Sample	A. V.	Weight, g.	Water used, cc.	H_2O/g. to ppt.	Character of ppt.
55	240	1.0125	66.50	65.50	Colloidal
29	204	1.0040	62.40	62.30	Colloidal
27	193	1.0007	46.20	46.20	Soft, gummy
28	184	1.0006	45.25	45.25	Soft, gummy
24	173	1.0036	41.40	41.30	Soft, gummy
20	155	1.0316	33.60	32.60	Soft, gummy
21	137	1.0065	23.36	23.26	Granular
40	126	1.0050	20.50	20.50	Granular

Approximately 1 g. of each of the glyceryl phthalate resins was dissolved in 50 cc. of C. P. acetone, the actual amount used being carefully weighed and recorded. Each solution was then titrated with distilled water to the point at which cloudiness was first observed. It was possible to obtain this end-point to within 0.05 cc. The data obtained are given in Table VII, and plotted in Fig. 9.

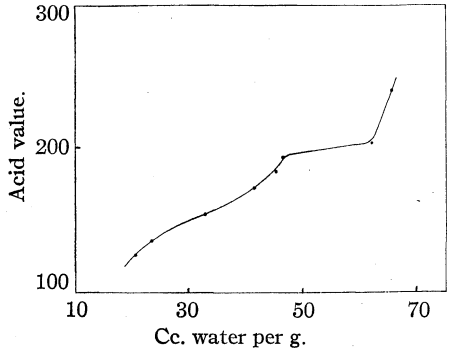

Fig. 9.—Glyceryl phthalate: water required for precipitation.

Theoretical

It has been shown by all the chemical examinations and supported by the infrared spectra data that only C–O–C linkages are formed.[18] Therefore, in modifying the assumption that interesterification was the only reaction involved, the possible secondary reactions to consider were ether formation, anhydride formation, and intraesterification. In the case where equivalent quantities of reactants are involved, as in the present investigation, there was little evidence for ether formation. Anhydride formation and intraesterification, however, appeared to be definite possibilities. A number of glyceryl phthalate samples for which the acid value, saponification value, average molecular weight, and water evolved had been determined were taken and examined as to whether or not possible combinations of polyesters could be postulated, following a common pattern, which would correlate all the data. On the basis of interesterification as the primary reaction with anhydride and intraesterification as secondary reaction possibilities, it has been found possible to derive approximate theoretical compositions which satisfy all of the determined values. In arriving at these calculations, a schematic postulation of the progress of reaction, such as is shown diagrammatically in Fig. 10, was used.

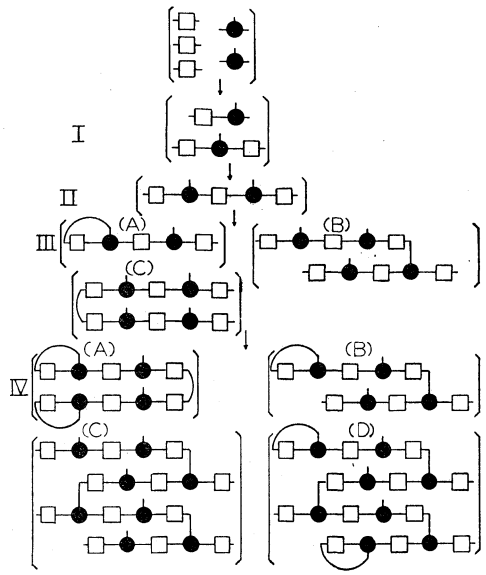

Fig. 10.—Glyceryl phthalate reaction, postulated progress: ratio of 2 moles of glycerol to 3 moles of phthalic anhydride.

Four typical glyceryl phthalate samples have been examined in detail, namely, those with acid values of 235, 184, 137 and 126. It has been possible to propose approximate compositions for each of these samples. These compositions, as well as the agreement between the calculated and the observed analytical data, are given in Table

TABLE VIII

	IVb	.083	
	IVc	.084	
	IVd	.083	
M_v = 1150			

VIII. Examination of this table shows that the agreement between the observed and calculated values is surprisingly good.

The value of M_v in this table requires explanation. It will be observed by examining Fig. 10 that every postulated polymeric molecule is a polybasic acid with a characteristic basicity. Thus the basicity of the molecule represented by IIIb is 3. Any given individual glyceryl phthalate sample will, therefore, have an average basicity, v, depending on the number and kind of polymeric molecules present. Carothers[4] has shown in linear systems, in which the basicity of the polymeric molecules remains essentially constant, that the molecular weights can be determined either by the usual methods or from the acid value. When the molecular weight is determined from the acid value, the following equation applies

$$MA_t = 56.1 \times 10^3 v \qquad (2)$$

wherein M is the average molecular weight, A_t is the acid value at time t, and v is the basicity. In linear polyesters, v is 1, therefore v did not appear in Carothers' calculations. But in the convertible polyesters, the value of v is important. In Table VIII the Mv value was obtained by using equation (2), first determining the average value of v from the composition finally suggested, then substituting this together with the acid value experimentally determined, and solving. It is seemingly additional evidence in favor of the compositions suggested that the molecular weights thus calculated agree very well with the average molecular weights, M, actually determined.

The compositions of the several glyceryl phthalate samples as calculated are in surprisingly good agreement with the various experimental facts observed. Thus, only when an acid value around 190 is reached in the reaction, do molecules of the species III type seemingly appear. From this point on to approximately an acid value of 135, molecules of the species III type are apparently forming. Further on, molecules of the species IV type, with their three dimensional complexities, begin to appear until finally their concentration is sufficiently great to cause arrested motion, that is, gelation. The grouping of the various samples with respect to the infrared spectra is now understandable. The marked change in the character of the precipitate from a gummy to that of a granular, easily filterable type at an acid value of 137 as acetone solutions are diluted with water is explained. When the basicities are taken into account and it is assumed that in monomolecular films the point of attachment to water is through the carboxyl groups, which all prior work on complex acids has indicated is the case, the changing character of the monomolecular areas is also understandable. The non-appearance of the complex three-dimensional polyester molecules of the species IV type, until acid values less than approximately 137 are reached, offers an explanation for the change in specific viscosity that was observed in the neighborhood of this acid value. The introduction of the intraesterification and anhydride modification also accounts for the character of the acid value–water loss relationship. In other words, the general schematic postulation of the progress of the reaction presented in Fig. 10 is consistent with the experimental data that have been obtained for glyceryl phthalate.

It must not be concluded that the polyester compositions developed above are being presented as definite fixed structures. Thus it is suggested that in a glyceryl phthalate resin, such as one represented by an acid value of 126, small amounts of polyesters of even higher degrees of polymerization or complexity than those postulated might well be present.

The possibility that the reaction proceeds entirely in a heterogeneous manner, governed completely by the random chance contact of active groups on the interacting molecules, each active group acting independently and in no organized molecular manner, is therefore questioned. When, however, the reaction has proceeded so that essentially tetramers are being formed and the concentration thereof has approximated 33 mole %, gelation occurs seemingly because, at this concentration, a sufficient complexity of three-dimensional molecules has been built up to bring about a state of arrested motion. It follows that gelation in polymerides is not necessarily attendant with the formation of gigantic macromolecules. Macromolecules may appear later, but gelation apparently occurs, or can occur, when there has formed a sufficient concentration of suitably complex three dimensional molecules of a relatively low degree of polymerization which are capable of intertwining. This may be thought of as analogous to a log jam which always results when a certain minimum concentration of logs becomes permanently interlocked.

Other convertible polyester systems also have

been investigated recently. It was found that the data obtained for these systems could be treated in a manner analogous to the glyceryl phthalate data. It is, therefore, suggested that the essential concepts developed herewith are applicable generally to convertible polymeric systems.

Summary

1. The reaction between glycerol and phthalic anhydride was reinvestigated. A special apparatus, designed so that the reaction could be carried out under controlled reproducible conditions, was used.

2. The reaction was studied in detail at 200°. Samples were taken at various stages of the reaction and their acid value, saponification value, ultimate analysis, and molecular weight determined. The infrared spectra, rheological properties, and spreading characteristics as monomolecular films were ascertained for each of the samples.

3. As the reaction proceeded at 200°, it was shown that the water evolved was greater than calculated from simple interesterification considerations.

4. A schematic progress of the reaction is suggested wherein it is proposed that the underlying reactions are essentially interesterification, modified by intraesterification and anhydride formation. Application of these concepts allowed approximate compositions of glyceryl phthalate polymerides to be derived at various stages of polymerization. The several constants calculated from these postulated compositions were found to agree very well with those measured experimentally.

5. Gelation has been shown to occur at a relatively low average molecular weight, suggesting that molecular growth proceeds until a sufficient concentration of intertwined three dimensional molecules has formed, whence arrested motion occurs.

6. Limited data are presented on precipitation and fractionation studies.

The Polyhydric Alcohol–Polybasic Acid Reaction. IV. Glyceryl Phthalate from Phthalic Acid

BY R. H. KIENLE, P. A. VAN DER MEULEN AND F. E. PETKE

All the studies on the glyceryl phthalate reaction thus far reported in the literature have been carried out with phthalic anhydride. In the present investigation, data are presented wherein phthalic acid was substituted for the anhydride.

The apparatus used and experimental technique employed already have been described fully.[1] The phthalic acid was obtained from resublimed phthalic anhydride (Selden Division, American Cyanamid Company) by dissolving in carbonate free sodium hydroxide solution, then precipitating with hydrochloric acid, thoroughly washing until the wash water tested free from chloride ion, and finally drying carefully at 60° in the air.

The present investigation was carried out at 190°. This temperature was chosen because it was found that at this temperature no anhydride formation occurred during the preheating period employed before the glycerol was added.

(1) Kienle, van der Meulen and Petke, THIS JOURNAL, **61**, 2258 (1939).

Experimental Data

The detailed data obtained for the glycerol–phthalic acid reaction at 190° are given in Table I.

In Fig. 1 the variations of both the acid value and the water evolved with time of reaction have been plotted. In the case of the water evolved–time curve, the observed points of a second independent experiment under identical conditions have been included to show how well the data could be duplicated. On the acid value–time curve, the values obtained from several independent determinations are also shown. Again they fall quite well on the curve.

The log acid value–log time relationship is shown in Fig. 2. It is strikingly similar in shape to the same relationship for glyceryl phthalate (anhydride) except that for glyceryl phthalate (acid) it has been possible to extend the relationship to much higher acid values.

In Fig. 2 changes in slope are observed at ap-

proximate acid values 275, 185 and 140. These agree rather well with the approximate acid values at which similar changes are found in the case of glyceryl phthalate (anhydride), namely, 190 and 138. In addition, acid value 275 is reasonably close to acid value 266, the instantaneous initial acid value always obtained when phthalic anhydride is employed.

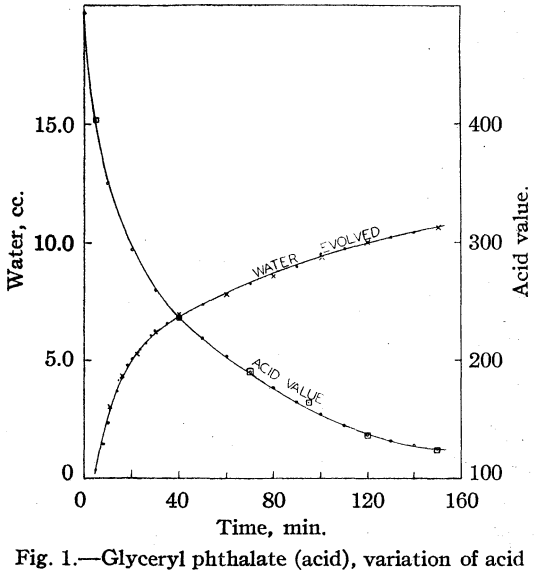

Fig. 1.—Glyceryl phthalate (acid), variation of acid value–water evolved with time, T = 190°.

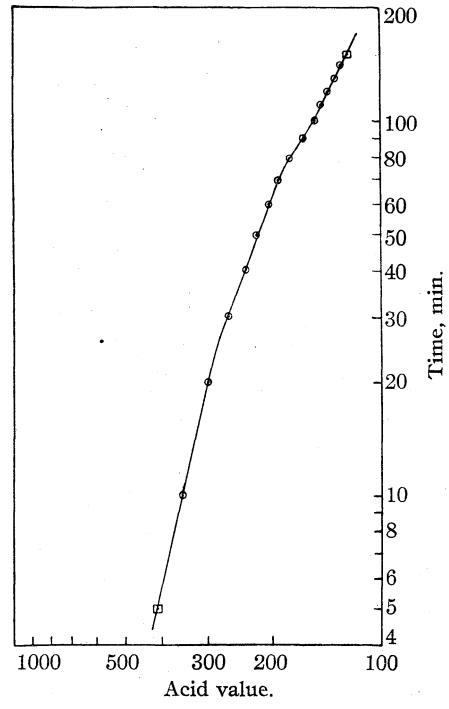

Fig. 2.—Glyceryl phthalate (acid); temperature, 190°.

The water evolved–acid value relationship is

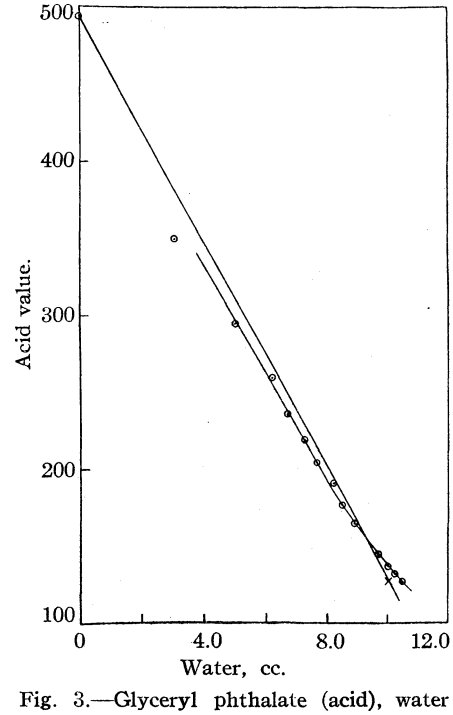

Fig. 3.—Glyceryl phthalate (acid), water evolved–acid value relationship.

given in Fig. 3. There is also included the theoretical relationship for glyceryl phthalate (acid) that should have resulted if the reaction had proceeded by interesterification only. It is interesting to note that the deviations from the theoretical are similar to that observed for glyceryl phthalate (anhydride). This is particularly true from an acid value of 266 on, the acid value representing 50% esterification. In the case of glyceryl phthalate (acid) the curve crosses the theoretical at acid value 155 as compared with acid value 158 observed for glyceryl phthalate (anhydride).

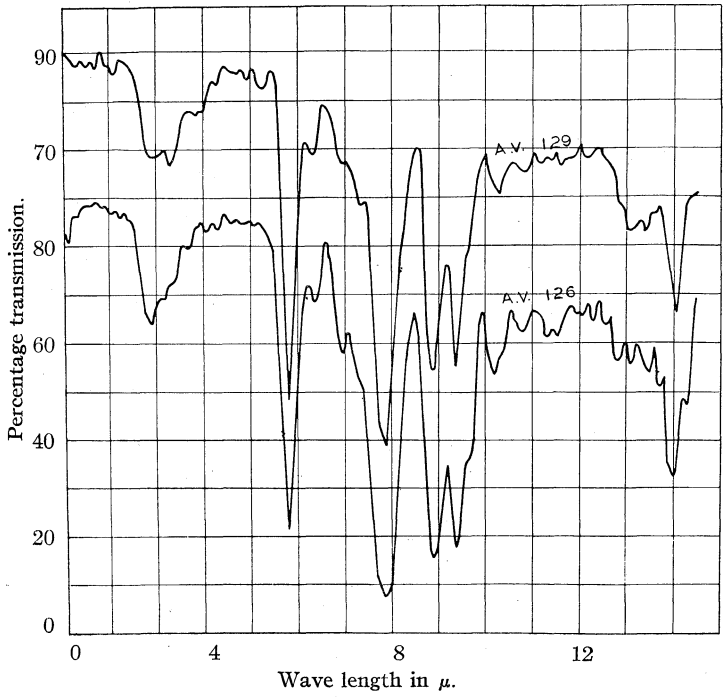

Fig. 4.—Infrared spectra: glyceryl phthalate (acid), A. V. = 129; glyceryl phthalate (anhydride), A. V. = 126.

Analytical.—The polymeride obtained just prior to gelation was a light amber, brittle resin similar in physical appearance to that from glyceryl phthalate (anhydride). Its analytical values are given in Table II. In this table there also are included data for an actual glyceryl phthalate (anhydride) sample of nearly the same acid value and, in addition, the calculated analytical values for glyceryl phthalate (anhydride) of exactly the same acid value determined, by extrapolation, from the curves of the recent glyceryl phthalate (anhydride) study. The water evolved data shown in parentheses for the anhydride samples were obtained by adding to the actual water evolved the water required theoretically to convert the phthalic anhydride to phthalic acid.

TABLE II

ANALYTICAL DATA

	Glyceryl phthalate (acid)	Glyceryl phthalate (anhydride) Calcd.	Exptl.
Acid value	129	129	126
Saponification value	560	551	552
% esterification	76.2	76.6	77.2
Av. molecular weight	910	920	1120
Water evolved, cc.	10.48	(10.51)	(10.63)
Ultimate analysis % C	59.5	59.9	60.2
Ultimate analysis % H	4.4	4.4	4.3

The infrared spectrum[2] from 1–15 μ of the glyceryl phthalate (acid) sample is shown in Fig. 4. There is also included the spectrum obtained for the glyceryl phthalate (anhydride) sample, acid value 126. The general closeness of the two spectra with respect to the over-all shape and positions of the absorption maxima is apparent.

Discussion

In the glyceryl phthalate reaction, when phthalic acid is substituted for phthalic anhydride, no initial temperature rise is observed and time is necessary to attain 50% esterification. When, however, 50% esterification has been attained, the reaction proceeds further in a manner quite analogous to that observed when phthalic anhydride is used. It appears that equivalent polymerides are eventually formed with quite similar degrees of molecular complexity. This perhaps is illustrated best by the comparison of the various analytical values and is further shown by comparing the water evolved for similar acid values, Table III. In setting up this table, the experimental values for glyceryl phthalate (anhydride) have again been corrected for the amount of water evolved to 50% esterification had phthalic acid been used.

TABLE III

Acid value	Water evolved, cc. Glyceryl phthalate acid	Glyceryl phthalate anhydride
190	8.10	8.47
150	9.50	9.55
129	10.48	10.51
Gel	10.80	10.74

(2) Acknowledgment is made to Mr. R. R. Brattain for determining this spectrum.

It appears that polybasic acids can be substituted for anhydrides in the polyester reaction to yield finally fairly equivalent polymerides.

Summary

The glyceryl phthalate reaction has been investigated substituting phthalic acid for phthalic anhydride. Differences in the early stages of the reaction were observed but the later portions of the reaction to gelation are comparable.

The Hydration of Unsaturated Compounds. VII. The Rate of Hydration of Crotonic Acid; the Rate of Dehydration of β-Hydroxybutyric Acid; the Equilibrium between Crotonic Acid and β-Hydroxybutyric Acid in Dilute Aqueous Solution

BY D. PRESSMAN AND H. J. LUCAS

Introduction

Crotonic acid has been shown to hydrate slowly in the presence of boiling 20% sulfuric acid to form β-hydroxybutyric acid.[1] This reaction is unlike the hydration of acrylic acid, since the latter occurs in the presence of hydroxide ion[2] while crotonic acid is not affected under these conditions. Moreover, only about 80% of the crotonic acid hydrates, for it appears that at this point it is in equilibrium with the hydroxy acid. The fact that the hydroxyl group enters into the β-position during the hydration is shown by the identical properties of the acid obtained by this method and of β-hydroxybutyric acid obtained by other methods. Also the ethyl ester of the hydroxybutyric acid prepared by this method is identical with that from hydroxybutyric acid obtained by other syntheses.[3]

It was desirable to extend the study of the hydration on unsaturated compounds to an investigation of the kinetics of the hydration of crotonic acid, of the kinetics of dehydration of β-hydroxybutyric acid, and of the equilibrium between crotonic acid, β-hydroxybutyric acid, and water. Since it was known that crotonic acid is not hydrated at an appreciable rate at 25° in 1 normal nitric acid,[4] the reaction was carried out in 1.06 and 2.06 normal perchloric acid solutions at 90.03 and 111.31° in order to obtain a measurable rate. These solutions were of 2.06 molal ionic strength. Nitric acid could not be used since its oxidizing power at the elevated temperature was appreciable, as evidenced by the liberation of the oxides of nitrogen.

Data and Discussion

Kinetics of the Reaction.—The hydration was found to be first order with respect to crotonic acid since the plots against time of the fraction of crotonic acid unreacted, C_t/C_0, are practically identical for two runs at hydrogen ion concentration of 1.06 molal where the initial crotonic acid concentration has the values 0.0128 molal and 0.0249 molal. Here C_0 and C_t are the molar concentrations of crotonic acid at the respective times, zero and t (Fig. 1). That the reaction is first order with respect to hydrogen ion concentration is evidenced through a comparison of the initial slopes of the plots of C_t/C_0 against t when the hydrogen ion concentrations are 1.06 and 2.06 molal. The slope at the higher concentration corresponds to a rate constant of 0.014, which is twice that of the lower, approximately 0.007. However, hydrogen ion is not used up in the reaction and thus is constant during any one run.

The independence of the equilibrium value with respect to the hydrogen ion concentration, except for small second order differences, is clearly evident from Fig. 2, which shows the complete runs of which Fig. 1 contains only the first portions. The equilibrium value of the crotonic acid fraction remaining is practically identical for both acid concentrations. The reaction then may be considered to be

$$H_3O^+ + H_2O + CH_3CH{=}CHCOOH \underset{k_2}{\overset{k_1}{\rightleftharpoons}} CH_3CHOHCH_2COOH + H_3O^+$$

where k_1 is the specific reaction rate constant of

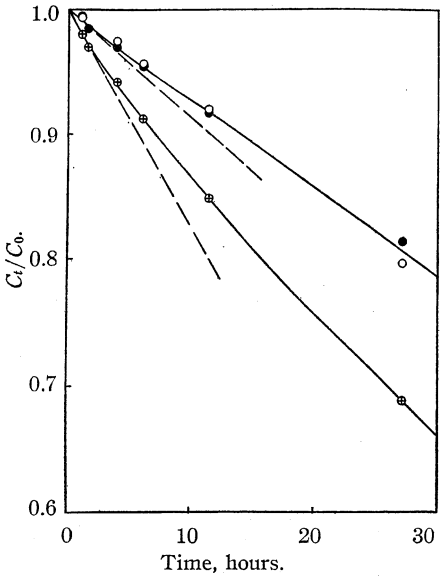

Fig. 1.—Hydration of crotonic acid showing the effect of hydrogen ion concentration and initial crotonic acid concentration on the initial slope of a plot of C_t/C_0 against time: T, 90.03°; μ, 2.06 molal.

	○	●	⊕

(H^+), molal	1.060	1.060	2.056

the forward reaction and k_2 is the specific reaction rate constant for the reverse reaction considering

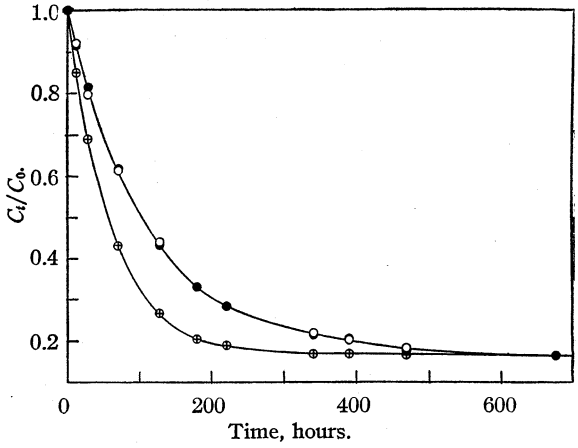

Fig. 2.—Hydration of crotonic acid showing the effect of hydrogen ion concentration and initial crotonic acid concentration on the equilibrium between crotonic acid and β-hydroxybutyric acid. Plot of C_t/C_0 against time. The last point is common to the three runs. T, 90.03°; μ, 2.06 molal.

	○	●	⊕
Crotonic acid, C_0, molal	0.02487	0.01282	0.01248
(H^+), molal	1.060	1.060	2.056

both reactions to be monomolecular with respect to the organic reactant.

$$-\text{d(crotonic acid)}/dt = k_1(\text{crotonic acid}) \quad (1)$$

$$-\text{d(hydroxybutyric acid)}/dt = k_2(\text{hydroxybutyric acid}) \quad (2)$$

Rather than calculate k_1 from the initial slope of the reaction rate curve, it was calculated by the analytical method which involves the integrated expression for a unimolecular reaction approaching equilibrium (equation 3) and the equilibrium constant (equation 4).

$$\log_{10}\frac{\epsilon}{\epsilon - x} = \frac{(k_1 + k_2)t}{2.303} \quad (3)$$

$$K = \frac{k_1}{k_2} = \frac{\epsilon}{1 - \epsilon} \quad (4)$$

Here ϵ is the fraction of the crotonic acid hydrated at equilibrium, x is the fraction hydrated at the time t, and K is the equilibrium constant. When the correct value of ϵ is chosen, a straight line results in a plot of $\log_{10}\epsilon/(\epsilon - x)$ against time. An example of this calculation is given in Table I, the data of which are plotted in Fig. 3. In order

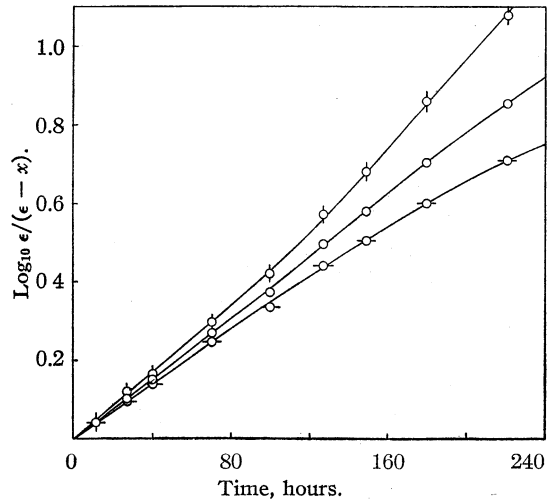

Fig. 3.—Effect of variation of ϵ on $\log_{10}\epsilon/(\epsilon - x)$ in the hydration of crotonic acid: initial crotonic acid, C_0, 0.01282 molal; T, 90.03°; (H^+), 1.060 molal; μ, 2.06 molal: ○, ϵ = 0.775; ○, ϵ = 0.834; -○-, ϵ = 0.892.

to show the effect of a variation of ϵ, the value was changed from the experimental value of 0.834 to 0.892 and 0.775. It can be seen that the experimental value produces a straight line but the variations induce marked curvature in the plots of $\log_{10}\epsilon/(\epsilon - x)$ against t. It will be noted that the values very close to equilibrium were discarded since very slight titration errors at these points in

the determination of the crotonic acid concentration would cause very appreciable errors in the value of $\log_{10} \epsilon/(\epsilon - x)$. In every case, the experimentally determined value for ε from the equilibrium constant gave an excellent straight line. The slope of this line is $(k_1 + k_2)/2.303$. The data of the several runs made are plotted in Figs. 4 and 5 as $\log_{10} \epsilon/(\epsilon - x)$ against time.

As a test of the stability of the system at equilibrium one run was permitted to stand for three hundred and fourteen hours, whereas the system apparently had come to equilibrium after seventy-three hours. However, there was no observable shift in the equilibrium value of the system. These data are shown in Table II and plotted in Fig. 6.

The calculation of the specific reaction rate constants for the dehydration of β-hydroxybutyric acid was carried out in a similar manner. In this case ε is the fraction of β-hydroxybutyric acid decomposed at equilibrium and x is the fraction decomposed at the time, t. A plot of $\log_{10} \epsilon/(\epsilon - x)$ against time for β-hydroxybutyric acid is found in Fig. 7. The specific reaction rate constants and

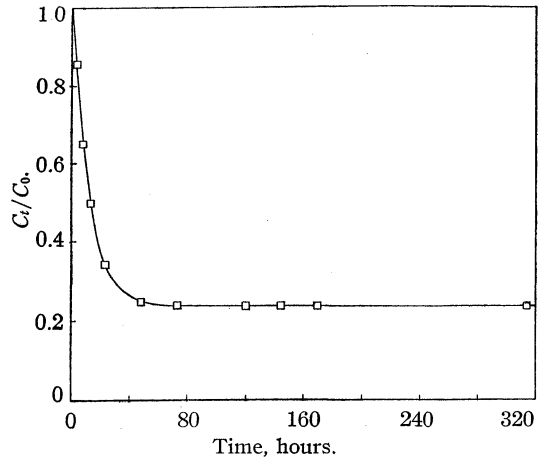

Fig. 6.—Stability of equilibrium between β-hydroxybutyric acid and crotonic acid when approached from crotonic acid. Plot of C_t/C_0 against time. Initial crotonic acid, C_0, 0.0200 molal; T, 111.31°; (H^+), 2.06 molal; μ, 2.06 molal.

the equilibrium constant determined in the dehydration run on β-hydroxybutyric acid are in excellent agreement with those obtained in the hydration of crotonic acid. This proves that a true equilibrium occurs since it can be approached from both sides.

The kinetic data obtained are listed in Table III. Experiments 1 to 5 deal with the hydration of crotonic acid while experiment 6 is concerned with the dehydration of β-hydroxybutyric acid. The specific reaction rate constants, k_1 and k_2, for the forward and reverse reactions are listed along with the constants which have been corrected for hydrogen ion concentration. The latter are listed as $k_1/(H^+)$ and $k_2(H^+)$. The constancy of these corrected values with acid concentration checks the observation that the reaction is first order with respect to hydrogen ion concentration.

The equilibrium constants, 5 at 90° and 3.4 at 111°, correspond to 84 and 78% hydration, respectively. These data substantiate the value of 80% hydration observed by Kaufel and Basel,[1] in boiling 20% sulfuric acid.

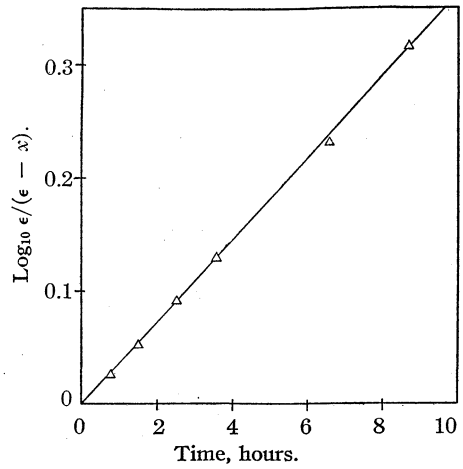

Fig. 7.—Dehydration of β-hydroxybutyric acid. Plot of $\log_{10} \epsilon/(\epsilon - x)$ against time. Initial β-hydroxybutyric acid, C_0, 0.0225; ϵ, 0.228; T, 111.31°; (H^+), 2.01 molal; μ, 2.01 molal.

Effect of Salt.—It is interesting to note that the equilibrium is shifted to the right when hydrogen ions are replaced by sodium ions. This shows that there is a relative increase in the activity coefficient of crotonic acid over the activity coefficient of β-hydroxybutyric acid when sodium ions replace hydrogen ions. This effect was also observed in the case of crotonaldehyde.[4] In Table IV a comparison is made of these effects in the two cases, crotonaldehyde and crotonic acid. It is evident that the equilibrium constant, at constant ionic strength, increases with decreasing hydrogen ion concentration.

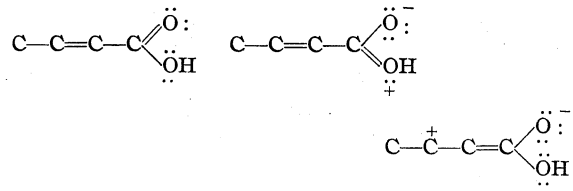
Thermochemistry of the Reaction.—Table V contains the thermal data for the reactions involved. The heat of the reaction, ΔH, the heats of activation, Q_1 and Q_2 of the forward and reverse reactions, and the temperature coefficients are listed individually for the runs in the solvents of different acid concentration. The values of k_1, k_2 and K for the two runs at 90.03° in 1.06 N perchloric acid were averaged in this calculation. This averaging accounts for the discrepancy between the difference in the heats of activation and the heat of the reaction, since the latter was calculated from the temperature coefficient of the averaged equilibrium constants and the former from the averaged values of the rate constants. The heat of activation of the forward reaction is smaller than that of the reverse reaction. Thus, there results a ΔH of -10.1 kcal. for the reaction. However, the heat of activation of 38.0 kcal. for the forward reaction is larger than any of those observed previously for unsaturated compounds, which were 23.4 kcal. for isobutene[5]; 21.04 kcal. for methylethylethylene[6]; 18.92 kcal. for trimethylethylene[7]; and 18.3 kcal. for crotonaldehyde.[4] The heat of activation for the reverse reaction is 48.1 kcal. for crotonic acid as compared with 24.5 kcal. for crotonaldehyde.

TABLE V

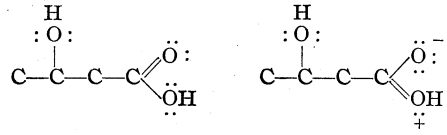
THERMAL DATA CONCERNING THE HYDRATION OF CROTONIC ACID

(H^+)	μ	Heats of activation Q_1, kcal.	Q_2, kcal.	ΔH, kcal.	Temp. coefficient 90–100° Hyd.	Dehyd.
1.06	2.06	37.85	47.85	− 9.8	4.08	5.94
2.06	2.06	38.15	48.4	−10.3	4.14	6.05
	Average	38.00	48.1	−10.1	4.11	6.00

The fact that the hydration of crotonic acid liberates 10 kcal. while the hydration of crotonaldehyde liberates only 6 kcal. indicates that β-hydroxybutyric acid is relatively more stable in aqueous solution with respect to crotonic acid than aldol is with respect to crotonaldehyde. Resonance explains the relatively lower stability of the aldol. Crotonic acid in the acid solution can resonate between the unexcited forms

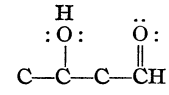


while β-hydroxybutyric acid resonates between the unexcited forms



On the other hand, crotonaldehyde can resonate between the unexcited forms

while the hydration product, aldol, can exist only in the single unexcited form



Thus, when crotonic acid hydrates it goes from a structure of principally three resonating forms to one of two, while crotonaldehyde loses nearly all of its resonance energy upon hydration. Hence, it would be expected that the evolution of energy during hydration would be less in the case of crotonaldehyde than in the case of crotonic acid, since each must retain energy equivalent to its loss of resonance energy and since the loss for the former is greater than for the latter. The difference in the heats of reaction, *viz.*, 4 kcal., is the difference in the resonance energy changes.

Ester Formation.—Gehrke and Willrath[8] have shown that β-hydroxybutyric acid loses water by itself to form a compound of lower free carboxyl content. This could be a linear ester, lactide or lactone since saponification of the compound of lower free carboxyl content liberates all these bound groups. In any case, it was stated that in a 0.1 molal solution of the hydroxy acid at 100° only 95.5% of the carboxyl groups are free. This would mean that 9% of the molecules are com-

(5) Eberz and Lucas, THIS JOURNAL, **56**, 1230 (1934).

bined as linear ester molecules or 4.5% are in the lactide or lactone form. Linear ester formation would be essentially negligible because of the high dilution, if it is assumed that in the pure acid, the extent of this reaction would be about 50%, as generally is the case in the formation of simple esters. At the concentration of 0.1 molal, esterification of this type would be only about 0.05%. Likewise, lactide formation and esterification of the β-hydroxy acid by crotonic acid would be negligible. However, lactone formation and lactone hydrolysis are essentially unimolecular reactions, and thus the equilibrium would not be affected by dilution. The formation of a four-membered ring as in the lactone would result in a low value of the lactone formation which may well be of the order of 5%.

Thus the equilibrium values as listed in Table III may be as much as 4.5% in error, due to the uncertainty of the β-hydroxybutyric acid concentration. However, in the important calculation, that of the heat of reaction, a ratio of equilibrium constants is taken and these errors occur then as second order corrections and are thus negligible.

Experimental

Materials. Crotonic Acid.—The crotonic acid used was the Eastman Kodak Co. product which had been recrystallized from water. It melted at 70.5–71.0° uncorr., and analysis for unsaturation showed 1.000 double bonds per mole.

β-Hydroxybutyric Acid.—This was prepared by the method of Kaufel and Basel[1] in which crotonic acid is hydrolyzed in the presence of boiling 20% sulfuric acid. The reaction mixture was neutralized to methyl orange with a freshly prepared paste of calcium hydroxide in order to remove sulfuric acid. The solution was filtered from the solid calcium sulfate and concentrated by vacuum distillation. This also removed most of the unconverted crotonic acid. A solid separated and was filtered. This was most likely a mixture of calcium sulfate and calcium β-hydroxybutyrate. The resulting sirup was extracted several times with ether to remove remaining crotonic acid. This was continued until the sirup indicated negligible unsaturation when analyzed by bromination. Upon standing in a vacuum desiccator over sulfuric acid, a precipitate of calcium hydroxybutyrate separated from the sirup. This was washed with alcohol and dried in a vacuum desiccator. An ash determination showed 15.9 and 16.0% calcium; calculated for calcium hydroxybutyrate 16.2% calcium. Since difficulties would occur in obtaining a known sample of the hydroxybutyric acid itself due to its self esterification and water loss, the calcium salt was used in its place since it could easily be weighed out quantitatively.

Perchloric Acid Solution of Constant Ionic Strength.—Equal portions of 60% perchloric acid were weighed out. To one was added enough sodium hydroxide to neutralize one-half of the acid. These portions were made up to equal volumes with distilled water. They were of equal ionic strength but unequal acidity.

Method of Analysis.—The solutions were analyzed by a quantitative bromination method. The solution to be analyzed was added to an excess of 0.05 normal bromate–bromide solution in an iodometric flask. If the solution to be analyzed did not contain a strong acid, 5 ml. of 6 *N* sulfuric acid was added at this time to liberate bromine. Potassium iodide solution was then added and the liberated iodine titrated with 0.02 *N* sodium thiosulfate solution. In the analysis of crotonic acid, it was found that a 50% excess of bromine gave theoretical bromination in five minutes while a 300% excess introduced an error of only 2% after one hour of standing. Experiments concerning the effect of bromine on hydroxybutyric acid showed that it substituted at the rate of 0.04%/minute when the mole ratio of bromine to β-hydroxybutyric acid was unity. Thus, the error incurred by the bromination of hydroxybutyric acid would be negligible under the conditions of analysis using a five-minute bromination period and a 50 or 100% excess of bromine.

Procedure of the Reaction.—Standard solutions of crotonic acid in perchloric acid were made up by roughly weighing the crotonic acid into an approximate volume of standard perchloric acid and then analyzing 20-ml. aliquots by bromination. The solutions of β-hydroxybutyric acid were made up gravimetrically by weighing out accurately a portion of calcium hydroxybutyrate and then making it up accurately to volume with perchloric acid solution. The runs were made by sealing off 20-ml. aliquots in test-tubes. These were placed in a thermostat at either 90.03° or 111.31 ± 0.05°. Tubes were withdrawn from time to time, quenched in water and the contents analyzed by bromination.

Summary

A study of the reversible hydration of crotonic acid to β-hydroxybutyric acid in 1.06 and 2.06 normal perchloric acid solutions of ionic strength 2.06 at temperatures of 90.03° and 111.31 ± 0.05° was made.

The hydration is first order with respect to crotonic acid and hydrogen ion. The dehydration is first order with respect to β-hydroxybutyric acid and hydrogen ion. The equilibrium is shown to be approachable from either the crotonic acid or the β-hydroxybutyric acid side. The equilibrium constant is 5.0 at 90° and 3.4 at 111°.

In solutions of constant ionic strength the equilibrium shifts toward crotonic acid with increasing acid concentration, thus showing that the replacement of sodium ion by hydrogen ion relatively increases the activity coefficient of β-hydroxybutyric acid over that of crotonic acid.

The energy of activation is 38.0 kcal. for the hydration and 48.1 kcal. for the dehydration.

The heat of the reaction is thus 10.1 kcal. The 4 kcal. greater heat of reaction than that which accompanies the hydration of crotonaldehyde is explained by a lower loss of resonance energy in the hydration of crotonic acid.

PASADENA, CALIF. RECEIVED MAY 29, 1939

[A CONTRIBUTION FROM THE YALE-IN-CHINA SCHOOL OF SCIENCE, HUA CHUNG COLLEGE]

The Reaction of Wijs Solution with Tung Oil

BY S. W. WAN AND D. B. HU

Tung oil contains mainly the glycerides of eleostearic acid and oleic acid and its drying power is due to the former unsaturated acid. In estimating the degree of unsaturation of tung oil with Wijs solution, the presence of eleostearic glyceride causes much uncertainty because the iodine value thus obtained varies with experimental conditions such as temperature, concentration and relative amount of reagent, and time of contact between reagent and oil.[1] Various methods have been tried for determining the percentage of eleostearic acid glyceride in tung oil, but have given no concordant results. Among the most recent methods may be mentioned the combined bromine vapor and Wijs method,[2] the differential halogen absorption method,[3] the polymerization method,[4] and the diene number method.[5] The peculiar properties of eleostearic acid giving rise to analytical difficulties have been explained by Böeseken and co-workers by assigning to it the molecular constitution $CH_3(CH_2)_3CH{=}CHCH{=}CHCH{=}CH(CH_2)_7COOH$,[6] which, in the light of Thiele's theory of partial valency, is expected to absorb halogens in two stages represented as

$$CH_3(CH_2)_3CH{=}CHCH{=}CHCH{=}CH(CH_2)_7COOH + 2X_2 \longrightarrow CH_3(CH_2)_3CHXCHXCH{=}CHCHXCHX(CH_2)_7COOH \quad (I)$$

$$CH_3(CH_2)_3CHXCHXCHXCHXCHXCHX(CH_2)_7COOH + X_2 \longrightarrow \quad (II)$$

With Wijs solution, X_2 being a molecule of iodine monochloride, the first stage reaction is much faster and produces a chloro compound.[6] On the other hand, compounds with non-conjugate double bonds take up the theoretical amount of iodine chloride in a short time, forming iodochloro compounds.

This paper gives an account of the authors' attempt to apply the above-mentioned property of eleostearic acid to the determination of the concentration of its glyceride in tung oil, and an account of their investigation in the chemical kinetics of reaction (II).

Materials.—Glacial acetic acid, C. P., tested free from reducible substances. Iodine, C. P., twice resublimed. Sodium oxalate, C. P., giving an assay of 99.98%. Sodium thiosulfate, potassium iodide, carbon tetrachloride, oleic acid, potassium permanganate, all C. P. grade. Tung oil, supplied from the Chinese Vegetable Oil Corporation, Hankow. α-Eleostearic acid, prepared according to the method of Thomas and Thomson,[7] m. p. 48.3°. Wijs solution, prepared according to the procedure given by Griffin[8] with the important modification that the iodine and chlorine contents in the solution were adjusted to be exactly equivalent in amount.

The sodium thiosulfate solutions used in these experiments were standardized against potassium permanganate as a secondary standard and sodium oxalate as a primary standard.

Experimental

Part I.—Approximately equal weights of the carbon tetrachloride solution of a sample were placed in glass-stoppered conical flasks. To each was then added a weighed amount of Wijs solution and the mixture allowed to react for a definite length of time by shaking in a thermostat maintained at 25 ± 0.1°. All reagents also had been allowed previously to reach temperature equilibrium in the same thermostat. The reaction in each mixture was stopped promptly by adding 20 cc. of 15% potassium iodide solution and the reaction mixture was immediately diluted with water and titrated with sodium thiosulfate solution from a weighing buret. A number of runs were made by following the above procedure and using samples of: (a) pure α-eleostearic acid with a reaction period of five minutes; (b) pure α-eleostearic acid with a reaction period of two minutes; (c) pure α-eleostearic acid with a reaction period of ten minutes; (d) pure oleic acid with a reaction period of ten minutes; (e) a known mixture of α-eleostearic and oleic acids with a reaction period of five minutes; (f) tung oil with a reaction period of five minutes.

Part II.—α-Eleostearic acid was weighed into a 100-cc. volumetric flask and carbon tetrachloride was added, mak-

(7) Thomas and Thomson, THIS JOURNAL, **56**, 898 (1934).
(8) Griffin, "Technical Methods of Analysis," McGraw-Hill Book Co., Inc., New York, N. Y., p. 310.

ing up to volume at 25.0°. This solution was transferred into a glass-stoppered conical flask containing the Wijs solution previously set in the same thermostat maintained at 25.0 ± 0.1°. While beginning the delivery of the carbon tetrachloride solution of α-eleostearic acid two stopwatches were started simultaneously, one of them being stopped just when the delivery was completed, and the time of half delivery was taken as the starting point of the reaction. The flask containing the reaction mixture was well shaken at the start and also occasionally as the reaction went on. At definite intervals, 25-cc. portions of the reaction mixture were withdrawn with a pipet and each portion was delivered into one of a series of 120-cc. cork-stoppered conical flasks containing about 20 cc. of 15% potassium iodide solution. The duration for this delivery was noted and its half value was considered as the stopping point of the reaction. Each flask had been weighed with the potassium iodide solution in it and was again weighed after adding the reaction mixture. The exact volume of a portion of the mixture thus withdrawn was calculated from its weight and the density of the reaction mixture. (The densities of the eleostearic acid solution and that of Wijs solution were found to be additive.) The contents of the flask were transferred quickly and washed into a 300-cc. flask and titrated with sodium thiosulfate solution from a weighing buret. By following the above procedure the following investigations were performed: (g) reaction between α-eleostearic acid and Wijs solution in conventional proportions; (h) reaction between α-eleostearic acid and an equivalent amount of Wijs solution just sufficient for the first stage saturation; (i) reaction between α-eleostearic acid and an excess of Wijs solution; (j) comparison of halogen absorption by α-eleostearic acid and by tung oil.

Results

For experiments in part (I), solutions of α-eleostearic acid were of the concentration of about 0.015 millimole per gram of solution; solutions of oleic acid were of the concentration of about 0.022 millimole per gram of solution; the concentration of Wijs solution was 0.1450 millimole of iodine monochloride per gram of solution and 1 g. of the sodium thiosulfate solution was equivalent to 0.06295 millimole of halogen. All original data have been converted into millimoles of iodine monochloride used per millimole or gram of sample, and millimoles of halogen absorbed or left over per millimole or gram of sample, respectively; these results are given in Table I.

Results of Part II are given in Tables II to VI, where a is the molar concentration of α-eleostearic acid in the mixture or in other words the initial concentration of α-eleostearic acid tetrachloride at the beginning of the second stage reaction; b is the initial molar concentration of iodine monochloride at the beginning of the second stage; b' which is equal to $2a$ is the initial molar concentration of free iodine liberated during the first stage; B is the sum of b and b'; x' is the molar concentration of the iodochloride of α-eleostearic acid tetrachloride and x'', that of the di-iodide of α-eleostearic acid tetrachloride formed during time t of the reaction; x is the sum of x' and x''; k_1, k_1^*, k_2, k_2^*, and k_3 are specific reaction rates described in another section of this paper (see Discussion).

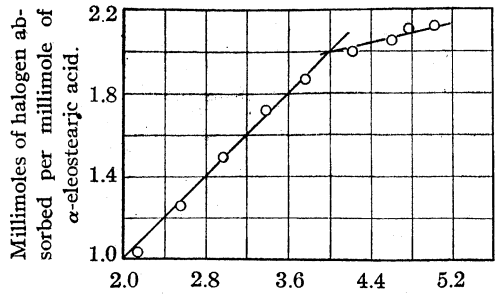
Discussion

The interpretation of the results from the experiments of part (I) is based on the following consideration. When x, representing the number of millimoles of iodine monochloride added to one millimole of acid, is plotted against y, the number of millimoles of halogen absorbed, then in the case of α-eleostearic acid, a linear relation, $y = x/2$, will be obtained until the point, $y = 2$, $x = 4$, is reached, because this acid absorbs chlorine and not iodine in the first stage reaction, each millimole of acid requiring two of chlorine obtainable from four of iodine monochloride. Beyond this point the plot will become a horizontal straight line, $y = 2$.

However, the above relation is valid only when the reaction period is long enough for completing the first stage absorption but not too long lest the second stage reaction become appreciable. If the second stage reaction takes place to an appreciable extent along with the first stage reaction, the plot will not be linear; if the reaction period is too short for the first stage saturation, the first part of the plot will have a slope less than $^1/_2$; and if the reaction period is too long for the first stage saturation, the first part of the plot will have a slope greater than $^1/_2$. Furthermore, if the second stage reaction can be detected in the presence of excess iodine monochloride, the second part of the plot will not be horizontal and not necessarily linear. These phenomena are clearly illustrated by Figs. 1, 2 and 3, in which are plotted the results of experiments (a), (b) and (c).

The results obtained from the reaction of oleic acid and iodine monochloride when treated in the same manner give a decisive answer to the question whether oleic acid absorbs chlorine alone or a whole molecule of iodine monochloride. Since oleic acid contains one double bond, the plot, in the former case, will be $y = {}^1/_2x$ up to $x = 2$,



Millimoles of iodine chloride per millimole of α-eleostearic acid.

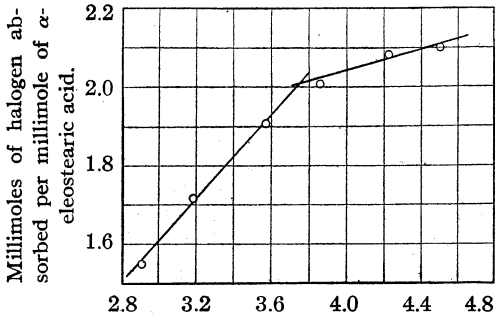
Millimoles of iodine chloride per millimole of α-eleostearic acid.

Fig. 2.



Millimoles of iodine chloride per millimole of α-eleostearic acid.

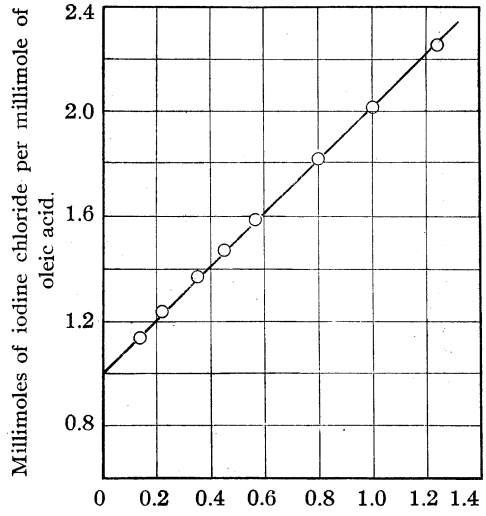
Fig. 3.

$y = 1$, and become $y = 1$ beyond that, while in the latter case it will be simply $y = x$ up to $x = 1$, $y = 1$ and then become $y = 1$ beyond that. On the other hand, if u represents the millimoles of iodine monochloride added to one of acid, and v, the millimoles of halogen left over, the plot will be $u = 2v$ up to $u = 2$ and $v = 1$, and become $u = v$ further on, in the former case; in the latter case, $u = v + 1$ throughout. The intercept of 1 on the u-axis is clearly brought out in Fig. 4.

With a mixture of the two acids, the results have been plotted on the basis of x millimoles of iodine monochloride added per gram of sample against y millimoles of halogen absorbed. Let r and s be the weight fractions; m_e and m_o, the millimolecular weights of α-eleostearic acid and oleic acid, respectively; p, the point at which just enough iodine monochloride has been used to satisfy both the oleic acid and the eleostearic acid first stage saturation. From the knowledge gained in these experiments concerning the behavior of iodine monochloride toward the two acids, it is evident that

$$x_p = 4\frac{r}{m_e} + \frac{s}{m_o} \quad \text{and} \quad y_p = 2\frac{r}{m_e} + \frac{s}{m_o}$$

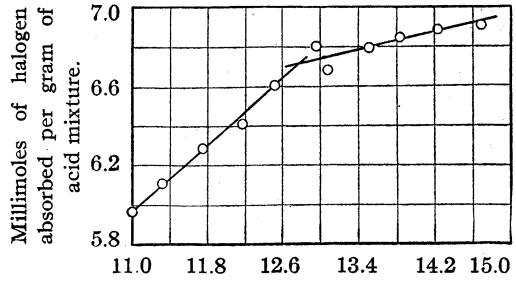
Hence r and s can be solved for simultaneously from the above equations.



Millimoles of halogen left per millimole of oleic acid.

Fig. 4.

In our analysis of a known mixture by this method, there has been good agreement between the actual and the calculated values for α-eleostearic acid (see Fig. 5). Only one determination



Millimoles of iodine chloride per gram of acid mixture.

Fig. 5.

has been made with tung oil (see Fig. 6) but further investigation is in progress because on the

whole the method thus developed seems very promising.

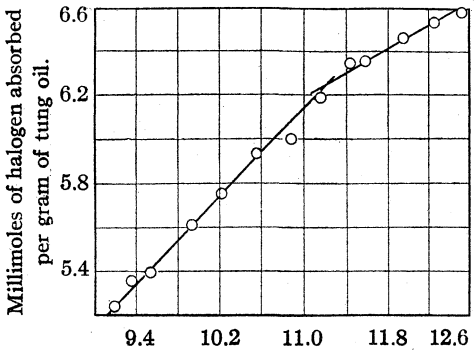


Fig. 6.

The data of experimental part (II) are the first of the kind making possible a study of the chemical kinetics for the reaction between α-eleostearic acid and iodine monochloride. For this reaction Böeseken[6] has proposed the scheme

$$CH_3(CH_2)_3CH{=}CHCH{=}CHCH{=}CH(CH_2)_7COOH + 4\ ICl \longrightarrow CH_3(CH_2)_3CHClCHClCH{=}CHCHClCHCl\text{-}(CH_2)_7COOH + 2I_2 \xrightarrow{+\ ICl} CH(CH_2)_3CHClCHClCHI\text{-}CHClCHClCHCl(CH_2)_7COOH \quad (III)$$

The second stage reaction according to the above scheme is bimolecular and therefore its reaction rate k_1 can be expressed by the second order relation

$$k_1 = 1/t(a - b) \ln b(a - x)/a(b - x) \quad (IV)$$

However, if the absorption involves the addition of chlorine or iodine (from iodine monochloride), instead of iodine monochloride itself, the specific reaction rate k_1^* of a third order reaction would be obtained from the equations

$$dx/dt = k_1^*(a - x)(b - 2x)^2 \quad (V)$$

and

$$k_1^* = 1/t(b - 2a)\{1/(b - 2a) \ln a(b - 2x)/b(a - x) - 1/(b - 2x) + 1/b\} \quad (VI)$$

There is still another possibility, namely, the absorption of iodine (liberated in the first stage) and iodine monochloride simultaneously in the second stage. In this case, the reaction rate would be governed by the relation

$$dx/dt = k_2(a - x)(b - x') - k_3(a - x)(b' - x'') \quad (VII)$$

The integration of equation (VII) would be a laborious process but as a first approximation the calculation may be simplified by either one of the following conditions. (1) The iodine monochloride concentration is just sufficient to complete the first stage absorption, so that $b = 0$ and $x' = 0$ and equation (VII) reduces to

$$dx/dt = k_3(a - x)(b' - x'') = k_3(a - x)(b' - x) \quad (VIII)$$

and

$$k_3 = 1/t(b' - a) \ln a(b' - x)/b'(a - x) \quad (IX)$$

(2) When excess of iodine monochloride is used, the relatively small amount of iodine liberated in the first stage may be disregarded so that equation (VII) becomes

$$dx/dt = k_2(a - x)(b - x') = k_2(a - x)(b - x) \quad (X)$$

and

$$k_2 = 1/t(b - a) \ln a(b - x)/b(a - x) \quad (XI)$$

The fact that values of k_1 and k_1^* given in Table II fail to correlate with equations (IV) and (VI), respectively, indicates that the mechanism suggested by Böeseken for the second stage reaction between iodine monochloride and α-eleostearic acid is incorrect, and that it is neither bimolecular nor trimolecular but most probably a combination of two simultaneous bimolecular reactions, one between the acid and the iodine liberated in the first stage and the other between the acid and iodine monochloride. This statement is supported by the data given in Table III and Table IV and plotted in Fig. 7 and Fig. 8 to show the linear relation between t and ln $(b' - x)/(a - x)$ and between t and ln $(b - x)/(a - x)$, respectively. It should be noted that when the

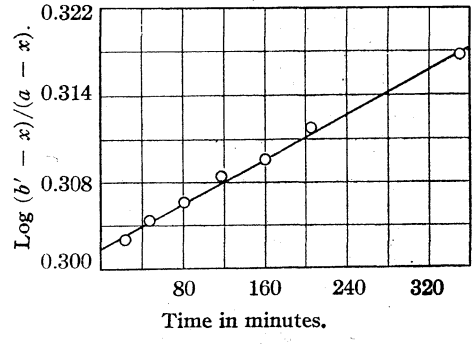

Fig. 7.

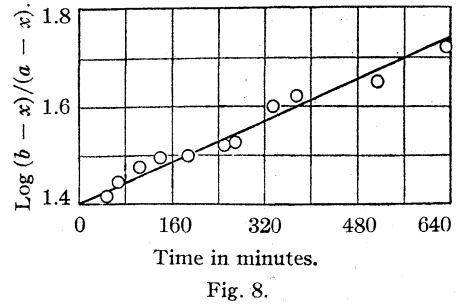

Fig. 8.

above plots are extrapolated to zero time, the values of ln (b/a) and ln (b'/a) are higher than the corresponding computed values. This may be accounted for by the presence of the beta form of eleostearic acid produced from the alpha acid on standing, the beta acid having a lower halogen-absorption rate.[10] Furthermore, the prompt stopping of a reaction in these experiments was done through adding to the reaction mixture, an excess of potassium iodide solution which might react with the iodo-chloride of α-eleostearic acid addition product forming a di-iodide which in turn might liberate iodine and restore the last-saturated double bond.[6]

The specific reaction rates k_2 and k_3 of the above-mentioned simultaneous bimolecular reactions are both small and of the same order of magnitude. If they could be assumed equal, equation (VII) would become

$$\begin{aligned} dx/dt &= k_4(a - x)(b + b') - (x' + x'') \\ &= k_4(a - x)(B - x) \end{aligned} \qquad \text{(XII)}$$

which is equivalent to a second order equation. As a matter of fact, a linear relation is obtained between t and log $(B - x)/(a - x)$ as shown in Fig. 9, which apparently confirms the contention made previously on the absorption of halogen by α-eleostearic acid in Wijs solution that the mechanism of the reaction is bimolecular.

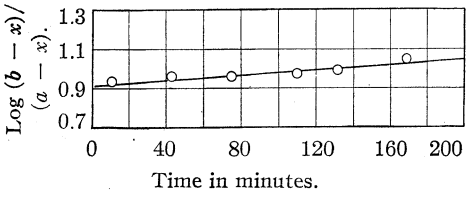

Fig. 9.

The similarity of the two curves in Fig. 10 serves to indicate that the reaction of halogen in Wijs solution with tung oil is much of the same nature as that with α-eleostearic acid. This property also has been applied in experimental part (I).

The increase of iodine value of the oil with increase of temperature or time of contact with Wijs solution can be explained easily in the light of what has been found from these experiments. The absorption of chlorine from iodine monochloride in the first stage explains the requirement of a minimum excess of Wijs solution for obtaining a normal iodine value.[1] The slight decrease of iodine value with increased amount of oil when the same amount of Wijs solution is used[11] may be accounted for by the fact that a relatively larger amount of α-eleostearic acid glyceride absorbs a correspondingly larger amount of iodine monochloride in the first stage and leaves a smaller excess of halogen which because of the kinetic relations mentioned above decreases the rate of halogen absorption in the second stage.

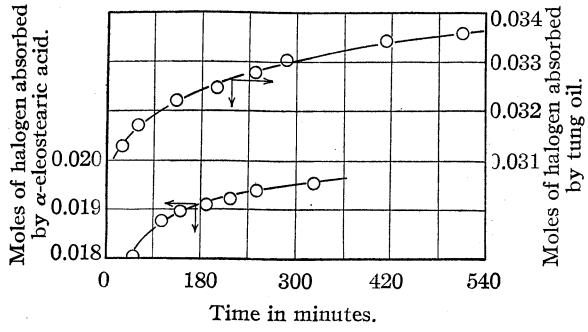

Fig. 10.

Finally, attention should be called to the fact that although experiment (i) was aimed at using a large excess of iodine monochloride relative to α-eleostearic acid so that b' and x'' might become insignificant compared with b and x', yet practical limitations made it possible to realize only a ratio of about 10 to 1 between b and b'. This ratio may not justify the process of simplifying equation (VII) to equation (X). Most probably errors have been introduced into the values of k_2 by this simplifying process which makes it necessary to use an extrapolated value for log (b/a) in order to obtain a fairly constant k_2^*. A more direct and accurate determination of both k_2 and k_3 is highly desirable. The authors are making this investigation.

Summary

1. The behavior of Wijs solution toward α-eleostearic acid, oleic acid and a mixture of the two acids has been studied by varying the proportion of Wijs solution to acid and the time of contact.

2. The two-stage halogen absorption from Wijs solution by α-eleostearic acid forming a tetrachloro addition product in the first stage, and the addition of iodine monochloride to oleic acid have been quantitatively established.

3. The difference in halogen absorption between α-eleostearic acid and oleic acid has been applied to the analysis of a mixture of the two acids and to the analysis of α-eleostearic acid

(10) Van Loon, *Chem. Umschau, Fette, Oele, Wachse, Harze*, **37**, 269 (1930).

(11) *Chemistry* (China), **1**, 1 (1934).

glyceride in tung oil, further work being carried on for developing the latter analysis into a reliable method.

4. The chemical kinetics for the absorption of halogen from Wijs solution by α-eleostearic acid has been studied and two specific reaction rates have been determined.

5. Böeseken's assumption of a bimolecular reaction for the second stage halogen absorption by α-eleostearic acid from Wijs solution has been found incorrect. A combination of two simultaneous bimolecular reactions has been suggested

$$CH_3(CH_2)_3CHClCHClCH{=}CHCHClCHCl(CH_2)_7COOH$$

$$\xrightarrow{+ICl} CH_3(CH_2)_3CHClCHClCHICHClCHClCHCl(CH_2)_7COOH$$

$$\xrightarrow{+I_2} CH_3(CH_2)_3CHClCHClCHICHICHClCHCl(CH_2)_7COOH$$

6. The variation of the iodine value of tung oil with temperature, excess of reagent and time of contact with reagent has been explained.

[A CONTRIBUTION FROM THE YALE IN CHINA SCHOOL OF SCIENCE, HUA CHUNG COLLEGE]

Physicochemical Studies of Alpha and Beta Eleostearic Acids. I. Molar Refractivity and Parachor

BY S. W. WAN AND M. C. CHEN

Alpha and beta eleostearic acids were names suggested by Maquenne[1] for the isomeric eleomargaric and eleostearic acids so named and first isolated from the oil of *Eleococca Vernicia* by Cloez.[2] Tung oil is mainly a triglyceride of the alpha acid, and because of its special properties which make tung oil a highly important and useful material, a large amount of data has been accumulated. However, there were differences in opinion concerning its constitution[3] until Böeseken and co-workers[4] suggested the formula, $CH_3(CH_2)_3CH{=}CHCH{=}CHCH{=}CH(CH_2)_7COOH$ which has correlated many important phenomena not satisfactorily explained before. Although experimental findings from different sources have not entirely converged toward a common conclusion, most investigations seem to confirm this constitution.

One of the arguments put forth by Böeseken and co-workers[4] for suggesting the above formula was based upon the molar refractivity of the eleostearic acids. Melting points of 47 and 67° were given, respectively, for the specimens of alpha and beta isomers prepared for their experiments. Since then the method of preparation has been much improved. The authors have followed the method of Thomas and Thomson[5] with increased repetition of recrystallization, and have obtained from a large batch of original crystals a small crop of highly purified product with melting points higher than the previously reported values. A series of physicochemical determinations is being made with the highly purified alpha and beta eleostearic acids thus obtained.

Experiments and Data.—Alpha and beta eleostearic acids were prepared from their corresponding glycerides in tung oil, the beta-glyceride being formed when tung oil was allowed to stand in contact with a trace of sulfur. Density, surface tension and index of refraction of the alpha and beta acids were determined, respectively, at 50 ± 0.01° and 75 ± 0.01°. The surface tension of each was measured by the capillary rise method and the index of refraction by the use of an Abbe refractometer. The following data were obtained.

TABLE I

Acid	α-Eleostearic	β-Eleostearic
Melting point, °C.	49.0–49.2	71.5–72.0
Density	0.9028 at 50°	0.8909 at 75°
Surface tension	33.42 at 50°	31.04 at 75°
Refractive index	1.5112 at 50°	1.5022 at 75°

Results and Discussion

From the above data the parachor, P, and molar refractivity, R, of the eleostearic acids were calculated and are given in Tables II and III. P' and R' in the tables are, respectively, the theoreti-

(1) Maquenne, *Compt. rend.*, **135**, 696 (1902).

(3) Kametaka, *J. Chem. Soc.*, **83T**, 104 (1903); Mania, *Chem. Inst., Univ. Kiel. Ber.*, **42**, 674 (1909); Vercruysse, *Bull. soc. chim. Belg.*, **32**, 151 (1923); Nicolet, THIS JOURNAL, **43**, 938 (1921); Ishio, *J. Pharm. Soc., Japan*, **529**, 228 (1926); Eibner, Merz and Munzert, *Chem. Umschau*, **31**, 69 (1924).

(4) Böeseken and Ravenswaay, *Rec. trav. chim.*, **44**, 241 (1925); *Verslag. Akad. Wetenschappen, Amsterdam*, **34**, 204 (1925); Böeseken and Gelber, *Rec. trav. chim.*, **46**, 158 (1927); Böeseken, Hoogl, Broek and Smit, *ibid.*, **46**, 619 (1927).

(5) Thomas and Thomson, THIS JOURNAL, **56**, 898 (1934).

cal parachor, and the theoretical molar refractivity less exaltation due to conjugation of double bonds between carbon atoms. In calculating the theoretical values, Böeseken's formula for eleostearic acid and the data compiled by Sugden[6] and Smyth,[7] respectively, for parachor and molar refractivity were adopted. In Table III are also given for comparison the data of Böeseken and Ravenswaay, those of Ishio, and those of Toyama and Tsuchiyu for punicic and trichosanic acids, considered as stereoisomers of eleostearic acid.

TABLE II

Acid	P	P'	Diff.
α-Eleostearic	741.0	709.0	32.0
β-Eleostearic	736.9	709.0	27.0

TABLE III

R for α-eleostearic acid	92.36
R for β-eleostearic acid	92.20
R' for above acids	85.47
Böeseken's R for α-acid	93.05
Ishio's value for α-acid	98.62
R for punicic acid	92.4
R for trichosanic acid	92.4

An explanation is desirable for the difference between P and P' since it cannot be accounted for by the conjugation of double bonds which, although having a large influence upon many other physical constants, shows no measurable effect on parachor. Interpretation of these results has to be postponed until further investigation in this Laboratory throws more light on the nature and amount of exaltation in molar refractivity due to conjugated double bonds in general. Nevertheless, the technique of the present procedure has been tested with a sample of purified oleic acid giving the results in Table IV.

TABLE IV

	Molar refractivity of oleic acid	Parachor of oleic acid
Observed value	86.6	731.4
Calculated value	86.4	731.0

Maleic anhydride was suggested by Kaufmann and Baltes[8] for detection and determination of conjugated double bonds in fats and oils. However, it does not seem satisfactory in distinguishing between the presence of two and of three conjugated double bonds. Incidentally, it may be pointed out that the reaction products between maleic anhydride and the alpha and beta eleostearic acids reported by Kaufmann and Baltes were, respectively, the reverse of those reported by Morrel and Samuels[9] and Morrel.[10] As a rule, it is very difficult to obtain clear-cut results from eleostearic acid by chemical methods alone.

Summary

Highly purified specimens of alpha and beta eleostearic acids having melting points higher than previously reported values were prepared, and their molar refractivity and parachor were determined accurately. The molar refractivity of the alpha acid was compared with data from other sources. For the molar refractivity and parachor of the beta acid and the parachor of the alpha acid, no previous data were available. Other physicochemical measurements are being made with both eleostearic acids.

On the Properties of Dipicrylaminates

BY JACOB KIELLAND

Very little has been published about the chemical and physical properties of dipicrylaminates, though dipicrylamine (2,4,6-hexanitrodiphenylamine) has been known as an explosive for many years, and its sodium or ammonium salt ("Aurantia") has been used on account of its dyeing properties, and as a light filter in photography.

Recently, dipicrylamine has been shown to be of importance for the quantitative determination of potassium[1]; consequently, these compounds and their properties are of some interest. Further, it has been shown by the author that specific attraction forces, of interest for the theory of strong electrolytes, occur even in very dilute solutions of dipicrylaminates. Hence, he feels justified in presenting some measurements recently made.

Purification of Material.—The hexanitrodiphenylamine (made by Skaanska Bomullskrutsaktiebolaget) was dissolved by the equivalent amount of alkali to give an aqueous solution (at about 50°) containing 15 to 20% dipicrylaminate. After filtration, a crude mass of sodium dipicrylaminate was salted out by the addition of an equal volume with concentrated (50°) aqueous sodium nitrate. In order to remove any impurities still present, the red crystalline mass was then treated three times with an excess of 65–70% nitric acid, leaving a yellow crystalline mass of dipicrylamine.[2] The washed crystals (solubility product about 10^{-10}, according to Kielland[1]) were dissolved in alkali and salted out as described above, filtered and washed rapidly with a little chilled water. After recrystallizing twice from conductivity water, the brilliant red crystal mass finally was dried to constant weight in a desiccator at room temperature.

Color

Solutions.—Dipicrylaminate solutions are strongly colored, yellow at high dilutions, and orange to red at intermediate and high concentrations. The solvent effect is of minor importance, as was found from preliminary absorption measurements, carried out with a Zeiss Stufenphotometer.

The molecular extinction coefficient at 463 mμ was in all cases about 2.2×10^4, but the curves in acetone, etc., appeared a little steeper than in water. For dilute solutions in water, Bouguer–Beer's law was found approximately valid, but since the Stufenphotometer does not work with monochromatic light, one does not feel justified in presenting more extensive data.

In order to give an idea of the color of the aqueous solutions, in the "fundamental, universal color language,"[3] a chromatic analysis was carried out, on the basis of measured extinction curves at different concentrations. Hardy's method of ten selected ordinates[3] was applied, and the computation based upon ICI normal observer, ICI illuminant C and ICI primary stimuli. From Table I, the pronounced change in hue at about 10^{-4} N is easily seen; the color is typical orange between 10^{-4} and 10^{-3} N, red at higher, and yellow at lower concentrations. The very high excitation purity of all solutions above 10^{-4} N, together with the relatively high corresponding brightness figures, is of importance for the use of dipicrylaminates as light filters.

TABLE I

CHROMATIC ANALYSIS OF AQUEOUS SOLUTIONS OF DIPICRYLAMINATES

		(Concentration 10^6 × moles per liter) 0	5	10	20	40	60	100	200	500	1000

Trichromatic coefficients	red	0.310	0.332	0.352	0.389	0.446	0.478	0.511	0.549	0.595	0.628
	green	.316	.343	.368	.415	.468	.484	.482	.448	.403	.371
	violet	.374	.325	.280	.196	.086	.038	.007	.003	.002	.001

Solids.—The color of solid dipicrylamine is yellow to orange (according to purity and particle size), that of the solid dipicrylaminates red. Using the Zeiss Stufenphotometer with Kugel-reflector, some spectral reflection curves were measured, and the resulting chromatic analysis (Table II) may serve as an illustration (based on ICI illuminant C).

Particle Size

Ultrafiltration.—Ultrafiltration analysis according to Ferry[4] was carried out with 10^{-3} N potassium dipicrylaminate in water at 20°. As filters were used Membran- and Ultrafeinfilter from Membranfiltergesellschaft in Göttingen, membranes of the Elford type made according to the directions given by Bauer and Hughes,[5] as well as cellophane, swollen in concentrated zinc chloride as suggested by McBain and Stuewer.[6] Normal filtration was effected in all experiments, with no blocking effects detectable. The maximum relative concentration[7] was 100% even at mean pore diameters of only 10 mμ, and very near to 100% at about 4 mμ. The end-point consequently was so low as to justify the conclusion that the dipicrylaminate did not appear in colloidal dispersion.

Dialysis.—The dialysis coefficient of the dipicrylaminate anion in 10^{-3} N aqueous solution was measured by a Cuprophane membrane at 18°, by the method of Brintzinger.[8] The solvent was in all cases 0.5 N sodium nitrate; concentrations were measured photometrically, and ferricyanide and thiosulfate were employed as reference substances.

The resulting ionic weight was found equal to the formula weight (438) ± 10%. Hence, in very dilute solutions, the dipicrylaminate anion probably carries no complex bound water in the sense described by Brintzinger,[9] nor is it associated or polymerized in such a manner as to affect the process of dialysis. In this connection perhaps it may be mentioned that Brintzinger and Schall[10] also found the theoretical molecular weight for most of the ionic dyes studied by them.

The precision of measurement, however, does not exclude the possibility that a small fraction of the anions may have been present as double ions.

Density and Molal Volume.—The densities $d^{18}{}_4$ of sodium dipicrylaminate solutions were measured at molalities from 0.01 to 0.13, using a pycnometer (volume about 30 ml.) of the Sprengel type, as modified by Riiber.[11] All solutions were made up by weight, and all weighings corrected to vacuum. Temperature was maintained with a precision of ±0.01°. The results are given in Table III.

TABLE III

MEASURED DENSITIES OF SODIUM DIPICRYLAMINATE SOLUTIONS

G. per 1000 g. of water	Molality	$d^{18}{}_4$
5.68	0.01232	1.00140
6.885	.01493	1.00198
13.66	.02963	1.00526
35.90	.0779	1.01582
60.45	.1311	1.02710

Since the work of Masson[12] it has been known that for most electrolytes the apparent molal volume of a solute is a linear function of $c^{1/2}$, and a convenient method of computation has been suggested by Gucker.[13] In the present case there results the equation

$$\Phi(V_2) = 235 + 3.0c^{1/2} \text{ ml. per mole} \qquad (1)$$

The densities of solutions obeying Masson's rule are found from

$$d = d_1 + c(M_2 - d_1\,\Phi^0)/1000 - c^{3/2}\,(d_1/1000)(\partial\Phi/\partial c^{1/2}) \qquad (2)$$

Hence, for sodium dipicrylaminate at 18°

$$d^{18}{}_4 = 0.99862 + 0.2263c - 0.0030c^{3/2} \qquad (3)$$

The densities at other temperatures may be calculated similarly, taking[14] the molal volume at 0 and 10° approximately 4 and 2.5 ml. lower than the figure at 18°.

Freezing Point Depression.—The freezing points of aqueous solutions of sodium dipicrylaminate at concentrations from 5×10^{-3} to 5×10^{-2} N were measured, using a platinum resistance thermometer[15] for calorimetric purposes, of the type described by Dickinson and Mueller,[16] and made by the Leeds and Northrup Company.

A differential method of measurement was used. The arrangement made it possible to detect temperature variations of about 1 to 2 × 10^{-4}°. Samples for analysis were taken with a chilled pipet immediately after the final readings, and the concentrations determined[17] by measuring the conductivity at 0°. The results are reported in Table IV.

TABLE IV

FREEZING POINT DEPRESSIONS OF SODIUM DIPICRYLAMINATE IN WATER

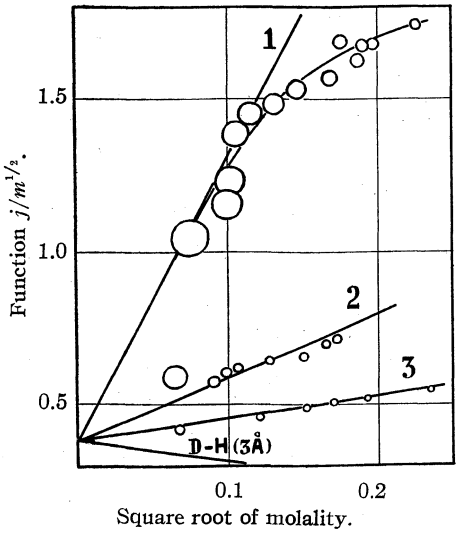

Fig. 1.—Freezing point measurements of sodium dipicrylaminate (1); picric acid (2); and sodium dinitrophenolate (3).

Activity Coefficients.—The activity coefficients of the solute at 0° were computed from plottings (Fig. 1) of $j/m^{1/2}$ against $m^{1/2}$, according to the method of Abel, Redlich and Lengyel[18]

$$-\log_{10}\gamma_{\pm} = (j + 2\int_0^{m^{1/2}} (j/m^{1/2})\, dm^{1/2})/2.303 \quad (4)$$

where j is the Lewis–Randall function $[1 - \vartheta/(3.718\ m)]$. The values at even molalities are given in Table V, and may be represented by the equation

$$-\log_{10}\gamma_{\pm} = 0.486\mu^{1/2}/(1 + \mu^{1/2}) + (9.0 - 50m)m \quad (5)$$

where μ denotes the ionic strength $\mu = {}^1/_2\Sigma m_i z_i^2$.

TABLE V

MEAN STOICHIOMETRIC ACTIVITY COEFFICIENTS OF SODIUM DIPICRYLAMINATE IN WATER AT 0°

Concn., moles per 1000 g. of water	Activity coefficient $\gamma_{\pm}$
0.001	0.947
.002	.916
.005	.840
.01	.739
.02	.602
.03	.509
.04	.440
.05	.387

In Fig. 2 are also plotted the activity coefficients at 0° for the related compounds sodium dinitrophenolate, sodium picrate and picric acid, calculated from the freezing points measured by Lange and Herre.[19] The dipicrylaminates obviously have such low activities that some strong association effects must be present. From pH measurements it is evident, however, that dipicrylamine is not a typical weak electrolyte. Thus, it is most probable that strong forces appear between the anions, a view which is confirmed by the measurements below.

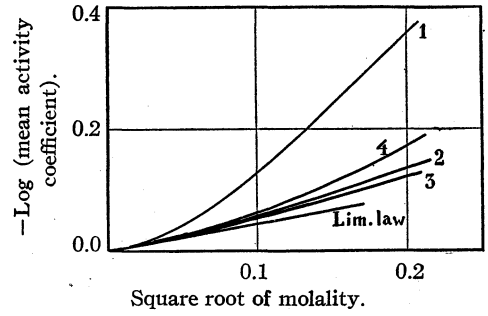

Fig. 2.—Activity coefficients at 0° for sodium dipicrylaminate (1); sodium picrate (2); sodium dinitrophenolate (3); and picric acid (4).

Equivalent Conductivity

Experimental.—Conductivity measurements were carried out in a 20-ml. cell of the pipet type designed by Washburn.[20] The cell constants were determined with the 0.1 and 0.01 D solutions of potassium chloride described by Parker and Parker.[21] The measurements were made with an improved Wheatstone bridge described by Jones and Josephs.[22] Measurements at 700 and 2000 cycles gave identical results within ±0.05%.

All solutions were made up by weight from purified (see above), dried sodium dipicrylaminate and doubly distilled "equilibrium" water.[23] Since the carbonic acid present may produce some colloidal dipicrylamine which may disturb the electrode functions and sound minima, a little sodium carbonate was usually added to the distilled water; the conductivity of the latter thus was increased from about 0.5 to 1.0 × 10^{-6} mhos, the proper correction of which was allowed for.

Results.—The conductance measurements were carried out at 0° with solutions of concentrations ranging from 10^{-3} to 10^{-1} N, and the results are presented in Table VI and in Fig. 3.

Up to concentrations about 0.03 N, the measurements may be given by the equation

$$1 - f_{\mu} = (0.219 + 29.5/\Lambda_0)c^{1/2} - Bc \quad (6)$$

TABLE VI

CONDUCTIVITY OF SODIUM DIPICRYLAMINATE IN WATER AT 0°

Concn. moles per liter	Density d^0_4	Conductivity $10^3 \times K$	Equiv. cond. Λ_c
0.00138	1.0002	0.0515	37.3
.00582	1.0012	.2120	36.45
.00667	1.0014	.2427	36.35
.00936	1.0020	.3370	36.0
.01480	1.0032	.527	35.6
.0211	1.0047	.744	35.3
.0294	1.0066	1.022	34.75
.0426	1.0096	1.450	34.0
.0475	1.0107	1.600	33.65
.0764	1.0173	2.458	32.15
.1177	1.0268	3.521	29.9

The coefficient $B = 2.5$ is probably larger than for any other uni-univalent electrolyte, the highest value reported being given by Lange and Herre[19] as $B = 1.7$ for sodium picrate.

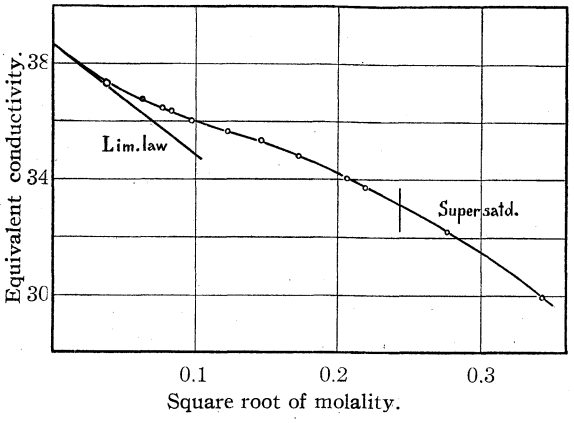

Fig. 3.—Equivalent conductivity of sodium dipicrylaminate in water at 0°.

The large conductivity of the dipicrylaminate at intermediate concentrations, together with the very low activity coefficients given above, must probably be interpreted as a pronounced association of anions, increasing with increasing concentration.

At about 0.025 N, however, we have an inflection point of the conductivity curve, perhaps caused by the interaction between associated anions and the cations.

Ion Mobilities.—The extrapolation to infinite dilution was made by the method of Shedlovsky.[24] The plotting of $\Lambda_0' = (\Lambda_c + 29.5c^{1/2})/(1 - 0.219c^{1/2})$ against c gave a straight line below $c = 0.025$, with the result $\Lambda_0 = 38.7$ for sodium dipicrylaminate. If 25.85 be taken[25] as Λ_0 for sodium ion at 0°, one obtains the limiting equivalent conductivity for the dipicrylaminate anion at 0° equal to 12.8, which is a fairly probable figure (compare the known figure for picrate anion, 15.2).

Mobility values at other temperatures may be computed from the empirical Johnston–Angel[26] formula

$$\Lambda_0(t) = \Lambda_0(t_1) \times [\varphi_t/\varphi t_1]^m \qquad (7)$$

where φ denotes the fluidity of water; $m = c/a$, where c equals the temperature coefficient of ion mobility, and a that of the fluidity of water. Since m represents the deviation from Stokes' law, a deviation which decreases with decreasing mobility and also with increasing size of the hydrated ions, we have from plottings of c against mobilities extrapolated to a probable figure $m = 0.98 \pm 0.01$ for the dipicrylaminate anion. Then we have

$$\Lambda_{0t} = 21.5\ [1 + 0.0251(t - 18) + 0.000125(t - 18)^2]^{0.98} \qquad (8)$$

Heat of Solution

The integral heat of solution of sodium dipicrylaminate in water was determined at 0.005 and 0.01 N, also the heat of dilution of a 0.125 N solution. The measurements were carried out at 20° in a Dewar vessel of 1.5-liter capacity, with 2- to 4-g. samples of sodium dipicrylaminate crystals. The temperature curves were taken with the platinum resistance thermometer described above. Calibration of the calorimeter was made with potassium chloride, the heat of solution of which was obtained from the tables of Bichowsky and Rossini.[27] The results are seen from Table VII (in the last column is shown the error caused by an uncertainty of 3×10^{-4} degree in the original temperature measurements).

TABLE VII

INTEGRAL HEAT OF SOLUTION OF SODIUM DIPICRYLAMINATE IN WATER

Concn., moles per liter	Heat of soln., kcal. per mole
0.005	−12.35 ± 0.06
.010	−12.32 ± 0.04
.125	−10.9 ± 0.1

The absorption of heat is seen to be fairly high, reaching about twice the figure for sodium picrate.

(24) Shedlovsky, THIS JOURNAL, **54**, 1405 (1932).

(25) Landolt–Börnstein–Roth, "Physikalisch-chemische Tabellen," 5 Aufl., III Erg. bd., Verlag von Julius Springer, Berlin, 1936, p. 2059.

(27) Bichowsky and Rossini, "The Thermochemistry of the Chemical Substances," Reinhold Publishing Corp., New York, N. Y., 1936.

Discussion.—The figures above indicate a relative partial molal heat content at 0.05 N equal to $\bar{L}_2 \doteq -0.8$ kcal., while the non-ideal free energy change is calculated to $\bar{F}_2 \doteq -0.5$ kcal. Hence,[28] we can conclude that in such solutions some molecule-molecule effect must be quite overwhelming. Taking into consideration also the results of the activity and conductance measurements, we see that, owing to strong van der Waals forces between the two large organic, polarizable anions, considerable association occurs between ions of equal sign, in spite of electrostatic repulsion. A more quantitative treatment of the degree of association will appear elsewhere.[29]

Phase Phenomena

The writer recently happened to make some interesting observations, a preliminary report of which might be mentioned here.

On mixing at room temperature perhaps 1 g. of sodium dipicrylaminate crystals with 10 ml. of a 1 N aqueous sodium chloride solution, part of the crystal mass is dissolved, while the remainder sinks to the bottom, still in the crystalline state. Making the same experiment with calcium chloride instead of sodium chloride, part of the crystals dissolve readily, but the remainder after some minutes will have changed into a *heavy, clear and red colored liquid.* Heating to 53° causes complete miscibility. On cooling below 52°, the dark colored liquid phase again separates as a turbidity which soon collects to larger drops, subsiding to the bottom. As an example may be mentioned that the separated liquid phase from one of the experiments had a specific gravity of 1.33 and contained about 45% of water, the rest being calcium dipicrylaminate together with some chloride.

Such systems, with definite temperatures of complete miscibility (the same result obtained by increasing as by decreasing the temperature), were also observed at other normalities of calcium chloride, as well as with different weights of dipicrylaminate added. The results of these preliminary experiments, carried out in sealed glass tubes of 1-ml. capacity, are given in Fig. 4.

(29) Kielland, to be published in *J. Chem. Education.*

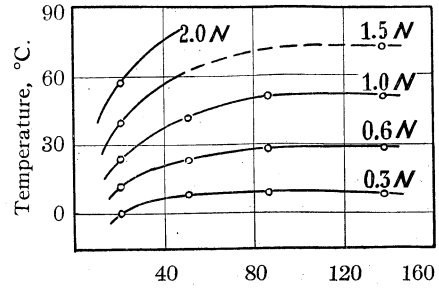

Fig. 4.—Curves of complete miscibility of dipicrylaminate in calcium chloride solutions of different normalities.

At present the writer is not able to give a satisfactory explanation of the astonishing distribution of the electrolyte dipicrylaminate on *two* aqueous solutions in equilibrium with each other, though it is in accordance with the phase rule. An extensive and thorough study of the problem seems very desirable, particularly because, on account of the strong specific forces observed in dilute solutions, interesting structural relationships are likely to occur in such concentrated solutions as obtained during the miscibility experiments.

Acknowledgments.—The writer wishes to acknowledge his indebtness to Norsk Hydro-Elektrisk Kvælstofaktieselskab, Oslo, to Norges Tekniske Höiskole (Chemistry Department), Trondheim, and to "Nansenfondet" for a grant.

Summary

1. A short color analysis of dipicrylaminates is given.

2. The molal volume of sodium dipicrylaminate in water has been determined, and density figures of aqueous solutions are reported.

3. Freezing point depressions and equivalent conductivities of sodium dipicrylaminate have been measured at 0°, also its heat of solution.

4. Strong association effects due to van der Waals forces have been found to exist between the dipicrylaminate anions even in dilute aqueous solutions.

5. An interesting case of partial miscibility has been discovered in mixtures of dipicrylaminates with aqueous calcium chloride solutions.

PORSGRUNN, NORWAY RECEIVED DECEMBER 10, 1938

[CONTRIBUTION FROM THE CHEMISTRY LABORATORIES OF NEW YORK UNIVERSITY]

The Rate of Dissolution of Iron in Acids

BY MORRIS B. ABRAMSON AND CECIL V. KING

Previous work in this Laboratory has indicated that a modified Nernst diffusion layer theory accounts, in large part at least, for the dissolution rates of magnesium and marble in acids, of zinc and cadmium in acids with certain depolarizers present, of copper in ferric salt solutions (but not in acids with depolarizers), of benzoic acid in dilute alkali and for the rate of heat transfer from solid to solution.[1] Other work on magnesium in aqueous solutions[2] can for the most part be interpreted on this basis, though in ethyl alcohol solutions the rate for magnesium seems to be partly diffusion, partly chemically, controlled.[3]

Van Name and his co-workers[4] have shown very clearly the conditions under which dissolution rates are controlled by diffusion rates or by chemical rates, and have studied cases believed to be of each type. They point out that if the chemical rate is very rapid compared to the physical transport rate, the reagent concentration falls to zero at the surface and a diffusion gradient equal to the full reagent concentration will be set up; if the chemical rate is very slow, no concentration gradient between the surface and the bulk of the solution will exist; and finally if chemical and physical transport rates are comparable in magnitude, a definite reagent concentration will exist at the solid surface, less than that in the bulk of the solution. The intermediate case where both the physical and chemical factors are operative has been treated theoretically by Roller.[5]

The general criteria of a diffusion-controlled rate are: (1) Various solids dissolve in the same reagent at the same rate. (2) In different reagents the rate is an exponential function of the diffusion coefficient.[1b] (3) The rate increases with stirring speed, the exact function depending on the type of stirring. (4) The rate follows the same function of the viscosity as the diffusion coefficient. (5) The temperature coefficient is in general less than 1.5 per 10°. If the chemical reaction is slow and controls the observed rate, then (1) the rate should be independent of stirring speed, viscosity and diffusion coefficient; and (2) the temperature coefficient should be, in general, greater than 2.0 per 10°.

Iron was chosen for the present investigation because it is less active than zinc, and its chemical reaction rate should be lower; also it was known that the metal dissolves faster in nitric acid than other dilute acids, indicating that nitrate acts as a depolarizer; and nitro compounds are reduced by iron and acid without hydrogen evolution. The disadvantages are that salts of weak acids hydrolyze and form insoluble films, and the dual valence leads to some complication, fortunately found not to be serious.

The dissolution rate of iron has not been measured previously with the present objectives in mind. The rate in more concentrated acid, with no depolarizer but with other metals as coupling agents, has been measured by Centnerszwer and Straumanis.[6]

Friend and Dennett[7] found that the rate of dissolution from a rotating iron disk, in dilute acid with no depolarizer, was linear with rotational speed up to 4000 r. p. m., and that the temperature coefficient was about 2 per 10°. Huber and Reid[8] also measured the effect of rotational speed with an iron disk, in 0.1 *N* sulfuric acid with no depolarizer, up to 11,360 r. p. m., and the rate of reduction of nitrobenzene in acid with the iron disk rotating up to 10,560 r. p. m.

Experimental.—Cylinders of the purest iron available commercially[9] of dimensions given in the figures, were rotated in 250 cc. of solution for all experiments at the lower speeds; at speeds above 6000 r. p. m. in 2000 cc. of solution. In most of the experiments the cylinders were removed, dried and weighed after five minutes in the solution at 25 ± 0.5°, and were repolished with fine emery paper before using again. The reproducibility was in general ±2 to 4% except in those cases where visible films formed on the metal.

1.—The rates were measured in four concentrations of hydrochloric acid at 2000 r. p. m., 25°, with increasing

amounts of potassium nitrate added until maximum rates were reached. In one series the cylinder was polished after each run; in another series it was allowed to become fully etched. It showed a fine, uniform crystalline structure with no inhomogeneities. These maximum rates were considerably higher than with the polished cylinder. In both cases yellow films appeared at low nitrate concentrations, and the rates were quite erratic with the etched metal. No films were visible at higher nitrate concentrations and the rates became reproducible. Under similar conditions the dissolution rate of zinc is linear with nitrate concentration, and less nitrate is necessary to reach the maximum rate.

Typical rates are plotted in Figs. 1 and 2 up to the nitrate concentration at which they become constant.

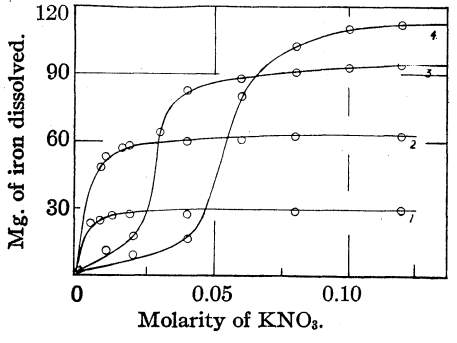

Fig. 1.—Mg. of iron dissolved in five minutes in 250 cc. of hydrochloric acid and potassium nitrate at 2000 r. p. m., at 25°: iron polished; cylinders about 1.8 cm. in diameter, 2.6 cm. in length; 1, 0.01 *N* HCl; 2, 0.025 *N* HCl; 3, 0.04 *N* HCl; 4, 0.05 *N* HCl.

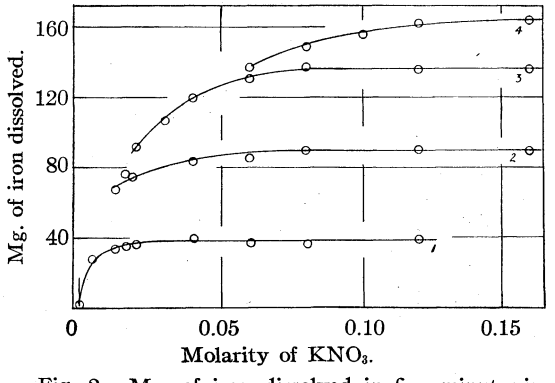

Fig. 2.—Mg. of iron dissolved in five minutes in 250 cc. of hydrochloric acid and potassium nitrate at 2000 r. p. m. at 25°: iron etched; cylinders 1.8 cm. in diameter, 2.6 cm. in length; 1, 0.01 *N* HCl; 2, 0.025 *N* HCl; 3, 0.04 *N* HCl; 4, 0.05 *N* HCl.

2.—Similar experiments were carried out with the polished cylinders in perchloric, nitric, sulfuric, acetic and tartaric acids with added potassium nitrate. Rates with the sulfuric and perchloric acids are shown in Figs. 3 and 4. No satisfactory maxima are reached with the higher acid concentrations, the rate increasing steadily with

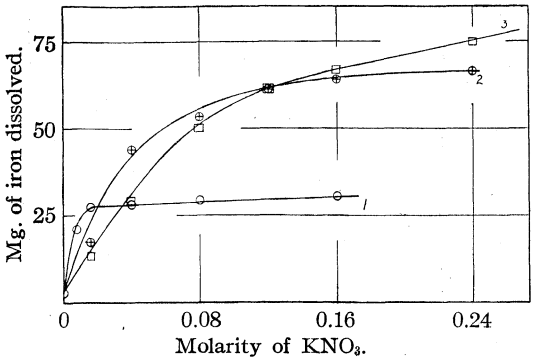

Fig. 3.—Mg. of iron dissolved in 250 cc. of solution in five minutes at 25° and 2000 r. p. m.: cylinders 1.8 cm. diameter, 2.6 cm. long; polished between runs; 1, 0.01 *N* H_2SO_4; 2, 0.025 *N* H_2SO_4; 3, 0.05 *N* H_2SO_4.

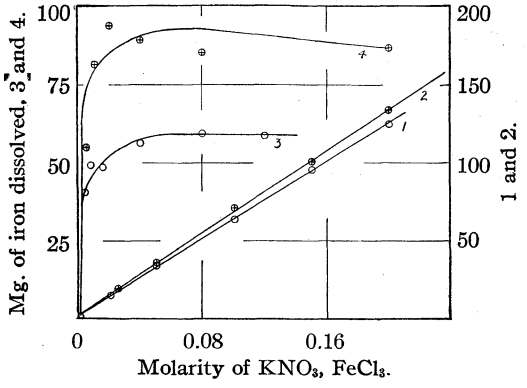

Fig. 4.—Mg. of iron dissolved in 250 cc. of solution in five minutes at 25°, at 2000 r. p. m.: cylinders 1.8 cm. diameter, 2.6 cm. long; polished between runs; 1, $FeCl_3$ + 0.01 *N* HCl; 2, $FeCl_3$ + 0.05 *N* HCl; 3, 0.025 *N* $HClO_4$ + KNO_3; 4, 0.05 *N* $HClO_4$ + KNO_3.

sulfuric, and decreasing with perchloric, acid after reaching a maximum which is lower than that in hydrochloric acid. The rates in 0.01 *N* acids, however, are about the same as in hydrochloric acid, and those at 0.025 *N* are only slightly lower. Added potassium nitrate did not have a very large effect on the rate in nitric acid; this is shown in Fig. 5, where the maximum rates, or the highest rates obtained, in these three acids and also in hydrochloric acid, are plotted. Only the rates in hydrochloric acid are linear with acid concentration, and none of them extrapolate to zero. The extrapolated rate may be due to a solvent reaction, which cannot be obtained experimentally at zero acid concentration because of insoluble reaction products.

The rates in acetic and tartaric acids were about one-tenth as great as in the strong acids. Visible films were formed and the rates were not very reproducible. These rates are not tabulated or shown in the figures.

3.—Experiments carried out in various solutions showed that the rate follows the unimolecular law over at least half the reaction in all the solutions mentioned, except those of very low nitrate concentration. The cylinders were rotated for two- or three-minute periods in the same

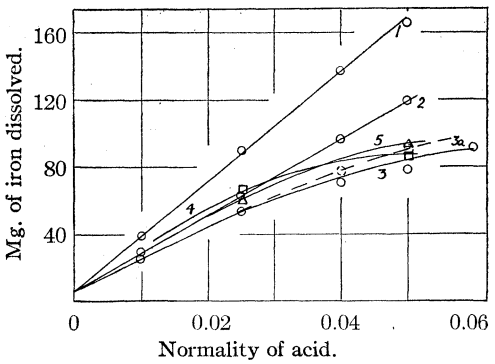

Fig. 5.—Effect of acid concentration on maximum rates of iron dissolving in 250 cc. of solution at 25° and 2000 r. p. m.: 1, HCl + KNO_3, etched iron; 2, HCl + KNO_3, polished iron; 3, HNO_3, polished iron; 3a, HNO_3 + KNO_3; 4, H_2SO_4 + KNO_3; 5, $HClO_4$ + KNO_3.

solution until most of the acid was used up. In calculating rate constants from the equation $k = \frac{2.3V}{At} \log \frac{a}{a-x}$ (where the symbols have the usual significance) it was assumed that two equivalents of hydrogen are used per atom of iron. The deviation from the equation in the later stages shows that this is not strictly true. Tests after the runs showed that one-tenth to one-fifth of the dissolved iron was in the ferric state, probably due to oxygen absorption or oxidation of ferrous ion by nitrate and hydrogen ion. The nitrate reduction also probably requires more than two hydrogen ion equivalents per iron atom. On the other hand, any ferric ion formed will begin to dissolve iron without using up hydrogen ion.

The highest rate constants thus obtained are given in Table I.

4.—Hydrogen peroxide and potassium nitrite were tried as depolarizers with hydrochloric acid. The rates obtained are shown in Fig. 6. The initial rates are nearly linear with peroxide concentration, but the maxima are not as high as with nitrate and tend to fall off with increasing peroxide at the higher acid concentrations. With nitrite the maxima are still lower and the rates fall off rapidly with higher nitrite concentration. In both cases heavy yellow or brown films account for these results. Neither substance can be considered a satisfactory depolarizer.

A few experiments showed that *p*-nitrophenol was even less satisfactory. Iron dissolves to some extent in persulfates; addition of hydrochloric acid had little effect on the rate.

5.—The rates were measured in ferric chloride solutions, with 0.01 and 0.05 *M* hydrochloric acid present. These rates are plotted in Fig. 4. They are linear with ferric chloride concentration at least to 0.2 *M*, are not greatly influenced by added acid, and follow the unimolecular law at all concentrations.

6.—In an attempt to explain irregularities in the preceding curves, the effect of various salts on the rate in nitric acid was determined. These rates are shown in Fig. 7. Small amounts of chloride and bromide increase the rate somewhat, while larger amounts have a remarkable depressing effect. Sulfate ion has only a retarding effect. The rates were unimolecular at low salt concentration, but in the presence of 0.08 *N* salt showed an autocatalytic trend where repeated runs were made in the same solution even though the iron cylinder was repolished between runs. Addition of 0.04 *M* potassium nitrate to 0.05 *M* nitric acid, 0.08 *M* potassium chloride nearly doubled the rate, which still was autocatalytic; addition of 0.08 *M* potassium nitrate increased the rate from 15 to 106 mg. dissolved in five minutes and caused the rate to become unimolecular again.

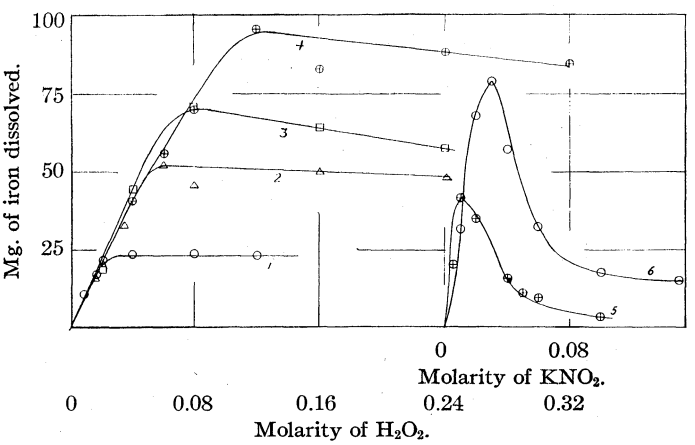

Fig. 6.—Mg. of iron dissolved in five minutes in 250 cc. of HCl with either KNO_2 or H_2O_2 at 2000 r. p. m. and 25°: 1, 0.01 *N* HCl + H_2O_2; 2, 0.025 *N* HCl + H_2O_2; 3, 0.04 *N* HCl + H_2O_2; 4, 0.05 *N* HCl + H_2O_2; 5, 0.025 *N* HCl + KNO_2; 6, 0.05 *N* HCl + KNO_2.

7.—The effect of rotational speed on the dissolution rate was determined in a number of solutions. These rates are plotted in Figs. 8, 9 and 10. Only in ferric chloride solution is the rate proportional to the speed up to the highest values of the latter. In all other cases the rate reaches a maximum and in hydrochloric acid decreases again at higher speeds. In the hydrochloric, perchloric and sulfuric acids, sufficient nitrate was present to give the maximum rate at 2000 r. p. m. In the more concentrated hydrochloric acid, and in nitric acid with the higher sulfate ion concentrations, the maximum rate is reached at lower stirring speeds. Apparently ions which

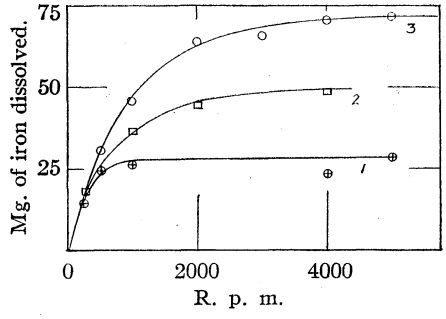

Fig. 10.—The effect of stirring on the amounts of iron dissolving in 250 cc. of solution in five minutes at 25°: 1, 0.025 *N* HNO_3 + 0.04 *N* K_2SO_4; 2, 0.025 *N* HNO_3 + 0.008 *N* K_2SO_4; 3, 0.025 *N* H_2SO_4 + 0.16 *M* KNO_3.

These temperature coefficients evidently fall into two distinct groups. In ferric chloride at low and high stirring speeds and in the other solutions at low stirring speeds, the temperature coefficients lie between 1.29 and 1.43; in the acid solutions at higher speeds, at which the maximum dissolution rates have been reached, the temperature coefficients lie between 2.04 and 2.34. Obviously two different reaction mechanisms are involved.

Discussion

According to the criteria given in the introduction, the effect of stirring speed and the low and high temperature coefficients indicate that these two mechanisms which control the dissolution rates are (a) diffusion and (b) chemical reaction.

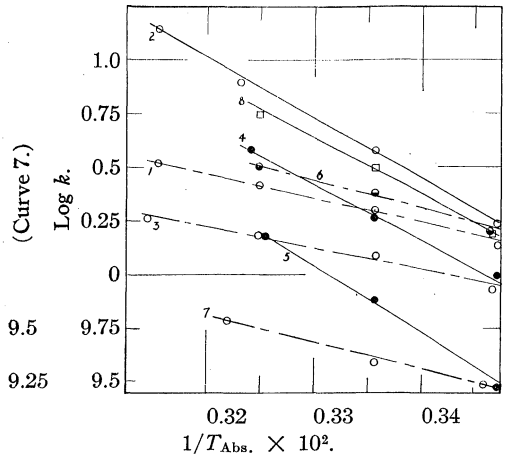

Fig. 11.—Effect of temperature on the rate constants. For legend, see Table IV.

The maximum rates for the polished cylinders in dilute hydrochloric acid at 2000 r. p. m. (Fig. 1), agree well with those found previously for zinc and magnesium. For example, from a cylinder of zinc 2.44 cm. in diameter, 1.88 cm. long, 3.75 mg. of zinc dissolves per sq. cm. in five minutes in 500 cc. of 0.0142 *M* hydrochloric acid at 25°, 1440 r. p. m.[10] From this we calculate $k = 1.87$, in excellent agreement with the value 1.89 of Table I obtained at the same peripheral speed. Comparison with the work of King and Schack[11] at higher peripheral speeds also shows good agreement.

In ferric chloride at 2000 r. p. m. (Fig. 4), the value of k is 0.357. A copper cylinder of similar diameter, in dilute ferric chloride at 2000 r. p. m., gives a somewhat higher value, $k = 0.500$.[12] In ferric chloride at a peripheral speed of 24,000 cm./min. (about 4000 r. p. m., Fig. 9), the rate constant for iron is about 0.755; at the same peripheral speed the rate constant for copper in ferric chloride with no added acid is 0.829 (ref. 12, Table VI). The rate of dissolution of copper in ferric nitrate is lower and under similar conditions the rate constant is 0.666 (ref. 12, Table V).

The etched iron dissolves considerably faster than the polished metal and we must attribute this to the increased surface, in spite of statements frequently made to the effect that etching or pitting has little effect on these diffusion-controlled rates. Such tests usually have been made at comparatively low stirring speeds. Experiments in this Laboratory have shown that magnesium is little affected by polishing or etching, while c. p. zinc dissolves more slowly if not frequently cleaned and polished, due to accumulation of impurities on the surface.

If the rates are actually controlled by the chemical reaction at higher stirring speeds, it is difficult to see why the rate should decrease as the speed increases, in certain solutions (Fig. 8). This is in some way connected with the retarding effect of chloride ion, as shown at 2000 r. p. m. (Fig. 7). The more chloride or sulfate ion present, the lower the speed at which the maximum rate is reached (Figs. 8 and 10). Undoubtedly the rate at 2000 r. p. m., 0.08 *N* chloride or sulfate (Fig. 7) would be "chemically controlled" (high temperature coefficient). This chloride ion effect is sufficient to obscure the effect, at the maximum, of increasing the hydrogen ion concentration (Fig. 8).

It is evident that the rate in hydrochloric acid at low nitrate concentrations (Fig. 1) is influenced both by film formation and by a slow "chemical rate." The maximum rate is not reached sharply and the excess nitrate necessary for the maximum rate increases with the acid concentration. The rate is also lower in stronger than in more dilute acid in this region, at the same nitrate concentration. This indicates that considerable excess nitrate must be present at the immediate surface of the metal if hydrogen ion is to react as rapidly as it reaches the surface, *i. e.*, if the hydrogen ion concentration is to fall to zero at the surface.

The same thing is true of sulfuric though not of perchloric acid. It seems probable that this need for excess nitrate ion and also the retarding effect of chloride, bromide and sulfate ions is connected with the efficiency of nitrate as a depolarizer. The oxidizing potential of nitrate may be barely high enough to overcome the overvoltage of hydrogen on iron under the conditions present, and either this potential or the overvoltage may be influenced by various ions, or the latter by the rotational speed; it seems unlikely that a true chemical rate would vary in this way with salt concentration and stirring speed, with otherwise constant conditions. Also the large increase in rate on addition of excess nitrate (to 0.05 *M* nitric acid, 0.08 *M* potassium chloride, already noted) indicates that the effect of chloride and other ions is to diminish the depolarizing action of nitrate.

A few experiments showed that addition of sucrose has the normal effect in those solutions giving definitely diffusion-controlled rates (*i. e.*, rate inversely proportional to viscosity). Sucrose

added to sulfuric acid (plus potassium nitrate) at a stirring speed high enough to give the maximum rate, diminishes the rate to the same extent, which does not indicate a chemically-controlled rate.

For these reasons we hesitate to call the rate at higher stirring speeds a true chemical rate until it has been investigated further. It is probable that a very high stirring speed, or a sufficiently high concentration of certain salts, would reduce the rate to the value it has with no depolarizer present, where the temperature coefficient is also high[7]; in this case the mechanism might also be identical.

The increase in the rate in nitric acid on addition of small amounts of chloride and bromide (Fig. 7) may be ascribed to an increase in the diffusion coefficient of the acid. While the diffusion coefficient of nitric acid has not been determined in the presence of salts, it is lower than that of hydrochloric acid in water ("International Critical Tables").

The maximum rates in the various acids at 2000 r. p. m. are roughly proportional to the diffusion coefficients, except for perchloric acid, as shown in Table I. Because of the irregularities found, including film formation with the weaker acids, a quantitative comparison would be impossible.

Summary

The rate of dissolution of very pure iron has been measured in solutions of several acids, with potassium nitrate, hydrogen peroxide, potassium nitrite and *p*-nitrophenol as depolarizers. Of these only the nitrate was found to be reasonably satisfactory as a depolarizer.

The rate was studied as a function of the depolarizer concentration, the acid concentration, the concentration of various added salts, the stirring speed and the temperature. The rate was also measured in ferric chloride solutions of various concentrations, at various stirring speeds and temperatures, with and without added acid.

The rate is shown to be diffusion-controlled under all conditions in ferric chloride; at low stirring speeds in hydrochloric acid with sufficient nitrate present, and approximately so in nitric acid with certain chloride concentrations. Under other conditions (higher stirring speeds, higher salt concentrations, low nitrate concentrations) it is in whole or part controlled by a slower reaction perhaps of chemical nature at the metal surface.

Under conditions where the rate is diffusion-controlled, the temperature coefficient is about 1.35 per 10°; where it is "chemically" controlled, the temperature coefficient is 2.0–2.4 per 10°. The activation energies vary accordingly.

Studies of Purified Palladium Sols Prepared by Electric Sparking

BY W. PAULI, W. HOFF AND F. LICHTENSTERN[1]

The series of investigations of different purified and concentrated Bredig sols of the noble metals,[2] carried out at this Institute over a period of years, has been continued with the study of palladium sols. As in the previous studies our concern was to observe the relations between origin of charge and stability on the one hand and inorganic chemical properties of palladium on the other by physical-chemical methods of analysis. Thus it was possible to make comparisons in the same way with the other sols of noble metals already investigated.

The methods of preparing, purifying and concentrating were disintegration by the electric spark and an improved process of electrodecantation.[2]

One of the first results was that it is impossible to prepare a palladium sol by electrodispersion in *conductivity water* (spec. cond. 7×10^{-7} mho). Regardless of the dispersion time, in every case precipitates are formed instantly. This behavior contrasts with that of platinum and silver.[2b,c] The explanation is that pallado oxide is less acid than platino oxide[3]; a hydroxo acid of palladium is not known, while a hydroxo acid of platinum

(1) The experiments were carried out at the Institut für medizinische Kolloidchemie der Universität Wien in 1936 and 1937.

Z.*, **58**, 22 (1932); Eirich and Pauli, *ibid.*, **67**, 186 (1934); Pauli, Russer and Brunner, *ibid.*, **72**, 26 (1935); (b) platinum sols: Pauli and Schild, *ibid.*, **72**, 165 (1935); Pauli and Baczewski, *Monatsh.*, **69**, 204 (1936); (c) silver sols: Löffler and Pauli, *Kolloid. Z.*, **60**, 146 (1932); Hoff and Pauli, to be published, with list of literature.

(3) P. Pascal and P. Baud, "Traité de Chimie Minérale," Tome XI, Masson et Cie, Paris, 1932, p. 793.

has been shown to be the charging group of Bredig platinum sols in conductivity water.[4] On the other hand, palladium is more noble than silver (silver oxide is a strong base). In the case of silver the anodic oxidation (during electrodispersion) furnishes the stabilizing complex by forming ultimately silver hydroxide,[2c] which in the case of palladium in conductivity water is not possible. This demonstrates a similarity with gold, which for analogous reasons does not form a electrodispersion sol in conductivity water.[5]

We found similar conditions by electrodispersion in sulfuric acid (1×10^{-3} N). An adhering surface complex could not be expected because of the high solubility of palladium sulfate in water.[3] Since the formation of an oxo complex (as a result of electrolysis) is not possible either, we have no sol formation. Silver and gold form very instable colloids in dilute aqueous sulfuric acid solutions. The corresponding experiments with platinum have not yet been undertaken. Such experiments would be interesting because of the great number of complex acids known to be formed by platinum and the sulfate radical.

The behavior of palladium when dispersed in solutions of potassium chloride was unexpected. Within the concentration range 1×10^{-4} to 1×10^{-2} N a dark brown sol is formed, but it coagulates within one day at the most. These sols, therefore, are still less stable than the corresponding silver sols. The explanation probably is that the reaction of palladium metal while being dispersed in potassium chloride solutions does not lead to a noticeable complex formation. The formation of silver sols (dispersed under the same circumstances) was favored by the simultaneous formation of oxo complexes. Thus one may consider the Bredig silver sols in potassium chloride solutions as stabilized by chloro hydroxo mixed complexes (Löffler–Pauli[2c]), so that the extraordinary sensitiveness of the pure hydroxo silver sols to carbon dioxide was considerably decreased.

The question was raised, therefore, to what extent the behavior of palladium would prove analogous. For this purpose the electrodispersion in sodium hydroxide solutions (optimal concentration 1×10^{-3} N) was tried. We obtained dark brown sols which were stable for months if sufficiently protected against carbon dioxide. As hydroxo sols (which they obviously are) they showed a high sensitiveness to carbon dioxide and electrodialysis, just as do the corresponding silver sols. The exchange of sodium ion for hydrogen ion forced by membrane hydrolysis processes during electrodialysis leads again to rapid discharge by complex decomposition. The reaction is the same as of silver sol (Löffler–Pauli[2c]), namely, a neutralization of the hydrogen ions by the complex hydroxo groups (see also the silver nitrate titration of a chloro hydroxo palladium sol discussed later in this paper).

Sols dispersed in nitric acid solutions proved not to be resistant to carbon dioxide or electrodialysis in spite of the fact that the nitrate ion is a favored complex partner of palladium. They were even less resistant than the sols dispersed in sodium hydroxide. This behavior would suggest the presence of hydroxo nitrato mixed complexes. If perfectly protected from carbon dioxide, the sols are stable for a long time. This demonstrates that the coagulation is due not only to the high solubility of the palladium complex mentioned, but also to its decomposition. This decomposition is caused by hydrolytical processes aided by reaction with carbon dioxide or electrolysis.

By far the best sols were obtained by electrodispersion in hydrochloric acid solutions. In the optimal concentration (1×10^{-3} N) the time of dispersion may be extended to three hours. Excellent sols with a content up to 0.2 g. of palladium per liter are attainable directly; they are not sensitive to carbon dioxide and laboratory air. Only sols with a smaller content (0.12 g. of palladium per liter and one to two hours time of dispersion) which may easily be concentrated to more than 1 g. of palladium per liter are suitable for electrodecantation. The conductivity of the dispersion medium decreases during dispersion (by 5–8%) and continues to decrease after completing the electrodispersion.[6] After eighteen to twenty days the limiting value of conductivity (equilibrium) is reached. In case the primary sols were too concentrated (0.2 g. of palladium per liter), the period of decreasing conductivity is interrupted by an increase about the thirteenth day after dispersion. Shortly thereafter these sols coagulate spontaneously.

(4) S. W. Pennycuick [*J. Chem. Soc.*, 2108 (1928); 623 (1929)] has postulated a hexahydroxo platini acid as charging complex. A platino hydroxo acid $H_2Pt(OH)_4$ is more probable. This acid possibly is in oxidation and detachment equilibrium with a platini complex (Pauli and Baczewski[2b]). For further details, see Pennycuick, *Kolloid Z.*, **49**, 407 (1929); *Z. physik. Chem.*, **148**, 413 (1930).

(5) Beans and Eastlack, THIS JOURNAL, **37**, 2667 (1915) and [2a].

(6) Under certain favorable circumstances observations have been made of an analogous behavior of gold and platinum sols. After dispersion the complexes are filled up by consumption of free acid.

The electrodispersion sols (before electrodecantation) contain nearly the same concentration of chlorine and hydrogen ions (about 8×10^{-4} N), ascertained by conductometrical titration. But this amount of ions is not yet sufficient to explain the total conductivity. Therefore we have to assume a further amount of electrolyte (about 3–6 $\times 10^{-4}$ N). We suppose it is the colloid electrolyte with the "gegenions" (contra-ions) H^+ and Pd^{++} which is present besides molecularly disperse hydrochloric acid and pallado chloride. The molecularly disperse contaminations are removed to a large extent by electrodecantation. In order to avoid an entire hydrolysis of the complexes the electrodecantation has to be stopped at the right moment. Besides, a decomposition equilibrium seems to exist between the charging groups and pallado chloride. In sols purified and concentrated by electrodecantation, a small amount of pallado chloride therefore is always present.

The sols concentrated and purified by electrodecantation show a continual increase of conductivity with time, accompanied by spontaneous layer formation and partial flocculation. Nevertheless, among our number of specimens were some sols with nearly constant conductivity after concentrating. These sols show the same amount of (free) hydrogen ions titrated either by sodium hydroxide or barium hydroxide. On the other hand, all sols the conductivity of which increases with time show a sodium hydroxide consumption greater than the concentration of free (conductance-active) hydrogen ions and a consumption of barium hydroxide still larger than that of sodium hydroxide. The greatest number of our sols obviously possess further heteropolar surface groups which may be filled up to chlorohydroxo mixed complexes, besides the charging complexes. In this respect they are similar to the chloro platinum sols (Pauli–Schild[2b]).

With our concentrated sols which are freed to a large extent from molecular electrolytes (in so far as these are not re-formed by complex decomposition), we also found the amount of titrated hydrogen ions insufficient to explain the total conductivity. They contain on the average the same concentration of other cations (Pd^{++}). Less highly purified sols are more strongly charged (the membrane hydrolysis of surface complexes is not so far advanced), but they contain up to twenty times as many other cations as hydrogen ions. A part (up to one-half) of this amount of cations can be ascribed to molecularly disperse pallado chloride, as may be ascertained by simultaneous determination of free chlorine ions by conductometrical titration.

This may be illustrated by some results:

	Sol VII	Sol XXII	Sol X
Content, g. Pd/liter	0.35	0.66	1.10
k of last upper layer, mho $\times 10^6$	7.0	2.7	5.7
k of sol, mho $\times 10^5$	2.36	1.09	2.80
Concn. of active H^+, $N \times 10^5$	0.92	2.1	4.6
Concn. of cations other than H^+, $N \times 10^5$	20	1.5	9.6
Concn. of free chloride ion, $N \times 10^5$	8.9	<1	~3.1

Sol VII incompletely purified, sol XXII highly purified, sol X middle degree of purification; k = specific conductivity at 25°.

As one may see from this table, continued purification causes removal of molecularly disperse pallado chloride and exchange of the "gegenion" (contra-ion) Pd^{++} for H^+. This is in agreement with the previous experience with other negative colloids. Simultaneously the absolute amount of charging ionogen groups is decreased by the accompanying complex decomposition.

Coagulation by freezing produces a decrease of conductivity in the freezing liquid (liquid produced by thawing the frozen colloid and by separation from the coagulum, without Tyndall phenomenon). The sols mentioned above as of constant conductivity are exceptions: they maintain their constant conductivity in the freezing liquid also after coagulation. In all cases where the conductivity of the freezing liquid is lower than that of the sol, the hydrogen ion concentration of the sol is decreased in the freezing liquid. The cations present other than H^+ are in some cases increased, in some decreased, by freezing. This leads to the conclusion that the bulk of hydrogen ions, being "gegenions," goes into the coagulum or vanishes by reaction with the hydroxyl groups of the charging chloro hydroxo complex which is partially destroyed, and pallado chloride is set free. But the amount of pallado chloride liberated by freezing in some cases may be ten times as much as could be produced by complex decomposition at the maximum. This abundance of pallado chloride is probably originated by non-ionogen heteropolar surface groups of the sol particles which are rich with chlorine. In other cases, on the contrary, the amount of pallado chloride is considerably decreased by

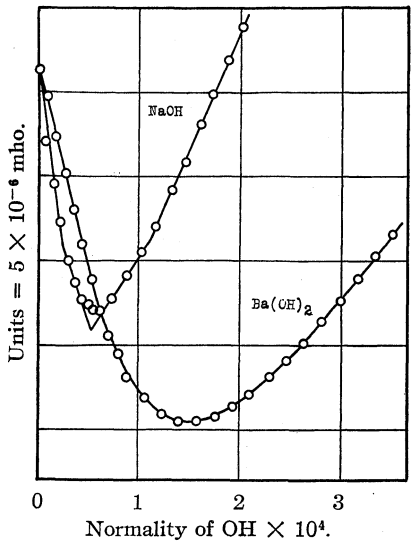

Fig. 1.—Correlative sodium hydroxide and barium hydroxide titrations of 3 cc. of sol X.

freezing. This may be due to a filling up of non-ionogen heteropolar surface groups that are low in chlorine. Thereby the cation (Pd^{++}) will be inactivated. This behavior is in agreement with the results of the barium hydroxide titration. Figure 1 shows an example of a characteristic pair of correlative sodium hydroxide and barium hydroxide titrations.

The existence of non-charging heteropolar surface groups in addition to the charging groups had been proved in the case of platinum sols (Pauli–Baczewski,[2b] Pennycuick[4]) by comparison of sodium hydroxide and barium hydroxide titrations. A filling up of the heteropolar surface groups to ionogen complexes is more favored in the presence of barium hydroxide than of sodium hydroxide because of the more strongly inactivating and associating divalent barium ion.

The presence of palladium ions in the freezing liquid could be proved in all cases by a special palladium test.

This palladium test is analogous to the platinum test of Pauli–Schild.[2b] The procedure is reduction of the palladium compound by formic acid under special conditions and addition of phosphorous–molybdenic acid. The blue color of the solution indicates palladium concentrations of 0.2–1 γ per cc.; green color.

The determination of the colloid equivalent—number of palladium atoms per one free charge—was possible only in cases where nearly all gegenions were hydrogen ions. The calculated values varied between 100 and 300.

The conductometrical determination of chlorine had to be carried out by silver sulfate titration instead of the usual silver nitrate titration, for some sols had the capacity of taking the nitrate radical into their complexes. This could be proved by titration with potassium nitrate, nitric acid and by the comparison of silver sulfate and silver nitrate titrations. This behavior was obvious with freezing liquids which had been reduced by hydrogen gas. If titrated by silver nitrate they showed a less consumption of the reagent after reduction than before. The explanation is that the complex present in the freezing liquid and capable of adding the nitrate radical, loses this capacity by reduction.

A further interesting result of titration analysis was also found by silver nitrate titration. The charging complexes of some sols are destroyed by reaction with silver ion, *i. e.*, after removal of chlorine, a reaction between hydrogen ion and complex hydroxyl groups takes place. The nitrate radical instead of chlorine cannot form a stable complex. In such cases the silver nitrate titration diagrams show the particular character of acid–base titration plots, since during titration the hydrogen ion is stoichiometrically consumed (Fig. 2). There seems to be only one equation possible for the corresponding reaction: $[Pd(OH)_2Cl_2]H_2 + 2AgNO_3 = 2AgCl + Pd(NO_3)_2 + 2H_2O$, because for one hydrogen ion conductivity equivalent that vanishes, one salt conductivity equivalent has been found to be set free.

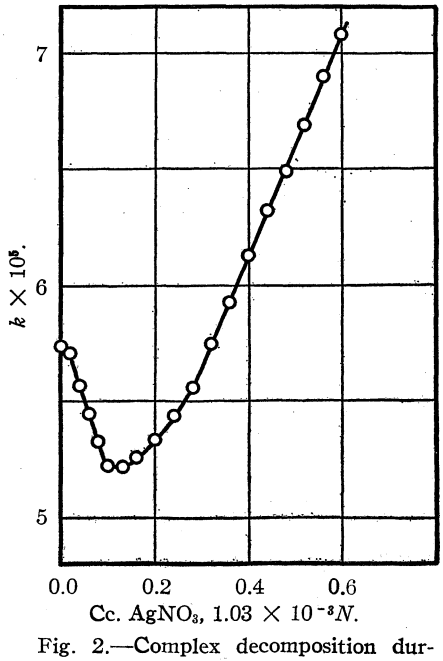

Fig. 2.—Complex decomposition during silver nitrate titration: sol IX, 3 cc.

The chlorohydroxo palladium sols (even if not concentrated and purified) are coagulated by boiling. The conductivity is then slightly increased, the charging groups are probably detached entirely, and the titrable hydrogen ion is transferred completely into the "boiling liquid."

Summary

1. Preparations of palladium sols by sparking under the solvents: conductivity water, and 10^{-3} normal solutions of sulfuric acid, sodium hydroxide, nitric acid, potassium chloride, hydrochloric acid, are related and discussed briefly.

2. The charging group of the sols prepared in the case of the chlorides very probably is a chlorohydroxo mixed complex of varying constitution. This complex maintains a decomposition equilibrium with molecularly disperse pallado chloride. Besides there are heteropolar groups on the particle surface that are non-ionogen and therefore not charging. These groups may react in a variety of ways.

The Quantum Yield of Monochloroacetic Acid Hydrolysis

BY R. NELSON SMITH, PHILIP A. LEIGHTON AND WESLEY G. LEIGHTON

A direct comparison of the uranyl oxalate and monochloroacetic acid photolyses at 2537 Å. shows, on the basis of the published quantum yields for these reactions, a startling discrepancy. Since both reactions have been widely used as chemical actinometers and results interpreted on the basis of the existing quantum yields, it seemed necessary to find the source of this discrepancy. In a recent note[1] the authors reported a redetermination of both yields. A solution 0.01 *m* in uranyl sulfate and 0.05 *m* in oxalic acid gave an average quantum yield at 2537 Å. of 0.60, in agreement with the value reported by W. G. Leighton and Forbes[2] for this wave length. For a solution 0.5 *m* in monochloroacetic acid at room temperature and 2537 Å. the quantum yield was found to lie between 0.3 and 0.4, as compared with the value of 1.07 given by Rudberg.[3] We, accordingly, have reinvestigated this reaction, and now find the quantum yield to be strongly dependent on temperature.

Experimental

Monochloroacetic acid was purified by a series of distillations in an all-glass apparatus, starting samples from several sources being employed. Freshly prepared solutions, before exposure to light, showed no chloride ion. Quantum yields were based on the amount of chloride ion produced, which was determined by potentiometric titration against standard (0.0075 *m*) silver nitrate. The cell consisted of a calomel electrode connected to an Ag–AgCl electrode by a saturated potassium nitrate bridge (Cl^- free). The method was checked by titration of standard chloride solutions. Radiation at 2537 Å. was supplied by a mercury arc in conjunction with a quartz monochromator. The rectangular reaction cell was entirely of fused silica and contained 8.23 cc. of solution in which the average light path was 25 mm. Absolute energies were determined by thermopile, calibrated against U. S. B. S. radiation standards. In the course of the investigation, two independent monochromators, four light sources, including lamps giving both reversed and non-reversed lines at 2537 Å., as well as lamps giving both continuous and intermittent radiation (with respect to time), two thermopiles, one surface and one linear, and four U. S. B. S. standard lamps were used, all with uniform results.

Energy measurements were carried out by the method of horizontal integration[4] taking thermopile readings at 2-mm. intervals across the back of the cell. The length of the monochromator slit was adjusted so that the divergent beam, after passing through the cell filled with water or solution, fell entirely within the vertical limits of the thermopile surface. Variations in arc intensity during a run and between different series of integration measurements were followed by placing the thermopile in a fixed and reproducible position at the front of the cell. The methods of applying corrections and of computation were those employed by the authors in previous work.[2,5]

For runs at elevated temperatures the cell, with the exception of the front window, was enclosed in an insulated heating jacket and energy measurements were made as before except that variations in intensity were not followed during the course of the run. Rates of decomposition by the dark reaction were determined for several different temperatures, and from a plot of log k *vs.* $1/T$ the correction for the amount of decomposition due to the dark reaction during a photolysis was determined.

Results

Numerical results are given in Tables I and II. Percentages decomposed ranged from 0.04 to 2. Runs 5 to 8 show that Φ is constant over a 13-fold variation in light intensity, and runs 7 and 10 that it is constant over a 4-fold variation in chloroacetic acid concentration. The variation in quantum yield of the photolysis with temperature is shown in Fig. 1. The rate of the dark reaction is given by the equation

$$\log k = 5.40 - (5240/T),\ k = \text{moles cc.}^{-1}\ \text{sec.}^{-1}$$

This corresponds to an activation energy of 24,000 cal./mole. While at 25° the dark reaction rate was only about 1% of the rate during photolysis, at 69° it amounted to 57% of the total rate and at higher temperatures became so large as to make quantum yield determinations uncertain.

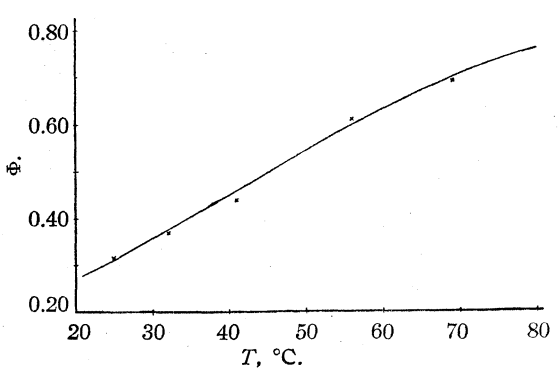

Fig. 1.—Variation in quantum yield of monochloroacetic acid hydrolysis with temperature. The points are experimental, the curve calculated.

25	976	34.6	2.50×10^{19}	1.58×10^{19}	0.632
25	816	35.9	2.29×10^{19}	1.30×10^{19}	.566

Discussion

The variation in quantum yield with temperature may be accounted for by a mechanism which assumes a competition between secondary reactions which lead to deactivation or to decomposition, *viz.*

(1) $CH_2ClCOOH + h\nu \longrightarrow CH_2ClCOOH^*$ ϕI_a

(2) $CH_2ClCOOH^* + M \longrightarrow CH_2ClCOOH + M$ k'_2

(3) $CH_2ClCOOH^* + 2H_2O \longrightarrow CH_2OHCOOH + H_3O^+ + Cl^-$ k'_3

Assuming a steady state concentration for $CH_2ClCOOH^*$ and including (M) and (H_2O) with the values of k'_2 and k'_3, this mechanism gives for the over-all quantum yield

$$\Phi = \frac{+d(Cl^-)/dt}{I_a} = \frac{\phi}{1 + k_2/k_3} \qquad (1)$$

If now

$$k_2 = A_2 e^{-E_2/RT} \text{ and } k_3 = A_3 e^{-E_3/RT}$$

equation (1) becomes

$$\Phi = \frac{\phi}{1 + \frac{A_2}{A_3} e^{(E_3 - E_2)/RT}} \qquad (2)$$

The curve in Fig. 1 was obtained from this equation by setting $\phi = 1$, $A_2/A_3 = 8.3 \times 10^{-6}$, and $E_3 - E_2 = 7400$ cal./mole. It fits the observed points within experimental error. The value of 7400 cal. for the difference in activation energies between reactions 3 and 2 appears reasonable. The ratio of the temperature independent factors, A_2/A_3, implies that in the deactivating step the excited chloroacetic acid molecules must withstand at least 10^5 collisions before deactivation occurs. Although direct evidence indicating that activated molecules can enter into secondary reactions is very meager in photochemistry, in this instance a free radical mechanism appears unlikely and the reactions given are the simplest which will fit the facts.

The results of this investigation are definitely at variance with those of Rudberg[3] and of Harris and Kaminsky.[6] The difference between our values and that of Rudberg may be due first to the fact that he used a Hefner lamp for calibration of his thermopile and second to the extremely small amounts of photolysis which he obtained, requiring only about 0.2 ml. of 0.0002 *m* silver nitrate for titration.

Harris and Kaminsky, by a comparison of the rate of coloration of malachite green leucocyanide with the monochloroacetic acid hydrolysis found $\Phi_{HClAc} = 1.05$ at 2537 Å. and 26–29°. The source of the variation between their result and ours is not apparent.

Farkas[7] determined Φ for monochloroacetic acid in the region 1850–2000 Å. by comparison with the photolysis of ammonia. The temperature of the solution was not given. Assuming $\Phi_{NH_3} = 0.25$, he obtained $\Phi_{HClAc} = 0.9$. From the newer work of Wiig[8] the value of Φ_{NH_3} at the pressure used by Farkas (1 atm.) is $\sim$0.16. Making this correction one obtains $\Phi_{HClAc} \sim 0.58$.

Farkas, and Farkas and Hirschberg[9] used the monochloroacetic acid reaction, assuming $\Phi = 0.9$, as an actinometer for determination of quantum yields in the photolysis of ethyl alcohol and of various aldehydes and acids. Again the temperatures were not given, but assuming that they were the same as in the comparison of monochloroacetic acid with ammonia, the yields given by Farkas, and Farkas and Hirschberg should be reduced by the ratio 0.58/0.9. In addition, in the equation used by Farkas and Hirschberg[9] (p. 2452) the factor 0.9 should be in the numerator rather than the denominator. Making both corrections, the yields reported by these authors should be reduced by approximately one-half.

Frankenburger and Klinkhardt[10] assumed a quantum yield of unity in using the monochloroacetic acid hydrolysis as an actinometer in a study of the photosensitized hydrogen–oxygen reaction. The temperature of the actinometer solution was 65°. Using our value of $\Phi_{HClAc} = 0.67$ at 65°, the quantum yields given by them for the H_2–O_2 reaction should be reduced by the ratio 0.67/1. This change would not appear appreciably to affect their interpretation of results.

Lyons and Dickinson[11] used the monochloroacetic acid hydrolysis as an actinometer in a careful study of the photoöxidation of liquid carbon tetrachloride at 2537 Å. and room temperature. Using Rudberg's value for Φ_{HClAc}, they found an over-all yield of close to unity for the oxidation, which in turn led to difficulty in explaining the very low yield ($\Phi < 0.01$) in the photolysis of pure carbon tetrachloride. On the basis of our results the yield for the oxidation of carbon tetrachloride becomes *ca.* 0.33, which removes the difficulty.

Summary

The quantum yield of the monochloroacetic acid hydrolysis is found to be considerably lower than the previously established values, and to vary with temperatures, at 2537 A., from 0.31 at 25° to 0.69 at 69°. The yield is independent of light intensity and concentration over the ranges studied. A mechanism involving competition between deactivation and decomposition is suggested. The relation of these results to publications in which this reaction has been used as an actinometer is discussed.

The Isoelectric Point of Collagen

BY JOHN H. HIGHBERGER

Although the isoelectric point of collagen is usually given as *p*H 4.7, a second critical point in the behavior of collagen and gelatin has frequently been noted at *p*H 7.7. Wilson and Gallun[1] found two points of minimum plumping of limed calf skin, at *p*H 5.1 and 7.6, and Wilson and Kern[2] located similar points at *p*H values of 4.7 and 7.7 in studying the swelling of gelatin. Davis and Oakes[3] found a minimum in the viscosity of 1% gelatin sols at about *p*H 8, when measured at 40°, but none at 4.7. Just the opposite result was obtained by Hitchcock,[4] whose curves show a minimum viscosity at 4.7, but not at 8. Hitchcock attributed the difference between his results and those of Davis and Oakes to the practice of the latter workers of heating their sols to 75° in the course of their preparation. Higley and Mathews[5] studied the absorption of light by gelatin sols as a function of *p*H, and found two sharply defined minima in the wave lengths absorbed, at *p*H values of 4.7 and 7.7. Kraemer and Dexter,[6] on the other hand, found a maximum in the light scattering of gelatin at *p*H 8 only in the case of pig skin gelatin, while for other gelatins it was found close to *p*H 5. Electrophoretic studies[7] have established the isolectric point of commercial calf skin gelatin as close to *p*H 4.7 to 4.8, the exact location depending upon the nature and ionic strength of the buffer salts present.

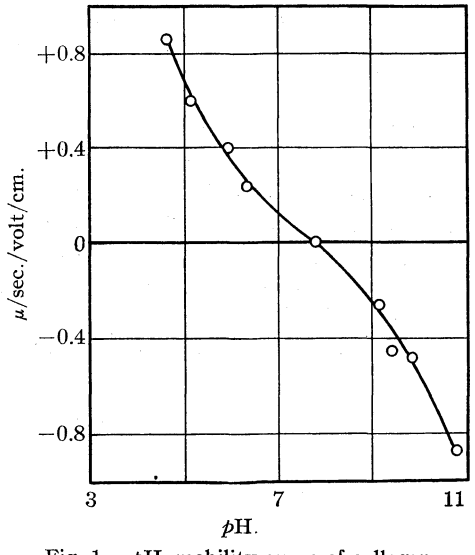

Fig. 1.—*p*H–mobility curve of collagen.

Experimental

A study of the electrophoresis of the collagen of animal skin, using the technique described by Moyer,[8] has been in progress in this Laboratory for some time. Several lots of collagen prepared from fresh steer hide by a process previously described by the writer,[9] and varying in ash content from 0.05 to 0.08%, have been used in this work. Powdered material which had passed a 100-mesh sieve was used to make suspensions in acetate, phosphate, and borate buffers of ionic strength 0.005, and covering the *p*H range from 4 to 11. Relatively dilute buffer systems were found necessary on account of the unusually small slope of the mobility curve over a considerable range of *p*H.

All measurements were made in the vertical microelectrophoresis cell of Abramson, Moyer and Voet,[10] which was found to be very satisfactory for use with these rather rapidly settling suspensions. At least ten particles were timed at each of the stationary cell levels 0.2 and 0.8, and the results averaged. The particles measured ranged in size from about 15 to about 75 μ. No temperature correction was made. Room temperature varied between 23 and 26° during the observations. Hydrogen electrode measurements were made in duplicate, using Clark rocking electrode vessels and a saturated calomel electrode. The reference standard was "standard acetate," of *p*H 4.65.[11]

The *p*H–mobility curve thus obtained is given in Fig. 1, from which it will be seen that this collagen is isoelectric at *p*H 7.8 under the experimental conditions mentioned. This observation is in accord with swelling data already reported[12] for similar collagen preparations, which showed a pronounced minimum zone between *p*H 7 and 10 in unbuffered solutions. An experiment by Beek[13] indicates that the isoionic point of this collagen is also close to *p*H 7.7.

Preliminary observations on a mixed gelatin made by extracting a similar collagen preparation several times with distilled water at 100° indicate that this gelatin is isoelectric at *p*H 6.1, when adsorbed on collodion particles and observed in buffers of ionic strength 0.005. Qualita-

tive observations on a sample of standard hide powder[14] showed it to be isoelectric in the neighborhood of *p*H 5.

Discussion

Wilson has interpreted the two critical points, at *p*H values of 4.7 and 7.7, as the respective isoelectric points of the gel and the sol forms of collagen and gelatin.[15] The fact that the collagen used in the present work received only a mild alkaline treatment with half-saturated calcium hydroxide solution in the course of its preparation, while commercial hide powder and gelatin are given a much more drastic alkaline treatment, suggests that the isoelectric point of native collagen is near *p*H 7.8, and that treatment with alkaline solutions causes some structural change the effect of which is to lower the isoelectric point of the collagen and of the gelatin made from it.[16] The work of Briefer,[17] who found that gelatin made from alkaline pretreated collagen possesses minimum jelly consistency and maximum turbidity at about *p*H 5, while that made from acid pretreated collagen has similar properties at about *p*H 8, is recalled in this connection.

In addition to its unusually small slope, the curve of Fig. 1 displays a further feature of interest when compared to similar curves for other proteins. The curvature in such cases, while slight, is usually convex in the region of positive mobilities and concave in the negative. Just the opposite relations are found in the curve of Fig. 1. No explanation of this difference in shape, which is undoubtedly related to the mode of linkage of the polar groups of the protein, will be attempted at this time. Further work on the cause of the shift in the isoelectric points of collagen and gelatin is in progress in this Laboratory.

The author wishes to acknowledge the valuable assistance of Dr. H. J. Kersten in mounting the vertical microelectrophoresis cell. The cell itself was made by Mr. J. D. Graham of Haddonfield, New Jersey, to whom the author's thanks are also due.

Summary

The isoelectric point of collagen prepared from steer hide with a minimum alkaline treatment has been shown, by measurements of electrophoretic mobility, to be at *p*H 7.8 in buffers of ionic strength 0.005. It is suggested that the shift of the isoelectric point to *p*H 4.7 in the case of commercial gelatin and hide powder is due to some structural change in the protein caused by the alkaline treatment given these materials.

(16) After the completion of this work a paper on the electrophoresis of collagen was presented by Beek and Sookne at the meeting of The American Leather Chemists Association at Shawnee-on-Delaware, Penna., June 7, 1939. Using a horizontal cell and buffers of ionic strength 0.02, they located the isoelectric point of collagen similar to that used in the present work at about *p*H 7, and attributed the shift to a more acid value in the case of commercial gelatins to the hydrolysis of the amide groups during the liming treatment.

A Study of the Boric Acid Color Reaction of Flavone Derivatives

BY C. W. WILSON[1]

It was observed in this Laboratory that lemon juice dried in the presence of boric acid produced a brilliant yellow color. Later the color reactive substance was identified as a constituent of Szent-Györgyi's citrin.[2]

This color reaction is sufficiently sensitive to detect 0.004 mg. of citrin or 0.002 mg. of quercitrin in 0.5 ml. of solution. The work here reported is an attempt to determine the specificity of the boric acid color reaction.

Experimental

Several representative flavones[3] and flavanones were purified by recrystallization from dilute alcohol at least three times. Table I shows the structural formulas of some of these substances and their boric acid color reactions.

The hydroxychalcones shown in Table I were prepared by alkaline treatment of naringin and hesperidin. A suspension of 2 g. of naringin or hesperidin with 25 ml. of water was placed in a 50-ml. flask equipped with a stopcock, the flask

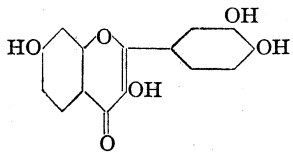
(3) The flavones used in this work were obtained by Mr. A. J. Lorenz from Dr. C. E. Sando of the U. S. Bureau of Chemistry and Soils.

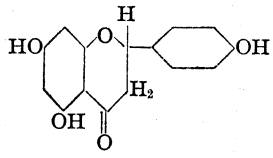
TABLE I

CONFIGURATION OF VARIOUS ORGANIC SUBSTANCES, AND CORRELATION WITH BORIC ACID COLOR REACTION

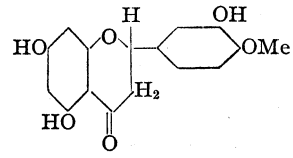
NEGATIVE REACTIONS



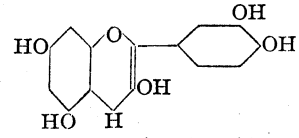
Fisetin



Naringenin

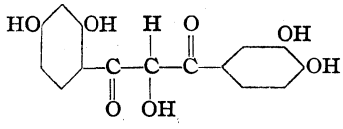


Hesperetin

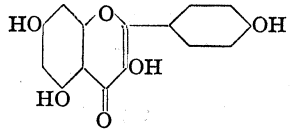


Cyanidin (as glycoside from apple)

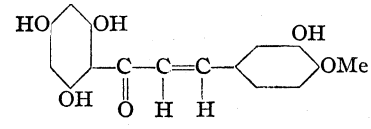
POSITIVE REACTIONS



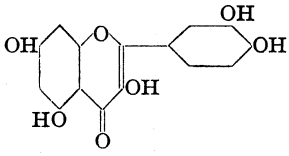
Alkali treated fisetin



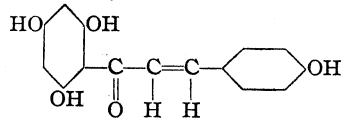
Kaempferol



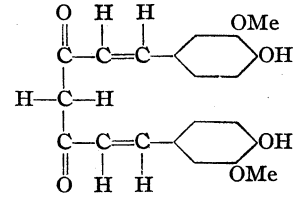
2′,4′,5,6′-Tetrahydroxy-4-methoxychalcone (from hesperetin)



Quercetin



2′,4,4′,6′-Tetrahydroxychalcone (from naringenin)



Curcumin. The positive color is pink and not confusable with the flavone color

evacuated until the liquid boiled and the stopcock then closed. Into the flask was drawn 25 ml. of 2.5 *N* sodium hydroxide solution. The dark reddish solution was mixed thoroughly and allowed to stand for twenty-four hours at room temperature. It was then poured into 12.5 ml. of 5 *N* hydrochloric acid. The very slightly acid solution was evaporated to dryness in vacuum, and the hydroxychalcone extracted from the residue with absolute methyl alcohol.

The compounds so obtained were water soluble, orange powders.

The reagent used for determining the boric acid reactivity of a compound was made by mixing equal parts of two separate solutions, one composed of 100 ml. of absolute acetone saturated with boric acid, and the other 100 ml. of absolute acetone containing 10 g. of anhydrous citric acid.[4] Sufficient of the mixed solutions was prepared for each day's requirements, since it was found that while each solution was stable indefinitely, a very slow color formation took place in the acidified boric acid solution. This color was sometimes observable after as short an interval as two days.

For carrying out the determination of reactivity, approximately 0.5 mg. of the flavone derivative or other substance was dissolved in about 1 ml. of dry acetone, and the solution divided into two equal portions. To one portion was added about 2 ml. of the boric acid–citric acid–acetone reagent, and the other portion was diluted to an equal volume with a mixture of equal parts of the citric acid–acetone solution and acetone. The colors of the two tubes were compared at the end of a few minutes, and any definitely stronger color in the boric acid containing tube was reported in Table I as a positive reaction.

In addition to testing the aglycones (non-sugar parts) shown in Table I, the effect of the presence of sugar groups was checked by comparing the reactivity of two of the glycosides of quercetin; isoquercitrin (sugar group in the position marked X)[5] and quercimeritrin (sugar group in the position marked Y). With quercetin all three gave positive reactions. In these cases, the presence or position of the sugar group was without influence.

(4) Made by allowing crystalline acid to effloresce completely in air at 30–40°, then heating in a thin layer to 100° for two hours.

(5) Attree and Perkin, *J. Chem. Soc.*, 234–240 (1927).

Since treatment of naringenin and hesperetin with dilute sodium hydroxide caused formation of a substance that gave a positive reaction with the borocitric acid reagent, it was decided to try the effect of the same treatment on fisetin. In this case, also, a positive reacting compound was formed.

Hesperetin heated with 1 volume of concentrated hydrochloric acid in 2 volumes of alcohol formed an orange solution which was carefully neutralized with sodium hydroxide solution and the liquid was evaporated over a steam-bath. The residue was extracted with acetone, and the extract gave a positive reaction with borocitric acid reagent.

U. S. P. tannic acid gave no reaction when treated directly with the borocitric acid reagent, nor after alkaline or acid treatment as described above.

Other substances not shown in Table I but tested in view of their possible occurrence in nature with flavones gave negative reactions. These included coumarin, coumarinic acid, dextrose, alkali treated dextrose, phloroglucinol, quinhydrone, salicylic acid, sucrose, and alkali treated sucrose.

Discussion of Results

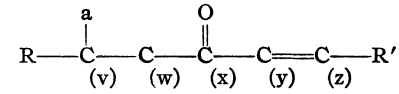
Of the flavone derivatives tested, the flavanones give no color reaction with boric acid, whereas all of the flavones except fisetin gave a reaction. With this one exception, if a substance is established as being a flavone or a flavanone by the cyanidin test, but does not give a color with borocitric acid reagent, the supposition would be that it was a flavanone.

Comparing the lack of reaction of fisetin with the reactivity of quercetin, the importance of the hydroxyl (or some other auxochromic) group in the 5-position is evident.

Comparing the reactivity of kaempferol with the lack of reactivity of naringenin leads to the speculation of whether the OH in the 3-position or the double bond between the 2 and 3 carbon atoms is responsible for the difference.

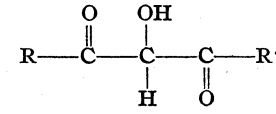
Opening the pyran ring to give the equivalent chalcone definitely establishes the importance of the double bond, and indicates that the pyran ring is unnecessary for color formation.

The configuration of a chalcone suggests that of curcumin, and causes one to feel that the color formation of curcumin with boric acid under similar conditions may be further indicative of the configuration required. If this reactivity is comparable, the benzene ring near the ketone (or quinone) group is unnecessary provided an auxochromic group is attached to the second carbon atom from the C=O group. The indicated configuration for reactivity is

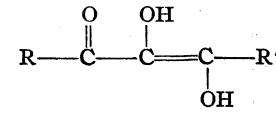


in which "a" is an auxochromic group which may probably be =O, OH, OCH_3, etc., and in which R, C_v and C_w may form a benzene ring, and C_x, C_y and C_z may form a portion of a pyran ring. In all of this work, R′ has been a benzene ring containing either methoxyl or hydroxyl groups.

When the pyran ring of fisetin is opened by treatment with an alkali, the formation of the hydroxyl group in the ortho position on one of the benzene rings fulfils the boric acid color forming requirement of having an OH (or other auxochromic) group on the second carbon atom from a C=O group. The double bond between carbon atoms on the other side of the C=O group is missing in the formula shown in Table I. Compounds of this type, however, are known to exist at least to some extent in enolic forms,[6] and instead of



the enolic form would be



which, when R and R′ have the proper configurations, as is the case in the present instance, would be expected to yield the observed coloration.

Another possible explanation is that in the alkali treatment of the fisetin there are formed other secondary compounds responsible for the color reaction.

Acknowledgment.—The author wishes to express his appreciation to the California Fruit Growers Exchange for the opportunity to carry on and publish this work and to Mr. W. E. Baier, Manager of the Research Department, for his suggestions and interest.

Summary

Citrus juices have been observed to give a yellow color when dried with boric acid.

This yellow color forming substance is concentrated in the citrin fraction of Szent-Györgyi.

Many flavone derivatives have been found to give the color reaction. Of non-flavone substances commonly found in plant tissues, none have so far been found to give a confusable color reaction.

The color reaction has been correlated with molecular constitution.

Organoselenium Compounds. I. Diphenylselenium Dihydroxides and Diphenylselenides

BY C. KENNETH BANKS[1] AND CLIFF S. HAMILTON

In order to investigate some of the therapeutic properties of organoselenium compounds, a series of compounds in which the effect of the valence of selenium could be studied, as well as the effect of changes in substituent groups, was prepared. This paper deals with some of the derivatives of diphenylselenium dihydroxide and diphenylselenide derived from the phenoxyalkanols, as these compounds have led to some therapeutically valuable arsenicals.

The reaction of Alquist and Nelson[2] and Kunckell[3] by which anisole and its homologs were condensed with selenium oxychloride to give *bis*-(*p*-alkyloxyphenyl)-selenium dichlorides was extended to three other ethers, β-phenoxyethanol, γ-phenoxypropanol and α-methyl-β-phenoxyethanol. The first two gave ether insoluble gums, while the last gave a crude crystalline mass. The crude products were purified by dissolving in chloroform, treatment with activated charcoal and "Celite," and reprecipitation with benzene. By means of this procedure all three crystallized in stable forms. The dichlorides hydrolyzed to the dihydroxides in the presence of sodium carbonate, all three of which were white crystalline solids.

The above dihydroxides, as well as *bis*-(4-methoxyphenyl)-selenium dihydroxide, were then nitrated using fuming nitric acid (sp. gr. 1.5) at 0° as the nitrating agent. A large excess of acid was required for complete nitration, probably due to the formation of an alcohol dinitrate of the dinitrodietherdiphenylselenium dinitrate. The gum formed when the nitration mixture was poured over ice was solidified by neutralizing the excess acid with sodium carbonate and boiling. These compounds proved to be of the formula *bis*-(3-nitro-4-R-phenyl)-selenium dihydroxide, R representing the ether group. The position of the nitro group was shown by cleaving with hydriodic acid, giving *o*-nitrophenol.

The nitro compounds were reduced catalytically to the diamines, using Raney catalyst.[4] At 40 pounds (2.67 atm.) pressure and room temperature the selenium was also reduced. The amines were of the general formula *bis*-(3-amino-4-R-phenyl) selenide.

Of theoretical interest was the extension of the reaction to another type of compound, acetanilide. The reaction was first tried in ether but it was found that the product was a double salt of acetanilide and selenium oxychloride. As the salt was soluble in chloroform, the reaction was run in that medium. After five days, a thick gum separated. This gum was hydrolyzed with sodium carbonate, giving a water insoluble white compound which, on purification, proved to be *bis*-(4-acetaminophenyl)-selenium dihydroxide. This compound was reduced to the corresponding diphenyl selenide and then hydrolyzed to the free amine. The last two compounds have been prepared by Theobald[5] from sulfonamide and selenic acid. The acetylated compound was obtained in two crystalline modifications, one melting at 216° as reported by Theobald, the other at 176°. The two forms were chemically identical.

Experimental

1. Diphenylselenium Dichlorides.—One-half mole of the aromatic ether was treated with selenium oxychloride according to the procedure of Alquist and Nelson.[2] The solvent was decanted from the gum or crystals formed and

purified by solution in chloroform, treatment with activated charcoal and "Celite" and reprecipitation with benzene.

2. Diphenylselenium Dihydroxides.—The above dichlorides (0.2 mole) were added to an excess of sodium carbonate in water (30 g. in 200 ml.) and the mixture heated for half an hour. On cooling, if the dihydroxide crystallized, it was filtered off; if it remained an oil, the water was decanted, fresh water added, heated and cooled. This was repeated until a solid was obtained. The crude dihydroxides were recrystallized from ethyl alcohol.

3. Nitro Compounds.—The dihydroxide was added slowly with stirring to fuming nitric acid (sp. gr. 1.5) at 0° (0.025 mole to 25 ml. of acid). After the addition was complete, the stirring was continued for fifteen minutes and the nitration mixture then poured over chipped ice. Water was added and the acid neutralized with an excess of sodium carbonate. The mixture was boiled and then cooled. The nitro compounds solidified on stirring. The methoxy and γ-hydroxypropoxy compounds were recrystallized from ethyl alcohol, the β-hydroxyethoxy compound from ethyl cellosolve and the β-hydroxypropoxy compound from methyl cellosolve.

4. Amines.—The nitro compounds were suspended in ethyl alcohol (10 g. in 50 ml.), Raney nickel prepared by the method of Adkins[6] was added and the reduction carried out with electrolytic hydrogen at 40 pounds (2.67 atm.) pressure and room temperature. The solution and suspended amine were removed from the reduction container, heated to boiling and the catalyst filtered off. Most of the alcohol was removed by evaporation under reduced pressure, water and hydrochloric acid added and the solution decolorized with charcoal. The amine was then precipitated with ammonium hydroxide. Water–alcohol mixtures were used to recrystallize the amines.

5. *bis*-(3-Amino-4-methoxyphenyl) Selenide Dihydrochloride.—The corresponding amine (10 g.) was dissolved in an excess of 6 *N* hydrochloric acid and the solution evaporated until precipitation started to occur while hot. On cooling the hydrochloride crystallized out; yield 9.5 g.

6. Double Salt of Acetanilide and Selenium Oxychloride.—Eight grams of acetanilide was dissolved in 200 ml. of dry ether and an equal weight of selenium oxychloride added with shaking. A white precipitate formed almost immediately. It was purified by solution in chloroform and reprecipitation with ligroin.

7. *bis*-(4-Acetaminophenyl)-selenium Dihydroxide.—One-fifth mole of acetanilide was treated with selenium oxychloride in chloroform as in procedure 1. The excess solvent was decanted from the gum formed, an excess of sodium carbonate in water was added and the temperature raised to the boiling point. The solution was filtered hot, removing any excess acetanilide. The precipitate was dissolved in alcohol, decolorized with charcoal and reprecipitated with water.

8. *bis*-(4-Acetaminophenyl) Selenide.—Ten grams of the dihydroxide was dissolved in warm alcohol, Raney catalyst added, and the reduction carried out under the same conditions as for the reduction of nitro compounds. After the reduction was complete, the catalyst was removed and the solution reduced in volume, and water was added, precipitating the diphenyl selenide. The product was recrystallized from a water–alcohol mixture.

9. *bis*-(4-Aminophenyl) Selenide.—Ten grams of the above product was refluxed with 100 ml. of 20% hydrochloric acid. When all the material had gone into solution, the solution was charcoaled and filtered. On cooling and making basic with sodium hydroxide, the amine precipitated.

Analytical

A modification of the method of Arne Fredga[7] was used in determining the percentage of selenium. A tenth-gram sample was digested with 5 ml. of concd. sulfuric acid until it was well charred. Fuming nitric acid was added (about 1 ml.) until the solution cleared. The excess nitric acid was boiled off, the digestion transferred to a beaker containing 50 ml. of water and the whole diluted to 150 ml. Hydrazine sulfate was added and the solution heated on a hot-plate until the precipitated selenium coagulated. The precipitate was collected in a semi-

(7) A. Fredga, *Uppsala Univ. Arsskrift*, No. 5, 232 (1935).

micro sintered glass crucible containing a thin layer of asbestos. After washing well with water, alcohol and ether, the crucible was dried and weighed on a semi-micro balance. The nitric acid must not be added until the compound is well charred or polynitro compounds resisting digestion will be formed. The precision of this method of analysis is ±0.0%.

Summary

1. Three new *bis*-(4-hydroxyalkyloxyphenyl)-selenium dichlorides and their corresponding dihydroxides were prepared by the condensation of selenium oxychloride with mixed ethers.

2. The dinitro derivatives of the above compounds and the corresponding methoxy compound were obtained. These compounds were reduced catalytically to the *bis*-(3-amino-4-R-phenyl) selenide.

3. The condensation of selenium oxychloride with benzene derivatives was extended to acetanilide, resulting in *bis*-(4-acetaminophenyl)-selenium dihydroxide. On reduction, *bis*-(4-acetaminophenyl) selenide was formed. The corresponding amine also was prepared.

Studies in the Sitosterol Complex. The Structure of α_1-Sitosterol

BY SEYMOUR BERNSTEIN[1] AND EVERETT S. WALLIS

In their experiments on α-sitosterol, Wallis and Fernholz[2] showed that this material first described as a compound by Anderson and his coworkers[3] was in reality a mixture of at least two new sterols, α_1- and α_2-sitosterol.

Besides recording the physical properties of these two new compounds and their derivatives, these investigators[2] made the following observations. Neither α_1- nor α_2-sitosterol are isomers of β- and γ-sitosterol. α_1-Sitosterol is an isomer of stigmasterol, $C_{29}H_{48}O$, and α_2-sitosterol is in all probability a homolog, $C_{30}H_{50}O$. By titration with perbenzoic acid they showed that two double bonds are present in both sterols. They give the same Liebermann color reaction. The final color is a dark blue with a reddish tint. The Salkowski reaction for both α_1- and α_2-sitosterol was found to be similar to that of ergosterol, the sulfuric acid layer becomes colored, while the chloroform stays colorless. The opposite is true for cholesterol, γ-sitosterol and stigmasterol. They also noted that both α_1- and α_2-sitosterol are precipitated by digitonin.

In this paper we wish to report the results of further experiments on α_1-sitosterol which to us seem pertinent to the elucidation of its structure. That the two double bonds in α_1-sitosterol are not conjugated was shown by an absorption spectrum study. No maxima were observed. It is also to be noted that α_1-sitosterol does not form an addition compound with maleic anhydride. Taken together these two facts indicate that this sterol cannot have its double bonds conjugated within one ring or between two adjacent rings.

The results which we obtained from a hydrogenation study on α_1-sitosterol are of special interest. From preliminary experiments we learned that only one of the two double bonds can be hydrogenated under ordinary conditions. If the hydrogenation, however, be carried out at a higher temperature (65–70°) in the presence of a small amount of concentrated hydrochloric acid, complete saturation is possible. It was further observed that the double bond originally resistant to hydrogenation can be isomerized by dry hydrogen chloride into a position which is easy to hydrogenate under ordinary conditions.

With the above facts in mind, α_1-sitosteryl acetate (I) was hydrogenated with a platinum catalyst at room temperature and atmospheric pressure. As a result, α_1-dihydrositosteryl acetate (II) was obtained. This acetate was then isomerized in a chloroform solution with dry hydrogen chloride at 0°. A new acetate, α_1-isodihydrositosteryl acetate (III), was isolated and characterized. On hydrogenation at room temperature and atmospheric pressure this compound gave a completely saturated acetate, α_1-sitostanol acetate (IV). This same substance was also obtained when α_1-sitosteryl acetate was hydrogen-

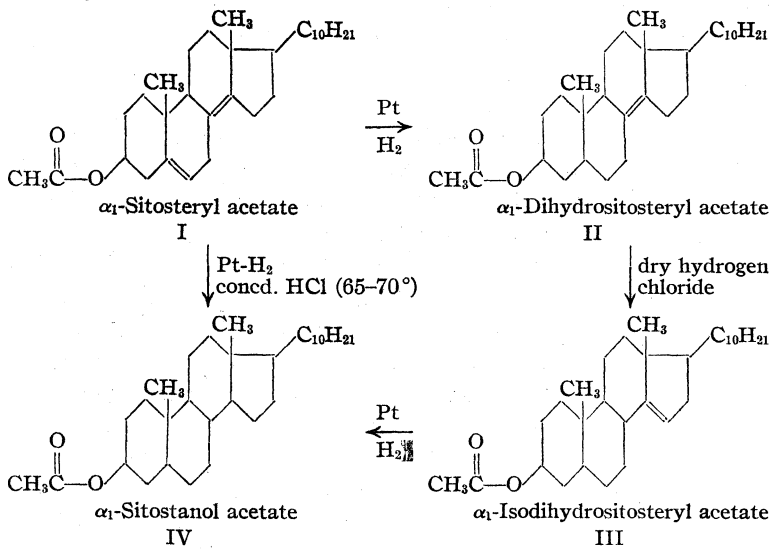
ated with a platinum catalyst at 65–70°, and at atmospheric pressure in the presence of a small amount of concentrated hydrochloric acid.

These results may be explained as follows



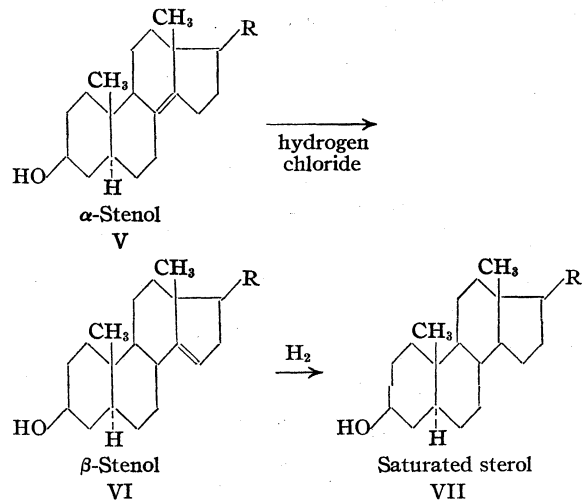
In Table I there are also listed the properties of α_1-sitosterol and its various hydrogenation products.

TABLE I

Compound	M. p., °C.	$[\alpha]_D$(CHCl3)
α_1-Sitosteryl acetate	137	+29
α_1-Sitosterol	164–166	− 1.7
α_1-Dihydrositosteryl acetate	108.5–110.5	+35.1
α_1-Dihydrositosterol	152–154.5	+10.9
α_1-Isodihydrositosteryl acetate	137.5–138.5	+42.0
α_1-Isodihydrositosterol	152–154	+31.0
α_1-Sitostanol acetate	147–148	+39.4
α_1-Sitostanol	185–186	+27.0

The structures which we have proposed for this sterol and its hydrogenation products may be supported by the following arguments. All natural sterols whose structures are known have been found to have an hydroxyl at the C_3-position. That the hydroxyl group in α_1-sitosterol is *cis* to the C_{10} methyl group is supported by the formation of an insoluble digitonide, a characteristic property of all sterols of this type. The proposed non-conjugation of the double bonds in α_1-sitosterol is supported by the negative Diels–Alder reaction and by the results of the absorption spectrum study. All natural sterols which are unsaturated have been found to have one double bond at the 5,6-position. It is also to be recalled that a $\Delta^{5,6}$-sterol is hydrogenated easily. One double bond in α_1-sitosterol is hydrogenated easily under ordinary conditions.

The fact that the second double bond in α_1-sitosterol is resistant to hydrogenation but can be isomerized into a position in which it can be hydrogenated easily is a phenomenon not unknown in sterol chemistry. The naturally non-occurring sterols α-ergostenol[4] (V) and α-cholestenol[5] (V) have been found to be resistant to hydrogenation under ordinary conditions but can be isomerized with dry hydrogen chloride to give β-ergostenol (VI) and β-cholestenol (VI), respectively. These products then can be hydrogenated easily to give the corresponding saturated compounds (VII). The fact that the cholestanol obtained from α-cholestenol by this method is identical

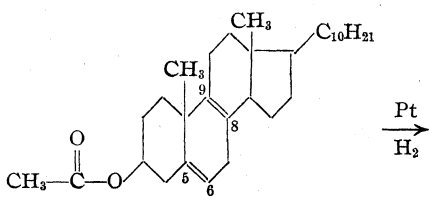


with the cholestanol obtained by hydrogenation of cholesterol shows that rearrangement with hydrogen chloride and subsequent hydrogenation do not produce epimerization at any asymmetric center. Therefore it may be argued that rearrangement of α_1-dihydrositosterol and subsequent hydrogenation, likewise, does not produce any epimerization. If such be the case, it therefore follows that α_1-sitostanol and stigmastanol differ solely due to isomerism of the hydrocarbon side chain.

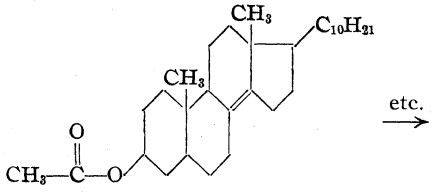
(4) Reindel, Walter and Rauch, *Ann.*, **452**, 34 (1927); Reindel and Walter, *ibid.*, **460**, 212 (1928); Achtermann, *Z. physiol. Chem.*, **225**, 141 (1934); Laucht, *ibid.*, **237**, 236 (1935).

(5) (a) Schenck, Buchholz and Wiese, *Ber.*, **69B**, 2696 (1936), (b) Windaus, Linsert and Eckhardt, *Ann.*, **543**, 22 (1938).

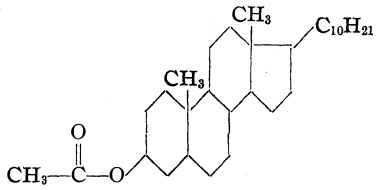
In this connection it should be recalled that a δ-stenol, such as δ-cholestenol, also has been found to be resistant to hydrogenation, and that during the course of attempted hydrogenation with palladium it is converted into the α-stenol[5b] modification. Hence the possibility presents itself that α_1-sitosterol may be in reality unsaturated at the 5,6- and 8,9-positions. The course of hydrogenation would then become



α_1-Sitosteryl acetate



α_1-Dihydrositosteryl acetate



α_1-Sitostanol acetate

Against this formulation may be cited our observation that in our hands α_1-sitosteryl acetate does not give a ketone at C_7 on oxidation with chromic acid, as would be expected if its double bonds were located at the 5,6- and 8,9-positions.

TABLE II

Unsaturated at $\Delta^{5,6}$	$[\alpha]_D$ ($CHCl_3$)	Saturated at $\Delta^{5,6}$	$[\alpha]_D$ ($CHCl_3$)
Stigmasterol	−45°	Stigmastanol	+23.8
β-Sitosterol	−37°		
α_1-Sitosterol	− 1.7°	α_1-Sitostanol	+27.0

Our assignment of the positions of the double bonds in α_1-sitosterol and its intermediate hydrogenation products may be strengthened further by considering the relation of optical rotatory power and constitution.[6] It has been observed, qualitatively, that a compound unsaturated at the 5,6-position always will have a levo or a lower dextro rotation than the corresponding saturated compound which will always have an appreciable dextro-rotation. α_1-Sitosterol fits very well into this observation, as may be seen in Table II.

That α_1-dihydrositosterol and α_1-isodihydrositosterol are α- and β-stenols, respectively, is likewise indicated by a qualitative interpretation of the optical activity of these compounds. An α-stenol, in general, will have a positive rotation lower in degree than the corresponding saturated compound. A β-stenol will, in general, have a positive rotation, higher in degree than the corresponding saturated compound. These two statements are borne out by Table III.

Further evidence for the proposed structure of α_1-isodihydrositosteryl acetate (III) (which is represented as a β-stenol) has also been obtained. We have found that if α_1-isodihydrositosteryl acetate be treated with perbenzoic acid, an oxide (VIII) is obtained. Hydrolysis of the oxide ring with glacial acetic acid and concentrated sulfuric acid gives a doubly unsaturated compound (IX), and not a triol diacetate (X).

The formation of this doubly unsaturated compound from the oxide is in accordance with the experimental observations of other investigators on similar compounds. For example, Morrison and Simpson[7] have found that when β-ergostenol oxide (XI) is dissolved in hot ethyl alcohol and treated with dilute sulfuric acid with subsequent heating for fifteen minutes on the steam-bath, a doubly unsaturated sterol, dehydroergostenol (XII), is produced. They[8] also have reported that α-ergostenol oxide (XIII) under similar treatment gives the same dehydroergostenol. Since Callow[9] has shown experimentally that the most probable formula for this latter doubly un-

TABLE III

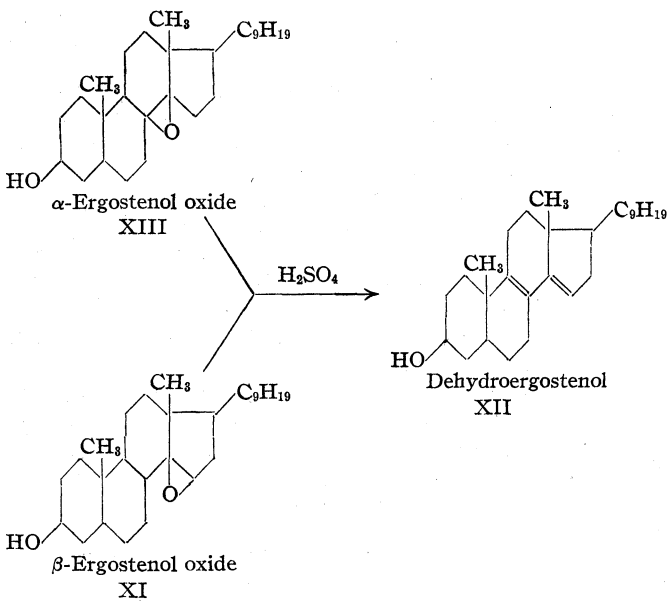
saturated sterol is as indicated below, it follows that the doubly unsaturated compound obtained by us from α_1-isodihydrositosteryl oxide is to be represented as given and therefore is, accordingly, $\Delta^{8,9;\ 14,15}$ α_1-sitostadiene acetate-3.



Experimental Part

Preparation of α_1-Sitosteryl Acetate.—Two and one-half grams of α_1-sitosterol (m. p. 159–166°) isolated from the sitosterol complex (1627 g.) of wheat germ oil by the method of Wallis and Fernholz[2] was heated on the water-bath for one hour with acetic anhydride. Crystallization from methyl alcohol gave 2 g. of α_1-sitosteryl acetate, m. p. 136–137°.

The Reaction of α_1-Sitosteryl Acetate with Maleic Anhydride (Diels–Alder Reaction).—A mixture of 50 mg. of α_1-sitosteryl acetate, 20 mg. of maleic anhydride and 10 cc. of acetic anhydride was refluxed for eight hours. During this time a brown coloration appeared. The reaction mixture was evaporated to dryness *in vacuo*. The residue was crystallized from ethyl alcohol and gave a material melting at 137–138°. A mixed melting point determination with α_1-sitosteryl acetate (136–137°) indicated identity since no depression was observed.

The Diels–Alder reaction was repeated, with xylene as the solvent. The starting material was again recovered and no indication of a positive addition reaction was observed.

An absorption spectrum study of α_1-sitosterol (m. p. 166°) was carried out by Dr. T. J. Webb of the Research Laboratories, Merck and Company, Inc. It was found not to have any maxima in the ultraviolet region of the spectrum.

Hydrogenation of α_1-Sitosteryl Acetate at 60° and Atmospheric Pressure.—One-tenth of a gram of α_1-sitosteryl acetate dissolved in glacial acetic acid was hydrogenated for five hours at 60° and atmospheric pressure, with a previously reduced platinum catalyst prepared according to Adams. The catalyst was then filtered off and the acetic acid was removed by vacuum distillation. After four crystallizations from ether and methyl alcohol needles were obtained which melted at 107–108°, $[\alpha]^{25}D$ +36.6° (0.0191 g. in 2 cc. of chloroform solution gave $\alpha^{25}D$ +0.35°). The Liebermann test was positive. The Salkowski test was similar to that for ergosterol, α_1- and α_2-sitosterol; the chloroform layer was colorless, while the sulfuric acid layer became colored.

Hydrogenation of α_1-Sitosteryl Acetate at 65–70° in the Presence of Concentrated Hydrochloric Acid.—Two-tenths of a gram of α_1-sitosteryl acetate was dissolved in glacial acetic acid to which was added 0.5 cc. of concd. hydrochloric acid. It was then hydrogenated at 65–70° and atmospheric pressure for five and one-half hours with a platinum catalyst prepared according to Adams. The

catalyst was reduced in the presence of the sterol acetate. The hydrogenation mixture took up the calculated amount for the complete saturation of the two double bonds. The catalyst was filtered off, and the reaction mixture was evaporated to dryness *in vacuo*. The residue gave a negative Liebermann test. After several crystallizations from dilute alcohol needles were obtained which melted at 147–148°, $[\alpha]^{19}D$ +39.4 (0.0208 g. in 2 cc. of chloroform solution gave $\alpha^{19}D$ +0.41°).

Anal. Calcd. for $C_{31}H_{54}O_2$: C, 81.16; H, 11.87. Found: C, 80.89; H, 11.71.

Preparation of α_1-Sitostanol.—α_1-Sitostanol acetate was hydrolyzed by refluxing it for one hour with a 5% alcoholic solution of potassium hydroxide. The sterol was then worked up in ether in the usual manner. Recrystallization from dilute alcohol gave needles which melted at 185–186°, $[\alpha]^{25}D$ +27.0 (10.4 mg. in 2 cc. of chloroform solution gave $\alpha^{25}D$ +0.14).

Anal. Calcd. for $C_{29}H_{52}O$: C, 83.58; H, 12.58. Found: C, 83.71; H, 12.48.

Preparation of α_1-Dihydrositosteryl Acetate.—Nine hundred and sixty milligrams of α_1-sitosteryl acetate dissolved in glacial acetic acid was hydrogenated at room temperature and atmospheric pressure with 0.14 g. of a platinum catalyst prepared according to Adams. The catalyst was reduced in the presence of the sterol acetate. Only one mole of hydrogen was taken up, and the hydrogenation was complete in fifteen minutes. The catalyst was filtered off, and the solvent was evaporated *in vacuo*, leaving an oily residue which crystallized on cooling. Recrystallization from ethyl alcohol gave needles of m. p. 108.5–110.5° $[\alpha]^{20}D$ +35.1 (0.0442 g. in 5 cc. of chloroform solution gave $\alpha^{20}D$ +0.31°). The Liebermann test was positive. This material is identical with that obtained by hydrogenation of α_1-sitosteryl acetate at 60° and atmospheric pressure. A melting point determination showed no depression.

Anal. Calcd. for $C_{31}H_{52}O_2$: C, 81.52; H, 11.48. Found: C, 81.30; H, 11.33.

Preparation of α_1-Dihydrositosterol.—One hundred and two milligrams of α_1-dihydrositosteryl acetate was hydrolyzed by refluxing it on the water-bath with 5% alcoholic potash solution. The sterol was precipitated with water and filtered. Purification was obtained by crystallization from ethyl acetate and methyl alcohol; needles m. p. 152–154°, $[\alpha]^{20}D$ +10.9° (0.0238 g. in 2 cc. of chloroform solution gave $\alpha^{20}D$ +0.13°).

Anal. Calcd. for $C_{29}H_{50}O$: C, 83.98; H, 12.15. Found: C, 83.9; H, 11.9.

Acetylation of α_1-dihydrositosterol with acetic anhydride gave back α_1-dihydrositosteryl acetate, m. p. 108°. The melting point was not depressed by α_1-dihydrositosteryl acetate previously prepared by hydrogenation of α_1-sitosteryl acetate.

Preparation of α_1-Isodihydrositosteryl Acetate.—Dry hydrogen chloride was passed for two hours into a chloroform solution of α_1-dihydrositosteryl acetate kept at 0°. The reaction mixture was then evaporated to dryness *in vacuo*. The oily residue gave a negative Beilstein test. Since the residue had a slight coloration it was taken up in ether and decolorized with animal charcoal. Recrystallization from ethyl alcohol gave pure α_1-isodihydrositosteryl acetate in the form of plates m. p. 137.5–138.5°, $[\alpha]^{20}D$ +42.0° (0.0572 g. in 5 cc. of chloroform solution gave $\alpha^{20}D$ +0.48°).

α_1-Isodihydrositosteryl acetate gives a positive Liebermann test. It gives a depression of the melting point when intimately mixed with α_1-sitosteryl acetate (m. p. 136–137°).

Anal. Calcd. for $C_{31}H_{52}O_2$: C, 81.52; H, 11.48. Found: C, 81.4; H, 11.6.

Preparation of α_1-Isodihydrositosterol.—One hundred and thirty milligrams of α_1-isodihydrositosteryl acetate was hydrolyzed by refluxing it for one hour with a 5% alcoholic potash solution. The sterol was worked up in ether. Recrystallization from ethyl alcohol gave needles melting at 152–154°, $[\alpha]^{20}D$ +31.0° (0.0452 g. in 5 cc. of chloroform solution gave $\alpha^{20}D$ +0.28°). The melting point is depressed by α_1-dihydrositosterol.

Anal. Calcd. for $C_{29}H_{50}O$: C, 83.98; H, 12.15. Found: C, 83.7; H, 11.9.

Acetylation of a sample of α_1-isodihydrositosterol with acetic anhydride again gave back α_1-isodihydrositosteryl acetate, m. p. 137°.

Hydrogenation of α_1-Isodihydrositosteryl Acetate.—α_1-Isodihydrositosteryl acetate dissolved in glacial acetic acid was hydrogenated at room temperature and atmospheric pressure with a platinum catalyst prepared according to Adams. The catalyst was reduced in the presence of the sterol acetate. α_1-Sitostanol acetate was again obtained, m. p. 147°.

Preparation of α_1-Isodihydrositosteryl Acetate Oxide-(14,15).—Sixty-five milligrams of α_1-isodihydrositosteryl acetate (m. p. 137.5–139) was treated for ten days at room temperature with a large excess of a chloroform solution of perbenzoic acid. The reaction mixture was washed once with water, twice with dilute sodium hydroxide, and then with water until neutral. The chloroform solution was dried with anhydrous sodium sulfate, and evaporated to dryness *in vacuo*. The residue was crystallized from methyl alcohol. Needles were obtained which melted at 152–154°.

Anal. Calcd. for $C_{31}H_{52}O_3$: C, 78.76; H, 11.09. Found: C, 78.71; H, 10.97.

α_1-Isodihydrositosteryl acetate oxide was dissolved in dry pyridine and treated with acetic anhydride for one-half hour on the water-bath. The reaction mixture was worked up in ether in the usual manner. Recrystallization from methyl alcohol gave back the starting material, m. p. 152°.

Preparation of $\Delta^{3,9;14,15}$-α_1-Sitostadiene Acetate-3.—α_1-Isodihydrosteryl acetate oxide was treated with 1 cc. of glacial acetic acid and one small drop of concentrated sulfuric acid. The reaction mixture was warmed on the water-bath for a very short time to dissolve completely the oxide. The reaction mixture was allowed to stand at room temperature for twenty-four hours. Small needles separated. The product was taken up in ether. The ether solution was washed successively with water, sodium bicarbonate, and water, and dried with anhydrous sodium sulfate. The ether solution was decolorized with animal charcoal. Evaporation of the ether left an oil which was crystallized from petroleum ether (30–60°) and methyl

alcohol, and methyl alcohol. Needles were obtained which melted at 121.5–122°.

Anal. Calcd. for $C_{31}H_{50}O_2$: C, 81.88; H, 11.08. Found: C, 81.62; H, 10.90.

We wish to take this opportunity to express our thanks to the Rockefeller Foundation for a grant-in-aid for this work, to Merck & Co., Inc., of Rahway, New Jersey, for the analytical and absorption spectrum data and to Dr. O. H. Emerson of the University of California for kindly furnishing part of the crude sterol from wheat germ oil from which the α_1-sitosterol used in these experiments was isolated.

Summary

1. Certain experimental results on the determination of the structure of α_1-sitosterol are described.

2. An absorption spectrum study, and the non-formation of an addition compound with maleic anhydride, indicate that the two double bonds in α_1-sitosterol are not conjugated.

3. Only one of the double bonds in α_1-sitosteryl acetate can be hydrogenated under ordinary conditions. α_1-Dihydrositosterol and its acetate have been prepared and characterized. Evidence is offered to show that α_1-dihydrositosterol is an *α-stenol.*

4. The second double bond which is resistant to hydrogenation can be isomerized by dry hydrogen chloride into a position which is easy to hydrogenate. α_1-Isodihydrositosterol and its acetate have been prepared and characterized. Evidence is offered to show that α_1-isodihydrositosterol is a *β-stenol.*

5. Hydrogenation of α_1-isodihydrositosteryl acetate gives α_1-sitostanol acetate. Certain characteristic properties of this latter compound have also been described and we have observed that it may be obtained also by the direct complete hydrogenation of α_1-sitosteryl acetate at 65–70° in the presence of a small amount of concentrated hydrochloric acid.

6. α_1-Sitostanol and stigmastanol are not identical. This difference is probably the result of isomerization in the hydrocarbon side chain.

7. A structural formula for α_1-sitosterol has been proposed.

Electrolytes and the Viscosity of Pectin Solutions[1]

BY HUGO P. KORTSCHAK

Introduction

That the addition of electrolytes to certain colloidal solutions will cause marked changes in the viscosity is well known, but no explanation has been offered that seems completely satisfactory for all cases. This paper describes the effect of electrolytes on pectin sols, and shows that the colloidal character of the solutions is not a determining factor.

Experimental.—The pectin used was Eastman Citrus, practical. This was not the same sample used in the previous paper;[2] solutions prepared from it had a somewhat higher viscosity, indicating greater purity. The equivalent weight was 1500–2000. Other reagents were C. P. grade. Ordinary distilled water was used. No precautions were taken to prevent contamination by atmospheric carbon dioxide, except for boiling before use with substances containing calcium.

Since it is difficult to reproduce pectin sols exactly, a correction factor (always less than 2%) was applied to values at 0.1% pectin, to make them more easily comparable. Correction was made for density at salt concentrations above 0.1 *N* but no other correction factors were applied. For other experimental details see previous paper.[2] Viscosities reported are relative to water at the temperature of measurement, 27.5 ± 0.5°.

Discussion

It is evident that substances which increase the hydroxyl ion concentration raise the viscosity at low concentrations. Where the added substance is a strong base, as with sodium and potassium hydroxides, the maximum occurs when base and pectin are present in approximately equivalent concentration. This increase may be explained very simply. Pectin is an acid which is not completely ionized in the concentrations used. When neutralized with sodium hydroxide, the more highly ionized sodium salt is formed. If we admit that an increase in the electric charge causes increased hydration, and thus increased viscosity, the results are as would be expected.

A comparison of the viscosities of pectin and sodium–pectin sols supports this viewpoint (Table II). At great dilutions, where the acid would be largely dissociated, there is little difference between the two.

The increased viscosity at high salt concentrations is not, in most part, due to the presence of the pectin, as can be seen by a comparison between the viscosities of salt solutions with and without pectin (Table IV). Table V shows the behavior with varied pectin concentration. With higher salt concentration, a greater viscosity increase is to be noted in the series containing pectin than in the series of sodium chloride in water. Except for the most concentrated solution with 0.5% pectin, however, this effect is small when compared to the total viscosity increase, or to the viscosity decrease in more dilute solution. Some additional viscosity increase is to be expected

[c] "International Critical Tables." [d] Apparently not previously reported. At higher concentrations: 2 *N*, 1.330; 5 *N*, 2.23; 10 *N*, 7.4. [e] Note difference in quantitative values from those previously reported,[2] due to different pectin sample.

when pectin is present, since the pectin concentration, referred to water alone, is significantly greater in such concentrated salt solutions.

If the electric charge on the pectin micelle were reversed to any appreciable extent, one would expect the viscosity to remain at a value approximately that of a pectin sol containing no added electrolyte.

It is not suggested that the effect of the salt on water alone will suffice to explain all similar viscosity minima, but in some cases[3,4] the possibility apparently has not been considered.

The viscosity increase found here cannot be the same phenomenon as has been noted in the case of hydrophobic sols, for instance by Dhar.[5] In that case even potassium chloride produced an increase in viscosity, which is not the case here, and in all cases the rise commenced at salt concentrations which were far too low to give a measurable viscosity effect in water alone.

The decrease in viscosity which occurs at low salt concentrations is most probably due to a decrease in hydration.

From the data presented it can be seen that variation of the anion has no effect (with the exception of OH^-, due to the acid character of the pectin). Variation of the cation produces some change, but the minimum viscosity is nearly the same for all salts and acids.[6] The order of increasing effectiveness of the different cations follows the lyotropic series, Li, Na, K, Ca; the same order as is found, for instance, in solubility measurements.[7,8] This is the order of increasing hydration, and of increase in size of the ions.

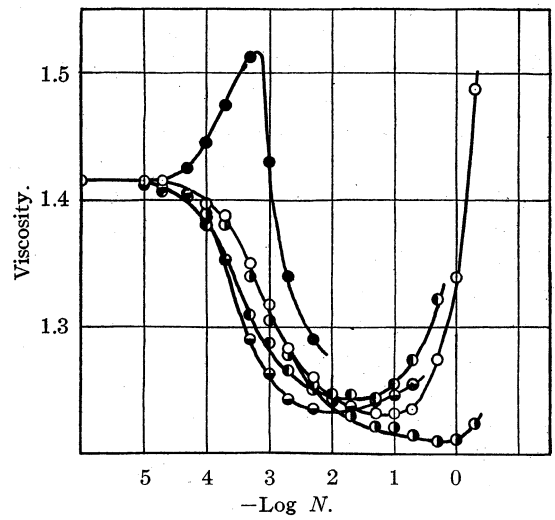

Fig. 1.—Viscosity of 0.1% pectin sols: ●, NaOH; ◒, HCl; ◐, $CaCl_2$; ◑, KCl; ○, NaCl.

Since the original purpose for which these measurements were made required only relative accuracy, no effort was made to obtain absolutely accurate values. For this reason it seems unprofitable to apply the concept of activity, or, especially in view of the uncertain equivalent weight of pectin, to attempt a test of the applicability of the Debye–Hückel equation.

This decrease in viscosity conceivably could be due to any of several different influences: (1) A solvent effect, the pectin remaining unchanged except for loss of water of hydration. In this case, the salt concentration required to produce minimum viscosity should be almost independent of the pectin concentration, which is not the case (see also the previous article). (2) Change in the acid dissociation of the pectin. The addition of electrolytes increases the dissociation constant of weak acids.[8] Also, the fact that the addition of alkalies will lower the viscosity, after a maximum has been reached, would make this explanation impossible. In view of the similarity of the curves for a strong acid, as hydrochloric acid, and for neutral salts, there can be no question of the effect being due to change in *p*H. (3) Adsorption

(5) D. N. Chakravarti and N. R. Dhar, *J. Phys. Chem.*, **29**, 1556 (1925).

(6) That an amount of citrate equal in weight to the pectin present produced the solutions of minimum viscosity,[2] must be purely a coincidence, due to the ratio of the equivalent weights of the citrates and the pectin, and to the concentrations employed.

of ions, causing changes in the electric charge of the pectin micelle, or (4) the formation of undissociated salts of the pectin.[9]

These last two are very much the same thing, except that in the case of adsorption no definite limit to the amount of ion which can be adsorbed is to be expected, whereas with salt formation a definite limit exists, when the stoichiometric quantity of cation has combined with the pectin. It is this latter type of combination which seems to represent the facts most closely. Were more than an equivalent amount of cation to combine with the pectin, it would be expected that a considerable increase would occur in the viscosity. However, as has been pointed out above, no such large increase was found.

It is in accordance with this explanation, of the formation of an undissociated salt, that NaCl + NaOH, NaCl, $CaCl_2$, and HCl are progressively more effective in the order given. This agrees with the findings of Stuewer,[10] that calcium pectin is more highly dissociated than pectin itself, and sodium pectin still more so.

That the minimum ratio of electrolyte to pectin, which is necessary in order to attain the minimum viscosity, decreases with increasing pectin concentration (Table V), would be expected with both adsorption and salt formation.

When the viscosity has first been lowered with sodium chloride, subsequent addition of sodium hydroxide raises it only slightly (Table I), showing that there is less undissociated pectin acid present than in the absence of sodium chloride. The presence of additional ions does, of course, increase the dissociation constant of a weak acid,[8] which would account for this, but increased ionization appears to be associated with increased viscosity (see above). One must conclude that Na has replaced acid H in the pectin micelle (compare the conclusions of Rabinovich[11]).

Comparison of Pectin and Electrolyte Solutions.—The neutralization of an acid generally results in increased viscosity, *i. e.*, a sodium chloride solution has a greater viscosity than an equivalent hydrochloric acid solution. Similarly, the viscosity of a pectin sol increases when the pectin is neutralized (Table I).

(9) By "undissociated salt" is meant only that the entire hydrated pectin micelle contains no excess of either positive or negative ions. To economize space, the well-known references to McBain, Loeb, Pauli, *et al.*, will not be given here.

(10) R. F. Stuewer, *J. Phys. Chem.*, **42**, 305 (1938).

(11) A. I. Rabinovich, *Z. physik. Chem.*, **116**, 97 (1925); *cf. C. A.*, **19** 3048 (1925).

It has been noted previously that the viscosities of solutions containing two electrolytes are lower than would be expected on the assumption of a purely additive effect.[12] Since the viscosities of electrolyte solutions are low compared to those of equivalent pectin sols, an actual decrease in viscosity rarely has been noted, when a second salt has been added to an electrolyte solution. The data of Ruby and Kawai[12] show this effect when the measurements of 0.4 *N* hydrochloric acid solutions are examined (Table VI).

TABLE VI

VISCOSITY OF 0.4 *N* HYDROCHLORIC ACID (RUBY AND KAWAI)

c KCl	η	Calcd.
0[a]	1.0257	1.0257
0.1	1.0250	1.0260
.6	1.0221	1.0238
1.6	1.0285	1.0298

[a] Interpolated.

On the assumption that an electrolyte giving more viscous solutions than hydrochloric acid would show the effect more clearly, the data of Table VII were measured. (About ten measurements were made at each concentration, and the average reported. The average deviation of the individual measurements was 0.0015. Assuming statistical significance of the data, the probable error is less than 0.001 at each concentration.)

TABLE VII

VISCOSITY OF 1 *N* CITRIC ACID

c KCl	η	*c* KCl	η
0[a]	1.151	0.20	1.146
0.01	1.149	.50	1.147
.02	1.148	1.00	1.153
.05	1.148	2.00	1.183
.10	1.146		

[a] Interpolated.

It is evident that the behavior of citric acid is qualitatively similar to that of pectin. The viscosity is increased by 1 *N* potassium chloride, a concentration which decreases the viscosity of water. This would seem to be similar to the behavior of the more concentrated pectin sols (Table V).

Combination of some kind has been postulated in many papers reporting the conductivities of mixed electrolytes, whereas others use the "mixture rule" and its modifications.[13] It would seem that any satisfactory explanation must also account for the viscosity effects.

(13) See, for instance, R. W. Bremner, T. G. Thompson and C. L. Utterback, THIS JOURNAL, **61**, 1222 (1939), and literature there cited.

Summary

1. The viscosity of pectin sols as affected by the addition of various electrolytes has been determined.

2. Three separate effects are present with increasing electrolyte concentrations: (a) An increase in viscosity at low electrolyte concentration, when an alkaline substance is added. This is due to the formation of the more highly ionized pectin salt from the pectin acid. (b) A decrease in viscosity to a minimum, further increase in electrolyte concentration having no apparent effect on the pectin. The formation of practically uncharged, undissociated salts of pectin is suggested, causing dehydration, and thus decreased viscosity. (c) Increase in viscosity at high salt concentration, due to interaction of the added electrolyte and water; an increase greater than this being due, in part at least, to the increased concentration of pectin with respect to water alone.

3. Any increase in viscosity which could be ascribed to reversal of charge on addition of excess electrolyte is either absent or very small.

4. The viscosities of solutions of pectin and of truly soluble electrolytes change in similar manner with increasing electrolyte concentration.

The Preparation of Acetyl-5-fluorosalicylic Acid

BY C. M. SUTER AND ARTHUR W. WESTON[1]

As a part of a program of preparing various aromatic fluorine compounds[2] for the purpose of determining their pharmacological properties, it has seemed of interest to synthesize 5-fluorosalicylic acid and its acetyl derivative (fluoroaspirin). 4-Fluorosalicylic acid (4-fluoro-2-hydroxybenzoic acid) was prepared some time ago by Hodgson and Nixon[3] but its physiological properties were not investigated.

5-Fluorosalicylic acid was prepared by carbonation of the Grignard reagent obtained from 2-bromo-4-fluorophenetole,[2] followed by deëthylation of the ethoxy acid by hydriodic acid. It was noted by Hodgson and Nixon[3] that while 4-methoxy-2-fluorobenzoic acid could not be demethylated, the 2-methoxy-4-fluoro isomer reacted readily with hydrogen iodide. It is evident from the behavior of 5-fluoro-2-ethoxybenzoic acid that the position of the fluorine has little effect upon the ease of dealkylation when the alkoxy group is ortho to carboxyl.

Preliminary data obtained in a comparison of the toxicity of the 5-fluorosalicylic acid and its acetyl derivative with the fluorine-free compounds[4] using white mice as test animals show that 5-fluorosalicylic acid is approximately twice as toxic as salicylic acid while the acetylfluoro acid is about 50% more toxic than aspirin. Although it has been reported[5] that 5-bromosalicylic acid is twice as effective against several types of bacteria as the chlorine compound, no experiments on animal toxicity have been carried out. 5-Chlorosalicylic acid has the same germicidal action as salicylic acid.

(4) We are indebted to Dr. Maurice L. Moore, Research Laboratories of Sharp and Dohme, for these results.

Experimental

2-Ethoxy-5-fluorobenzoic Acid.—A Grignard reagent was prepared using ethyl bromide as a starter from 35 g. (0.16 mole) of 2-bromo-4-fluorophenetole and 4 g. (0.17 mole) of magnesium and the ether solution dropped with stirring into a beaker containing 40 g. of crushed dry ice. After the excess carbon dioxide had evaporated, ice and dilute hydrochloric acid were added, the ether layer separated and the water again extracted with ether. The combined portions of ether were extracted several times with 10% sodium bicarbonate and the latter acidified. There resulted 19 g., a 64.5% yield, of a slightly yellow solid which after crystallization from dilute alcohol or a mixture of benzene and petroleum ether melted at 65.5–66.5°. The acid is soluble in benzene, alcohol, acetic acid and slightly soluble in carbon tetrachloride.

Anal. Calcd. for $C_9H_9O_3F$: neut. equiv., 184.1. Found: neut. equiv., 184.6.

5-Fluorosalicylic Acid.—The ethoxy compound was deëthylated by refluxing 17 g. with 150 ml. of hydriodic acid (d. 1.7) for ten hours. The white solid which separated as the reaction proceeded was filtered off on a sintered glass funnel. Dilution of the filtrate with water and extraction with ether gave only a little more product. 5-Fluoro-2-hydroxybenzoic acid crystallizes from water in fine white needles which melt at 178.5–179.5°. It is

(5) Rochaix and Pinet, *Bull. sci. pharmacol.*, **34**, 486 (1927).

soluble in ether and alcohol. The yield was 12.5 g. or 87% of the theoretical amount. A purple-violet color was obtained with ferric chloride solution. The methyl ester has the "oil of wintergreen" odor.

Anal. Calcd. for $C_7H_5O_3F$: neut. equiv., 156. Found: neut. equiv., 157.4.

Acetyl-5-fluorosalicylic Acid.—Acetylation was effected by warming 4.5 g. of the hydroxy acid with 10 ml. of acetic anhydride and a few drops of sulfuric acid. After cooling the mixture, adding 100 ml. of water, and filtering there was obtained 3.2 g. (56% yield) of product which crystallized from benzene as fine needles melting at 130–131° which gave no ferric chloride color test. The compound is soluble in alcohol, ether, hot benzene and insoluble in ligroin.

Anal. Calcd. for $C_9H_7O_4F$: neut. equiv., 198.1. Found: neut. equiv., 198.4.

Summary

5-Fluorosalicyclic acid and its acetyl derivative have been prepared. These are more toxic than the unfluorinated compounds.

Syntheses of Polyenes. I. Hexatriene and its Polymers

BY M. S. KHARASCH AND E. STERNFELD[1]

Introduction

In the course of an investigation on highly unsaturated compounds containing conjugated systems, the need of a simple and efficient method of synthesis became apparent. The general method now in use (the reduction of unsaturated carbonyl compounds to pinacols, replacement of the hydroxyl groups by halogens, and elimination of the halogens by zinc) necessitates the use of large quantities of materials, involves difficult experimental procedures, and usually the over-all yield of the polyene is poor.

Preparation of Hexatriene and its Polymers.—Ordinarily, when organic halides are treated with bases, halogen acids are eliminated and ethylene derivatives are formed. In certain cases, however, two molecules of the halide condense in the course of the reaction to form an unsaturated dimer. Specifically, 9-fluorenyl bromide reacts with potassium hydroxide in acetone solution to yield bifluorenylidene.[2] In our laboratory sodamide in liquid ammonia has been used successfully as a condensing agent. The equation below represents the reaction of allyl chloride with sodamide in liquid ammonia.

$$H_2C{=}C(H){-}CH(Cl)H + Cl{-}C(H){-}C(H){=}CH(H) \xrightarrow[NH_3]{NaNH_2} HC{\equiv}C{-}C(H){=}CH{-}CH{=}CH_2$$

Our hypothesis which has now been verified in a number of cases is that halides of weakly electronegative radicals[3] will condense when treated with sodamide in liquid ammonia if there is a hydrogen atom on the carbon atom to which the halogen atom is attached.

Since the electronegativity of the allyl radical would be decreased by substituents on the α-carbon atom and only very little affected by substituents on the β-carbon atom, this general method applies to the preparation of many substituted hexatrienes.

Our method of preparing hexatrienes has many advantages over the methods of van Romburgh, namely, the decomposition of *s*-divinylglycol diformate,[4] or the dehydration of 1,5-hexadien-4-ol. The operations involved are simple and rapid. The sodamide used is produced preferably by the action of sodium on liquid ammonia in the presence of finely divided iron as a catalyst.[5] It is then added to a liquid ammonia solution of allyl chloride as rapidly as the violence of the reaction permits, and the products are isolated as described in the experimental part.

It was found that the yield of hexatriene was dependent upon the order of addition; thus sodamide added to allyl chloride gave 30% hexatriene, whereas when the allyl chloride was added to sodamide only a 10% yield of hexatriene was obtained along with a proportionately greater amount of a high boiling material. This is accounted for on the basis that a concentrated solu-

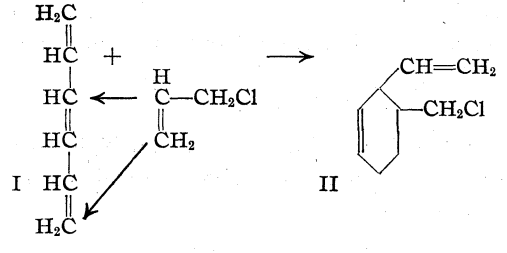
tion of sodamide causes the hexatriene to polymerize.

We are not prepared to state whether the hexatriene made from allyl chloride in this manner is *cis* or *trans;* in our opinion there is not sufficient evidence to show that either pure *cis*- or pure *trans*-hexatriene has ever been isolated. The constants of our hexatriene are nearer to those obtained by Farmer and co-workers[6] for the *cis*-hexatriene.

The nature of the higher boiling material obtained by the reaction of allyl chloride with sodamide in liquid ammonia is dependent upon the experimental conditions. When three moles of allyl chloride was dissolved in liquid ammonia and two moles of sodamide added, the main product (50%) was a compound boiling at 44–48° at 8 mm., containing one chlorine atom. The molecular weight of the substance was 156 and it was identified as 1-chloromethyl-2-vinyl-cyclohexene-3. The product undoubtedly is formed by the condensation of allyl chloride with hexatriene as indicated in the following schematic representation



The structure of the substance (II) was proved by hydrogenation to 1-ethyl-2-methylcyclohexane. The boiling point and index of refraction of this substance agreed with those recorded in the literature.[7]

This type of condensation has been discussed recently by Alder and Windemuth,[8] who condensed cyclopentadiene and anthracene with a number of allyl compounds, including allyl chloride. They found that temperatures about 150–180° and fairly high pressures were necessary to bring about the condensations. Compound II is formed readily under our experimental conditions at −33° and atmospheric pressure.

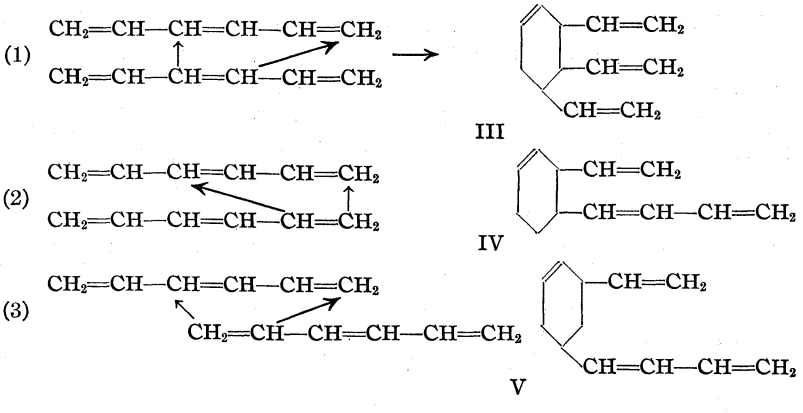
However, if an excess of sodamide is employed, polymers of hexatriene can be isolated uncontaminated with halogen compounds. In particular one fraction can be isolated which boils 50–55° at 3 mm., in over 40% of the calculated yield. The only investigation of the polymers of hexatriene mentioned in the literature was conducted by van Romburgh[4] who distilled a five-year-old sample of hexatriene and obtained a liquid which boiled at 99.5° at 16 mm. The molecular weight indicated that it was a dimer of hexatriene. Because of the density of the liquid van Romburgh assumed that a ring had been formed with the elimination of two double bonds. However, he made no attempt to establish the structure of his dimer.

Upon hydrogenation of the dimer a saturated hydrocarbon (molecular weight 168) is obtained. The fact that the substance absorbs eight hydrogen atoms corresponding to four double bonds indicates a ring structure for the molecule, since the straight chain molecule would have five double bonds. The index of refraction of the saturated dimer is much too high for a straight chain paraffin hydrocarbon but is normal for a cyclohexane derivative.

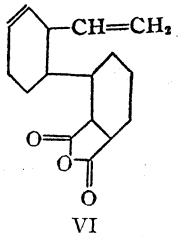
Dimerization of hexatriene to give a ring compound may take place in two ways: 1,4-addition of a medial double bond of a hexatriene molecule to another hexatriene molecule as in scheme 1, or 1,4-addition of a terminal double bond, as in scheme 2 or 3.



Of the three dimers, IV and V contain conjugated systems and will react with maleic anhydride. Since the dimer gives a well-defined crystalline derivative with maleic anhydride, its structure is either IV or V.

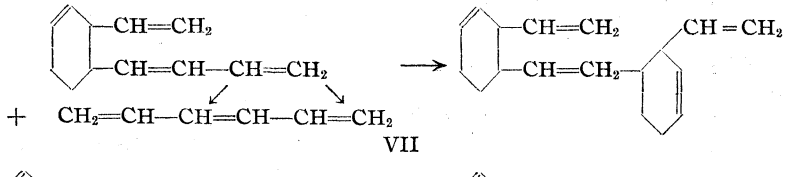
Hydrogenation of the dimer yields a liquid which is either 1-butyl-2-ethyl or 1-butyl-3-

ethylcyclohexane. Neither of these cyclohexanes is recorded in the literature. We synthesized the 1-butyl-2-ethylcyclohexane using the procedure suggested by Signaigo and Cramer.[7] α-Ethylcyclohexanone from α-chlorocyclohexanone and ethylmagnesium bromide was added to butylmagnesium bromide and the mixture, upon hydrolysis, gave 1-butyl 2-ethylcyclohexanol. This substance was dehydrated by distillation with iodine and then hydrogenated to the saturated hydrocarbon. The constants of 1-butyl-2-ethylcyclohexane agreed with those of the saturated hexatriene dimer. The unsaturated compound is, therefore, 1-butadienyl-2-vinylcyclohexene-3 (IV) and the maleic anhydride derivative is represented by VI. The dimerization of hexatriene is analogous to the dimerization of butadiene to vinylcyclohexene, and of phenylbutadiene to phenylstyrylcyclohexene. These conjugated systems, therefore, as well as hexatriene upon condensation give rise to six-membered rings by 1,4-addition of a terminal double bond in preference to the addition of a medial double bond.

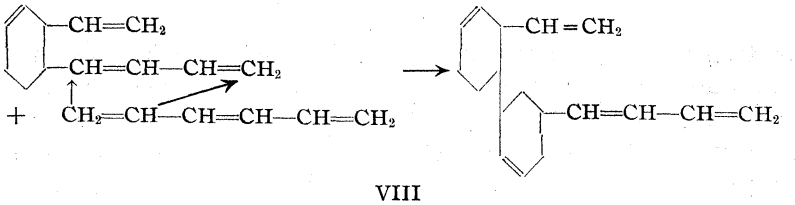


VI

With the aid of a molecular still we isolated the trimer and tetramer of hexatriene. The structure of the trimer, which has five double bonds, may be represented by two different formulas, according to two possible reactions by which it may be formed



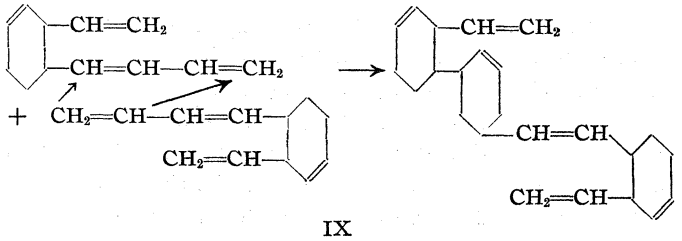
VII



VIII

That VII is probably the correct structure is indicated by the fact that the trimer does not react with maleic anhydride.

The tetramer of hexatriene was obtained as a light-yellow viscous liquid whose color became darker in air. It has six double bonds and a molecular weight of 320. It does not react with maleic anhydride. These facts, in conjunction with the observation that the tetramer is formed under conditions that favor the presence of large concentrations of the dimer, indicate that the tetramer results from the 1,4-addition between two molecules of dimer as follows.



IX

This work is being continued. We are also engaged in an extensive study of other polyenes prepared by treating sodamide in liquid ammonia with substituted allyl compounds of the type

in which Y is a halogen atom and X is either a halogen atom, a hydrocarbon radical, or a carbethoxy group.

Experimental Part

Preparation of Hexatriene and Butadienylvinylcyclohexene.—The sodamide was prepared in an 800-cc. unsilvered Dewar flask (equipped with a stirrer and a dropping tube) from 23 g. of sodium in 600 cc. of liquid ammonia. About half a gram of ferric nitrate was dissolved in the ammonia and then the sodium added in 2–3 g. portions, each piece being allowed to react before the next was added. The sodamide suspension was forced over into a 3-liter Dewar, equipped with a good stirrer and containing 1 liter of liquid ammonia and 76 g. (1 mole) of allyl chloride. The flow of sodamide suspension had to be regulated carefully and only small portions added at a time as the reaction was very violent.

In later runs the sodamide was made in large quantities by the above procedure and stored, after evaporation of the ammonia, in a sealed bottle until used. It was added to the reaction mixture by means of an adapter cut short at the narrow end and connected to a glass tube of the same diameter in the

rubber stopper of the Dewar flask by a short piece of rubber tubing. This procedure allowed much greater control of the speed of the reaction and was more convenient than the earlier method in the reactions where the sodamide was added to the allyl chloride.

After all the sodamide was added the mixture was poured into a 3-liter round-bottomed flask and the ammonia evaporated on the steam-bath. Water was then added to dissolve the sodium chloride, and the mixture extracted successively with several portions of ether. The combined ether portions were washed thoroughly with water, dried over anhydrous sodium sulfate, and the ether removed. The remaining material was separated into fractions. Two different procedures were used. In the first experiments the product was fractionated with the aid of a column. The low boiling material was hexatriene (8.6 g., 24%), b. p. 76–80°, $n^{20}D$ 1.4330, d^{20}_4 0.7182. This material, dissolved in methyl alcohol, hydrogenated smoothly in the presence of platinum oxide to *n*-hexane, b. p. 68°, $n^{20}D$ 1.3748.

The second fraction was the dimer, 14 g. (41%), b. p. 50–55° at 3 mm., $n^{20}D$ 1.5137.

Anal. Calcd. for $C_{12}H_{16}$: C, 89.92; H, 10.08; mol. wt., 160. Found: C, 89.20; H, 9.75; mol. wt. (in triphenylmethane), 174.

Upon hydrogenation 0.4234 g. of liquid in absolute methyl alcohol absorbed 254.1 cc. of hydrogen (corr.). Calcd. for $C_{12}H_{16}$ and four double bonds, 264 cc. The ethylbutylcyclohexane had a b. p. 208°, $n^{20}D$ 1.4493.

Anal. Calcd. for $C_{12}H_{24}$: C, 85.71; H, 14.29. Found: C, 85.42; H, 14.19.

By using a column the liquid is kept at 75–80° for some time during the distillation of the hexatriene and polymerization takes place. To avoid this the product was sealed in a system containing a flask and several bomb tubes and connected to a vacuum line by a yoke. The liquid was cooled, the system evacuated to the limits of a three-stage mercury pump, degassed, and sealed off. The flask containing the liquid was allowed to come to room temperature while one of the tubes was cooled. In this way a 30% yield of hexatriene was obtained after twenty-four hours. The remaining liquid was distilled on an oil pump, yielding 33% of the dimer.

Preparation of Hexatriene Dimer, Trimer, and Tetramer.—The yield of butadienylvinylcyclohexene was increased to 50% by adding 100 g. (1.33 moles) of allyl chloride to a solution of 70 g. (2 moles) of sodamide in 2 liters of liquid ammonia and stirring the mixture for thirty to forty-five minutes after the addition of the halide. The aforementioned procedure was then followed and the ether-free product distilled in a molecular still. Twenty-seven grams of dimer distilled at 20–35° at 10^{-4} mm.

Five grams of trimer distilled at 70–80° at 10^{-4} mm., $n^{20}D$ 1.5232.

Anal. Calcd. for $C_{18}H_{24}$: C, 89.92; H, 10.08; mol. wt., 240. Found: C, 89.27; H, 9.84; mol. wt. (in triphenylmethane), 227. *Hydrogenation:* 0.2450 mg. in methyl alcohol absorbed 113.1 cc. of hydrogen (corr.). Calcd. for $C_{18}H_{24}$ and five double bonds, 114.3 cc.

Five grams of tetramer distilled at 120–133° at 10^{-4} mm., $n^{20}D$ 1.5330.

Anal. Calcd. for $C_{24}H_{32}$: C, 89.92; H, 10.08; mol. wt., 320. Found: C, 88.98; H, 9.72; mol. wt. (in triphenylmethane), 341. *Hydrogenation:* 0.2837 g. in methyl alcohol absorbed 126 cc. hydrogen (corr.). Calcd. for $C_{24}H_{32}$ and six double bonds, 119.5 cc.

Preparation of Chloromethylvinylcyclohexene.—Forty grams of sodamide was added over a period of one and one-half hours to a solution of 100 g. of allyl chloride in liquid ammonia. After the usual treatment the following fractions were obtained: 13 g., b. p. 70–85° (hexatriene contaminated with halogenated compounds) and 23 g. of chloromethylvinylcyclohexene, b. p. 44–48° at 8 mm., $n^{20}D$ 1.4670.

Anal. Calcd. for $C_9H_{13}Cl$: Cl, 22.66; mol. wt., 156.45. Found: Cl, 22.91; mol. wt. (in camphor), 156.

It was hydrogenated under pressure of 40 pounds (2.7 atm.) in presence of platinum oxide. The resulting liquid, after some purification, yielded a fraction b. p. 156°, $n^{20}D$ 1.4412, which is identical with 1,2-ethylmethylcyclohexane.

Synthesis of 1,2-Butylethylcyclohexane.—Twenty grams of ethylcyclohexanone was added to butylmagnesium bromide from 4.5 g. of magnesium and 23 g. of butyl bromide in 150 cc. of ether at 0°. The mixture was allowed to warm up to room temperature, then hydrolyzed with dilute sulfuric acid and ice. The layers were separated, the ether solution was washed with saturated sodium bisulfite and water, dried over anhydrous sodium sulfate, and distilled. The carbinol left after distillation of the ether, 20 g., was distilled immediately with 0.5 g. of iodine and gave a mixture of olefin and water boiling from 100–200°. The olefin, 15 g., was separated, dried, dissolved in glacial acetic acid and hydrogenated at an initial pressure of 36 pounds (2.5 atm.) in the presence of 0.3 g. of platinum oxide. The saturated hydrocarbon was separated by the addition of water, washed with cold concentrated sulfuric acid, dried and distilled. Upon fractionation was obtained 7 g. of pure 1,2-butylethylcyclohexane, b. p. 205–206°, $n^{20}D$ 1.4479.

Reaction of Hexatriene and its Dimer with Maleic Anhydride.—By heating equivalent amounts of hexatriene and maleic anhydride in benzene at 90–100° for three hours the vinyl (or ethylidene) tetrahydrophthalic anhydride, m. p. 45°, described by Farmer and Warren[9] was obtained. The free acid, m. p. 160°, was hydrogenated; 0.2108 g. absorbed 45.64 cc. of hydrogen (corr.). Calcd. for vinyl tetrahydrophthalic acid, 47.93 cc. Ethyl hexahydrophthalic acid, m. p. 117°, was the product.

Butadienylvinylcyclohexene reacted smoothly in benzene with maleic anhydride at 90–100°. The resulting anhydride was not crystallized, but was converted to the free acid, m. p. 178°.

Anal. Calcd. for $C_{16}H_{20}O_4$: C, 69.70; H, 7.26; neut. equiv., 138. Found: C, 70.05; H, 7.65; neut. equiv., 138.

Summary

1. A simple method of obtaining hexatriene and compounds derived from hexatriene in comparatively good yields by the condensation of allyl chloride is described.

(9) Farmer and Warren, *J. Chem. Soc.*, 897 (1929).

2. The structures of the hexatriene polymers are elucidated.

3. Work is being continued on the chemistry of these compounds and also on the synthesis of similar compounds containing substituent groups.

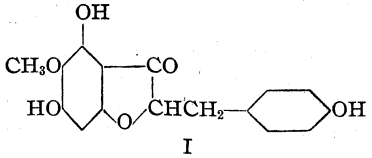
Derivatives of Coumaran. IV. The Structure of Tectorigenin

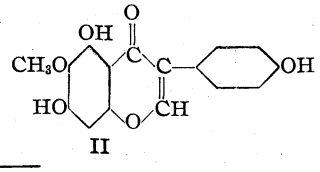
BY R. L. SHRINER, EDWARD J. MATSON AND R. E. DAMSCHRODER

The glucoside, tectoridin, was isolated by Shibata[1] from the rhizomes of *Iris tectorum* Maxim. Recently Mannich, Schumann and Lin[2] have shown that the glucoside, shekanin, in the rhizomes of the blackberry lily, *Belamcanda chinensis* (L.) Leman, is identical with tectoridin. Hydrolysis of tectoridin produced glucose and tectorigenin. Since the products of alkaline decomposition of tectorigenin were *p*-hydroxyphenylacetic acid, formic acid and iretol (V), Shibata first proposed the coumaran-3-one structure shown in formula I. Later, on the basis of the absorption spectrum, Asahina, Shibata and Ogawa[3] suggested the isoflavone structure of formula II. It is obvious that the isomeric formulas III and IV also represent possible structures which would yield the same degradation products.

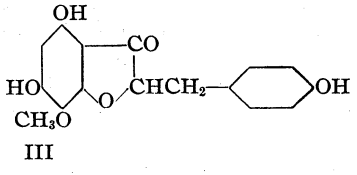
The coumaranone structures I and III have two atoms of hydrogen more than the isoflavone structures but the combustion analyses were not sufficiently accurate to distinguish between them. None of these structures has been synthesized previously. This paper reports the synthesis of the two isomeric coumaranone structures, I and III, and of their completely methylated derivatives.



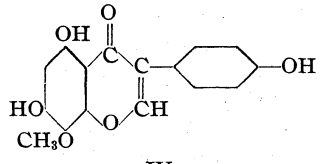
I



II



III



IV

The general method[4] of synthesis used involved the preparation of the coumaranones properly substituted in the benzene nucleus, condensation of the active methylene group in the heterocyclic ring with an aldehyde followed by reduction. The necessary coumaranones are most conveniently made by treating phenols with chloroacetonitrile followed by hydrolysis and ring closure.

Application of this method to iretol (V) yielded two isomeric coumaranones which were separated by fractional crystallization. The structure of the two isomeric coumaranones produced by hydrolysis and ring closure of α-chloro-2,4,6-trihydroxy-3-methoxyacetophenonimine hydrochloride (VI) was established by methylation and synthesis of each of the methylated compounds. The less soluble isomer was 4,6-dihydroxy-5-methoxycoumaran-3-one (VII); the more soluble was 4,6-dihydroxy-7-methoxycoumaran-3-one (X).

The methylated isomer, 4,5,6-trimethoxycoumaran-3-one (VIII), was prepared from antiarol (XIII), which underwent a Hoesch reaction with chloroacetonitrile to yield the α-chloroacetophenone (XIV). Ring closure gave the desired coumaranone (VIII). In a similar fashion the isomeric methylated compound, 4,6,7-trimethoxy-

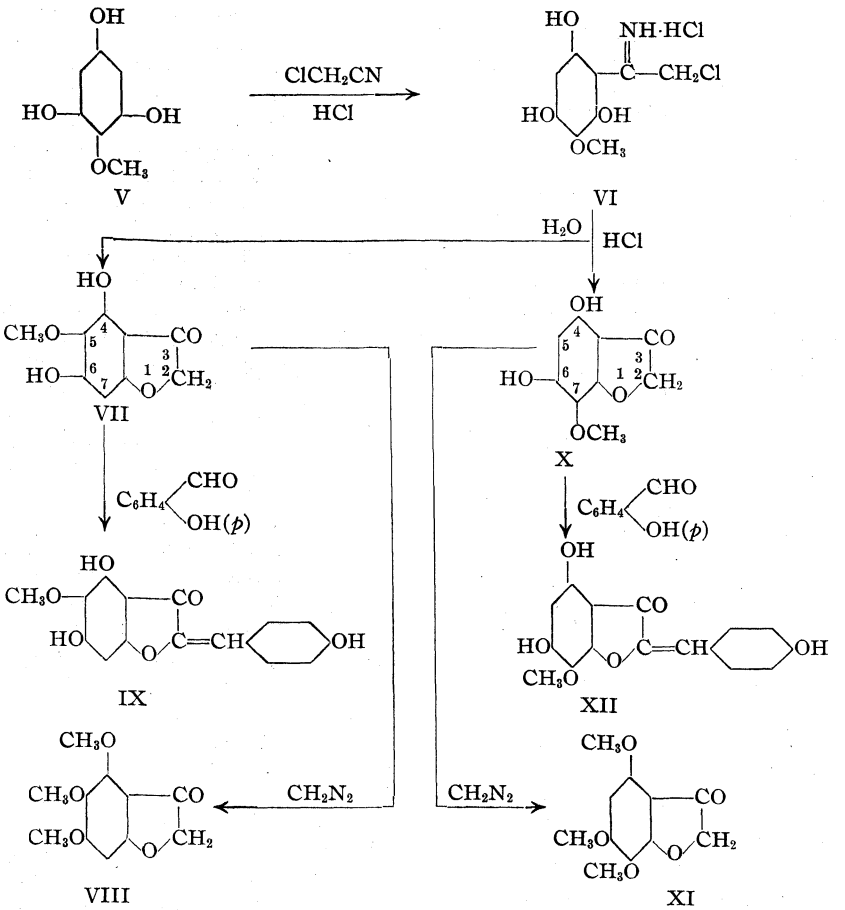
(2) Mannich, Schumann and Lin, *Arch. Pharm.*, **275**, 317 (1937).

(3) Asahina, Shibata and Ogawa, *J. Pharm. Soc. Japan*, **48**, 1087 (1928).

(4) Shriner and Damschroder, THIS JOURNAL, **60**, 894 (1938); Shriner and Anderson, *ibid.*, **60**, 1415 (1938).



coumaran-3-one (XI), was synthesized from 2,5-dimethoxyresorcinol (XVII).

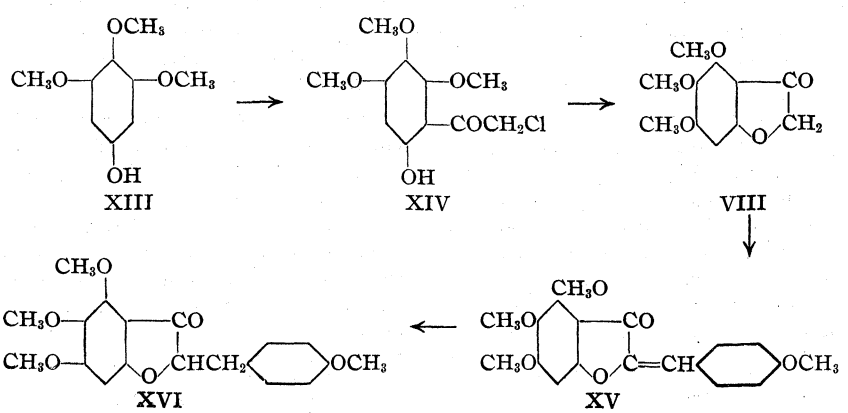
A Hoesch reaction gave the α-chloroacetophenone (XVIII), which was cyclized to the coumaranone (XIX). Methylation with diazomethane gave the completely methylated ether (XI).

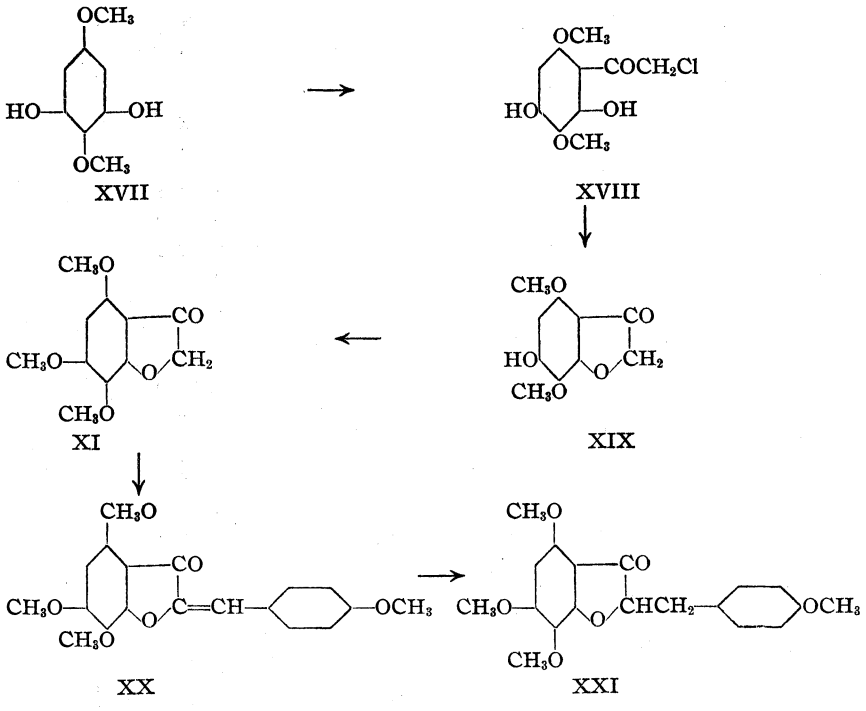
In order to obtain the 2-(*p*-hydroxybenzyl)-coumaranones (I and III) each of the isomeric coumaranones (VII and X) was condensed with *p*-hydroxybenzaldehyde and the benzal derivatives were reduced catalytically. The products of reduction proved to be very unstable and could not be isolated in the pure state but their properties were totally different from those of the natural product, tectorigenin.

The synthesis of the methylated derivatives was accomplished by condensing the trimethoxycoumaranones (VIII and XI) with anisaldehyde and reducing the anisal derivatives. The two isomeric methylated coumaranones (XVI and XXI) were isolated.

For purposes of comparison, tectoridin was isolated from the rhizomes of *Iris tectorum* and hydrolyzed to tectorigenin. Methylation of the latter yielded dimethyltectorigenin, which could not be methylated to trimethyltectorigenin although eleven different methylation procedures were used. Mannich, Schumann and Lin[2] also found that only a dimethyl derivative of tectorigenin could be obtained.

Although it was not possible to make a direct comparison with trimethyltectorigenin, the properties of the two synthetic trimethoxycoumaranones are quite different from those of the known methylated derivatives of tectorigenin. Compound XVI melts at 93–94°, and compound XXI at 116°. The melting points of tectorigenin and





its derivatives are: demethylated tectorigenin,[2] 270°; tectorigenin,[1] 230°; monomethyltectorigenin,[2] 191–192°; dimethyltectorigenin,[2] 188°.

The remarkable resistance to complete methylation exhibited by tectorigenin is probably due to the fact that the hydroxyl group ortho to the carbonyl group is strongly chelated as well as sterically hindered. This constitutes some evidence that the heterocyclic ring is six-membered rather than five-membered. It will be noted that the 4-hydroxyl group in the coumaranone (VII) was readily methylated.

The instability of the unmethylated coumaranones (I and III) obtained by reduction of IX and XII, and the differences in ease of methylation exhibited by all these coumaranones in comparison with tectorigenin show that the natural product is not a coumaranone derivative and favors the isoflavone structure II.

Experimental

α - Chloro - 2,4,6 - trihydroxy - 3 - methoxyacetophenonimine Hydrochloride (VI).—Dry hydrogen chloride gas was passed into a solution of 3 g. of iretol[5] and 1.5 g. of chloroacetonitrile[6] dissolved in about 300 cc. of dry ether. After forty-five minutes the solution became warm and after one hour yellow crystals began to be formed on the walls of the flask. The stream of hydrogen chloride was maintained eight hours longer, at which time the volume of ether had decreased to 100 cc. The flask was stoppered and allowed to stand overnight. The yellow crystals were then collected on a filter and washed quickly with dry ether. The yield of the crude product was 4.5 g. (87.5%).

The sample analyzed was purified by dissolving it in absolute alcohol into which dry hydrogen chloride had been passed for fifteen minutes. This solution was diluted with five volumes of dry ether. After the solution had stood for several hours, golden-yellow crystals precipitated. These were collected and dried in a vacuum desiccator over calcium chloride. The pure compound decomposed at 164–165°.

Anal. Calcd. for $C_9H_{11}Cl_2NO_4$: N, 5.22. Found: N, 5.37.

Hydrolysis of the Ketimine Hydrochloride.—A solution of 4 g. of the ketimine hydrochloride (VI) in 50 cc. of water was refluxed for one hour. The light-yellow solution gradually became red. The solvent was then removed slowly by surrounding the flask containing the hydrolysis mixture with calcium chloride in a vacuum desiccator. The pressure was reduced carefully until the water began to boil. After twenty-four hours the calcium chloride was replaced. When one-half the solvent had been removed in this manner, the rose-colored precipitate was removed by filtration. This less soluble fraction was recrystallized twice from water using norit and 0.9 g. of colorless needles of 4,6-dihydroxy-5-methoxycoumaran-3-one (VII) melting at 208.5 to 209.5° obtained.

Anal. Calcd. for $C_9H_8O_5$: C, 55.09; H, 4.11. Found: C, 55.29; H, 4.30.

The dark red filtrate from the above was concentrated to a volume of 8 cc. and the red precipitate filtered. Two recrystallizations from water using norit gave 1.5 g. of colorless crystals of 4,6-dihydroxy-7-methoxycoumaran-3-one (X) which melted at 177–178°.

Anal. Calcd. for $C_9H_8O_5$: C, 55.09; H, 4.11. Found: C, 55.05; H, 4.32.

Methylation of 4,6-Dihydroxy-5-methoxycoumaran-3-one.—A dioxane solution of diazomethane was prepared according to the method of Arndt.[7] Thirty-five milligrams of the coumaranone was dissolved in 25 cc. of dioxane and to this was added 1 cc. of the diazomethane solution containing about 90 mg. of the reagent, four times the theoretical amount necessary. The solution was allowed to stand overnight, and then the same amount of diazomethane was added again. After the solution had stood for ten hours longer it was evaporated to dry-

(5) Damschroder and Shriner, THIS JOURNAL, **59**, 931 (1937).

ness. The yield of colorless needles of 4,5,6-trimethoxycoumaran-3-one (VIII) was quantitative. The material was purified by repeated crystallization from absolute alcohol. It melted at 142.5–143.5°.

Anal. Calcd. for $C_{11}H_{12}O_5$: C, 58.93; H, 5.36. Found: C, 59.03; H, 5.48.

Methylation of 4,6-Dihydroxy-7-methoxycoumaran-3-one (X).—Sixty milligrams of this coumaranone was dissolved in 4 cc. of dioxane and 1.7 cc. of the above diazomethane solution was added. This contained about 150 mg. of diazomethane, four times the theoretical amount required. The procedure followed was the same as above and quantitative methylation resulted. The colorless needles of 4,6,7-trimethoxycoumaran-3-one (XI) melted at 153.5–154.5°.

Anal. Calcd. for $C_{11}H_{12}O_5$: C, 58.93; H, 5.36. Found: C, 59.28, 59.24; H, 5.25, 5.21.

Antiarol (3,4,5-Trimethoxyphenol) (XIII).—Antiarol was prepared from pyrogallol trimethyl ether according to the procedure of Chapman, Perkin and Robinson[8] except that the reduction of the intermediate 2,6-dimethoxyquinone was accomplished with sulfur dioxide instead of hydrogen sulfide, as recommended by Hattori.[9] The product used melted at 148°.

α - Chloro - 2 - hydroxy - 4,5,6 - trimethoxyacetophenone (XIV).—In 25 cc. of dry ether were suspended 5 g. of antiarol, 1.5 g. of chloroacetonitrile, and 2 g. of powdered anhydrous zinc chloride. Dry hydrogen chloride was passed into the mixture. Almost at once a paste began to form and heating occurred. The stream of hydrogen chloride was continued six hours, during which time half the ether evaporated. The flask was stoppered and allowed to stand overnight, then 25 cc. of cold water was added slowly. The resulting solution was shaken thoroughly with 25 cc. of ether, and the water layer was separated and refluxed one-half hour. The flask was cooled in ice and the voluminous precipitate which had formed was removed by filtration. The yield was 3 g. (42%). The sample analyzed was purified by repeated recrystallization, each time with the aid of norit. The crystals were dissolved in hot absolute alcohol, norit was added and the solution was warmed for a few minutes. The solution was filtered and then warmed again to boiling, and warm water was added until the solution was permanently cloudy. The flask was allowed to stand until it had reached room temperature. The pure product consisted of small colorless needles which, in the mass, had a faint greenish tinge. The m. p. was 107–107.5°.

Anal. Calcd. for $C_{11}H_{13}ClO_5$: C, 50.67; H, 4.99; Cl, 13.60. Found: C, 50.82; H, 4.93; Cl, 13.31.

4,5,6-Trimethoxycoumaran-3-one (VIII).—In a 25-cc. Erlenmeyer flask were mixed 0.71 g. of the above chloro ketone, 0.83 g. of powdered sodium acetate, and 7 cc. of alcohol. The mixture was refluxed two hours, becoming rose-colored, and was then poured into 110 cc. of a cold saturated sodium chloride solution. The voluminous rose-colored precipitate, collected on a filter, contained some sodium chloride. It was extracted with boiling absolute alcohol which was then treated twice with norit. The final filtrate was cooled in a dry ice–ether mixture, and the colorless needles formed were separated by filtration. A recrystallization gave no change in the m. p. of 142.5–143.5°. Decomposition occurred at the melting point. The yield of pure product was 0.55 g. (91%).

Anal. Calcd. for $C_{11}H_{12}O_5$: C, 58.93; H, 5.36. Found: C, 58.79; H, 5.37.

A mixed melting point with the methylation product of 4,6-dihydroxy-5-methoxycoumaran-3-one (VII) showed no depression.

2,5-Dimethoxyresorcinol (XVII).—This compound was prepared from pyrogallol tribenzyl ether by the method of Baker, Nodzu and Robinson[10] as modified by Shah, Mehta and Wheeler.[11]

α - Chloro - 2,4 - dihydroxy - 3,6 - dimethoxyacetophenone (XVIII).—About 3.5 g. of 2,5-dimethoxyresorcinol was dissolved in 40 cc. of dry ether, along with 1.55 g. of chloroacetonitrile. Dry hydrogen chloride was passed into the solution for six hours, crystals appearing on the walls of the flask a short time after the reaction was started. The reaction mixture was allowed to stand overnight, and then the ether was decanted. The brownish mass was washed with dry ether and then was treated with 40 cc. of water. The mixture was warmed on a steam-bath for one hour and then cooled, when the oil which had separated solidified. A small amount of pink crystals, weighing 0.16 g., remained suspended in the water. This was collected on a filter and recrystallized by dissolving in absolute alcohol, treating the solution with norit, and reprecipitating by adding 3 volumes of water to the filtrate. The total yield of product, after one recrystallization, was 1.3 g. (about 25%). The colorless needles of the pure compound had a m. p. of 150.5–151.5°.

Anal. Calcd. for $C_{10}H_{11}ClO_5$: C, 48.70; H, 4.50. Found: C, 48.53; H, 4.66.

4,7-Dimethoxy-6-hydroxycoumaran-3-one (XIX).—In 12 cc. of alcohol were put 1.1 g. of the above chloro ketone and 1.2 g. of powdered sodium acetate. The solution was refluxed two and one-half hours, during which time it gradually became red, and then was poured into 190 cc. of cold saturated sodium chloride solution. After standing overnight in a refrigerator, the precipitate was removed by filtration. It consisted of a mixture of cubic sodium chloride crystals and the colorless monoclinic prisms of the product. This mixture was extracted with 40 cc. of boiling absolute alcohol. This extract was treated with norit, concentrated to 5 cc., and cooled. This solid was collected on a filter and was recrystallized to constant melting point from absolute alcohol. The pure compound melted at 180–181° with decomposition. The yield of purified material was 0.4 g. (43%).

Anal. Calcd. for $C_{10}H_{10}O_5$: C, 57.15; H, 4.80. Found: C, 57.31; H, 4.94.

4,6,7-Trimethoxycoumaran-3-one (XI).—In 25 cc. of dioxane was dissolved 0.32 g. of the above hydroxycoumaranone. Seven cubic centimeters of the diazomethane solution previously mentioned was added; this contained about 0.45 g. of diazomethane, four times the theoretically required amount. The solution was allowed to

stand overnight, and then the same amount of diazomethane solution was added again. Seven hours later the solution was evaporated to dryness *in vacuo* to give 0.27 g. (80%) of colorless needles, which were recrystallized from absolute alcohol to give a product melting at 153.5–154.5°.

A mixed melting point with the methylation product of 4,6-dihydroxy-7-methoxycoumaran-3-one (X) showed no depression.

4,6 - Dihydroxy - 2 - (*p* - hydroxybenzal) - 5 - methoxycoumaran-3-one (IX).—The method of von Auwers and Pohl[12] was employed. A solution of 0.5 g. of 4,6-dihydroxy-5-methoxycoumaran-3-one and 0.4 g. of *p*-hydroxybenzaldehyde in 10 cc. of absolute alcohol was warmed to 65–70°. Five drops of concentrated hydrochloric acid was then added, the solution immediately becoming red. The temperature was kept at 65–70° for two hours, and the solution was then poured into 200 cc. of water. After the mixture had stood for two days the brown precipitate which had formed was removed by filtration and was dissolved in a few cubic centimeters of alcohol. This red solution was treated with norit and then filtered. The orange filtrate was diluted with 5–10 volumes of water. After the flask had been cooled and scratched with a glass rod, yellow needles formed which weighed 0.55 g. (72%). The sample analyzed was recrystallized again as described. The golden-yellow needles were dried in a vacuum desiccator at 2 mm. over calcium chloride for twenty-four hours, and then for three hours in an Abderhalden drier over phosphorus pentoxide at 2 mm. and 110°. The product so prepared decomposed at 291° on a Maquenne block.

Anal. Calcd. for $C_{16}H_{12}O_6$: C, 63.98; H, 4.03. Found: C, 64.18; H, 3.99.

A small amount of this material in alcoholic solution was treated with hydrogen at 3 atm. pressure and with an equal weight of platinum oxide catalyst present. Reduction occurred rapidly; the solution on evaporation to dryness under reduced pressure in a nitrogen atmosphere gave a white residue melting at 114–117° which decomposed rapidly and could not be purified.

2 - (*p* - Anisal) - 4,5,6 - trimethoxycoumaran - 3 - one (XV).—In 5.5 cc. of warm absolute alcohol was dissolved 0.6 g. of 4,5,6-trimethoxycoumaranone, 0.42 g. of anisaldehyde, and 2 drops of concentrated hydrochloric acid. The mixture was heated at 60–70° for two hours, the solution gradually becoming red. It was poured into 60 cc. of water and the mixture was allowed to cool. The reddish-brown solid formed was separated by filtration and after one recrystallization from alcohol weighed 0.7 g. (77%). Repeated recrystallization from alcohol, with the aid of norit, gave golden-yellow crystals melting at 148–149°. The solid quickly assumed an orange color on exposure to air.

Anal. Calcd. for $C_{19}H_{18}O_6$: C, 66.65; H, 5.30. Found: C, 66.63; H, 5.18.

2 - (*p* - Anisyl) - 4,5,6 - trimethoxycoumaran - 3 - one (XVI).—One-tenth gram of the above anisalcoumaranone and 0.1 g. of platinum oxide catalyst were suspended in 30 cc. of absolute alcohol, and the mixture was shaken with hydrogen at 3 atm. pressure. Absorption was complete and the solution was colorless in five minutes. The alcohol was distilled *in vacuo* to 1 cc., low-boiling petroleum ether was added, and the solution was cooled in an acetone–dry-ice bath. Seventy milligrams (70%) of colorless needles was collected on a filter and was recrystallized with absolute alcohol and low-boiling petroleum ether to give 6 mg. of a product melting at 93–94°. Some decomposition seemed to occur at each crystallization, since the alcoholic solution became slightly yellow when heated.

Anal. Calcd. for $C_{19}H_{20}O_6$: C, 66.25; H, 5.85. Found: C, 65.73; H, 5.95.

4,6 - Dihydroxy - 2 - (*p* - hydroxybenzal) - 7 - methoxycoumaran-3-one (XII).—To a solution of 1 g. of 4,6-dihydroxy-7-methoxy-coumaranone and 0.8 g. of *p*-hydroxybenzaldehyde in 10 cc. of absolute alcohol at 65–70°, 10 drops of concentrated hydrochloric acid was added. The deep red solution was kept at 65–70° for two hours and was then poured into 200 cc. of water. The brick-red precipitate weighed 1.4 g. (92%).

The sample analyzed was purified by dissolving in 75% alcohol, treating the solution with norit, filtering, and diluting the filtrate with 4 volumes of water. The mixture was allowed to stand in the refrigerator for two days. The red crystals formed were removed by filtration and again dissolved in alcohol. Addition of 10 volumes of water caused rapid precipitation of the product as an orange powder. This was dried in an Abderhalden drier over phosphorus pentoxide at 2 mm. and 110° for eighteen hours. The product so prepared decomposed at 282° on a Maquenne block.

Anal. Calcd. for $C_{16}H_{12}O_6$: C, 63.98; H, 4.03. Found: C, 64.16; H, 4.25.

A small amount of this material in alcoholic solution was treated with hydrogen at 3 atm. pressure in the presence of an equal weight of platinum oxide catalyst. Reduction took place rapidly; the solution on evaporation to dryness under reduced pressure in a nitrogen atmosphere gave a light-yellow solid which melted with decomposition at about 155–170°. The material decomposed when manipulated and could not be purified.

2 - (*p* - Anisal) - 4,6,7 - trimethoxycoumaran - 3 - one (XX).—In 3.5 cc. of absolute alcohol were suspended 0.26 g. of 4,6,7-trimethoxycoumaranone, 0.18 g. of anisaldehyde, and 2 drops of concentrated hydrochloric acid. This mixture was held at 65–70° for one and one-half hours. The red solution was then poured into 35 cc. of water, and the mixture was allowed to stand for one hour. The red solid was collected on a filter; it weighed 0.3 g. (76%). The solid was dissolved with difficulty in 125 cc. of boiling absolute alcohol; the solution was filtered and concentrated *in vacuo* to 5 cc. On cooling a greenish-yellow precipitate was formed which was separated by filtration. Water added to the filtrate caused the formation of another precipitate which after several recrystallizations decomposed over a wide range at about 180°; it was discarded. The first precipitate was recrystallized by dissolving in a large volume of boiling absolute alcohol and reprecipitating by adding water. The yellow prisms, melting at 195–196°, tended to take on a greenish tinge on exposure to air.

Anal. Calcd. for $C_{19}H_{18}O_6$: C, 66.65; H, 5.30. Found: C, 66.61; H, 5.27.

2 - (*p* - Anisyl) - 4,6,7 - trimethoxycoumaran - 3 - one (XXI).—A suspension of 85 mg. of the above anisalcoumaranone and 85 mg. of platinum oxide catalyst in 30 cc. of absolute alcohol was treated with hydrogen at 3 atm. pressure. Reduction was practically complete in two minutes. After ten minutes the platinum catalyst was removed by filtration and the filtrate was concentrated *in vacuo* to 1 cc. Low-boiling petroleum ether was added, causing precipitation of colorless needles. After two hours 70 mg. (82%) of product was collected on a filter. The material was recrystallized by dissolving in hot absolute alcohol and precipitating with low-boiling petroleum ether. Since this was a rather complete precipitation, there were also precipitated the products of the serious decomposition caused by heating the alcoholic solution. Consequently, the last two recrystallizations were carried out by cooling the alcohol solution in a dry ice–acetone bath and collecting the crystals which formed. This materially improved the product, but the loss of product in each crystallization was great and only two such manipulations could be employed. The final product, weighing 2 mg., melted at 116°.

Anal. Calcd. for $C_{19}H_{20}O_6$: C, 66.25; H, 5.85. Found: C, 65.87; H, 6.06.

Isolation of Tectoridin.—Difficulty was experienced in attempting to follow the procedure given by Shibata.[1] The following modification proved satisfactory. A 2950-g. quantity of the fresh rhizomes of *Iris tectorum* Maxim was trimmed of sprouts and adventitious roots, leaving 1985 g. of the stripped rhizomes. These were cut in 1/4-in. (6-mm.) slices and were dried at 80° for thirty hours under a 25-in. vacuum. They then weighed 675 g. This material was ground to a fine powder by passing the dried rhizomes three times through a colloid mill.

The powder was extracted twice for one and one-half hours with 1400-cc. portions of ethyl alcohol. The volume of the alcoholic solution was reduced *in vacuo* to 700 cc. The tannin impurities were then precipitated by adding a 5% alcoholic solution of lead acetate in portions until no further precipitation was observed. The lead tannate precipitate was removed by filtration and the excess lead in the filtrate was precipitated with hydrogen sulfide. The filtrate from the lead sulfide was evaporated to dryness under reduced pressure.

The residue was treated twice with 500-cc. portions of boiling ethyl acetate, for one hour. The extract was discarded. The mass remaining was stirred into 500 cc. of water. The white solid left suspended in the water was collected on a filter and was washed with absolute alcohol and then ether. The tectoridin thus obtained weighed 5.4 g. and melted at 258°.

A further 55 mg. of tectoridin was recovered from the lead tannate precipitate by suspending it in alcohol, removing the lead with hydrogen sulfide, and adding benzene to the concentrated alcoholic filtrate.

By the above procedure a total of 9.4 g. of tectoridin was isolated from 4550 g. of fresh rhizomes.

Tectorigenin.—One gram of crude tectoridin was heated with 75 cc. of 20% sulfuric acid, with stirring, in an oil-bath maintained at 90°. After the mixture was cooled, 0.83 g. of tectorigenin, m. p. 230°, was separated by filtration.

Dimethyltectorigenin.—Tectorigenin was methylated by the reaction with methyl sulfate and alkali according to the method of Mannich, Schumann and Lin.[2] This ether was also made by methylation with diazomethane. It melted at 188°.

Attempts to convert dimethyltectorigenin into trimethyltectorigenin were made by treatment with an excess of methyl sulfate and alkali, treatment with an excess of diazomethane in methanol and dioxane solutions, methyl iodide and silver oxide, methyl iodide and sodium in liquid ammonia, methyl iodide and phenyllithium, methyl iodide and triphenylmethylsodium. Acetylation of dimethyltectorigenin by acetic anhydride and pyridine yielded the acetyl derivative which melted at 213–214°. Attempts to convert this acetyl derivative to the methyl derivative according to Nierenstein's method[13] were not successful.

Summary

The structure of the two isomeric coumaranones produced by ring closure of α-chloro-2,4,6-trihydroxy-5-methoxyacetophenone was established by methylation and synthesis of each of the methylated compounds. One of these methylated isomers, 4,5,6-trimethoxycoumaran-3-one, was obtained by the following sequence: pyrogallol trimethyl ether → 2,6-dimethoxyquinone → 2,6-dimethoxyhydroquinone → 3,4,5-trimethoxyphenol (antiarol) → α-chloro-2-hydroxy-4,5,6-trimethoxyacetophenone → 4,5,6 - trimethoxycoumaran-3-one. The isomeric product, shown to be 4,6,7-trimethoxycoumaran-3-one, was synthesized as follows: pyrogallol tribenzyl ether → 2,6-dibenzyloxyquinone → 2,6-dibenzyloxyhydroquinone → 2,6-dibenzyloxy-1,4-dimethoxybenzene → 2,5-dimethoxyresorcinol → α-chloro-2,4-dihydroxy - 3,6 - dimethoxyacetophenone → 6 - hydroxy-4,7 - dimethoxycoumaran - 3 - one → 4,6,7-trimethoxycoumaran-3-one.

Condensation of each of these trimethoxycoumaranones with anisaldehyde yielded the 2-anisal derivatives, which were reduced and the two isomers 2-(*p*-anisyl)-4,5,6-trimethoxycoumaran-3-one and 2-(*p*-anisyl)-4,6,7-trimethoxy-coumaran-3-one were isolated.

Tectoridin was isolated from the rhizomes of *Iris tectorum* Maxim and hydrolyzed to tectorigenin. Methylation of tectorigenin yielded only a dimethyl derivative. No trimethyltectorigenin could be obtained, even under drastic conditions. Comparison of the properties of the known methyl derivatives of tectorigenin with those of the above synthetic coumaranones showed that tectorigenin does not possess the coumaranone structure.

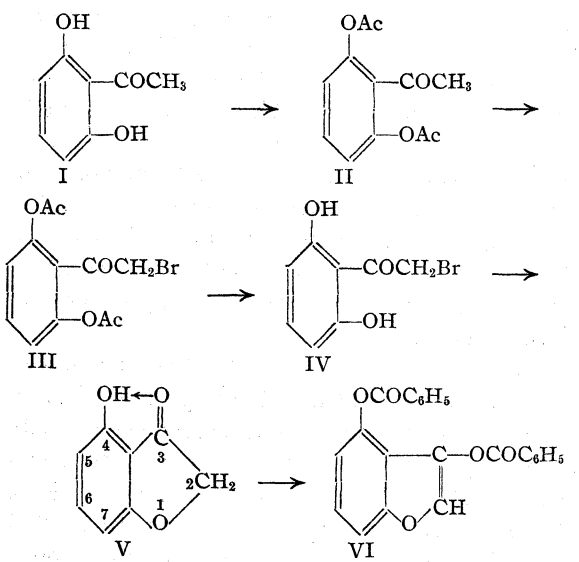
Derivatives of Coumaran. V. Synthesis of 4-Hydroxycoumaran-3-one

BY R. L. SHRINER AND MICHAEL WITTE

The synthesis of many substituted coumaranones has been accomplished by the reaction of phenols with α-halo acid chlorides[1] or with α-halonitriles.[2] These methods have proven useful for the synthesis of coumaranones with hydroxyl groups in the 6- and 7-positions. This paper reports the synthesis and properties of 4-hydroxycoumaran-3-one (V).

Acetylation of 2,6-dihydroxyacetophenone[3] (I) yielded the diacetoxy derivative (II).[4] When this 2,6-diacetoxyacetophenone was treated with bromine in carbon disulfide solution, substitution took place in the side chain giving an 80% yield of the monobromo compound (III). If 2,6-dihydroxyacetophenone is brominated without acetylation nuclear substitution takes place as well as side chain halogenation and a mixture is produced. If acetic acid is used instead of carbon bisulfide, a dibromo derivative is produced. Kröhnke[5] has pointed out that monohalo ketones are in equilibrium with dihalo ketones.

Hydrolysis of the 2,6-diacetoxy-α-bromoacetophenone with dilute hydrobromic acid yielded the 2,6-dihydroxy-α-bromoacetophenone (IV) which underwent ring closure upon treatment with sodium acetate to produce 4-hydroxycoumaran-3-one (V). Benzoylation by the Schotten–Bauman method yielded the dibenzoate, (VI). This is analogous to the oxygen acetylation of coumaran-3-ones previously reported.[6]



The physical properties of 4-hydroxycoumaran-3-one (V) are quite different from those of other monohydroxycoumaranones. It began to sublime at 85° and melted at 120°. 6-Hydroxycoumaran-3-one[7] melts at 243° and the 7-hydroxy isomer[8] at 184°. The 4-hydroxy isomer is also more soluble than the others. This suggests that the hydroxyl group is chelated with the carbonyl group as shown in Formula V. The chelated conjugated system in this structure is in agreement with the suggestion of Mills and Nixon[9] that the two carbon atoms common to the benzene ring and a five-membered ring are joined by a single bond.

Experimental

2,6-Diacetoxyacetophenone.[10]—A solution of 15 g. of 2,6-dihydroxyacetophenone[11] and 45 cc. of acetic anhydride was refluxed for five hours; then, while still hot, it was poured into ice water. A greenish oil separated which upon standing crystallized. The crude compound was recrystallized twice from isoamyl alcohol to give 19 g. of white platelets melting at 60° (corr.).

Anal. Calcd. for $C_{12}H_{12}O_5$: C, 61.01; H, 5.10. Found: C, 60.99; H, 5.47.

2,6-Diacetoxy-α-bromoacetophenone.—Four grams of 2,6-diacetoxyacetophenone was dissolved in 75 cc. of carbon disulfide and 2.8 g. of bromine dissolved in 25 cc. of carbon disulfide was added dropwise with stirring. The addition took one hour and sometimes heating was required to initiate the reaction. The reaction went to completion at room temperature. The carbon disulfide was then removed from the reaction mixture by distillation and the resulting crude brominated compound was twice recrystallized from isopropyl alcohol to give 4.3 g. (80%) of white crystals, m. p. 112° (corr.).

Anal. Calcd. for $C_{12}H_{11}O_5Br$: C, 45.71; H, 3.49; Br, 25.43. Found: C, 45.71; H, 3.60; Br, 25.30.

(9) Mills and Nixon, *J. Chem. Soc.*, 2510 (1930).
(10) Dattatraya, Balkrishna, Limaye and Gorind, *J. Ind. Chem. Soc.*, **12**, 788 (1935), prepared this compound, but reported that they had to distil the above at 180° and 10 mm. and inferred that they had an oil. No mention of a solid was made by these authors although their compound analyzed correctly for C and H.
(11) This compound was prepared by modification of Baker's[3] method developed by Alfred Russell of the University of North Carolina. The details will be published by him.

2,6-Diacetoxy-α,α-dibromoacetophenone.—Four grams of 2,6-diacetoxyacetophenone was dissolved in 50 cc. of glacial acetic acid and 5.6 g. of bromine dissolve in 25 cc. of glacial acetic acid was added dropwise with stirring. The addition took one hour and sometimes heating was required to initiate the reaction which then continued to completion at room temperature. The reaction mixture was then poured into ice water with stirring and the crude brominated compound separated in greenish crystals. These were filtered and twice recrystallized from isopropyl alcohol to give 5.3 g. of white crystals which melted at 113° (corr.).

Anal. Calcd. for $C_{12}H_{10}O_5Br_2$: C, 36.54; H, 2.53; Br, 40.50. Found: C, 36.79; H, 2.66; Br, 39.82.

Both of the above halogen compounds gave an active halogen test by first heating with alcoholic sodium ethoxide solution, then testing the resulting solution after acidification with silver nitrate.

2,6-Dihydroxy-α-bromoacetophenone.—A mixture of 3 g. of 2,6-diacetoxy-α-bromoacetophenone, 80 cc. of 60% ethanol, 20 cc. of hydrobromic acid (40%) and 1 mg. of sodium hydrosulfite was refluxed for one hour. The solvent was then distilled at 30° and 30 mm. pressure to leave yellow platelets which were recrystallized twice from benzene to give a yield of 1.6 g. It melted at 143° (corr). This compound gave a green ferric chloride test.

Anal. Calcd. for $C_8H_7O_3Br$: C, 41.55; H, 3.03. Found: C, 41.84; H, 2.99.

4-Hydroxycoumaran-3-one.—A solution of 1 g. of 2,6-dihydroxy-α-bromoacetophenone, 1 g. of sodium acetate trihydrate, 1 mg. of sodium hydrosulfite and 50 cc. of ethanol was refluxed for one hour. Twenty cubic centimeters of water was added and 30 cc. of ethanol was distilled from the reaction mixture. The resulting solution was allowed to cool and placed in a refrigerator overnight. Brown crystals separated and were filtered and recrystallized twice from high boiling petroleum ether to give 0.4 g. of brown granular crystals. This compound began subliming at 85° and finally melted at 120° (corr.). It gave a violet ferric chloride test for phenols.

Anal. Calcd. for $C_8H_6O_3$: C, 64.00; H, 4.00. Found: C, 64.21; H, 4.17.

In this last reaction a few milligrams of sodium hydrosulfite was added to the reaction mixture to minimize oxidation of the rather unstable 2,6-dihydroxy-α-bromoacetophenone.

3,4-Dibenzoxybenzofuran.—A solution of 0.5 g. of 4-hydroxycoumaran-3-one, 1 g. of benzoyl chloride, 1 g. of sodium carbonate, 10 cc. of water and 15 cc. of acetone was warmed gently for thrity minutes, then poured into ice water. The benzoylated compound separated and was filtered. It was recrystallized from ethyl acetate to give 1.0 g. of colorless needles; m. p. 183° (corr.).

Anal. Calcd. for $C_{15}H_{10}O_4$: C, 73.74; H, 3.91. Found: C, 73.47; H, 4.03.

Summary

4-Hydroxycoumaran-3-one has been synthesized by the following sequence: 2,6-dihydroxyacetophenone ⟶ 2,6-diacetoxyacetophenone ⟶ 2,6-diacetoxy-α-bromoacetophenone ⟶ 2,6-dihydroxy-α-bromoacetophenone ⟶ 4-hydroxycoumaran-3-one. The low melting point and tendency to sublime exhibited by this compound indicate that the hydroxyl group is probably chelated with the carbonyl group.

Electrical Properties of Solids. IV.* The Influence of Thermal History on Polyvinyl Chloride Plastics

BY RAYMOND M. FUOSS

I. Introduction.—Plastics containing polyvinyl chloride have two characteristics which sharply differentiate them from most of the systems ordinarily studied by physico-chemical methods: the electrical properties of a given sample depend on the method of preparing the sample[1] and, after preparation, the properties of a given sample change with time. Obviously the influence of the corresponding variables must be eliminated before any correlation between properties and chemical composition and structure is attempted. The most important item in the preparation of the sample is the thermal history; two samples of the same composition with identical thermal histories will give results which check as precisely as might be desired (assuming that trivial variables, such as those due to surface effects and humidity, are eliminated).[2]

The changes with time are of at least two kinds: (1) a slow decrease of dielectric constant, amounting to several per cent., while the density remains constant and (2) a slow increase of d. c. conductance, which in turn induces an increase in dielectric constant and a. c. absorption. These two effects combine to produce a minimum in the dielectric constant–time curve.

It is the purpose of this paper to present and

(*) Paper III, THIS JOURNAL, **60**, 456 (1938).

(2) Fuoss, THIS JOURNAL, **59**, 1703 (1937).

discuss some experimental results of a study of the properties outlined above. Not enough data are yet available to give a complete description of the plastic solid, because so very much more remains to be done. Enough has been accomplished, however, to show several promising lines of attack on the general problem, and it is believed that the results are sufficiently interesting and suggestive to be made available to other workers in this field.

II. Experimental Methods.—All measurements were made on disks of plastic 10 cm. in diameter and 6 mm. in thickness. All samples were surfaced in some way to eliminate series capacity due to air films between the sample and electrodes. Diluted aquadag, powdered graphite, or tin foil, the latter rubbed on with a minute amount of petrolatum, all gave satisfactory results; depending on the composition and flexibility of the sample, one or another method was preferred. (It might be well to point out that *tin* must be used in the foil method: all other available foils were too hard to give adequate contact.)

The cell[1] and bridges[1-3] used in the measurements have been described previously.

In general, the samples were prepared by cold mixing a weighed amount of polyvinyl chloride and plasticizer. (The polyvinyl chloride was from the same lot as that used in preparing samples for the two previous papers of this seiries.[3,4]) The mixture was then worked on a rubber mill under controlled and recorded conditions (time and temperature of milling, thickness of sheet, speed of rolls and size of batch) Disks about 0.5 mm. thick and 9.84 cm. in diameter were stamped from the final mill sheet. These disks will shrink much more parallel to the milling direction (as much as 40%) on heating to 150° than perpendicular to this direction, but heating above 100° under pressure will gradually destroy this elastic memory. In order to obtain samples for electrical measurements which would remain circular, 15–20 disks from the mill sheet were stacked with mill directions crossed on consecutive sheets and compressed to a single disk in a hot closed mold under hydraulic pressure. Time and temperature of pressing were always recorded. After pressing, the sample was weighed, surfaced, placed in the cell and allowed to come to temperature equilibrium in an oil thermostat held at 40.00 ± 0.01°.

Electrical measurements were then made. Thickness of cell plus sample was determined before and after the electrical measurements, and also during them, if the run lasted more than an hour. (As previously pointed out,[1] the dimensions change with time, and since the thickness enters the calculation of dielectric constant and conductance explicitly, it must be determined accurately.)

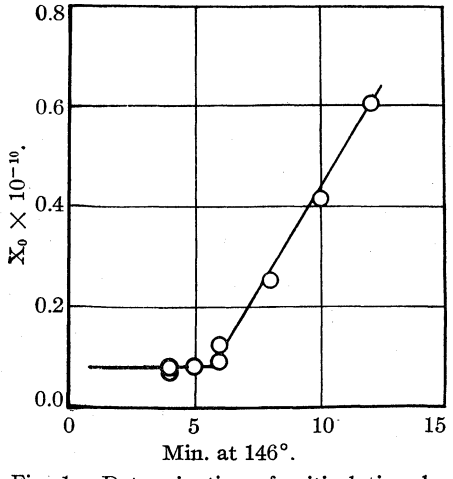

Fig. 1.—Determination of critical time by conductance method.

III. Results and Discussion.—It has been shown[1] that the d. c. conductance of plastics containing polyvinyl chloride plasticized with tricresyl phosphate increases on exposure to heat. The preparation of the sample involves two heat treatments, milling and pressing. The relation between d. c. conductance, which is a measure of the hydrogen chloride produced by pyrolysis, and the time and temperature of heating, is given by the equation

$$\kappa_0 = A \int_0^t \exp.\,[-B/T(t)]\,dt \qquad (1)$$

where A depends on the composition of the plastic and on the temperature at which the electrical measurement is made.

In order to find a correlation between conductance and the actual amount of hydrogen chloride present, a series of samples was made up, with various amounts of lead abietate dissolved in the plasticizer. These samples were then heated for different times at different temperatures. A typical result is shown in Fig. 1, which is for a set of samples containing 0.5% lead abietate in the tricresyl phosphate. The composition was 60% polyvinyl chloride by weight. After milling fifteen times at 105°, which was sufficient to plasticize the polymer, the samples were pressed at 145° for times ranging from four to twelve minutes. As will be seen in the figure, the d. c. conductance, measured at 40°, was low (0.08×10^{-10}) and independent of heating time up to six minutes; beyond this time, however, the conductance increased rapidly with further heating. The break in the curve clearly corresponds to the time required for the lead present initially as abietate to be converted into chloride. After the lead is consumed, the conductance rises parallel to the conductance–time curve for the blanks (similar sample containing no dissolved lead).

(3) Fuoss, THIS JOURNAL, **60**, 451 (1938).
(4) Fuoss, *ibid.*, **60**, 456 (1938).

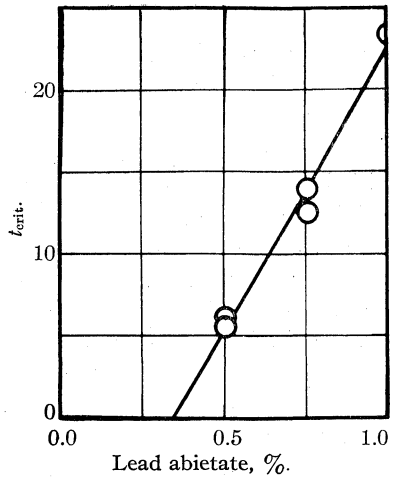

Fig. 2.—Dependence of critical time on lead content.

Figure 2 is a summary of data referring to samples heated at 145°, containing various percentages of lead abietate. The ordinate is the time required to consume the lead added. Since the line does not go through the origin, we conclude that the components of the plastic contained some material which reacts with lead abietate before the pressing. The intercept at zero time in Fig. 2 corresponds to 0.35% of lead abietate; 100 parts per million of hydrogen chloride originally in the polyvinyl chloride would use up this quantity of lead. An aqueous extract of the polyvinyl chloride gave a turbidity with silver nitrate solution, which indicated this order of magnitude of extractable chloride. After allowing for the lead consumed initially, 1.00 g. of lead abietate per 100 g. of plasticizer corresponds to 60 mg. of hydrogen chloride per 100 g. of polyvinyl chloride in the 40:60 plastic.

The dependence of lead consumption on temperature of heating is shown in Fig. 3, where data covering the range 130–160° are presented. The times were obtained as the breaks in the conductance–heating time curves; these samples contained 0.7% lead abietate in the tricresyl phosphate. Assuming that the amount of lead chloride formed is measured by the time to the break in the heating curve, the slope of the line in Fig. 3 gives 33 kcal. as the energy associated with the reaction between the products of pyrolysis and the lead abietate in the plastic. This value is practically the same as that found by Dr. M. M. Sprung[5] for the pyrolysis of dry polyvinyl chloride in a stream of nitrogen. The rate of evolution of hydrogen chloride at various temperatures was plotted against reciprocal of absolute temperature; a straight line was obtained, whose slope gave 35 kcal. In a typical experiment, 47 mg. of hydrogen chloride was obtained per 100 g. of polyvinyl chloride in fifteen minutes at 150°. This is about twice as much as was found by the lead abietate (21 mg. hydrogen chloride per 100 g. polyvinyl chloride in twelve minutes at 146°) method in the plastic, and suggests that several reactions, competing for hydrogen chloride, are taking place in the presence of tricresyl phosphate containing lead abietate.

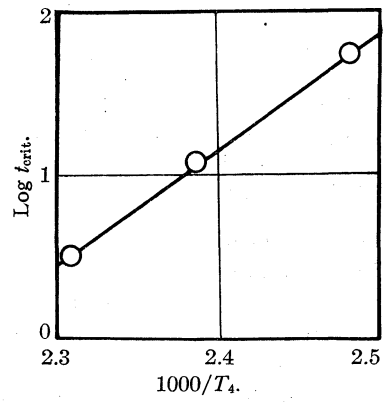

Fig. 3.—Temperature coefficient of pyrolysis.

There is other experimental evidence that the chain of reactions in the plastic is not simple pyrolysis of polyvinyl chloride to give hydrogen chloride, followed by metathesis between hydrogen chloride and lead abietate. If samples are made up containing 60 parts polyvinyl chloride and 40 parts of another plasticizer, such as dibenzyl sebacate, dibutyl phthalate, diphenyl ether, amylnaphthalene and so on, their d. c. conductance is always much higher (regardless of the intrinsic conductance of the plasticizer) for a given thermal history than that of samples made with tricresyl phosphate. This suggests the possible explanation that the hydrogen chloride set free by pyrolysis of the polymer reacts with the tricresyl phosphate, forming phosphorus oxychloride as the ultimate end-product of reaction by the reverse of the usual synthesis of tricresyl phosphate. Then the products of this reaction in turn react with the lead abietate. This assumption was checked by adding 10% octyl borate to a sample made up with dibenzyl sebacate: the resulting sample gave a conductance as low as that obtained with tricresyl phosphate, and octyl borate is a compound

(5) Unpublished work done in this Laboratory.

which one would expect to react with hydrogen chloride to give non-electrolytic products.

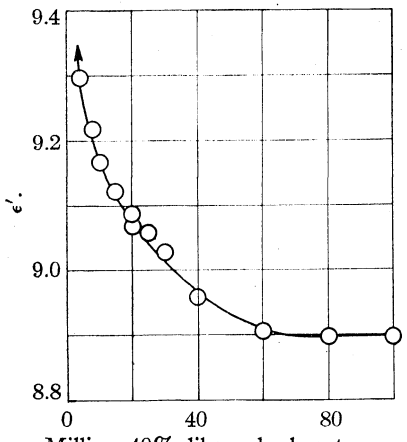

Fig. 4.—Dependence of dielectric constant on milling for polyvinyl chloride–dibenzyl sebacate.

It should be mentioned that the milling was kept to the minimum for thorough mixing in the above set of samples where press time and temperature were under investigation. Separate experiments showed that the d. c. conductance produced by the milling alone was 0.02×10^{-10}, or about 25% of the lowest and 2% of the highest d. c. conductance involved. The minimum value of 0.08×10^{-10} at 40° is due to the presence of electrolyte which will not react with lead abietate; the latter is an extremely weak electrolyte.[6,7]

For plastics made with tricresyl phosphate as plasticizer, the primary effect on electrical properties of milling is an increase of d. c. conductance due to pyrolysis. This is not in general true, however; for example, with dibenzyl sebacate as plasticizer, the dielectric constant decreases with increased number of millings, and becomes constant after about fifty times through the mill at 105° as is shown in Fig. 4. Apparently different plasticizers require different amounts of milling to reach homogeneity. With tricresyl phosphate, the dielectric constant was independent of the number of times the mixture was milled; in fact, samples made by hot pressing an unmilled mixture of polyvinyl chloride and tricresyl phosphate, which had been thoroughly rubbed together cold in a mortar, gave the same dielectric constant as milled material, if allowance for differences in d. c. conductance were made.

The density was the same for the various samples of Fig. 4, and the dielectric constant *decreased* with increased milling; hence the action of the mill in the plasticization process is more than mere mixing for the case of dibenzyl sebacate. The rate at which the dielectric constant–milling curve reaches its asymptote at a fixed milling temperature might be used as a measure of plasticizing power of a given liquid. On this basis, tricresyl phosphate is a more effective plasticizer than dibenzyl sebacate.

Practically all of the plastics studied so far show a small but systematic change of dielectric constant with time. An example is shown in Fig. 5 for 60 and 1000 cycle measurements at 40° on a sample containing 40% tricresyl phosphate and 60% polyvinyl chloride. If the logarithm of the difference between the dielectric constant at time t and its asymptotic value is plotted against the square root of the age of the sample, reckoned from the time it was cooled in the disk mold, a straight line is obtained. The slope depends upon frequency.

A similar relation between logarithm of relaxation and time elapsed after elastic strain has been observed by Dr. W. I. Patnode of this Laboratory in a study of the mechanical properties of plastics. When the samples considered here are taken from the disk mold, there is an immediate shrink of about 1% in diameter, together with an increase in thickness. These changes continue for days, but occur in such a way that the density, within an experimental error of 0.1%, is con-

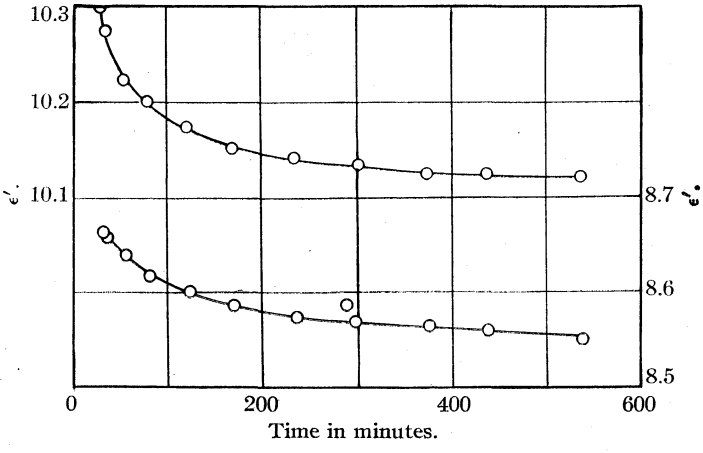

Fig. 5.—Aging curves at 60 (top) and 1000 (bottom) cycles.

(6) Deitz and Fuoss, THIS JOURNAL, **60**, 2394 (1938).
(7) Elliott and Fuoss, *ibid.*, **61**, 294 (1939).

served. The change in dielectric constant is therefore due to an internal rearrangement of some sort. Polyvinyl chloride molecules are chains of enormous length, held together in the chain direction by C–C bonds. When a sample is pressed, local strains are set up, as shown by the colored patterns which appear in polarized light. If the sample has a fairly high viscosity (less than 70% plasticizer), these strains can relax only slowly, because freedom of orientation comparable to that in liquids is made impossible by the chain structure. Relative motion of whole molecules is impossible in general, but segments of chains can slip past one another, given sufficient energy, so that there exists in the plastic the analog of liquid viscosity, but one dimension of freedom of motion is lost. Adjacent parts of the same or different molecules in a given configuration may have a position of lower potential energy available, but can reach it only when a positive fluctuation in kinetic energy gives them sufficient energy to get over the potential barrier between the metastable and the stable positions. Obviously at the start of the relaxation process, there will be many strained regions which can easily rearrange, irreversibly, of course; therefore the initial change in dielectric constant, which is a measure of internal orientation, is rapid. But as more and more energy is required to rearrange the remaining strained regions, the number of probable transitions per unit time must necessarily decrease, and the system asymptotically approaches a state in which all molecules occupy stable mutual positions. Similar arguments based on increase of entropy have been advanced to explain the relaxation of stress in stretched rubber and like compounds.[8]

After several days, the dielectric constant of a polyvinyl chloride plastic slowly starts to increase again. This change is quite different from the initial decrease, and can be correlated with the simultaneous increase in d. c. conductance. The production of hydrogen chloride which occurs in the pressing continues at room temperature (although at a very much reduced rate), and as hydrogen chloride concentration increases, the dielectric constant increases with it. Simultaneously, the pure a. c. absorption, as measured by the loss factor, ϵ'', increases.

The loss factor is defined for our present work by the equation

$$\epsilon'' = 18 \times 10^{11}(\kappa - \kappa_0)/f \qquad (2)$$

where κ is the specific conductance at frequency f and κ_0 is the d. c. conductance measured on a d. c. bridge.

Equation (2) tacitly implies that the electrolytic conductance is independent of frequency and that its value is determined by d. c. measurement; obviously any variation of electrolytic conductance with frequency would induce a spurious change in apparent a. c. loss factor as defined above. This assumption may require later scrutiny; certainly in the range of high frequencies, it is known that electrolytic conductance is a function of frequency due to relaxation effects.

The correlation between a. c. and d. c. properties is shown in Figs. 6 and 7, where ϵ' and ϵ'' are plotted against the *square root* of d. c. conductance. (It was found empirically that the data approximate linearity with this choice of coördinates; we are at present unable to say whether this form is significant or coincidental.) The important fact shown by Figs. 6 and 7 is that the a. c. properties can be correlated directly with the d. c. conductance; since the latter is determined by the thermal history; we have in the d. c. conductance a variable which summarizes the thermal history as far as electrical properties are concerned.

The samples whose constants are shown in Figs. 6 and 7 were all 40% tricresyl phosphate–60% polyvinyl chloride. Different thermal histories were obtained by varying time and temperature of milling and pressing. It will be noted that data, self-consistent within a few tenths per cent. in dielectric constant, were obtained. In order to eliminate the effect of aging, all data for Figs. 6 and 7 were interpolated to two hours after preparation, from a series of measurements made on each sample. The rate of change of ϵ' and ϵ'' with electrolytic conductance decreases with increasing frequency; details of this behavior will be presented in a later paper.

The data of Figs. 6 and 7 show that we may write

$$\epsilon' = \epsilon_0 + A\sqrt{\kappa_0} \qquad (3)$$

$$\epsilon'' = \epsilon_0'' + B\sqrt{\kappa_0} \qquad (4)$$

where ϵ_0' and ϵ_0'' are the a. c. constants referring to the hypothetical electrolyte-free plastic. The terms in $\sqrt{\kappa_0}$ represent the contributions to a. c. mechanism due to the presence of electrolyte. It is planned to study this question further by using known concentrations of known electrolytes in plastics of various compositions. Incidentally,

(8) Meyer, *Chemistry & Industry*, **57**, 439 (1938).

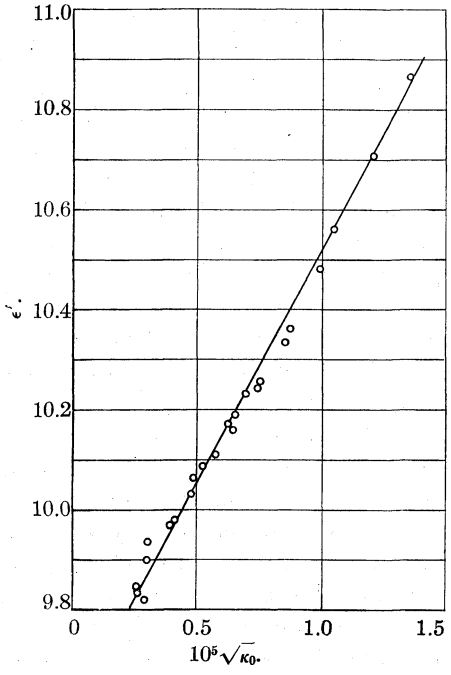

Fig. 6.—Dependence of 60 cycle dielectric constant on d. c. conductance.

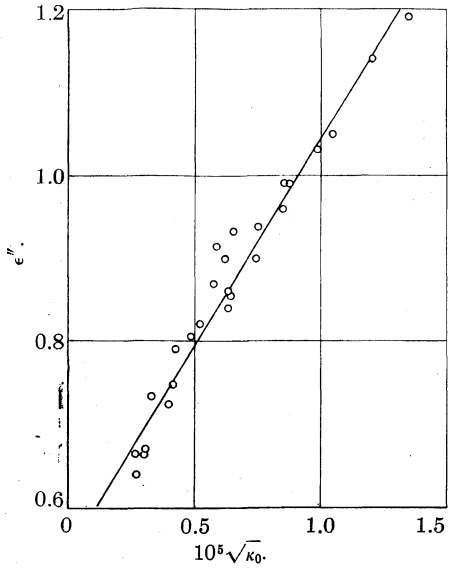

Fig. 7.—Dependence of 60 cycle loss factor on d. c. conductance.

this will permit a study of electrolytic conductance in the range of very high viscosities ($\eta \sim 10^6$ poises).

Summary

1. The electrical properties of polyvinyl chloride plastics depend on thermal history. Increased time and temperature of heating give increased d. c. conductance.

2. The amount of pyrolysis can be followed by adding a soluble lead compound such as lead abietate to the plasticizer and determining the conductance for various heating times and temperatures.

3. The dielectric constant changes with time in a way which suggests a relaxation mechanism.

4. There is a one to one correlation between d. c. conductance, dielectric constant and loss factor.

Electrical Properties of Solids. V. Their Variation at 40° with Frequency and Composition in the System Polyvinyl Chloride–Tricresyl Phosphate

BY RAYMOND M. FUOSS

I. Introduction

Polyvinyl chloride as ordinarily obtained is an amorphous white powder, which can be converted under hydraulic pressure at 120° into a transparent brittle solid. By the addition of various liquids, such as tricresyl phosphate, it can be softened or "plasticized," to give solids ranging from glass-like to jelly-like substances, going through a tough rubber-like form at about 35–45% plasticizer. Dilute solutions of the polymer in plasticizers are very viscous liquids. The two-phase system polymer–plasticizer thus permits a study of electrical properties over an enormous range of macroscopic viscosity. By varying the chemical nature of the two components, or by adding a third, a wide range of conductance and dielectric constant can then be investigated.

In previous papers in this series, experimental methods[1] for obtaining electrical data of reasonable precision on solids have been described, and a preliminary account of some of the properties of the system polyvinyl chloride–tricresyl phosphate

has been presented.[1b] This paper represents the first part of a systematic study of the properties of plastic solids. The conductance and dielectric constant have been determined at 40° over the frequency range 20 to 10^4 cycles (low voltage[1c]) for the system polyvinyl chloride–tricresyl phosphate, over the entire concentration range.

II. Experimental Methods

Cells, bridges, materials, method of preparing and measuring samples and experimental precautions already have been described.[1,2]

Milling was the minimum necessary for thorough mixing, and pressing was only ten minutes at 120°. By using mild thermal conditions in the preparation of this series of samples, pyrolysis of the polyvinyl chloride was kept small, so that the accompanying d.c. conductance due to hydrogen chloride from pyrolysis would not be too serious a disturbing factor.

III. Results

Measurements were made at a number of frequencies between 15–20 cycles and 10 kilocycles. In order to save space in presentation, values of dielectric constant ϵ' and a. c. loss factor ϵ'' have been interpolated from the data to round frequencies in the above range, and are given in Tables I and II. The d. c. conductance was also measured; these values are summarized in Table III.

The a. c. loss factor is defined as

$$\epsilon'' = 18 \times 10^{11} (\kappa - \kappa_0)/f \qquad (1)$$

where κ is the conductance at frequency f and κ_0 is the electrolytic conductance as measured on a d. c. bridge. It is assumed, for the present, that κ_0 is independent of frequency.

Densities were determined by weighing the samples and measuring their dimensions with vernier scales. For the 60 polyvinyl chloride–40 tricresyl phosphate samples some densities were also determined by weighing under water; the two methods checked within several tenths of one per cent., the experimental precision of the former method. As nearly as we can conclude from the data, polyvinyl chloride and tricresyl phosphate mix to form a plastic without volume change.

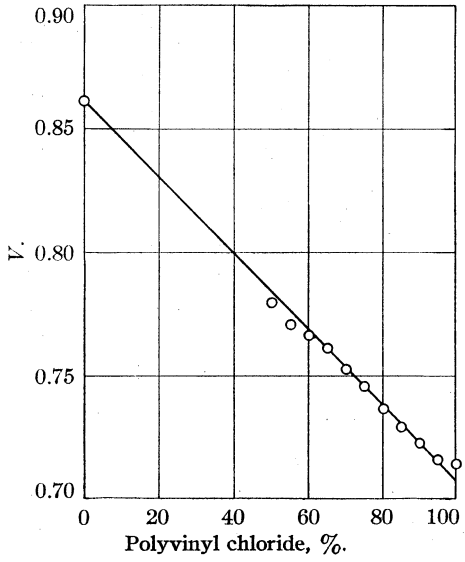

Fig. 1.—Specific volumes of polyvinyl chloride–tricresyl phosphate plastics.

In Fig. 1 the specific volume is plotted against composition by weight; the circles are observed and the solid line is that corresponding to

$$v = p_1 v_1 + p_2 v_2 \quad (2)$$

$$p_1 + p_2 = 1 \quad (3)$$

where $v_1 = 0.706$ and $v_2 = 0.861$ cc./g. are, respectively, the specific volumes of pure polyvinyl chloride and of tricresyl phosphate. This result is in accord with Brönsted's view[3] that all solutions of high polymers are very dilute solutions from the thermodynamic point of view, on account of the enormous molecular weight of the polymer.

IV. Discussion

In general, most polar substances show a high dielectric constant at low frequencies, and a small dielectric constant approaching the square of the index of refraction at high frequencies. The transition from high to low values usually occurs over a fairly narrow range of frequency; about 90% of the inflection region of the ϵ'–f curve lies within two decades of frequency. In this frequency range, the loss factor goes through a maximum, and approaches zero for higher or lower frequencies. The plastic solid, as exemplified by the system under discussion here, shows a markedly different behavior. The dielectric constant decreases (Fig. 2) with increasing frequency,

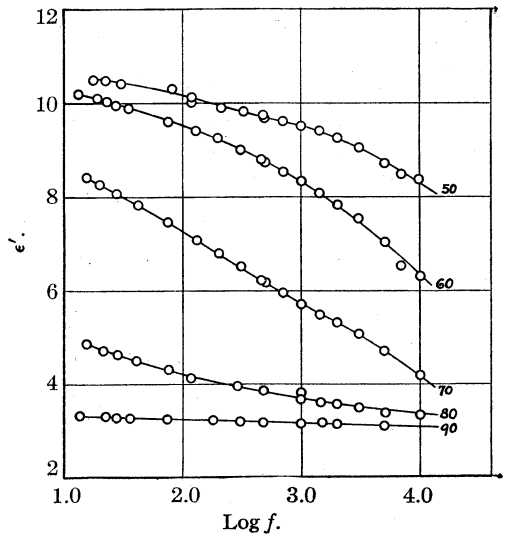

Fig. 2.—Dependence of dielectric constant on frequency and composition.

but only very slowly as compared to normal polar systems. The loss factor shows a maximum (Fig. 3) in the range 80–65% polyvinyl chloride within our present frequency range, which is nearly three decades wide, but is still relatively far from zero at the extreme frequencies. In other words, the plastic system roughly resembles ordinary systems in that the dielectric constant decreases with increasing frequency, and the loss factor has a maximum at some definite frequency (for a given temperature), but differs from them in the width of the dispersion region. The inflection slope on an ϵ'–f plot is much shallower for the plastic, and the ϵ'' maximum is very much broader.

(3) Brönsted, *Compt. rend. trav. Lab. Carlsberg, Sér. chim.*, **22**, 99 (1937).

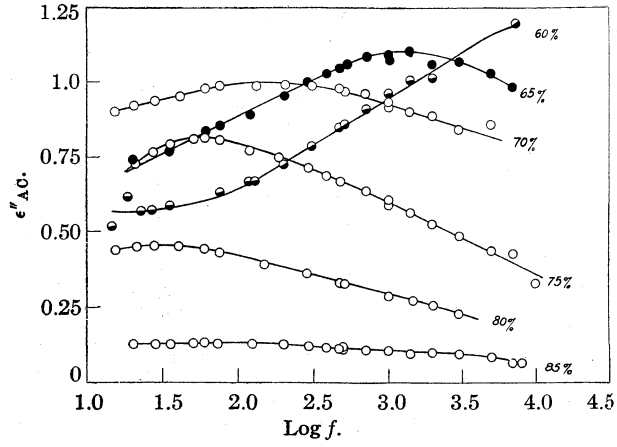

Fig. 3.—Dependence of loss factor on frequency and composition.

If a much wider range of frequency were available, an S-shaped ϵ'–f curve would probably have been obtained for all the systems of Table I. As it is, those containing between 90 and 70% polyvinyl chloride give concave-up ϵ'–log f curves in the range 0.01–10 kc. (inflection at lower frequencies). The 70% sample gives a practically linear ϵ'–log f curve, which indicates an inflection point within this range of frequency (at about 150 cycles, judging from the maximum in the ϵ''–log f curve). Those containing less than 70% polyvinyl chloride give curves that are concave-down, which suggests that their inflection points lie at higher frequencies than 10 kc. The loss factor curves similarly show a shift of the absorption maxima to higher frequencies as the plasticizer content increases.

Another reversal in curvature appears near the pure polyvinyl chloride end of the composition range. Pure polyvinyl chloride gives a concave-down ϵ'–log f curve, and an ϵ''–log f curve which rises with frequency in the 0.01–10 kc. range, indicating a center of dispersion at higher frequencies than 10 kc. The addition of 5% tricresyl phosphate decreases the dielectric constant, converts the ϵ'–log f curve almost to a straight line and decreases the rate of increase of ϵ'' with frequency; the center of the dispersion is therefore at lower frequencies than for the 100% sample, although still beyond 10 kc. At 10% plasticizer, the ϵ'–log f curve is nearly linear, and ϵ'' now decreases with increasing frequency in the experimental range, corresponding to a center of dispersion *below* 10 cycles. At 15% tricresyl phosphate, the center of dispersion appears to be just about at 10 cycles. Then with increasing plasticizer, the dispersion moves regularly to higher frequencies. The critical region between 95 and 85% polyvinyl chloride, where the dispersion crosses the frequency band from high to low frequencies and back again, will require further study.

Attention has already been called to the bluntness of the absorption maxima and the width of the dispersion on a frequency scale. There is further experimental evidence that the dispersion is much broader than can be shown by actual a. c. measurement by our present methods. If the

observed conductance is plotted against frequency for the samples of Table II, approximate straight lines are obtained *which extrapolate linearly to the d. c. conductance.*[1b] Even for those samples for which a maximum in ϵ'' was found, the per cent. change in ϵ'' was nevertheless small; the fact that the a. c. data extrapolate *linearly* to the d. c. conductance (*cf.* eq. 1) is equivalent to saying that ϵ'' will not change much with frequency until extremely low frequencies are reached. On the basis of any of the present theories of absorption, ϵ'' must reduce to zero at zero frequency; *i. e.*, the κ–f plots must approach κ_0 with a horizontal tangent in the limit. No evidence of curvature was observed at 40°; at higher temperatures, the κ–f curves do, however, become concave-up in the low (10–100 cycles) frequency range.

A number of possible explanations of the width of the dispersion have been suggested, but no general theory with only a small number of arbitrary constants with assignable physical significance has been advanced. The fundamental difference between a solution of simple dipole molecules such as ethyl chloride and a plastic containing polyvinyl chloride is, aside from the obvious difference in viscosity, the fact that the ethyl chloride molecules are free to assume a normal distribution of orientations in thermal equilibrium, while the dipoles of polyvinyl chloride are constrained to fluctuations about orientations fixed by the accidental convolutions of the chain molecule which carries them. The components of moment in the direction of the field are thus subject to a different distribution law than for free dipoles. An eventual theory of the electrical properties of dipolar polymers must include explicitly this influence of structure on distribution.

The influence of such a distribution on the a. c. absorption can be qualitatively described. Under the action of the field, adjacent parts of the same or different chain molecules can be irreversibly twisted into new positions, in much the same way as elastic strains relax in the plastic. This process corresponds to a loss factor independent of frequency. If a second frequency-sensitive absorption (Debye relaxation or Maxwell–Wagner polyphase dielectric) were also present, curves like those of Fig. 3 would be obtained; these curves would resemble normal absorption curves, if the frequency axis were higher. In other words, the plastic behaves as if the loss factor could be broken up into two terms

$$\epsilon'' = \epsilon_s'' + \epsilon''(f) \qquad (4)$$

where ϵ_s'' is the power absorption due to irreversible slipping of molecules in the field against a static friction, and $\epsilon''(f)$ is a frequency-sensitive absorption which reduces to zero in a normal way for both very high and very low frequencies.

As a function of composition at fixed frequency, very interesting curves are obtained. These are shown in Figs. 6 and 7. As plasticizer content increases, the flexibility (plasticity, viscosity) increases, and has its most obvious change in the region centering around 30% plasticizer, where the transition from brittle to soft takes place. In the same range of composition, the dielectric constant has its maximum rate of change, and the loss factor goes through a sharp maximum. This region corresponds to a dispersion which is produced by varying the time of relaxation through

change of internal viscosity, as contrasted to the usual dispersion curves which are obtained by varying frequency at fixed temperature or *vice versa*. A rough estimate of the viscosity of the 60 polyvinyl chloride–40 tricresyl phosphate from the dispersion gives 10^6 poises, which is a reasonable order of magnitude.

The rapid change of viscosity is best illustrated by the change of d. c. conductance with composition, as is shown in Fig. 8. All the samples had as nearly as possible the same thermal history; consequently the hydrogen chloride concentration should be of about the same order in each, and any gross change of κ_0 with composition can be ascribed to changing viscosity. As seen in the figure, the conductance increases exponentially with increasing plasticizer content in the middle of the concentration range.

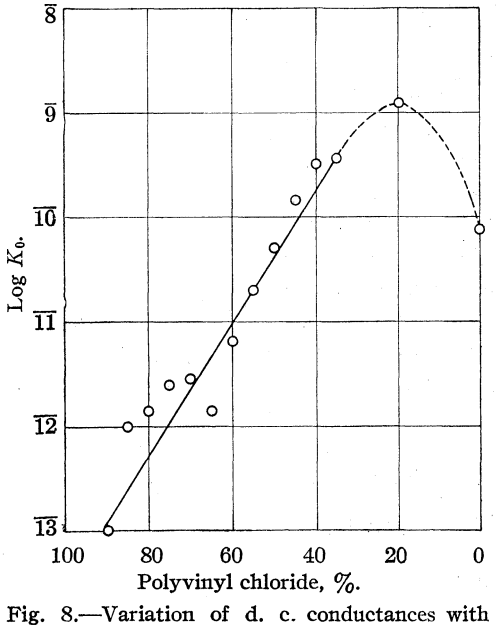

Fig. 8.—Variation of d. c. conductances with composition.

The two ends of the curves of Figs. 6 and 7 exhibit several striking characteristics. The dielectric constant of polyvinyl chloride is at first decreased by the addition of tricresyl phosphate. The decrease is greater than simple volume replacement of relatively more polarizable halogen compound by a compound containing only carbon, hydrogen, oxygen and phosphorus atoms. The index of refraction of tricresyl phosphate at 40° is 1.5494, which gives a specific refractivity.

$$r = (n^2 - 1)/\rho \qquad (5)$$

equal to 1.210; for polyvinyl chloride, $n = 1.565$ and $r = 1.023$. As a function of composition, the electrical susceptibility

$$\sigma = (\epsilon' - 1)/\rho \qquad (6)$$

shows a minimum; and even after subtracting $(p_1r_1 + p_2r_2)$ to allow for the greater polarizability of chlorine atoms, the non-optical susceptibility

$$\sigma^* = (\epsilon' - 1)/\rho - (p_1r_1 + p_2r_2) \qquad (7)$$

still shows a minimum. This may indicate a coupling between the dipoles of polymer and plasticizer.

After this initial decrease in dielectric constant, a minimum appears, followed by the rapid rise already discussed. The maximum which next appears is described most easily as a viscosity effect: starting with pure tricresyl phosphate, we obtain an increase in dielectric constant because we are increasing the content of polar solute, but simultaneously the viscosity increases, so that the two competing influences finally produce a maximum. It is impossible, of course, to consider the properties on a mole fraction scale, because the molecular weight of the polymer is unknown, but we can plot the results on a mole ratio scale, which is proportional to the mole fraction scale. If the susceptibility of the polyvinyl chloride in the plastic, defined by the equation

$$\sigma_1 = (\sigma - p_2\sigma_2)/p_1 \qquad (8)$$

where σ_2 is the total susceptibility of the pure plasticizer, is plotted against the mole ratio, approximate linearity is obtained in the range 0–70% polymer (Fig. 9). The quantity σ_1 extrapolates to 14.5 cc./g. at zero concentration. In order of magnitude, this is a very reasonable figure, if the electrical behavior of the plastic were primarily due to chlorine dipoles in a viscous medium. If we assume that E/F, the ratio of external and in-

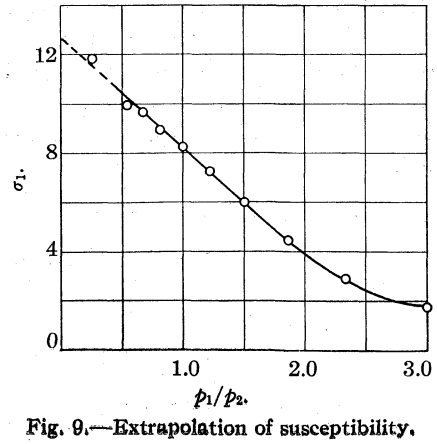

Fig. 9.—Extrapolation of susceptibility.

ternal fields, is of order unity, the molecular polarization per —CH_2CHCl— group is 30 cc., because

$$p = \frac{E}{F}\frac{\epsilon' - 1}{3} \qquad (9)$$

This corresponds to a moment equal to 1.2×10^{-18}, which compares favorably with the values found for Cl-dipoles in simple molecules, where liquid friction is the only restraint on molecular rotation.

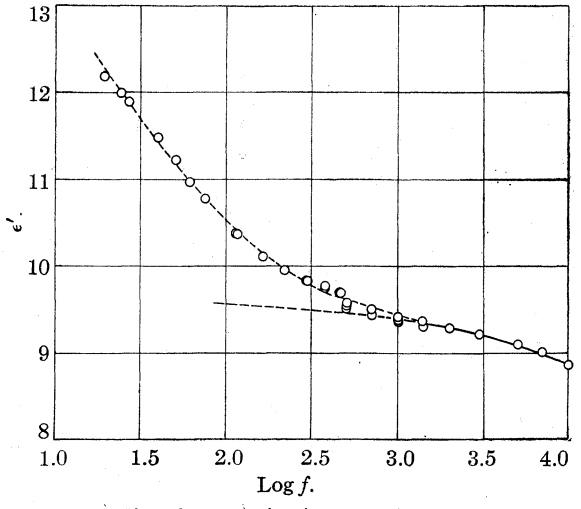

Fig. 10.—Polarization capacitance.

Two other interesting facts are contained in the data. The first is the sudden increase (Fig. 10) with decreasing frequency of the dielectric constant of the 35 polyvinyl chloride–65 tricresyl phosphate sample. This may be due to polarization capacity acting at the electrodes; more data are needed to decide the question. The second is the corresponding rise in loss factor for this sample. If these two properties really are volume properties and not surface effects, the system polyvinyl chloride–tricresyl phosphate has two dispersion regions. The region from the gel stage through the viscous solutions to dilute solutions of polymers in plasticizer needs considerable more investigation, which must be prefaced by a study of experimental methods for handling these materials.

Summary

1. Dielectric constants and loss factors at 40° and 20 cycles to 10 kilocycles under low voltage are reported for the system polyvinyl chloride–tricresyl phosphate, over the entire concentration range.

2. As a function of composition, the maximum absorption and the dielectric dispersion appear in the range 70–50% polymer, where the macroscopic viscosity has its most rapid rate of change with composition.

3. A characteristic difference between free dipoles and dipolar polymers is pointed out: the former can assume a normal distribution of orientations, while the latter have a distribution determined by the chain orientation.

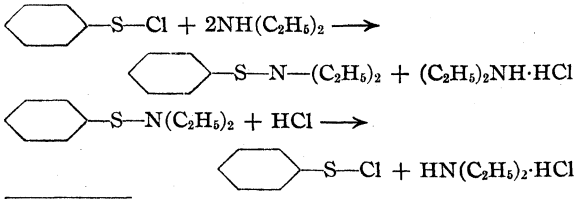
The Use of *o*-Nitrobenzenesulfenyl Chloride in the Identification of Amines

BY JOHN H. BILLMAN AND EUGENE O'MAHONY

It has been reported by Zincke[1] and Lecher[2] that amines would react with aromatic sulfenyl chlorides to produce amides of sulfenic acid which upon treatment with hydrochloric acid could be hydrolyzed. In certain cases, solid amides were obtained.



(1) T. Zincke and F. Farr, *Ann.*, **391**, 57–88 (1912).
(2) H. Lecher and F. Holschneider, *Ber.*, **57**, 755–758 (1924).

The purpose of our work was to investigate further these reactions using substituted benzenesulfenyl chlorides in an attempt to produce suitable solid derivatives of amines for means of identification and to examine the ease of hydrolysis of the amides back to the amines.

It was found that *o*-nitrobenzenesulfenyl chloride was quite satisfactory as a reagent. The compound is easily prepared and does not react readily with water or alcohol, thereby affording the identification of amines in water solution.

The reactions between reagent and amines were carried out in ether solution and in all cases took place spontaneously. However, no reaction could

be obtained when *o*-nitrobenzenesulfenyl chloride was treated with *o*-nitroaniline or diphenylamine. All of the derivatives were insoluble in 10% alkali.

TABLE I

PROPERTIES OF AMINE DERIVATIVES

Amine	M. p.[a] of amide, °C.	M. p. of hydrochloride, °C.	Analyses of amide, % Calcd.	Found

n-Propylamine	Oil	157–158		
o-Toluidine	115.5–116	215	S, 12.31	12.20
m-Toluidine	106.5–107	228	N, 10.77	10.90
p-Toluidine	136–136.5	243	N, 10.77	10.86

[a] Melting points are corrected. [b] Melting points differ from those previously reported in the literature. [c] Softens at 125°.

These solid amides of *o*-nitrobenzenesulfenic acid, when dissolved in ether and treated with gaseous hydrogen chloride, for three minutes, regenerated the sulfenyl chloride and gave an approximately quantitative recovery of the amine in the form of its hydrochloride.

TABLE II

AMIDES HYDROLYZED

Amide of	% recovery of amine hydrochloride
Cyclohexylamine	98.5
m-Toluidine	95.0
Dimethylamine	97.4
Aniline	98.7

Further experiments are being carried out using other sulfenyl chlorides in an attempt to obtain derivatives of tertiary amines and higher melting amides of the aliphatic amines.

Experimental

The *o*-nitrobenzenesulfenyl chloride was prepared from *o,o'*-dinitrodiphenyl disulfide and chlorine by the method described in "Organic Syntheses."[3]

The amides described in this paper were all prepared by the addition of an ether solution of *o*-nitrobenzenesulfenyl chloride to an ether solution of the amine. When an aqueous solution of the amine, as dilute as 25%, was used, enough ether was added to produce a homogeneous solution before treatment. The amount of reagent required for the reaction was determined by slowly adding the sulfenyl chloride and observing whether or not further precipitation of the hydrochloride occurred. The hydrochloride formed was filtered and washed thoroughly with dry ether. The filtrates were collected and the ether evaporated off. The remaining material was easily solidified and recrystallized from 95% alcohol.

The hydrolysis of the amides was accomplished by dissolving the amide in a slight excess of dry ether and passing in dry hydrogen chloride. At the end of three minutes the gas was turned off and the solution filtered. The insoluble amine hydrochloride was then washed with dry ether and weighed. To recover the amine, sodium hydroxide was added to the hydrochloride.

Summary

1. *o*-Nitrobenzenesulfenyl chloride has been found to form a large number of solid derivatives of amines.

2. The reaction goes quickly and gives sharp melting compounds.

3. The amide derivatives are readily hydrolyzed to the amine hydrochloride in three minutes.

4. Anhydrous and aqueous amines were both used in the experiment without difficulty.

Sulfanilamide Derivatives. I

BY ROGER ADAMS, P. H. LONG AND A. J. JOHANSON[1]

The intensive study of sulfanilamide derivatives during the past few years has been with the objective of discovering compounds of higher activity, lower toxicity and more advantageous physical properties. The work described in this communication involved especially the preparation of a variety of *p*-acylamidobenzenesulfonalkanolamides and *p*-aminobenzenesulfonalkanolamides in order to determine, (1) the effect of the alkanolamine, (2) the effect of the acyl radical, and (3) the effect of changes in water solubility on the toxicity and antistreptococcal activity of the molecules. A few of these compounds have been described by other investigators[2] since the initiation of the research but they are included in order to show the general comparisons. The description of certain simple amides,[3] morpholides and double ring compounds is also included.

The compounds were prepared by condensation of the proper substituted *p*-aminobenzenesulfonyl chloride (Table I) and an alkanolamine, ammonia, morpholine, or *p*-aminobenzenesulfonalkanolamide, according to the equation

$$RNHC_6H_4SO_2Cl + NH_2CH_2CHOHR \longrightarrow RNHC_6H_4SO_2NHCH_2CHOHR$$

The individual compounds are listed in Tables II–X.

The following general statements can be made concerning these various compounds:

(a) The aminobenzenesulfonalkanolamides are more soluble in water than sulfanilamide. The antistreptococcal activity of these compounds is from slight to moderate but lower in every instance than that of sulfanilamide. The least activity is found in the 2,3-dihydroxypropylamine derivative. The therapeutic ratio is more favorable in many of the derivatives than in sulfanilamide.

(b) The acylamidobenzenesulfonalkanolamides were less soluble in water than the unacylated analogs. The antistreptococcal activity was usually lower though not so in all instances. The toxicity, however, was greatly reduced so that in many of these compounds the therapeutic ratio was more favorable than in sulfanilamide. As the acyl group increased in size, the water solubility decreased and the antistreptococcal activity was less. The toxicity, however, remained very low except in the isobutyryl derivative.

Several compounds in the series of acylamidobenzenesulfonmorpholides showed slight to moderate activity and materially reduced water solubility.

Carbethoxyaminobenzenesulfonalkanolamides were similar in solubility, effectiveness and toxicity to the lower acyl derivatives.

The *p*-acylamidobenzenesulfonamides were less effective than sulfanilamide with the valeryl derivative somewhat more effective than the propionyl.

The substituted benzenesulfonanilide derivatives were all ineffective.

A few compounds in which an alkyl or a benzyl group was substituted for one of the hydrogens in the amino group of an aminobenzenesulfonalkanolamide showed properties not very dissimilar to those of the analogous unsubstituted amino compound.

Several 4-methoxy-3-aminobenzenesulfonamides and the analogous alkanolamides showed essentially no antistreptococcal activity.

The various compounds were also tested for antimeningococcal activity. There appeared to be no correlation with antistreptococcal activity. On the other hand, a large number of the compounds possessed antimeningococcal activity equivalent to that of sulfanilamide. Since the toxicity of most of these compounds was much less than that of sulfanilamide, the therapeutic ratio in respect to antimeningococcal activity of the new compounds is much more favorable than in sulfanilamide.

These preliminary toxicity, antistreptococcal and antimeningococcal tests were carried out in Johns Hopkins University Medical School by Dr. P. H. Long. In the tables, ++++ is the equivalence in activity to sulfanilamide.

Experimental

Substituted (*p*)-Aminobenzenesulfonyl Chlorides.—*p*-Acetamidobenzenesulfonyl chloride was prepared by the method of Stewart.[4] A series of *p*-acylamidobenzenesulfonyl chlorides (Table I) was synthesized in essentially the same manner, by the reaction of chlorosulfonic acid with the appropriate anilide. In each case, 1 mole of the anilide was added to 5 moles of chlorosulfonic acid at 10–20° with stirring. The reactions were, with the exception of numbers 6 and 7, allowed to proceed, with stirring, from one to five hours at room temperature followed by a final period of from one to five hours at 50–60°. In the cases of numbers 6 and 7 the mixtures gradually were heated to 80° and the reactions continued at that temperature for three hours.

p-Carbethoxyaminobenzenesulfonyl chloride was prepared by adding 1 mole of phenylurethan to 5 moles of chlorosulfonic acid and stirring for five hours at room temperature followed by heating at 60° for one hour.

In no case was hydrogen chloride evolution as extensive as with *p*-acetamidobenzenesulfonyl chloride. Most of the sulfonyl chlorides tended to separate when poured into the ice–water mixture, as sticky gummy masses, light tan in color. After standing from fifteen minutes to one hour, these masses solidified and could be filtered. In most cases the solidification could be hastened by transferring the gum to a fresh ice–water mixture, and stirring and kneading.

4-Methoxy-3-acetamidobenzenesulfonyl chloride[5] was prepared in the same manner as the *p*-acetamidobenzenesulfonyl chloride except that the mixture was stirred at room temperature for twenty hours and then poured into the ice–water mixture.

The crude, moist sulfonyl chlorides were used directly in the condensation reactions. Small portions were purified for characterization by recrystallization from benzene and were obtained as small white crystals. In contrast to Stewart's acetyl compound, these sulfonyl chlorides were all found to be very soluble in hot benzene.

Although no exact determinations were made on a pure basis, the yields, excepting in the cases of numbers 6 and 7 in Table I, appeared to be about the same as with the acetyl compound. The yields of numbers 6 and 7 were not more than 15 to 20% of theoretical.

(5) German patent 573,193 (1931); *Friedlaender*, **19**, (I), 699 (1934).

Condensation of the Substituted *p*-Aminobenzenesulfonyl Chlorides with Amino Compounds.—The substituted *p*-aminobenzenesulfonyl chlorides were condensed with the various amino compounds using molar portions of each and one of the following as a condensing agent to take up hydrogen chloride: (1) an additional mole of the amine (plus a small excess to neutralize hydrochloric and sulfuric acids not removed from the crude sulfonyl chloride in the washing process); (2) potassium hydroxide in 10 to 20% aqueous solution, in sufficient quantity to maintain alkalinity throughout the reaction (about 1.5 moles); (3) an excess (3 or 4 moles) of pyridine; (4) in the case of the unsubstituted sulfonamides a large excess of concentrated aqueous ammonia.

For the preparation of *p*-acetamidobenzenesulfon-(β-hydroxyethyl)-amide and *p*-acetamidobenzenesulfon-di-(β-hydroxyethyl)-amide and all the morpholides, method 1 was found satisfactory. Method 3 was most satisfactory for the substituted benzenesulfonanilide derivatives. All the other compounds were prepared using method 2.

General Procedure.—The amino compound and the condensing agent were placed in an open beaker. To the mixture was added, with stirring, a quantity of the crude damp benzenesulfonyl chloride derivative estimated to contain the desired amount of pure substance. Heat usually was evolved, but the temperature of the mixture was held below 45° by means of an ice-bath. In some cases the sulfonyl chloride dissolved to form a clear yellow solution. In others, as the sulfonyl chloride dissolved, the product separated immediately in solid form or as a heavy dark oil. The mixture was heated about thirty minutes at 70–80°, cooled to room temperature and neutralized with concentrated hydrochloric acid to brilliant yellow as indicator. At this point, the product if not already in suspension in solid form or present as an oily layer in the bottom of the beaker, usually separated, either in crystalline form or as an oil which upon cooling and standing eventually solidified. Evaporation to small volume, cooling and standing caused separation in cases where precipitation did not occur directly when the mixture was neutralized.

The products were usually recrystallized from water or aqueous ethanol of various dilutions. In almost every case one or more treatments with norite was necessary to remove color.

Hydrolysis of Acetamidobenzenesulfonamides.—The compounds shown in Tables V and VI were prepared by acid hydrolysis of the corresponding acetamido compounds.

The acetamido compound (1 mole) was added to dilute

hydrochloric acid (4–6 *N*) containing at least 1.4 moles of the acid. The mixture was heated under reflux for two to five hours at 70–80°. If the material did not dissolve completely on heating, a small quantity of ethanol was added to bring about solution. After completion of the hydrolysis, the solution was cooled and neutralized to litmus with solid sodium carbonate. In nearly every case the amine separated as a heavy oil, which after stirring, cooling and standing became solid. Purification was effected by recrystallization from water or dilute ethanol. Treatment with norite to remove color was necessary in most cases.

[a] Usually small glistening white crystals. Yields varied from 60 to 84%. Slightly soluble in water. Recrystallized from water, excepting number 4 which was recrystallized from dilute ethanol.

Summary

A variety of *p*-acylamidobenzenesulfonamides, *p*-acylamidobenzenesulfonalkanolamides, *p*-aminobenzenesulfonalkanolamides, *p*-alkyl- and *p*-aralkylaminobenzenesulfonalkanolamides, *p*-carbethoxyaminobenzenesulfonamides, *p*-acylamidobenzenesulfonmorpholides, *p*-aminobenzenesulfonmorpholide, *p*-acyl- and *p*-aminobenzenesulfonanilides and derivatives of 4-methoxy-3-aminobenzenesulfonamide have been prepared.

All show less antistreptococcal activity than sulfanilamide but practically all are much less toxic.

The antimeningococcal activity of many is equivalent to that found in sulfanilamide.

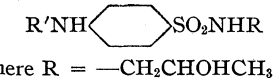
Sulfanilamide Derivatives. II

BY ROGER ADAMS, P. H. LONG AND ALLENE JEANES[1]

In the previous paper[2] it was demonstrated that the acyl groups in acylamidobenzenesulfonalkanolamides greatly reduced the toxicity of the molecule. The antistreptococcal activity was generally lower than that of sulfanilamide but the therapeutic ratio in many instances was more favorable. Consequently, a variety of other substituted acyl substituents has been introduced either directly or indirectly into the molecule. The compounds studied are shown below.



where R = $—CH_2CHOHCH_3$ and

R′ = $HOOC(CH_2)_2CO—$ I

$C_2H_5OOC(CH_2)_2CO—$ II

XI

All the compounds were prepared either (1) by introduction of the sulfonyl chloride grouping into

(1) The authors are indebted to The Chemical Foundation for grants which made possible the work described in this communication.

(2) Adams, Long and Johanson, THIS JOURNAL, 61, 2342 (1939).

the properly substituted anilide followed by treatment with ammonia or an amine, or (2) by introduction of the proper acyl group into sulfanilamide or into sulfonalkanolamide.

Only a few of the products showed any antistreptococcal activity. Compound II and the isopropanol derivative of the diketopiperazide showed very slight, and compound V, moderate activity.

Experimental

Succinanil.—This was prepared by a modification of the method of Tingle and Cram.[3]

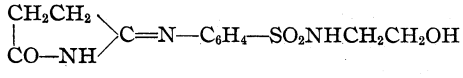
A mixture of 170 cc. of freshly distilled aniline and 225 g. of pulverized succinic acid was heated in an open flask in an oil-bath at 140–150° for four hours. The mixture was then distilled at atmospheric pressure which, due to the high temperature necessary, converted the succinic acid monoanilide into the anil. The distillate was crystallized from 95% ethanol: colorless needles, m. p. 156–158°; yield, 246 g. (75%). Menschutkin[4] reports the same melting point.

Mono-(*p*-aminosulfonylphenyl)-succinamide (VI).—Succinanil was treated with five moles of chlorosulfonic acid according to the method in "Organic Syntheses."[5] After heating to 60–65° for two hours, the product was poured slowly into well-stirred crushed ice and water. The crude sulfonyl chloride was washed and used directly.

To an excess of ice-cold 28% aqueous ammonia, 60 g. of the crude, moist sulfonyl chloride was added. The chloride dissolved and a mass of white crystals separated. The mixture was heated to 70° for a half hour and was then cooled. The product was purified by recrystallization from water, using norite; white needles, m. p. 234–238° with decomposition.

Anal. Calcd. for $C_{10}H_{13}N_3O_4S$: N, 15.50. Found: N, 15.55.

Succinamide Derivative (IV).—The crude acid chloride from chlorosulfonic acid and succinanil was treated with 2 molecules of ethanolamine dissolved in 7% aqueous potassium hydroxide (containing 2.5 moles of potassium hydroxide for each mole of acid chloride) and heated to 70° for a half hour. After neutralization and concentration to small volume, a thick oil was obtained. This was dissolved in butanol and two crystalline products separated. The first and main fraction was a granular product which formed slowly in the undisturbed solution; the second, a by-product, glistening plates which formed rapidly after removal of the first fraction. This by-product was probably the compound



as shown by analysis. After recrystallization from butanol, and washing with dry ether, the first product melted at 137–142°; the second at 85–93°.

Anal. (m. p. 137–142°). Calcd. for $C_{14}H_{21}N_3O_6S$: N, 11.70. Found: N, 11.35 (m. p. 85–93°) Calcd. for $C_{12}H_{15}N_3O_4S$: N, 14.14. Found: N, 14.20.

Succinamide Derivative (I).—The product from the acid chloride and isopropanolamine was obtained in the same manner as described for the ethanolamine. It remained as an oil, however, and was hydrolyzed directly by boiling for ten minutes with the calculated quantity of 10% aqueous potassium hydroxide and then acidifying with concentrated hydrochloric acid. Addition of a small amount of water gave a gummy precipitate which was dried and then crystallized from water, using norite: colorless needles, m. p. 179–192° with decomposition; yield, 30 g. from 60 g. of succinanil.

Anal. Calcd. for $C_{13}H_{18}N_2O_6S$: N, 8.48. Found: N, 8.71.

The ethyl ester (II), produced by the action of ethanol and a drop of sulfuric acid, was purified from very dilute ethanol; white crystals, m. p. 125–128°.

Anal. Calcd. for $C_{15}H_{22}N_2O_6S$: N, 7.82. Found: N, 7.94.

(*p*) - Methoxyacetamidobenzenesulfon - (β - hydroxyethyl)-amide (V).—The *p*-methoxyacetamidobenzene sulfonyl chloride was prepared in the usual way from methoxyacetanilide and chlorosulfonic acid. It was condensed with ethanolamine (2 moles) in 7% aqueous potassium hydroxide and the mixture heated to 60° during the course of five minutes. On cooling the product separated. The reaction mixture was neutralized, the substance filtered and purified from water; white crystals, m. p. 125–127°.

Anal. Calcd. for $C_{11}H_{16}N_2O_5S$: N, 9.72. Found: N, 9.80.

p **- (α - Acetoxypropionamido) - benzenesulfonamide (VII).**—A solution of 16 g. of α-acetoxypropionyl chloride (1 mole) in dry ether was added slowly to 35 g. of sulfanilamide (2 moles) in dry ether. After stirring overnight, the precipitate was filtered and treated with water, followed by dilute hydrochloric acid. The product was purified from water, using norite; white crystals, m. p. 192.5°.

Anal. Calcd. for $C_{11}H_{14}N_2O_5S$: N, 9.79. Found: N, 9.70.

The same product was also obtained from α-acetoxypropionanilide and chlorosulfonic acid, followed by treatment with aqueous ammonia.

p **- (α - Hydroxypropionamido) - benzenesulfonamide (VIII).**—A mixture of 0.75 g. (1 mole) of the acetoxy compound just described and 4 cc. of 1.5 *N* aqueous sodium hydroxide was heated at 50–55° for three and one-half hours. At the end of the reaction, the solution was made slightly acid, and the product filtered. It was purified by recrystallization from water; transparent prisms, m. p. 196°.

Anal. Calcd. for $C_9H_{12}N_2O_4S$: N, 11.47. Found: N, 11.50.

p **- (α - Acetoxypropionamido - N - (2 - hydroxy - 1-propyl)-benzenesulfonamide (III).**—Addition of 25 g. of α-acetoxypropionanilide to 73 g. of chlorosulfonic acid according to the usual procedure gave little evolution of gas until the mixture was heated to 30°, when the reaction became vigorous. The reaction mixture was held be-

[(*p*)-$HOCH_2CH_2NHSO_2C_6H_4NHCOCH_2]_2CH_2$	196–198	H_2O	10.60	10.70
[(*p*)-$CH_3CHOHCH_2NHSO_2C_6H_4NHCOCH_2]_2CH_2$	187–190	EtOH	10.07	10.04

tween 30–60° for three hours, cooled and added very slowly to a well-stirred mixture of ice and water. The sticky gum which formed was washed with ice water, then condensed immediately. The sulfonyl chloride was assumed to be 50% pure.

The sulfonyl chloride was added gradually in the cold to a cold solution of 2 moles of isopropanolamine in 30 cc. of 7% aqueous potassium hydroxide. The mixture was warmed to 60° during the course of ten minutes, filtered and neutralized with hydrochloric acid. Concentration of the solution at room temperature to a small volume resulted in the separation of an oil. By cooling and standing, this solidified and was purified from water using norite; white crystals, m. p. 97–103°.

Anal. Calcd. for $C_{14}H_{20}N_2O_6S$: N, 8.13. Found: 8.03.

Dibasic Acid Derivatives of the Type (*p*)-$RNHSO_2C_6H_4NHCO(CH_2)_xCONHC_6H_4SO_2NHR$(*p*).—These were all prepared by the same general method. The dianilides of malonic, succinic and glutaric acids were synthesized, the first by the action of aniline on diethyl malonate,[6] the latter two by the action of aniline on the dibasic acid chlorides in dry ether. The dianilides were converted to the corresponding disulfonyl chlorides by the method described in "Organic Syntheses."[5] These products were then condensed with ethanolamine and isopropanolamine dissolved in 7% aqueous potassium hydroxide and more alkali was added during the course of the reaction to maintain alkalinity. The reactions were completed by heating for a half hour at 70°. Neutralization caused precipitation of the products which were then recrystallized, using norite, from water or alcohol. The products separated as white crystals upon slow cooling.

Diketopiperazine Derivatives of the Type

(*p*)-$RNHSO_2C_6H_4$—N(CO—CH_2 / CH_2—CO)N—$C_6H_4SO_2NHR$-(*p*)

Compound in which R = —CH_2CH_2OH.—N,N'-Diphenyldiketopiperazine[7] was converted into the corresponding disulfonyl chloride and then condensed with ethanolamine in the usual way. The product was purified from water; white microcrystals, m. p. 260–270° with decomposition.

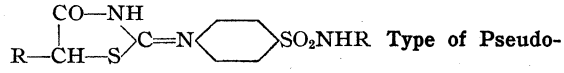
Anal. Calcd. for $C_{20}H_{24}N_4O_8S_2$: N, 10.93. Found: N, 11.00.

Compound in which R = —$CH_2CHOHCH_3$.—This substance was prepared like the above using isopropanolamine; white needles, m. p. 280–284° with decomposition.

Anal. Calcd. for $C_{22}H_{28}N_4O_8S_2$: N, 10.37. Found: N, 10.66.

Compound in which R = H.—Made in a similar manner with ammonia, the product was purified from water; white microcrystals, m. p. 325° with decomposition.

Anal. Calcd. for $C_{16}H_{16}N_4O_6S_2$: N, 13.20. Found: N, 13.20.



Type of Pseudothiohydantoin Derivatives.—The above structure for the following compounds was assigned on the basis of those suggested by Wheeler and Johnson[8] for the stable and labile forms of aryl-substituted pseudothiohydantoins.

Isopropanolamine Compound (IX).—*p*-Chloroacetamidobenzenesulfonyl chloride was prepared from *p*-chloroacetanilide and chlorosulfonic acid in the usual way and then condensed with isopropanolamine. An oil which separated from the reaction mixture was removed and the desired isopropanolamine derivative obtained by concentration of the solution. On purification from water, it formed colorless needles, m. p. 125–129°.

Anal. Calcd. for $C_{11}H_{15}N_2O_4SCl$: N, 9.13. Found: N, 9.10.

This product was treated with 1.5 moles of ammonium thiocyanate in sufficient absolute ethanol to dissolve it. The mixture was boiled gently for one and one-half hours and then the solvent removed by means of a current of air. The resulting product was crystallized from water, using norite; yellow needles, m. p. 209–212°.

Anal. Calcd. for $C_{12}H_{15}N_3O_4S_2$: N, 12.76. Found: N, 12.87.

Isopropanolamine Compound (X).—α-Bromopropionanilide was converted with chlorosulfonic acid to the sulfonyl chloride and then condensed with isopropanolamine. The product melted at 140–143° after purification from ethanol. It was then dissolved in absolute ethanol and refluxed gently for one and one-half hours with one and one-half moles of ammonium thiocyanate. Much longer heating caused no further change. Removal of the solvent at room temperature gave a mixture of an oil and a solid, which was converted into a solid by agitation with 2.5% sodium carbonate solution. Acidification of the basic filtrate from this treatment gave more of the same substance as a white solid.

The combined solids from the sodium carbonate treatment were dissolved in boiling water, a small amount of a highly insoluble yellow product was removed, and the solution allowed to cool. The desired compound sepa-

rated slowly, sometimes only after agitation and concentration of the solution. A second recrystallization from water gave white needles, m. p. 190–192°.

Anal. Calcd. for $C_{13}H_{17}N_3O_4S_2$: N, 12.24. Found: N, 12.22.

3 - (*p* - Aminosulfonylphenyl) - pseudothiohydantoin (XI).—A mixture of 7.5 g. of *p*-chloroacetamidobenzenesulfonamide[9] in 150 cc. of absolute ethanol and 3.5 g. of ammonium thiocyanate was refluxed for thirty minutes. Longer heating produced no further change. The precipitate that formed was filtered, washed with 5 g. of aqueous sodium carbonate and recrystallized from water with norite. From the slow cooling of the solution, a colorless non-crystalline precipitate was obtained which darkened from 238°, melted at 258°, with decomposition.

Anal. Calcd. for $C_9H_9N_3O_3S_2$: N, 15.49. Found: N, 15.26.

Summary

A number of sulfanilamide derivatives was prepared in which the amino group was substituted by various complex acyl groups and the amido group by ethanol and isopropanolamine. None showed activity comparable with sulfanilamide.

Alepric, Aleprylic, Aleprestic and Aleprolic Acids, New Homologs of Chaulmoogric Acid

BY HOWARD IRVING COLE AND HUMBERTO T. CARDOSO

In analyzing *Hydnocarpus wightiana* oil by the method described by us[1] the high optical rotation and iodine numbers of the lower boiling fractions of ethyl esters indicated that there must be present at least one more optically active fatty acid besides those already known (chaulmoogric, hydnocarpic and gorlic[2] acids). By repeated fractional vacuum distillation of 200 l. of *H. wightiana* ethyl esters and fractional crystallization of the free acids we have succeeded finally in isolating two new homologs of chaulmoogric acid. The presence of two other homologs has been proved and they have been obtained 70.5 and 42% pure, respectively. Lack of sample prevented further purification. Because of their relationship to the treatment of leprosy we have named these four new homologs, alepric, aleprylic, aleprestic and aleprolic acids.

Alepric acid is the next lower homolog to hydnocarpic acid, differing from it by C_2H_4, having the formula $C_{14}H_{24}O_2$. Our final sample still contained a small amount of another unsaturated acid as indicated by the iodine number and optical rotation. The acid is colorless when liquid, white when solid, almost odorless and melts at 48°. The melted acid upon solidifying forms characteristic beautiful branching crystals rising above the surface of the acid. They are very similar to those already reported by us as characteristic of hydnocarpic and chaulmoogric acids.[3] Our purest sample of alepric acid gave a specific optical rotation of +77.12°. The theoretical value from the molecular weight–optical rotation curve is +80°.

Aleprylic acid is the next lower homolog to alepric acid containing two carbon atoms and four hydrogen atoms less than the latter. It has the formula $C_{12}H_{20}O_2$. It was obtained absolutely pure. It crystallizes in the same characteristic manner as the other homologs. Aleprylic acid melts sharply at 32° and has a specific optical rotation of +90.78°. It is colorless when liquid, white when solid and has a slight aromatic odor when warmed.

Aleprestic acid is the next lower homolog to aleprylic acid differing from it by C_2H_4 and having the formula $C_{10}H_{16}O_2$. It was obtained only 70.5% pure (Table I, 51W, 2) based upon its specific optical rotation which would be +100.5° as determined from the curve for the other homologs of this series of acids.

Although the next homolog to aleprestic acid may be present, our experimental data neither prove nor disprove its presence (Table I, 49W, 3, 4 and 5). On the other hand the second homolog below aleprestic acid is definitely proven to be present by the boiling point of the ethyl ester and the optical rotation and iodine number (Table I, 49W, 1). Computed from its rotation value we have obtained it 42% pure. We have named this lowest homolog aleprolic acid. It differs from aleprestic acid by C_4H_8 and has the

formula $C_6H_8O_2$. From the curve of the other homologs its specific optical rotation would be +120.5° when pure.

In these low boiling fractions of *H. wightiana* ethyl esters there is also present an optically inactive unsaturated acid containing one double bond and probably a saturated acid. The sample at our disposal was not large enough to isolate and identify these acids (Table I, 49W, 2 and 50W, 2).

Experimental

The *H. wightiana* oil used was obtained from Ernakulam, India. The ethyl esters were made in the usual manner by esterifying with ethyl alcohol and sulfuric acid and washing to remove glycerol and acid. Two hundred liters of the ethyl esters was fractionally distilled in a 2-l. still at 10 mm. The first 10% (20 l.) fractions were redistilled in the same manner. The 2 liters of low boiling esters thus obtained was refractionated carefully several times in a Podbielniak Model B high temperature fractionating apparatus at 10 mm. The apparatus and technique used were described in a previous paper.[1] Plateaus in the distillation curves were finally obtained at 122, 148 and 174° (Table I). These fractions upon being changed to acids and recrystallized several times from acetone proved to be three new homologs of chaulmoogric acid (Table I, 51W, 2; 31W, 2; 53W, 2). The fourth and lowest homolog is clearly shown to be present in fraction 49W, 1 by the very sharp drop in rotation in the next higher fraction, 49W, 2.

Alepric Acid.—Alepric acid was much more difficult to isolate than aleprylic acid as it was impossible to free it entirely from the other unsaturated acid and from palmitic acid without very great loss. We finally obtained it 96.4% pure as calculated from actual and theoretical rotations (77.1 and 80.0). The constants for alepric acid and for ethyl aleprate are given in Tables II and III.

Ethyl aleprolate	140.1	70[a]	101.8[a]	181.5	1.4514[a]	...
Ethyl gorlate	306.3	232	55.6	167.0	1.4667	.912

[a] Calculated.

Anal. Calcd. for $C_{14}H_{24}O_2$: C, 74.93; H, 10.78; iodine no., 113.4; mol. wt., 224.2. Found: C, 74.86; H, 10.86; iodine no. (Hanus), 116.7; mol. wt., 224.5.

Aleprylic Acid.—Aleprylic acid was purified fairly easily by several fractional distillations of the ethyl ester and fractional crystallizations of the acid. The latter must be done in an electric refrigerator as the acid melts at 32°. The constants for aleprylic acid and ethyl aleprylate are given in Tables II and III. They indicate that the acid and ester were 100% pure.

Anal. Calcd. for $C_{12}H_{20}O_2$: C, 73.41; H, 10.27; iodine no., 129.7; mol. wt., 196.15. Found: C, 73.54; H, 10.24; iodine no. (Hanus), 129.6; mol. wt., 196.2.

CALCULATIONS FOR SPECIFIC OPTICAL ROTATION

Compound	Grams	$CHCl_3$, cc.	Ang. rotn. 100-mm. tube	$[\alpha]^{25}D$
Alepric acid	2.2703	25	7.00	77.12
Ethyl aleprate	2.5562	25	6.80	66.54
Aleprylic acid	2.6712	50	4.85	90.78
Ethyl aleprylate	4.0433	50	6.40	79.14

Aleprestic Acid.—Since this acid was obtained only 70.5% pure we can determine its constants only from the curves made with the other pure homologs. These probable constants are shown in Tables II and III.

Aleprolic Acid.—Fraction 49W, 1, Table I, clearly indicates the presence of this very low homolog of chaulmoogric acid. The boiling point of ethyl aleprolate should be 70° at 10 mm.; being impure it boiled slightly lower.

The homolog between ethyl aleprestate and ethyl aleprolate should boil at 96° at 10 mm. It is probably present but our final fractions were too small to attempt further fractionation to prove its presence.

An optically inactive unsaturated acid with one double bond must be present in fraction 50W, 2 to account for the iodine number found. There may also be present a saturated acid of low molecular weight.

For purposes of comparison the constants of the other known optically active acids and their ethyl esters are included in Tables II and III.

Summary

Four optically active fatty acids hitherto unknown have been discovered in *Hydnocarpus wightiana* oil. They have been named alepric, aleprylic, aleprestic and aleprolic acids.

The characteristics of these new acids and their ethyl esters are given and their relationship to their previously known homologs, hydnocarpic and chaulmoogric acids, is shown.

RIO DE JANEIRO, BRAZIL RECEIVED APRIL 20, 1939

[CONTRIBUTION FROM THE INTERNATIONAL LEPROSY CENTER, RIO DE JANEIRO]

Analysis of Chaulmoogra Oils. III. *Hydnocarpus Wightiana* Oil

BY HOWARD IRVING COLE AND HUMBERTO T. CARDOSO

Of the various chaulmoogra oils used in the treatment of leprosy, that expressed from the seeds of *Hydnocarpus wightiana* is by far the most generally employed. This is largely due to the fact that an oil of excellent quality is easily obtainable in large quantities at a reasonable price. *H. wightiana* occurs abundantly in southwestern India. The tree grows to a height of 7 to 10 meters. The fruit measures 6 to 12 cm. in diameter. The seed is about 2 cm. long with longitudinal grooves and a knot on the end. The species is one of the most abundant and easily accessible of the *Hydnocarpaceae*. Although *H. wightiana* oil has been so widely used for the past fifteen years in the treatment of leprosy, no accurate qualitative or quantitative analysis has ever been made due to the difficulty in separating the constituents. In 1905 Power and Barrowcliff[1] reported that the total fatty acids of this oil consisted chiefly of hydnocarpic and chaulmoogric acids and that they found evidences of a still lower homolog of the same series having the formula $C_{14}H_{24}O_2$ in the mother liquor but were unable to isolate it. Since the iodine number of the final mother liquor was so large (140.7) they concluded that it indicated the presence of an acid or acids belonging to the linolic or linolenic series. Our analysis shows that acids of neither of these series are present but that the high iodine number (and high rotation, 50.4) that they obtained are due to gorlic acid.[2] No evidence of the presence of palmitic acid was found by them and they make no mention of oleic acid. Since their analysis was made practically nothing has been added to our knowledge of the composition of this important medicinal oil. A single reference has been made to the possible presence of gorlic acid.[3] We have succeeded in analyzing *H. wightiana* oil by the method for chaulmoogra oils given in the first article of this series.[4] Our analysis is shown in Table I. It shows six fatty acids not previously reported in this oil, four of which are new homologs of chaulmoogric acid.

Experimental

The sample of oil was taken from a 300-liter drum of *H. wightiana* oil, cold-pressed from fresh, selected seeds imported for the routine production of leprosy drugs for Brazil from the Ernakulam Trading Co., Ernakulam, South India. The characteristics of the oil were as follows: sp. gr. $^{25}/_{25}$, 0.9549; F. F. A. (as % oleic), 2.7; sapon. no., 201; iodine no. (Hanus), 98.4; sp. rotn.,

(4) Cole and Cardoso, THIS JOURNAL, **60**, 614 (1938).

+55.0°; ref. index (at 25°), 1.4799; unsaponifiable matter, 0.25%.

Method of Analysis.—Since the medicinal properties of chaulmoogra oils depend on the percentage of optically active acids, the analysis is reported in percentage of the various fatty acids present. The sample of oil was saponified and the fatty acids liberated and washed in the usual manner. The solid acids were separated from the liquid acids by crystallization from 80% ethyl alcohol. The two fractions were changed to ethyl esters and then fractionally distilled in a Podbielniak Model B high temperature fractionating apparatus. The details of the separation and distillation were given in the first article of this series, the only change being that the two final crystallizations for the separation of the liquid acids were made with 80% acetone to prevent the formation of ethyl esters.

Qualitative Analysis

The fatty acids of *H. wightiana* oil contain hydnocarpic, chaulmoogric, gorlic, oleic, palmitic, alepric, aleprylic and aleprestic acids besides a very small amount of a low-boiling, optically inactive, unsaturated acid with one double bond and another homolog of chaulmoogric acid containing only six carbon atoms which we have named aleprolic acid. The acids were identified as follows.

Hydnocarpic Acid.—This acid was isolated easily from fraction 2, Table III, by repeated crystallization from 80% ethyl alcohol. It gave the correct optical rotation, iodine number, neutralization equivalent and melting point for pure hydnocarpic acid as well as the characteristic crystalline growth previously described.[5]

Chaulmoogric Acid.—Pure chaulmoogric acid was obtained readily from fraction 4, Table III, by crystallization to constant melting point from 80% ethyl alcohol. It gave the correct optical rotation, iodine number, neutralization equivalent and melting point for pure chaulmoogric acid.[5]

Gorlic Acid.—Ethyl gorlate was isolated by several fractional distillations of fraction 4, Table II. It gave the correct optical rotation, iodine number and boiling point for ethyl gorlate. Changed to acid it also gave the correct constants for gorlic acid.[2]

Oleic Acid.—Oleic acid was not obtained pure but its presence was indicated in the liquid fraction by the distillation curve of the ethyl esters and by the correct iodine numbers for mixtures containing ethyl oleate in fractions 2, 3 and 4, Table II. The elaidic acid test could not be used as gorlic acid gives a similar reaction. Hydrogenation tests were equally unsatisfactory in the presence of hydnocarpic and chaulmoogric acids.

Palmitic Acid.—It is practically impossible to separate ethyl palmitate from hydnocarpate by distillation but the separation can be accomplished easily by cooling a fraction of esters high in palmitate in the icebox. By separating the solid ethyl palmitate and crystallizing it twice from alcohol it was obtained pure (m. p. 24°). Upon changing it to palmitic acid and crystallizing two or three times the correct melting point and neutralization equivalent for palmitic acid was obtained.

Alepric Acid.—This acid is the next lower homolog to hydnocarpic acid, differing from the latter by C_2H_4 and having the formula $C_{14}H_{24}O_2$. It occurs in very small amount (less than 0.5%) in *H. wightiana* oil. No attempt was made to isolate it in the sample here analyzed but it was isolated from a much larger sample (200 liters) and its properties were determined. The method of separation of this homolog and the determination of its properties as well as those of the following homologs of chaulmoogric acid form the subject of another paper.[6]

Aleprylic Acid.—This acid is a homolog of chaulmoogric acid next lower in the series to alepric acid having the formula $C_{12}H_{20}O_2$. In the same sample about ten times as much of this acid can be isolated as of alepric or aleprestic acid. *H. wightiana* oil contains about 3% of aleprylic acid. It was isolated from the large sample mentioned above and its properties were determined.[6]

Aleprestic Acid.—This is the next lower homolog to aleprylic acid having the formula $C_{10}H_{16}O_2$. It occurs in very small amounts in *H. wightiana* oil (less than 0.5% and was not isolated from this sample but was obtained 70.5% pure from the large sample mentioned above.

Aleprolic Acid.—This is the lowest homolog of chaulmoogric acid yet discovered, being the second lower homolog after aleprestic acid having the formula $C_6H_8O_2$. Even from the large sample mentioned above we obtained only a very small amount of this acid, but the boiling point of its ethyl ester (65° at 10 mm.) and its specific rotation indicated its presence and from the latter we were able to determine its purity (42%). From our distillation curves we were unable to say whether or not the homolog between aleprestic and aleprolic acids was present.

In the sample at our disposal we were unable to isolate the optically inactive unsaturated acid with one double bond indicated as present by the iodine number.

Quantitative Analysis

The total fatty acids of *H. wightiana* oil when separated into liquid and solid acids by the method described by us consisted of 84.3% solid acids and 15.7% liquid acids. Although the separation is by no means complete, the breaks in the distillation curves of the ethyl esters made from these two fractions are much more distinct than when the whole esters are used. Complete separation is not necessary as the amounts of the various constituents can be computed by taking advantage

of the boiling points, optical activity and iodine numbers or absence of one or both of the two latter constants as described in part one of this series. The results of these computations are given in Tables II and III and these are summarized in Table I. Fraction 1 of Table II and of Table III were too small to be further divided but we know from distillation of much larger samples that there is about ten times as much aleprylic acid in this first fraction as there is of the homolog above and below it or of the optically inactive, unsaturated acid. We have therefore figured these two fractions on the basis of the specific optical rotation of ethyl aleprylate (79.14) which gives us 0.9% for the amount of saturated ester present in fraction 1, Table II, and 1.4% in fraction 1, Table III. This is admittedly only an approximation.

Summary

The qualitative and quantitative analyses of the total fatty acids of *H. wightiana* oil have been made by the method described in the first article of this series.

This is the first quantitative analysis that has been made of this oil. Six constituents not previously reported have been found, four of which are new homologs of chaulmoogric acid.

This analysis shows *H. wightiana* oil to be quite similar in composition to *Carpotroche braziliensis oil.*

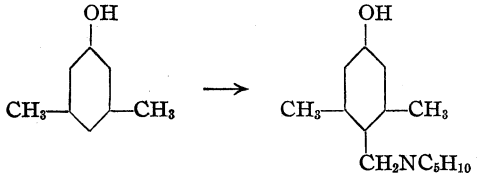
A Study of Orientation of Nuclear Methylation in Phenols and Naphthols

BY WILLIAM T. CALDWELL AND THOMAS R. THOMPSON

We described recently[1] a simple method for the introduction of one or more methyl groups into the nucleus of phenols, a method requiring merely treatment of the phenol with dimethylamine and formaldehyde and subsequent fission of the substituted benzylamine by catalytic high pressure hydrogenation.

In all reactions carried out at that time, we obtained only ortho substitution as proved by the structure of the methylated phenol formed. Indeed, the ease with which we were always able to purify these phenols indicated that they were substantially free of isomers or homologs which might have formed had any intramolecular rearrangements occurred during the hydrogenation, an unlikely possibility at best.

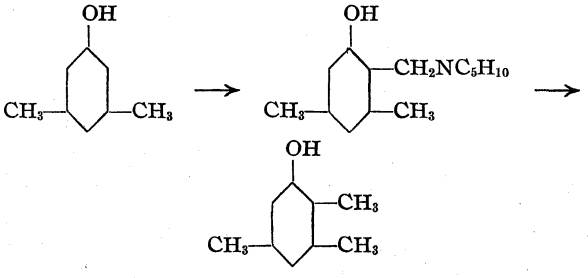
In 1906, Auwers and Dombrowski[2] prepared a number of analogously constituted benzylpiperidines by the action of piperidine and formaldehyde upon various phenols. They assumed that the piperidinomethyl groups entered the nucleus preferentially in the para position to the hydroxyl and that ortho substitution took place only when the para position was blocked. Thus, they formulated the reaction with 3,5-dimethylphenol to give a substituted piperidinomethyl derivative as follows



We already had prepared, in the course of our work, substituted benzylamines by using secondary amines other than dimethylamine; for example, 3,5-dimethylphenol formed a beautifully crystalline product with morpholine and formaldehyde which gave the same trimethylphenol on hydrogenolysis as did the dimethylaminomethyl derivative, namely, 2,3,5-trimethylphenol.

Although it appeared improbable that the use of piperidine instead of morpholine would bring about a different orientation in the product, this was not impossible; furthermore, if such were the case, we would have a desirable method of influencing the direction of nuclear methylation of phenols in which para and ortho positions are open.

We, therefore, prepared piperidinomethyl-3,5-dimethylphenol according to the directions given by Auwers and Dombrowski[2] and subjected it to hydrogenolysis. Again we obtained 2,3,5-trimethylphenol in accord with the steps indicated



Since this proved that the assumption of Auwers and Dombrowski had been erroneous in this particular case, we subjected additional piperidinomethyl phenols, for which they had assumed para substitution, to hydrogenolysis in order to ascertain whether or not this assumption was generally incorrect. In this way, we were able to prove that, although their assumption of para substitution was also wrong in the piperidinomethyl derivatives of *m*-cresol and of naphthol-1, it was correct in 4-piperidinomethyl-3-methyl-6-isopropylphenol and in 4-piperidinomethyl-2,5-dimethyl phenol. In addition, we subjected to hydrogenolysis some of the morpholinomethyl phenols described by Bruson[3] in order to determine their orientations. All of these methylations are summarized as follows

3-Methylphenol ⟶ 3,6-dimethylphenol
4-Methylphenol ⟶ 2,4-dimethylphenol
3,5-Dimethylphenol ⟶ 2,3,5-trimethylphenol
2,3,5-Trimethylphenol ⟶ 2,3,5,6-tetramethylphenol
2,5-Dimethylphenol ⟶ 2,4,5-trimethylphenol
3-Methyl-6-isopropylphenol ⟶ 3,4-dimethyl-6-isopropylphenol
Hydroquinone ⟶ 2,5-dimethylhydroquinone
Catechol ⟶ 2,4-dimethylcatechol
Naphthol-1 ⟶ 2-methylnaphthol-1
Naphthol-2 ⟶ 1-methylnaphthol-2

(1) Caldwell and Thompson, THIS JOURNAL, **61**, 765 (1939).
(2) Auwers and Dombrowski, *Ann.*, **344**, 285 (1906).
(3) H. Bruson, U. S. Patent 2,040,039 and 2,040,040 (May, 1936).

We have thus shown that, although para substitution does not occur preferentially, our surmise that ortho substitution would prove general is equally without foundation.

The formation of 3,4-dimethyl-6-isopropylphenol from 3-methyl-6-isopropylphenol is interesting when viewed in the light of what happens when this reaction is applied in two successive stages to 3,5-dimethylphenol. Attempts to introduce two dimethylaminomethyl or two morpholinomethyl groups into 3,5-dimethylphenol have not been successful in our hands; however, once we obtained 2,3,5-trimethylphenol we had no difficulty in converting it to 2,3,5,6-tetramethylphenol. Yet, to our surprise, we found that the piperidinomethyl group enters the para position in thymol. From this observation it appears that, although the ortho position is open, some factor other than a steric one causes preferential reaction in the para position. In view of the fact that 3,5-dimethylphenol had undergone successive methylations in the ortho positions, it seemed interesting to us to treat similarly 2,5-dimethylphenol, which differs from thymol only in having a methyl instead of an isopropyl group ortho to the hydroxyl. Here, too, substitution occurred in the para position although the ortho was as open as in 3,5-dimethylphenol or 2,3,5-trimethylphenol, and steric factors were alike.

Methylcarvacrol was prepared from carvacrol but has not been described in the literature. Its empirical formula has been proved by analysis and it is assumed that since carvacrol has a structure analogous to that of thymol and of 2,5-dimethylphenol, the methyl group enters para to the hydroxyl. The evidence at our disposal at this point, then, indicates that while the directional influences at play produce a single isomer, no simple prediction of orientation appears feasible, for comparatively slight changes in the constitution of the original phenol are, at times, sufficient to change the direction of the reaction.

An attempt was made to introduce an additional aminomethyl group into 2,5-dimethylhydroquinone and 3,4-dimethyl-6-isopropylphenol, in each of which an ortho position was still open, and into methylcarvacrol in which an ortho position was presumably open—at least an ortho or para position was certainly free. In none of these cases was any evidence of reaction obtained, and the original phenols were recovered and identified.

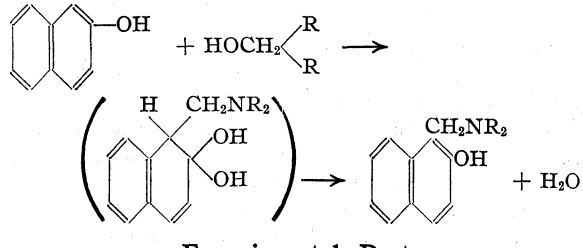
Again, 2,3,5,6-tetramethylphenol, in which only a para position is open, was submitted to the same treatment, but was recovered after giving no evidence of reaction.

The results obtained with catechol are particularly interesting in that one group entered the nucleus ortho to one hydroxyl while the other went into the para position with respect to the second hydroxyl. We have not been able to isolate, as yet, a product from catechol containing only one substituted aminomethyl group; hence, we cannot say whether the first substituent enters the ortho or para position, nor whether it does so exclusively in one way or to form a mixture of isomers. In any event, when disubstitution occurs, although both para positions as well as both ortho positions are free, the product formed indicates that one of each of these positions is involved.

In the naphthalene series we found that substitution took place with naphthol-2 in the position indicated by Auwers and Dombrowski, but not with naphthol-1. With the former, 1-methylnaphthol-2 was obtained in which an unhindered ortho position is still open. Therefore an attempt was made to introduce another piperidinomethyl group into this position, C_3. No evidence of reaction was obtained and the original material was recovered. Since steric factors do not seem to be involved, we believe that this observation properly may be regarded as additional evidence for the point of view[4] that the two ortho positions in naphthol-2 are not equivalent.

The reaction between a phenol, formaldehyde and a secondary amine apparently involves first the formation of a substituted aminomethanol which then reacts with the phenol, for we have not been able to obtain a substituted benzylamine by treating 2,6-dimethylol-4-methylphenol with morpholine.

Corresponding then to one formulation of the coupling of a diazo compound with naphthol-2, we may write



Experimental Part

The following piperidinomethyl phenols were made ac-

Piperidinomethylcarvacrol, (see text)	184–185	183

3,5-Dimorpholinomethyl Catechol.—One-quarter mole (27.5 g.) of practical catechol was mixed with 42 g. (0.5 mole) of morpholine and enough 95% alcohol added to keep the ingredients in solution; 45 ml. (0.5 mole) of formalin was added slowly and the mixture set aside. Crystals formed overnight and, after five days, were filtered off, giving a nearly quantitative yield; large, colorless prisms crystallized from 95% alcohol, m. p. 173–174°.

Anal. Calcd. for $C_{16}H_{24}O_4N_2$: N, 9.1. Found: N, 9.1.

2-Morpholinomethyl-3,5-dimethylphenol.—To one mole of technical 3,5-dimethylphenol were added one mole of morpholine and, then, while keeping the temperature between 25–35°, one mole of formaldehyde (as formalin) with vigorous stirring. On cooling in an ice-bath with continued agitation the product solidified in small aggregates which were filtered off and washed with water, giving an almost quantitative yield. Recrystallized from methyl alcohol, it melts at 96.5–97.0°.

Anal. Calcd. for $C_{13}H_{19}O_2N$: N, 6.3. Found: N, 6.3.

6-Morpholinomethyl-2,3,5-trimethylphenol.—Two and three-tenths grams of 2,3,5-trimethylphenol was treated with 5 g. of morpholine and 5 ml. of formalin and heated on the steam-bath for three hours. After adding some water, an oil formed which solidified on standing. Colorless needles crystallized from benzene: yield 70%; m. p. 78°.

Anal. Calcd. for $C_{19}H_{24}O_2N$: N, 5.88. Found: N, 5.81.

All hydrogenations were carried out in the following manner. The aminomethylphenol and copper chromite catalyst were placed in the copper liner of the high pressure hydrogenation apparatus and the dioxane solvent added. Under a pressure of 1500 lb. (102 atm.) and, with the rocker in motion, the electric heating element was adjusted so that in the course of one and one-half hours the temperature was 165°, at which it was kept constant for an additional hour and a half. Upon opening the bomb the odor of regenerated amine was quite noticeable. After filtering off the catalyst and removing the solvent, the mixture was acidified with hydrochloric acid and the phenol distilled with steam.

2,4-Dimethylphenol.—Eight and five-tenths grams of 2-piperidinomethyl-4-methylphenol, 1 g. of catalyst and 100 ml. of dioxane were hydrogenated. A colorless oil separated from the steam distillate and was extracted with ether, dried, and distilled: yield 1 g.; b. p. 205–206°. Jacobsen[6] gives b. p. 211.5° (corr.). The phenoxyacetic acid was made by condensing with monochloroacetic acid in 33% sodium hydroxide solution; m. p. 141°. Gluud and Breuer[7] give m. p. 141.6° for 2,4-dimethylphenoxyacetic acid.

2,5-Dimethylphenol.—Thirty-five grams of 2-piperidinomethyl-5-methylphenol, 5 g. of catalyst, and 200 ml. of dioxane were hydrogenated. Four grams of product solidified from the steam distillate and was crystallized from petroleum ether; m. p. 75°. Jacobsen[6] gives m. p. 74.5° for 2,5-dimethylphenol. A mixed melting point with an authentic sample showed no depression.

2,3,5-Trimethylphenol.—Eleven and five-tenths grams of 2-piperidinomethyl-3,5-dimethylphenol, 2 g. of catalyst, and 150 ml. of dioxane were hydrogenated. The white needles that crystallized from the steam distillate and also collected in the condenser were crystallized from petroleum ether; m. p. 93°; when mixed with an authentic sample of 2,3,5-trimethylphenol no depression of melting point occurred.

3,4-Dimethyl-6-isopropylphenol.—Eleven and five-tenths grams of 4-piperidinomethyl-3-methyl-6-isopropylphenol, 1.5 g. of catalyst, and 100 ml. of dioxane were hydrogenated. Six grams of product solidified from the steam distillate and, after crystallization from petroleum ether, the colorless needles melted at 70–71°; yield, 78%. Clemmensen[8] gives m. p. 70–71° for 3,4-dimethyl-6-isopropylphenol.

Methylcarvacrol.—Twenty grams of piperidinomethylcarvacrol, 2 g. of catalyst, and 200 ml. of dioxane were hydrogenated. An oil separated from the steam distillate and was extracted with ether. Distillation of the dried ether solution gave a colorless liquid which turned light brown on standing, b. p. 244–246°. The product became very viscous on cooling to −15°: yield 4 g., or 30%.

Anal. Calcd. for $C_{11}H_{16}O$: C, 80.5; H, 9.75. Found: C, 80.3; H, 9.70.

The phenoxyacetic acid derivative was made by condensing with monochloroacetic acid in the presence of 33% sodium hydroxide solution; colorless needles from benzene, m. p. 173°.

2-Methyl-1-hydroxynaphthalene.—Sixteen and one-tenth grams of 2-piperidinomethylnaphthol-1, 1.6 g. of catalyst, and 200 ml. of dioxane were hydrogenated. Two grams of product was volatile with steam; after crystallization from petroleum ether, fluffy needles were obtained, m. p. 61.5–62°; yield, 19%. Lesser[9] gives m. p. 62°.

1-Methyl-2-hydroxynaphthalene.—Fifteen grams of 1-piperidinomethyl-naphthol-2, 2 g. of catalyst, and 200 ml. of dioxane were hydrogenated. Two and eight-tenths

grams of substance was volatile with steam and after crystallization from petroleum ether melted at 107–108°. A sublimed portion melted at 109°. Betti and Mundici[10] give m. p. 110° for sublimed 1-methyl-2-hydroxynaphthalene. The acetate was found to melt at 65°; Betti and Mundici give m. p. 66°.

3,5-Dimethylcatechol.—Twenty-five grams of 3,5-dimorpholinomethylcatechol, 3 g. of catalyst, and 200 ml. of dioxane were hydrogenated. The product was not volatile with steam; it was therefore extracted three times with ether. The dried, ethereal solution gave, on distillation, 3 g. of colorless oil, b. p. 235–240°, which solidified on cooling to room temperature. Crystallization from petroleum ether–benzene mixture gave yellow needles, m. p. 73.5–74.0°; yield, 36%. Hodgkinson[11] gives m. p. 73–74°.

Anal. Calcd. for $C_8H_{10}O_2$: C, 69.6; H, 7.25. Found: C, 69.5; H, 7.25.

2,3,5,6-Tetramethylphenol.—Two and three-tenths grams of 2-morpholinomethyl-3,5,6-trimethylphenol, 0.5 g. of catalyst, and 50 ml. of dioxane were hydrogenated. Nine-tenths gram was volatile with steam and after crystallization from petroleum ether–benzene mixture melted at 117.5–118°. A sublimed portion melted at 118°. Jacobsen and Schnapauff[12] give m. p. 117°. Bromination in acetic acid gave the bromide, m. p. 117.5–118.5°. Jacobsen and Schnapauff give m. p. 118° for bromodurenol.

2,3,5-Trimethylphenol.—Twenty-five grams of 2-morpholinomethyl-3,5-dimethylphenol, 3 g. of catalyst, and 150 ml. of dioxane were hydrogenated. Four and five-tenths grams of product was volatile with steam and after crystallization from petroleum ether melted at 94°; yield, 29%.[1] The residual liquor from the steam distillation was filtered from a small amount of resinous material, and neutralized with sodium carbonate, giving a light brown precipitate weighing 15 g. After recrystallization from methyl alcohol, the melting point was 96–97° (2-morpholinomethyl-3,5-dimethylphenol). The yield, based on the amount of 2-morpholinomethyl-3,5-dimethylphenol converted, was 73%.

2,4,5-Trimethylphenol.—Six grams of 4-piperidinomethyl-2,5-dimethylphenol, 1 g. of catalyst, and 100 ml. of dioxane were hydrogenated. The product separated from the steam distillate and also in the condenser. Crystallization from petroleum ether gave needles, m. p. 70°. Auwers and Marwedel[13] give m. p. 70°. The yield, 0.8 g., was 21%.

Attempted Preparation of Certain Aminomethyl Derivatives.—As previously stated, we were unable to obtain aminomethyl derivatives of several phenols. As an example, we may record here our experience with 2-isopropyl-4,5-dimethylphenol: 1.6 g. (m. p. 70–71°) was mixed with equivalent amounts of piperidine and formalin in 75% alcohol. After standing for several days, no separation of oil or crystals occurred; the mixture then was acidified and, upon steam distillation, 1.2 g. of crystals, m. p. 70–71°, was recovered.

Summary

Although the formation of a substituted benzylamine from a phenol by the action of a secondary amine and formaldehyde occurs in such fashion that the ortho position generally is preferentially affected, contrary to the assumptions of Auwers and Dombrowski, nevertheless some factor or factors not always of a steric nature bring about para substitution in certain cases.

The failure of this reaction to take place with 1-methylnaphthol-2 is adduced as additional evidence bearing upon the nature of the two ortho positions and the disposition of the double bonds in naphthol-2.

A formulation of the reaction between a phenol, secondary amine and formaldehyde is suggested.

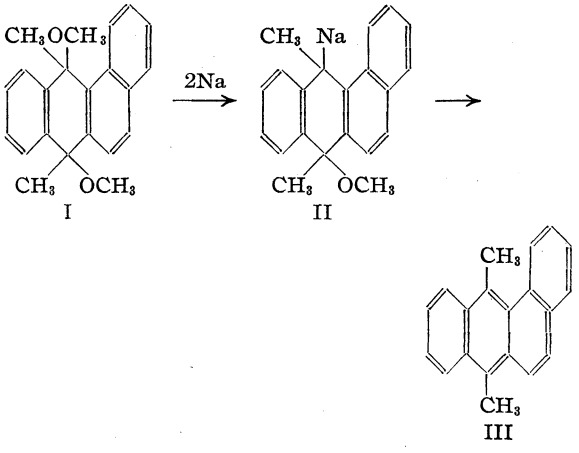
The Synthesis of 9,10-Dialkyl-1,2-benzanthracenes

BY W. E. BACHMANN AND J. M. CHEMERDA[1]

Recently[2] we described the synthesis of 9,10-dimethyl-1,2-benzanthracene and two other hydrocarbons containing alkyl groups in the 9,10-positions of the 1,2-benzanthracene molecule.[3] The mechanism by which 9,10-dimethyl-9,10-dimethoxy-9,10-dihydro-1,2-benzanthracene (I) is converted to 9,10-dimethyl-1,2-benzanthracene (III) by reaction with sodium has now been investigated.

In considering a mechanism the following facts must be kept in mind: (1) the reaction occurs between one mole of the dimethyl ether of the diol and two equivalents of sodium; (2) the 9,10-dimethyl-1,2-benzanthracene is present in the reaction mixture as the hydrocarbon and not in the form of a derivative; (3) the reaction mixture remains practically colorless throughout the reaction, an indication that no disodio derivative of the hydrocarbon is present. All of these facts receive a satisfactory explanation if we assume that the diol dimethyl ether reacts with sodium to give the intermediate II, which yields 9,10-dimethyl-1,2-benzanthracene by transannular elimination of sodium methylate.



We consider this reaction more probable than the simultaneous elimination of both methoxy groups by reaction with sodium.

Apparently the hydrocarbon begins to be formed as soon as the reaction is initiated. Since the solution remains practically colorless, our mechanism implies that none of the hydrocarbon which is formed reacts with the sodium as long as any diol dimethyl ether is present. Although this did not seem reasonable in view of the rapidity with which the 9,10-dimethyl-1,2-benzanthracene reacts with sodium in the absence of the diol dimethyl ether, an experiment designed to test this point showed that this is indeed the case. When equimolar amounts of 9,10-dimethyl-1,2-benzanthracene and 9,10-dimethyl-9,10-dimethoxy-9,10-dihydro-1,2-benzanthracene were allowed to compete for two equivalents of sodium, no disodio addition product was formed and the diol dimethyl ether was converted completely to the hydrocarbon. One other mechanism, involving the intermediate formation of 9,10-dimethyl-9,10-disodio-9,10-dihydro-1,2-benzanthracene and its subsequent reaction with the diol dimethyl ether, was excluded from consideration when it was found that the two compounds did not react to produce any appreciable quantity of 9,10-dimethyl-1,2-benzanthracene.

We also examined the utilization of other ethers for the sodium reaction. Of the four alcohols, ethyl, *n*-propyl, isopropyl, and *n*-butyl alcohol, only the ethyl alcohol yielded an ether under the conditions employed for the preparation of the dimethyl ether. From the diethyl ether and sodium, 9,10-dimethyl-1,2-benzanthracene was obtained although in lower yield. The diol dimethyl ethers are undoubtedly the best intermediates as they form easily and crystallize readily. In the case of the product from the interaction of 1,2-benzanthraquinone and *n*-propylmagnesium bromide the diol has not been obtained crystalline[4]; the diol dimethyl ether, however, crystallizes readily and yields 9,10-di-*n*-propyl-1,2-benzanthracene by reaction with sodium.

We have employed our method of synthesis to prepare 5-ethyl-9,10-dimethyl-1,2-benzanthracene (IV) and 5-*n*-propyl-9,10-dimethyl-1,2-benzanthracene (V). For the preparation of the intermediate 5-ethyl-1,2-benzanthracene we employed the reaction between 5-keto-tetrahydro-

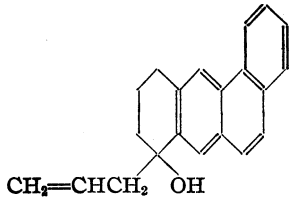
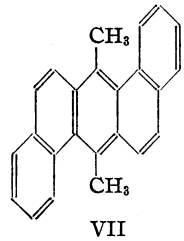
V

1,2-benzanthracene and ethylmagnesium bromide, followed by treatment of the resulting carbinol with palladium on charcoal as was done in the preparation of 5-methyl-1,2-benzanthracene.[5] When the cyclic ketone was treated with *n*-propylmagnesium bromide, considerable reduction took place. The 5-*n*-propyl-1,2-benzanthracene was best prepared by the catalytic dehydration and isomerization of the carbinol VI, which was obtained in good yield by interaction of the cyclic ketone and allylmagnesium bromide.



VI



VII

Our reaction also offers a convenient preparation of 9,10-dimethyl-1,2,5,6-dibenzanthracene (VII). This hydrocarbon has been prepared previously by Cook[6] by cautious reduction of the corresponding diol and by Akin and Bogert[7] by means of the Pschorr synthesis.

Experimental

Reaction of Sodium with a Mixture of 9,10-Dimethyl-1,2-benzanthracene and Diol Dimethyl Ether.—A mixture of 1.0 g. of 9,10-dimethyl-9,10-dimethoxy-9,10-dihydro-1,2-benzanthracene and 0.80 g. of 9,10-dimethyl-1,2-benzanthracene (equimolar proportions) in 25 cc. of benzene and 25 cc. of ether was shaken with 0.14 g. of powdered sodium and some sharp glass particles. After one day's shaking, a nearly colorless solution was obtained and all of the sodium had reacted. From the solution 1.59 g. (99%) of the calculated amount of the 9,10-dimethyl-1,2-benzanthracene was isolated; m. p. 122–123°.

Reaction of 9,10-Dimethyl-9,10-disodio-9,10-dihydro-1,2-benzanthracene with Diol Dimethyl Ether.—The disodium derivative was prepared by shaking 1.25 g. of 9,10-dimethyl - 9,10 - dimethoxy - 9,10 - dihydro - 1,2 - benzanthracene with 0.36 g. of powdered sodium in 30 cc. of ether and 30 cc. of benzene. After a week, the solution had a color reminiscent of the permanganate ion. The addition of 1.25 g. of the diol dimethyl ether did not decolorize the solution; the solution seemed to take on a brighter tinge of red. After a week, no further change was observed and the solution was treated with carbon dioxide to remove the disodium derivative. From the benzene–ether solution 0.75 g. (58%) of pure diol dimethyl ether was isolated. The mother liquor gave lower melting material from which no 9,10-dimethyl-1,2-benzanthracene could be isolated.

In another experiment, the disodium derivative was prepared by shaking the hydrocarbon with the theoretical amount of sodium. In the same manner as described above, 80% of the added diol dimethyl ether was recovered.

9,10 - Dimethyl - 9,10 - diethoxy - 9,10 - dihydro - 1,2-benzanthracene.—A suspension of 1.0 g. of 9,10-dimethyl-9,10-dihydroxy-9,10-dihydro-1,2-benzanthracene[4] in 5 cc. of absolute alcohol was treated with 0.05 cc. of sulfuric acid in 1 cc. of absolute alcohol. In ten minutes a clear solution was obtained and the diol diethyl ether crystallized out. After standing at room temperature for one hour the diol diethyl ether was collected, dissolved in benzene and washed with ammonium hydroxide to remove traces of sulfuric acid. It is highly essential that the ether be as pure as possible for the successful preparation of the hydrocarbon in the sodium reaction. The benzene solution was concentrated, alcohol was added and the diol diethyl ether crystallized in clumps of colorless narrow prisms; yield 0.84 g., m. p. 167.5–171°. After two recrystallizations from benzene–alcohol the **9,10-dimethyl-9,10-diethoxy-9,10-dihydro-1,2-benzanthracene** melted at 172–173.5°.

Anal. Calcd. for $C_{24}H_{26}O_2$: C, 83.2; H, 7.6. Found: C, 83.1; H, 7.4.

A mixture of 0.84 g. of the above diol diethyl ether and 0.11 g. of powdered sodium in 15 cc. of benzene and 20 cc. of ether was shaken with a half-dozen sharp glass particles. In the course of a day, a greenish-blue mixture was obtained. The mixture was decolorized with methanol and washed with dilute hydrochloric acid. By recrystallization of the product from acetone–alcohol, 0.38 g. (61%) of 9,10-dimethyl-1,2-benzanthracene was obtained.

9,10-Di-*n*-propyl-1,2-benzanthracene.—The reaction mixture from 5.16 g. of 1,2-benzanthraquinone and *n*-propylmagnesium bromide, obtained according to the procedure of Bachmann and Bradbury,[4] was hydrolyzed and the solvent evaporated at room temperature. Treatment of the oil with a solution of 0.25 cc. of sulfuric acid in 50 cc. of methanol resulted in an immediate crystallization of the diol dimethyl ether. After standing overnight at room temperature, the diol dimethyl ether (3.9 g.) was filtered off and treated in the manner already described. From benzene–methanol, 3.25 g. of **9,10-di-*n*-propyl-9,10-dimethoxy-9,10-dihydro-1,2-benzanthracene** was obtained as colorless needles; m. p. 174–176°. One recrystallization from benzene–ethyl acetate raised the melting point to 176.5–177.5°. The compound gives a brown color with sulfuric acid.

Anal. Calcd. for $C_{26}H_{30}O_2$: C, 83.4; H, 8.1. Found: C, 83.5; H, 8.2.

A mixture of 2.31 g. of the diol dimethyl ether in 25 cc.

(7) Akin and Bogert, THIS JOURNAL, **59**, 1564 (1937).

of benzene and 25 cc. of ether shaken with 0.28 g. of powdered sodium for one day gave 1.83 g. (95%) of **9,10-di-*n*-propyl-1,2-benzanthracene;** m. p. 98.5–100°. After purification through the picrate and recrystallization from benzene–alcohol, the hydrocarbon formed thick colorless needles; m. p. 100.5–101°.

Anal. Calcd. for $C_{24}H_{24}$: C, 92.3; H, 7.7. Found: C, 92.1; H, 7.5.

The **picrate** of the hydrocarbon crystallized from absolute alcohol in black needles; m. p. 107.5–108°.

Anal. Calcd. for $C_{24}H_{24}\cdot C_6H_3O_7N_3$: N, 8.1. Found: N, 8.0.

5-Ethyl-1,2-benzanthracene.—To a solution of the Grignard reagent prepared from 22 g. of ethyl bromide and 50 cc. of ether was added 50 cc. of benzene. To the ice-cold solution was added 13.8 g. of 5-keto-5,6,7,8-tetrahydro-1,2-benzanthracene. After standing at room temperature for half an hour, the mixture was hydrolyzed with ice-cold ammonium chloride solution. The reaction product obtained by evaporation of the solvent was heated with 1.0 g. of palladium on charcoal[8] at 310–320° for half an hour in an atmosphere of nitrogen. The cooled solid was extracted with acetone–benzene. After concentrating and adding alcohol, 9.95 g. of slightly yellow hydrocarbon was obtained; m. p. 115–117°. An additional 1.3 g. of hydrocarbon was obtained by treating the product in the mother liquor once more with the catalyst making a total yield of 79% based on the cyclic ketone. After distillation at 0.4 mm. the hydrocarbon crystallized from acetone–alcohol in colorless plates; yield, 9.3 g. (65%); m. p. 118–119°. Cook and his co-workers[9] reported a melting point of 120° for the compound prepared from 5-keto-dodecahydro-1,2-benzanthracene.

In another run with 5.0 g. of the cyclic ketone, the product was heated with 10 g. of powdered potassium bisulfate at 150–160° for one hour. The benzene extract of the hydrocarbon was clarified and concentrated, by addition of alcohol giving 3.46 g. of **5-ethyl-7,8-dihydro-1,2-benzanthracene.** A sample of the hydrocarbon after sublimation under reduced pressure crystallized from alcohol in colorless prisms; m. p. 110–112°.

Anal. Calcd. for $C_{20}H_{18}$: C, 93.0; H, 7.0. Found: C, 92.9; H, 7.1.

Dehydrogenation of the dihydro derivative by palladium on charcoal[8] at 330–340° for one hour gave the hydrocarbon in 70% yield.

5 - Ethyl - 9,10 - dimethyl - 1,2 - benzanthracene.—Five grams of 5-ethyl-1,2-benzanthracene was dissolved in 50 cc. of hot acetic acid. After cooling to 70°, 5.81 g. of pure sodium dichromate dihydrate was added in portions and the mixture was heated on the steam-bath for an hour. The quinone was precipitated by the addition of 15% sulfuric acid. Recrystallization from acetone–alcohol gave 4.1 g. of 5-ethyl-1,2-benzanthraquinone; m. p. 96–98°. A second recrystallization gave 3.75 g.; m. p. 97–98° (Cook,[9] 97–98°).

5-Ethyl-1,2-benzanthraquinone (3.75 g.) was added to an ice-cold solution of the Grignard reagent prepared from 4 cc. of methyl iodide and 12 cc. of ether and 12 cc. of benzene. After hydrolysis with ice-cold ammonium chloride solution, 3.54 g. of the diol was isolated. Recrystallized twice from ethyl acetate the **5-ethyl-9,10-dimethyl - 9,10 - dihydroxy - 9,10 - dihydro - 1,2 - benzanthracene** formed microscopic needles; m. p. 201.5–204.5°. It gives a purple color with sulfuric acid. Since the diol retains solvent of crystallization tenaciously, it was analyzed as the dimethyl ether. The latter was prepared by treating a suspension of the diol (3.0 g.) in 15 cc. of methanol with a solution of 0.15 cc. of sulfuric acid in 5 cc. of methanol. After one hour at room temperature the diol dimethyl ether was filtered off and purified in the usual manner. Recrystallization from benzene–methanol gave colorless needles of **5-ethyl-9,10-dimethyl-9,10-dimethoxy-9,10-dihydro-1,2-benzanthracene;** yield, 2.36 g.; m. p. 194–195°. Two more recrystallizations raised the melting point to 197–200°.

Anal. Calcd. for $C_{24}H_{26}O_2$: C, 83.2; H, 7.6. Found: C, 83.4; H, 7.9.

A mixture of 2.36 g. of the above diol dimethyl ether (m. p. 194–196°) and 0.31 g. of powdered sodium in 25 cc. of ether and 25 cc. of benzene was shaken with a half-dozen sharp glass particles for one day. Worked up in the usual manner, 1.56 g. (80%) of the hydrocarbon was obtained. The hydrocarbon does not form a stable picrate. After purification by passage of a benzene solution through a tower of anhydrous alumina, **5-ethyl-9,10-dimethyl-1,2-benzanthracene** crystallized from acetone in light yellow plates; m. p. 107–108°.

Anal. Calcd. for $C_{22}H_{20}$: C, 92.9; H, 7.1. Found: C, 92.6; H, 6.8.

5-*n*-Propyl-1,2-benzanthracene.—(a) A mixture of 10 g. of 5-keto-5,6,7,8-tetrahydro-1,2-benzanthracene, 2 g. of magnesium, 20 cc. of ether and 40 cc. of benzene was placed in a dry flask equipped with a reflux condenser. When 10 cc. of allyl bromide was added, a vigorous reaction was initiated in a few minutes. The contents were swirled occasionally until all the cyclic ketone dissolved (ten to twenty minutes) the mixture being cooled in a pan of cold water when necessary. The product began to crystallize from the hot mixture. After twelve hours in a refrigerator, the product was filtered off, washed with benzene and hydrolyzed with ice-cold ammonium chloride solution. The carbinol which crystallized out was filtered off, dissolved in benzene to free it from magnesium salts and returned to the benzene solution of the carbinol. Spontaneous evaporation of the solution gave practically colorless carbinol; yield 9.87 g. (84%). From dilute methanol, **5-allyl-5-hydroxy-5,6,7,8-tetrahydro-1,2-benzanthracene** crystallizes in colorless needles; m. p. 82–82.5°. With sulfuric acid it gives a brown color.

Anal. Calcd. for $C_{21}H_{20}O$: C, 87.5; H, 7.0. Found: C, 87.3; H, 7.0.

Five grams of the allylcarbinol was heated with 0.5 g. of palladium on charcoal[8] for half an hour at 300° in an atmosphere of nitrogen. At this temperature there was a sudden evolution of hydrogen which was reabsorbed for the most part by the end of the experiment. The cooled malodorous melt was extracted with acetone, filtered and allowed to evaporate spontaneously. A gum settled out on the bottom and crystalline material along the

(8) Zelinsky and Turowa-Pollak, *Ber.*, **58**, 1295 (1925).
(9) Cook, Robinson and Gulden, *J. Chem. Soc.*, 393 (1937).

sides. These portions, distilled separately at 0.4 mm. and recrystallized from acetone–alcohol, gave pure colorless needles of 5-*n*-propyl-1,2-benzanthracene; yield 3.55 g.; m. p. 90–92°. Cook and Haslewood[10] prepared the compound (m. p. 92°) from 5-keto-dodecahydro-1,2-benzanthracene.

(b) Five grams of 5-keto-5,6,7,8-tetrahydro-1,2-benzanthracene was added to an ice-cold solution of the Grignard reagent prepared from 4 cc. of *n*-propylmagnesium bromide and 20 cc. of ether followed by the addition of 20 cc. of benzene. The mixture was kept in a refrigerator for twenty-four hours and the crystalline product was filtered off and washed with benzene. The crystalline material was hydrolyzed with ice-cold ammonium chloride solution containing a little benzene. By spontaneous evaporation of the benzene solution and trituration of the residue with benzene–ligroin, 2.2 g. of **5-*n*-propyl-5-hydroxy-5,6,7,8-tetrahydro-1,2-benzanthracene** was obtained. The carbinol crystallized from benzene–ligroin in colorless threads; m. p. 107–108.5°. With sulfuric acid it gives a brownish-yellow color. It was not obtained analytically pure. By dehydrating the carbinol by heating with formic acid and dehydrogenating the product with palladium on charcoal, a 69% yield of 5-*n*-propyl-1,2-benzanthracene (m. p. 86–88°) was obtained.

5-*n*-Propyl-9,10-dimethyl-1,2-benzanthracene.—In the same manner as described for the ethyl homolog, 4.42 g. of 5-*n*-propyl-1,2-benzanthraquinone (obtained in 66% yield by the oxidation of 5-*n*-propyl-1,2-benzanthracene) was treated with methylmagnesium iodide. The clear yellow gum obtained was scratched until crystallization set in and the diol triturated with benzene–ligroin; yield 3.9 g.; m. p. 160–161°. **5-*n*-Propyl-9,10-dimethyl-9,10-dihydroxy-9,10-dihydro-1,2-benzanthracene** crystallized from ligroin–ethyl acetate in microscopic needles; m. p. 161.5–163°. With sulfuric acid it gives a purple color. It retains solvent of crystallization tenaciously and was analyzed as the dimethyl ether. In the manner previously described, 3. 0 g. of the diol dimethyl ether was obtained from 3.4 g. of the diol. **5-*n*-Propyl-9,10-dimethyl-9,10-dimethoxy-9,10-dihydro-1,2-benzanthracene** crystallizes from benzene–methanol in colorless rectangular prisms; m. p. 157–159°.

Anal. Calcd. for $C_{25}H_{28}O_2$: C, 83.3; H, 7.8. Found: C, 83.3; H, 7.9.

A mixture of 2.23 g. of the diol dimethyl ether reacted with 0.29 g. of powdered sodium in 25 cc. of ether and 25 cc. of benzene in the manner previously described to give 1.64 g. (89%) of **5-*n*-propyl-9,10-dimethyl-1,2-benzanthracene.** Purified by passage of a benzene solution of the hydrocarbon through anhydrous alumina and crystallized from acetone–alcohol, the hydrocarbon formed yellowish nacreous plates; m. p. 84–85°.

Anal. Calcd. for $C_{23}H_{22}$: C, 92.6; H, 7.4. Found: C, 92.4; H, 7.7.

(10) Cook and Haslewood, *J. Chem. Soc.*, 428 (1934).

9,10-Dimethyl-1,2,5,6-dibenzanthracene.—One and one-half grams of the crude methyl diol, obtained according to Cook's[6] procedure, was treated with a solution of 0.2 cc. of sulfuric acid in 10 cc. of methanol and 20 cc. of benzene. The diol dissolved and the diol dimethyl ether crystallized in fine needles. After purification in the usual manner the **9,10-dimethyl-9,10-dimethoxy-9,10-dihydro-1,2,5,6-dibenzanthracene** (1.2 g.) crystallized from benzene in fine narrow colorless prisms; m. p. 310–320° with decomposition.

Anal. Calcd. for $C_{26}H_{24}O_2$: C, 84.8; H, 6.6. Found: C, 84.7; H, 6.7.

A mixture of 0.092 g. of powdered sodium and 0.74 g. of the diol dimethyl ether in 20 cc. of ether and 20 cc. of benzene was shaken for two days. A yield of 0.52 g. (85%) of hydrocarbon was obtained; m. p. 202–205°. From the mother liquor an additional 0.06 g. was obtained which gave 0.07 g. of fairly pure picrate; m. p. 174–176°.

The first crop was picrated in benzene and the benzene solution of the regenerated hydrocarbon passed through anhydrous alumina. From benzene the 9,10-dimethyl-1,2,5,6-dibenzanthracene crystallized in glistening yellow plates; m. p. 205.5–206.5°, the same melting point reported by Cook.[6]

9,10-Dimethyl-1,2,5,6-dibenzanthracene and picric acid dissolved in hot alcohol containing a little benzene deposited bright red needles of a **dipicrate;** m. p. 175°.

Anal. Calcd. for $C_{24}H_{18}\cdot 2C_6H_3O_7N_3$: N, 11.0. Found: N, 11.0.

Care must be exercised to avoid undue exposure of solutions of the hydrocarbon to light, for the hydrocarbon readily forms a peroxide. In one experiment, after purification, colorless needles of the peroxide were obtained instead of the usual yellow plates; m. p. 206–207° with decomposition. When placed in a bath at 200°, a melting point of 218–219° with bubbling and complete decomposition was observed. This same compound was prepared by exposure to sunlight of a solution of 0.10 g. of the hydrocarbon in 5 cc. of benzene. After forty-five minutes, 0.07 g. of clumps of colorless needles of **9,10-dimethyl-1,2,5,6-dibenzanthracene peroxide** was filtered off; m. p. 212–213° with decomposition when placed in the bath at 200°.

Anal. Calcd. for $C_{24}H_{18}O_2$: C, 85.2; H, 5.4. Found: C, 84.4; H, 5.5.

Summary

The mechanism by which 9,10-dimethyl-1,2-benzanthracene is formed by interaction of sodium and 9,10-dimethyl-9,10-dimethoxy-9,10-dihydro-1,2-benzanthracene has been investigated.

5-Ethyl- and 5-*n*-propyl-9,10-dimethyl-1,2-benzanthracene, 9,10-di-*n*-propyl-1,2-benzanthracene and 9,10-dimethyl-1,2,5,6-dibenzanthracene have been prepared.

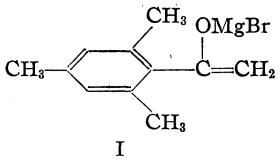
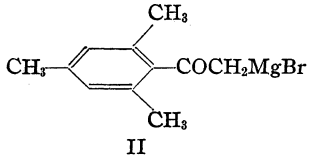
Reactions of Bromomagnesium Enolates of Mesityl Ketones. II. Condensation

BY REYNOLD C. FUSON, W. O. FUGATE AND C. H. FISHER

The bromomagnesium derivative of acetomesitylene may be formulated as an enolate (I) or as a compound of the RMgBr type (II).



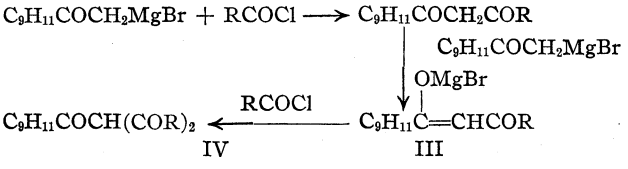
I



II

A study of its reactions has revealed the somewhat surprising fact that in all cases it behaves as though it were a true Grignard reagent. This is perhaps most striking in connection with condensation with carbonyl compounds. In the work presently reported condensation has been effected with acid chlorides, esters, carbon dioxide, aldehydes and ketones. The product in each instance is that which is predicated by formula II.

Acid chlorides and *esters* proved to be especially interesting in this connection for they reacted to give carbonyl compounds rather than carbinols. The reason for this interruption was that the newly formed aldehyde or ketone reacted in the enolic form, decomposing the excess of the original bromomagnesium derivative:



Indeed, if the amount of acid chloride present is not controlled carefully the bromomagnesium derivative of the diketone (III) is transformed to a triketone (IV).[1]

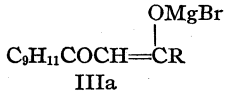
However, acetyl chloride and benzoyl chloride give satisfactory yields of the corresponding diketones when one mole of the chloride is added gradually to two moles of the bromomagnesium compound (II). Similar results were obtained with propiomesitylene and benzoyl chloride.

(1) Kohler and Baltzly, THIS JOURNAL, **54**, 4015 (1932).

With hindered acid chlorides such as 2,4,6-trimethylbenzoyl chloride this control was unnecessary; evidently the bromomagnesium derivative of the diketone in these cases had no appreciable tendency to undergo further acylation with the hindered acid chloride.

That esters also yield diketones is explained in a similar manner. The product with ethyl formate–oxymethyleneacetomesitylene showed remarkable stability.

It should be pointed out in passing that formula IIIa is less probable than III for the postulated enolate. It is known that the mesityl radical promotes enolization to a greater degree than do other radicals; this would favor III over IIIa.



IIIa

Aldehydes and *ketones* condense with the bromomagnesium derivative of acetomesitylene (II) to give carbinols. This seems to be a general property of the bromomagnesium derivatives of hindered ketones for it also has been observed with α - benzohydrylacetomesitylene,[2] propiomesitylene[3] and isobutyromesitylene.[3] Actually, in the present work carbinols were isolated only from benzaldehyde and benzophenone. When 2-methoxy-1-naphthaldehyde and acetophenone were used the products were the corresponding substituted vinyl mesityl ketones.

Carbon dioxide reacted with the bromomagnesium derivatives of acetomesitylene, propiomesitylene, isobutyromesitylene and 3,5-dibromoisobutyromesitylene to give the corresponding β-keto acids. While this type of reaction seems to proceed with unusual ease with these highly hindered substances, it is by no means novel.[4] The acids were identified by decarboxylation to the original ketones.

Coupling was effected by treating the bromomagnesium derivative with anhydrous cupric chlo-

ride. However, the yield of the resulting ethane was small. Bromine induced no coupling but led to the formation of α-bromoacetomesitylene.

Experimental

Condensation with Acid Chlorides and Esters.—The same general procedure was employed with slight modifications in all of the reactions studied. For a 0.1 mole run the bromomagnesium derivative was prepared by adding a solution of 0.1 mole of the mesityl ketone in 25 cc. of dry ether during thirty minutes to 100 cc. of an ethereal solution of a slight excess of ethylmagnesium bromide. The bromomagnesium derivative began to precipitate when about half of the ketone had been added. Refluxing was continued for thirty minutes after all of the ketone had been added.

An ether solution of the acylating agent was added to the mixture and, after the reaction was complete, the resulting mixture was decomposed with iced hydrochloric acid. The ether layer was then washed with 10% sodium carbonate solution. The diketone was usually obtained as the copper derivative by shaking the ether solution with a saturated solution of cupric acetate for several minutes and subsequently removing the ether.

The diketones or β-keto aldehydes were obtained easily by shaking an ether suspension of the copper derivative with dilute hydrochloric acid.

2,4,6,2′,4′,6′-Hexamethyldibenzoylmethane.—In a 0.031-mole run equivalent amounts of the reagent and 2,4,6-trimethylbenzoyl chloride were employed. The reaction was complete after five hours of gentle refluxing. Acidification of the sodium carbonate solution gave 1.5 g. of 2,4,6-trimethylbenzoic acid. The yield of copper derivative was 6.5 g. (64%). The dark green copper derivative was recrystallized from benzene.

Anal. of the copper derivative. Calcd. for $C_{42}H_{46}O_4Cu$: C, 74.34; H, 6.84. Found: C, 74.74; H, 7.04.

The diketone, which melted at 96–97°, was identical with that previously reported.[5]

2,4,6-Trimethyl-2′,4′,6′-triethyldibenzoylmethane.—Four hundredths mole of the bromomagnesium derivative of acetomesitylene was treated with an equivalent amount of 2,4,6-triethylbenzoyl chloride and the resulting mixture refluxed overnight. Three grams of the acid was recovered from the sodium carbonate solution. After recrystallization from a mixture of carbon tetrachloride and ligroin, the olive green copper derivative melted at 287°; yield 6.5 g. (49%).

Anal. of the copper derivative. Calcd. for $C_{48}H_{58}O_4Cu$: C, 75.59; H, 7.66. Found: C, 75.72; H, 7.68.

The diketone was a pale yellow oil, b. p. 188–190° (2 mm.), $n^{20}D$ 1.5697. It gave a red color with ferric chloride.

Anal. Calcd. for $C_{24}H_{30}O_2$: C, 82.28; H, 8.57. Found: C, 82.07; H, 8.75.

In a similar experiment the same copper derivative was prepared by treating 0.1 mole of the bromomagnesium derivative of 2,4,6-triethylacetophenone with an equivalent amount of 2,4,6-trimethylbenzoyl chloride. The yield of the copper derivative was 15 g. (46%).

(5) Fisher, Snyder and Fuson, THIS JOURNAL, **54**, 3665 (1932).

α-Benzoylacetomesitylene.—A suspension of 0.1 mole of the bromomagnesium derivative of acetomesitylene was cooled in a salt–ice bath and 0.05 mole of benzoyl chloride added during ten minutes. Stirring was continued at this temperature for ten minutes and the mixture decomposed. Steam distillation of the ether layer gave 8 g. of acetomesitylene. The residue was taken up in ether, the ether solution dried over magnesium sulfate and evaporated to dryness. A small amount of the triketone (IV) crystallized during the evaporation. The residue was recrystallized from petroleum ether; yield 10 g. (75%); m. p. 76–78.5°. The α-benzoylacetomesitylene was identical with that prepared by cleavage of the corresponding enol methyl ether.[6]

α-Benzoylpropiomesitylene.—A solution of 0.025 mole of benzoyl chloride was added to a cold suspension of the bromomagnesium derivative of propiomesitylene and the mixture stirred for two hours at room temperature. The yield of the copper derivative of α-benzoylpropiomesitylene was 5 g. (65%). Distillation of the residue gave 4.4 g. of propiomesitylene. The residue in the distilling flask gave, after recrystallization, 0.7 g. of the enol benzoate of α-benzoylpropiomesitylene. Both the diketone and its enol ester were identified by comparison with the compounds previously reported.[3]

α-Acetylacetomesitylene.—(a) One-tenth mole of the enolate was cooled in an ice–salt bath and a solution of 0.05 mole of acetyl chloride added during five minutes. Stirring and cooling were continued for one hour. After decomposition the ether layer was dried, the ether removed and the residue distilled. Eight grams of acetomesitylene was recovered and 7 g. (69%) of the diketone boiling at 143–146° (8 mm.) obtained. After recrystallization from methanol the diketone melted at 45–46°. It was identified by a mixed melting point with an authentic specimen.[7]

(b) A solution of 0.1 mole of ethyl acetate in 25 cc. of ether was added during two and one-half hours to a suspension of 0.1 mole of the bromomagnesium derivative of acetomesitylene. The mixture was then refluxed overnight.

The diketone was isolated in the manner described above. Ten and five-tenths grams of acetomesitylene was recovered and 5.5 g. (26%) of the acetyl derivative was obtained.

Hydroxymethyleneacetomesitylene.—To a suspension of 0.1 mole of the bromomagnesium derivative of acetomesitylene, 7.4 g. (0.1 mole) of ethyl formate in 25 cc. of ether was added during the course of one hour. The enolate dissolved during this time and refluxing was continued for several hours. The copper derivative of the aldehyde was recrystallized from a mixture of carbon tetrachloride and ligroin; yield, 7.2 g. (33%). Nine grams of acetomesitylene was recovered from the filtrate.

Anal. of the copper derivative. Calcd. for $C_{24}H_{26}O_4Cu$: C, 65.22; H, 5.88. Found: C, 64.86; H, 6.05.

The hydroxymethylene compound was a colorless oil, b. p. 108–110° (3 mm.); $n^{20}D$ 1.5641. It gave a blood red color with ferric chloride and dissolved slowly in 10% sodium hydroxide solution.

[a] These acids were identified by thermal decomposition to give the corresponding ketones. The ketones were identified as the 3,5-dinitro derivatives. [b] Decomposition of α-3,5-dibromo-2,4,6-trimethylbenzoylisobutyric acid gave 3,5-dibromoisobutyromesitylene; m. p. 69.5–70.5°.

Anal. Calcd. for $C_{12}H_{14}O_2$: C, 75.79; H, 7.37. Found: C, 75.81; H, 7.74.

Preparation of the β-Keto Acids.—The procedure used in the preparation of α-2,4,6-trimethylbenzoylisobutyric acid is typical. A solution of 19 g. of isobutyromesitylene in 25 cc. of ether was added during thirty minutes to 100 cc. of a solution containing a slight excess of ethylmagnesium bromide. The resulting mixture was then refluxed for thirty minutes and transferred to a catalytic reduction[8] machine whose tank contained carbon dioxide which passed into the mixture under pressure. During the first forty-five minutes the mixture was shaken by hand and cooled in a freezing mixture. The pressure dropped from 38 to 24 lb. (2.5 to 1.7 atm.). Mechanical shaking was then commenced and the mixture shaken at room temperature for twelve hours.

The mixture was then chilled in an ice-bath and poured very slowly into iced hydrochloric acid. The ether layer was extracted with cold sodium carbonate solution and the sodium carbonate extract acidified carefully with iced hydrochloric acid. The yield of α-2,4,6-trimethylbenzoylisobutyric acid was 18 g. (77.4%). The acid was recrystallized by dissolving it at room temperature in ether, adding a small amount of petroleum ether and then removing the solvent slowly under reduced pressure; m. p. 86–87° with decomposition. The original mesityl ketone was obtained when the acid was heated on a steam-cone for two hours.

2-(2,4,6-Trimethylbenzoyl)-1-phenylethanol.[9]—To a suspension of 0.2 mole of the bromomagnesium derivative of acetomesitylene in approximately 275 cc. of ether, 22 g. of freshly distilled benzaldehyde in 100 cc. of dry ether was added over a period of one hour. During this time the enolate gradually disappeared. Refluxing was continued for three hours.

The mixture was poured into iced hydrochloric acid, the ether layer separated and the aqueous layer extracted twice with ether. The combined ether solution was dried over sodium sulfate. Evaporation of the ether left a reddish-brown oil which deposited crystals of the carbinol on addition of a few cubic centimeters of ligroin. The yield of 2-(2,4,6-trimethylbenzoyl)-1-phenylethanol was 25 g. (47%). Recrystallization from petroleum ether gave 22 g. of the pure material, m. p. 77–77.5°.

Anal. Calcd. for $C_{18}H_{20}O_2$: C, 80.59; H, 7.46. Found: C, 80.13; H, 7.42.

Distillation of the residual oil gave small amounts of benzaldehyde and acetomesitylene and 13 g. (26%) of benzalacetomesitylene, b. p. 215–221° (16 mm.).

(9) This synthesis was carried out by Mr. R. V. Lindsey, Jr.

β-(2-Methoxy-1-naphthyl)-vinyl Mesityl Ketone.—A solution of 9.5 g. of 2-methoxy-1-naphthaldehyde in a mixture of 25 cc. of dry ether and 75 cc. of benzene was added dropwise during three hours to a suspension of 0.05 mole of the bromomagnesium derivative of acetomesitylene. During the addition, the enolate was converted to a chrome yellow solid. To ensure complete reaction, the mixture was then refluxed gently for three hours. The complex was decomposed with iced hydrochloric acid, the ether–benzene layer washed once with water and dried. After removal of the solvent by distillation, an oil remained which solidified when its solution in hot methyl alcohol was allowed to cool slowly, yield 13.5 g. (82%) of β-(2-methoxy-1-naphthyl)-vinyl mesityl ketone melting at 100–103°. After two recrystallizations from methanol the product melted at 107–108°. It reacted slowly with bromine in carbon tetrachloride.

Anal. Calcd. for $C_{23}H_{22}O_2$: C, 83.64; H, 6.67. Found: C, 83.43; H, 7.07.

α,β-Dibromo-β-(2-methoxy-1-naphthyl)-propiomesitylene.—To an ice-cold solution of 1.5 g. of β-(2-methoxy-1-naphthyl)-vinyl mesityl ketone in 3 cc. of carbon tetrachloride a solution of bromine in carbon tetrachloride was added in small portions until the red color of the bromine solution persisted. Crystallization began before the bromination was complete. After all the bromine was added, 1.5 g. of α,β-dibromo-β-(2-methoxy-1-naphthyl)-propiomesitylene melting at 145–147° with decomposition was collected on a filter. The product was recrystallized by dissolving in the minimum of hot carbon tetrachloride and adding ligroin; m. p. 148–149°.

Anal. Calcd. for $C_{23}H_{22}O_2Br_2$: C, 56.33; H, 4.49; Br, 32.65. Found: C, 56.17; H, 4.80; Br, 32.75.

β-Methylbenzalacetomesitylene.—During a period of one and one-half hours, 96 g. (0.8 mole) of acetophenone in 100 cc. of ether was added to a suspension of 0.7 mole of the bromomagnesium derivative of acetomesitylene in 400 cc. of ether. During this time the enolate was converted to a thick gum. Refluxing was continued for six hours.

The mixture was decomposed by pouring it into 1 kg. of cracked ice and 200 cc. of concentrated hydrochloric acid, the ether layer washed with water and dried over magnesium sulfate. After removal of the ether, no product could be induced to crystallize. However, when distillation was attempted a solid began to form and, on addition of a small amount of petroleum ether, β-methylbenzalacetomesitylene, a pale yellow solid melting at 79–82°, began to crystallize. Sixty-three grams of the solid was collected on a filter. Distillation of the mother liquor gave 38 g. of acetophenone, 20 g. of acetomesitylene, and an additional 35 g. of the α,β-unsaturated ketone. After

three recrystallizations from alcohol the compound melted at 85.5–87°. Kohler and Barnes[6] reported the melting point as 84°. The yield of β-methylbenzalacetomesitylene was 98 g. (69%).

Anal. Calcd. for $C_{19}H_{20}O$: C, 86.36; H, 7.55. Found: C, 86.15; H, 7.51.

The identification was completed by conversion to β,β-dimethyl-β-phenylpropiomesitylene by the method of Kohler and Barnes.[6]

1,1 - Diphenyl - 2 - (2,4,6 - trimethylbenzoyl)-ethanol.—To a suspension of 0.05 mole of the bromomagnesium derivative of acetomesitylene in 120 cc. of ether, 10 g. of benzophenone in 60 cc. of ether was added during the course of two hours. The enolate dissolved completely as the last of the ketone was added. The mixture was then refluxed gently overnight.

The ether solution was poured slowly with stirring into iced hydrochloric acid, the ether layer separated, dried and the ether allowed to evaporate spontaneously. The nearly colorless residual oil was taken up in warm methyl alcohol. When the solution was allowed to cool 13.2 g. (76.5%) of 1,1-diphenyl-2-(2,4,6-trimethylbenzoyl)-ethanol was obtained, m. p. 70–72°. After recrystallization from methanol, the product melted at 74–75°. A mixture with an authentic sample prepared by the method of Kohler and Barnes[6] showed no depression in melting point.

α - Bromoacetomesitylene.—Three and three-tenths grams of acetomesitylene was converted to the bromomagnesium derivative, the mixture cooled in a salt–ice bath and a slight excess of bromine in 15 cc. of ether added dropwise. The reaction was complete in twenty minutes.

The reaction mixture was treated with dilute hydrochloric acid, the ether layer separated, dried over magnesium sulfate, and the ether removed. After recrystallization from petroleum ether, 2.7 g. (56%) of α-bromoacetomesitylene was obtained, m. p. 52–55°. After purification the product melted at 55–56°, and was identified by a mixed melting point with an authentic sample.

1,2-Di(2,4,6-trimethylbenzoyl)-ethane.—Seven and five-tenths grams of anhydrous cupric chloride was added in small portions to an ether suspension of 0.05 mole of the bromomagnesium enolate of acetomesitylene in 125 cc. of dry ether and the mixture refluxed gently for twenty hours. During this time a crimson solid appeared in the reaction flask. The mixture was cooled in an ice-bath, decomposed by slowly adding iced hydrochloric acid, the ether layer dried over anhydrous magnesium sulfate and the ether removed by distillation. When the resulting liquid was distilled, 6.1 g. (75.4%) of acetomesitylene was recovered.

The residual oil was left standing for several days during which a solid began to form. The solid, after two recrystallizations from alcohol melted at 137–139°, the melting point of the ethane reported by Kohler and Baltzly[1] and by Conant and Lutz.[10]

1,3-Di-(2,4,6-trimethylbenzoyl)-propane.—Three and two-tenths grams of acetomesitylene was converted to the bromomagnesium enolate. To the resulting vigorously stirred suspension of the enolate in about 40 cc. of ether, a solution of 3.5 g. of vinyl mesityl ketone[11] in 20 cc. of dry ether was added during a period of thirty minutes. The resulting clear solution was refluxed gently for one hour. After the complex was decomposed with iced hydrochloric acid, the ether layer was separated and dried. When the ether was evaporated, there remained 5.5 g. (82%) of 1,3-di-(2,4,6-trimethylbenzoyl)-propane. After recrystallization from methanol the diketone melted at 131–132°. It was identical with the product previously reported.[12]

Summary

The bromomagnesium derivative of acetomesitylene reacts as a true Grignard reagent. This behavior has been observed in the condensations of this derivative with acid chlorides, esters, carbon dioxide, aldehydes and ketones.

Propylene. The Heat Capacity, Vapor Pressure, Heats of Fusion and Vaporization. The Third Law of Thermodynamics and Orientation Equilibrium in the Solid

BY T. M. POWELL AND W. F. GIAUQUE

Several cases are known where molecules containing somewhat similar atoms in otherwise equivalent positions enter the crystal lattice without appreciably distinguishing between the similar atoms. This situation which corresponds to thermodynamic equilibrium at the freezing point is sometimes unable to readjust itself to an ordered molecular arrangement as the temperature of the solid is lowered sufficiently to make this the stable state.

This effect was first observed by Johnston and Giauque[1] in the case of nitric oxide which polymerizes to N_2O_2. They showed that a residual entropy of R ln 2 per mole of N_2O_2 remained near the absolute zero. The above explanation was advanced by Clayton and Giauque,[2] who investigated the similar effect in carbon monoxide. These authors pointed out that this was the usual case in molecules containing isotopes and was to be expected in other cases where the atoms are of somewhat similar size. In addition to the above cases this effect has been observed in the case of nitrous oxide NNO by Clusius[3] and Blue and Giauque.[4] Clayton and Giauque[2] also pointed out that this effect was to be expected in the case of certain carbon compounds.

The experimentally investigated cases mentioned above involve only lack of discrimination between atoms but it is evident that cases may occur where false equilibrium may exist at low temperatures with respect to groups of atoms. This paper is a report on a calorimetric investigation of propylene, $CH_2{=}CH{-}CH_3$, which shows that the CH_3 and CH_2 groups are located without discrimination when they enter the crystal lattice under equilibrium conditions at the freezing point. Propylene lacks the mechanism to rotate the molecule within the solid so as to produce an ordered arrangement corresponding to zero entropy as the absolute zero of temperature is approached.

The apparatus and method of measurement have been described previously.[4-8] The measurements were made in a calorimeter with the laboratory designation Gold Calorimeter II.

Preparation and Purity of the Propylene.—A sample of propylene was donated by the Shell Development Company. Several heat capacity measurements in the region just below the melting point were made on the original sample and from the heat effect due to premelting the liquid soluble–solid insoluble impurity was estimated at 0.2 mole %. The material was then fractionated and subsequent calorimetric measurements of the premelting indicated that the impurity had been reduced to 0.02 mole %. Table I shows the several estimates of impurity as obtained by the total premelting which occurred up to the several temperatures.

TABLE I

PREMELTING DATA ON THE SAMPLE OF PROPYLENE

.063	60.4	8.5	.024
		Average	.022

The Vapor Pressure of Propylene.—The vapor pressure of propylene was measured by means of a mercury manometer and a standard meter with a cathometer used as a comparison instrument. The acceleration of gravity was taken as 979.973 cm. sec.$^{-2}$ for this location and the standard acceleration as 980.665 cm. sec.$^{-2}$.

The results have been represented by the equation, 165.8 to 225.9°K.

$$\log_{10} P_{(\text{inter. cm. Hg})} = -\frac{1196.9}{T} - 3.92 \times 10^{-3} T + 8.07544 \quad (1)$$

The vapor pressure observations are compared with Equation 1 in Table II.

The temperatures are given to 0.001° only because the high relative accuracy permits the data to be used in obtaining derivatives.

From Equation 1 the boiling point of propylene was found to be 225.35°K.

A summary of observations on the melting point is given in Table III. The gradual increase with

The Calorimetric Observations.—The heat capacity measurements on solid and liquid propylene are recorded in Table V. The results on the liquid were corrected for vaporization into the small gas space when the vapor pressure made the effect appreciable. In making this correction the measurements of Maass and Wright[10] on the density of liquid propylene were utilized. A small pressure of helium gas was used to facilitate thermal equilibrium in the solid. The amount of propylene taken for the measurements was determined by condensing the material in a steel bomb equipped with a valve and weighing at room temperature: 64.227 g. equivalent to 1.5264 moles was used for the measurements; 4.1832 international joules was taken equal to 1 calorie (15°).

[a] Values include premelting heat effect.

Results taken from a smooth curve through the data are given in Table VI. The curve should represent the heat capacity to 0.1–0.2% above 35°K. At 20°K. the error may be 1% and at 15°K. several %.

The data are shown graphically in Fig. 1 where the dotted curve below the melting point shows the rise in heat capacity due to the premelting resulting from 0.02 mole % of impurity.

The heat capacity of propylene, above 68.9°K., has been measured by Huffman, Parks and Barmore.[12] The observations agree well with the present results, as may be seen from a comparison included in Table VI.

The observations on the heat of fusion are given in Table VII. The runs started several degrees below the melting point and ended somewhat

4	83.099–91.698	865.95	149.95	1.38	717.3
				Average	717.6

The heat of fusion also has been measured by Huffman, Parks and Barmore,[12] who obtained the value 701.4 cal. mole^{-1}. This value is 2% less than the one obtained in the present research. As the heat capacity in the earlier work had not been measured to temperatures sufficiently below the melting point to permit an estimate of the effect of impurity, it is presumed that the deviation is due to unconsidered premelting rather than to error in the actual calorimetric observation.

For measurements of the heat of vaporization the amount evaporated was measured by means of a 5-liter thermostatted bulb, initially filled with mercury which was removed automatically as the gas was accepted at constant pressure. This apparatus has been described previously.[6] At the conclusion of energy input the line leading from the calorimeter was closed, the mercury was lowered to a suitable calibration mark and a pressure observation was taken. The propylene from three such observations was collected and weighed in the steel bomb mentioned above. From these data a value of the gas density was calculated. The data are collected in Table VIII.

TABLE VIII

GAS DENSITY OF PROPYLENE AT 25°

Bulb volume, cc.	Pressure inter. cm. Hg	Total amt., g.
5330.9	71.574	
5358.5	73.233	26.823
5320.9	74.120	

$$P_0V_0 = RT = 22411.5 \times \frac{298.10}{273.10} \text{ cc. atm.}$$

$$PV = RT(1 + \lambda P)$$

$$\lambda = -0.0149 \text{ atm.}^{-1}$$

The density calculated to 1 atmosphere was 1.7461 g./l. at 25.00°. Before and after the measuring bulb was connected to the calorimeter the temperature was not exactly the vaporization temperature and suitable corrections were applied for the effect of temperature change on calorimetric heat content and the small amount of gas in the connecting line. The measurements of the heat of vaporization are given in Table IX.

TABLE IX

HEAT OF VAPORIZATION OF PROPYLENE

Boiling point, 225.35°K.

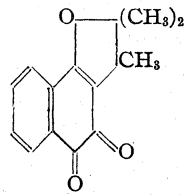
Run	Moles evaporated	Time of energy input, min.	ΔH vap. cal. mole^{-1}
1	0.20483	54	4400
2	.21618	57	4405
3	.21744	57	4405
4	.20770	56	4399
		Average	4402

The entropy calculation from 0°K. to the boiling point is summarized in Table X.

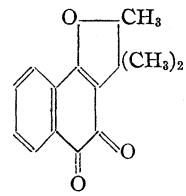
No red color will result when R^1 is in any of the following:

(a) $-CH_2CH_2COOH$ (b) $-CH{=}C(COOH)COOC_2H_5$
(c) $-CH_2COCH_3$ or the tautomeric form $-CH{=}C(OH)CH_3$
(d) $-COCH_2COCH_3$ or the tautomeric forms
(e) $-CH_2Cl$ (f) CH_3 (g) C_2H_5

It is interesting in connection with structure IV for the red compounds that Price and Robinson[15] have investigated a naturally occurring *red* pigment, dunnione, for which they propose structure XII or XIII, and that as a result of their study of the absorption spectra of naphthoquinone derivatives, Cook, Macbeth and Winzor[10] agree with Price and Robinson that dunnione is either XII or XIII.



XII



XIII

Experimental Part[16]

The apparatus and procedure used for obtaining the absorption curves have been described in a previous paper.[1b]

2,2,7,8-Tetramethylchroman-5,6-quinone (IV, R^1 = CH_3; R^2 = H).—A solution of 2,2,5,7,8-pentamethyl-6-hydroxychroman (I, $R^1 = CH_3$; R^2 = H) (500 mg.) in absolute ethanol (500 cc.) and concd. nitric acid (100 cc.) was warmed for ten minutes on the steam-bath. The solution was cooled rapidly, diluted with water (1800 cc.) and extracted thoroughly with ether (six times). The combined extracts were washed with water until the washings were neutral to litmus, then once with dilute sodium carbonate and finally twice with water. The ether was removed on the steam-bath, the last traces being taken off under reduced pressure. The residue solidified to a red solid which was crystallized, first from petroleum ether (b. p. 28–38°) and then from ether–petroleum ether. The substance formed red needles which melted at 109–110° and which did not depress the melting point of a specimen made by the action of silver nitrate upon the chroman according to the directions of John.[2a]

The red compound forms deeply colored, red-violet solutions with cold, concd. hydrochloric acid, cold concd. sulfuric acid, or with hot dilute aqueous alkali. When hydrochloric acid is used, the solution finally deposits a brown amorphous solid melting above 200°. This brown solid gives a yellow solution in ether and a deep red solution in alcohol. All of these yellow and colorless transformation products are very soluble and so far we have not been able to isolate any pure compounds from them. These color changes with acids and alkali parallel strongly those observed by Hooker[17] in the lapachol series when an *o*-quinone of the type of IV (red) was transformed, by opening the hetero ring and recyclizing, into a *p*-quinone of type III (yellow), and the new pigment, dunnione, shows a similar series of color changes under the same circumstances.[10]

Phenazine.—The crude, moist quinone (0.43 g.) was dissolved in acetic acid (25 cc.) and warmed on the steam-bath. To this solution was added *o*-phenylenediamine (0.25 g.) and the solution was heated for ten minutes. It was then diluted with water to incipient cloudiness, and cooled. The fine yellow needles (0.11 g.) were removed and crystallized twice from dilute acetic acid. The substance formed glistening yellow needles which melted at 151–151.5°; the compound could be sublimed *in vacuo*, but this did not result in a higher melting point.

Anal. Calcd. for $C_{19}H_{20}ON_2$: C, 78.08; H, 6.85; N, 9.59. Found: C, 77.43; H, 7.10; N, 9.51.

Tetramethylphenazine.—To a boiling solution of the red quinone (50 mg.) in acetic acid (2 cc.) was added a solution of prehnitenediamine hydrochloride (60 mg.) in acetic acid (5 cc.) containing a crystal of sodium acetate. On cooling, a yellow granular solid precipitated, which was removed and crystallized twice from acetic acid. It melted at 204–205°, but the amount of it was too small to crystallize to analytical purity.

Anal. Calcd. for $C_{23}H_{28}ON_2$: C, 79.31; H, 8.05. Found: (2 mg. sample) C, 77.1; H, 8.04.

In ultraviolet light, these phenazines show a powerful green fluorescence, which is visible, though much fainter, even in daylight. Neither of these phenazines gives a positive phenol test (Folin). When, however, the phenazine of m. p. 151–151.5° is reduced catalytically (platinum oxide), the colorless solution gives a positive phenol test. The colorless solution of the reduction product is re-oxidized rapidly in the air.

Bisulfite Reduction of IV.—When shaken with 20% aqueous sodium bisulfite, the red quinone dissolved, giving a pale straw colored solution. Acidification and boiling to remove sulfur dioxide regenerated the deep red color; similarly, the red color reappears on boiling with a little nitric acid or alkali. In the latter case, the solution becomes red, then purple.

Reaction of IV with Alkali.—The quinone IV (1.7 mg.) was added to potassium hydroxide solution (1 cc., 5%). On warming, the solution became deep violet. It was boiled for ten seconds, then cooled and acidified with acetic acid (0.2 cc.). The color at once became yellow. Water was added and the solution was extracted with ether. Evaporation of the ether left an oil, soluble in benzene and insoluble in petroleum ether. This oil gave a positive phenol test but it could not be crystallized.

Cleavage of IV.—When the red quinone was boiled with acetic acid, potassium acetate and hydrogen peroxide (3%), the solution decolorized completely. An attempt was made to isolate the cleavage product as the barium salt, but no product could be obtained.

Addition of Isoprene to *o*-Xylohydroquinone.—Isoprene (2.2 cc.) was added to a hot solution of the hydroquinone

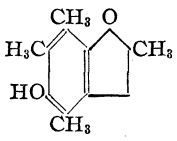
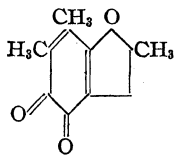
$R^1 = CH_3$; $R^2 = C_{15}H_{31}$)[12] from α-tocopherol (I, $R^1 = CH_3$; $R^2 = C_{15}H_{31}$) gives a phenazine, which is also an oil, but which shows the same strong green fluorescence in ultraviolet light as is shown by the simpler phenazine of IV ($R^1 = CH_3$; $R^2 = H$).[13]

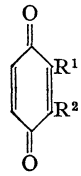
Formation of the red ortho quinones by oxidation is not limited to 6-hydroxychromans. It has been shown by Furter[14] and in a previous paper from this Laboratory[1b] that the reaction occurs also in the case of 5-hydroxycoumarans such as IX. By analogy the red compounds derived from these substances would have structures such as X, although this point has not yet been investigated thoroughly.



IX



X



XI

With regard to the mechanism whereby these red compounds are produced from the chromans (I) and the related quinones (II), it is not possible at present to do more than speculate. Certain facts, however, have been discovered which must be taken into account in formulating a mechanism; since these facts have a bearing upon the applicability of the Furter and Meyer method of photometric analysis, they are given here.

An alcohol or possibly a phenol is necessary as a solvent in order to produce the red solutions from the tocopherols and related substances. Using 2,4,6,7 - tetramethyl - 5 - hydroxycoumaran (IX) as the test substance, red solutions were obtained in methanol, ethanol, 2-propanol, *t*-butyl alcohol, and mesitol. The *intensity* of the color developed in the alcohols in a given time, however, decreased in the order they are named—that is, primary alcohols were more effective than secondary, and these more so than tertiary. Red solutions are not formed in petroleum ether, acetic acid, or acetone, although Furter and Meyer observed that a mixture of ethanol and acetone could be used in the case of the tocopherols. It appears from these results that alcohols are essential for the production of the red color, and this leads to the suspicion that the alcohol plays the role of a reagent as well as that of a solvent in the reaction, especially when taken along with the fact that acetone (negative) is the oxidation product of isopropyl alcohol (positive). There is definite evidence that the alcohol is oxidized during the reaction: in methanol, formaldehyde was detected, and in ethanol, acetaldehyde. Naturally these oxidation products might have been produced by the nitric acid in the absence of any substance capable of giving a red solution, but it is perhaps significant in this connection that the color in *t*-butyl alcohol was developed *very* much more slowly than in the other three alcohols tested, and all of the solvents giving negative results are substances quite resistant to the action of nitric acid over fairly short periods of time.

As to the nature of the substances capable of giving the red colors, the following can now be added to those previously reported:[1b,4] *m*-xylotocopherol (synthetic), 2,4,6-trimethyl-7-allyl-5-hydroxycoumaran, *o*-allyl-*p*-aminophenol, tetramethyl-*o*-benzohydroquinone, catechol, and the substances described in this paper. The positive reaction with catechol is important in connection with the Furter and Meyer method of analysis for tocopherols when applied to preparations or concentrates obtained from natural sources, for catechol derivatives are very common among certain classes of natural products. In the case of the *o*-quinones and catechol the red color is developed in the cold, as soon as the nitric acid is added, but it fades to yellow on standing, a behavior which also is shown by the red *o*-quinones such as IV, although here the color persists for a day or so. These substances did not give a red color under the conditions of the Furter and Meyer reaction: duroquinone, trimethylethylquinone, 2,5,7,8 - tetramethyl - 6 - hydroxychromone, 2,4,5-trimethyl-3,6-diacetoxybenzyl chloride, trimethyl-(β-carboxy ethyl)-*p*-benzoquinone, mesitol.

When the results obtained from all of the compounds so far tested are assembled, they lead to the conclusion that if the heterocyclic compound can be oxidized readily to a quinone of type XI (vacant positions may be occupied by alkyl or substituted alkyl groups), *a positive reaction* (formation of a red ortho quinone of type IV, with elimination of the group R^2) will occur when the group R^1 is any of the following:

(a) $-CH_2CH_2CH(OH)CH_3$ (b) $-CH_2CH_2C(OH)(CH_3)_2$
(c) $-CH_2CHOHCH_3$ (d) $-CH(CH_3)CHOHCH_3$
(e) $-CH(C_2H_5)CHOHCH_3$ (f) $-CH_2CH_2C(OH)(CH_3)R$
(g) allyl

(12) Dr. H. M. Evans has assayed this red oil for vitamin E activity; it is inactive at 3 and 6 mg. doses.

(13) Furter and Meyer[4] carried out this reaction with α- and β-tocopherols; our experiments were limited to α- and γ-tocopherols.

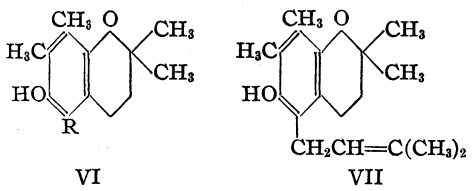
lished the results of a thorough investigation of the absorption spectra of some naphthoquinones and their derivatives. They conclude that a maximum of about 4000–4400 Å. is characteristic of ortho-naphthoquinones, while it is absent in the para-quinones. Our curve for β-lapachone is identical with theirs in the range accessible to us. The location of the characteristic maximum in ortho-benzo- and β-naphtho-quinones is not identical, but involves a slight shift to the longer wave lengths in the case of the benzoquinones, which accounts for the deeper color of these substances. The fact that the red oxidation products absorb most strongly in the region of 4500 Å. may be taken as good evidence that the *o*-quinoid structure is present.

On the chemical side, the results are decisively in favor of the *o*-quinoid structure IV for these red oxidation products. The red substance, m. p. 109–110° (IV, $R^1 = CH_3$; $R^2 = H$), forms a phenazine with m. p. 151–152° with *o*-phenylenediamine, and a tetramethylphenazine of m. p. 204–205° with tetramethyl-*o*-phenylenediamine. These phenazines are yellow and their alcoholic solutions show a pale green fluorescence; in ultraviolet light the fluorescence is quite brilliant.[11] Hooker found that most of the azines of the lapachol group exhibited this greenish fluorescence. The phenazine from tetramethyl-*o*-benzoquinone[8] also exhibits a strong green fluorescence in ultraviolet light although this is lacking in ordinary light. When reduced the bright red solution of IV ($R^1 = CH_3$; $R^2 = H$) becomes completely decolorized in a few minutes. The reduction product, however, is oxidized in the air with extreme rapidity—so rapidly that the compound becomes reoxidized and the solution turns bright red before the insoluble material (catalyst, zinc, etc.) can be filtered off.

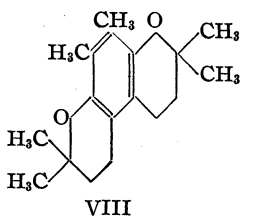
In order to prove structure IV, it was necessary to locate definitely the position occupied by the methyl group eliminated in the conversion of the quinone II to the red compound IV. This methyl group must be one of those in the benzene ring, for Karrer, Fritzsche and Escher showed that 2,5,7,8-tetramethyl-6-hydroxychroman (I, $R^1 = R^2 = H$) gave a red compound $C_{12}H_{14}O_3$ which was a lower homolog of IV, $C_{13}H_{16}O_3$. Since all of the substituents in the benzene ring of the pentamethylchroman are alike, structure V for the red compound, although improbable, is not rigidly excluded.

(11) Hooker, *J. Chem. Soc.*, **63**, 1376 (1893).

It is obvious that, if structure IV is correct, the same red compound must result from any 6-hydroxychroman of the type of VI. Accordingly, *o*-xylohydroquinone was condensed with isoprene. The product was a mixture, as is usual in these condensations when the hydroquinone possesses more than one vacant position ortho to the hydroxyl groups. Unchanged hydroquinone was removed from this product by extraction with



VI VII



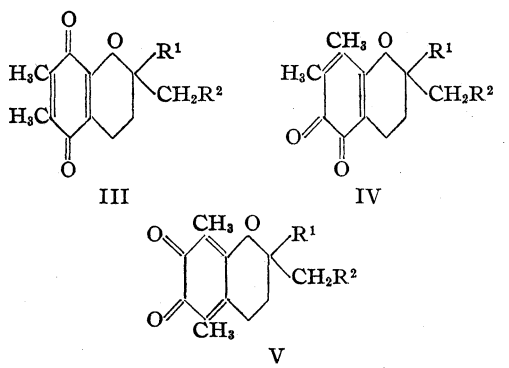
VIII

aqueous sodium hydroxide, and the insoluble portion was then separated by extraction with Claisen's alkali into (a) a phenolic constituent, the chroman VI, R = H, possibly containing also the chroman VII and (b) a non-phenolic constituent, the double chroman VIII. These materials were not further purified, but were subjected directly to oxidation, the non-phenolic constituent by silver nitrate, and the phenolic constituent by nitric acid under the conditions of the Furter reaction. *Both of these substances gave in excellent yield, the same red compound IV*, m. p. and mixed m. p. 109–110°. In fact, the red compound from the phenolic constituent melted at 109.5–110.5°, the highest melting point so far recorded for this compound. It is thus apparent that the group eliminated in these oxidations of 6-hydroxychromans is the one in the 5-position, and that this reaction will occur even though both oxygen atoms of the hydroquinone are involved in heterocyclic systems; furthermore, when hydrogen occupies the 5-position, the composition of red compound IV will be that of the quinone II minus two hydrogen atoms only.

α-, β- and γ-tocopherols give deep red compounds when they are oxidized by nitric acid in alcohol solution. These substances are obtained in good yield, but they are oils which we have so far been unable to crystallize. The red oil (IV,

ever, the reproducibility of the Furter and Meyer reaction under standard conditions is very good.

John and his associates[2a] established that the red compounds differed in composition from the para-quinones II by one carbon atom and four hydrogen atoms; thus the red compound from the pentamethylchroman had the composition $C_{13}H_{16}O_3$, and Karrer and his associates[2b] established that there was a similar change in composition when the quinone (II, $R^1 = R^2 = H$) from 2,5,7,8-tetramethyl-6-hydroxychroman (I, $R^1 = R^2 = H$) was converted into the analogous red compound $C_{12}H_{14}O_3$, m. p. 140°. In their recent paper, Karrer, Fritzsche and Escher[2b] have shown that the red compound obtained from 2,5,7,8-tetramethyl-6-hydroxychroman (I, $R^1 = R^2 = H$) contains no active hydrogen atoms and that it is a quinone, for on reduction it absorbs two atoms of hydrogen to give a colorless hydroquinone. They have proposed a tentative structure for this red compound, which by analogy would become III ($R^1 = CH_3$; $R^2 = H$) when applied to the pentamethylchroman I ($R^1 = CH_3$; $R^2 = H$).



The red substance, however, is not a para-quinone, but is an ortho-quinone. First of all, the red color is in itself a strong argument against such a formulation as III. It has been shown by Hooker and his associates, in a series of remarkable papers, that in the naphthoquinone series all of the hydroxy-α-quinones and the chromans and coumarans derived from them are yellow, the only exceptions being those 2-hydroxy-α-naphthoquinones with a side chain in the 3-position containing a double bond α,β- to the ring—these, and only these, are red, whereas *all* of the derivatives of 4-hydroxy-β-naphthoquinone, as well as the chromans and coumarans derived from them, are red.[7] In Fig. 2 are given the absorption curves for

(7) Hooker, *et al.*, THIS JOURNAL, **58**, 1163, 1168, 1179, 1181, 1198, 1202 (1936). References to previous work by Hooker are given in these papers. See also Fieser, *ibid.*, **49**, 857 (1927).

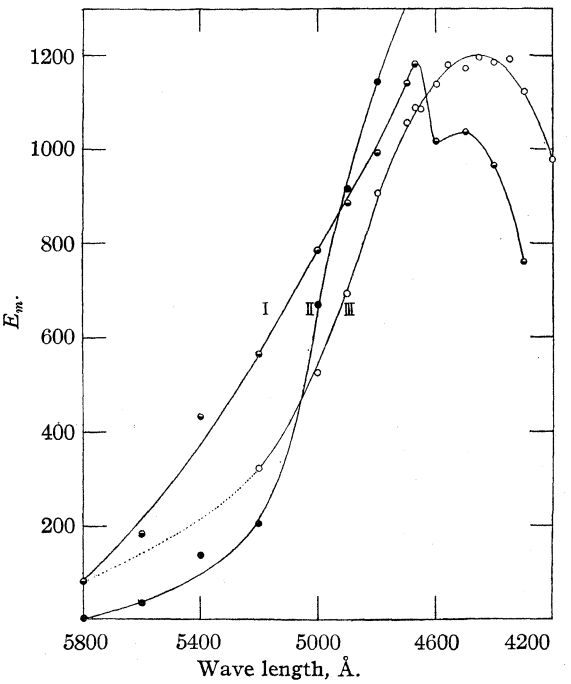


Fig. 2.—◒, Curve I, $C_{13}H_{16}O_3$ (IV), m. p. 109–110°, in absolute ethanol; ●, Curve II, β-lapachone in absolute ethanol; ○, Curve III, tetramethyl-*o*-benzoquinone.

the red compound (pure; m. p. 109–110°) in ethanol, together with curves for two known ortho-quinones—tetramethyl-*o*-benzoquinone[8] and β-lapachone.[9] The curves for the red compound (curve I) and tetramethyl-*o*-benzoquinone (curve III) show good agreement, particularly with respect to the molecular extinction coefficient at the maximum. The shift of the maximum from about 4460 Å. in curve III to 4670 Å. in curve I may be ascribed to the 6-membered hetero ring, because this maximum is characteristic of the red oxidation products of all 6-hydroxychromans which have so far been investigated. The curves reported previously for the red solutions obtained in the Furter reaction from 5-hydroxycoumarans[1b] show a maximum at 4400 Å., which agrees well with an *o*-quinone structure as for instance with tetramethyl-*o*-benzoquinone. Our absorption curve for β-lapachone (curve II, Fig. 2) does not allow for inferences as to structural units, because the range of our instrument was not sufficiently great to include all of the significant parts of the curve. However, while this work was under way, Cook, Macbeth and Winzor[10] have pub-

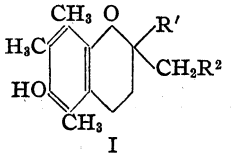
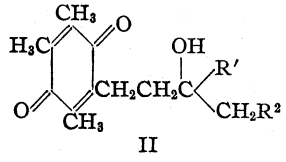
The Chemistry of Vitamin E. XVII. The Oxidation Products of α-Tocopherol and of Related 6-Hydroxychromans[1]

BY LEE IRVIN SMITH, WILLA B. IRWIN AND HERBERT E. UNGNADE

When α-tocopherol (I, $R^1 = CH_3$; $R^2 = C_{15}H_{31}$), 2,2,5,7,8-pentamethyl-6-hydroxychroman (I, $R^1 = CH_3$; $R^2 = H$) and similar substances are oxidized by ferric chloride, gold chloride or, under certain circumstances by silver nitrate, the products are yellow para-quinones, II.[2]



I



II

When, however, the action of silver nitrate is prolonged, the oxidation proceeds beyond the yellow para-quinone stage and brilliant red solutions are obtained.[2,3] Red solutions also result when nitric acid is used as the oxidizing agent, and Furter and Meyer[4] have developed an elegant photometric method of analysis for tocopherols based upon the production of these red solutions with nitric acid. This reaction has been extended in this Laboratory to para hydroxy coumarans and chromans in general.[5]

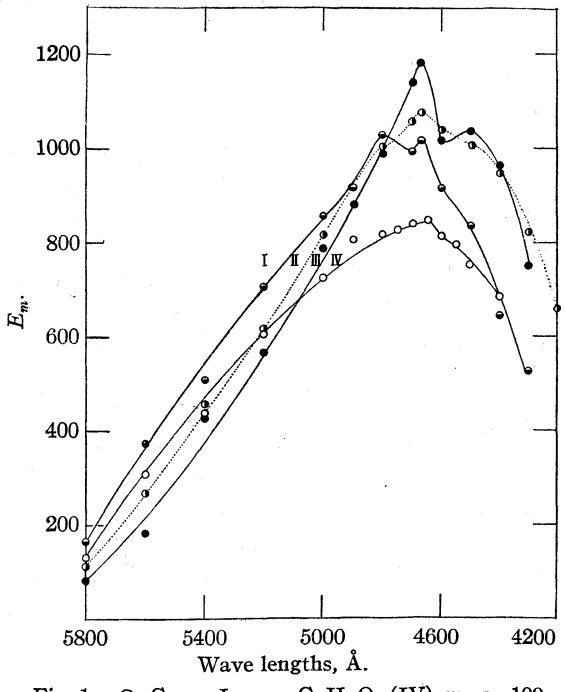


Fig. 1.—◒, Curve I, pure $C_{13}H_{16}O_3$ (IV) m. p. 109–110° in 5 cc. abs. ethanol + 1 cc. concd. HNO_3; ◑, Curve II, $C_{13}H_{16}O_3$ (IV) m. p. 107.5–108.5° from $AgNO_3$ method in abs. ethanol; ●, Curve III, pure $C_{13}H_{16}O_3$ (IV) in absolute ethanol; ○, Curve IV, further reaction on pure 2,2,5,7,8-pentamethyl-6-hydroxychroman.

We have obtained, from the chroman I ($R^1 = CH_3$, $R^2 = H$), the same red crystalline compound using either silver nitrate or nitric acid as the oxidizing agent. The substance forms brilliant red needles which have a melting point (and mixed melting point) of 109–110°.[6] These results show that this compound, m. p. 109–110°, is the substance responsible for the color in the Furter and Meyer reaction with the pentamethylchroman. This is also shown by the curves in Fig. 1. In these curves, the molecular extinction coefficient, E_m, is plotted against the wave length in Ångström units. Curve IV represents the data obtained when the pentamethylchroman was analyzed photometrically by the method of Furter and Meyer; curve III represents the data for the pure (m. p. 109–110°) red substance in absolute ethanol; curve II represents the data for a slightly less pure specimen (m. p. 107.5–108.5°, obtained by silver nitrate oxidation of the chroman) in absolute ethanol, while curve I was obtained using a solution of the pure substance (m. p. 109–110°) in absolute ethanol (5 cc.) containing nitric acid (1 cc.) in the proportions in which they are used in the photometric method of analysis. Comparison of the curves shows that the effect of the nitric acid is to decrease the maxima at 4670 and 4500 Å. (curve III) and to produce a new maximum at 4800 Å. (curve I). These effects, however, are not sufficient to account for the curve obtained in the Furter reaction (curve IV), and it appears that in the Furter reaction the yield of the red compound is not quantitative, due either to incomplete reaction or to the slow destruction of the red compound by the nitric acid, a reaction which is known to occur. How-

suggests a number of reactions that the "isodione" should undergo and the investigation will be continued at the first opportunity.

Experimental

Absorption Spectra.—The spectra were taken with a Bausch and Lomb medium quartz spectrograph in conjunction with a Hilger Spekker photometer and a hydrogen discharge tube. The alkaline solutions of "isonorechinocystenedione" were prepared by adding to a solution of 7.1 mg. in 9 cc. of ethanol, 0.1 cc. of 3 *N* aqueous sodium hydroxide and allowing the solutions to stand for fifteen minutes before beginning the photographing of the spectra. In the case of norechinocystenedione, 0.1 cc. of 2 *N* sodium hydroxide in 90% ethanol was added to a solution of 3.9 mg. of the dione in 5 cc. of ethanol. The dilution effect of this addition of alkali was neglected in the calculation of the molecular extinction coefficients.

The preparation of a suitable alkaline solution of norechinocystenone was difficult because of the low solubility of this substance. A clear solution containing 0.1 ml. of a 2 *N* sodium hydroxide solution in 90% ethanol was finally obtained but as the precise concentration with respect to the ketone was uncertain, exact molecular extinction coefficients could not be calculated. The curve therefore is not reproduced although qualitatively it is similar to that obtained in the absence of alkali (maximum at 2930 Å.) and of the same order of intensity.

Isomerization of "Isonorechinocystendione."—A solution of 0.5 g. of the "isodione" and 0.5 g. of potassium hydroxide in 50 cc. of 95% ethyl alcohol was refluxed for one and one-half hours. The solution became yellow in color and later a deep amber. It was poured into water, most of the alcohol removed by boiling and the precipitate filtered. The crude material after drying melted at 169–181° and after three crystallizations from methyl alcohol the melting point remained constant at 199–200°. A mixed melting point with norechinocystenedione, m. p. 200–203°, gave no depression. The specific rotation was $[\alpha]^{24}D$ −93.2° in dioxane compared with the previously recorded value for norechinocystenedione[2] of −92.7°.

Monoxime of "Isonorechinocystenedione."—A solution of 0.5 g. of the "isodione," 0.1 g. of fused sodium acetate and 0.5 g. of hydroxylamine hydrochloride in 75% aqueous ethyl alcohol was refluxed for two hours. Hot water then was added to turbidity and the solution cooled. The crude product weighed 0.44 g. and melted at 248–252° with some decomposition. After four crystallizations from methyl alcohol the melting point remained constant at 254–257° when the bath was preheated to 240°.

Anal. Calcd. for $C_{29}H_{45}O_2N$: C, 79.21; H, 10.33; N, 3.18. Found: C, 79.12; H, 10.28; N, 3.33.

Dioxime of Norechinocystenedione.—To the alkali insoluble material from the saponification of 1 g. of the diketomethyl ester was added 5 g. of hydroxylamine hydrochloride in 10 cc. of water and 20 cc. of 1% sodium hydroxide solution and then methyl alcohol was added until complete solution had taken place at the boiling point. After refluxing for two hours, concentrating and cooling a product was obtained which after four crystallizations from methyl alcohol melted at 248–249°.

Anal. Calcd. for $C_{29}H_{46}O_2N_2$: C, 76.60; H, 10.20; N, 6.16. Found: C, 76.41; H, 9.89; N, 6.28.

Oxime of Norechinocystenone.—The oxime was prepared as above in methyl alcohol solution from 0.045 g. of norechinocystenone, 0.25 g. of hydroxylamine hydrochloride and 1 cc. of 1% sodium hydroxide. The crude product melted at 253–253.5° and the melting point was unchanged on recrystallization from methyl alcohol.

Anal. Calcd. for $C_{29}H_{47}ON$: C, 81.82; H, 11.13; N, 3.29. Found: C, 82.01; H, 10.62; N, 3.45.

Summary

1. The ultraviolet absorption spectra of norechinocystenone and norechinocystenedione confirm the presence of isolated carbonyl groups. That of "isonorechinocystenedione" indicates the absence of carbonyl groups in ether solution but the presence of one or more carbonyl groups in alkaline ethyl alcohol solution.

2. Norechinocystenone and norechinocystenedione form a monoxime and dioxime, respectively, whereas "isonorechinocystenedione" forms only a monoxime.

3. On heating with alcoholic alkali "isonorechinocystenedione" is converted into norechinocystenedione. A possible interpretation of the isomerization is suggested.

CONVERSE MEMORIAL LABORATORY
CAMBRIDGE, MASSACHUSETTS RECEIVED JUNE 16, 1939

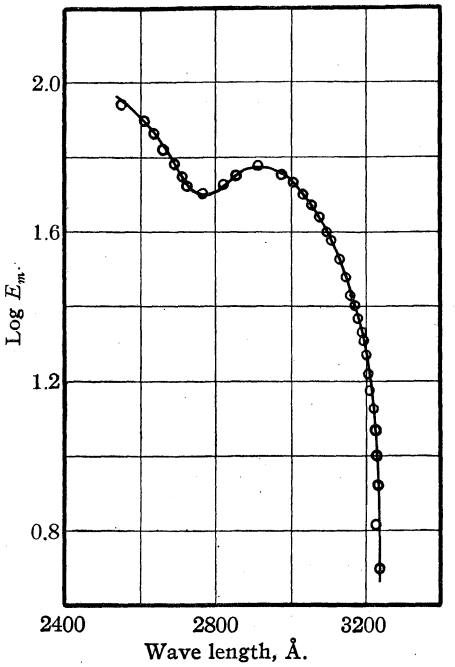

Fig. 1.—Absorption spectrum of norechinocystenone in ethanol.

abnormal behavior cannot be due to a keto–enol type of equilibrium since in the presence of the excess alkali (approximately eighteen moles) one would expect the enolic form to predominate whereas alkali seems to favor the production of the keto form.

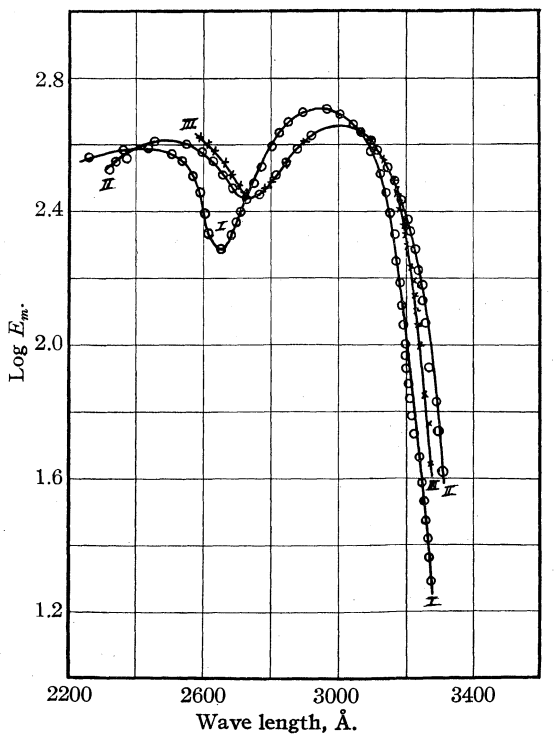

Fig. 2.—Absorption spectra of norechinocystenedione: Curve I in ether, II in ethanol, III in alkaline ethanol.

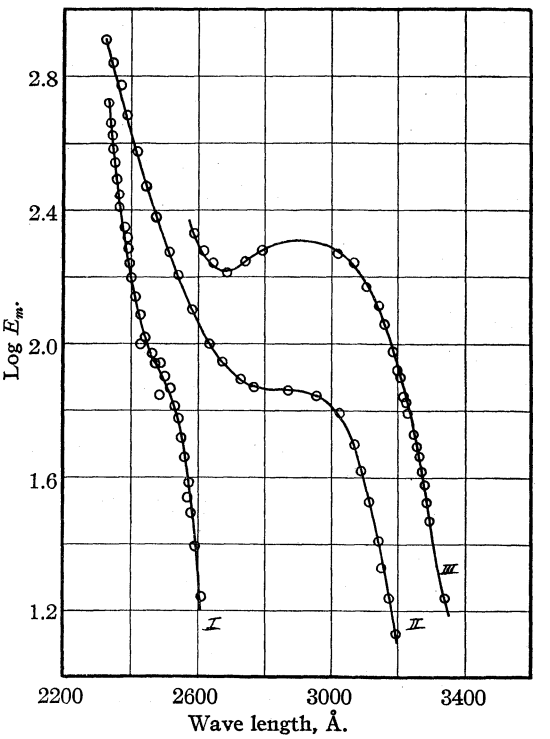

Fig. 3.—Absorption spectra of "isonorechinocystenedione": Curve I in ether, II in ethanol, III in alkaline ethanol.

The above observations led us to return to the chemical investigation of "isonorechinocystenedione." On boiling it with alcoholic potassium hydroxide, it was converted into norechinocystenedione as shown by melting point, mixed melting point and optical rotation. In spite of the spectrographic evidence against the presence of a carbonyl group, the "isodione" reacts with aqueous alcoholic hydroxylamine acidified with acetic acid to give a product the analysis of which is that of a monoxime. Norechinocysteneone and norechinocystenedione give the expected mono- and dioximes, respectively. While the results so far obtained are not sufficient to give a clear picture of the reactions involved, the conversion by alkali of a substance lacking a carbonyl group into a diketone suggests that the "isodione" may be a cyclic hemiacetal of a monoenol form of the diketone. The reaction product with hydroxylamine in acid solution would then be formed by loss of water between hydroxylamine and the hydroxyl group of the cyclic hemiacetal. Such a structure

ether. The ether solution was washed with 5% sodium carbonate solution and evaporated to dryness. The residue was boiled with 5 cc. of ligroin (b. p. 60–70°), the solution decanted and concentrated to approximately 1 cc. Cooling gave needles, m. p. 196–205°. After three recrystallizations from acetone platelets were obtained melting at 211–214°. Neotigogenone when mixed with tigogenone, m. p. 201–207°, melted at 191–205°.

Anal. Calcd. for $C_{27}H_{42}O_3$: C, 78.21; H, 10.21. Found: C, 78.24; H, 9.90.

A solution of 0.0233 g. in 3 cc. of chloroform gave $\alpha = -0.47°$ in a 1-dm. tube; $[\alpha]^{25}D$ −60.6°.

Neotigogenone Oxime.—A mixture of 23 mg. of neotigogenone, m. p. 205–210°, with 0.04 g. of hydroxylamine hydrochloride, 0.46 g. of sodium acetate, 1 cc. of water and 4 cc. of ethyl alcohol was boiled for one hour. Water was added and the mixture was filtered, dried, and recrystallized by dissolving in 7 cc. of acetone, concentrating to 1.5 cc. and allowing to cool slowly. This gave 12 mg. of fine needles which melted with decomposition at 224.5°. Repeated recrystallization from acetone raised the melting point to 231–232° with decomposition.

Anal. Calcd. for $C_{27}H_{43}O_3N$: C, 75.48; H, 10.09; N, 3.25. Found: C, 75.20; H, 9.87; N, 3.33.

Attempted Isomerization of Tigogenin.—One gram of tigogenin, m. p. 200–202.5°, was dissolved in 100 cc. of 95% ethyl alcohol and this was added to a mixture of 66 cc. of 95% ethyl alcohol and 30 cc. of concentrated hydrochloric acid. After heating for thirty-six hours the mixture was concentrated, cooled and filtered. On fractional crystallization from ethyl alcohol almost all of the material was separated into fractions which melted close to the melting point of tigogenin and gave no depression when mixed with tigogenin. However, about 5 mg. of material melting from 189.5–194.5° was obtained from the mother liquors. This gave no Beilstein test for halogen and a mixture with tigogenin, m. p. 206.5–209°, melted at 193–206°.

Summary

A new steroid sapogenin has been obtained which is isomeric with tigogenin and has been named "neotigogenin." It has been isolated as the acetate and characterized by oxidation to a monoketone and conversion of the ketone into the oxime.

Saponins and Sapogenins. XII. The Product of Direct Oxidation of Echinocystic Acid with Dichromic Acid

BY R. NORMAN JONES,[1] DAVID TODD AND C. R. NOLLER

When methyl echinocystate is oxidized with dichromic acid in glacial acetic acid solution, a diketo ester is formed which on saponification loses carbon dioxide to give a diketone, norechinocystenedione.[2] However, if free echinocystic acid is oxidized under the same conditions, one obtains instead of the expected norechinocystenedione an isomeric compound which was believed to be an isomeric diketone and was named "isonorechinocystenedione."

In the hope that a clue would be provided as to the difference in structure of these two compounds we have determined their ultraviolet absorption spectra (Figs. 2 and 3) as well as that of the monoketone, norechinocystenone (Fig. 1). All three compounds contain a carbon–carbon double bond and the nature of the absorption precludes the possibility that this is conjugated with a carbonyl group since such a structure would give an intense absorption band with a maximum near 2350 Å. (log E_m about 4.2) and a second band of lower intensity with a maximum near 3200 Å.[3] An α-diketone is excluded also since such a structure causes absorption in or near the visible region of the spectrum.

Norechinocystenone and norechinocystenedione gave typical carbonyl absorption bands in ethanol (Fig. 1 and Curve II, Fig. 2) with low-intensity maxima between 2900 and 3000 Å. This was not appreciably altered by the addition of alkali (Curve III, Fig. 2) or, in the case of the dione, by changing the solvent to ethyl ether (Curve I, Fig. 2). The second low-intensity maximum in the spectrum of the dione at 2450 to 2500 Å. cannot be attributed to simple carbonyl absorption and will be investigated further.

In the case of "isonorechinocystenedione" it was surprising to find no evidence of carbonyl absorption in ethyl ether (Curve I, Fig. 3). In absolute ethanol, however, it appeared as an inflection (Curve II) which developed in moist alcoholic sodium hydroxide solution into a clearly defined maximum at 2930 Å. (Curve III). This

Saponins and Sapogenins. XI. Neotigogenin, a New Steroid Sapogenin

BY L. H. GOODSON AND C. R. NOLLER

During the course of the preparation of tigogenin acetate using acetic anhydride and pyridine,[1] a low melting fraction was accumulated which appeared to be a mixture of two or more components and could not be separated readily by repeated crystallization. When solutions of this fraction in ethyl alcohol were allowed to evaporate spontaneously, two types of crystals separated, a fine white powder and small regular octahedra. After mechanical separation it was found that the powder was chiefly tigogenin acetate. The octahedra were recrystallized from isopropyl alcohol and were found by melting point and mixed melting point to be a different compound. Analysis of this compound showed that it is isomeric with tigogenin acetate. Saponification of the new acetate gave a sapogenin which, although it has a melting point very close to that of tigogenin, produced a marked melting point depression when mixed with tigogenin. Oxidation of the sapogenin gave a ketone which was not identical with tigogenone[2] so the isomerism does not involve the carbon atom bearing the hydroxyl group. Moreover, the properties of the new compound and its derivatives are different from those of sarsasapogenin,[3] isosarsapogenin,[4] *epi*-sarsasapogenin[5] and smilagenin.[6] The compound does not appear to be related to tigogenin as isosarsasapogenin is related to sarsasapogenin[4] because tigogenin was practically unchanged by boiling with alcoholic hydrochloric acid. This conclusion is only tentative, however, because the tigogenin was altered partially to give a small amount of low melting material, but we have not yet succeeded in isolating the new compound from this altered tigogenin. Because the new sapogenin has been obtained in relatively small amounts and is difficult to isolate, we are unable to state at the present time whether it is one of the original hydrolysis products of the extract of *Chlorogalum pomeridianum* or is formed by isomerization during the acetylation. Because of the uncertainty concerning the seat of the isomerism we prefer to name the new compound "neotigogenin."

Experimental

Neotigogenin Acetate.—The acetylation of tigogenin, m. p. 198–203°, obtained from *Chlorogalum pomeridianum* was carried out at temperatures below 50° using acetic anhydride and pyridine. The yield of easily purified tigogenin acetate in this acetylation varied from 80–85%. The lower melting fractions which were more soluble in ethyl alcohol than tigogenin acetate were collected from several acetylations and combined. Fractional crystallization from ethyl alcohol yielded only a small amount of tigogenin acetate together with fractions melting over ranges of 10 to 30° and as low as 135°. Solutions of these low-melting fractions on spontaneous evaporation at room temperature over a period of weeks yielded two types of crystals, a white powder which appeared amorphous through a low-power microscope and small regular octahedra. The octahedra were separated mechanically and washed with isopropyl alcohol, when they melted at 172–174°. After one crystallization from isopropyl alcohol they melted at 174–176° and further crystallization from this solvent did not change the melting point. Approximately 40 mg. of neotigogenin acetate was obtained from the acetylation of 10 g. of tigogenin.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.94; H, 10.11. Found: C, 76.10, 76.02; H, 10.21, 10.21.

A solution of 0.0414 g. in 3 cc. of chloroform gave $\alpha = -1.01°$ in a 1-dm. tube; $[\alpha]^{25}D$ −73.4°.

When this substance was mixed with tigogenin acetate, m. p. 202–208°, the mixture melted at 163.5–185°.

Neotigogenin.—A solution of 41 mg. of neotigogenin acetate, m. p. 174–176°, and 0.08 g. of potassium hydroxide in methyl alcohol was boiled under reflux for forty-five minutes and then a small quantity of water was added. On cooling needles separated which after recrystallization from 4 cc. of methyl alcohol weighed 35 mg. and melted at 200–203°. Further crystallization from methyl alcohol narrowed the melting point range to 202–203°. Neotigogenin when mixed with tigogenin, m. p. 206.5–209°, melted at 182–188° while a mixture with a sample of sarsasapogenin, m. p. 193.5–197.5°, melted below 140°. Neotigogenin separated with alcohol of crystallization and was dried for analysis at 135° and 2 mm.

Anal. Calcd. for $C_{27}H_{44}O_3$: C, 77.83; H, 10.64. Found: C, 77.96; H, 10.45.

A solution of 0.0537 g. in 3 cc. of chloroform gave $\alpha = -1.16°$ in a 1-dm. tube; $[\alpha]^{26}D$ −64.9°.

Neotigogenone.—To a solution of 72 mg. of neotigogenin (alcohol-free) in 2 cc. of acetic acid at room temperature was added dropwise a solution of 0.012 g. of chromium trioxide in 2 cc. of 80% acetic acid. The mixture was allowed to stand until the solution was a light clear green in color. This was diluted with water and extracted with

alkaline solution of formaldehyde should give a greater increase in the yield of hydrocarbon. This expectation was realized and the following table shows that quite a wide variety of compounds have been deaminated in yields of 50–80%. Some substances such as 2,5-dichloroaniline and anthranilic acid, which are deaminated in the poorest yields by this method, are the ones which succeed best by the time-honored alcohol method. Thus the two processes supplement each other. A typical experiment is described and the table shows the yields obtained with other compounds by using the same procedure.

Experimental Part

Deamination of *p*-Toluidine to Toluene.—A solution of 0.5 mole (53.5 g.) of *p*-toluidine in 150 cc. of concentrated hydrochloric acid and 400 cc. of water was chilled by the addition of 400 g. of ice and diazotized in the usual manner with 36 g. of sodium nitrite. A solution of 100 g. of commercial sodium hydroxide in 600 cc. of water was then prepared and placed with 500 g. of shaved ice into a 5-liter flask which was fitted with a mechanical stirrer. The stirrer was started and 75 cc. of formalin (37% formaldehyde) added. The solution of *p*-tolyldiazonium chloride was then poured in a slow stream into the rapidly stirred alkaline solution of formaldehyde. The rapid escape of nitrogen caused considerable frothing. After all of the diazonium chloride solution had been added the stirring was continued for two to three minutes, after which the stirrer was removed, the mouth of the flask covered with a watch glass and the reaction mixture allowed to stand with occasional shaking for thirty to forty minutes. The toluene in the upper oily layer was then removed by distillation in steam, separated from the water, dried and distilled. The yield of toluene, b. p. 108–111°, was 36–38 g. (78–82%).

TABLE I

YIELD OF DEAMINATED PRODUCTS FROM DIAZONIUM SALTS

Amino compound	Product and % yield	
Aniline	Benzene	60
o-Toluidine	Toluene	80
p-Toluidine	Toluene	80
o-Anisidine	Anisole	75
p-Anisidine	Anisole	72
o-Phenetidine	Phenetole	75
p-Phenetidine	Phenetole	65
2,4-Dimethylaminobenzene	*m*-Xylene	80
p-Chloroaniline	Chlorobenzene	50
o-Chloroaniline	Chlorobenzene	55
4-Aminodiphenyl ether	Diphenyl ether	60
2-Aminodiphenyl ether	Diphenyl ether	60
2-Amino-4′-methyldiphenyl ether	4-Methyl diphenyl ether	50
4-Amino-4′-methyldiphenyl ether	4-Methyl diphenyl ether	50
2,5-Dichloroaniline	*p*-Dichlorobenzene	10
Anthranilic acid	Benzoic acid	25
o-Nitraniline	Nitrobenzene	20
m-Nitraniline	Nitrobenzene	10
p-Nitraniline	Nitrobenzene	10

Discussion.—The addition of the diazonium salt to the alkaline formaldehyde may produce both the *syn* and *anti* diazotates, the former of which might be reduced more rapidly than the latter. However, after the reduction had proceeded for five minutes, reacidification of the solution and again making it alkaline did not increase the yield. Neither was the yield of toluene increased by addition of sodium stannite, zinc dust or ferrous sulfate to the alkaline solution of formaldehyde. The use of alkaline pyrogallol in place of alkaline formaldehyde gave a little toluene but chiefly an azo dye (coupling reaction) with excessive frothing. Since no alcohol is used in the method, the formation of an ether is avoided. The loss of material in each experiment was accounted for by the formation of tarry substances which were chiefly polymers of the aromatic radical and remained in the flask after steam distillation. Replacement of *p*-tolyldiazonium chloride by the sulfate reduced the yield of toluene from 80 to 75% and an increase in the concentration of the sulfate ion by the addition of 1 g. mole of sodium sulfate further reduced the yield of toluene to 55%. The low yield of nitrobenzene from the three nitroanilines is explained by the fact that the nitro group is largely reduced by the alkaline formaldehyde to a mixture of azo compounds. The reaction of phenyldiazonium chloride with alkaline acetaldehyde in place of formaldehyde gave a red dye as reported by Bamberger and Müller.[8] In our experiments the yield of benzene by this reaction was less than 5%.

Summary

The reduction of a number of diazonium salts with alkaline formaldehyde has been found to produce good yields of hydrocarbons. This procedure often gave the best yields of hydrocarbons in cases where the classical reduction with alcohol gave the poorest yields and vice versa. Hence the two methods supplement each other.

LAWRENCE, KANSAS RECEIVED JUNE 30, 1939

(8) Bamberger and Müller, *J. prakt. Chem.*, [2] **64**, 199 (1901).

Acetone precipitation was most satisfactory for the preparation of concentrates. The fraction soluble at 50% but insoluble in 55% aqueous acetone was redissolved in water. This solution had a "Kat. f." of 1800, representing a threefold concentration of the original activity. Stern has used acetone in the preparation of liver catalase concentrates.[7]

A cottonseed extract (*p*H 6.4) was only slightly affected by heating at 50° for thirty minutes. At 60° the catalase was destroyed completely in fifteen minutes, and at 70° no activity remained after five minutes. However, dry ether-extracted cottonseed meats could be heated at 105° for several hours without destruction of the enzyme. Commercial cottonseed meal contained no catalase; this material is generally subjected to a steaming process for twenty to forty minutes prior to the pressing operation.

The activity of concentrates was almost entirely repressed in 0.02 *N* sodium cyanide solution.

During the first forty-eight hours of germination, the catalase concentration of whole seeds increased from 120 to 140% of the original content.

The characteristics of this enzyme are not essentially different from those of other plant catalases.[3] The availability of a plant source of somewhat greater original catalase content should facilitate its further investigation.

(7) K. J. Stern, *J. Biol. Chem.*, **112**, 661 (1935–36).

Summary

Cottonseeds contain appreciably more catalase than do a number of other seeds examined. Some properties of the enzyme have been described.

Reduction of Diazonium Salts to Hydrocarbons with Alkaline Formaldehyde

BY RAY Q. BREWSTER AND JOHN A. POJE

It is well known that the classical method[1] for the reduction of a diazonium salt such as phenyldiazonium chloride or sulfate to a hydrocarbon by reaction with an alcohol produces an ether as well as the hydrocarbon. In most cases the ether is the major product. An experiment by Hantzsch and Jochem,[2] which is typical of many recorded in the literature, produced 1.6 g. of benzene and 34.1 g. of phenetole from the reaction of ethyl alcohol upon 64 g. of phenyldiazonium chloride. Similar results with varying proportions in the yield of hydrocarbon (hydrogen reaction, I) and ether (alkoxy reaction, II) have been obtained by a large number of investigators.[3] The extent to which the reaction between any given diazonium salt and an alcohol will follow one course or the other depends upon the character of the radical (R) and upon the nature of the alcohol. In general the yield of hydrocarbon increases with the

$$RNNCl + C_2H_5OH \longrightarrow RH + CH_3CHO + HCl + N_2 \quad (I)$$

$$RNNCl + C_2H_5OH \longrightarrow ROC_2H_5 + HCl + N_2 \quad (II)$$

substitution of a carboxyl, halogen or nitro group ortho to the diazonium radical, and the hydrogen reaction becomes quite predominant in the case of 2,4,6-tribromophenyldiazonium sulfate where the yield of tribromobenzene[4] is 75–78% of the theoretical quantity. The alcohols used most commonly are methyl and ethyl, of which the latter usually gives the better yield of hydrocarbon. Some experiments using other alcohols are to be found in the literature and they are being extended in this Laboratory.

In the deamination of certain aminodiphenyl ether derivatives in which we were interested, the alkoxy reaction occurred almost exclusively and it was necessary to devise some other method for replacement of the amino group by hydrogen. Inasmuch as the hydrogen reaction involves a reduction of the carbon atom to which the diazonium salt is joined, it would seem that a reducing agent considerably stronger than an alcohol should be used. Such reducing agents as sodium alcoholate,[5] stannous chloride[6] and hypophosphorous acid[7] in certain cases have increased somewhat the yield of the hydrocarbon but it would seem that the more effective reducing action of an

Composition of Cottonseeds. II. Catalase

BY H. S. OLCOTT AND C. D. W. THORNTON

During an investigation of cottonseed proteins, hydrogen peroxide was added to an aqueous extract of cottonseeds in an attempt to bleach the colored extractives. The extensive foaming which occurred suggested that a catalase was present in appreciable amounts. The results of further experiments indicated that cottonseeds contained more catalase than any of several other seeds examined.

The following routine method of assay for catalase activity was used.[1] To 5 cc. of approximately 0.02 *N* hydrogen peroxide solution were added 1 cc. of 0.067 *N* phosphate buffer (*p*H 6.85) and 1 cc. of catalase extract suitably diluted so that 10 to 20% of the peroxide was decomposed in two minutes at room temperature (25–28°). At the end of this period 10 cc. of 10% sulfuric acid was added. The peroxide remaining was determined iodimetrically; 10 cc. of 10% potassium iodide and three drops of 1 *N* ammonium molybdate solution were added, and the liberated iodine was titrated with 0.005 *N* sodium thiosulfate with starch for an indicator.

In most cases parallel determinations were run at four- and six-minute intervals. The computed monomolecular reaction constant diminished with increased time of reaction. Activity indices were calculated from the reaction constant at two minutes rather than from that obtained by extrapolation to 0 time in order to obtain minimum values. The index of catalase activity ("Kat. f." of von Euler and Josephson[2]) was obtained by dividing the reaction constant by the weight of solids added in the catalase extract. Approximate indices were obtained experimentally with crude aqueous extracts of a number of ground whole seeds (dehulled in the case of cottonseed, hempseed, and soybean), and rat and beef liver (Table I). Zeile[3] reported that an extract of pumpkin seeds was one-fifteenth as effective as one prepared from horse liver by the same method. According to Sumner and Dounce[4] the "Kat. f." (0°) of crystalline beef liver catalase is 35,000.

TABLE I

CATALASE CONTENT OF AQUEOUS EXTRACTS FROM VARIOUS SOURCES

Source of extract	Kat. f.
Cottonseed[a]	600
Corn	90
Hempseed[a]	60
Wheat	40
Flaxseed[a]	15
Soybean[b]	15
Rapeseed[a]	1
Beef liver	5,000
Rat liver	3,000

[a] Ether extracted. [b] Petroleum ether extracted.

Ether-extracted cottonseed meats[5] were leached with water to obtain the active enzyme solutions. Preserved with chloroform, the extracts retained their activity for several days at 0°. A number of experiments designed to concentrate the catalase fraction were only partially successful.

In the extraction of catalase from cottonseed meal by dilute acids and alkalies, the most active preparations were obtained with neutral or slightly alkaline extractants. Acids destroyed the catalase activity. Aqueous extracts were most effective at a *p*H of 6.8 to 7.2 (phosphate and borate buffers). However, there was no sharp peak in the *p*H–activity curve; the preparations were almost equally active in the *p*H range 6 to 9.

The addition of ammonium sulfate to 0.6 saturation did not precipitate the enzyme, but at 0.75 saturation most of the activity could be accounted for in the precipitate. During the dialysis procedure used to remove the ammonium sulfate, the catalase content spontaneously decreased so that no marked concentration was effected by this method.

Several attempts to concentrate the enzyme by adsorption on moist alumina[6] were unsuccessful, as was the dioxane precipitation method described by Sumner and Dounce.[4]

The catalase was partially precipitated from its aqueous solution by the addition of an equal part of anhydrous alcohol. With 60% alcohol precipitation was complete. The total activity rapidly decreased in the presence of this solvent.

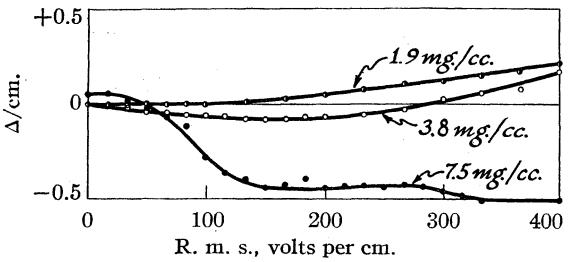

Fig. 5.—The double refraction of several concentrations of tobacco mosaic virus (preparation A) at *p*H 5.1 ± 0.1, plotted as a function of field strength.

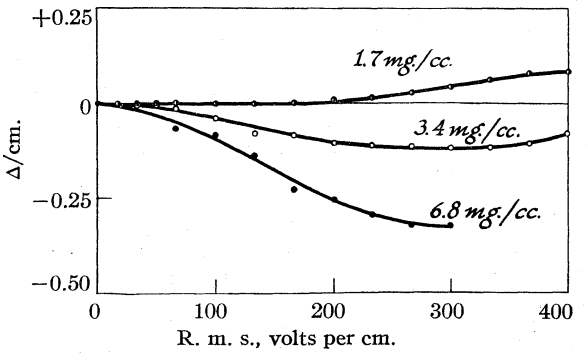

Fig. 6.—The double refraction of several concentrations of aucuba mosaic virus at *p*H 5.2 ± 0.1, plotted as a function of field strength.

higher field strength, just as could have been predicted from the foregoing considerations. By comparing Figs. 3 and 6, it may be seen that, in general, the aucuba mosaic virus responds to the addition of acid in a similar manner. The effect on the inversion point of aging of tobacco mosaic virus at *p*H 5, already described, may be accounted for in a similar manner, for it is known that upon long standing under such conditions the virus undergoes partially irreversible linear aggregation.

The point of view just outlined could be subjected to further tests by studying the phenomenon in viruses with alternating fields of various frequencies. If it is correct, raising the frequency should tend to result in an apparent increase of the negative effect for weak fields and in an inversion point at a higher field strength. It is recognized that many obstacles remain in the path of the complete acceptance of the proposed interpretation of the electrical double refraction of the viruses. Nevertheless, it is hoped that the observations and suggestions herein presented eventually may prove of use in understanding the nature of the electro-optical effect in colloidal solutions.

Summary

It has been found that solutions of tobacco mosaic virus, aucuba mosaic virus, and potato latent mosaic virus exhibit the Kerr electro-optical effect. In dilute solutions in an alternating electric field of 60 cycles, the double refraction of tobacco mosaic virus appears to be positive for all values of the field strength, but for more concentrated solutions the effect becomes negative in weak electric fields, passes through an inversion point for stronger fields, becomes positive for still stronger fields, and finally attains a maximum value. The inversion point occurs at higher field strengths in more concentrated solutions. By bringing the virus nearer its isoelectric point, the negative effect is generally increased and the inversion point is shifted to stronger fields. Aging the virus has a similar effect. In an attempt to explain these observations, it was suggested that two opposing forces control the orientation of the particles. One of these may be a negative orienting effect which varies with the first power of the field strength and which does not follow the alternations of the field. Opposing it and eventually overcoming it in strong fields, there was assumed to be a positive orienting effect, perhaps due to a permanent dipole moment, an effect which varies with the second power of the field strength, but which does follow the alternations of the field, and which is, therefore, affected by interparticle attraction.

PRINCETON, N. J. RECEIVED JUNE 23, 1939

trical double refraction of these materials would seem to be due to the orientation of rod-shaped particles, parallel to the electrical field for the case of positive birefringence, and perpendicular to the field for the case of negative birefringence.

It would seem reasonable to assume that the positive orientation of the virus particles is due, at least in part, to a dipole moment in the direction of the long axis of the rods. In such a case, in sufficiently weak fields, the positive double refraction should be proportional to the second power of the field strength. In order to explain the negative double refraction at low field strengths, it is necessary to assume further that opposing the positive orienting tendency is some negative orienting tendency which is greater than the positive one for weak fields, but which increases less rapidly than the positive effect as the field strength is increased, and which is thereby finally overtaken by the positive effect. This condition would be satisfied if the negative double refraction varied with approximately the first power of the field strength. This would suggest some type of mechanical force, perhaps one associated with the electrokinetic properties of the viruses. However, whatever the nature of the orienting tendencies may be, by postulating a negative tendency proportional to the first power of the field strength which is opposed by a positive tendency proportional to the second power of the field strength, it is possible to explain the existence of negative double refraction in weak fields and positive double refraction in strong fields. In fact, except for the higher values of the field strength, many of the data obtained in this study can be described moderately well by equations of the form, $y = Ax^2 - Bx$. However, the change in inversion point with change of concentration of the virus solutions still remains unexplained. Hence, a consideration of other properties of virus solutions which depend upon concentration becomes necessary.

At concentrations of tobacco virus somewhat greater than the highest shown in Fig. 1, the material is spontaneously doubly refracting, *i. e.*, the particles spontaneously orient themselves parallel to each other in small doubly refracting elements of volume.[16] This means that between the particles there exist forces of attraction which should vary in some manner inversely with the interparticle distance.[17] If the positive orientation of the viruses is due largely to a permanent dipole moment in the direction of the long axis of the particles, it would have to follow the alternations of the field. In such a case, forces of attraction between the particles and actual aggregation of particles should tend to increase the relaxation time of positive orientation. From the estimates of the rotational diffusion constant of tobacco mosaic virus obtained by Mehl,[18] it follows that the critical frequency for the virus is of the same order of magnitude as the frequency here employed. Under such circumstances, an increase in relaxation time will result in a decrease in average positive orientation for a given orienting force. If we assume further that the negative orientation does not follow the alternations of the field, as it should not if it were due to mechanical causes, the negative birefringence should not be diminished by forces of attraction between particles. Hence, the net result of imposing interparticle attraction upon the system should be an apparent increase in the negative double refraction and an inversion point at a higher field strength, all of which would be due mainly to the decrease of the positive birefringence. Dilution of the solution, which results in a decrease of the interparticle attraction, should result in an apparent decrease in the negative effect and a corresponding lowering of the inversion point. As Fig. 1 shows, this is consistent with the experimental observations.

There is considerable evidence[8] which indicates that when a solution of tobacco mosaic virus is acidified to *p*H 5 there is an end to end aggregation of rod-like particles. This has the effect of decreasing the ratio of mean interparticle distance to particle length and should, therefore, result in more interaction between particles. As a matter of fact, changing a relatively concentrated sol from neutrality to *p*H 5 causes it to acquire the properties of a gel. The particles in an acidified solution, then, should have an increased relaxation time and should, therefore, show a retarded positive orientation. By comparing Fig. 5 with Fig. 1, it may be seen that bringing the acidity of a solution of tobacco mosaic virus from *p*H 6.4 to 5.1 results in a general increase of the negative effect and in an inversion point at a

In a superficial way, at least, this phenomenon resembles the magnetic double refraction of ferric oxide sols, known as the Majorana effect, which has been described and studied by Cotton and Mouton.[11] However, the electrical double refraction of the viruses is perhaps more closely related to the behavior of bentonite sols as described by Mueller[5] and by Norton.[6] Norton

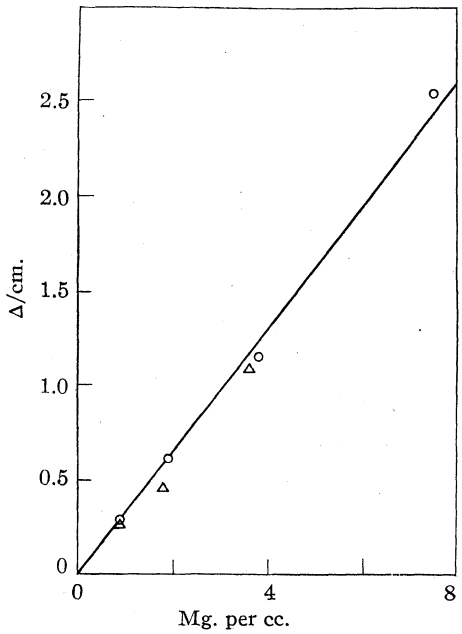

Fig. 2.—The electrical double refraction of tobacco mosaic virus in an electric field of 400 r. m. s. volts/cm., plotted as a function of the concentration of virus: ○, preparation A; △, preparation B.

found that the electrical double refraction of a 1% bentonite sol varied in sign and magnitude with the frequency of alternation of the electric field, it being negative for frequencies up to 630 cycles and positive at higher frequencies. Mueller extended this observation by demonstrating that, at a given frequency, a 1% bentonite sol may show negative double refraction, but that as the sol is diluted the double refraction decreases to zero and finally becomes positive. The transition point varies with the frequency. These observations were made in relatively weak electric fields. It may be seen from Fig. 1 that in fields weaker than 100 volts per cm., the phenomenon here reported seems to be identical with that just described for bentonite sols.

A considerable body of physical evidence, recently reviewed,[12] shows that the particles of tobacco mosaic virus are rod-shaped bodies about 12–15 mμ in thickness and about 400–500 mμ in length. Recent studies with the electron microscope[13] substantiate the conclusions concerning the shape and thickness of the particles and indicate a probable length of about 300 mμ. The amount of double refraction of flow shown by all three of the viruses here studied is about the same,[14] indicating that the conclusions concerning the physical nature of the tobacco mosaic virus probably apply, in general, to the other two. The double refraction of flow of tobacco mosaic virus is always positive, and it has been shown by the author to be due to the orientation of rod-shaped particles which are themselves isotropic or nearly so.[15] In view of these facts, the elec-

Description of the Method and the Materials.—The apparatus used for measuring double refraction resembled somewhat that described by Kunitz.[9] It consisted of a polarizing microscope equipped with a Babinet compensator and external analyzer. A mercury quartz lamp provided with filters which transmit only the mercury 5461 Å. green band was used as the source of illumination. The Kerr cell consisted of a flat-bottomed glass tube 2.5 cm. deep and 1.5 cm. in diameter containing 2 platinum electrodes 5 mm. wide and long enough to reach nearly to the bottom of the tube. In order to facilitate mounting onto the stage of the microscope, the glass tube was fitted into a hollow hard rubber cylindrical housing. The electrodes were firmly held 3 mm. apart by a second housing, which acted as a cap for the first, and were thus permitted to dip into the solution in the glass tube. As a source of potential, 120-v., 60-cycle alternating current was used, and fractional parts of this voltage were obtained by employing the principle of the potentiometer. The voltages actually applied across the terminals of the Kerr cell were measured with a Weston a. c. voltmeter. During the course of actual measurements, the light from the polarizer passed between the platinum electrodes of the Kerr cell in such a manner that the direction of the electric field made an angle of 45° with the plane of polarization of the incident light. With an experimental arrangement of the type described, good comparative data may be obtained on systems showing as much double refraction as that shown by reasonably concentrated tobacco mosaic virus solutions, but no great precision may be claimed for the absolute magnitudes of the quantities measured.

The viruses used in this study were purified by ultracentrifugation and then dissolved in distilled water. Preparation A of tobacco mosaic virus was stored for about two months in the cold at about *p*H 6.5. Preparation B was dialyzed against distilled water and stored for about six months at about *p*H 5. It was brought to neutrality before using. The aucuba mosaic virus was stored for about four months at about *p*H 6.5, and the latent mosaic virus for two months at about *p*H 6.7.[10]

Presentation and Discussion of Results.—The electrical double refraction shown by each of the 3 viruses was determined for electric fields ranging from 0 to 400 root mean square volts per cm. In the case of tobacco mosaic and aucuba mosaic viruses, these measurements were carried out for various concentrations of virus and at acidities near neutrality and near the isoelectric zones. The data are presented in Figs. 1–6. In these figures, field strengths in root mean square volts per cm. or concentration of virus in milligrams per milliliter are plotted as abscissas and displacements in wave lengths per cm. of solution as ordinates. The latter is equal to the quotient of the double refraction divided by the wave length of the light used. An inspection of Fig. 1 reveals that in relatively concentrated solutions of tobacco mosaic virus (preparation A) the electrical double refraction is negative for the lower values of the field strength, but reverses in sign and finally appears to approach a maximum for higher values of the field strength. By simply diluting the solution, the negative effect gradually disappears, until in the more dilute solutions the double refraction appears to be positive for all values of the field strength. Preparation B of tobacco mosaic virus, which had been allowed to age for six months instead of two months as in the case of A, behaved in a manner very similar to that just described, except that the transition points from positive to negative double refraction were more than twice those of the first preparation. However, as may be seen in Fig. 2, the maximum values of the positive double refraction approached by both preparations are approximately proportional to the virus concentration and are the same on a concentration basis. As is revealed by Figs. 3 and 4, the unusual type of reversal found for tobacco mosaic virus is common to all 3 of the viruses examined.

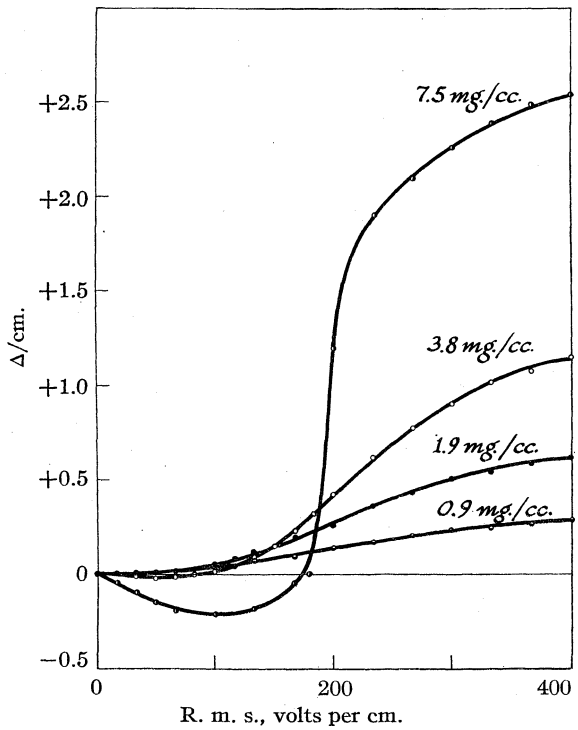

Fig. 1.—The double refraction of several concentrations of tobacco mosaic virus (preparation A) at *p*H 6.4 ± 0.2, plotted as a function of the field strength.

were obtained with benzene and dioxane. Ethanol, glacial acetic acid and acetonitrile were better and only occasionally showed a tendency to form a precipitate. Methanol, dimethylformamide and excess pyridine all were free from this objectionable feature.

Analytical Methods Used.—In the absence of sulfur dioxide, analyses for strong acidity as hydriodic or sulfuric acid were obtained by titration with standard 0.5 *N* sodium hydroxide to a phenolphthalein end-point. The samples were then titrated back to the brom phenol blue end-point with 0.5 *N* hydrochloric acid to obtain a measure of pyridine. This titrimetric procedure was found by control experiments to be reproducible within ±0.2% and to account for at least 99% of the pyridine and inorganic acid added. Sulfate was determined by Raschig's benzidine method[15] and iodide argentimetrically using fluorescein as an adsorption indicator,[16] in both cases removing most of the pyridine by making alkaline to phenolphthalein with sodium hydroxide and boiling for fifteen to twenty minutes before proceeding with the analysis. Free and "periodide" iodine was obtained by thiosulfate titration after acidification to a *p*H of 4. In the presence of sulfur dioxide, the sample was boiled for ten to fifteen minutes with a known excess of standard hydrochloric or sulfuric acid, depending on whether sulfate or iodide was being determined. This modified analytical scheme was applicable to spent Fischer reagent. The alkali and acid titrations of mixtures containing free or "periodide" iodine were made successfully after destroying the iodine with sodium thiosulfate. The presence of this salt and its reaction product, sodium tetrathionate, did not interfere with the double titration procedure for strong acids and pyridine. When analyzing for sulfate and iodide ions, hydrazine hydrate in neutral or slightly alkaline solution was used instead of sodium thiosulfate to reduce iodine.

Summary

1. The stoichiometric relations and mechanism of the reaction of water with Karl Fischer reagent have been investigated.

2. Crystalline intermediates and products of the reaction have been identified by optical crystallographic methods.

3. The nature of a parasitic reaction affecting the stability of the reagent has been clarified.

4. The effect of substituting other amines for pyridine and other solvents for methanol has been investigated.

The Electro-optical Effect in Certain Viruses

BY MAX A. LAUFFER

Introduction

Kerr[1] was the first to observe that many substances become doubly refracting when placed in a strong electrical field, behaving like uniaxial crystals with optic axes in the direction of the field. As a result of the studies of Raman and Sirkar[2] and of Kitchin and Mueller,[3] it is now known that this effect in homogeneous liquids is due to the orientation of molecules. Colloidal solutions containing rod-like or plate-like particles, such as those of vanadium pentoxide, benzopurpurin, ferric oxide, and bentonite, also show the Kerr effect. It is thought that this is due to the orientation of the anisometric colloidal particles. However, the studies of Errera, Overbeek, and Sack[4] on vanadium pentoxide and benzopurpurin sols and those of Mueller[5] and of Norton[6] on bentonite sols show that the phenomenon in colloids is rather complex and not as yet encompassed by a single simple theory.

Bawden and associates[7] first reported that the particles of tobacco mosaic virus can be oriented by an electric field, *i. e.*, that the material exhibits electrical double refraction. This double refraction was reported recently by the author[8] to be positive with respect to the direction of the electric field. However, more detailed studies have substantiated this observation only in part, for it has been found that under some circumstances the electrical double refraction shown by the viruses may be negative. It is the purpose of this communication to describe further studies on the electrical double refraction of tobacco mosaic virus, the closely related aucuba mosaic of tomato virus, and latent mosaic of potato virus.

nary compound, no appreciable thermal change was observed to accompany the mixing of the two binaries, although appreciable heat was evolved during the formation of the individual compounds. The two binary compounds deserve some attention because of the great confusion in the literature regarding their composition and physical properties. Pyridine diiodide was obtained from a 20% solution of iodine in pyridine both by spontaneous evaporation of the solution on a micro slide and also by precipitation by the gradual addition of several volumes of water or hexane. The compound was obtained in glistening orange plates or scales of probable monoclinic symmetry. The crystals decomposed rapidly in air to form a deep brown derivative of greater iodine content, probably $C_5H_5N \cdot I_4$. The compound was more stable under water, hexane or Nujol but gradually darkened. The structure is probably $\left[I \begin{smallmatrix} C_5H_5N \\ I \end{smallmatrix} \right]$,[6] involving an atom of positive monovalent iodine. The identity of the above preparations with a crystalline phase isolated from concentrated Fischer reagent was readily established by measurement of the optic axial angle and observation of the characteristic horizontal dispersion. The compound of pyridine with sulfur dioxide has been formulated both as $C_5H_5NSO_2$[7] and $(C_5H_5N)_2SO_2$.[2] Observations of the melting points in the vicinity of these compositions disclosed a 1:1 compound melting sharply at -4.4 to $-4.8°$ while the 2:1 mixture melting over the range -11 to $-50°$ was obviously not homogeneous. André's 1:1 compound[7] was described as a solid at room temperature, hence was probably polymeric. A small amount of a similar material of unknown composition was obtained on adding about 1% of water to the 1:1 compound.

Nature of Parasitic Side Reactions.—The deterioration of Fischer's reagent on standing was investigated in an effort to discover the reactions responsible and, if possible, prevent their occurrence. Considerable light was thrown upon the side reactions, although no method of inhibiting their progress was found. Chemical analyses of the strong reagent immediately after preparation and after standing for one month disclosed the following facts: (1) essentially complete recovery of iodine as iodide ion regardless of standing time; (2) a pronounced disappearance of both pyridine and total acidity after standing. In freshly prepared reagent, treatment with water and distillation from excess sodium hydroxide permitted a recovery of 97% of the initial pyridine. After standing for one month, similar treatment accounted for only 71% of the pyridine. After the distillation residue became more concentrated, a small amount of distillate with a very sharp amine odor somewhat like piperidine was obtained. This material was alkaline, and reduced potassium permanganate solution rapidly but did not form a crystalline picrate. A considerable amount of brown tarry material remained in the flask. A sample of methylpyridinium iodide distilled with aqueous sodium hydroxide apparently produced the same volatile base, hence it is assumed the methylpyridinium ion was present in both samples. According to Meyer and Jacobson[14] N-alkyldihydropyridines are formed when alkylpyridinium salts are distilled with strong alkali. These are reducing substances. It is not certain whether reaction 5 or 6 is responsible for the formation of the methylpyridinium ion. Reaction 6 is supported by the fact that pyridine and diethyl sulfite on heating reacted sufficiently to give an alkyldihydropyridine on subsequent distillation with alkali.

Substitution of Other Nitrogen Bases for Pyridine.—Separate solutions were prepared by dissolving 42.3 g. of iodine in 50 ml. of methanol and 125 ml. of one of a group of dry nitrogen bases, then cautiously adding 25 ml. of liquid sulfur dioxide to the mixture cooled in a bath of methanol and "dry ice." The solutions were finally made up to 250 ml. with methanol. Each solution was used at intervals to titrate known quantities of water in methanol. The relative stability of the different mixtures was found in this way. The bases tried were quinoline, aniline, dimethylaniline, tri-*n*-butylamine and triethanolamine, with pyridine as a control. All of the above bases had some value as substitutes for pyridine but the reagent employing aniline decomposed almost completely in twenty-four hours. Dimethylaniline was somewhat better. Decomposition of the reagent during preparation was difficult to avoid in the case of triethanolamine. Quinoline and tri-*n*-butylamine closely paralleled pyridine. Other experiments, however, showed that more of the aliphatic amine was required on a molal basis than in the case of pyridine. All of the above amines were analyzed carefully for water content.

Substitution of Other Solvents for Methanol.—Samples of iodine weighing 8.5 g. were each dissolved in 25 ml. of pyridine and 5 ml. of liquid sulfur dioxide carefully added. Each sample was diluted with 50 ml. of one of the following solvents: benzene, dioxane, glacial acetic acid, ethanol, acetonitrile, dimethylformamide, pyridine or methanol. On using these samples to titrate a standard solution of water in methanol, precipitates obscuring the end-point

TABLE I

OPTICAL PROPERTIES AND MELTING POINTS OF CRYSTALLINE COMPOUNDS ISOLATED

Formula	M. p., °C.[a]	Optic axial angle[b]	Optical character	Dispersion	Miscellaneous observations
$C_5H_5N \cdot I_2$	62	$2H_a = 59 \pm 1°$; $2E = 96.5 \pm 1°$	+	$r > v$, moderate; distinct horizontal dispersion	Orange plates elongated $\parallel \alpha$
$C_5H_5N \cdot HI$	231 (slow dec. at 195°)	Uniaxial	−		Compact colorless or pale yellow crystals
$C_5H_5N \cdot HI \cdot I$	193–195	Uniaxial	+		ω & $\epsilon > 1.75$; pleochroism yellow $\parallel \omega$; red-brown to black $\parallel \epsilon$
$C_5H_5N \cdot H_2SO_4$	101–105	$2H_a = 51 \pm 1°$	−	$r > v$, moderate	$\alpha = 1.430^c \pm 0.005$; $\beta = 1.615 \pm .005$
$C_5H_5N \cdot SO_3$		$2H_0 = 135 \pm 10°$	−		$\alpha = 1.470 \pm .003$; $\beta = 1.690 \pm .003$
$C_5H_5N \cdot HSO_4CH_3$	112–117	$2H_a = 24 \pm 1°$; $2H_0 = 135 \pm 5°$		$r > v$, moderate	Needles and plates elongated $\parallel \beta$

[a] Corrected melting points by Kofler–Hilbck micro heating stage. [b] For details regarding this constant see Bryant, THIS JOURNAL, **60**, 1394 (1938). [c] All refractive indices referred to 5461 Å. Hg light at 25 ± 3°.

$(C_5H_5N)_2H_2SO_4$. Repeated attempts to prepare a "neutral" sulfate of pyridine were unsuccessful. Evaporation of sulfuric acid with large excesses of pyridine invariably gave the acid salt, $C_5H_5NH_2SO_4$, confirming the smaller ratios found in the above experiments. Although the absence of methanol did not prevent the removal of the brown iodine color by water, an abrupt change in the actual amount of water absorbed occurred as the molal ratio of methanol to iodine was reduced below one, while above this ratio only minor differences were observed. In the absence of methanol the water absorbed per mole of iodine at the characteristic end-point varied from 1.1 moles, when water was added to the reagent, to 1.9 moles in the reverse process. In the presence of one mole or more of methanol, about 0.7 mole of water was absorbed regardless of the order of mixing. This is preliminary evidence that, (a) the combination of the reagent with water occurs in two stages, and (b) that methanol can replace water in one stage. The nature of the intermediate and final products will be considered in the following section.

Isolation and Identification of Crystalline Phases.—A mixture of iodine, sulfur dioxide and pyridine in the stoichiometric ratios was not homogeneous at room temperatures but contained some $C_5H_5NI_2$ as a solid phase. Even after the addition of sufficient excess pyridine to produce a homogeneous solution, crystalline solid phases were obtained on the addition of water. When water was added directly to this mixture much heat was evolved and a slightly yellowish crystalline phase was obtained consisting of pyridine hydriodide and pyridine hydrogen sulfate. When, however, the reagent mixture was poured slowly onto chopped ice and stirred to prevent local heating, fine buff-colored plate-like crystals were formed. This material was identified as pyridine-sulfur trioxide, and is undoubtedly the intermediate compound predicted in the molal composition studies. In agreement with Baumgarten,[3] the compound was difficultly soluble and stable for an hour or two in ice water. It was converted rapidly to pyridine hydrogen sulfate by hot water and to pyridine methyl sulfate by methanol at room temperature. The action of methanol is evidently much less at 0°, since the "inner salt" was obtained by ice treatment of strong reagent containing up to ten moles of methanol. Vacuum evaporation of partly "spent" reagent also yielded some pyridine-sulfur trioxide along with brown crystals of pyridine hydroperiodide, $C_5H_5NHI \cdot I$.

Identification of the above crystalline materials was made by comparing the optical crystallographic properties with those of the known salts. This did not involve a complete optical study but simply observation or measurement of a sufficient number of optical properties to ensure identification (Table I).

Analytical data for the compounds included in Table I are as follows

Compound	Calculated, %	Found, %
$C_5H_5N \cdot I_2$	I, 76.3	I, 75.4, 75.7
$C_5H_5N \cdot HI$	HI, 61.8; C_5H_5N, 38.2	HI, 62.1; C_5H_5N, 37.4
$C_5H_5N \cdot HI \cdot I$	I, 38.0	I, 38.5
$C_5H_5N \cdot H_2SO_4$	H_2SO_4, 55.4; C_5H_5N, 44.6	H_2SO_4, 53.8; C_5H_5N, 44.5; H_2O, 0.6
$C_5H_5N \cdot SO_3$	SO_3/C_5H_5N, 1.000	SO_3/C_5H_5N, 1.002
$C_5H_5N \cdot HSO_4CH_3$	HSO_4CH_3, 58.7; C_5H_5N, 41.3	HSO_4CH_3, 57.8; C_5H_5N, 41.1

Analyses of $C_5H_5NSO_3$ indicated the presence of a considerable amount of "adsorbed" water. Consequently the observed SO_3/C_5H_5N ratio is given instead of the weight composition.

Chemical Nature of the Reagent.—It was first believed that the active constituents of Fischer's reagent were present as a complex compound of pyridine with sulfuryl iodide analogous to acetylpyridinium chloride formed from pyridine and acetyl chloride. However, all evidence to this effect has so far been negative and the reagent is now believed to be a mixture of the two binary compounds $C_5H_5NI_2$ and $C_5H_5NSO_2$. In addition to the failure to isolate a crystalline ter-

line, aniline, dimethylaniline, tri-*n*-butylamine and triethanolamine can be used although not with equal success. Close to four moles of tri-*n*-butylamine instead of three are necessary. The stability of the reagents prepared with aniline, dimethylaniline and triethanolamine was very poor. All factors considered, pyridine was the most satisfactory base employed.

The principal disadvantage of most organic solvents when incorporated in the reagent is their failure to dissolve the amine salts produced by the action of water. Where salts are thrown out of solution, the end-point is obscured to a serious degree. Only a few solvents were found free from this objection. Methanol, dimethylformamide and pyridine are satisfactory. Ethanol is fairly good but shows some tendency to deposit pyridine hydriodide crystals.

Fischer has discussed applications of his analytical technique in the determination of water in liquids and solids, both organic and inorganic, including benzene, liquid sulfur dioxide, methanol, acetone, petroleum fractions, fuller's earth, hydrated copper sulfate and calcium carbonate.[9] As a result of three years' laboratory experience with the method, the present writers recommend it for the determination of water in the following classes or organic compounds: alcohols, hydrocarbons, including saturated, ethylenic and aromatic types, carboxylic acids (except formic acid) and esters. Some weak tertiary amines can be titrated directly, but a better and more general procedure for amines involves the solution of the amine in an excess of glacial acetic acid of known water content, before titration. On titration with the regular reagent, the behavior of aldehydes and ketones is unsatisfactory due to the formation of acetals and ketals with the large excess of methanol in the reagent and the attendant liberation of water. Rapidly fading end-points and erroneously high apparent water contents are characteristic.[10] By greatly reducing the methanol content and increasing the pyridine in regular Fischer reagent, a modified reagent is obtained which reacts normally in the presence of ketones provided large amounts of the lower alcohols are absent. The writers have confirmed Fischer's surprising observation that the iodine in the reagent shows practically no tendency to react with ethylenic double bonds.

(9) Kaufmann and Funke [*Fette und Seifen*, **44**, 345 (1937)] describe the use of the reagent in determining water in fats.

(10) Fischer's apparent success with acetone is difficult to explain.

Experimental

Preparation of the Reagent.—One-liter quantities of Karl Fischer reagent are prepared by dissolving 84.7 g. (0.33 mole) of Mallinckrodt resublimed U. S. P. iodine in a mixture of 269 ml. (3.3 moles) of pyridine and 667 ml. of du Pont synthetic methanol. The above solution is cooled in a slurry of chopped ice and 64 g. (1 mole) of liquid sulfur dioxide cautiously added. The final dark brown solution is about twice as strong as Fischer employed but is essentially the same in other respects. The water content of the solvents used should not exceed 0.1% since the presence of as much as 6 g. of water per liter will completely exhaust the reagent. (The color of the spent reagent is chromate yellow.) The solution deteriorates rapidly during the first week but more slowly thereafter.[11] The special reagent for use in the presence of ketones is prepared as above but using 860 ml. of pyridine and 90 ml. of methanol per liter instead of the quantities originally specified. A suction-filling reservoir buret[12] protected by calcium chloride towers is the most satisfactory dispensing device.

Standardization of the Reagent.—A supply of dry methanol (<0.1% water) is reserved for the preparation of a standard water solution. Several 10-ml. samples of it are titrated with the unstandardized reagent and the average titer recorded. About 18 ml. of distilled water is weighed carefully into a 1-liter volumetric flask, made up with the methanol and adjusted to volume after standing in a thermostat at 25 ± 1°. Ten-ml. samples of this solution are titrated with the reagent until the brown color of iodine persists. The average titer is recorded. It can be assumed with sufficient precision that this titer corresponds to the aliquot of the water weighed in, plus 98% of the titer of the original methanol. Deduction of the titer due to water originally present with the methanol gives the titer due solely to the added water, which constitutes a standardization of the Fischer reagent. Reference to the uncorrected titer of the water solution now permits a calculation of the water in the final methanol solution. The latter solution is preserved as a standard for daily evaluation of the reagent.

Establishment of the Stoichiometric Composition.—Since the brown color of Fischer reagent evidently is due to the presence of free iodine, its disappearance on the addition of water affords a means of verifying the stoichiometric ratios of the individual constituents of the reagent. Starting with aliquots of a dimethylformamide solution each containing 8.5 g. of iodine (33 mmol.), the relative amounts of the other constituents, sulfur dioxide and pyridine were decreased individually until titration with a molar solution of water in dimethylformamide just failed to discharge the brown color of the solution. The minimum ratios were: $I_2:SO_2:C_5H_5N = 1:1:3$. Fischer's equation corresponds to the ratios, 1 : 1 : 4[13] and is based on the assumption that pyridine forms a "neutral" sulfate,

(11) Little if any loss of strength occurs before the addition of sulfur dioxide, hence it is convenient to store the solution in this form and defer adding sulfur dioxide until a day or two before use. The reagent is conveniently prepared in 3-liter quantities.

(12) Item No. 750, supplied by Eck and Krebs, 131 West 24th St., New York, N. Y.

(13) The regular reagent contains a considerable excess of sulfur dioxide and pyridine, corresponding to ratios of 1:3:10.

Only the first involves water absorption, and the stoichiometric amount of this substance is but half that required for Fischer's reaction 1. The intermediate compound,  , can be isolated,[3] especially if methanol is omitted from the reagent. It was found possible to prepare a modified reagent (without methanol) by which the water absorbed approached the two moles required by equation 1

 (3b)

The general use of such a reagent, however, appears undesirable for the following reasons. First, reaction 3b is not specific for water as is reaction 2 but also takes place with alcohols (reaction 3a) and presumably with other compounds containing active hydrogen. Second, reaction 3b may be used only indirectly since it is not accompanied by a color change. (The indicator action of reaction 2 may be utilized in certain cases to follow the course of 3b.) Third, the water equivalence of the reagent varies greatly with minor differences of technique. Fourth, in the absence of methanol the reagent soon discolors.

By reducing the ratios of sulfur dioxide and pyridine to iodine, until in each case the iodine color no longer could be discharged on titration with a standard water solution, the stoichiometric ratios were found to be $I_2:SO_2:3C_5H_5N$, in support of equation 2. Further it was found that the presence of as much as one mole of methanol per mole of iodine would completely inhibit absorption of the second mole of water according to equation 3b, in support of equation 3a. In addition to the compound  , all of the other products of reactions 2, 3a and 3b have been isolated and identified by comparison with the synthetic materials.

The literature gives little indication of the chemical nature of solutions of iodine and sulfur dioxide in pyridine. Since according to Mellor[4] iodine and sulfur dioxide do not combine appreciably to form sulfuryl iodide

$$I_2 + SO_2 = SO_2I_2 \qquad (4)$$

(3) This substance is really the "inner salt" of pyridinium hydroxide-N-sulfonic acid. It has been prepared previously by other methods. Baumgarten, *Ber.*, **59**, 1166 (1926); **64**, 1502 (1931); **64**, 1582 (1931).

(4) Mellor, "A Comprehensive Treatise on Inorganic and Theoretical Chemistry," Longmans, Green and Co., Ltd., London, 1930, Vol. X, p. 676.

this iodide as such is not regarded as a likely constituent of the reagent although it may possibly be involved in the mechanism.

Binary combinations of pyridine with both iodine[5,6] and sulfur dioxide[2,7] are known, although accounts of their composition are conflicting. The existence of the binary compounds $C_5H_5NI_2$ and $C_5H_5NSO_2$ was verified in this Laboratory and some of their physical constants observed. The composition of the sulfur dioxide compound was established by melting point studies, and the formula $2(C_5H_5N)_2SO_2$ postulated by Karl Fischer shown to be incorrect. It is believed that the iodine and sulfur dioxide in Fischer reagent are present largely as the 1:1 compounds with pyridine. No ternary compounds have as yet been isolated.

While equations 2 and 3a fix the maximum absorption of water by the regular reagent at one mole per mole of iodine, this theoretical efficiency is rarely attained because of side reactions. Freshly prepared reagent is usually equivalent to 70% of the theoretical water but in the course of a month or two its strength falls to about 40%. The side reactions have been found to involve the reduction of iodine to the iodide ion and the formation of quaternary methylpyridinium salts, probably as follows

$I_2 + SO_2 + 3C_5H_5N + 2CH_3OH =$  (5)

or

$I_2 + 2SO_2 + 4C_5H_5N + 3CH_3OH =$  (6)

Contrary to earlier assumptions on this subject,[8] no evidence of the iodination of pyridine has been observed, since practically all of the iodine can be recovered from the spent reagent as iodide. The reagent is so readily standardized empirically that the lack of stability is only a minor consideration in connection with its analytical use.

Substitution of other bases for pyridine in the preparation of Fischer reagent proved feasible although not advantageous. For example, quino-

This equation indicates that titanium is somewhat more effective as a deoxidizer in steel than would be calculated from the equation of Chipman, which gives for the reaction

$$\Delta F^\circ = -151{,}000 + 57.3T$$

The deoxidation constants usually are expressed as the reciprocals of the constants of the deoxidation reactions; *i. e.*, $K = [\%\text{Ti}] \times [\%\text{FeO}]^2$. The values of these constants calculated from the authors' and from Chipman's equations are compared in Table II at several temperatures.

TABLE II

DEOXIDATION CONSTANTS

Temp., °C.	1500	1600	1700
Chipman	8.2×10^{-7}	8.1×10^{-6}	6.2×10^{-5}
Authors	3.2×10^{-9}	4.3×10^{-8}	4.4×10^{-7}

The authors wish to thank Professor J. G. Aston of Pennsylvania State College who made available the standard couple, S-6, for calibration of our calorimeter; Dr. C. S. Barrett of the Metals Research Laboratory of this Institute for the X-ray photographs of the oxide used in this investigation; and Mr. J. W. Stewart, of the same laboratory, for the spectroscopic analysis.

Summary

1. The heat capacity of titanium dioxide (rutile) has been determined from 68–298°K.

2. The entropy of titanium dioxide has been computed from these measurements and found to be 12.45 e. u. at 298.1°K.

3. The thermodynamic properties of titanium dioxide have been evaluated, and applied to the problem of the deoxidation of steel by titanium.

Analytical Procedures Employing Karl Fischer Reagent. I. Nature of the Reagent

BY DONALD MILTON SMITH, W. M. D. BRYANT AND J. MITCHELL, JR.

The determination of water in mixtures by specific chemical methods has become an essential part of analytical chemistry. The senior authors[1] described such a procedure based on the hydrolysis of acetyl chloride in the presence of pyridine. Almost simultaneously another water method of unusual simplicity and range of application but based on a different chemical reaction was described by Karl Fischer.[2] The latter method involves a direct titration of the wet material with a solution of iodine, sulfur dioxide and pyridine in methanol, the reagent serving as its own indicator. The two methods have unique advantages in specific types of analysis, but the general analytical value of Fischer's method is sufficiently great to render desirable a detailed study of its underlying chemistry and a presentation of some of its significant applications.

Fischer has given a good practical discussion of the preparation and use of his reagent but has only briefly outlined the reactions involved. The latter, however, while partly correct as given, do not adequately explain the observed quantitative results. For example, his reaction

$$2H_2O + I_2 + SO_2 \cdot 2C_5H_5N + 2C_5H_5N = (C_5H_5N)_2H_2SO_4 + 2C_5H_5NHI \quad (1)$$

calls for the removal of two moles of water for each mole of iodine introduced, while the writers find that actually about one mole or less of water is removed by the unmodified reagent. In order to shed more light on the mechanism and stoichiometric relations upon which Fischer's method is based, the present paper includes a study of the fundamental molal ratios of the various constituents of the reagent and their relation to water removal. By working with concentrated solutions, crystalline intermediates and products were isolated and identified by optical crystallographic methods. Other bases were substituted for pyridine and other solvents for methanol, and the effect of the various modifications noted.

One of the most interesting results was the discovery that the fundamental reaction occurs in two distinct steps:

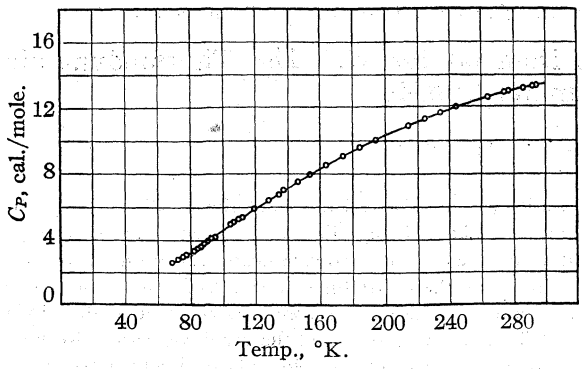

Fig. 1.—Molal heat capacities of TiO_2.

68–175°K. At 68°K., the contribution of the Debye function to the entropy was 1.23 e. u., while that of the two equal Einstein functions was less than the probable experimental error. Between 68–298.1°K., the entropy change was evaluated graphically and amounted to 11.22 e. u. The sum of these values yields 12.45 e. u. for the entropy of titanium dioxide(rutile) at 298.1°K. The accuracy of this figure, with the small extrapolation, is estimated to be within ±0.1 e. u.

Thermodynamic Properties of Titanium Dioxide.—Using accepted[5] values for the entropies of the elements, $\Delta S_{298.1} = -43.18$ e. u. for formation of the oxide. The heat of formation of titanium dioxide has been determined by several investigators, and the latest and apparently most reliable value is that of Neumann, Kroger and Kunz.[6] They find $\Delta H_{298} = -225{,}300 \pm 300$ cal. for formation of the oxide. From this value and the entropy of formation we calculate $\Delta F^\circ_{298.1} = -212{,}430$ cal., for the standard free energy of formation, and thus we can write

$$Ti(s) + O_2(g) = TiO_2(rutile);\quad \Delta S_{298.1} = -43.18 \text{ e. u.};\quad \Delta H_{298.1} = -225{,}300 \text{ cal.};\quad \Delta F_{298.1} = -212{,}430 \text{ cal.}$$

Nasu[7] has studied the equilibrium

$$Ti_2O_3(s) + H_2O(g) = 2TiO_2(s) + H_2(g)$$

and has calculated from these equilibrium measurements, $\Delta H_{298.1} = -4700$ cal.; $\Delta F^\circ_{298.1} = -5280$ cal. Combining these data with those for TiO_2 and $H_2O(g)$ we calculate for the entropy of $Ti_2O_3(s)$; $S_{298.1} = 9.0$ e. u. This value appears much too low for an oxide of this type for which an entropy between 20 and 30 e. u. would be expected. This might indicate some serious error in the equilibrium measurements.

Deoxidation of Steel by Titanium.—Titanium is used occasionally as a deoxidizer in steel and Chipman[8] has attempted to approximate the free energy equation for the deoxidation reaction

$$2FeO(\%\text{ in Fe}) + Ti(\%\text{ in Fe}) = 2Fe(l) + TiO_2(s)$$

From the data on the formation of titanium dioxide, given above, it should be possible to arrive at a satisfactory free energy equation for this reaction applicable at liquid steel temperatures. From the tables by Kelley[9] we find for the reaction: $Ti(s) + O_2(g) = TiO_2(s)$, $\Delta C_p = -5.37 + 6.14 \times 10^{-3}T + 5.788 \times 10^5 T^{-2}$, and in the usual manner express the standard free energy change of the reaction

$$\Delta F^\circ = -222{,}030 + 5.37T \ln T - 3.07 \times 10^{-3}T^2 - 2.894 \times 10^4 T^{-1} + 5.70T$$

In the temperature range, 1500–1800°C., this can be put in the linear form, approximately

$$\Delta F^\circ = -223{,}800 + 41.2T$$

To convert from Ti(s) to Ti(l), the melting point of titanium is taken as 2273°K. and the ΔH of fusion is estimated on the assumption that, like silicon, the entropy of fusion is 5.5 e. u./gram atom at the melting point, from which it follows

$$Ti(s) = Ti(l);\quad \Delta F^\circ = 12{,}500 - 5.5T$$

Evaluation of ΔF° for the change Ti(l) = Ti(% in Fe) presents some difficulty since a compound Fe_3Ti appears in the iron–titanium system and hence in dilute liquid solutions of titanium in iron marked negative deviations might be expected, and the limiting Henry's law value of the activity coefficient, a/N, for titanium must reach a value considerably less than unity. In the study of liquid metal systems from which intermetallic compounds appear as solid phases, one of the authors[10] has shown that a reasonable estimate of the value of this coefficient is of the order of 0.2. Hence, we can write for low concentrations of titanium

$$Ti(l) = Ti(\%\text{ in Fe})$$
$$\Delta F^\circ = -4.58T \log \frac{100 \times 47.9}{0.2 \times 55.84} = -9.5T$$

Chipman[8] has determined the standard free energy change for the reaction: $Fe(l) + \frac{1}{2}O_2(g) = FeO(\%\text{ in Fe})$, for which in the steel-making temperature range: $\Delta F^\circ = -31{,}780 - 1.16T$. Combining the four equations

$$2FeO(\%\text{ in Fe}) + Ti(\%\text{ in Fe}) = 2Fe(l) + TiO_2(s)$$
$$\Delta F^\circ = -172{,}700 + 58.5T$$

The Heat Capacities of Titanium Dioxide from 68–298°K. The Thermodynamic Properties of Titanium Dioxide

BY HUGH J. MCDONALD[1] AND HARRY SELTZ

In an extension of a program of research in these Laboratories on the thermodynamic properties of metal systems, a low temperature calorimeter of the Nernst type has been constructed. In this paper, the results of heat capacity measurements on titanium dioxide from 68–298°K. are described and the entropy of this compound is calculated. From published heats of formation and heat capacities at higher temperatures, the complete thermodynamic properties of the oxide are derived.

Material.—The titanium dioxide used in these measurements was the purest that could be obtained commercially. Spectroscopic analysis showed that the only detectable impurity present was silica. Chemical analysis fixed the amount of this oxide at less than 0.4% and, as the difference between the heat capacity of titanium dioxide and silicon dioxide is small, the error thereby introduced is negligible. There are three allotropic modifications of titanium dioxide, rutile, anatase and brookite, and it was necessary to establish the form of the material used in this investigation from an X-ray powder photograph. Comparison of the X-ray pattern obtained with that of rutile showed perfect agreement for all the characteristic lines.

In order to get the greatest weight of the oxide, which was quite fluffy, into the calorimeter it was pressed into pellets which were ignited in a large platinum crucible for two hours and then broken into small pieces. The X-ray diffraction pattern was not altered by the ignition. The total charge of titanium dioxide used was 87.958 g. (*in vacuo*), or 1.1008 moles.

Apparatus.—The calorimeter used in these measurements was modeled after that described by Gibson and Giauque,[2] and since no significant modifications were made, it will not be described further. The calibrations of the calorimeter and shield windings were made by comparison with copper–constantan couples previously checked against a standardized couple, S-6, which was made available through the kindness of Professor J. G. Aston of Pennsylvania State College. This couple had been calibrated in terms of a helium thermometer.[3] In comparing our couples with S-6 they were soldered with Wood's metal in deep holes in a copper cylinder and electromotive force readings were made with a White double potentiometer over the entire temperature range under conditions comparable to those in the actual measurements. These couples were then soldered in wells in the shield and in the calorimeter and the resistances of the windings were calibrated against them. Frequent checks during specific heat runs have shown no significant variations in the resistances of these windings during the past year. The specific heat measurements were carried out as described by Gibson and Giauque[2] and the usual corrections for heat interchange between the shield and calorimeter were made. The free space in the calorimeter was filled with hydrogen during the measurements and rapid distribution of heat was achieved as indicated by a negligible temperature lag after introduction of the electrical energy. The over-all accuracy of the measurements of the heat capacities of titanium dioxide is believed to be ±0.3%.

Experimental Results

In Table I, the experimental heat capacities for titanium dioxide are given. The conversion from electrical energy to defined calories was made on the basis of 1 calorie = 4.1833 international joules. The results are plotted in Fig. 1.

Calculations

The Entropy of TiO_2.—The method suggested by Kelley[4] was used to extrapolate the heat capacity values from 68–0°K. It was found that

$$C_v = D(306/T) + 2E(670/T)$$

fitted the experimental curve satisfactorily from

On cooling, a bright orange powder formed. This was washed with alcohol and ether.

Anal. Calcd. for $[Coen_2leu]Cl_2$: Cl, 18.66. Found: Cl, 19.26.

This salt was converted to the *d*-bromo-pi-camphorsulfonate through the action of the silver salt. Attempts to crystallize an active salt from water and water–alcohol solutions met with failure, as only glassy solids were formed.

The Reaction between Racemic Propylenediamine and Optically Active Cobalt Salts.—Racemic propylenediamine was added in 100% excess to solutions of $[Co(l\,pn)_2Cl_2]Cl$, $[Co(l\,pn)_2(NO_2)_2]NO_2$, and $[Co(l\,pn)_2CO_3]_2CO_3$ at various temperatures and concentrations. Complete reaction took place in every case. The excess propylenediamine was recovered (by vacuum distillation or steam distillation) as the racemic base, so the two isomers must have entered the complex at equal rates.

The Preparation and Reactions of the Luteo Chromammines.—Triethylenediamine chromic chloride[12] was resolved and converted to the active iodide as described by Werner.[13] The iodide in 0.5% solution showed $[\alpha]^{25}D$ +67°, somewhat higher than the +60° reported by Werner.

Tri-levo-propylenediamine chromic chloride may be prepared in the same way or by the method of Pfeiffer.[14] The latter method gives a good yield only if concentrated (80% or more) propylenediamine is used. The luteo chloride may be converted readily by metathetical reactions to the less soluble and more stable bromide, iodide, or thiocyanate. The iodide was recrystallized from boiling water.

Anal. Calcd. for $[Cr(l\,NH_2CH(CH_3)CH_2NH_2)_3]I_3\cdot H_2O$, 56.61% iodide. Found, 56.43%. For a 0.55% solution, $[\alpha]^{25}D$ −26.04°.

The two luteo salts react with phenylalanine in the same way, so only one experiment need be described. To 6 g. of phenylalanine in 250 cc. of water was added 5 g. of $[Cren_3]Br_3\cdot 3H_2O$, and the mixture was heated on the steam-bath for six hours. The lavender precipitate which formed was filtered from the pink solution and washed with hot water. The yield is nearly quantitative.

Anal. Calcd. for $(C_6H_5\,ala)_2Cr\langle{}^{OH}_{OH}\rangle Cr(C_6H_5\,ala)_2$: Cr, 13.10; N, 7.05. Found: Cr, 13.41; N, 7.23.

The compound is insoluble in hot or cold water and the usual organic solvents. It is easily soluble in nitric acid, but only slightly soluble in hydrochloric and 50% sulfuric acids. The acid solutions slowly turn green, indicating decomposition. In the attempted resolutions, a 100% excess of phenylalanine was allowed to react with $d[Cren_3]I_3\cdot H_2O$ or $[Cr(l\,pn)_3]I_3\cdot H_2O$. The precipitated tetraphenylalanine-diol-dichromium was examined for optical activity in 50% sulfuric acid. None was observed in any case. The filtrate from the lavender precipitate was made basic, the ethylenediamine or levo-propylenediamine steam distilled out, and the residual phenylalanine examined for optical activity. In every case, it was inactive.

Summary

1. The possibility of using optically active complex ions of cobalt and chromium in the resolution of diamines, dibasic acids and amino acids has been investigated. Positive results have not yet been obtained.

2. An improved method of preparing dichlorodipropylenediaminocobaltic chloride is described.

3. The reaction of luteo chromic salts with phenylalanine has been investigated. This is apparently a new type of reaction, and leads to the formation of tetraphenylalanine-diol-dichromium. The insolubility of this compound suggests the possibility of its use in the separation of phenylalanine from other amino acids.

URBANA, ILLINOIS RECEIVED JUNE 12, 1939

(12) Balthis and Bailar, THIS JOURNAL, **58**, 1474 (1936). A much better method of preparing these salts has been devised since this work was done. It will be described in a forthcoming article.

(13) Werner, *Ber.*, **45**, 866 (1912).

$[Cr(l\text{-pn})_3]I_3$ and optically active $[Cren_3]I_3$. The complex compounds containing levo-propylenediamine may offer an advantage over those of ethylenediamine because they do not racemize; the optically active diamine forces a definite configuration upon the complex ion.

The reaction of racemic propylenediamine with the cobalt complexes is a simple penetration reaction, both antipodes of the base taking part with equal readiness

$$2[Co(l\text{-pn})_2X_2]X + d,l\text{-pn} \longrightarrow [Co(l\text{-pn})_3]X_3 + [Co(l\text{-pn})_2(d\text{-pn})]X_3$$

The mixed complex ion doubtless rearranges at once, as Smirnoff[4] has shown. The compound formed when alanine reacts with $[Co(l\text{-pn})_2Cl_2]Cl$ is quite stable, and evidently has the formula $[Co(l\text{-pn})_2(ala)]Cl_2$. Both the *d*- and the *l*-alanine react, and several stereoisomers of the product are possible. Their excessive solubility prevented their separation, however. The reaction of $[Coen_2Cl_2]Cl$ with leucine was studied with the thought that each form of the amino acid might react selectively with one form of the complex ion. This would give rise to two mirror-image isomers, $[Coen_2(leu')]^{++}_D$ and $[Coen_2(leu'')]^{++}_L$,[5] which might be separated by resolution. The two forms of the amino acid could then be recovered from these complexes. Unfortunately, however, the salts are so soluble that all attempts at resolution failed.

The reaction of phenylalanine with the luteo chromic salts is more complicated, as the diamine molecules are completely expelled from the complex

$$[CrA_3]I_3 + C_6H_5CH(NH_2)CH_2COOH \longrightarrow [(Phenylala)_2Cr(OH)_2Cr(Phenylala)_2] + 3A\cdot HI$$

The reaction must take place in steps, so at least the first phenylalanine molecules which react are subject to whatever stereochemical influences the complex may exert. The optically active luteochromic salts did not effect a resolution of the phenylalanine, but the reaction is of some interest because of the insolubility of the tetraphenylalanine-diol-dichromium. It might possibly be used in the separation of phenylalanine from other amino acids. Ley and Ficken[6] have prepared the corresponding glycine and alanine compounds, and report them to be somewhat soluble in water.

(5) leu' and leu'' represent the two mirror image forms of leu.

(6) Ley and Ficken, *Ber.*, **45**, 380–382 (1912).

Experimental

Preparation of $[Co(l\text{ pn})_2Cl_2]Cl$.—The method of Werner and Frolich[7] was modified as follows: 50 g. of cobalt chloride hexahydrate is dissolved in 1200 cc. of water, containing 25 g. of *l*-propylenediamine. The base is resolved according to the directions of Bauman[8] except that calcium hydroxide is substituted for potassium hydroxide. Air is bubbled through the solution for sixteen hours, slowly at first, so as not to sweep out any of the uncoördinated propylenediamine. Twelve hundred cubic centimeters of concentrated hydrochloric acid is added, and the solution concentrated *in vacuo* (at a temperature not above 70°) to 200 cc. On standing at room temperature for a day, 30 g. of the green *trans*-dichloro salt separate. Evaporation of the filtrate to 150 cc. yields another 3 g. of slightly less pure material. The crystals may be purified by dissolving in alcohol and precipitating with ether. The *trans* salt readily may be changed to the gray-purple *cis* isomer by heating to 100° in an acid-free atmosphere. This was not necessary in these studies, as rearrangement to the *cis* form takes place when an amino acid or propylenediamine is introduced into the molecule. The dichloro salt may be changed to the dinitro or to the carbonato salt by treatment with the appropriate silver salt.

The reaction of alanine with $[Copn_2Cl_2]Cl$ was adapted from the directions of Meisenheimer, Angermann and Holsten.[9] A solution of 1.5 g. of alanine in 20 cc. of water was added slowly and with stirring to a mixture of 5 g. of $[Co(l\text{ pn})_2Cl_2]Cl$ and 2 g. of sodium acetate in 30 cc. of water. The solution became blood red at once, but was heated on the steam-bath for one-half hour to ensure completion of the reaction. The extremely soluble salt was obtained in crystalline form by evaporation to dryness, solution in absolute alcohol, and precipitation with ether. The red crystals were kept over phosphorus pentoxide for several days before analysis.

Anal. Calcd. for $[Co(l\text{ pn})_2ala]Cl_2$: C, 29.51; H, 7.15; N, 19.13. Found: C, 29.38; H, 7.52; N, 19.38.

In another experiment the $[Co(l\text{ pn})_2Cl_2]Cl$ was allowed to react with twice the theoretical amount of racemic alanine. The unused alanine was precipitated as the double mercury salt,[10] freed from the mercury by hydrogen sulfide, and recrystallized from water. Slightly more than half of the alanine was recovered. It showed no optical activity.

The reaction of leucine with $[Coen_2Cl_2]Cl$ was carried out in a similar manner. Five and eight-tenths grams of *trans* $[Coen_2Cl_2]Cl$,[11] 3.49 g. of leucine and 1 g. of sodium carbonate were heated together on the steam-bath in 75 cc. of water. Carbon dioxide was evolved slowly, and the blood red color of the carbonato salt gave way to orange-red. After twelve hours, the reaction was apparently complete, and the mixture was evaporated to about 15 cc.

shown[4] that graphite on oxidation with nitric acid and alkaline permanganate furnishes mellitic and carbonic acids exclusively and studies on the behavior of mellitic acid in the bomb, under the same conditions which were used for the oxidation of graphite, showed that 97% of the carbon of a 25-g. sample was converted to carbon dioxide in twenty-four hours.

The method used for isolation of the individual acids, barium salt fractionation, followed by esterification and vacuum fractionation of the esters, was essentially the same as applied to the acids prepared by the action of alkaline permanganate on the Pittsburgh Seam coal. As in that work, it was found that a significant fraction of the methyl esters will not distil under conditions where the least volatile of the esters of the benzene carboxylic acids, the hexamethyl mellitate, distils rapidly.

Summary

Several types of carbonaceous materials, ranging in rank from an Illinois bituminous coal to artificial graphite, have been oxidized to simple acids by oxygen at elevated pressures, at temperatures of 200 to 250°, in the presence of aqueous alkali. With the lower rank materials a significant fraction of the carbon can be recovered as simple organic acids. From the materials of rank higher than a low temperature coke, decreasing recoveries of organic acids are obtained, and with graphite the soluble products consist almost exclusively of carbonic acid. The effects of temperature, time, oxygen partial pressure, catalysts, surface, and nature of the alkali on the course of the oxidation of a Pittsburgh Seam coal have been studied. Oxalic, trimellitic, pyromellitic, prehnitic, and terephthalic acids have been identified. A significant fraction of the acids forms non-distillable methyl esters, indicating the presence of structures more complex than the benzenecarboxylic acids.

The Stereochemistry of Complex Inorganic Compounds. IV. The Introduction of Racemic Organic Molecules into Some Optically Active Complex Ions of Cobalt and Chromium[1]

BY JOHN C. BAILAR, JR., C. A. STIEGMAN, J. H. BALTHIS, JR., AND E. H. HUFFMAN

The penetration of a molecule of an optically active diamine, dibasic acid or amino acid into an optically active complex of the type $[MA_2X_2]$[2] offers several stereochemical possibilities. In some cases, all of the possible stereoisomers of the reaction product are realized. Thus, levo-1,2-*trans*-diaminocyclopentane reacts with racemic dichlorodiethylenediaminocobaltic chloride, $[Coen_2Cl_2]Cl$, to give both the D and the L forms of $[Coen_2$-*l*-Cptdn$]Cl_3$.[3]

Sometimes, however, the entrance of the new group takes place only in certain preferred ways; this gives part, but not all, of the possible stereoisomers. The reaction of racemic diaminocyclopentane with racemic dichlorodiethylenediaminocobaltic chloride gives only two of the four possible isomers; each of the antipodes of the $[Coen_2Cl_2]Cl$ reacts preferentially with one form of the diaminocyclopentane. This effect is certainly not absolute, and may be very slight. It suggests, however, that the reaction between an optically active complex and an *excess* of a racemic coördinating substance might be selective to some extent—that is, that the complex might accept one antipode of the coördinating material preferentially, thus effecting a resolution. Some studies of this possibility are reported here. The results indicate that the preference of the complex for one antipode over the other is slight in these reactions.

The reactions studied were those of propylenediamine and alanine with cobalt complexes containing two molecules of levo-propylenediamine, that of leucine with dichlorodiethylenediaminocobaltic chloride, and that of phenylalanine with

(2) The following symbols are used in this paper: M = metal ion, A = coördinating group occupying two corners of the octahedron, X = an acido group occupying one corner, en = ethylenediamine, pn = propylenediamine, Cptdn = 1,2-*trans*-diaminocyclopentane, Hala = alanine, Hleu = leucine. D and L refer to the dextro and levo configurations of the complex ion, and *d* and *l* to the configurations of the "A" groups.

(3) Jaeger and Blumenthal, *Z. anorg. allgem. Chem.*, **175**, 161–230 (1928).

teristic; those prepared at 200° were deep brown and contained acid precipitable products, "humic acids"; those from the 250° oxidations were pale yellow and no acids precipitated on acidification; while those formed at 225° were intermediate in color and showed variable behavior on acidification.

The data on the effect of oxygen partial pressure at a constant temperature of 225° and an oxidation period of twenty-four hours indicate an increase in rate of formation of carbon dioxide with higher oxygen partial pressures.

Replacement of the potassium hydroxide by sodium hydroxide was found to reduce the rate of oxidation markedly; the fraction of the carbon converted to carbon dioxide was 25% lower at the end of twelve hours. It seems probable that this is due to differences in solubility of the sodium and potassium salts of the organic acids formed in the early stages of the reaction, where the rate of oxidation must be greatly affected by the rate at which fresh coal surfaces are exposed by solution of the initial oxidation products.

Five out of the six equivalents of potassium hydroxide could be replaced by equivalent amounts of calcium hydroxide without adverse effect on the reaction rate. With calcium hydroxide alone only a small fraction of the carbon of the coal, less than 3%, was converted to soluble products, under the same conditions where complete conversion took place with potassium hydroxide.

The distribution of the carbon of a Pittsburgh Seam coal, among the various oxidation products, as a function of time, was studied in detail. The results, which are shown in Fig. 1, are similar to those obtained with oxidizing agents such as nitric acid and alkaline permanganate.

The results of a study of the behavior of several different types of carbonaceous materials, using a standard oxidation procedure, are summarized in Table II. Under these conditions all of the coals investigated and the 500° coke can be oxidized completely to water-soluble products. The 700° coke, the high temperature coke, and the pitch are incompletely oxidized and the soluble products consist largely of carbonic acid. In the case of graphite, carbonic acid is the only soluble acid present in significant amounts. It has been

[a] The sources of these materials are given in ref. (4). Oxidized for twenty-four hours at 250°; estimated oxygen partial pressure 137 lb. (9 atm.); −200-mesh, 50-g. sample, except where noted.

The tetramethyl ester of pyromellitic acid (1,2,4,5-benzenetetracarboxylic acid), was isolated from the ester fraction distilling at 125° prepared by the action of diazomethane on the fraction of acids forming barium salts insoluble in water and acetic acid, but soluble in formic acid; m. p. 141°.

Anal. Calcd. for $C_{14}H_{14}O_8$: C, 54.19; H, 4.52. Found: C, 53.90; H, 4.73.

Results and Discussion

Early in the work it was found that the rate of oxidation, measured by the amount of carbon dioxide formed per unit of time, was relatively independent of the weight of coal present. This indicated that the rate was determined by some constant factor, and in view of the rather low oxygen partial pressure employed and the correspondingly low solubility of oxygen, it appeared that the oxidation must be taking place chiefly at the gas–liquid interface and that the area of this interface was the rate controlling factor. Experiments in which the area of this interface was increased by the introduction of packing material confirmed this analysis and showed definitely increased reaction rates, and, as was to be expected, the packing was much more effective at lower oxygen partial pressures (see Table I). The packing consisted of 69 pieces of 2.5 × 20 cm. 6-mesh monel screen twisted into stick form, 6 mm. in diameter.

[a] −200 mesh, 50-g. sample; 350 cc. water; 335 g. potassium hydroxide or its equivalent. [b] Values represent single measurements except where otherwise noted. [c] Packing was used in all experiments except where otherwise noted. [d] Mean of 30 oxidations; all values within ±2% of mean. [e] Mean of 2 oxidations. [f] Mean of 3 oxidations.

In a study of the effect of the addition of various anions and cations upon the course of the reaction, 5 g. per 50 g. of coal of the following substances was used: copper sulfate, silver sulfate, zinc sulfate, mercuric chloride, titanium sulfate, cerium sulfate, thorium nitrate, antimony trichloride, chromic sulfate, tungstic acid, uranium nitrate, selenium, manganous sulfate, ferrous sulfate, nickel nitrate, cobalt sulfate, potassium permanganate, potassium chromate, and sodium nitrate. The values for percentage carbon converted to carbonic acid in the oxidations when additions were made did not vary more than a few units from the average of those without additions, run under identical conditions, except in those experiments where copper or cobalt salts were used. Two experiments with addition of copper sulfate gave 79.3 and 78.5% carbon converted to carbonic acid, and one experiment with cobalt sulfate gave 66.7%, as compared with 49.5% for the average of experiments without catalysts. Unfortunately these catalysts appear to have little effect on the rate of initial oxidation of the coal, but accelerate markedly the conversion of the soluble acids to carbon dioxide and water. When an attempt was made to preserve the soluble acids by shortening the oxidation period, considerable coal remained unattacked. The catalytic effect of copper and cobalt also was observed in oxidations of cokes. A 500° coke gave 61.3 and 91% for uncatalyzed and copper-catalyzed reactions, respectively; a 700° coke, 59.8 and 86.8%. No effect was found with graphite.

The oxidations at 200, 225 and 250°, at an approximately constant oxygen partial pressure, showed that the effect of increased temperature was most marked in the later stages of the reaction, after the coal had been largely converted to the alkali-soluble "humic acids." At 200° the amount of soluble carbon and the carbonate carbon both remained nearly constant over the last twelve hours; at 225° there was definite evidence of attack on the "humic acids," over the same period; and at 250°, there was a large increase in the fraction of the carbon appearing as carbon dioxide, with a corresponding marked drop in the carbon in the form of organic acids. The color of the alkaline solutions of the oxidation products obtained at the different temperatures, as well as their behavior on acidification, were very charac-

so that even during oscillation the end of the pressure line was above the liquid level in the bomb. Bomb and pressure tubing were filled with 100–300 pounds (7–21 atm.) of oxygen, depending upon the final pressure to be used, before starting heating or agitation. After the bomb reached the desired temperature the full oxygen pressure was applied and agitation started. The temperature of the bomb was measured by a chromel–alumel couple placed in a well extending from the head to the middle of the bomb. Temperatures were maintained constant to ±2° by a Leeds and Northrup controller.

Total pressures were measured with a Bourdon tube gage placed in the oxygen inlet line near the trap. Oxygen partial pressures were calculated by taking the difference between total gage pressure and the aqueous vapor pressure, at the temperature of the oxidation, of a sodium hydroxide solution of equivalent concentration to the potassium hydroxide actually used, since no data are available for the latter. For this reason the absolute value of the oxygen partial pressure is somewhat uncertain.

In the preliminary experiments the rate of the reaction was followed by oxygen absorption, in the later ones, analytically, through examination of the products formed at the end of definite time intervals.

The analytical procedure was as follows. After cooling, the alkaline solution from the bomb was drained into a 2000-cc. volumetric flask, and bomb, head, and packing material, when used, were washed carefully and the washings and contents of the bomb combined in the volumetric flask, made up to volume and mixed thoroughly. After standing to permit any insoluble matter to settle to the bottom of the flask, which in most cases consisted of inorganic material, aliquot portions were withdrawn from the clear supernatant liquid for determination of total carbon, carbonate carbon, oxalate carbon and, in a few cases, carbon in the form of volatile acids. The volatile acids were never found to constitute more than 1 to 2% of the carbon of the material oxidized and in the later experiments this determination was omitted. The methods used for the determination of the various forms of carbon have been described in a previous publication.[6]

The greater part of the work was done with a Pittsburgh Seam coal, Edenborn Mine, but for comparison oxidations were also carried out on Illinois No. 6, High Splint coal, Pocahontas No. 3, a Pennsylvania anthracite, 500° and 700° cokes, prepared in this Laboratory from the Pittsburgh coal, a commercial high temperature coke, Acheson electrode graphite, and a pitch from a high temperature carbonization process.[7]

In order to obtain sufficient material to examine the aromatic acids in detail, eleven oxidations of Edenborn coal were carried out. Fifty grams of −200 mesh coal was treated at 225° with an oxygen partial pressure of approximately 380 pounds (25 atm.), total pressure 600 pounds (40 atm.), for a period of eighteen hours. The alkaline solution from the bomb was filtered to remove insoluble material, chiefly inorganic, the filtrate was neutralized with sulfuric acid, and excess acid added until the concentration was about 3 *N*. This acid solution was treated with manganese dioxide in an amount about twice the theoretical required to oxidize the oxalic acid present. The excess manganese dioxide was filtered off, the filtrate and washings concentrated to 1500 cc. and the acidity again adjusted to about 3 *N*. A total carbon determination at this point showed, on the average, 85% of the carbon present which was previously calculated to be aromatic from the analytical data, so that presumably this method of removal of oxalate also attacks some aromatic carbon.

This solution was then subjected to ether extraction in a continuous extractor[8] for a period of a week. Of the aromatic carbon which was placed in the extractor an average of 80% was recovered in the seven-day extraction. The greater part of this was recovered in the first twenty-four hours.

The yield of aromatic acids actually obtained in this way, from 50 g. of Edenborn coal, ranged from 15 to 20 g. They were orange to pale yellow in color; slightly hygroscopic; easily soluble in water, except about 1%, which was found to be terephthalic acid; easily soluble in acetone and alcohol; moderately soluble in ether and ethyl acetate, and almost insoluble in benzene.

A sample from a 225°, twenty-four hour oxidation, dried to constant weight at 85°, showed the following average properties: C, 51.91%; H, 2.87%; N, 0.45%; S, 1.03%; residue on ignition, 0.58%; equiv. wt., by titration using phenolphthalein, 73.1; mol. wt. by boiling point elevation in acetone, 230. This average composition, except of course for nitrogen and sulfur, is close to that of a benzenetricarboxylic acid: C, 51.41%; H, 2.85%.

The yellow color was found to be a function of the severity of the oxidation treatment, lighter colored acids resulting from prolonged treatment. Samples of the more deeply colored acids had higher average equivalent and molecular weights ranging up to 76 and 260, respectively.

The methods of barium salt fractionation, esterification and vacuum fractionation of the esters were like those previously described,[6] except that a somewhat more effective design of molecular still was employed and longer time periods were used for distillation of the ester fractions. Terephthalic acid (1,4-benzenedicarboxylic acid), because of its relative insolublity in water, was separated readily before the barium salts were formed. Trimellitic acid (1,2,4-benzenetricarboxylic acid) was found in the water-soluble barium salt fraction and was purified by crystallization from concentrated nitric acid, followed by vacuum distillation. The purified acid melted 215–225°, was converted to the anhydride by heating at 250° and the anhydride vacuum distilled. The m. p. of the anhydride was 166°.

(8) Discussed in ref. 6.

If oxygen is present in the fluid, the discharge leads to activation, with formation of hydrogen peroxide or direct chemical reaction of activated oxygen with certain compounds present in solution such as aminophthalichydrazide. Sonic chemiluminescence then results, as shown by Flosdorf, Chambers and Malisoff.[6] Sonoluminescence is remarkably independent of substances dissolved in the water phase but is quenched by high vapor pressure of water (from rise in temperature) or by specific volatile organic compounds.

Oxidation of Carbonaceous Materials to Organic Acids by Oxygen at Elevated Pressures[1]

BY R. C. SMITH, R. C. TOMARELLI AND H. C. HOWARD

Coals, cokes, and pitches yield significant amounts of organic acids when subjected to controlled oxidation with oxidizing reagents such as alkaline permanganate and nitric acid,[2] and small amounts of aromatic acids have also been isolated from oxidation products formed by the action of air, at elevated temperatures and pressures, upon suspensions of coal in aqueous alkali.[3]

In the present investigation oxidations were carried out in aqueous alkali at temperatures from 100 to 250° and oxygen partial pressures from approximately 100 to 375 pounds (7–25 atm.). Below 225°, reaction rate was very slow. Bituminous and anthracite coals and low temperature coke can be oxidized completely to carbon dioxide and water or to any desired intermediate stage. High temperature coke and graphite are partially oxidized under the same conditions, 50–60% of the carbon appearing as carbon dioxide, but much smaller amounts of organic acids are recovered. In the case of graphite no significant amount is obtained because mellitic acid is the principal organic acid formed in the oxidation degradation of these higher rank carbonaceous materials,[4] and it has been found to be unstable under the conditions of this oxidation.

Increase in area of gas–liquid interface, by introduction of packing material into the bomb, has been found to increase significantly the reaction rate in the early stages of the degradation.

Of some nineteen different catalysts investigated, only copper and cobalt salts affect reaction rate significantly, and these chiefly in the later stages of the oxidation.

Carbon balances show that under the proper conditions approximately 50% of the carbon of bituminous and anthracite coals can be converted to water soluble organic acids, the rest of the carbon appearing as carbon dioxide. Of the carbon recovered in the form of organic acids about one-fourth is oxalic acid and the balance aromatic acids. The actual amount of the latter recovered by oxidation of a Pittsburgh Seam coal was 30–40 g. per 100 g. of coal.

Experimental.—The oxidations were carried out in an all-nickel bomb of 1-liter capacity of identical design with those supplied for hydrogenation,[5] except that a silver gasket was used. The bomb was heated externally by an electric furnace and agitated in the usual way by oscillation approximately 30° above and below the horizontal, about a transverse axis. Oxygen was introduced through a spiral of high pressure tubing from an oxygen reservoir of constant pressure. Since maintenance of the oxygen partial pressure depended upon absorption of the carbon dioxide formed, the amount of coal oxidized at one time was limited primarily by the amount of alkali which could be introduced. The maximum amount of coal which could be used was 50 g. and with materials of higher carbon content such as graphite it was necessary to reduce the size of the sample. The material to be oxidized was ground to −200 mesh and in most cases was suspended in a solution of 335 g. of potassium hydroxide in 350 cc. of water. In a few oxidations the potassium hydroxide was replaced by equivalent amounts of sodium hydroxide or calcium oxide.

In the early experiments considerable difficulty was encountered with the alkaline solution working back into the pressure tubing which supplied the oxygen. To prevent this a trap was provided in the pressure line just before it entered the head of the bomb and the line was continued inside the bomb and turned upward at the tip,

ment shows conclusively that aggregation and coalescence of the gas bubbles cavitated by other means than supersonic does not lead to luminescence.

Duration of Sonoluminescence.—In order to determine whether any substance is produced with which luminescence is associated and which persists for even a short fraction of a second, the flow method of Hartridge and Roughton[28] was adopted. Water from the faucet flowed through a glass tube of 0.78 cm. internal diameter, touched to the oil over the vibrating crystal. With no flow, a faint sonoluminescence of water appeared in the tube. With increasing flow the light became brighter and remained bright up to a certain maximum flow when it began to flicker, first appearing then disappearing over the crystal. A slightly faster flow quenched the light permanently and there was no return of light until the rate of flow had decreased considerably. The fastest rate, just before the light permanently disappeared, corresponded to 100 to 150 ml. per second. For a diameter of 7.8 mm. this means that a column of fluid 200 to 300 cm. long would move past the crystal in one second. *The luminescence never spread even a few mm. beyond the edge of the crystal* so that it could not have persisted over 0.001 second.

By fusing a side-tube connected to a pressure gage to the flow tube it can be shown that the increased luminescence with low rates of flow is due to a slight increase in pressure (0.3 to 1.3 atm.) and the disappearance of the light at a certain rate of flow is due to increase in pressure to above 1.3 atm., which is itself sufficient to prevent cavitation and consequently luminescence (see next section). The disappearance of luminescence is not due to the velocity but to the pressure of water in the tube and we can say that there is no persistence of sonoluminescence with any rate of flow that can be attained by a pressure that allows cavitation. Luminol solution pumped through the glass tube over the crystal also shows no persistence of luminescence with a flow velocity of 130 cm./sec. The luminescence is brighter when the fluid is under slight pressure.

Pressure and Luminescence.—A study of the effect of pressure on sonoluminescence becomes a study of the effect of pressure on cavitation. A pressure chamber was constructed (Fig. 1) which consists of a brass tube with a glass test-tube sealed in one end with picene. At the other end is a cap with stopcock and at the sides a pressure gage and pressure piston are soldered on. The pressure apparatus is completely filled with water and the stopcock closed. By turning the screw thread of the pressure piston any desired pressure can be obtained. It must be emphasized that under these conditions the gas dissolved in the water in the pressure chamber is in equilibrium at atmospheric pressure and not at the pressure indicated by the gage. It was found that the luminescence (and cavitation) becomes intermittent at about 1.3 atm. and disappears at pressures above this figure. The light shifts to the top of the tube just before going out. When the pressure is decreased from above 1.3 atm., light does not again appear until it has reached about 0.8 atm. At slight pressure (0.3 to 1 atm.) the light is brighter than with no pressure. This optimum pressure for sonoluminescence above atmospheric pressure, can be compared with the optimum pressure for supersonic cavitation to produce emulsification, observed by Bondy and Söllner.[29]

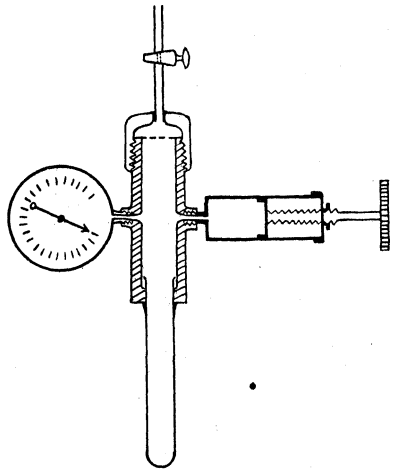

Fig. 1.

Under reduced pressure (in equilibrium with air at the same pressure) sonoluminescence of water is apparent until 31 cm. is reached, when no more luminescence appears and no cavitation is visible.

The sonic chemiluminescence of aminophthalichydrazide behaves under pressure as does the sonoluminescence of water since both are dependent on cavitation. The important fact is the increased luminescence under slight pressures.

Conclusions

The fact that sonoluminescence of pure water and bromine water occur in nitrogen but not in hydrogen is strong evidence for the view that the light is not the result of oxidation but is connected with the development of balloelectric potentials, since these are known to be large in nitrogen and small in hydrogen. The occurrence of luminescence in pure nitrogen shows definitely that activation of dissolved oxygen is not involved. No facts are directly opposed to the balloelectric discharge theory of sonoluminescence. We may therefore picture the minute bubbles of cavitated gas as developing a considerable electrical charge. When they collapse their capacity decreases and their voltage rises until a discharge takes place in the gas of the bubble, giving rise to a weak luminescence. The discharge may be thought of as occurring near the instant of complete collapse. Since velocity of collapse of the bubble would be favored by slightly increased hydrostatic pressures, it is not surprising to find the sonoluminescence intensity increased under slight pressures.

tetrachloride, chloroform, *o*-xylene, nitrobenzene, benzyl alcohol, paraffin oil, olive oil, *n*-butyl phthalate, bromoform and bromobenzene did not affect the sonoluminescence of water. With carbon disulfide in water the luminescence was brighter than with pure water alone.

When the above compounds are added to luminol solutions which are subjected to the supersonic field, only ethyl butyrate, aniline, benzene and ethyl ether completely quench the chemiluminescence. In chloroform and carbon tetrachloride the sonic chemiluminescence persists. This is due to the liberation of chlorine, as noted by Schmitt, Johnson and Olson[3] in their study of chemical effects of supersound waves.

A survey of the liquids, non-miscible with water, which quench the sonoluminescence of water shows no obvious relation to other properties. The dipole moment may be zero or high and the vapor pressure at 20° may be great or small. Since the development of balloelectric potentials as well as electrical discharges in gases is markedly affected by various conditions, which have been incompletely investigated, it is not surprising to find a quenching of sonoluminescence by certain vapors.

Sonoluminescence of Halogens.—Of the many substances added to water and tested for luminescence at 20° during the present investigation, only bromine water emits a strikingly bright light (comparable to that of luminol) when subjected to supersonic fields. This is true even when saturated bromine water of a deep brown red color is tested. It is especially bright at 0° and faint at 40°. No luminescence was observed in pure bromine. Iodine dissolved in potassium iodide or in water does not luminesce in the supersonic field with any greater brightness than water at the corresponding temperatures, but chlorine water, although about as bright as distilled water at 20°, is decidedly brighter than pure water at 0°. Chlorine water and iodine dissolved in potassium iodide are very very faint at 40°. Just as in the case of pure water, the luminescence of these halogens is brighter the lower the temperature. When salts of these halogens are tested in dilute water solutions (sodium chloride and bromide, potassium iodide), the sonoluminescence intensity is like that of pure water.

The cause of the sonic luminescence of bromine water is of special interest. First it may be noted that bubbling oxygen or ozone through chlorine water, bromine water, or iodine in water does not result in the emission of light either at 20 or at 0°, nor does the addition of hydrogen peroxide to chlorine water, bromine water or iodine water, either with or without a catalyst (platinum black). There is also no visible luminescence at an anode of bright or platinized platinum when bromine water in dilute sulfuric acid is electrolyzed with potentials of 1.5 to 6 v. although the acid bromine water emits a bright sonoluminescence. Therefore the luminescence does not appear to be connected with any source of active oxygen.

A similar conclusion is reached from a study of dissolved gases. When pure hydrogen was bubbled through distilled water and over bromine to flush out the oxygen and the two then mixed in a hydrogen atmosphere and subjected to a supersonic field, the bromine water gave no trace of luminescence. However, if the same experiment is carried out with pure nitrogen, the sonoluminescence in bromine water is just as bright as in air. Luminescence of the bromine cannot therefore be due to any reaction involving oxygen and must be a phenomenon similar to the sonic luminescence of water. Unfortunately no lines can be detected in the spectrum of the bromine water sonoluminescence but only a very faint band in the yellow region.

We now may inquire in more detail into the conditions under which luminescence may accompany cavitation of gas from liquids.

Reynolds Tube Cavitation.—Since water can be made to cavitate by other means than sound waves, it is of interest to look for luminescence in these cases also. A flask of water cavitates dissolved gas and also water vapor just before it boils; a ship's propeller cavitates the water just behind it as it revolves and may become badly corroded from effects of cavitation; water flowing through a constriction in a tube cavitates as a result of the increased velocity of flow and corresponding decrease in pressure, a Reynolds tube.[27] There are no records of luminescence about ship's propellers (apart from the luminescence of disturbed micro-organisms in the sea) and I have not been able to observe a trace of luminescence just before a flask of water boils.

In a Reynolds tube there is also no luminescence. This tube was made of glass 8.5 mm. internal diameter narrowing to 2.5 mm. and then expanding to 8.5 mm. again. It was attached to the water faucet and during flow beautiful cavitation with a hissing sound occurred but no trace of luminescence. A large Venturi meter (with a glass window), 5 in. (12.6 cm.) inside diameter narrowing to 2 in. (10.1 cm.) in the Engineering Building at Princeton University also was observed but no luminescence occurred during the abundant cavitation.

Luminol pumped through a Reynolds tube cavitates abundantly but exhibits no luminescence. Evidently the conditions for building up potentials and for activation of oxygen are very different in the sonic field from those in the Reynolds tube.

Preformed Gas Bubbles.—Although gas bubbles rising through a fluid are electrically charged, it is easy to demonstrate that already formed gas bubbles are not responsible for luminescence in the supersonic field. This experiment is carried out by exhausting the dissolved gas in a weak soap solution with a filter pump. In a tube in the supersonic field this solution does not luminesce, since it cannot cavitate. Then air is forced through a porous diaphragm into the solution while in the supersonic field. The minute bubbles, which are prevented from uniting by the soap film, travel upward, but no luminescence is visible until a certain amount of air has dissolved (after eight seconds). Then the newly air saturated solution cavitates and sonoluminescence appears. The air bubbles show beautiful aggregation as the result of sound wave pressure but not coalescence.

If a Reynolds tube of flowing water was placed over the vibrating crystal, there was no brighter luminescence around the minute bubbles of gas cavitated by the Reynolds effect than from other regions, although the bubbles immediately coalesce in the supersonic field. The experi-

(27) Reynolds, "Papers on Mechanical and Physical Subjects," Cambridge, Vol. II, 1901, p. 578.

that this substance luminesces with relative brightness in the supersonic field even when shielded from all electrostatic influences.

The behavior of luminol solutions when saturated with various gases confirms the chemiluminescent origin of most of the light and in addition shows that the sonoluminescence of pure water has another origin than that of activated oxygen. In carbon dioxide there is no luminescence, since cavitation does not occur with the sound intensities available (and oxygen is absent). In pure hydrogen there is no luminescence since activated oxygen cannot form. In nitrogen (either purified by passing over red hot copper or mixed with 7% of hydrogen and passed over platinized asbestos) there is no bright sonic chemiluminescence of luminol but there still remains the faint sonoluminescence[24] which appears in pure water in absence of oxygen. In neon also the bright sonic chemiluminescence of luminol disappears but a faint luminescence remains similar to that in neon saturated water. Finally, if sodium hydrosulfite is added to luminol in a nitrogen atmosphere, there is no sonic chemiluminescenee but only the sonoluminescence of water.

Therefore, we can conclude definitely that this compound shows a true sonic chemiluminescence when subjected to high frequency sound waves, as the result of the activated oxygen produced.

Temperature.—The sonoluminescence of water and also of solutions is brighter the lower the temperature and is quite marked at 0°. At 30° the intensity is considerably less than at 20° and above 40° there is practically no luminescence, although water at 90° will cavitate. It seems reasonable to suppose that the increased vapor pressure of water at high temperatures suppresses the discharge in the cavitated gas bubbles.

Luminol subjected to supersonics also luminesces more brightly the lower the temperature but the light is easily visible at 60° and does not disappear until a temperature of 85 to 90° is reached.

Hydrogen Peroxide and Luminescence.—Since hydrogen peroxide added to various substances can cause the emission of light and hydrogen peroxide is undoubtedly formed during sonic treatment of water, it seemed important to determine whether substances which combine with hydrogen peroxide or which catalyze the decomposition of hydrogen peroxide affect the sonoluminescence of water or the sonic chemiluminescence of luminol.

First it may be recorded that the mixing of hydrogen peroxide and water does not result in light emission nor does a brighter sonoluminescence appear in the subsequent mixtures than in pure water. I also have never observed luminescence during the decomposition of hydrogen peroxide, whether this is induced by inorganic catalysts (manganese dioxide, platinum black) or by catalase, and whether the decomposition is relatively slow or occurs (with catalase) with explosive violence. Therefore it appears that hydrogen peroxide can play little part in the sonoluminescence of water. Similar evidence is obtained from a study of hydrogen peroxide catalysts which might be expected to decompose hydrogen peroxide before it could react further with possible emission of light.

Since catalase is a hydrogen peroxide catalyst so powerful that solutions of it showing no trace of color decompose hydrogen peroxide explosively, it was prepared[25] from beef liver by the method of Sumner and Dounce,[26] which involves extraction with dioxane. It was washed free of dioxane by half-saturated ammonium sulfate and dissolved in 0.1 *N* phosphate buffer at *p*H 7.4. This solution gave the usual sonoluminescence of water, although it decomposed hydrogen peroxide instantly.

When made slightly more alkaline and luminol added, the relatively bright sonic chemiluminescence of the luminol appeared of the same intensity as in a similar control tube without catalase. The catalase in the more alkaline luminol solution was found to be highly active in decomposing hydrogen peroxide. We are, therefore, led to the conclusion previously reached in sonic experiments by Flosdorf, Chambers and Malisoff[6] that the luminescence of luminol is due chiefly to the activated oxygen rather than the hydrogen peroxide formed by the supersonics.

On the contrary, the oxidation of potassium iodide by supersonics is due largely to the hydrogen peroxide formed. Two tubes of potassium iodide, one containing catalase and the other not, were subjected to a supersonic field for one minute. Then starch solution was added to both. The tube with catalase gave only a trace of blue color while the one without catalase turned blue-black from the abundant liberated iodine and starch.

Ozone and Luminescence.—Although all observers report little if any ozone formed by supersonic treatment of water, it is possible that traces might form that are responsible for luminescence, since ozone passed through many organic substances will emit light. Ozone passed through distilled water or sodium chloride, bromide or iodide solution does not result in luminescence but if a trace of luminol is added, each bubble of ozone rising through the solution luminesces brilliantly. Therefore ozone cannot be concerned with the sonoluminescence of water but might add to the sonic chemiluminescence of luminol.

Inhibition of Sonoluminescence.—Although the sonoluminescence of water is remarkably independent of dissolved substances of various kinds (see a previous section), there are certain compounds which prevent its appearance. This was first noted in a study of sonoluminescence during emulsification by sound waves. It was observed that layers of water and mercury luminesced (somewhat brighter than pure water alone) when emulsified but layers of water and benzene did not. Therefore a systematic study was made of a number of fluids non-miscible with water. One drop of the liquid was added to 10 cc. of water.

It was found that propyl, butyl, amyl and capryl alcohols, ethyl butyrate, amyl acetate, ethyl ether, β,β-dichloroethyl ether, benzene and 1,4-dioxane prevented luminescence; that toluene, thiophene, petroleum ether and aniline allowed a faint luminescence, while carbon

(24) This faint luminescence was probably overlooked by Flosdorf, Chambers and Malisoff,[6] who noticed no luminescence of luminol containing nitrogen in the sonic field.

(25) I am greatly indebted to Mr. R. G. Ballentine for the sample of pure catalase.

(26) Sumner and Dounce, *J. Biol. Chem.*, **121**, 417 (1937).

saturated with neon. When the tube was touched to the supersonic fountain of oil a luminescence appeared of about the same intensity as when water saturated with air at 0° is tested. No trace of red color that might be evidence of excitation of the neon by electrical discharge appeared and no difference in intensity or shade was detected when neon saturated and air saturated sonoluminescence was observed through red, orange or blue-green filters. The neon in the tube gave a bright red luminescence when excited with a leak tester at 0° but none at 20°, due to quenching by water vapor.

Either sonoluminescence in neon (1) is too weak to distinguish color or (2) excitation of the neon does not occur within the cavitated gas bubbles. That the first explanation is correct can be proved easily by a direct experiment. The light from a neon lamp at different distances falling on an opal glass screen is observed by completely dark adapted eyes. All trace of red color disappears from the neon light at intensities considerably greater than those resulting from sonic luminescence of the neon saturated (or air saturated) water. Therefore, the sonoluminescence in pure distilled water cannot be connected with activation of dissolved oxygen and we are probably dealing with electroluminescence from discharge in the cavitated neon, too faint to detect a red color. A similar electroluminescence occurs in nitrogen but it is still less intense.

Hydrogen is of special interest since it is an easily excited gas and one might expect to observe a sonoluminescence in hydrogen saturated water. However both Lenard[17] and Thomson[18] found that the waterfall potentials appearing where water is atomized in a hydrogen atmosphere are much less than in other gases. Therefore sufficient potential is not built up with cavitated hydrogen for a discharge to take place. The gas experiments definitely lead to the view that the sonoluminescence in pure water is balloelectrical in origin.

Effect of Dissolved Substances.—The sonoluminescence of distilled water containing air is remarkably independent of dissolved substances. Thus it is observed of nearly the same intensity[19] whether acid (10% sulfuric acid, 0.1 *N* hydrochloric acid) or alkaline (10% potassium hydroxide, 0.1 *N* ammonium hydroxide, 0.1 sodium hydroxide); whether the salt content (and electrical conductivity) is high [saturated sodium chloride, saturated ammonium sulfate (rather bright), concentrated calcium chloride, "hypo"], medium (sea water) or low (tap water, 0.01 *N* potassium cyanide); in presence of heavy metals (1% copper sulfate, satd. mercuric chloride); of strong oxidants [dilute hypochlorite or hypobromite, potassium bichromate (faint), potassium persulfate, ferric chloride, acid cerium sulfate, potassium ferricyanide, 10% nitric acid, hydrogen peroxide] and strong reductants [sodium hydrosulfite, alkaline stannous chloride, ammonium sulfide (faint), 42% hydrazine hydrate (faint)]; of inert suspensions (zinc stearate, talc, infusorial earth, pumice and kaolin); of emulsions [mercury (rather bright), olive oil in dilute alkali]; of colloidal solutions (ferric hydroxide, starch), of surface active substances (saponin, sodium glycocholate, soap, egg albumin); of peroxide inhibitors and developers (diphenylamine, hydroquinone, resorcinol, phloroglucinol, amidol, elon, pyrogallol) and dilute solutions of many other organic compounds (glucose, α-methyl glucoside, acetanilide, glycerol, ethylene glycol, ethyl and methyl alcohols).

The wide variety of conditions under which the sonoluminescence occurs, especially in either reducing or oxidizing solutions, is additional evidence against the view that the light is chemiluminescent in origin.

Relation to Other Luminescent Compounds.—Conditions which produce luminescence in cavitated water might conceivably excite fluorescence in solution. Very dilute fluorescein, eosin, erythrosin, rose bengale, cyanin, dicyanin A, pinacyanol chloride, rhodamin B, quinine sulfate,[20] uranyl nitrate, lophin and esculin were tested, but the luminescence was not *markedly* brighter than in pure water alone.

When insoluble fluorescent substances such as anthracene, salophen, salicylamide, natural willemite powder and phosphorescent zinc sulfide were suspended in water at 20° and subjected to supersonics, again not markedly greater luminescence appeared than in pure water. The salophen and salicylamide were also treated at 0° since low temperatures favor luminescence, but no *greatly* increased luminescence occurred.

In addition to being fluorescent in ultraviolet light, salophen and salicylamide are also triboluminescent, and lophin and aesculin are chemiluminescent when warmed with alkali in alcohol. Dilute pyrogallol (0.001 *M*) can be excited to luminesce in various ways,[21] most easily by peroxidase and hydrogen peroxide, or by potassium ferricyanide and hydrogen peroxide, or by passage of ozone, but no brighter light appears when high frequency sound waves are conducted through dilute pyrogallol than in distilled water. Crude solutions of luciferin or luciferase from the luminous crustacean, *Cypridina*, also give the same intensity of sonoluminescence as pure water.

One chemiluminescent compound, aminophthalichydrazide, hereafter referred to as *luminol*, responds brilliantly to supersound waves, as first demonstrated for sonic treatment by Flosdorf, Chambers and Malisoff,[6] who used it to detect the presence of active oxygen and of hydrogen peroxide formed from activated oxygen in cavitated gas bubbles reacting with water.

Sonic Chemiluminescence.—Aminophthalichydrazide and related compounds in alkaline solution, as shown by Albrecht[22] and studied by numerous investigators, gives a brilliant bluish luminescence when oxidized in various ways (as by bromine water, ferricyanide or permanganate) and particularly in presence of active oxygen. Luminescence also appears at the anode of solutions containing luminol, electrolyzed with potentials of 0.5 v. or over; with hydrogen peroxide in presence (or absence) of catalysts; by bubbling of ozone (but not molecular oxygen); or even at metallic surfaces (Al, Zn, Cd) which dissolve in water with evolution of hydrogen and formation of hydrogen peroxide.[23] It is not surprising, then, to find

(22) Albrecht, *Z. physik. Chem.*, **136**, 321 (1928).

(23) Harvey, *J. Phys. Chem.*, **33**, 1456–1459 (1929).

the hydrogen peroxide arises from frictional electrical discharges (Reibungselektricität) which lead to activation of oxygen in cavitated air bubbles and reaction of the oxygen with water to form hydrogen peroxide. Such discharges themselves easily could give rise to luminescence, with hydrogen peroxide formation a secondary effect.

A more extended investigation of the luminescence is described by Levsin and Kzevkin.[7] They found that four times distilled water will luminesce and conclude that the light is due to electrical discharge in water vapor in cavities within the liquid. All observations, including my own, agree that the luminescence appears when fluids are completely shielded from the electrical field and that it is always connected with cavitation, being brightest where cavitation is most marked.

Electric potentials produced by increase in the surface of a fluid (as when it is atomized) are called balloelectric or Lenard potentials (Wasserfallelektricität) and were first suggested as an explanation of the extraordinary chemical effects of cavitation in hydraulic problems by Föttinger.[8] They have been emphasized by Richards[9] who, in collaboration with G. Hobart, was able to detect random variation in potentials in water in the cavitating region of a Reynolds tube.

If sonoluminescence is due to electrical discharge, it should make little difference what gas is dissolved in the fluid, provided cavitation of the gas occurs. On the other hand, if light emission depends on the activation of oxygen, *i. e.*, if it is a chemiluminescence, there should be no luminescence in hydrogen or nitrogen. Actually both types of luminescence can be observed under different conditions. Experiments to determine these points together with other observations on sonoluminescence are reported herein. The most striking effect is the sonoluminescence of bromine water which emits a light far brighter than that of water alone or of water with any other added substance.

Apparatus.—The oscillator (in a light-tight box) is of the tuned grid tuned plate type with two push-pull 852 tubes and a power input of approximately 300 watts. The quartz crystal is 5.3 cm. in diameter and 0.51 cm. thick, between two thin copper electrodes in transformer oil. Its natural period is 550 kilocycles. At full power, a fountain of oil about 4 cm. high is produced, making possible a demonstration of the well known phenomena associated with supersound waves, including cavitation of gas.[9-14] The oscillator is not strong enough to cavitate vapor from a degassed fluid such as water. Glycerol or nitrobenzene also gave no evidence of cavitation. Black paper screens prevented an occasional sparking at electrodes from disturbing the observation of luminescence in fluids which were placed in test-tubes and touched to the surface of the oil over the crystal. Unless otherwise mentioned the temperature was about 20°.

It gives me great pleasure to thank Mr. Charles Butt, Research Assistant in Physiology, for constructing the oscillator and for faithful assistance during the experiments, and Mr. Alfred L. Loomis, Tuxedo Park, N. Y., for the loan of the quartz crystal and other apparatus.

Effect of Gases.—Pure water cavitates in the supersonic apparatus here described when saturated with air, nitrogen, hydrogen, oxygen and neon but not (or only slightly) if saturated with carbon dioxide or if evacuated with a filter pump or if saturated with air at atmospheric pressure and placed under 1.7 atm. hydrostatic pressure. However, luminescence only appears in air, oxygen, neon and weakly in nitrogen. In hydrogen purified by passing over heated platinized asbestos, there is no trace of luminescence. This might indicate that sonoluminescence depends on oxygen.

However, if nitrogen (purified by passing over freshly reduced copper in the apparatus described by Kendall[15] and led to an all-glass vessel by lead tubing sealed with de Khotinsky cement) is bubbled through distilled water for one and one-half hours, a weak luminescence still appears in the water when exposed to supersonic radiation. There is not enough oxygen present in this nitrogen to allow luminescence of luminous bacteria, which can detect about 0.01 mm. oxygen.[16]

Since luminescences are extraordinarily sensitive tests for oxygen, another method of purifying the nitrogen was used. It was mixed with 2.5% hydrogen in one experiment and with 7% in another. The mixture was then passed over heated platinized asbestos in a quartz tube connected with the vessel by a lead tube. Water saturated with nitrogen purified in this way still showed a faint sonoluminescence in high frequency sound waves and the conclusion is reached that *oxygen is not necessary for sonoluminescence of water.*

The neon gas experiments were undertaken in the hope of observing the characteristic reddish glow from electrical excitation of neon when water saturated with neon is radiated with supersonic waves. Water in a glass test-tube sealed to a 120° stopcock was thoroughly exhausted of gas by boiling at reduced pressure, cooled to 0° and

0.03 to 0.15%. This is the range occurring in the majority of human urines. These concentrations sensitize the Benedict test for the very concentration range of glucose (0.05–0.3%) which yields doubtful results by other methods. A higher creatinine content, such as 0.2%, fortunately not common, in a urine containing 0.1% of glucose, delays the appearance of the opacity beyond the three-minute water-bath time recommended,[22] while the 0.4% creatinine level reported by Folin[24] for a starch and cream diet prevents the precipitation entirely, as it would in any other copper reduction test. On the other hand, creatinine concentrations below the optimum range, which can occur readily after copious water intake, cause the urine to react like an aqueous glucose, so that a 0.1–0.3% glycosuric urine with less than 0.03% creatinine gives in the Benedict test only a barely perceptible red haze, which would be considered negative by its author's instructions. In the Fehling or Trommer tests such a urine would give typical positive results.

It is evident, therefore, that at low glucose levels it is the accompanying content of creatinine which determines the sensitivity of a Benedict test. With this knowledge and the better understanding of the role of the various ingredients of alkaline copper solutions which has accumulated in the years since the appearance of Benedict's method, it may be possible to devise a more nearly infallible test and one sensitive to any significant concentration of glucose in urine. Progress of work on improved methods for the detection of sugar in urine is to be reported in a later paper.

(22) Benedict recommended one to two minutes of boiling over a flame. A three-minute period in a water-bath was shown by Folin and McEllroy (ref. 23) to be equivalent to the two minutes over a flame. The five-minute water-bath time, recommended in many texts, is an unwarranted extension and leads to many doubtful or false positive tests.

Summary

1. Benedict's test, in distinction to other alkaline copper tests used for the qualitative detection of sugar, is more sensitive to urinary glucose solutions than to aqueous ones.

2. Creatinine is the opacity promoting or sensitizing factor in urine which causes bulky opacity in positive Benedict tests with low concentrations of glucose.

3. The properties of cuprous creatinine account for the interfering effect of creatinine in the precipitation of cuprous oxide in Trommer's and Fehling's tests, and for its opacity promoting effect in the Benedict test.

4. The concentration of creatinine present in the majority of human urine samples has opacity promoting properties in the Benedict test on low glucose urines.

5. Exceptional concentrations of creatinine, higher or lower than the normal proportions, may lead to false results in the Benedict test.

Sonoluminescence and Sonic Chemiluminescence

BY E. NEWTON HARVEY

Introduction

It is customary to designate a luminescence by the method of excitation, as electroluminescence, photoluminescence, triboluminescence, etc. Accordingly the luminescence which appears when sound waves pass through liquids has been called acoustic or sonic luminescence, for short, sonoluminescence. This type of light emission was first observed by Frenzel and Schultes[1] for supersonic and by Chambers[2] for audible frequencies. Using a magnetostriction oscillator of 8900 frequency, Chambers studied 36 pure liquids and found 14 of them to luminesce, the brightness varying inversely as the temperature and directly as the product of viscosity and dipole moment.

Frenzel and Schultes were led to look for luminescence accompanying supersonic waves in water from the formation of hydrogen peroxide which many observers (Schmitt, Johnson and Olson,[3] Beuthe,[4] Liu and Wu,[5] and Flosdorf, Chambers and Malisoff[6]) have found in fluids subjected to sonic treatment. Beuthe[4] believes

The ratio of copper to creatinine in the complex was determined, using a preparation made from an alkaline copper mixture reduced by fructose instead of glucose, to speed up the reaction and avoid errors due to reducing action of creatinine or its entrainment by precipitation in uncombined form. An aliquot of the complex made in this way was analyzed for copper by the thiosulfate method[13] and for creatinine by the Folin method,[14] preliminary work with the latter having shown no interference by copper in the development of the picramic acid color.

The ratio of copper to creatinine in the aliquot taken was found to be 0.2624 g./0.4444 g., which varies only slightly from the calculated ratio 63.57/113 for one atom of copper to one molecule of creatinine. The complex probably is a simple addition compound, $C_4H_7ON_3 \cdot CuOH$. Such compounds with zinc chloride, silver nitrate or similar salts are well known. More recently it has been shown[15] that creatinine forms addition compounds even with alkali hydroxides.

Previous Work on Cuprous Creatinine.—The existence of this compound was first suggested by Maly,[16] investigating previous observations that Trommer's test is less sensitive to urinary glucose than to aqueous glucose. Maschke[17] prepared such a complex by saturating creatinine solutions with sodium carbonate and adding Fehling solution, but did not analyze it. The work of these investigators appears to have been overlooked in subsequent reports on the influence of creatinine on alkaline copper reactions.[7,18,19] In Merck's "Reagenzien-Verzeichnis"[20] as well as in "Beilstein," Maschke's finding is referred to as a test for creatinine detection, as the author emphasized, rather than as a complex important in copper tests for urinary glucose.

Cuprous Creatinine in Alkaline Copper Tests on Urine.—Aside from its susceptibility to oxidation, cuprous creatinine is a very stable compound, the bond being resistant to alkali, other than a slow conversion of creatinine to creatine which is slight in the time needed for a test. The complex is very soluble in alkali hydroxide, so that in a Trommer or Fehling test on glycosuric urine, containing also sufficient creatinine to combine with all the cuprous oxide formed, no visible precipitate results. In carbonate solution, on the other hand, the cuprous creatinine complex is quite insoluble (Table I), and very voluminous. These properties lead, in effect, to an enormous magnification of the volume of the precipitated cuprous oxide in a positive Benedict test.

The properties of cuprous creatinine, therefore, explain both the sensitivity of Benedict's test for urinary glucose, and the delay in precipitation in alkaline copper reagents employing hydroxide. The explanation of Benedict[10,11] that in the latter creatinine delays precipitation due to the fact that the normal reduction of the solution is inhibited for a period long enough to allow the strong alkali present to decompose the reducing substance formed from the sugar molecule into compounds which have no reducing power is not correct. It may be shown by following the reduction with phosphomolybdic acid as in blood sugar analysis, that any delay by creatinine on the reduction of copper by glucose is negligible. The delay in Trommer and Fehling tests reported by Von Babo and Meissner,[5] Winogradoff,[6] Worm-Müller,[18] Eury,[19] MacLean,[7] and Laird,[21] actually is a delay in the appearance of a precipitate and not a delay in the reduction of copper by glucose.

The Paradoxical Role of Creatinine in the Benedict Test.—It is well known that in addition to creatinine there are other substances either normally present in urine or resulting from pathological conditions or administration of medicaments, which disturb the normal course of alkaline copper reactions. Reduction by creatinine, uric acid, urochrome, etc., has a greater interfering effect in those tests which use a large proportion of urine to reagent (Trommer and most Fehling variations) than in the Benedict test, in which the urine comprises less than 10% of the liquid in the test. It is probable that this low ratio of urine is just as important in the Benedict test as is the use of carbonate as alkali and the stability of the reagent. Even in this restricted urinary proportion, however, creatinine still has interfering properties as well as the desirable sensitizing effect.

The opacity promoting property of creatinine is effective only in a range of concentrations from

aqueous glucose solutions which yield typical Trommer or Fehling tests give a barely perceptible red haze by Benedict's method. For urinary work, however, Benedict's reagent is unexcelled, since it gives bulky opacities with glucose concentrations which fail to precipitate with other reagents, and clear tests with urines containing no glucose but which give reductions with the Trommer or Fehling tests. The possibility that the increased delicacy of the Benedict test on urine might be due to a urinary ingredient was the origin of the work reported in this paper.

Creatinine as Opacity Promoter in the Benedict Test.—It is easy to show that an ingredient of urine promotes the typical Benedict test opacity with minimal amounts of glucose. Normal urine if shaken with blood charcoal yields a water-white filtrate which on addition of 0.1% of glucose gives in the Benedict test the barely perceptible red haze of cuprous oxide characteristic of aqueous glucose. A similar concentration of glucose added to the original urine gives the usual opaque test, showing that the urine contains a promoter which is removed by the charcoal. Lloyd's alkaloidal reagent, a type of fuller's earth used by Folin and Berglund,[12] has a similar action. Of the substances known to be removed from urine by Folin and Berglund's method, creatinine alone was found to be an opacity promoter. Solutions made of glucose with a proper amount of creatinine react in the Benedict test exactly as does glucose in urine.

Experimental.—To 37.5 cc. of urine were added 12.5 cc. of 0.1 *N* sulfuric acid and 4 g. of Lloyd's earth. After shaking for two minutes, the mixture was filtered, the filtrate neutralized and glucose added to 0.1%. The solution reacted to the Benedict test like aqueous glucose. The opacity promoter is removed readily from the Lloyd's earth by elution with dilute carbonate solution. The elution plus 0.1% glucose gives an opaque Benedict test.

Cuprous Creatinine.—The knowledge that creatinine is the sensitizer or opacity promoter directs attention to a possible mechanism. Reduction experiments on Benedict solution with glucose and creatinine at lower temperatures than the usual boiling, give at 60° a bulky, slightly yellowish precipitate, at 50° a voluminous white one which agglutinates readily on shaking and filters well. The same reaction goes on at room temperature, slower but complete overnight. Further experiment showed the precipitate to be a compound of creatinine and cuprous oxide, the existence of which has been reported previously, in incomplete form, by several investigators, whose work will be discussed a little later.

(12) Folin and Berglund, *J. Biol. Chem.*, **51**, 209 (1922).

Experimental.—A mixture of 60 cc. of 0.5 *M* creatinine (5.65%) in *N* hydrochloric acid and 25 cc. of 3 *M* glucose was added to 1200 cc. of Benedict reagent and allowed to stand overnight. The bulky white precipitate was filtered off on a Büchner funnel and washed free from cupric ion with 15% sodium carbonate solution. The white solid was removed from the filter and cautiously neutralized with 20% acetic acid, atmospheric oxidation producing some blue color. The heavy neutral suspension was transferred to centrifuge tubes and washed free from cupric ion by repeated settling and resuspension in water. Air oxidation of the moist precipitate may be hindered by storing it in practically full, tightly stoppered tubes. Solubility data for the substance are given in Table I; the aqueous solution shows *p*H 6.5. It is soluble in acids, without effervescence.

TABLE I

SOLUBILITY DATA OF CUPROUS CREATININE, $C_4H_7ON_3 \cdot CuOH$

Solvent	Soly., g./100 cc.
Pure water	1.1
Sodium carbonate, 7.5%	1.0
Sodium carbonate, 8%	0.87
Sodium carbonate, 9%	.14
Sodium carbonate, 10%	.054
Sodium carbonate, 15%	.018
Sodium carbonate, 20%	.016
Sodium carbonate, 30%	.008
Benedict solution at 25°	.019
Benedict solution at 100°	.09

The presence of creatinine in the precipitate may be shown by the picric acid or nitroprusside test, while cuprous copper is proved by oxidation and by precipitation with sulfide, cyanide, ferrocyanide, ferricyanide, or thiocyanate, the last three showing the precipitates characteristic of cuprous ion. Neutral chlorides have no effect but dilute hydrochloric and hydrobromic acids give a white precipitate, soluble in excess.

A saturated aqueous solution of the complex on addition of carbonate gives a bulky and voluminous precipitate rather than the creamy and chalk-like original neutral suspension. High concentrations of citrate and sulfate cause a clouding of the saturated aqueous solution, while tartrate, pyrophosphate, oxalate, acetate, salicylate and sulfite have no visible effect.

Cuprous creatinine may be prepared rapidly in small quantities by heating the mixture to incipient boiling, and then cooling rapidly in running water. Aside from its pure white color, the resulting opacity is similar to that of a positive Benedict test.

lytic activity of the corresponding ammonium salts upon the ammonolysis of esters in liquid ammonia. Like ammonia, butylamine is a strongly basic solvent in which ionization of weak acids is presumably enhanced. On the other hand, however, the low dielectric constant ($\epsilon = 5.4$)[7] of the solvent undoubtedly promotes formation of inactive ion pairs, or even larger aggregates, with the consequence that stoichiometric concentrations give little or no insight into the concentrations of either the butylammonium ions or the negative ions in solution.

It also should be pointed out that the presence of a fairly large mole fraction of ester in the solutions under investigation undoubtedly influences the ionization of the butylammonium salts. Actually, very concentrated solutions of ester in amine were used in all experiments.

It is also apparent from a comparison of the experimental series 4, 9 and 10, that the ratio of amine to ester affects the rate of the reaction very appreciably. In the first eight series the molar ratios of amine, ester and catalyst are given approximately by the numbers 380:200:7. As the mole ratio of amine to ester is increased, the value for the specific reaction rate constant also becomes larger. It is obvious, therefore, that the reaction is not even pseudo-bimolecular in character, except for specified conditions. To obtain more rapid reaction it is advisable to use quantities of amine considerably in excess of those required stoichiometrically.

The tremendous effect of the addition of the relatively small quantity of butylammonium salt is emphasized by a comparison of the half-life times of the first ten series, with that for the uncatalyzed reaction. These findings again emphasize our contention[5] that the mechanism of all solvolytic reactions, whether they be hydrolytic, ammonolytic or aminolytic, is fundamentally the same as illustrated by the reaction

$$\left.\begin{matrix}\mathrm{HOH}\\ \mathrm{HNH_2}\\ \mathrm{R''NH_2}\end{matrix}\right\} + \mathrm{RCOOR'} \xrightarrow{\mathrm{S{\cdot}H^+}} \mathrm{RCO}\left\{\begin{matrix}\mathrm{OH}\\ \mathrm{NH_2}\\ \mathrm{NHR''}\end{matrix}\right. + \mathrm{R'OH}$$

(7) Schlundt, *J. Phys. Chem.*, **5**, 503 (1901).

Summary

1. The aminolysis of ethyl phenylacetate in *n*-butylamine to yield the N-butylamide of phenylacetic acid is catalyzed by butylammonium salts.

2. The catalytic effect of equimolar concentrations of various butylammonium salts decreases with the anion in the following order: $Cl^- > C_2H_3O_2^- > C_6H_5COO^- > Br^- > NO_3^- > CNS^- > I^- > ClO_4^-$.

The Relation of Cuprous Creatinine to Tests for Sugar in Urine[1]

BY MEYER SAMSON

It is almost a hundred years since Trommer[2] published the first practical directions for a copper reduction test for sugar. Of the hundreds of modifications[3] subsequently proposed, only the methods of Trommer, Fehling[4] and Benedict are largely used today.

Most of the proposed modifications were designed to avoid interference. Creatinine soon was recognized as the principal source of trouble, which arose from its own reducing powers, as well as from its property of holding in solution the cuprous oxide formed in the presence of glucose.[5-7]

Benedict,[8] in reviving the forgotten idea of Possoz[9] of using carbonate in place of hydroxide as alkali, believed he had found a copper solution on which creatinine was without appreciable effect.[10] When he later proposed the copper carbonate–citrate mixture in the solution[11] known by his name, he claimed it to be more sensitive to glucose either in pure solution or in urine than is Fehling's fluid. This is not correct, since

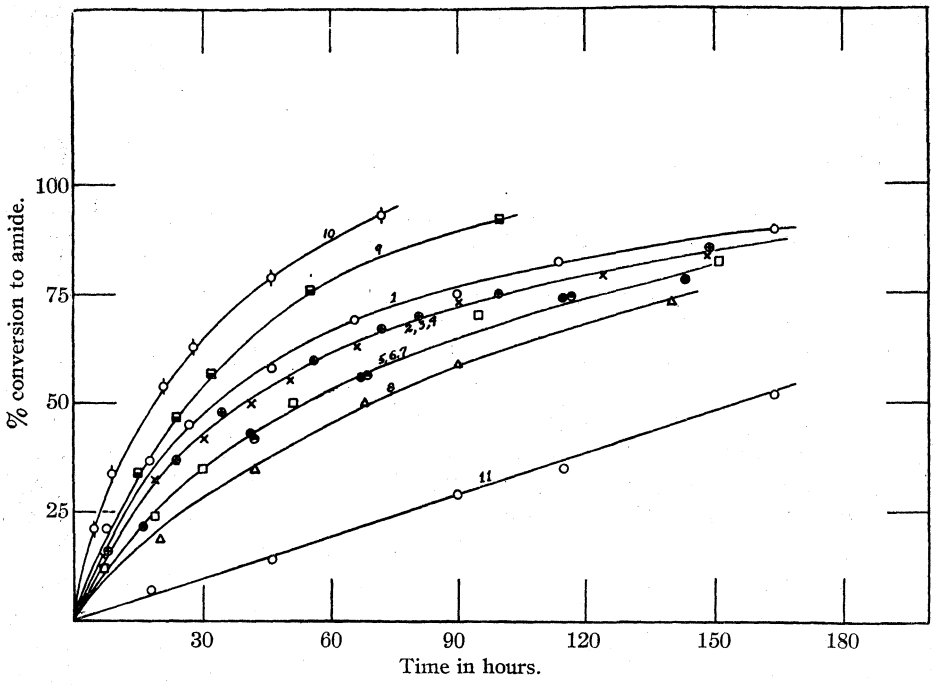

Fig. 1.—Catalytic effect of various butylammonium salts on the reaction between *n*-butylamine and ethyl phenylacetate (see Table I for specific data). Curves represent the use of equimolar quantities of different catalysts (S = $C_4H_9NH_2$): 1, S·HCl; 2, 3, 4, S·HBr, S·$HC_2H_3O_2$, S·$HOOCC_6H_5$; 5, 6, 7, S·HNO_3, S·HSCN, S·HI; 8, S·$HClO_4$; 11, no catalyst. Curves 4, 9, and 10 show the effect of increasing the molar ratio of amine to ester using $C_4H_9NH_2$·HBr as catalyst.

lytic effect is definitely dependent upon the nature of the anion.

A plot of the function log $(a - x)/(b - x)$ against time indicates that these reactions are pseudo-second order, but it is obvious that the butylammonium salt plays a definite part in the reaction, since the values of the specific reaction rate constants as given in Table I vary with the nature of the salt. The data in Table I indicate a specific anion effect which for equimolecular concentrations of added butylammonium salts decreases in the order

$$Cl^- > C_2H_3O_2^- > C_6H_5COO^- > Br^- > NO_3^- > CNS^- > I^- > ClO_4^-$$

No information is available in the literature concerning the physical properties (conductivity, degree of ionization, etc.) of the respective butylammonium salts in butylamine. It is significant, however, that the above order parallels, except for the position of the chloride, the order of cata-

Acid Catalysis in Amines. II. The Catalytic Effect of Various Butylammonium Salts on the Aminolysis of Ethyl Phenylacetate in Anhydrous *n*-Butylamine

BY PAUL K. GLASOE, J. KLEINBERG AND L. F. AUDRIETH

Experimental evidence already has been presented to demonstrate that the ammonolysis of esters in anhydrous liquid ammonia is markedly catalyzed by the presence of ammonium salts.[1-4] The catalytic effect of equimolar concentrations of different ammonium salts has been found to decrease in the following order: $C_2H_3O_2^- > C_6H_5COO^- > Cl^- > Br^- > NO_3^- > I^- > ClO_4^-$.[2,4] This result is quite unexpected, especially if this effect is to be interpreted as an example of acid catalysis in a non-aqueous solvent. This anion order is exactly opposite from what might be expected from a consideration of those physical properties of ammonium salts in liquid ammonia which presumably permit a quantitative estimation of the ammonium ion concentration.

In extending these studies from ammonia to amines it has been shown that aminolytic reactions are also catalyzed by the solvated proton, introduced into the reaction mixture in the form of the amine salt.[5] In view of the anomalous behavior of ammonium salts in accelerating the ammonolysis of esters it became of distinct interest to determine whether the catalytic effect of equimolar concentrations of different amine salts also varied with the nature of the anion, as observed in the case of liquid ammonia. The present investigation was therefore undertaken to study the influence of various butylammonium salts on the rate of the reaction between anhydrous butylamine and ethyl phenylacetate.

Experimental

Procedure.—Due to the excessive solubility of the various butylammonium salts in anhydrous butylamine, and their hygroscopicity, the method used in the actual isolation and preparation of analogous cyclohexylammonium salts[5] could not be employed satisfactorily.[6] Consequently, butylammonium salts were in most instances not isolated, but prepared in butylamine by adding a definite quantity of ammonium salt to an excess of amine. The resulting mixtures were then warmed on the steam-bath under slightly reduced pressure to effect removal of ammonia, yielding solutions of known content of butylammonium salts.

In preparing standard solutions for reaction velocity studies a definite quantity of ester was added to the amine solution of the specific salt and the mixture diluted with amine to exactly 25 cc. Two-cc. samples of this mixture were transferred to small Pyrex test-tubes which were immediately sealed and placed in a thermostat at 25°. At definite intervals of time tubes were removed, broken into an excess of standard hydrochloric acid and back titrated with standard sodium hydroxide using a methylene blue–methyl red indicator. The difference between these titrations and an initial one carried out at the beginning of each series of runs gave a measure of the amount of amine used and therefore a measure of the amount of ester which had reacted to form the N-substituted amide.

Discussion of Results

Ethyl phenylacetate reacts with butylamine in accordance with the equation: $C_6H_5CH_2COOC_2H_5 + C_4H_9NH_2 \longrightarrow C_6H_5CH_2CONHC_4H_9 + C_2H_5OH$. The reaction is very slow, as is evident from Curve 11, Fig. 1, in which the % yield of amide is plotted as a function of time. Addition of butylammonium salts, presumably acting as acids in butylamine because of the presence of the $C_4H_9NH_2.H^+$ ion, accelerates aminolysis markedly. However, the magnitude of the cata-

(6) It was also observed in the attempted preparation of butylammonium nitrate from butylamine and ammonium nitrate that aminolysis with evolution of ammonia was limited to dilute solutions and that further quantities of ammonium nitrate could be dissolved subsequently in the amine without reaction.

or semi-liquid samples were analyzed by introducing them by a capillary pipet into a tin foil cup of double thickness. An ethanolysis blank on the 1-phenylpropyl ester was similar to those obtained for methanolysis. The experimental values (corrected on the basis of the controls) are shown graphically in Figs. 1 and 2.

Synthesis of the Compounds.—1-Phenylpropanol was prepared in 44% yield according to Klages' method[10]; b. p. 102–104° at 13–14 mm.

2-Phenylpropanol was synthesized in five stages: (1) α,α-phenylmethyl-β-chloroethanol was made by a slight modification of Tiffeneau's procedure[11] from chloroacetone and phenylmagnesium bromide. The reaction mixture was stirred mechanically at −10° during the addition of the Grignard reagent and then allowed to warm slowly to room temperature; a 55% yield of light-yellow liquid, b. p. 129–132° at 21 mm., was obtained. (2) The chlorohydrin was decomposed with sodium ethoxide[12] to give 79% of phenylmethylethylene oxide, a colorless liquid, b. p. 72–75° at 10–11 mm. (3) The oxide was isomerized to hydratropic aldehyde, in 66% yield, by treating with hydrochloric acid.[13] A fraction boiling at 80–87° at 10–11 mm. was collected. (4) Zinc dust–acetic acid reduction of the aldehyde[13] gave 57% of 2-phenylpropyl acetate, b. p. 95–105° at 10–11 mm. Cohen, *et al.*, record a b. p. 125° at 14 mm. while Wohl and Berthold[14] give 103–105° at 11 mm. (5) Saponification of the acetate[13] gave 70% of 2-phenylpropanol, b. p. 110–113° at 11 mm.

2-Phenylisopropyl alcohol was prepared in 58% yield according to Austerweil and Cochin.[15] Carpenter,[16] using phenylmagnesium bromide and propylene oxide, obtained a mixture of this alcohol and 2-phenylpropanol. We obtained by this method only 2-phenylisopropyl alcohol (49% yield, b. p. 105–107° at 22 mm., the same as that for the product of the other reaction). The phenyl urethan, prepared from both products, melted at 87–88°. Emde and Runne[17] give a m. p. of 90°.

1-Phenylisopropyl alcohol resulted in 58% yield when Klages' procedure,[18] with special precautions against too great a rise of temperature during the extraction, was used. Its b. p. was 95–96° at 14–15 mm.

The *p*-nitrobenzoyl esters of the aromatic alcohols, with the exceptions noted, were prepared from the alcohol and the acid chloride (10% excess) in dry pyridine. After standing for several hours at room temperature the ester was extracted with ether, the ether layer was shaken with dilute sulfuric acid, then with dilute sodium carbonate and dried over anhydrous sodium sulfate. The phenyl ester was prepared from the acid chloride and phenol without solvent.[19] The methyl ester was made by dissolving the benzyl ester (2 g.) in methanol (10 ml.), adding about 0.1 equivalent of sodium and allowing the solution to stand one-half hour at room temperature. The ethyl ester was prepared by the action of a dilute sodium ethoxide solution on the ester residues from previous experiments.

Acknowledgments.—The author wishes to acknowledge the assistance given him by the late Dr. F. B. Allan, by Professor W. S. Funnell and Dr. G. F. Wright.

Summary

1. The relative rates of alcoholysis of several aralkyl *p*-nitrobenzoates in methanol, methanol–ether, and ethanol–ether have been studied.

2. Methanolysis takes place more rapidly than ethanolysis.

3. The relative reactivity of eight aralkyl groups has been shown to be dependent largely upon the molecular weight of the aryl alcohol

suitable without modification. The results are shown in Table II.

The efficacy of the method was demonstrated by submitting synthetic ester–alcohol mixtures to the entire procedure. Of the total weight of esters taken, 94–97% could be recovered.

Method II

Reagents.—The methanol (Kahlbaum "zur Analyse") contained 0.35% water, a value that remained constant during four months. The ether was Merck "anhydrous" dried with sodium and redistilled in 5–10 ml. lots just before use. The ethanol was prepared by dehydration of "absolute" alcohol with diethyl phthalate and sodium[8] and was protected from carbon dioxide. Of the sodium methoxide solution the following volumes were used for 0.100 g. of ester: benzyl, 0.47 ml.; phenylethyl, 0.44 ml.; phenylpropyl, 0.41 ml. (0.0110 equivalent sodium per mole ester) and of the sodium ethoxide solution, 0.50 ml., 0.47 ml., and 0.44 ml. (0.0083 equivalent sodium).

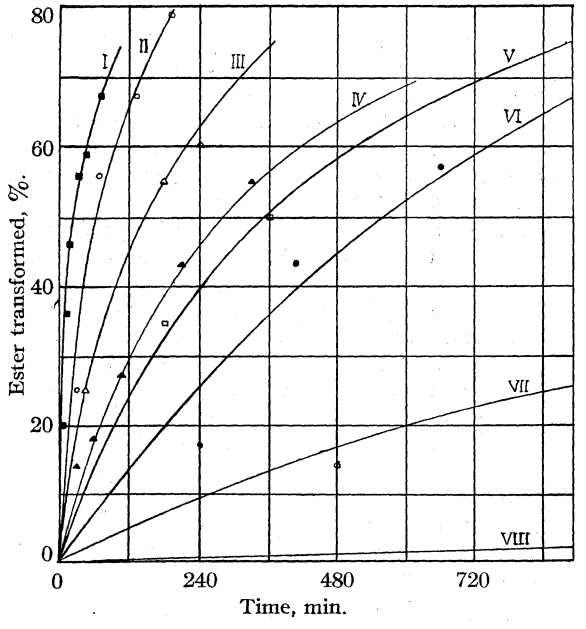

Fig 1.—Rates of methanolysis of aralkyl *p*-nitrobenzoates at 25° in MeOH–ether; 0.0110 equiv. sodium as catalyst; 0.35% water in MeOH: Curve I ■, benzyl; II ○, 2-ph-ethyl; III △, 2-ph-propyl; IV ▲, 3-ph-propyl; V □, 1-ph-propyl; VI ●, 1-ph-ethyl; VII ◪, 2-ph-isopropyl; VIII 1-ph-isopropyl. Additional data: for V, 1080, 75.4%; 1770, 81.8%; VI, 1200, 79.5%; 1800, 89.5%; VII, 1020, 40.6%; 1740, 50.2%; VIII, 3180, 4.4%.

Procedure.—To 0.100 g. of dried ester were added 5.00 ml. of ether, 5.00 ml. of the alcohol, and the catalyst solution, all at 25.0°. The methanolyses were stopped as in Method I while for the ethanolyses a small piece of solid carbon dioxide was used. Both gave consistent results. The solution was transferred to a weighed 15-ml. centrifuge tube provided with a hook of nichrome wire and the solvent was removed *in vacuo* over sulfuric acid; in order to prevent loss by bumping, the tube was provided near the top with a side-arm pulled out to a capillary of 1–2 mm. bore and the top of the tube was closed with a rubber stopper. Methanol could be removed quantitatively in two and one-half to three hours, ethanol in three and one-half to four hours. Control experiments proved that no measurable alcoholysis occurred during the separation. In some of the ethanolyses the intermediate ester–carbinol mixtures obtained were liquid or semi-liquid in which case last traces of solvent were removed in a drying pistol over phosphorus pentoxide. The residue was melted down and, when possible, allowed to crystallize by dipping the tube into ice water. The amount of methyl or ethyl ester present was determined by duplicate analyses.

Synthetic mixtures corresponding to (a) 50% and (b) 100% methanolysis of the original ester, when analyzed by Pregl's procedure, gave inconsistent results, due chiefly to insufficient heating of the sample (twenty minutes). The shorter, volumetric Vieböck method, as adapted by Lieff, Marks and Wright,[9] together with a heating time of forty-five minutes, yielded reproducible values. The blanks were somewhat higher than the theoretical, because of partial codistillation of the aromatic iodide; at half-conversion the error was about 4% and at complete converson, about 11%. Therefore, experimental points above 80% conversion were not considered. Determination of ethoxyl required seventy-five minutes of heating and higher reflux of the vapors in the apparatus. Liquid

sults being obtained with peroxide-free solvent and with that giving a strong ferrous chloride test.

Although there is no simple, direct variation between the rate of alcoholysis and the molecular weight of the alcohol combined with the ester, the rate is strongly influenced by the length of the carbon chain. Introduction of one and two methylene groups into the benzyl radical to give 2-phenylethyl and 3-phenylpropyl results in successive, considerable decreases in reactivity. This order is the converse of that obtained by Fehlandt and Adkins[2a] from equilibrium studies of the corresponding acetates in a slightly acid medium. Phenyl *p*-nitrobenzoate reacts with methanol much more rapidly even than the benzyl ester.

The effect of branching of the carbon chain is somewhat more difficult to interpret. As in a large number of other reactions, the substitution of a hydrogen on the α-carbon atom by phenyl or methyl results in lowered reactivity. The tertiary aralkyl (8) is practically inert under the same conditions for which the isomeric primary and secondary radicals react. The secondary propyl and isopropyl groups (5) and (7) are replaced less readily than the primary (3) and (4); and the secondary ethyl (6) is less reactive than the primary (2). The effect of branching at either the β- or the γ-position, such as in (3) and (4)—which of course does not alter the nature of the functional alcoholic group—is not perfectly apparent, although it is reasonable to suppose that any blocking effect will be reduced the farther the substitution occurs from the reactive carbon atom.

Our observation is that methanolysis is a far more rapid reaction than ethanolysis under similar conditions; for instance, reaction in absolute methanol is extremely fast even at low catalyst concentrations while that in absolute ethanol can be very conveniently measured. Fehlandt and Adkins found that methyl alcohol has the highest replacement value of all the alcohols they studied. A possible explanation may be found in a consideration of these alcohols as weak acids in the sense suggested by Brönsted.[5] McEwen[6] has shown that methanol is a stronger acid than ethanol; therefore, it is reasonable to conclude that since more methoxyl ions than ethoxyl ions are available for addition to the ester carbonyl, methanolysis will be the faster reaction. McEwen has found that, in general, the relative acidity of alcohols is in the descending order, primary, secondary, tertiary, which is the same as for the alcoholysis of an ester. With the exception of (6), the order of relative reactivity toward both alcohols is the same. No explanation has been found for the apparently anomalous behavior of this ester.

Experimental Part

Two analytical procedures have been adopted: the first is applicable only to esters of alcohols possessing a certain solubility in water, *e. g.*, benzyl and 2-phenylethyl, while the second may be used for the esters of any alcohol provided that the latter has a sufficiently high boiling point. According to Method I the aryl alcohol formed during the reaction is removed prior to analysis; in Method II only the solvent alcohol is separated.

Method I

Reagents.—The methanol was C. A. F. Kahlbaum "zur Analyse," partially dehydrated by distilling from sodium. The fraction of b. p. 64.5–64.8° contained 0.60% water as determined according to Jones and Amstell.[7] It was protected from atmospheric carbon dioxide. The sodium methoxide solution, standardized by Pregl's micro-procedure, showed no variation in concentration on standing for two months.

Procedure.—The ester (0.100 g.), dried several hours *in vacuo*, was dissolved in 7.00 ml. of methanol at the temperature of the thermostat (25.0 ± 0.1° over short reaction periods and ±0.2° over longer intervals). For the benzyl ester 0.55 ml. of catalyst solution was added, and for the 2-phenylethyl ester, 0.52 ml. (0.0230 equivalent of sodium). The alcoholysis was stopped by adding a few drops of a hydrochloric acid–methanol solution. The solution was evaporated just to dryness on the water-bath, the residue was taken up in 5 ml. of ether and transferred to a 15-ml. separating funnel. The ethereal solution was allowed to drop slowly onto a micro filter (prepared according to Pregl for the halogen determination) which was supported in a Pyrex steam jacket attached to the outlet tube of a water-bath. The residual esters and aryl alcohol were separated by extracting the latter with water (5–10 ml.). After dissolving the esters in hot acetone (10 ml.), the solvent was removed, and the residue dried *in vacuo*, powdered fine and analyzed for methoxyl (in duplicate). Pregl's gravimetric method was found to be

The Relative Rates of Alcoholysis of Certain Aralkyl *p*-Nitrobenzoates

BY LAURENCE F. KING

Previous investigations on the alcoholysis of esters, chiefly those of aliphatic alcohols, indicate that the nature of the functional alcoholic groups involved, and the amount of branching of the carbon chain of the alkyl rather than its length, are the chief factors determining both the relative velocity with which replacement of alkyl radicals occurs[1] and the extent to which reaction will proceed until equilibrium is attained.[2] Tertiary alkyls are less reactive than secondary, which in turn are less reactive than primary. The replacement values of straight-chain groups, derived from both types of measurement, are generally of the same order of magnitude no matter what the length of the carbon chain, and are greater than those of more centralized radicals. These generalizations are in disagreement with the observations of Bellet[3] on rates of replacement of certain aromatic alkyls.

The present paper constitutes a method for measuring the velocities with which esters of aromatic alcohols react in a faintly alkaline medium with aliphatic alcohols of low molecular weight. In order to eliminate the necessity for the customary fractional distillation of the reaction mixture, methanol and ethanol were chosen as the solvent alcohols; separation could then be effected quantitatively at room temperature and analysis made by a methoxyl or ethoxyl determination. Rates of reaction of the readily purified solid esters with the sodium alkoxide in a large excess of the alcohol were studied, absolute ether being used as a diluent in most cases.

Pseudo first-order velocity coefficients decrease markedly but regularly with the progress of the reaction; the existence of side reactions is indicated whether the medium is methanol, ethanol or diluted with ether. Kremann[4] has shown that hydrolysis of the ester may be a relatively important factor, and in confirmation of this we observed that the rates of methanolysis of phenyl and benzyl *p*-nitrobenzoates are influenced to an abnormally high degree by slight variations in the concentration of alkali and water in the solvent. Hydrolysis is not the only disturbing side reaction, however, since the K-values in ethanol exhibit no greater constancy than those in methanol; in the latter case the concentrations of alkali and water are much higher than in the former. Assumptions of other than a simple first-order reaction lead to no greater constancy of K. In order to relate, more or less quantitatively, the reactivities of the ester alkyl groups, the first-order coefficients were averaged for the same reaction interval (15–40% ester conversion) and the benzyl radical was assigned a value of 100 (see Table I). The limits of accuracy shown are an indication only of the "fading" of the K-values and not of errors of measurement. The presence of anhydrous ether is apparently of little consequence as far as relative rates are concerned: for groups (1) and (2) the ratio K_1/K_1 is approximately equal to K_2/K_2. The peroxide content of the ether is not a determining factor, identical re-

1.00	4.10	.135	.170	11.4	11.6

An increase in gum arabic concentration resulted in a decrease in the reaction rate, but it was not proportional to the concentration. Thus, at *p*H 4.16, *R* equalled 0.169 for a solution containing 0.133% gum arabic. When the percentage was increased fivefold to 0.665, *R* only dropped to 0.100.

Discussion

The kinetics of the reduction of silver ion by hydroxylamine show some interesting departures from those of the hydroquinone reduction. In the case of hydroquinone, a direct proportionality was observed between the reaction rate and the concentration of the reducing agent. This is approximately true for hydroxylamine at *p*H 3.8 but, as the *p*H increases, the dependence upon the concentration of reducing agent falls off, until at *p*H 8.54 the rate depends upon about the 0.3 power of the concentration. No indication of similar behavior was obtained with hydroquinone. The dependence of the rate upon the solution *p*H follows a similar course and, in the region 3.7–4.4, the dependence upon the power of the hydroxyl-ion concentration is almost exactly double that of the hydroxylamine concentration. These results indicate clearly that the active form of the reducing agent is the ion NH_2O^-. They indicate further that the hydroxylamine *is adsorbed to the silver by means of the amino group*. At low *p*H the hydroxylamine exists chiefly as NH_3OH^+, which presumably is not adsorbed. The concentration of NH_2OH is very small, and this accounts for the power of nearly unity. As the *p*H increases, the concentration of the free amine increases and the power of the concentration in the Freundlich isotherm representing the adsorption decreases. At *p*H 8.54 the hydroxylamine exists almost completely as free amine, and fairly strong adsorption is indicated. Adsorption involving the $-O^-$ end of the molecule is rendered doubtful by the failure of hydroquinone to show any evidence of adsorption.

The dependence of the rate upon the silver-ion concentration almost exactly parallels that found previously in the study of the reaction with hydroquinone. At *p*H 4.16 a power of 0.64 was obtained for hydroxylamine as compared with 0.66 for hydroquinone at *p*H 5.74; and at *p*H 8.54, a power of 0.53 was obtained for hydroxylamine as compared with 0.55 for hydroquinone at *p*H 8.9. Further, the dependence of the rate upon the $SO_3^=$ concentration observed at *p*H 8.54 shows that a reaction between hydroxylamine and the silver sulfite complex does not encroach measurably upon the reaction with silver ion.

In contrast to the hydroquinone–silver-ion reaction, it was possible in the present case to obtain a measure of a preliminary reaction in the gold-nucleated solutions. This preliminary reaction may be either the homogeneous reduction or the gold-catalyzed reduction. Presumably, it is largely the latter, at least in the acid solutions. If we take as a measure of the rate of this preliminary reaction the reciprocal of the *T* values given in Tables I to III, no evidence of adsorption of hydroxylamine is obtained, either in the acid region or at *p*H 8.54. The rate in the *p*H range 3.7–4.4 varied almost exactly as the square of the hydroxyl-ion concentration and as the first power of the hydroxylamine concentration. Once more, however, a dependence upon approximately the two-thirds power of the silver-ion concentration appeared. In addition to the results recorded previously, the real existence of this preliminary reaction received confirmation from the fact that when a freshly prepared nuclear silver sol was employed in place of the gold, only the silver-catalyzed reaction could be detected.

Summary

1. The reaction between silver ion and hydroxylamine is catalyzed by colloidal gold and colloidal silver. The rate of formation of silver was shown to equal the rate of evolution of nitrogen.

2. The reaction in gold-nucleated solution can be resolved into two parts, the silver-catalyzed reaction and a preliminary reaction which is probably gold-catalyzed.

3. Both reactions involve the ion NH_2O^- as the active reducing agent. The kinetics suggest that the ion is adsorbed to silver by way of the amino group in the silver-catalyzed reaction. No adsorption of hydroxylamine is indicated for

evidence was obtained of complications resulting from reduction of silver ion by the sulfite. Once more, nitrogen was evolved in the theoretical amount. In most of the work, sulfite was present in considerable excess, and in calculations of the silver-ion concentration it was assumed that $Ag(SO_3)_2^{\equiv}$ was the only complex ion present. The dissociation constant of this ion was taken as 3×10^{-9}. This rough figure is adequate for calculations of relative concentrations.

The variation of reaction rate with concentration of silver ion and of excess sodium sulfite is given in Tables IV and V. A plot of log R against log C gives an acceptable straight line of slope about 0.53 in the case of silver-ion variation, and of slope about 1.08 in the case of excess sulfite-ion variation.

The salt effect on the silver-catalyzed reaction is negligible, as shown by the data in Table VI.

data is based upon the rate equation derived in the previous paper.[1] The extension downward of this straight line cuts the t-axis at fairly large values of t when the reaction mixture is nucleated with gold sol. As will appear subsequently, the gold-catalyzed reaction is slower than the silver-catalyzed reaction and involves some difference in mechanism. As the reaction proceeds, however, the gold particles become coated with silver, and the reaction goes over into that of the silver-catalyzed reduction. In the following, the rates of the silver-catalyzed reaction are expressed in terms of the slope of the $V^{1/3}$–t straight-line plots, where the volumes are at 20° and 760 mm. As a measure of the preliminary reaction or reactions, the reciprocal of the time, T, required to yield a nitrogen volume of 0.08 ml. (determined from the straight-line intersection) is employed. Time is expressed in minutes.

Parallel determinations of optical density and nitrogen evolution were made under several sets of conditions, and found to yield identical results within experimental error. This is illustrated for one set of data in Fig. 1. In the construction of this figure, the density and volume units were adjusted to give the same maximum value. These results establish the practical identity of the two methods of following the reaction. Further, they show that, if nitrogen evolution is the result of a subsequent reaction, as suggested by Equations 1 and 2, the reaction must be very rapid in comparison with the reduction of the silver ions.

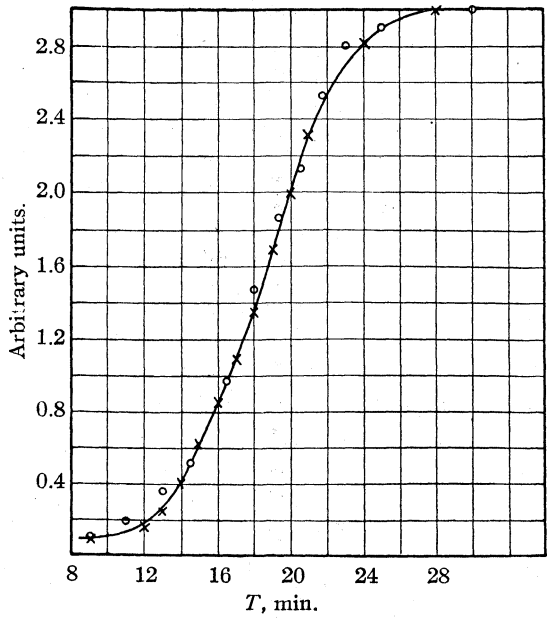

Fig. 1.—Reduction of silver ions by hydroxylamine: ○, silver; ×, N_2 volume.

The variation of reaction rate with *p*H is given in Table I. A plot of log R against pH

TABLE I

VARIATION OF RATE WITH pH

0.2 M sodium acetate, 25 ml.; 1.0 M acetic acid, x ml.; $AgNO_3$, 0.50 mmole.; hydroxylamine sulfate, 2.0 mmole.; gum arabic, 0.133%.

pH	R	2 + log R	T	Log (100/T)
3.70	0.0254	0.405	44.0	0.36

[COMMUNICATION NO. 736 FROM THE KODAK RESEARCH LABORATORIES]

The Reduction of Silver Ions by Hydroxylamine

BY T. H. JAMES

Hydroxylamine appeared to be ideally suited for use in a continuation of the investigation of the reduction of silver ions by developing agents.[1]

The reaction rate can be followed by two independent methods, *i. e.*, optical determination of silver, as previously described, and measurement of nitrogen evolution. The reaction has been subjected to analytical study.[2] Further, it was found that this reaction supplied a transition between the relatively simple kinetics of the hydroquinone reduction and the complicated behavior encountered in a study of the reduction by *p*-phenylenediamine.

Nichols showed that ammoniacal silver nitrate reacts with hydroxylamine to give pure nitrogen. Strongly alkaline silver nitrate–sodium sulfite solution, on the other hand, yields a mixture of nitrogen and nitrous oxide, but the amount of nitrous oxide produced decreases with decreasing alkalinity. For the production of nitrogen, Nichols postulates the alternative mechanisms

$$Ag_2O + 2NH_2OH \longrightarrow 2Ag + H_4N_2O_2 + H_2O$$
$$H_4N_2O_2 \longrightarrow N_2 + 2H_2O \quad (1)$$

or

$$2Ag_2O + 2NH_2OH \longrightarrow 4Ag + H_2N_2O_2 + 2H_2O$$
$$H_2N_2O_2 + 2NH_2OH \longrightarrow 2N_2 + 4H_2O \quad (2)$$

Nitrous oxide, when formed, is considered to arise from the decomposition of hyponitrous acid. Sheppard and Mees showed that the rate of reaction between silver ions and hydroxylamine is accelerated by the addition of alkali, and they concluded that the active species is the ion NH_2O^-. They further observed a catalysis by finely divided silver.

Under the conditions employed in the present investigation, only nitrogen was obtained as reaction product, and this was invariably in the theoretical amount. All measurements were made at 20 ± 0.02°, and a solution volume of 75 ml. was employed. The reactions were carried out in total darkness, or under a no. 1 Wratten safelight.

Materials and Procedure

Hydroxylamine Sulfate.—Eastman Kodak Company preparation recrystallized and dried in vacuum, m. p. 172°.

Colloidal Gold.—Phosphorus reduction[3] failed to show the Tyndall cone.

Salts.—General Chemical Company reagent grade. The reaction mixture was prepared in two parts, one containing the silver nitrate and buffer solution, the other containing the hydroxylamine, 2 ml. of 5% gum arabic solution, and, in general, 2 ml. of gold sol. The solutions were freed from oxygen by means of a stream of pure nitrogen, allowed to attain the temperature of the thermostat, and mixed rapidly at time 0. When nitrogen evolution was employed to follow the reaction course, the apparatus previously employed in the measurement of autoxidation rates[4] was used. The reaction chamber was filled with nitrogen and the buret with water at thermostat temperature. The shaking rate employed was adequate to prevent supersaturation of the reaction mixture with nitrogen. When silver determinations were made, a special apparatus was employed which permitted removal of samples at suitable intervals without allowing air to enter the reaction vessel. The solution was stirred by pure nitrogen throughout the course of reaction.

The reduction of silver ions by hydroxylamine is catalyzed by colloidal gold, and more strongly by colloidal silver. Beyond a nitrogen evolution of 0.08–0.10 ml., a plot of $V^{1/3}$ against t yields a straight line for about one-fourth of the entire reaction. This method of the treatment of the

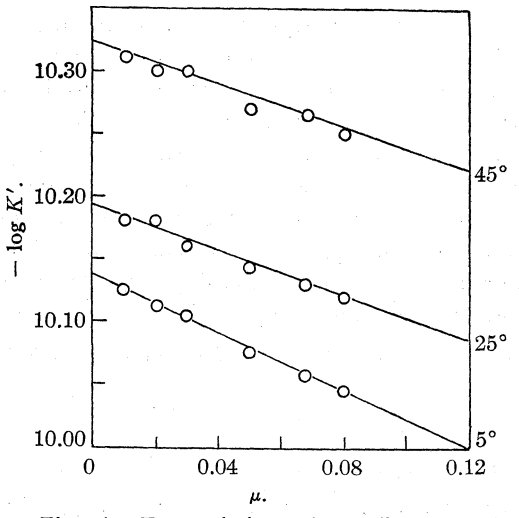

Fig. 1.—Extrapolation plots, diameter of circles equals 0.01 in log K' or approximately 0.4 mv.

may prove important in determining the standard potential in these media of low dielectric constant. It is clear from the nature of the extrapolation plots that an accurate determination of E_0 is possible if the ionization constant is known. A good determination of this quantity by conductance measurements combined with these results would permit the evaluation of E_0 to within ±0.2 mv. Further, there is reason to believe that with an altered technique the accuracy of the present results may be increased.

As previously observed for acetic acid in water and water–organic solvent mixtures of lower dielectric constant, the ionization constant has a maximum value which in this case occurs at about 15°. Owing to the uncertainty of the temperature variation in E_0 and the resulting error in K, we cannot regard the heat data derivable from these results with a high degree of certainty, and have omitted their calculation.

Variation of log K with Mole Fraction of Dioxane–Interpolation Functions.—It has been shown[2] that the plots of log K, or log K_0 − log K, where K_0 is the value of the ionization constant in water, *versus* $1/D$ show considerable curvature both for acetic acid and water. On the other hand, as indicated by Fig. 2, the plot of this quantity against the mole fraction of water or dioxane is nearly linear. This fact can be employed for interpolation by using the equation

$$\log K = -C - C'N_2 \qquad (2)$$

where C and C' are constants and N_2 is the mole fraction of dioxane. The constants were determined from the values of log K in water and 82% dioxane–water mixtures so that the deviations at these solvent compositions are zero. The values of C and C' are given in Table II at all temperatures. The last three columns contain the deviations of the observed results from equation (2) at the concentrations at which K was determined. From these deviations plots can be constructed readily from which log K can be read with an accuracy of the order of 0.002.

Summary

1. From measurements of the cells $H_2|HAc$ (m_1), NaAc (m_2), NaCl (m_3), dioxane (X), H_2O (Y)|AgCl–Ag, the ionization constant of acetic acid has been determined from 5 to 45° in a solvent containing 82% by weight of dioxane, the dielectric constant of which is 9.3 at 25°.

2. The principal source of error in this determination is caused by the uncertainty in the

taken to be constant over the temperature range. The accuracy of its determination is of the order of ±5 cal.

Summary

1. From measurements of the cells, $H_2|NaOH$ (m_1), NaCl (m_2), Dioxane (X), H_2O (Y)|AgCl–Ag, the ionization constant of water has been determined in 20, 45 and 70% dioxane mixtures, and at 5° intervals from 0 to 50° inclusive.

2. The heat content and heat capacity changes of the ionization reaction have been evaluated.

3. The uncertainty in the determination of the ionization constant increases with the dioxane content of the solvent. This is caused by the change in relative solubility of silver chloride and hydroxide and cannot be remedied as long as silver–silver chloride electrodes are employed. Cells containing silver–silver bromide or iodide electrodes would probably be more suitable, but, unfortunately, their standard potentials are not known in these media.

The Properties of Electrolytes in Mixtures of Water and Organic Solvents. III. Ionization Constant of Acetic Acid in an 82% Dioxane–Water Mixture

BY HERBERT S. HARNED AND LESLIE D. FALLON

From the measurements of the electromotive forces of the cells

$H_2|HAC$ (m_1), NaCl (m_2), NaCl (m_3), Dioxane (X), H_2O (Y)|AgCl–Ag

Harned and Kazanjian[1] determined the ionization constant of acetic acid in 20, 45 and 70% dioxane–water mixtures. The first computations depended on standard potentials derived by the Debye–Hückel theory without the use of the extended terms, and have been revised somewhat by Harned.[2] These results have now been extended to 82% dioxane mixtures.

Experimental Results

It was more difficult to obtain high accuracy with these cells than with those containing mixtures of higher dielectric constant. This is caused by the long period of time for equilibrium to be reached, particularly in the cases of cells containing ions at low ionic strengths. However, the average reproducibility of the cells was of the order of ±0.3 mv. The concentrations of acetic acid, sodium acetate and sodium chloride were made equal. These concentrations were known with an accuracy of 0.1% and, consequently, any error from this source was less than that caused by error in the electromotive force measurements. Cells were run in triplicate and the mean values of the electromotive forces taken. These results are compiled in Table I.

TABLE I

Ionization Constant

The equation for the cell may be written in the form[3]

$$\frac{F(E - E_0)}{2.303\,RT} + \log \frac{m_1 m_3}{m_2} = -\log \frac{\gamma_H \gamma_{Cl} \gamma_{HAc}}{\gamma_{H} \gamma_{Ac}} - \log K = -\log K' \quad (1)$$

If the left side or $-\log K'$ is plotted against μ, the intercept at zero μ equals $-\log K$. In Fig. 1, plots of $\log K'$ *versus* μ are shown and it is clear that the values of $-\log K$ can be determined to within ±0.005, or about ±0.2 mv. This uncertainty is very much less than that in the values of the standard potentials, E_0. The difficulty of obtaining E_0 in media of as low a dielectric constant as the present one (D_{25} = 9.53) has been discussed carefully by Harned, Walker and Calmon.[4]

This situation suggests that the present cell

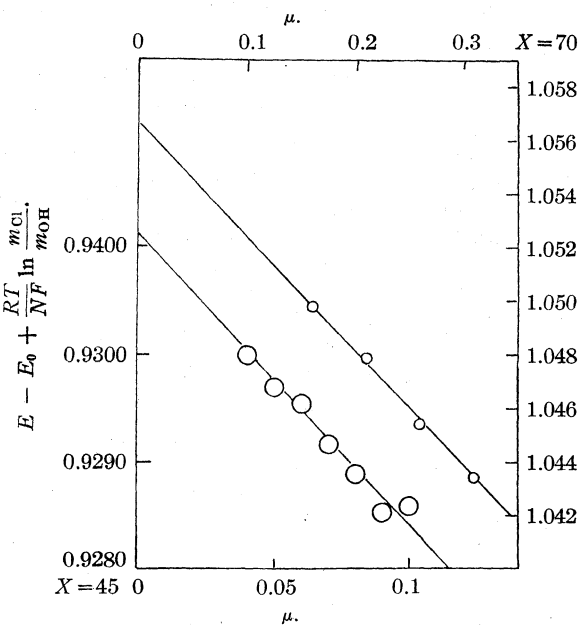

Fig. 2.—Extrapolation of 45 and 70% dioxane–water mixtures at 25°: lower plot ($X = 45$) (diameter of circles equals 0.2 mv.); upper plot ($X = 70$) (diameter of circles equals 0.4 mv.).

in the same manner, the temperature variation of K should be known quite accurately. This is also true of the values of K of the 70% dioxane mixtures in which case the absolute accuracy may not be greater than 0.5 to 1 mv. The values of the standard potentials employed in the case of the 45% dioxane mixtures were those given by Harned and Donelson[7] and for the 70% dioxane mixtures, those obtained by Harned and Calmon.[8] The values of K are given in Table II. For the sake of completeness, values in pure water determined by the same method have been included.[11]

In order to compute the change in heat content and heat capacity of the ionization reaction, we have employed the equation

$$\frac{d \log K}{dT} = \frac{\Delta H_i}{RT^2} \quad (3)$$

and the assumption that ΔH_i varies linearly with temperature. This leads to the equations

$$\log K = (A/T) + B \log T + C \quad (4)$$

$$\Delta H_i = -2.303\,RA + BRT = A' - B'T \quad (5)$$

$$\Delta C_p = BR \quad (6)$$

for K, ΔH_i and ΔC_p, respectively. The constants of these equations derived by the method of least squares are contained in Table III. The

TABLE III

CONSTANTS OF EQUATIONS (4), (5) AND (6)

	X = 20	X = 45	X = 70
A	−6161.329	−6377.395	−5926.389
B	− 24.814	− 27.006	− 24.415
C	67.447	72.472	62.437
A'	28.19	29.18	27.12
B'	49.31	55.66	48.51
ΔC_p	− 49.3	− 53.7	− 48.5

values of the change in heat content, ΔH_i, are given in Table II. Equation (4) with these numerical constants reproduces the observed values of log K with an average accuracy better than ±0.001. It is difficult to estimate the accuracy of this determination of ΔH_i. As previously mentioned, the temperature variation of log K is probably determined fairly accurately even in the case of the 70% dioxane mixtures even though the absolute values of K are somewhat in error. As a tentative estimate, we regard the accuracy of determination of ΔH_i to be of the order of ±50 cal.

ΔC_p according to the method of calculation is

Figure 2 shows the extrapolations in the cases of 45 and 70% mixtures. Although straight lines could be drawn through the points corresponding to the left side of the equation, the extrapolation becomes less certain as the percentage of dioxane increases because the values of μ are so far from the zero axis. As previously explained, it is impossible to remedy this difficulty as long as silver–silver chloride electrodes are employed. The derived values of K in the 45% mixtures are clearly more certain than those for the 70% dioxane mixtures and the absolute values are probably known to within ±0.2 mv. This error in extrapolation is greater than the estimated error of ±0.1 mv. in the evaluation of E_0. However, since extrapolations at all temperatures were made

The Properties of Electrolytes in Mixtures of Water and Organic Solvents. II. Ionization Constant of Water in 20, 45 and 70% Dioxane–Water Mixtures

BY HERBERT S. HARNED AND LESLIE D. FALLON[1]

Very little is known concerning the ionization constant of water in solvents other than water. In order to determine this quantity in media of lower dielectric constant, the electromotive forces of the cells

$$H_2 \mid NaOH\ (m_1),\ NaCl\ (m_2),\ Dioxane\ (X),\ Water\ (Y) \mid AgCl\text{–}Ag$$

have been measured. The results cover the temperature range from 0 to 50° throughout which results of high accuracy may be obtained. The measurements were made in media containing 20, 45 and 70% dioxane by weight.

Experimental Data

The solutions were prepared with an accuracy greater than that caused by the errors in the measurements of the electromotive forces. In the 20% dioxane mixtures the reproducibility was 0.05 mv. and in the 45 and 70% dioxane solutions it was 0.1 mv. The technique with slight modifications was that employed previously for measurements of this kind.[2]

Unfortunately, an unforeseen circumstance made an accurate determination of the ionization constant impractical in the mixtures containing over 70% dioxane. With the 20% dioxane solutions, one to one ratios of sodium chloride to hydroxide yielded very satisfactory results. In the case of the cells containing 45% dioxane and a one to one ratio of salt to hydroxide, the cell electromotive forces were very erratic. However, when the ratio of salt to hydroxide was three to one or greater, a reproducibility of 0.1 mv. was obtained. With the 70% dioxane–water mixtures, erratic results were obtained until a fifteen to one ratio of chloride to hydroxide or greater was employed. With this latter condition the cell reproducibility was again 0.1 mv.

This behavior is attributed to the change in relative solubility of silver chloride and hydroxide in passing from pure aqueous solutions to those containing the higher percentages of dioxane. Since in the media containing much dioxane, suitable points on the graph used for extrapolation could not be obtained near the zero axis, the determination of ionization constant is somewhat uncertain. Since both silver bromide and iodide are less soluble than the chloride in water, cells containing these electrodes would have been more suitable for the present purpose. Unfortunately, the standard potentials of these electrodes in dioxane–water mixtures have not yet been determined.

In Table I, the observed electromotive forces of the cells have been recorded.

Ionization Constant and Derived Thermodynamic Quantities.—The electromotive force, E, of the cell is given by the equation

$$E - E_0 + \frac{RT}{NF}\ln\frac{m_{Cl}}{m_{OH}} = \frac{RT}{NF}\ln\frac{\gamma_H\gamma_{OH}}{\gamma_H\gamma_{Cl}a_{H_2O}} - \frac{RT}{NF}\ln K^{3,4} \quad (1)$$

where E_0 is the standard potential, m_{Cl} and m_{OH} are the stoichiometrical molalities of the chloride and hydroxide, γ_H, γ_{OH} and γ_{Cl}, the activity coefficients of the species denoted by subscripts, a_{H_2O} the activity of water, and K the ionization constant. In these computations, a_{H_2O} as well as $\gamma_H\gamma_{OH}$ and $\gamma_H\gamma_{Cl}$ have been assigned the value unity at zero electrolyte concentration in each solvent. Since

$$K = \frac{\gamma_H\gamma_{OH}}{a_{H_2O}} m_H m_{OH} \quad (2)$$

it is equal to $m_H m_{OH}$ at zero ionic strength in all solvents.

That the extrapolation in the case of the 20% dioxane mixtures can be carried out with high accuracy is shown in Fig. 1. Here the radii of the circles equal 0.01 mv. and the estimation of log K from the graphs is within ±0.02 mv. The standard potentials employed were those computed by Harned[5] from the data of Harned and Morrison.[6] It is probable that the largest source of error in the absolute magnitude of log K is caused by the error in determining E_0. An error of 0.1 mv. in E_0 causes an error of 0.002 in log K or 0.5% in K.

striking, and is several times their estimated experimental error. The discrepancy is also apparent if the activity coefficient of the acid be computed from the vapor pressure data (see Table IV) by means of the Gibbs relation[11]

$$d \ln \gamma m = -(55.51/3m) \cdot d \ln a_1 \qquad (5)$$

One is naturally hesitant to assert that the results of such a manifestly careful research as that of

TABLE IV

m	γ V. p.	γ E. m. f.	m	γ V. p.	γ E. m. f.

Harned and Hamer are in error. However, when one considers the difficulties encountered in e. m. f. measurements in strong solutions, and the possibility that the cell reaction in such solutions is not that postulated, and then contrasts this with the simplicity and directness of a vapor pressure measurement, it would seem advisable on the whole to place considerable reliance on the vapor pressure data.

Recently, Scatchard, Hamer and Wood[2] have compared isopiestically sodium chloride and sulfuric acid solutions. Up to 3 molal, values of a_1, computed from the osmotic coefficients in their Table IIa, agree with our Table II within a unit or so in the fourth decimal place; for 3.5 and 4 m, their ϕ yield values of a_1 which are 0.0003 and 0.0014 less than the values in Table II. The isopiestic results will be discussed in detail in a forthcoming paper; it is sufficient for the moment to say that their isopiestic ratios of concentration are in satisfactory agreement with the results of similar measurements carried out in this Laboratory, and, moreover, are consistent with the measurements of Gibson and Adams and ourselves for sodium chloride and the results recorded here for sulfuric acid. We feel fairly confident that vapor pressures of sulfuric acid solutions at 25° may be obtained from our Tables II and III accurate to 0.01 mm. or better.

(11) In effecting the integration of Eq. 5, Harned and Hamer's value of γ for $m = 1$ was adopted.

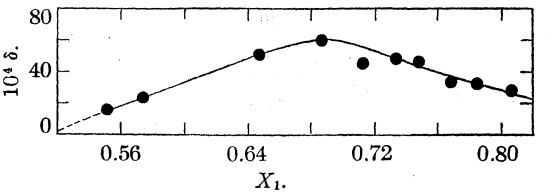

Fig. 2.

Summary

The vapor pressure of sulfuric acid solutions at 25° has been measured by the static method for concentrations ranging from 2 to 23 molal. The results are in good agreement with the vapor pressure measurements of Grollman and Fraser, and are consistent with the vapor pressure measurements of Collins up to 8 molal. They agree with the results of e. m. f. measurements up to 3 molal, but are in definite disagreement at higher concentrations.

Values of the activity of the water and of the activity coefficient of the acid in the solutions have been tabulated at round values of the concentration.

TORONTO, CANADA RECEIVED JUNE 26, 1939

(based on unpublished work of Negus[7]) correspond to $a_1 = 0.1793$ for the 21.53% solution, and, by a slight extrapolation, to $a_1 = 0.2464$ for the solution saturated at 25°, the apparent uncertainty in both cases being ±0.0005.

Table I summarizes the results for sulfuric acid; the first column gives the weight fraction of the acid, the second the molality, and the third the mole fraction of the water defined by

$$X_1 = (x_1/18.016)/(x_1/18.016 + x_2/49.04) \qquad (2)$$

where x_1 is the weight fraction of the water. The fourth column gives the mean observed value of a_1, the activity of the water in the solution (see Eq. 1); as a rule the individual values of a_1 showed a mean absolute deviation from the mean of 0.0002 or less, although in a few cases the deviation was somewhat larger.

.6695	20.65	.5733	.0720		.0718
.6894	22.63	.5509	.0538		.0538

For convenience in representation, two deviation functions were computed, defined by

$$0 < m < 8 \quad a_1 = 1 - 0.02678m - 0.00922m^2 + 0.000556m^3 + \delta_1 \qquad (3)$$

$$0.52 < X_1 < 0.82 \quad a_1 = f_1X_1 + \delta_2 \qquad (4)$$

where $\log f_1 = -5.5254 + 11.422X_1 - 5.8966X_1^2$. These forms are, of course, entirely empirical, but have the advantage that the resulting δ_1 and δ_2 are everywhere less than 0.01, and consequently can be handled graphically; see Figs. 1 and 2. From our values, and from those computed from the vapor pressure data of Grollman and Fraser[8] and from the electromotive force measurements of Harned and Hamer[9] for concentrations less than 3 molal, the smooth curves in the figures were drawn. From these again, with the aid of Eqs. 3 and 4, values of a_1 at round values of the molality for the dilute range (Table II) and at round values of the mole fraction of the water for the concentrated (Table III) were obtained. The interval in both tables is sufficiently fine to permit interpolation by the method of mean second differences[10] and still obtain results numerically accurate to a unit or so in the fourth decimal place; this is illustrated in the last two columns of Table I, which give the values obtained by interpolation in Tables II and III.

Discussion

A glance at Fig. 1 will show that, where they overlap, our results are consistent with those of Grollman and Fraser, who used a Rayleigh gage, although the scattering of their points from the curve at their highest concentrations would seem somewhat greater than their apparent experimental error. Figure 1 also shows the results of Collins, obtained by an isoteniscope with mercury manometer (his Table II). He records his results only to the nearest 0.1 mm. in the more dilute solutions, so that the smoothed entries in his table might be in error by 0.0040; actually, the agreement with our results is a good deal closer. For solutions between 50 and 65% by weight, however, his results disagree with ours by as much as 0.008 in a_1, and would be entirely off Fig. 2.

The position with respect to Harned and Hamer's electromotive force measurements (their Table II) is a curious one. Up to 3 m, the agreement with the vapor pressure data is excellent, the deviations corresponding to less than 0.05 mv.; at 5 and 7 m, however, the discrepancy is

the manometer. The scale had been ruled in millimeters by the dividing engine in the Physics Department of this University, and had been checked by a microscope comparator; interpolation to fractions of a millimeter was accomplished by means of the graticuled scale in the eyepiece of the telescope.

The manometer liquid in the earlier runs was butyl phthalate, which has been recommended by Gibson and Adams; we found it necessary to use the special grade supplied by Distillation Products if satisfactory results were to be obtained. Even when distilled into the manometer under high vacuum and shielded from contact with the air, however, it only could be used for about a week or so before it was necessary to replace it. In some later work, Cenco Hyvac pump oil (density at 25°, 0.895) was employed; this was first out-gassed in the vacuum pump, and was then transferred as quickly as possible to the manometer through a side neck, which was then sealed off; the oil was then refluxed in the manometer under high vacuum for several hours. It proved to be a stable and satisfactory manometer liquid, its principal disadvantages as compared with butyl phthalate being its greater viscosity and its somewhat hazier meniscus. Tests showed that both manometer liquids gave identical results (within the limit of error of the experiments) for the activity of the water in the solutions.

The most serious experimental difficulty in a static vapor pressure measurement is the removal of the residual air from the liquid. This was effected by freezing solution and solvent (as well as the solvent in the auxiliary flask[4] W) while they were boiling under vacuum, the resulting residual pressure being 0.002 mm. or less as determined on the McLeod gage. The flasks were then shut off from the rest of the apparatus, the contents melted, and the whole procedure repeated four or five times. For water, sodium chloride solutions, and for sulfuric acid solutions less than 4 *m*, a mixture of chloroform and dry ice served as freezing mixture, for acid solutions stronger than 4 *m*, liquid air. After out-gassing, the apparatus was allowed to come to temperature equilibrium, and the vapor pressures of water and of solution as well as the differential lowering were followed for a period of from one to three days.

Although the inherent error of a reading is somewhat less than 0.1 mm. of manometer liquid, a fluctuation of bath temperature of 0.01° would cause a change in the vapor pressure of water of nearly twice this amount. However, by having solution and solvent flasks placed symmetrically in the bath, and by always having the contents of the two flasks of approximately the same heat capacity, one would hope that the vapor pressures of both solution and solvent would "hunt" together, and that this error would largely cancel in the ratio. The high reproducibility of the results would seem to show that this is the case. For example, in a series of measurements on a 39.55% by weight solution (6.671 *m*), one result recorded about two hours after the apparatus had been brought on temperature was: $P^0 = 361.1$, $P_1 = 207.4_5$, $\Delta P = 153.7_5$ where P^0, P_1 and ΔP are the vapor pressure of water, the vapor pressure of solution, and the differential vapor pressure lowering, all expressed in mm. of pump oil. The activity of the water, given by

$$a_1 = 2P_1/(P^0 + P_1 + \Delta P) \qquad (1)$$

is thus 0.5744. Twenty-four hours later, a measurement gave $P^0 = 360.1$, $P_1 = 206.7$, $\Delta P = 153.4$, $a_1 = 0.5740$. Thus a_1 only changed by 0.0004, although the individual readings changed by about a part in 300. The mean of all measurements for this run, as recorded in Table I, is $a_1 = 0.5743$ with a mean absolute deviation from the mean of 0.0002.

Chemicals and Analysis.—C. P. sulfuric acid (sp. gr. 1.84) was distilled under vacuum in an all-glass apparatus, the first and last fractions of the distillate being rejected; the final product was free from sulfite. From this acid solutions of desired strength were made up by dilution with a good grade of conductivity water. At the end of each experiment, the acid solutions were analyzed by gravimetric titration with recrystallized sodium bicarbonate which had been fused and cooled in an atmosphere of dry carbon dioxide; after heating to boiling, 0.05 *N* sulfuric acid and carbonate-free sodium hydroxide were used for back titration to obtain the final end-point with methyl red as indicator.[5] Duplicate analyses agreed to 0.03% or better; in calculating the concentration, all weights were reduced to vacuum.

The sodium chloride was British Drug Houses "Analar"; the unsaturated solution used in one experiment was analyzed by evaporating it to dryness on a steam-bath and then heating to 600°.

Experimental Results

As a check on the apparatus and technique, a few preliminary measurements were carried out on sodium chloride solutions. At 25°, a 21.53% by weight solution gave $\Delta P/P^0 = 0.1801$; a saturated solution at 25° gave 0.2468, and at 20.28°, 0.2456. Gibson and Adams[4] have studied sodium chloride solutions at 25° by a dynamic method; interpolation[6] of their results gives for 21.53 weight per cent., 0.1804. By a slight extrapolation of their results to $x_2 = 0.2643$ (6.144 *m*), $\Delta P/P^0$ for the solution saturated at 25° is 0.2469; their result by the static method for the solution saturated at 20.28° is 0.2454. The agreement between our results and theirs in all three cases is satisfactory, and is within the apparent limit of error of either set of experiments. The results recorded in "International Critical Tables"

(5) T. W. Richards and C. R. Hoover, THIS JOURNAL, **37**, 95, 108 (1915).

(6) For the concentrations studied by Gibson and Adams, $\Delta P/x_2P^0$ is practically linear in x_2, the weight fraction of the salt.

deg.$^{-1}$ mole^{-1}. This value does not include the contribution due to nuclear spin.

We thank the Shell Development Company for donating the propylene used for these measurements and Dr. R. A. Ruehrwein for assistance with the experimental work.

Summary

The heat capacity of solid and liquid propylene has been measured from 14 to 226°K.

The melting and boiling points are 87.85 and 225.35°K., respectively. (0°C. = 273.10°K.)

The heats of fusion and vaporization were measured calorimetrically and were found to be 717.6 and 4402 cal./mole, respectively.

The vapor pressure of propylene was measured from 165.8 to 225.9°K. and the results have been represented by the equation

$$\log_{10} P_{(\text{inter. cm. Hg})} = -\frac{1196.9}{T} - 3.92 \times 10^{-3} T + 8.07544$$

The gas density of propylene was determined to be 1.7461 grams per liter at 25.00°C. and 1 atmosphere.

The calorimetric data have been used to calculate the entropy of propylene gas and the value at the boiling point was found to be 59.93 cal. deg.$^{-1}$ mole^{-1}. The value calculated for this temperature from available molecular data is 61.0 ± 0.3 cal. deg.$^{-1}$ mole^{-1}. The entropy discrepancy is interpreted as due to random end for end orientation of $CH_2{=}CH{-}CH_3$ molecules in the crystal lattice.

It is concluded that unsymmetrically placed double bonds in otherwise symmetrical hydrocarbons will lead to a disordered arrangement in the crystal lattice and a suitable entropy correction should be made to the $\int C_p \, d \ln T$.

The most reliable value for the entropy of propylene gas at 298.1°K. and 1 atmosphere is 64.0 cal. deg.$^{-1}$ mole^{-1}, calculated from molecular data.

The Vapor Pressure of Aqueous Solutions of Sulfuric Acid

BY S. SHANKMAN AND A. R. GORDON

The growing importance of the isopiestic method of investigating the thermodynamic properties of aqueous solutions has emphasized the need for reliable standards. In their pioneer work in this field, Sinclair and Robinson[1] adopted potassium chloride as reference substance, but, more recently, Scatchard, Hamer and Wood[2] have selected sodium chloride for their standard curve. While sodium chloride is eminently suitable for the dilute range of concentration, it cannot be employed for solutions in which the activity of the water is less than 0.75; sulfuric acid would seem to be the obvious alternative to serve as standard when studying the more concentrated range. While the vapor pressure and e. m. f. data for sulfuric acid solutions are of high precision and are in satisfactory agreement up to 3 molal, the case is somewhat different for higher concentrations. The vapor pressure measurements of Collins[3] (which are usually quoted in the literature) are not of the highest accuracy, and, moreover, are in disagreement with the e. m. f. measurements. We have therefore measured the vapor pressure of sulfuric acid solutions at 25° for concentrations from 2 molal to 23 molal by the static method.

Experimental

The apparatus was similar to that of Gibson and Adams[4]; we may say at once that we can fully substantiate their claims as to its convenience and accuracy. Since it has been discussed adequately, no lengthy description is needed here; its essential feature is that it is possible to measure the vapor pressure of the solution, the vapor pressure of the pure solvent, and the differential vapor pressure lowering by a suitable manipulation of stopcocks (see Fig. 1 of ref. 4).

In our apparatus, the flasks, containing about 25 cc. of solution or solvent, were of approximately 75 cc. capacity, and were placed symmetrically with respect to regulator, heater and stirrer in a water-bath controlled to 0.01°. The internal diameter of the manometer tubing was 15 mm.; the heights of the manometer liquid were measured by comparing them through a telescope with a vertical plate glass scale, placed immediately in front of the two legs of

TABLE X

SUMMARY OF ENTROPY CALCULATION

0–15°K. Debye function, $hc\nu/k$ = 100	0.482
15–87.85°K., graphical	11.543
Fusion, 717.6/87.85	8.168
87.85–225.35°K., graphical	20.014
Vaporization, 4402/225.35	19.534
Actual gas at boiling point	59.74 ± 0.1
Correction for gas imperfection	0.19
Ideal gas at 225.35°K.	59.93
$\int_{225.35}^{298.1} C_p(\text{gas})\, d\ln T$ from molecular data	3.0
Ideal gas at 298.1°K.	62.9 cal. deg.$^{-1}$ mole^{-1}

The correction for gas imperfection was made by means of an equation of state to be published shortly by Mr. E. E. Roper,[14] who has kindly calculated the value of $S_{\text{ideal}} - S_{\text{actual}}$ for us from his data.

The molecular data on propylene are not known very accurately but Kassel[15] has calculated the translational and rotational entropy by assuming values for interatomic distances which should be reasonably accurate. (Values used were C—C, 1.53×10^{-8} cm.; C=C, 1.35×10^{-8} cm.; C—H, 1.1×10^{-8} cm.; with tetrahedral angles.) From these data and the assumption of free rotation of the methyl group he obtains

$$S_{(\text{Trans. + rot.})} = 11.73 + 9/2\, R \ln T$$

However, Pitzer[16] has predicted that the rotation of the methyl group is hindered and has given tables,[17] based on the assumption of a reasonable type of potential function, which readily allow calculation of the entropy difference of a hindered rotator and a freely rotating group. These tables are expressed as functions of the moments of inertia of the rotating groups and the number and height of the potential barriers.

Kistiakowsky[18] has investigated the heat capacity of propylene gas and has reached the conclusion that the potential barrier lies between 600 and 800 cal. per mole for the rotation of the methyl group. Using 700 cal. per mole and taking the value 4.7×10^{-40} g. cm.^{2} as the moment of inertia for the methyl group, the entropy associated with translation and rotation was calculated. The entropy due to vibration was calculated from levels suggested by E. B. Wilson and used by Kistiakowsky. The values in cm.$^{-1}$ and the statistical weights are: 432, (1); 580 (1); 700, (1); 900, (3); 920, (1); 1100, (1); 1200, (1); 1247, (1); 1300, (1); 1415, (2); 1648, (1); 3000, (6). The entropy calculation is summarized in Table XI.

TABLE XI

THE ENTROPY OF PROPYLENE FROM MOLECULAR DATA

	223.35°K.	298.1°K.
$S_{(\text{Trans. + rot.})}$ assuming free rotation	60.17	62.67
Correction for hindered rotation	−0.23	−1.00
$S_{\text{vib. harmonic}}$	1.08	2.37
S of ideal gas in cal. deg.$^{-1}$ mole^{-1}	61.0 ± 0.3	64.0

The experimental value of the entropy calculated in Table X is 59.90 cal. deg.$^{-1}$ mole^{-1} or 1.1 units less than the calculated value, 61.0 cal. deg.$^{-1}$ mole^{-1}, given in Table XI. The discrepancy is outside the combined limits of error of the theoretical calculation and the experimental determination, and it is believed to be due to random end for end orientation of CH_2=CH—CH_3 in the crystal lattice. Complete lack of discrimination between the CH_2 and CH_3 groups would correspond to a discrepancy of $R \ln 2$ = 1.38 cal. deg.$^{-1}$ mole^{-1}.

This is the first case where false equilibrium due to random orientation of groups of atoms has been demonstrated and it leads to the conclusion that a similar effect is to be expected in all organic molecules where CH_3 and CH_2 groups occupy otherwise equivalent positions in a molecule. In larger molecules, with higher melting points than the 87.85°K. melting point of propylene, random orientation is still more likely to represent thermodynamic equilibrium when the substance solidifies, and the chance of attaining an ordered arrangement as the temperature is lowered is less. Moreover, it seems necessary to conclude that when one or more double bonds are unsymmetrically placed in internal positions in otherwise symmetrical hydrocarbons, a similar disorder will occur and an appropriate correction should be made to the entropy value obtained by the ordinary application of the third law of thermodynamics.

The most reliable value of the entropy for use in the thermodynamic calculations is 64.0 cal.

(2.5 g.) and zinc chloride (0.5 g.) in acetic acid (25 cc.). The mixture was allowed to stand for thirty minutes, a drop of sulfuric acid was added, and it was then refluxed for thirty minutes. The cooled solution was poured into water and extracted with petroleum ether. The extract was washed with water, and then extracted exhaustively first with aqueous sodium hydroxide (5%) and then with Claisen's alkali. The petroleum ether layer was then washed with water and dried.

From the aqueous alkali extractions, carbon dioxide precipitated a gummy solid (300 mg.), principally unchanged hydroquinone. Acidification and extraction of the Claisen's alkali extract gave 700 mg. of a brown, viscous oil. This was the chroman VI (R = H), possibly containing the chroman VII. The original petroleum ether solution, after extraction, yielded 700 mg. of a viscous oil, the double chroman VIII.

Oxidation of the Non-phenolic Constituent (VIII).—This material (700 mg.) was dissolved in absolute ethanol (35 cc.) and the solution was refluxed with silver nitrate (5 g.) for an hour and forty-five minutes. It was then diluted with water and extracted with ether. Removal of the ether left a red oil which was taken up in petroleum ether. This solution, on cooling, deposited the red quinone IV, m. p. and mixed m. p. 109–110°.

Oxidation of the Phenolic Constituents (VI and VII).—This material (700 mg.) was dissolved in absolute ethanol (500 cc.) and nitric acid (100 cc.) was added. The solution was heated on the steam-bath for fifteen minutes, then diluted with ice water (3000 cc.) and cooled to 0°. The cold solution was extracted exhaustively with ether and the extracts were washed free from acid. Removal of the ether left a red oil (400 mg.) which was taken up in ether–petroleum ether and crystallized. The product was the red quinone IV, m. p. 109.5–110.5°; mixed m. p. 109–110°.

Oxidation of α-Tocopherol; 2,7,8-Trimethyl-2-(4′,8′,12′-trimethyltridecyl-1)-chroman-5,6-quinone (IV, R = $C_{16}H_{31}$).—To a solution of synthetic *dl*-α-tocopherol (1.190 g.) in absolute ethanol (1190 cc.) was added concd. nitric acid (238 cc.). The solution was heated on the steam-bath for twenty-five minutes, then cooled and diluted with a large excess of ice water (3000 cc.). The mixture was extracted with ether, and the extracts were washed with water until free from acid. After drying the ethereal solution, the solvent was distilled off. The residue was a red oil which could not be crystallized.[18]

Phenazine.—The red oil from oxidation of α-tocopherol (0.225 g.) was dissolved in acetic acid (4.5 cc.) and *o*-phenylenediamine (0.159 g.) was added. After standing for three and a half hours, excess water was added and the product was extracted with a mixture of ether and petroleum ether. The extracts were washed with water and dried over sodium sulfate. The dry solution was chromatographed, using a column of Brockman alumina. The bulk of the material appeared in a wide yellow zone which fluoresced strongly in ultraviolet light. This zone was cut out and eluted with ether. The yellow ethereal solution showed a strong greenish fluorescence both in daylight and in ultraviolet light. The solvent was removed, but the residue was an orange oil which could not be crystallized.

Summary

1. When 6-hydroxychromans are oxidized by silver nitrate or by nitric acid, the products are red chroman-5,6-quinones. Any group in the 5-position of the hydroxychroman is eliminated in this reaction. Certain facts having a bearing on the mechanism of this reaction are reported.

2. The structure of the *o*-quinone from 2,2,5,-7,8-pentamethyl-6-hydroxychroman has been proved by synthesizing it from derivatives of *o*-xylohydroquinone.

3. Certain similarities between the absorption spectra of these red compounds and known ortho quinones are discussed.

4. The quantitative aspects of the photometric method of Furter and Meyer are discussed, and the limits of the reaction have been further defined and extended. It is pointed out that catechol derivatives, if present, may interfere.

5. The red chroman-5,6-quinone from α-tocopherol is an uncrystallizable oil. Evidence is presented to show that this substance forms a phenazine, although the latter is also an oil.

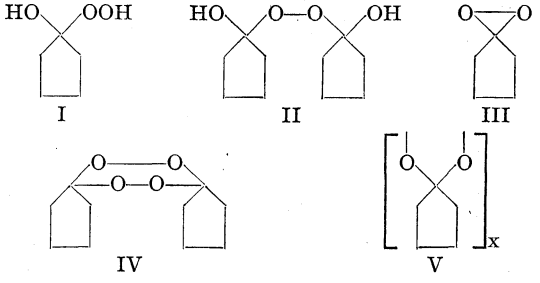
Studies in Organic Peroxides. VI. Cyclane Peroxides[1]

BY NICHOLAS A. MILAS, S. ARTHUR HARRIS[2] AND PAUL C. PANAGIOTAKOS

When cyclic ketones are allowed to react with anhydrous hydrogen peroxide three types of peroxides may form: 1-hydroxycyclanyl hydroperoxide-1 (I), 1,1′-dihydroxydicyclanyl peroxide-1,1′ (II) and cyclanylidene peroxides (III, IV, and V). Using cyclopentyl as the cyclopolymethylene radical these may be illustrated as follows



In certain cases, especially with cyclopentanone and straight chain ketones like acetone, type I reverts spontaneously to type III, IV or V, whereas in other cases this reaction needs a suitable dehydrating agent.

Inasmuch as very little work has been reported in this field[3] and we became interested in exploring it, the present communication describes some of our results in the synthesis of a number of cyclane peroxides. Hydrogen peroxide in aqueous solutions with a suitable catalyst or persulfuric acid have been found convenient reagents for the oxidation of cyclic ketones to the corresponding dicarboxylic acids.[3,4] However, when hydrogen peroxide is used in non-aqueous solvents such as ether or *t*-butyl alcohol, very little or no oxidation occurs but instead peroxides of the type I, II, IV and V are formed.

Experimental Part

1-Hydroxycyclopentyl Hydroperoxide-1 (I).—The cyclopentanone (Eastman Kodak Company) used was purified by fractionation and the fraction boiling at 129–130° collected. A solution of 5 g. of the ketone in 100 cc. of 0.6 molal hydrogen peroxide in anhydrous ether was allowed to stand at room temperature for a few days. The ether was then removed at room temperature under reduced pressure and the viscous residue subjected to a vacuum of about 1 mm. for several hours to remove any unconverted ketone and free hydrogen peroxide. The viscous residue, 6.2 g., was analyzed for active oxygen using an acetone solution of sodium iodide acidified with acetic acid and titrating the liberated iodine against standard sodium thiosulfate.

Anal. Calcd. for $C_5H_{10}O_3$: active (O), 13.6. Found: active (O), 13.9, 14.4.

This experiment was repeated a number of times with both ether and *t*-butyl alcohol as solvents with identical results. It may be mentioned here that the peroxide is highly explosive and on one occasion when the equivalent of 10 g. of cyclopentanone was used with the corresponding amount of hydrogen peroxide in ether, a violent explosion occurred causing a considerable amount of damage, as the ether was being removed under vacuum at the temperature of the water-bath.

1,1′-Dihydroxydicyclopentyl Peroxide-1,1′ (II).—A solution of 5 g. of cyclopentanone in 50 cc. of 0.6 molal hydrogen peroxide in anhydrous ether was allowed to stand at room temperature for a few days, then the ether was removed under reduced pressure and the viscous residue subjected to a vacuum of about 1 mm. for a few hours to remove all volatile products. The residue, 5.5 g., was analyzed for active oxygen.

Anal. Calcd. for $C_{10}H_{18}O_4$: active (O), 7.92. Found: active (O), 8.12, 7.84.

Dicyclopentylidene Peroxide (IV).—When 1-hydroxycyclopentyl hydroperoxide-1 is allowed to stand at room temperature for several days crystals (needles) begin to come out. These were separated and dried on a porous plate. Cooling the viscous residue to 0° for some time enhances crystallization. These crystals melt rather sharply at 73–75° and the melt begins to show evolution of gas at 105°. They explode violently when heated on a steel spatula.

Anal. Calcd. for $C_5H_{10}O_3 \cdot {}^1/_2H_2O_2$: active (O), 17.8. Found: active (O), 18.7, 18.6, 18.64.

This peroxide also has been prepared by allowing cyclopentanone (1 cc.) to react with 30% hydrogen peroxide, "Albone C," (1 cc.) for two days, then cooling the clear solution in an ice–salt mixture whereby a white crystalline solid separated out. This solid was dried on a porous plate and found to have a m. p. of 73–75° and an analysis of 18.6% active oxygen.

In view of these results, we have come to the conclusion that this peroxide is probably 1-hydroxycyclopentyl hydroperoxide-1 with half a mole of hydrogen peroxide of crystallization. Because of its explosiveness we were unable to run combustions for carbon and hydrogen. This also has been the case with all other peroxides obtained from cyclopentanone.

(4) Ruzicka and Stoll, *ibid.*, **11**, 1159 (1928).

Whenever the peroxide, m. p. 73–75°, was recrystallized from ether or from a 50–50 mixture of ether and petroleum ether, a new crystalline (needles) peroxide was obtained, m. p. 160° with effervescence. This peroxide is soluble in a number of organic solvents including ether, alcohol, acetone, dioxane, etc. It liberates iodine instantly from a sodium iodide solution in acetone acidified with acetic acid.

Anal. Calcd. for $C_5H_8O_2$: active (O), 16.0. Found: active (O), 16.13, 15.6, 16.5.

Inasmuch as the m. p. of this peroxide is too high for a five carbon substance, it was suspected early that it might be a polymer of cyclopentylidene peroxide. A molecular weight was therefore taken in *t*-butyl alcohol and in camphor and found to be 206 and 202, respectively, as against 200 calculated for dicyclopentylidene peroxide.

Polycyclopentylidene Peroxide.—When 1,1′-dihydroxydicyclopentylidene peroxide-1,1′ (II) is allowed to stand at room temperature for several days a solid peroxide separates out which melts at 166° with effervescence. A mixed m. p. with dicyclopentylidene peroxide showed no depression. However, unlike the latter peroxide this is completely insoluble in ether, alcohol, acetone and other common organic solvents, and, in view of this property, fails to liberate iodine from an acidified acetone–sodium iodide solution even after five days of standing at room temperature. Dioxane was the only suitable solvent, from which it was recrystallized several times with no change in m. p. An attempt to determine its molecular weight was unsuccessful. An analysis for active oxygen in an acidified solution of sodium iodide in dioxane gave highly unsatisfactory results. Finally, when it was refluxed in an acetone–acetic acid–sodium iodide solution for one hour, using appropriate blanks, it yielded only about three-fourths of its active oxygen.

Anal. Calcd. for $(C_5H_8O_2)_x$: active (O), 16.0. Found: active (O), 12.6.

Although this peroxide is very inert, under ordinary conditions, it explodes violently when heated on a steel spatula. A yield of over 50% was obtained as cyclopolypentylidene peroxide from the original reaction product.

This same polymer was also obtained in smaller quantities together with the dimer when the peroxide of m. p. 73–75° was treated with various solvents.

1-Hydroxycyclohexyl Hydroperoxide-1.—Five grams of cyclohexanone (b. p. 155–156°) was mixed with 85 cc. of 0.6 molal hydrogen peroxide solution in anhydrous ether and the mixture allowed to stand at room temperature for one day. The ether was then removed under reduced pressure and the viscous residue allowed to stand at room temperature, whereby it crystallized out after one day. The crystals were dried on a porous plate; yield, 3.8 g.; m. p. 76–78° which did not change appreciably after recrystallization from ether.

Anal. Calcd. for $C_6H_{12}O_3$: active (O), 12.13. Found: active (O), 12.94, 12.96.

This peroxide is rather stable and explodes only mildly when heated on a steel spatula.

1,1′-Dihydroxydicyclohexyl Peroxide-1,1′.—A solution of 8.8 g. of cyclohexanone in 87 cc. of 0.55 molal hydrogen peroxide in anhydrous ether was allowed to stand for two days. The ether was then removed under reduced pressure and the highly viscous residue was allowed to stand at 0° for twenty-four hours, whereby it was converted into a white crystalline mass which was recrystallized from ether; m. p. 68–70°. A yield of 4.1 g. of the pure product was obtained. This peroxide is insoluble in water and fails to liberate iodine from an acidified solution of potassium iodide. It was therefore analyzed by the acetone method used throughout this work.

Anal. Calcd. for $C_{12}H_{22}O_4$: active (O), 6.96. Found: active (O), 6.89.

When heated on a steel spatula this peroxide does not explode but burns with a smoky flame.

Hydroxymethylcyclohexyl Hydroperoxides and Peroxides.—Seven peroxides were obtained from the three methylcyclohexanones. For the hydroperoxides equimolecular proportions of the ketones (Eastman Kodak Company) and 0.6 molal hydrogen peroxide in anhydrous ether were mixed together and the mixtures allowed to stand at room temperature for some time. For the peroxides the molal ratio used of the ketone to peroxide was 2:1. After a number of days, in all cases the ether was removed under reduced pressure and the products obtained separated and analyzed. All peroxides thus obtained with the exception of those obtained from *o*-methylcyclohexanone were highly viscous liquids but failed to crystallize even when cooled to −20°. The viscosity of the peroxides from *o*-methylcyclohexanone was rather low and only increased slightly when cooled to −20°. Analytical and other data of these peroxides are given in Table I.

TABLE I

SUMMARY OF DATA FOR THE HYDROXYMETHYLCYCLOHEXYL HYDROPEROXIDES AND PEROXIDES

Peroxide	Formula	Yield, %	Active (O) Calcd.	Active (O) Found
1-Hydroxy-3-methylcyclohexyl hydroperoxide-1	$C_7H_{14}O_3$	89	10.95	10.25, 10.27
1-Hydroxy-2-methylcyclohexyl hydroperoxide-1	$C_7H_{14}O_3$	90	10.95	10.51
1-Hydroxy-4-methylcyclohexyl hydroperoxide-1	$C_7H_{14}O_3$	86	10.95	11.48, 11.30
1,1′-Dihydroxy-3,3′-dimethyldicyclohexyl peroxide-1,1′	$C_{14}H_{26}O_4$	98	6.21	6.21
1,1′-Dihydroxy-2,2′-dimethyldicyclohexyl peroxide-1,1′	$C_{14}H_{26}O_4$	89	6.21	6.13
1,1′-Dihydroxy-4,4′-dimethyldicyclohexyl peroxide-1,1′	$C_{14}H_{26}O_4$	89	6.21	6.07

When 1-hydroxy-3-methylcyclohexyl hydroperoxide-1 was allowed to stand at room temperature for a number of days, crystals began to separate which, after several recrystallizations from anhydrous ether, melted rather sharply at 120–121°.

Anal. Calcd. for $C_7H_{12}O_2 \cdot {}^1/_2H_2O_2$: active (O), 16.5. Found: active (O), 16.0.

This peroxide is highly explosive when heated on a steel spatula and behaves in all respects like the cyclopentylidene peroxide with hydrogen peroxide of crystallization. However, after several crystallizations we were unable to obtain 3-methylcyclohexylidene peroxide free from hydrogen peroxide.

1-Hydroxycycloheptyl Hydroperoxide-1.—Five grams of cycloheptanone was mixed with 100 cc. of 0.55 molal hydrogen peroxide in anhydrous ether and the mixture

was allowed to stand at room temperature for several days. When the ether was removed under reduced pressure, the highly viscous residue (4.5 g.) partly crystallized out, and the crystals separated and dried on a porous plate; m. p. 92–94°.

Anal. Calcd. for $C_7H_{14}O_3$: active (O), 10.95. Found: active (O), 10.00.

The dihydroxydicycloheptyl peroxide was not prepared.

1-Hydroxycycloöctyl Hydroperoxide-1.—A solution of 4.4 g. of cycloöctanone in 120 cc. of 0.55 molal hydrogen peroxide in anhydrous ether was allowed to stand at room temperature for several days. To remove the excess hydrogen peroxide the mixture was then shaken several times with a saturated ammonium sulfate solution until the aqueous layer gave a negative test for hydrogen peroxide. The ether layer was then dried with anhydrous magnesium sulfate, filtered and the ether removed under reduced pressure. A highly viscous semi-solid product, 4.4 g., was obtained which became curdy on standing for several weeks at room temperature, but failed to crystallize even when cooled to −78°.

Anal. Calcd. for $C_8H_{16}O_3$: active (O), 10.00. Found: active (O), 9.65.

1,1′-Dihydroxydicycloöctyl Peroxide-1,1′.—This peroxide was prepared in the same manner as the monocycloöctyl except that the proportions of reagents used were different. A solution of 2.6 g. (0.0206 mole) of cycloöctanone in 22 cc. of 0.55 molal hydrogen peroxide in anhydrous ether was allowed to stand at room temperature for several days. It was then shaken several times with a saturated solution of ammonium sulfate until the latter showed no test for hydrogen peroxide. Finally, the ethereal solution was dried with anhydrous magnesium sulfate, filtered and the ether removed under reduced pressure. A yield of 2.2 g. of highly viscous product was obtained which failed to crystallize.

Anal. Calcd. for $C_{16}H_{30}O_4$: active (O), 5.59. Found: active (O), 5.53.

We are indebted to Dr. R. B. Woodward of Harvard University for supplying the C_7 and C_8 ketones.

Summary

Seventeen cyclane peroxides have been prepared by the interaction of hydrogen peroxide in anhydrous ether with a number of cyclic ketones.

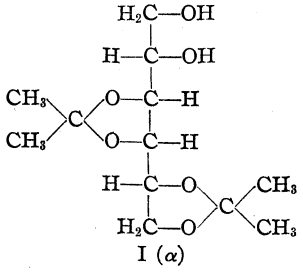
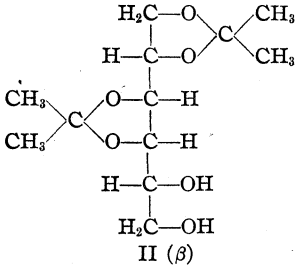
The Structures of the Diacetone Dulcitols[1]

BY RAYMOND M. HANN, W. DAYTON MACLAY AND C. S. HUDSON

Recently Pizzarello and Freudenberg[2] have proposed structures for the two diacetone dulcitols that were originally described by Fischer,[3] assigning to the α-diacetone dulcitol the structure of 3,4:5,6-diacetone dulcitol (I) and to the β-isomer that of 1,2:3,4-diacetone dulcitol (II).



I (α)



II (β)

Pizzarello and Freudenberg point out that the proposed structures are enantiomorphous and they emphasize that the ready separation of the α- and β-diacetone dulcitols by fractional crystallization is thus in conflict with general experience. It also may be added that the substances exhibit very different melting points, solubilities and crystalline forms (as shown by optical crystallographic measurements), all of which facts seem to exclude the idea of enantiomorphism. Neither of them is optically active. The basis of assignment of the enantiomorphous structures was (1) that lead tetraacetate oxidation in benzene solution of both diacetone dulcitols yielded formaldehyde, indicating the presence of contiguous hydroxyl groups, one of which must be primary, in the molecules and (2) that α-diacetone dulcitol could be transformed by alkaline permanganate oxidation to a derivative of D-galactonic acid (potassium diacetone D-galactonate) and (3) that β-diacetone dulcitol under similar oxidative procedure yielded the enantiomorphous derivative of L-galactonic acid (potassium diacetone L-galactonate). A review of the earlier researches of Fischer[3] and of Fischer and Bergmann[4] upon the diacetone dulcitols revealed that these substances undergo several interesting

and unexplained reactions. We have therefore, with the agreement of Dr. Freudenberg, undertaken a further study of the reactions of the isomeric diacetone dulcitols.

The lack of correspondence in physical properties of the α- and β-diacetone dulcitols seems to exclude the possibility of their being enantiomorphous forms, as has been mentioned. Further evidence on this point has now been obtained through the preparation of several of their derivatives. As is apparent from the data recorded in Table I, the melting points of corresponding derivatives are greatly different and the same is true for their crystalline appearances and solubilities; the trityl derivatives have different compositions. None of them exhibits optical activity. It is thus apparent that these derivatives are in no case enantiomorphous forms. One is driven to the conclusion that *the α- and β-diacetone dulcitols are not enantiomorphous substances and hence must be structural isomers.*

TABLE I

MELTING POINTS OF DERIVATIVES OF THE α- AND β-DIACETONE DULCITOLS

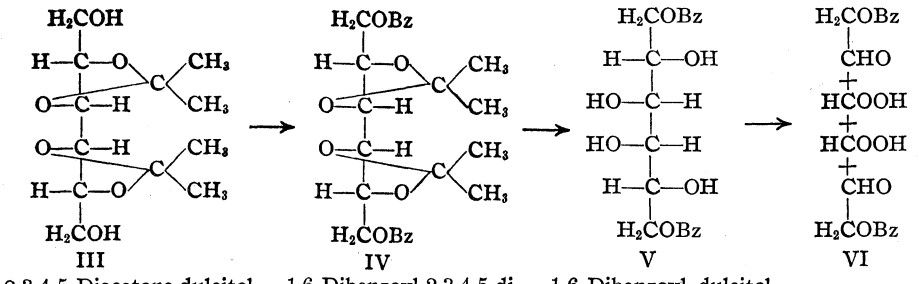
Derivative	From α-diacetone dulcitol	From β-diacetone dulcitol
Diacetate	89°	134°
Ditosylate	101°	165–166°
Trityl	(Monotrityl monoacetyl) 107–108°	(Ditrityl) 233–234°
Dibenzoate	82–83°[a]	183–184°[b]

[a] This is the substance which Fischer and Bergmann (ref. 4) designated empirically β-dibenzoyl-diacetone dulcitol. The proof that it is a derivative of α-diacetone dulcitol is presented later in this article. We change its name to dibenzoyl α-diacetone dulcitol. [b] This is the substance which Fischer (ref. 3) designated empirically α-dibenzoyl-diacetone dulcitol. The proof that it is a derivative of β-diacetone dulcitol is presented later in this article. We change its name to dibenzoyl β-diacetone dulcitol.

Our initial investigation of the action of various oxidizing agents on the diacetone dulcitols indicated that hydrolysis occurred readily in the presence of very dilute mineral acids and slowly even when organic acids were present. Periodic acid of 0.4 normality rapidly removed the acetone groups and attacked the free hydroxyls thus formed. On the other hand, sodium periodate in aqueous solution or lead tetraacetate in glacial acetic acid solution was essentially without effect over a period of twenty-four hours at room temperature and thereafter caused a slow oxidation, which presumably was preceded by some hydrolysis of the acetone groups. Evidently the oxidation that was reported by Pizzarello and Freudenberg, which was partly conducted at steam-bath temperatures, involved some hydrolysis of the acetone groups. The failure of either sodium periodate or lead tetraacetate to oxidize the diacetone dulcitols indicates that *there is no glycol grouping present in either of them and therefore the two hydroxyl groups present in each of them are not attached to adjacent carbon atoms.*

It is evident that if the conclusions that have now been reached are correct, neither of the formulas I and II can apply to the structures of either of the diacetone dulcitols.

The Structure of β-Diacetone Dulcitol.—The ditosyl derivatives of the diacetone dulcitols were of particular interest since it seemed possible that upon iodination by treatment with sodium iodide and acetone under pressure, iodo compounds of importance for structural determination might be obtained. This expectation was fulfilled when it was discovered that the ditosyl derivative of β-diacetone dulcitol gave a diiodo β-diacetone dulcitol in high yield, allowing the inference that the two tosyl groups were attached to two primary hydroxyl groups and that β-diacetone dulcitol therefore possesses two free primary hydroxyl groups. Support for this inference was obtained when it was found that β-diacetone dulcitol readily formed a ditrityl derivative upon treatment with pyridine and triphenylmethyl chloride. Both results are in agreement with the previously mentioned observation that sodium periodate or lead tetraacetate does not oxidize β-diacetone dulcitol. The evidence from these three sources thus makes it highly probable that β-diacetone dulcitol has free hydroxyl groups on carbons one and six. Conclusive proof of this structure was obtained through the following reactions. The β-diacetone dulcitol (III) was converted to dibenzoyl β-diacetone dulcitol (IV) which in turn was transformed to β-dibenzoyl dulcitol (V) by removal of the acetone groups through acid hydrolysis. A 1,6-dibenzoyl dulcitol, upon oxidation by lead tetraacetate, should consume three moles of oxidant and produce two moles of benzoyl glycolic aldehyde (VI) and two moles of formic acid. The oxidation of the dibenzoate prepared from β-diacetone dulcitol with 3.6 moles of lead tetraacetate in glacial acetic acid solution at room temperature for three and one-half hours consumed 3.15 moles of oxidant per mole of diacyl dulcitol.



III — 2,3,4,5-Diacetone dulcitol (β-diacetone dulcitol)

IV — 1,6-Dibenzoyl-2,3,4,5-diacetone dulcitol (dibenzoyl β-diacetone dulcitol)

V — 1,6-Dibenzoyl dulcitol (β-dibenzoyl dulcitol)

VI

From the reaction mixture benzoyl glycolic aldehyde was isolated as its crystalline semicarbazone in a yield of 79%. The fact that this yield is far above 50% proves that both carbons one and six carry benzoyl groups. In a separate experiment the benzoyl glycolic aldehyde was further identified by its oxidation with bromine water to benzoyl glycolic acid, the melting point of which agreed with that reported by Brigl and Grüner,[5] who prepared the substance from 1,6-dibenzoyl mannitol by alkaline permanganate oxidation. The β-dibenzoyl dulcitol is so slightly soluble in water that the oxidation by aqueous sodium periodate could not be studied, but it was possible to obtain analytical data on the periodate oxidation of the similarly prepared β-diacetyl dulcitol, which is moderately soluble in water. If the substance is 1,6-diacetyl dulcitol, 1 mole of it should consume 3 moles of periodate and generate 2 moles of formic acid; it was found to consume 3 moles of oxidant and the increase in acidity corresponded to the production of 2.05 moles of formic acid. The analytical data are thus in agreement with the formulation that *the β-diacyl dulcitols are 1,6-diacyl dulcitols, and the β-diacetone dulcitol is 2,3,4,5-diacetone dulcitol.* The attachment of the two acetone groups is limited to three structures, namely, 2,3:4,5, 2,4:3,5 and 2,5:3,4; decision among them must be deferred at this time. Formulas (III) and (IV) indicate provisionally a 2,3:4,5 arrangement of the acetone groups. In any case, the substances of the β-diacetone dulcitol series that are now known possess meso structures, which accounts for their lack of optical activity.

The Structure of α-Diacetone Dulcitol.—It has been mentioned that β-diacetone dulcitol yields a ditosyl derivative which is convertible to a diiodo derivative through the action of sodium iodide in acetone solution. Under similar experimental conditions α-diacetone dulcitol yields a ditosyl derivative, but iodination of this substance yields a mono-iodo monotosyl α-diacetone dulcitol in nearly quantitative yield. The two diacetone dulcitols also show a dissimilar behavior on treatment with triphenylmethyl chloride. As has been stated, the β-isomer forms a ditrityl derivative, but from similar tritylation reactions involving α-diacetone dulcitol no evidence of ditritylation has been observed, and the isolation of a monotrityl monoacetyl α-diacetone dulcitol in 95% yield indicated that none occurred. These results are good evidence that *α-diacetone dulcitol contains only one free primary hydroxyl group*, and are also inclusive independent proofs of the previous decision that the α- and β-diacetone dulcitols are structural isomers rather than enantiomorphous substances. There remains, then, the problem of determining the position of the secondary hydroxyl group in α-diacetone dulcitol.

Reference to Table II, column 2, shows that the maximum number of diacetone dulcitols which have either one or two free primary hydroxyl groups is fifteen. Three of these structures (nos. 1, 4 and 7) are *meso* forms, one of which must represent β-diacetone dulcitol, as has been proved. The remaining twelve structures are those of potentially optically-active substances for which there must be twelve enantiomorphous forms, not shown in the table. Thus the precise enumeration is three *meso* forms and twelve pairs of enantiomorphs. We digress from the argument at this point in order to explain the convention which we shall use in naming these enantiomorphs. The customary use of the word dulcitol with numbered carbon atoms indicating the places of attachment of substituent groups is unobjectionable in the case of *meso* structures for the reason that the name is the same whether the numbering of the dulcitol chain starts at one end or the other.

(5) Brigl and Grüner, *Ber.*, **65**, 643 (1932).

TABLE II

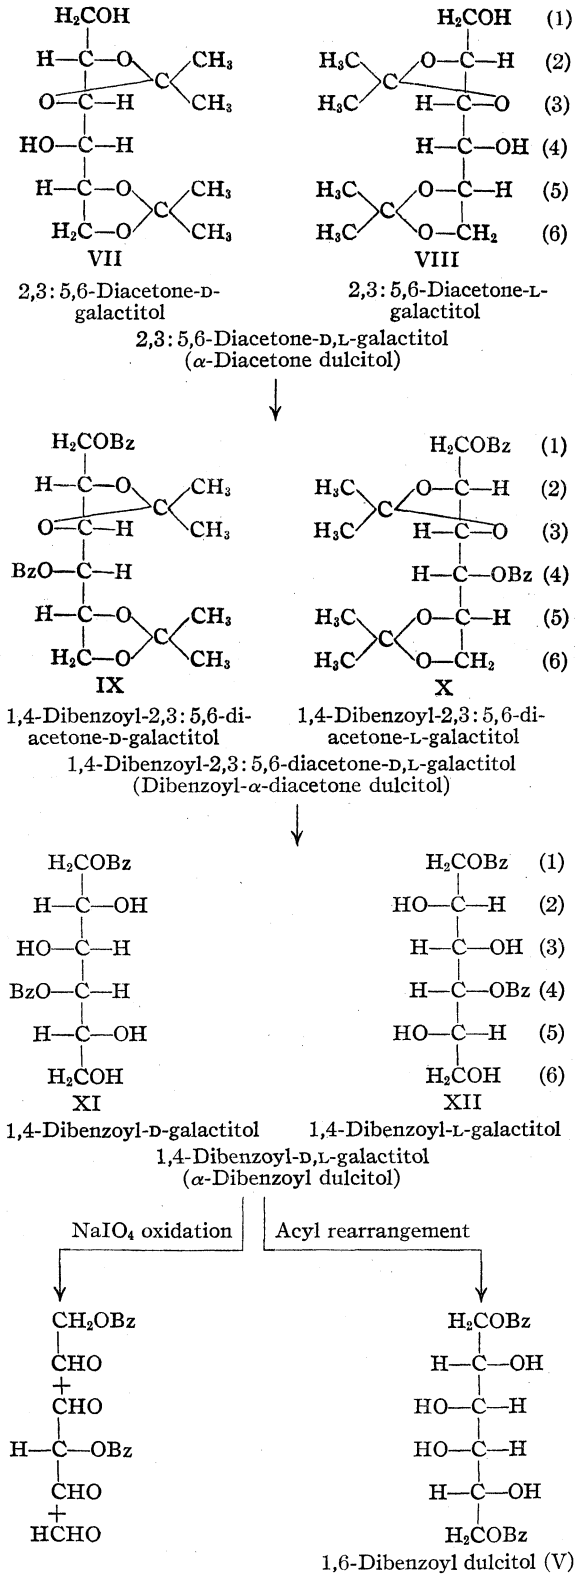
POSSIBLE ARRANGEMENTS OF TWO ISOPROPYLIDENE RESIDUES IN A DIACETONE DULCITOL CONTAINING ONE OR TWO FREE PRIMARY HYDROXYL GROUPS

No.	Acetone attachment	Excluded because of	Corresponding dibenzoyl dulcitol
1	2,3:4,5	Two primary OH's	
2	2,3:4,6	.....	1,5
3	2,3:5,6	.....	1,4
4	2,4:3,5	Two primary OH's	
5	2,4:3,6	.....	1,5
6	2,4:5,6	.....	1,3
7	2,5:3,4	Two primary OH's	
8	2,5:3,6	.....	1,4
9	2,5:4,6	.....	1,3
10	2,6:3,4	.....	1,5
11	2,6:3,5	.....	1,4
12	2,6:4,5	.....	1,3
13	3,4:5,6	Contiguous OH's	
14	3,5:4,6	Contiguous OH's	
15	3,6:4,5	Contiguous OH's	

But such is not the case with respect to the non-*meso* (optically active) structures; the numbering for them is formally different for the two ways of numbering dulcitol. This is illustrated by formulas I and II, with the numbering for their names as given by Pizzarello and Freudenberg; while it is clear after an inspection of the formulas that 3,4:5,6- and 1,2:3,4-diacetone dulcitols are enantiomorphous forms, the fact is not immediately apparent from their names alone because they do not have one and the same name to which the D- and L-symbols, which are customary for enantiomorphs, can be prefixed. We suggest for such cases the convention that the numbering be chosen to conform with that of the appropriate D- or L-galactose, since the numbering of the sugars is precise, and that the use of the convention be indicated by employing the name galactitol in place of dulcitol; thus structures I and II would receive the names, respectively, 3,4:5,6-diacetone D-galactitol and 3,4:5,6-diacetone L-galactitol, or 1,2:3,4-diacetone L-galactitol and 1,2:3,4-diacetone D-galactitol. Formulas VII–XII further illustrate this convention of nomenclature, especially its use for the naming of racemic forms. Returning now to the consideration of Table II, the three *meso* forms (nos. 1, 4 and 7) cannot represent α-diacetone dulcitol because the latter has been shown to possess only one primary hydroxyl group. Nos. 13, 14 and 15 also can be excluded because of the presence in them of contiguous hydroxyl groups. One of the remaining nine structures therefore must apply to α-diacetone dulcitol and, since this substance is optically inactive, as are also its derivatives (Table I), it must be a racemate. Upon dibenzoylation of the nine structures, as racemates, nine different dibenzoyl diacetone D,L-galactitols would result, but upon removing the acetone groups from them only three (1,3, 1,4 and 1,5) dibenzoyl D,L-galactitols can be formed; the problem of assigning the position of the free secondary hydroxyl group in α-diacetone dulcitol thus reduces to that of the establishment of the structure of the α-dibenzoyl dulcitol that results when the isopropylidene residues are removed from dibenzoyl-α-diacetone dulcitol. Fortunately it has proved possible to decide this question through a study of the periodate oxidation of the α-dibenzoyl dulcitol. A 1,5-dibenzoyl dulcitol should consume 2 moles of oxidant and yield 1 mole each of formic acid, 2-benzoylglyceric aldehyde, benzoylglycolic aldehyde and water; 1,4-dibenzoyl dulcitol should consume 2 moles of oxidant and produce 1 mole each of formaldehyde, benzoylglycolic aldehyde and benzoyltartronic dialdehyde, and 2 moles of water, *but no formic acid;* and finally 1,3-dibenzoyldulcitol should require 2 moles of oxidant and form 1 mole each of formic acid, formaldehyde, water and 2,4-dibenzoylthreose. It was found that the oxidation of α-dibenzoyldulcitol with sodium periodate in aqueous alcoholic solution consumed 2 moles of oxidant, but that no acid was produced;[6] it is therefore concluded that *α-dibenzoyl dulcitol is 1,4-dibenzoyl* D,L-*galactitol and α-diacetone dulcitol is accordingly 2,3,5,6-diacetone* D,L-*galactitol.* The question of the arrangement of the acetone groups awaits further study. The observed optical inactivity of the various dulcitol derivatives of the α- and β-series is to be ascribed, according to the structure here shown, to the presence of meso forms in the β-series and of racemic forms in the α-series, as previously mentioned. The reactions through which the structure of α-diacetone dulcitol has been disclosed are illustrated in the structural formulas (VII)–(XII), in which the attachment of the acetone residues at positions 2, 3, 5 and 6 is provisionally assumed to be at 2,3 and 5,6.

Rearrangements in the Dulcitol Series.—Upon melting α-dibenzoyl dulcitol in a capillary tube the substance liquefies completely at 170–

(6) As is described in the experimental part, there was found an apparent titratable acidity corresponding to 0.15 mole of formic acid but it is believed that this acidity is negligibly small and that it probably is due to enolization of benzoyl tartronic dialdehyde.



171° and if maintained at this temperature it rapidly resolidifies and then remelts at 202–203°. The closeness of the latter melting point to that of β-dibenzoyl dulcitol, namely, 209°, suggested that an acyl migration had occurred, the enantiomorphous structures (XI) and (XII) rearranging to the *meso* form (V). This hypothesis was verified by melting a larger amount of α-dibenzoyl dulcitol and crystallizing the melt from acetic acid, whereby pure β-dibenzoyl dulcitol was obtained in nearly quantitative yield. Several such migrations of an acyl group have been observed by others and the postulate has been advanced that they occur through the intermediate formation of dioxolone or meta-dioxane ring compounds.[7] The acyl migration in this case seems to be analogous to that of the benzoyl group in 3-benzoyl monoacetone glucose, which readily migrates to form 6-benzoyl monoacetone glucose.[8] The labile nature of the benzoyl group on carbon four in α-dibenzoyl dulcitol thus furnishes an explanation of the observation by Fischer and Bergmann[4] that β-dibenzoyl dulcitol can be obtained by boiling an aqueous solution of α-dibenzoyl dulcitol; this unusual change is now seen to be due to an acyl migration of the benzoyl group from carbon 4 to carbon 6.

We have confirmed the observation of Fischer[3] that α-diacetone dulcitol upon benzoylation with benzoyl chloride and quinoline at 100° yields a dibenzoate melting at 183–184°, which we designate dibenzoyl β-diacetone dulcitol (Formula IV, see also Table I, footnote b) because its debenzoylation yields β-diacetone dulcitol quantitatively. It is evident from the structures which have been developed for the diacetone dulcitols that *an acetone shift has occurred, the enantiomorphous structures (VII) and (VIII) passing on benzoylation to the meso structure (IV)*. This shift is discussed further in the experimental section ("Rearrangements") where it is shown that the rearrangement is catalyzed by such substances as quinoline hydrochloride and (in less degree) pyridine hydrochloride. Hibbert and his co-workers[9] have shown that the 1,1′ and the 1,2 methylidene, benzylidene, and *p*-nitrobenzylidene cyclic acetals of glycerol are interconvertible in the presence of a trace of hydrochloric acid; the catalysis of the isopropylidene shift in the dulcitol derivatives by quinoline and pyridine hydrochlorides appears to be an analogous reaction.

We are indebted to Mr. George L. Keenan of the Food and Drug Administration, U. S. Department of Agriculture, for the determination of optical properties of certain compounds, to Dr. W. T. Haskins for micro-analyses performed in connection with this work, and to the Atlas Powder Company for furnishing a supply of dulcitol.

Experimental

In the preparation of the diacetone dulcitols from dulcitol with acetone and dry hydrochloric acid gas, small variations of conditions markedly affect the yields; indeed Fischer and Bergmann have reported that they obtained at times the β-isomer under conditions which previously had yielded the α-derivative without being able to assign a cause for the difference in result. It seems from present knowledge that these variations may be due to cyclic acetal rearrangement of the sensitive α-diacetone dulcitol. We find that a separable mixture of the two diacetone dulcitols may be obtained readily with good regularity under the following conditions. A suspension of 50 g. of finely powdered dulcitol in 975 cc. of dry acetone containing 24.2 g. of dry hydrochloric acid gas was agitated vigorously for twenty-four hours at 20°; the dulcitol dissolved and pure α-diacetone dulcitol (m. p. 144–145°) crystallized in a yield of 24.3 g. (34%). The mother liquor was stirred with 150 g. of basic lead carbonate for one hour, the lead chloride and carbonate were removed by filtration, and the filtrate was concentrated to 275 cc. in the presence of some basic lead carbonate. Following filtration, the solution was seeded with α-diacetone dulcitol and allowed to stand overnight at 5°; a further crop of 10.5 g. of crude α-diacetone dulcitol (m. p. 138–140°) was obtained (yield of α, 48%). The mother liquor was concentrated to a volume of 90 cc., further crystallization occurring during the process; the magma was refrigerated for twenty-four hours and 31.1 g. of impure β-diacetone dulcitol (m. p. 104–108°) was removed by filtration. A further small amount of the same substance (1.4 g., m. p. 102–104°) was recovered from the final mother liquor upon treatment with petroleum ether (yield of β, 45%).

The α-diacetone dulcitol may be recrystallized from 5 parts of 95% alcohol in yields of 90%, separating in well-formed brilliant prisms. The substance melts at 144–145° (corr.) and is optically inactive in alcohol, acetone or chloroform solution. Optical-crystallographic data on this compound were kindly obtained by Mr. George L. Keenan. The refractive indices (determined by the immersion method in organic liquids) are $n_\alpha = 1.503$, $n_\beta = 1.507$, $n_\gamma = 1.538$, $n_\gamma - n_\alpha = 0.035$, all ± 0.003. In parallel polarized light (crossed nicols), the birefringence is strong, the polarization colors are brilliant, many fragments extinguishing sharply and others remaining bright under the same conditions. In convergent polarized light (crossed nicols), partial biaxial figures are frequently seen, one optic axis being perpendicular to many of the fragments.

The crude β-diacetone dulcitol may be purified by solution in 5 parts of acetone and addition of 10 parts of petroleum ether; it separates in groups of elongated prisms. The substance melts at 111° (corr.) and is optically inactive in alcohol, acetone or chloroform solution. The microscopical examination of the compound was made by Mr. Keenan. Its refractive indices are $n_\alpha = 1.478$, $n_\beta = 1.510$, $n_\gamma = 1.518$, $n_\gamma - n_\alpha = 0.040$, all ± 0.003. In parallel polarized light (crossed nicols), the birefringence is strong, some of the fragments extinguish sharply and others remain bright, the polarization colors being of the first order. In convergent polarized light (crossed nicols) biaxial figures showing the acute bisectrix are common, the optic sign being negative, and $2E = 30°$ (approximately). The optical-crystallographic properties are entirely unlike those of the α-diacetone dulcitol, a fact which precludes the possibility that the substances are enantiomorphous forms.

Periodic Acid Oxidation of α-Diacetone Dulcitol.—Pizzarello and Freudenberg identified formaldehyde qualitatively (as its dinitrophenylhydrazone) as an oxidation product from the action of lead tetraacetate on α-diacetone dulcitol in benzene solution. We have verified this qualitative observation but we doubt its interpretation in terms of structure because of the fact that the oxidation was partly conducted at elevated temperature and there is the possibility that α-diacetone dulcitol may have been hydrolyzed. It was found that at 20° lead tetraacetate in glacial acetic acid solution, or sodium periodate in aqueous solution, oxidized α-diacetone dulcitol to only a slight and negligible extent in twenty hours, but that aqueous periodic acid oxidizes it rapidly at 20°. To a solution of 0.4078 g. of α-diacetone dulcitol in 27 cc. of water, 19.97 cc. of 0.623 *M* periodic acid (8 moles) was added and the volume of the solution adjusted to 50 cc. Analysis of 5-cc. subsamples at fifteen and thirty minutes, one, four and twenty-two hours, indicated that 1.83, 2.77, 3.68, 5.01 and 5.17 moles of oxidant had been consumed at 20°. The results indicate that the acetone groups were hydrolyzed and the dulcitol which was thus liberated was completely oxidized. Such a series of reactions should consume 5.00 moles of periodic acid.

Sodium Periodate Oxidation of α-Diacetone Dulcitol.—To a solution of 0.2838 g. of α-diacetone dulcitol in 30 cc. of water, 12.38 cc. of 0.306 *M* sodium periodate solution (3.5 moles) was added and the volume adjusted to 50 cc. Analysis of 5-cc. subsamples at the expiration of fifteen, thirty and one hundred and forty-five minutes indicated that no oxidation had occurred at 20° and a similar analysis at twenty hours showed that only 0.35 mole of oxidant had been consumed. Evidently the acidity of sodium periodate is so low that hydrolysis is greatly retarded; and the oxidant appears to be without action on unhydrolyzed α-diacetone dulcitol.

Lead Tetraacetate Oxidation of α-Diacetone Dulcitol.—To a solution of 0.1347 g. of α-diacetone dulcitol in 73 cc. of glacial acetic acid, 25 cc. of 0.1282 *N* lead tetraacetate glacial acetic acid solution (3.2 moles) was added and the volume adjusted to 100 cc. with glacial acetic acid. Analysis of 10-cc. subsamples at fifteen, thirty and one hundred and twenty minutes showed that no oxidation had occurred at 20°, and similar analyses at nineteen and forty-five hours indicated that only 0.08 and 0.23 mole of oxidant had been consumed. Lead tetraacetate thus also appears to be without action on unhydrolyzed α-diacetone dulcitol.

Periodic Acid Oxidation of β-Diacetone Dulcitol.—To a solution of 0.3982 g. of β-diacetone dulcitol in 25 cc. of water, 19.44 cc. of 0.625 *M* periodic acid (8 moles) was added and the solution diluted to 50 cc. with water. At the expiration of one hour at 20°, 0.94 mole of oxidant had been utilized and in fifty hours 5.3 moles had been consumed, indicating the conversion of the diacetone dulcitol to free dulcitol and the complete oxidation of the latter compound.

Sodium Periodate Oxidation of β-Diacetone Dulcitol.—To a solution of 0.2692 g. of β-diacetone dulcitol in 25 cc. of water, 11.59 cc. of 0.31 *M* sodium periodate solution (3.5 moles) was added and the solution diluted to 50 cc. with water. Subsamples of 5 cc. were analyzed after the expiration of fifteen and thirty minutes, one and six hours, and at the end of four days, but no sodium periodate was consumed during this period at 20°. Evidently the β-isomer is considerably more resistant than the α-form to hydrolysis.

Lead Tetraacetate Oxidation of β-Diacetone Dulcitol.—To a solution of 0.1067 g. of β-diacetone dulcitol in 73 cc. of glacial acetic acid, 25 cc. of 0.1282 *N* lead tetraacetate acetic acid solution (3.2 moles) was added and the solution diluted to 100 cc. with the same solvent. Subsamples of 10 cc., which were analyzed at the expiration of fifteen, thirty and one hundred and thirty-five minutes, showed no consumption of oxidant at 20°; after twenty hours 0.03 mole of lead tetraacetate had been consumed and after eight days only 0.8 mole.

Summarizing, these oxidation experiments indicate that the diacetone dulcitols are stable toward two oxidizing agents that are known to attack specifically a glycol grouping, provided that the reagent itself is not acidic enough to cause hydrolysis of the isopropylidene residues.

Derivatives of β-Diacetone Dulcitol (2,3,4,5-Diacetone Dulcitol)

Diacetyl-β-diacetone Dulcitol (1,6-Diacetyl-2,3,4,5-diacetone Dulcitol).—To a solution of 1 g. of β-diacetone dulcitol in 5 cc. of pyridine 5 cc. of acetic anhydride was added. A slight warming occurred and within five minutes the formation of a crystalline deposit, which increased rapidly in amount on standing, was noted. After twenty-four hours the solid was removed by filtration, washed with alcohol, and dried; yield 1.3 g. (quantitative). The compound may be recrystallized from 10 parts of alcohol, separating in prisms which melt at 134° (corr.) and show no rotation in chloroform (*c*, 1.28).

Anal. Calcd. for $C_{16}H_{26}O_8$: C, 55.48; H, 7.57. Found: C, 55.62; H, 7.45.

The relative insolubility of diacetyl β-diacetone dulcitol in the acetylating mixture offers an easy procedure for the separation of a mixture of α- and β-diacetone dulcitols.

In a typical experiment, 10 g. of a mixture of m. p. 104–108° was acetylated in 50 cc. of pyridine and 50 cc. of acetic anhydride. Within two hours the β-diacetate began to crystallize and on standing overnight in the refrigerator 8.9 g. of the substance had separated. The diacetyl α-diacetone dulcitol was obtained in a yield of 3.4 g. by pouring the mother liquors into ice and water. The total recovery of acetate was 93%. The respective diacetone dulcitols were obtainable in quantitative yield upon deacetylation with either sodium or barium methylate.

Ditosyl-β-diacetone Dulcitol (1,6-Ditosyl-2,3,4,5-diacetone Dulcitol).—To a solution of 8.3 g. of *p*-toluenesulfonyl chloride (2.2 mols) in 23.6 cc. of pyridine (15 mols) cooled in an ice-bath, 5.1 g. of finely powdered β-diacetone dulcitol was added. Solution occurred readily and was followed by a separation of characteristic crystals of pyridine hydrochloride. The reaction mixture was then held at 40° for seventy-two hours. The solid mass was broken up with addition of 100 cc. of water and the precipitate removed by filtration and washed well with water; yield 10.5 g. (96%). The compound was recrystallized from 7.5 parts of glacial acetic acid, being obtained in small oblique plates which melted at 165–166° (corr.) and showed no rotation in chloroform (*c*, 1.36).

Anal. Calcd. for $C_{26}H_{34}O_{10}S_2$: C, 54.72; H, 6.00. Found: C, 54.75; H, 6.21.

Dityrityl-β-diacetone Dulcitol (1,6-Dityrityl-2,3,4,5-diacetone Dulcitol).—To a solution of 4.7 g. (2.2 mols) of triphenylmethyl chloride in 25 cc. of pyridine, 2.0 g. of finely powdered β-diacetone dulcitol was added. The solution was allowed to stand at room temperature for seventy-two hours and then crystallization of the dityrityl derivative was induced by gradual addition of 100 cc. of water. The precipitate weighed 6.3 g. (theory 5.7 g.) and was contaminated by triphenylcarbinol. The pure dityrityl compound was obtained, after several recrystallizations from 200 parts of acetone, in the form of small elongated glistening prisms which decomposed at 233–234° (corr.) and showed no rotation in chloroform (*c*, 0.39).

Anal. Calcd. for $C_{50}H_{50}O_6$: C, 80.40; H, 6.75. Found: C, 80.39; H, 6.76.

Diiodo-β-diacetone Dulcitol (1,6-Di-iodo-2,3,4,5-diacetone Dulcitol).—A solution of 5.0 g. of ditosyl-β-diacetone dulcitol and 3.9 g. (3 moles) of sodium iodide in 125 cc. of acetone was heated for two hours at 100° in a pressure bottle. The separated sodium salt of *p*-toluenesulfonic acid (2.5 g.; theory for 2 moles, 3.1 g.) was removed by filtration and the acetone mother liquors were concentrated to dryness by an air current. The dry residue was treated with 25 cc. of water and the insoluble portion filtered off and dried: yield, 4.4 g.; m. p., 102–103° (theory, 4.2 g.). By an initial recrystallization from acetone and a second from alcohol the compound was obtained in fine needles which melted at 108–109° (corr.) and showed no optical activity in chloroform solution (*c*, 1.36).

Anal. Calcd. for $C_{12}H_{20}O_4I_2$: C, 29.89; H, 4.18. Found: C, 29.88; H, 4.22.

β-Dibenzoyl Dulcitol (1,6-Dibenzoyl Dulcitol).—Four grams of dibenzoyl-β-diacetone dulcitol, which was prepared from β-diacetone dulcitol, benzoyl chloride and quinoline by the directions of Fischer and Bergmann[4] (see also the later section on "Rearrangements"), was refluxed for half an hour in 100 cc. of 80% acetic acid. On cooling, 2.6 g. of the desired deacetonated product crystallized and a further 0.4 g. was obtained from the reaction mixture upon concentration; yield, 3.0 g. (91%). Upon recrystallization from 25 parts of

glacial acetic acid it separated in shining platelets which melted at 209° (corr.) and showed no optical activity in acetic acid solution. Fischer reported a melting point of 210° and designated the compound α-dibenzoyl dulcitol, because it was the first dibenzoyl dulcitol isolated. It seems advisable, however, to name it a member of the β-series, particularly since we later describe a dibenzoyl dulcitol of the α-series.

Tetraacetyl-β-dibenzoyl Dulcitol (1,6-Dibenzoyl-2,3,4,5-tetraacetyl Dulcitol).—The solution of 2.0 g. of β-dibenzoyl dulcitol in 10 cc. of pyridine and 10 cc. of acetic anhydride was completed by refluxing the mixture for fifteen minutes. The desired acetate separated in a yield of 2.9 g. (quantitative) upon addition of water. The substance may be recrystallized from 10 parts of glacial acetic acid, and separates in diamond-shaped plates which melt at 225–226° (corr.) and show no rotation in chloroform solution (*c*, 1.40).

Anal. Calcd. for $C_{28}H_{30}O_{12}$: C, 60.21; H, 5.41. Found: C, 60.09; H, 5.44.

β-Diacetyl Dulcitol (1,6-Diacetyl Dulcitol).—A suspension of 5 g. of diacetyl β-diacetone dulcitol in 100 cc. of water and 10 cc. of acetic acid was refluxed for one hour, during which time solution gradually occurred. The solution was concentrated *in vacuo* to dryness and the dry residue transferred to a filter funnel with 35 cc. of warm absolute alcohol. The yield of 1.8 g. (m. p. 155–156°) was increased by 0.5 g. (m. p. 154–155°) by further recovery from the mother liquors (60%). The crude material, which apparently contained some dulcitol, was recrystallized from 10 parts of water; it separated in pure condition in large flat plates, melting at 167–168° (corr.) and showing no rotation in chloroform solution (*c*, 0.28).

Anal. Calcd. for $C_{10}H_{18}O_8$: C, 45.11; H, 6.81. Found: C, 45.06; H, 6.95.

Lead Tetraacetate Oxidation of β-Diacetyl Dulcitol.—A sample of 0.1120 g. of β-diacetyl dulcitol was dissolved in 70 cc. of glacial acetic acid, 25 cc. of 0.1267 *N* lead tetraacetate (8 moles) solution in acetic acid was added and the total volume adjusted to 100 cc. Subsamples of 10 cc. were analyzed at the expiration of fifteen and thirty minutes, one, two, eighteen and sixty-seven hours when 2.01, 2.64, 2.82, 2.89, 2.99 and 3.18 moles of lead tetraacetate were found to have been consumed. The expected consumption for 1,6-diacetyl dulcitol would be 3.00 moles.

Sodium Periodate Oxidation of β-Diacetyl Dulcitol.—This experiment was performed to obtain quantitative analytical data on the production of formic acid in the oxidation reaction. A sample of 0.4496 g. of the diacetyl compound was dissolved in 80 cc. of water, 16.51 cc. of 0.307 *M* sodium periodate (3 mols) solution added, and the volume adjusted to 100 cc. After forty-five minutes a 5-cc. subsample was titrated with 0.1 *N* sodium hydroxide, using methyl red as indicator, and found to require 1.72 cc., equivalent to 2.05 mols of formic acid. The expected production from 1,6-diacetyl dulcitol would be 2.00 mols.

Lead Tetraacetate Oxidation of β-Dibenzoyl Dulcitol.—(1) An amount of 0.1017 g. of β-dibenzoyl dulcitol was dissolved in 170 cc. of glacial acetic acid, 24.5 cc. of 0.1275 *N* lead tetraacetate (6 mols) solution in glacial acetic acid added, and the volume adjusted to 200 cc. Subsamples of 20 cc. were analyzed at the end of fifteen and thirty minutes, one, two, four, six and twenty-three hours, and 1.50, 2.21, 2.75, 2.94, 2.98, 3.01 and 3.19 mols of oxidant shown to be utilized progressively. After a further ninety-six hours, 4.32 mols had been consumed and a final analysis at the end of ten days showed 4.90 mols of oxidant had been consumed. The latter figure compares favorably with that expected, namely, 5.00 mols, if the benzoyl groups had been hydrolyzed completely.

(2) A suspension of 0.8062 g. of β-dibenzoyl dulcitol in 127.5 cc. of 0.1167 *N* lead tetraacetate (3.6 mols) acetic acid solution was agitated for three and one-half hours at room temperature whereby solution was completed. Analysis showed that 3.15 mols of oxidant had been consumed. To a subsample of 50 cc. of the oxidized solution, equivalent to 0.266 g. of benzoyl glycolic aldehyde, 0.8 g. of semicarbazide hydrochloride and 2 g. of sodium acetate were added, and on slight warming crystallization of the semicarbazone of benzoyl glycolic aldehyde occurred. After refrigerating overnight the precipitate was separated by filtration and obtained in a yield of 0.284 g. (79%). The fine needles which were thus produced melted at 193–194°, in close agreement with Aoyama's[10] value of 194–195° for benzoyl glycolic aldehyde semicarbazone, and showed the correct analysis.

Anal. Calcd. for $C_{10}H_{11}O_3N_3$: C, 54.29; H, 5.01. Found: C, 54.15; H, 5.04.

(3) To a suspension of 3.01 g. of β-dibenzoyl dulcitol in 50 cc. of glacial acetic acid, 11.3 g. of crystalline lead tetraacetate (3.3 mols) was added and the reaction mixture agitated for five hours, at which time analysis indicated that all the oxidant had been consumed. A small amount (0.2 g.) of unchanged dibenzoyl compound was removed and the residual solution, containing 2.24 g. of benzoyl glycolic aldehyde, was diluted with water and neutralized with sodium carbonate. It was then extracted successively with four 100-cc. portions of ether and the ether extract concentrated to a sirup. The sirup was dissolved in 100 cc. of water and 10 g. of strontium carbonate and 1.8 cc. of bromine added. After the solution had stood for twenty hours the excess bromine was removed by aeration and the strontium carbonate by filtration, and the solution acidified by addition of 10 cc. of *N* sulfuric acid. The benzoyl glycolic acid was extracted by treatment with four 100-cc. portions of ether, and the ether extract concentrated to dryness, crystallization occurring during the process. The dry residue was redissolved in 15 cc. of ether, the solution clarified, and 15 cc. of petroleum ether added. Upon slow evaporation at room temperature 0.84 g. (34%) of benzoyl glycolic acid was obtained in the form of large rhombs which showed a melting point of 110–111° (corr.). Brigl and Grüner[5] report a melting point of 112° for benzoyl glycolic acid isolated from 1,6-dibenzoyl mannitol.

Anal. Calcd. for $C_9H_8O_4$: C, 60.00; H, 4.48. Found: C, 60.20; H, 4.69.

(10) Aoyama, *J. Pharm. Soc. Japan*, **27**, 539 (1927).

Derivatives of α-Diacetone Dulcitol (2,3,5,6-Diacetone-D,L-galactitol)

Diacetyl-α-diacetone Dulcitol (1,4-Diacetyl-2,3,5,6-diacetone-D,L-galactitol).—A solution of 1 g. of α-diacetone dulcitol in a mixture of 5 cc. of pyridine and 5 cc. of acetic anhydride was allowed to stand overnight at room temperature, no crystallization taking place (contrast the behavior of the β-isomer). The reaction mixture was poured into 50 cc. of water, whereupon crystallization readily occurred, the desired diacetate being obtained in a yield of 1.3 g. (quantitative). It was recrystallized from 10 parts of 50% alcohol and obtained in colorless needles which melted at 89° (corr.) and showed no rotation in chloroform solution (*c*, 1.40).

Anal. Calcd. for $C_{16}H_{26}O_8$: C, 55.48; H, 7.57. Found: C, 55.53; H, 7.54.

Ditosyl-α-diacetone Dulcitol (1,4-Ditosyl-2,3,5,6-diacetone-D,L-galactitol).—The tosylation of α-diacetone dulcitol was carried out as described for that of β-diacetone dulcitol, a yield of 9.3 g. (85%) of the ditosyl derivative being obtained. It crystallized from its solution in 5 parts of alcohol in clusters of minute needles which melted at 101° (corr.) and were optically inactive in chloroform solution (*c*, 1.32).

Anal. Calcd. for $C_{26}H_{34}O_{10}S_2$: C, 54.72; H, 6.00. Found: C, 54.89; H, 5.94.

Monotrityl-monoacetyl-α-diacetone Dulcitol (1-Trityl-4-acetyl-2,3,5,6-diacetone-D,L-galactitol).—To a solution of 2.3 g. (1.1 mole) of triphenylmethyl chloride in 25 cc. of pyridine, 2 g. of finely powdered α-diacetone dulcitol was added and the resulting reaction mixture allowed to stand at room temperature for seventy-two hours. It was then cooled in a freezing mixture, 25 cc. of acetic anhydride added, and again allowed to stand for twenty-four hours at room temperature. Upon addition of water, the monoacetate precipitated in a yield of 4.0 g. (95%). The substance was recrystallized several times from 5 parts of alcohol to remove traces of triphenylcarbinol acetate, and was finally obtained in prisms melting at 107–108° (corr.). It is optically inactive in chloroform solution.

Anal. Calcd. for $C_{33}H_{38}O_7$: C, 72.50; H, 7.01. Found: C, 72.33; H, 6.95.

Mono-iodo-monotosyl-α-diacetone Dulcitol (1-Iodo-4-tosyl-2,3,5,6-diacetone-D,L-galactitol).—A solution of 2.9 g. of ditosyl-α-diacetone dulcitol and 2.3 g. of sodium iodide (3 mols) in 75 cc. of acetone was heated for one and one-half hours at 100° in a pressure bottle. The separated sodium *p*-toluenesulfonate (1.0 g., theory for 1 mol, 0.9 g.) was removed by filtration, the filtrate concentrated to dryness by an air current, and the dry residue treated with 50 cc. of water to remove the excess of sodium iodide. The insoluble crude reaction product weighed 2.6 g. (96%) and was recrystallized from 10 parts of methyl alcohol from which it separated in thick quadratic prisms. The pure compound melted at 120–121° and was optically inactive in chloroform solution (*c*, 1.04).

Anal. Calcd. for $C_{19}H_{27}O_7SI$: C, 43.35; H, 5.17. Found: C, 43.52; H, 5.12.

α-Dibenzoyl Dulcitol (1,4-Dibenzoyl-D,L-galactitol).—A solution of 8 g. of dibenzoyl-α-diacetone dulcitol, the preparation of which from α-diacetone dulcitol, benzoyl chloride and pyridine has been described by Fischer and Bergmann[4] (see also the later section on "Rearrangements"), in 100 cc. of 80% acetic acid was refluxed for thirty minutes and allowed to cool; there crystallized 0.6 g. of β-dibenzoyl dulcitol (m. p. 206–207°). The mother liquors were diluted with 500 cc. of water and allowed to stand overnight in the refrigerator, whereupon 2.4 g. of crude α-dibenzoyl dulcitol (m. p. 165–166°) crystallized, and a further yield of 2.4 g. of the same compound was obtained upon concentrating the solution to dryness and crystallizing the residue from 30 cc. of 50% alcohol (yield of the β-isomer, 9.1%; of the α-isomer, 72.7%). The production of some of the β-isomer in this reaction apparently is due to an acyl migration. The crude α-isomer is purified readily by recrystallization from 15 parts of alcohol, separating in clusters of fine needles which show no rotation in chloroform solution (*c*, 1.10). Upon heating in a capillary tube, it melts at 170–171° (corr.), resolidifies, and then remelts at 202–203° (corr.) (see also the later section on "Rearrangements").

Anal. Calcd. for $C_{20}H_{22}O_8$: C, 61.53; H, 5.68. Found: C, 61.35; H, 5.83.

Tetraacetyl-α-dibenzoyl Dulcitol (2,3,5,6-Tetraacetyl-1,4-dibenzoyl-D,L-galactitol).—Acetylation of the α-dibenzoyl dulcitol in pyridine solution by acetic anhydride at room temperature during twenty-four hours produced the tetraacetate in nearly quantitative yield. The compound was recrystallized from 10 parts of alcohol, separating in needles which melted at 113° (corr.) and showed no optical activity in chloroform solution (*c*, 0.82).

Anal. Calcd. for $C_{28}H_{30}O_{12}$: C, 60.21; H, 5.41. Found: C, 60.00; H, 5.57.

Lead Tetraacetate Oxidation of α-Dibenzoyl Dulcitol.—To a solution of 0.2000 g. of α-dibenzoyl dulcitol in 15 cc. of acetic acid, 33.4 cc. of 0.1105 *N* lead tetraacetate (3.6 mols) acetic acid solution was added and the volume adjusted to 50 cc. Subsamples of 5 cc. were analyzed at the end of fifteen and thirty minutes, one, two and nineteen hours and it was found that 1.94, 1.95, 1.95, 1.96 and 2.03 mols of oxidizing agent had been consumed. A 1,4-diacyl dulcitol should consume 2 mols of lead tetraacetate.

Sodium Periodate Oxidation of α-Dibenzoyl Dulcitol.—To a cooled solution of 0.1049 g. of α-dibenzoyl dulcitol in 15 cc. of alcohol, 1.84 cc. of 0.307 *M* sodium periodate (2.1 mols) was added and the solution volume adjusted to 25 cc. with water. Analyses of 5-cc. subsamples at the expiration of fifteen and thirty minutes indicated that 2.05 mols of oxidant had been consumed. Titration of a further 5-cc. subsample with 0.1 *N* sodium hydroxide required 0.08 cc. to obtain a decided alkaline reaction with methyl red indicator. This acidity, equivalent to 0.15 mol of formic acid in the sample, may be due to enolization of benzoyl tartronic dialdehyde; in any event it appears that the observed acidity is negligibly small. The formation of one mol of formic acid would require 0.53 cc. of 0.1 *N* alkali for neutralization of 5 cc. of the oxidized solution.

Rearrangements in the Dulcitol Series

1,6-Dibenzoyl Dulcitol from 1,4-Dibenzoyl-D,L-galactitol.—One gram of 1,4-dibenzoyl-D,L-galactitol

(Fischer and Bergmann's low melting dibenzoyl dulcitol) was heated in a small flask for fifteen minutes at 210° and the melt then recrystallized from 25 cc. of glacial acetic acid. Characteristic glistening platelets of 1,6-dibenzoyl dulcitol melting at 209° (corr.) were obtained in a yield of 90%.

Benzoylation of α-Diacetone Dulcitol (2,3,5,6-Diacetone-D,L-galactitol) in Quinoline.—Following the directions of Fischer, 10 g. of α-diacetone dulcitol was benzoylated with 2.2 mols of quinoline and 2 mols of benzoyl chloride for six hours at 100°. The reaction mixture was then refluxed for a few minutes with 120 cc. of alcohol to complete the solution of quinoline hydrochloride, refrigerated overnight, and the separated solid was removed by filtration: yield 11.8 g.; m. p. 183–184° (corr.); 66%. Fischer reported a melting point of 185–186° and a yield of 60% and called this substance dibenzoyl-α-diacetone dulcitol. The mother liquor was concentrated *in vacuo* to remove the alcohol, 300 cc. of water was added, and the oily suspension extracted four times with 25 cc. of carbon tetrachloride. The extract was washed successively four times with 100 cc. of ice cold 1% hydrochloric acid, twice with dilute sodium carbonate solution, and twice with water, and then concentrated to a dry sirup. The sirupy residue was dissolved in 20 cc. of 85% alcohol and upon standing for several days 2.0 g. (11%) of the isomeric dibenzoyl diacetone dulcitol of melting point 82–83° crystallized from the solution. The latter substance was not reported by Fischer and Bergmann as being obtained by benzoylation of α-diacetone dulcitol in the presence of quinoline, but they did obtain it when pyridine was employed in the diacylation. The isolation of *two* isomeric dibenzoyl diacetone dulcitols upon benzoylation of α-diacetone dulcitol indicated that a rearrangement had occurred in the course of diacylation.

Identification of the Dibenzoate Melting at 183–184° (Fischer and Bergmann's Dibenzoyl-α-diacetone Dulcitol) as a Derivative of β-Diacetone Dulcitol.—The dibenzoate of melting point 183–184° that was obtained from the benzoylation of α-diacetone dulcitol as just described, was recrystallized from 20 parts of carbon tetrachloride. It still melted at 183–184° (corr.) and was optically inactive in chloroform (*c*, 1.60).

Anal. Calcd. for $C_{26}H_{30}O_8$: C, 66.37; H, 6.43. Found: C, 66.28; H, 6.32.

A solution of 5 g. of it in 250 cc. of chloroform was cooled in ice and salt, and 21.9 cc. of 0.972 *N* sodium methylate (2 mols) added dropwise. After standing overnight at 5° the solution was held at 50° for one hour and the separated sodium benzoate removed by filtration. The filtrate was concentrated to dryness and the dry residue dissolved in 30 cc. of acetone. Upon addition of 30 cc. of petroleum ether the typical crystals of β-diacetone dulcitol separated in a yield of 1.0 g. (m. p. 110–111°) and a further amount of 1.0 g. was obtained by working up the mother liquors; yield, quantitative. A similar quantitative debenzoylation to β-diacetone dulcitol occurs if barium methylate be employed as the deacylation agent. Fischer and Bergmann's dibenzoyl-α-diacetone dulcitol (m. p. 183–184°) is therefore a derivative of β-diacetone dulcitol and is 1,6-dibenzoyl-2,3,4,5-diacetone dulcitol; its formation from α-diacetone dulcitol (2,3,5,6-diacetone-D,L-galactitol) results from a molecular rearrangement.

Identification of the Dibenzoate Melting at 82–83° (Fischer and Bergmann's Dibenzoyl-β-diacetone Dulcitol) as a Derivative of α-Diacetone Dulcitol.—This dibenzoate, the preparation of which was described above, is recrystallized conveniently from 6 parts of 85% alcohol, crystallization being rather slow and markedly hindered by presence of impurities. It separates in the form of needles and is optically inactive in chloroform solution (*c*, 1.52). Upon debenzoylation with barium methylate, α-diacetone dulcitol (m. p. 144–145°) was obtained in quantitative yield; the dibenzoate of melting point 82–83° is evidently 1,4-dibenzoyl-2,3,5,6-diacetone-D,L-galactitol.

Anal. Calcd. for $C_{26}H_{30}O_8$: C, 66.37; H, 6.43. Found: C, 66.36; H, 6.36.

Benzoylation of α-Diacetone Dulcitol in Pyridine.—To a solution of 20.8 g. of α-diacetone dulcitol in 18 cc. of pyridine (2.8 mols), 20.4 cc. of benzoyl chloride (2.2 mols) was added, and the reaction mixture heated for three hours at 100°. The reaction products were dissolved in 200 cc. of chloroform and the chloroform solution washed successively with ice cold 0.1% aqueous hydrochloric acid, 2% sodium carbonate solution, and water. The chloroform solution was concentrated *in vacuo* to dryness. Upon attempting to dissolve the dry residue in 180 cc. of 85% alcohol, crystalline dibenzoyl-β-diacetone dulcitol (1.5 g., m. p. 178–180°, 4%) was recovered as an insoluble precipitate. From the alcoholic solution 32 g. (86%) of dibenzoyl-α-diacetone dulcitol (m. p. 82–83°) was recoverable. These results indicate that some rearrangement also occurs upon benzoylation of α-diacetone dulcitol in pyridine at 100°. The failure of Fischer and Bergmann to obtain the β-derivative by the pyridine method of acylation at 100° appears to be due to a far smaller production of it with pyridine than with quinoline.

The Isopropylidene Rearrangement.—From the structural evidence which has been presented it is certain that the α-diacetone dulcitol, which we know to be 2,3,5,6-diacetone-D,L-galactitol, upon benzoylation under the experimental conditions cited, yields both 1,4- and 1,6-dibenzoyl derivatives, namely, 1,4-dibenzoyl-2,3,5,6-diacetone-D,L-galactitol and 1,6-dibenzoyl-2,3,4,5-diacetone dulcitol. The formation of the latter derivative could take place only if there occurred a cyclic acetal shift of an isopropylidene residue, which in terms of the formulas VII, VIII and III is from carbons 5,6 to 4,5 of the galactitol chain. It was found that the shift does not occur after the 1,4-dibenzoyl-2,3,5,6-diacetone-D,L-galactitol is produced. Two grams of the pure substance was heated in quinoline (2.8 moles) and benzoyl chloride (2.2 moles) at 100° for six hours, but no formation of the β-isomer could be demonstrated. In further experiments the pure substance was melted and the melt held at 100° for several hours; neither from this melt nor from a similar one, through which dry hydrochloric acid gas was bubbled, could any β-isomer be isolated. It was sought next to determine whether the isopropylidene shift is caused by a change of α-diacetone dulcitol to its β-isomer through heating at 100° in quinoline alone. Since the isolation of the diacetone dulcitols from quinoline solution did not appear to be feasible, we selected the following experimental test. Five grams of α-diacetone dulcitol was

heated in quinoline (2.5 moles) at 100° for six hours and the solution was then cooled in ice and benzoyl chloride (2.2 mols) was added. After standing for four hours at 0°, followed by twenty-four hours at 25°, the reaction product yielded by customary procedure 0.4 g. (4.4%) of 1,6-dibenzoyl-2,3,4,5-diacetone dulcitol and 6.5 g. (72.5%) of 1,4-dibenzoyl-2,3,5,6-diacetone-D,L-galactitol. The rearrangement in this test is so slight that the cause of the extensive rearrangement which occurs when the benzoylation reaction is carried out at 100°, cannot be attributed to an action of the quinoline alone, particularly if the result of the next experiment be considered. It was carried out with the same quantities of materials but some anhydrous quinoline hydrochloride (1.2 mols) was present during the period of heating at 100°; it yielded 3.8 g. (42.4%) of 1,6-dibenzoyl-2,3,4,5-diacetone dulcitol and 3.5 g. (39%) of 1,4-dibenzoyl-2,3,5,6-diacetone-D,L-galactitol. It appears therefore that the rearrangement is catalyzed by such substances as quinoline hydrochloride and (in less degree) pyridine hydrochloride.

Summary

It is shown that the properties of the α- and β-diacetone dulcitols, as well as those of several new derivatives of these substances, exclude the possibility that they can be enantiomorphous substances and prove that they are structural isomers. Evidence has been obtained from periodate and lead tetraacetate oxidations that neither α- nor β-diacetone dulcitol contains a glycol grouping. The results of a study of the ditosyl, diiodo and ditrityl derivatives of β-diacetone dulcitol indicate that it contains two free primary hydroxyl groups, and a study of the oxidation of the diacyl dulcitols, derivable from it, proves that its structure is that of 2,3,4,5-diacetone dulcitol, a *meso* form. The results of a study of the ditosyl, monotosyl-mono-iodo, and monotrityl-monoacetyl derivatives of α-diacetone dulcitol indicate that it contains one free primary hydroxyl group and one free secondary hydroxyl group, and a study of the oxidation of the dibenzoyl dulcitol derived from it proves that it is 2,3,5,6-diacetone-D,L-galactitol, a racemic form. An acyl migration by which 1,4-dibenzoyl-D,L-galactitol (a racemic form) passes to 1,6-dibenzoyl dulcitol (a *meso* form) has been demonstrated. A cyclic acetal shift has been shown to be the cause of the interesting and unusual changes which Fischer and Bergmann noticed upon acylation of α-diacetone dulcitol. The shift occurs as a stage in the benzoylation of α-diacetone dulcitol with benzoyl chloride and quinoline or pyridine at elevated temperatures and it is catalyzed by quinoline hydrochloride or pyridine hydrochloride. In structural terms it is represented as the passage of 2,3,5,6-diacetone-D,L-galactitol to 1,6-dibenzoyl-2,3,4,5-diacetone dulcitol. Reasons have been given for preferring the name galactitol to dulcitol in designating non-*meso* structures of derivatives of dulcitol which carry in their names a numbering of its carbon atoms.

[CONTRIBUTION FROM THE FRICK CHEMICAL LABORATORY OF PRINCETON UNIVERSITY]

Procedure for Preparation of Fully Methylated Carbohydrates and their Derivatives

BY EUGENE PACSU AND S. M. TRISTER[1]

For investigation of certain structural problems in carbohydrate chemistry, it is often necessary to methylate all free hydroxyl groups in the molecule. Methylation usually is carried out either with methyl iodide and silver oxide,[2] dimethyl sulfate and alkali solution,[3] alkali metals in liquid ammonia and methyl iodide,[4] or with the thallium salts of the carbohydrates and methyl iodide.[5]

However, none of these methods, if used alone, gives entirely satisfactory results for various reasons. For complete methylation usually a combination of two of these methods is necessary. In most instances first the dimethyl sulfate–alkali procedure is employed and the products obtained are then repeatedly treated with silver oxide and methyl iodide.

In this Laboratory excellent results were obtained from combination of Haworth's dimethyl sulfate–alkali procedure with a slightly modified process of Freudenberg and Hixon.[6] These

authors' simple but apparently seldom used method is based on the reaction between methyl iodide and the sodium alcoholates of the carbohydrates prepared in ether solution. In many instances we have observed that the incomplete methylation in the dimethyl sulfate–alkali procedure is mainly due to the resistance of the primary hydroxyl group toward the alkylating agent. Since this also holds true but in still higher degree for Purdie's reagent, it seemed to us impractical to attempt the completion of methylation of partially methylated sugars, or to start the methylation of sugar derivatives containing primary hydroxyl groups, by means of methyl iodide and silver oxide. We adopted, therefore, the Freudenberg procedure and found that metallic sodium reacted readily with such products giving sodium alcoholates soluble in ether, toluene and other inert solvents. These sodium alcoholates which can be analyzed easily for sodium, if necessary, would suffer partial decomposition in the presence of moisture, in which case the subsequent treatment with methyl iodide would result in products of low methoxyl content. We have found that this can be avoided if a little methyl iodide is added to the solution of the alcoholate before concentration under diminished pressure. The residue is then shaken vigorously with methyl iodide and the reaction mixture is allowed to stand for several hours. We have successfully applied this comparatively simple and inexpensive procedure to several carbohydrates and their derivatives always obtaining products with correct methoxyl content. Since many of these methyl derivatives represent new compounds to be described in forthcoming publications, in the experimental part of the present article only the methylation of sucrose is given for illustration of the details of the procedure.

Experimental

Preparation of Octamethylsucrose.—Purdie and Irvine[7] methylated sucrose with silver oxide and methyl iodide and after four such methylations isolated a product with a methoxyl content of 50.93% instead of the theoretical value of 54.63%. Haworth[3a] methylated sucrose with dimethyl sulfate and sodium hydroxide and found that after one methylation the isolated product had a methoxyl content of 50.5% which could not be increased after further treatment with the same methylating agent. However, by two subsequent methylations with Purdie's reagent the compound isolated had a methoxyl content of 54.12%. In a later paper[8] he claimed that by modifying the conditions somewhat a fully methylated sucrose was obtained after three operations using dimethyl sulfate and alkali as the only alkylating agent. It is interesting to note, however, that Irvine and Stiller,[9] repeating Haworth's procedure, claimed that the methylation yielded a complex mixture of partially methylated compounds boiling at approximately constant temperature.

In our experiment sucrose was methylated with dimethyl sulfate and potassium hydroxide and worked up in the usual manner. The sirup was non-reducing to Fehling's solution and had a methoxyl content of 45.36%. This upon a single methylation with sodium and methyl iodide gave pure octamethylsucrose with the correct methoxyl content of 54.48%. The methylation was carried out in the following way. A 5-g. sample of the partially methylated product (OCH_3, 45.36%) was dissolved in 50 cc. of absolute ether in a flask fitted with a calcium chloride tube and to the solution 1 g. of clean sodium wire was added. The mixture was gently shaken on an apparatus for several hours and allowed to stand overnight at room temperature. Then the solution was decanted rapidly into a distilling flask containing 10 cc. of methyl iodide. The mixture was evaporated under reduced pressure to a paste, to which 25 cc. of methyl iodide was added. The cloudy solution was shaken vigorously for several hours, then kept standing at room temperature for twelve hours. Throughout the above operation precautions were taken to exclude all atmospheric moisture from the reaction vessel. An equal volume of absolute ether was then added to the reaction mixture and the sodium iodide precipitate was filtered off with activated carbon and washed with absolute ether. The combined filtrate and washings were evaporated *in vacuo* at 30–40° to a sirup which was twice purified by filtration of its petroleum ether (b. p. 30–40°) solution with activated carbon. On evaporation under reduced pressure the clear filtrate gave 3.4 g. of a very pale yellow liquid, octamethylsucrose, with the correct methoxyl content (54.48%) and the following specific rotations for sodium light: 65.5° (chloroform solution; *c*, 1.634; *t*, 26°); 67.6° (methyl alcohol solution; *c*, 5.592; *t*, 25°); 65.6° (acetone solution; *c*, 6.007; *t*, 25°). Haworth[3a] reported 69.3° (methyl alcohol solution; *c*, 7.345) and 66.8° (acetone solution; *c*, 6.782).

In another experiment the partially methylated sample was dissolved in absolute toluene and to the solution sodium wire was added. After the reaction had subsided the mixture was heated on a water-bath at 80° for three hours, then cooled and worked up as described in the previous experiment. A pale yellow liquid with 54.37% methoxyl was isolated.

All the methoxyl estimations were carried out by the method of Vieböck and Schwappach[10] as modified by Clark.[11]

Summary

1. Combination of the Haworth methylation process with a slightly modified method of Freudenberg and Hixon is recommended for prepa-

The Acetone Derivatives of the Mercaptals of Some Monosaccharides. IV.[1] The 4,5-Monoacetone Derivative of the Dibenzylmercaptal and of the Dimethylacetal of *d*-Galactose

BY EUGENE PACSU, S. M. TRISTER[2] AND JOHN W. GREEN

Fifteen years ago it was shown by Pacsu[1] that new isomers of partially methylated hexoses could be obtained by a series of reactions in which the sugar mercaptals should first be converted into their di- and monoacetone derivatives. Subsequent methylation of the free hydroxyl group or groups would yield compounds which on deacetonylation and removal of the mercaptan residues would give rise to the respective mono- and trimethyl sugars. The exact positions of the methyl groups once determined, the structure of the intermediate acetone derivatives would be known. On the other hand, the knowledge of the positions of the acetone residues would determine the structure of the methylated sugars. At that time it appeared that the elucidation of the structure of the methylated sugars rather than that of the intermediate acetone derivatives was more feasible since methods for removal of the mercaptan residues without simultaneous hydrolysis of the acetone groups were unknown. Direct determination of the positions of the methyl groups in partially methylated sugars fifteen years ago presented almost insurmountable difficulties mainly due to the lack of suitable experimental methods. It was customary, therefore, to assign the structure of newly discovered partially methylated sugars by taking recourse to the method of elimination and to other indirect procedures. However, conclusions based on such negative evidence are usually valid only as long as the accepted structural formulas of the eliminated compounds remain unchanged. In the special field of partially methylated sugars new interpretation of some old experimental results became necessary after Brigl and Schinle discovered[3] that the true 2-methyl glucose[4] was capable of osazone formation with the loss of the methyl group. This striking discovery cast doubt on the structure of those partially methylated sugars the formulas of which previously had been assigned on the assumption, till then unquestioned, that a 2-methyl aldose could not possibly form an osazone. Among those partially methylated sugars affected by this discovery were the assumed 4-methyl sugars and all their mercaptal and acetonylated mercaptal derivatives previously described.[1] As was pointed out by Pacsu,[5] the assignment of position 4 to the methyl group in the new monomethyl glucose was left as the only possibility at the time when the compound was discovered, because a 2-methyl glucose with entirely different properties had been described already both by Pictet[6] and by Irvine.[7] Since Levene and co-workers[8] noticed that this supposed 4-methyl glucose was identical with the true 2-methyl glucose of Brigl, it followed that all the previous conclusions based on an unquestioned existence of the 2-methyl glucose of Pictet and of Irvine became necessarily invalid. In the light of these facts, therefore, a reinvestigation of the entire problem was begun and in the present paper the results concerning the structure of one of the monoacetone galactose mercaptals are presented.

In a preliminary communication[9] it was reported that the formerly described[1c] crystalline "2,3-monoacetone galactose dibenzylmercaptal" with m. p. 102–103° and $[\alpha]^{18}D$ 8.8° in acetylene tetrachloride solution, in spite of its apparent uniformity, is not a chemical individual. By repeated fractional recrystallization from acetone

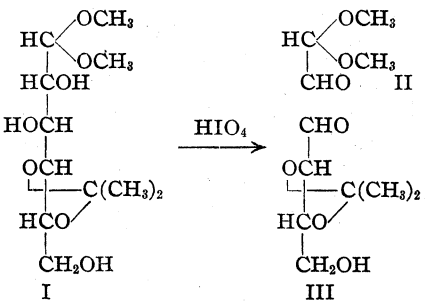
and from ethyl alcohol the substance was separated into two monoacetone mercaptals, one with m. p. 112.5° and $[\alpha]^{20}D$ 17.4° in chloroform solution, and the other with m. p. 103° and $[\alpha]^{20}D$ 31.0° in chloroform solution. Since the latter compound was more easily available in pure form, it was chosen as the first object of our investigation. On removal of the benzyl mercaptan residues in methyl alcoholic solution according to the method of Pacsu and Green,[10] the substance gave rise to a monoacetone galactosedimethylacetal with m. p. 125–126° and $[\alpha]^{20}D$ 37.4° in water solution. Although formation of dimethylacetals by application of this method to *l*-rhamnose- and fructosediethylmercaptal have been reported previously,[11] actually this was the first acetal obtained in this Laboratory, but its structure was unknown when the preliminary communication[9] was published. On the basis of the following experimental results it is now established definitely that the acetone residue is attached to carbon atoms 4 and 5, and, therefore, the starting material represents the 4,5-monoacetone galactosedibenzylmercaptal. Positive reaction of the latter compound with triphenylmethyl chloride in pyridine solution yielding a trityl derivative[12] was the first indication that a free hydroxyl group may be present in position 6. Acetylation of the 4,5-monoacetone dimethylacetal gave readily a triacetate, the 2,3,6-triacetyl 4,5-monoacetone galactose dimethylacetal with m. p. 55° and $[\alpha]^{20}D$ 17.8° in chloroform solution. In the methylation experiments five consecutive methylations of the 4,5-monoacetone dimethylacetal with silver oxide and methyl iodide failed to raise the methoxyl content (43.1%) to the theoretical value (50.3%). This indicated the presence of a primary hydroxyl group resistant to methylation. Finally by application of the modified Freudenberg procedure[13] to this incompletely methylated product, it was possible to obtain the fully methylated compound in one operation. The substance, representing the 2,3,6-trimethyl-4,5-monoacetone galactosedimethylacetal, was then hydrolyzed and the 2,3,6-trimethylgalactose obtained was oxidized with bromine yielding crystalline 2,3,6-trimethyl-γ-galactonolactone with m. p. 97–98° and initial specific rotation of −32.9° in water solution, which value changed after ten days to the constant value of −21.3°.

Application of the periodic acid oxidation method of Jackson and Hudson[14] to the 4,5-monoacetone galactosedimethylacetal (I) showed that one mole equivalent of periodic acid was used up for oxidation.



A survey of the possible structures of monoacetone galactosedimethylacetal indicated that only the 4,6- and 4,5-monoacetone derivatives would require one mole equivalent of periodic acid. If the acetal had its acetone residue at carbon atoms 4 and 6, then the methylated lactone isolated from it would be a 2,3,5-trimethyl derivative, whereas the 4,5-monoacetone derivative would yield a 2,3,-6-trimethyl lactone. On oxidation by periodic acid only the latter lactone should require one mole equivalent of periodic acid, whereas the 2,3,5-trimethyl lactone should not use any. Our experiments showed that the lactone in question required one equivalent of periodic acid for oxidation, therefore it could only be the 2,3,6-trimethyl lactone. In order to isolate and identify the scission products, glyoxal dimethyl acetal (II) and 2,3-monoacetone *d*-threose (III), expected from a 4,5-monoacetone galactosedimethylacetal on oxidation by periodic acid, the sugar acetal was treated with this reagent. The mixture of the scission products formed was separated by distillation of the aqueous solution. Glyoxal was found to be present in the distillate and was isolated as the *bis*-phenylhydrazone. The other component of the mixture, 2,3-monoacetone *d*-threose (III), was hydrolyzed by acetic acid to *d*-threose which was identified by its osazone. The *d*-threose was then oxidized with bromine to *d*-threonic acid which was characterized by its

(12) In the preliminary communication[9] it was stated that neither isomer reacted with triphenylmethyl chloride. Subsequently it was found that the triphenylmethyl chloride employed was of a very poor quality since it contained mostly triphenylcarbinol. Reactions carried out with a pure, crystalline preparation gave a positive result for the higher rotating compound but the tests were negative with the low rotating isomer.

(14) Jackson and Hudson, *ibid.*, **59**, 994 (1937).

brucine salt. Subsequent oxidation of *d*-threonic acid with nitric acid gave rise to *l*-tartaric acid which was isolated as the acid potassium salt. From these experimental results it follows that in the original starting material the acetone residue was attached to carbon atoms 4 and 5.

The investigation is being continued.

Experimental

Preparation of 4,5-Monoacetone Galactosedibenzylmercaptal and its 5,6(?)-Isomer.—Monoacetone galactosedibenzylmercaptal was prepared according to the directions of Pacsu and Löb,[1c] and after two crystallizations from chloroform and petroleum ether the fine needles obtained had m. p. 102–104° and $[\alpha]^{20}D$ 8.1° in acetylene tetrachloride solution, which values were in good agreement with those given by the authors for "2,3-monoacetone galactosedibenzylmercaptal." However, a third crystallization, this time from acetone and petroleum ether, gave two fractions with different rotations, which fact indicated that the preparation of Pacsu and Löb was a mixture. Subsequently it was found also that the composition of the preparation varied considerably with minor changes in the conditions of the experiment. In order to secure reproducible results the acetonylation was carried out for four hours at about 25° with copper sulfate monohydrate as dehydrating agent in equal weight of the mercaptal which was suspended in ten times its weight of acetone. Under such conditions the acetone solution at the end of the reaction contained only a little diacetone derivative and unchanged mercaptal. The monoacetone derivative was isolated according to the procedure of Pacsu and Löb and then it was submitted to fractional crystallization by addition of small quantities of petroleum ether to the acetone solution. Several fractions with different rotations were obtained. The fractions which had the highest rotations were united and recrystallized from ethyl alcohol. Finally a product was obtained in the form of long needles showing m. p. 102.5–103° and $[\alpha]^{20}D$ 31.0° in chloroform solution, which values did not change on further recrystallizations. Our investigation centered around the structure of this substance, which was proved to be the 4,5-monoacetone galactosedibenzylmercaptal. The fractions with the lower rotations were purified by recrystallizations from acetone and petroleum ether and finally from acetone alone. This substance crystallized in a jelly-like aggregate of very fine needles. The preparation finally obtained had m. p. 112.5° and $[\alpha]^{20}D$ 17.4° in chloroform solution, which values did not change on further recrystallization. This substance probably represents the 5,6-monoacetone galactosedibenzylmercaptal and its structure is being investigated. The two isomers formed in about equal quantities and the yields were quite satisfactory. When tested with pure[12] triphenylmethyl chloride in pyridine solution, the 4,5-monoacetone derivative gave a trityl derivative which, on account of its amorphous nature, was not investigated further. The other isomer gave negative results and the unchanged material was recovered. The two isomers were analyzed for acetone according to the procedure of Elsner.[15] In order to take out the mercaptan residues, 0.3 g. of mercuric chloride was added to the 0.15-g. samples in these acetone determinations.

Anal. 4,5-Monoacetone galactosedibenzylmercaptal, calcd. for $C_{16}H_{30}O_5S_2$: C, 61.3; H, 6.72; acetone, 12.9. Found: C, 61.45; H, 7.1; acetone, 12.75. 5,6(?)-Monoacetone galactosedibenzylmercaptal: Found: C, 61.2, 61.1; H, 6.64, 6.8; acetone, 12.4, 13.0, 12.8.

Conversion of 4,5-Monoacetone Galactosedibenzylmercaptal into 4,5-Monoacetone Galactosedimethylacetal.—The removal of the mercaptan residues was carried out at room temperature by the method of Pacsu and Green.[10] A solution of 33 g. of mercuric chloride (2 moles) in 75 cc. of absolute methyl alcohol was added in thirty minutes to a mixture of 27 g. of 4,5-monoacetone galactosedibenzylmercaptal, 27 g. of yellow mercuric oxide and a little drierite in 120 cc. of absolute methyl alcohol. After four hours of continuous stirring the mixture was filtered, the filtrate treated with 5 cc. of pyridine and kept at 0° for two hours. The pyridine mercuric chloride was filtered and the solution evaporated to a sirup *in vacuo* at 40°. The residue was dissolved in a little ice-cold water, the solution filtered and neutralized to phenolphthalein with a few drops of sodium hydroxide solution, then evaporated *in vacuo* at 45°. The residue was evaporated successively under reduced pressure from ethyl alcohol solutions and crystallized first from benzene, then from ethyl acetate. The pure substance represented the 4,5-monoacetone galactosedimethylacetal and had m. p. 125–126° and $[\alpha]^{20}D$ 37.4° in water solution; yield, about 70%. It was soluble in cold water and methyl alcohol, in hot acetone, ethyl acetate and dioxane.

Anal. Calcd. for $C_{11}H_{22}O_7$: C, 49.62; H, 8.27; OCH_3, 23.30. Found: C, 49.70; H, 8.22; OCH_3, 23.30.

On acetylation with acetic anhydride and pyridine, 2,3,6-triacetyl 4,5-monoacetone galactosedimethylacetal was obtained in the form of prismatic needles from petroleum ether, or from a mixture of chloroform and petroleum ether at 0°. The substance is very soluble in most of the organic solvents. It had m. p. 55° and $[\alpha]^{20}D$ 17.8° in chloroform solution (*c*, 2.057). In an acetyl estimation 0.2668 g. of the substance required 20.2 cc. of 0.1 *N* sodium hydroxide solution. The value calculated for the hydrolysis of three acetyl groups is 20.4 cc.

Anal. Calcd. for $C_{17}H_{28}O_{10}$: OCH_3, 15.8. Found: OCH_3, 15.4.

Preparation of 2,3,6-Trimethyl γ-Galactonolactone from 4,5-Monoacetone Galactosedimethylacetal.—Ten grams of the acetal was dissolved in 35 cc. of methyl iodide and the solution was treated with 20 g. of silver oxide according to the method of Purdie and Irvine.[16] The methylated material was extracted with chloroform and recovered. After a second methylation with the same amounts of the reagents the isolated sirup had a methoxyl content of 41.2% instead of 50.3% calculated for a fully methylated compound. After a third, fourth (OCH_3, 42.0%) and fifth (OCH_3, 43.1%) methylation, it was concluded that probably the primary hydroxyl group of the substance was resistant to methylation with these reagents. Therefore, the sirup was treated with sodium and methyl iodide

(15) Elsner, *Ber.*, **61**, 2364 (1928).

(16) Purdie and Irvine, *J. Chem. Soc.*, **83**, 1021 (1903).

according to the modified Freudenberg procedure.[13] A pale yellow liquid with 50.1% methoxyl content was obtained. Seven grams of this 2,3,6-trimethyl galactose-dimethylacetal was then dissolved in 50 cc. of 0.05 *N* hydrobromic acid and the solution was heated on a water-bath at 60–70° until constant rotation was observed (three and one-half hours). The solution, which contained 2,3,6-trimethyl galactose, was treated with 20 g. of bromine and kept at 35–40° for sixty-five hours. The non-reducing solution was then worked up in the usual manner (*i. e.*, bromine removed by aeration, acid neutralized with silver carbonate, silver salt decomposed with hydrogen sulfide). The resulting clear solution was concentrated *in vacuo* at 45–50°. A colorless, crystalline compound, the 2,3,6-trimethyl-γ-galactonolactone, separated out; yield, 2.5 g. The substance was recrystallized twice from aqueous methyl alcohol. The fine needles had m. p. 97–98° and an initial specific rotation of −32.9° in water solution (*c*, 1.686), which value after ten days changed to the constant rotation of −21.3°.

Anal. Calcd. for $C_9H_{16}O_6$: OCH_3, 42.3. Found: OCH_3, 41.9.

For the oxidation experiment 10 cc. of a 0.1 molar solution of the lactone was treated first with one equivalent of standard sodium hydroxide solution, and then with 20 cc. of a 0.1 molar periodic acid solution which had been neutralized previously. After thirty minutes 5 cc. of the reaction mixture was titrated for the excess of periodate with standard arsenite solution and it was found that 2.27 cc. of periodic acid was used up for the oxidation of the lactone (calcd. for one mole of periodic acid: 2.30 cc.). Five-cc. samples were again titrated after one hour (found: 2.27 cc.), two and one-half hours (found: 2.27 cc.) and twenty-four hours (found: 2.37 cc.). These results indicated that one mole of periodic acid was required for the scission of the lactone, which fact was considered as evidence that the analyzed product was the 2,3,6-trimethyl derivative.

Oxidation of 4,5-Monoacetone Galactosedimethylacetal with Periodic Acid to Glyoxal and 2,3-Monoacetone *d*-Threose.—It was found in a preliminary experiment that from an excess of a 0.1 molar periodic acid solution only one mole equivalent was used for the oxidation of the monoacetone derivative provided that the acid was previously neutralized with sodium hydroxide. In another experiment, in which the periodic acid was not neutralized, it was found that after one hour one mole equivalent was used up, but if the reaction mixture was allowed to stand for a longer period of time, then further oxidation occurred. This undoubtedly was due to the reaction of the oxidant with adjacent hydroxyl groups liberated by hydrolysis from the acid-sensitive primary oxidation products.

For the isolation of the scission products 3 g. of the 4,5-monoacetone galactosedimethylacetal was dissolved in 1355 cc. of water and to the solution 45 cc. of a 0.2631 molar periodic acid was added (5% excess). After twenty minutes it was found by titration of a sample with arsenite solution that one mole of periodic acid was used up. The solution was then neutralized with barium hydroxide solution to phenolphthalein. Immediately a white, flocculent precipitate separated out. The mixture was kept at 0° for two hours, filtered and the precipitated iodates washed with ice water. To the combined filtrate and washings 3 g. of barium carbonate was added and the mixture was allowed to stand overnight at room temperature. The filtered solution was distilled *in vacuo* at 40–50°. On treatment with phenylhydrazine dissolved in five parts of glacial acetic acid, the distillate gave a yellow precipitate. The residual sirup was dissolved in water and concentrated *in vacuo*, this process being repeated until the distillate gave no more reaction with phenylhydrazine (thirty hours of distillation). The combined precipitates were recrystallized from 85% alcohol; yield, 1.9 g. of pale yellow needles; m. p. 168–169°. The substance represented the *bis*-phenylhydrazone of glyoxal first obtained by Fischer,[17] who gave m. p. 169–170°. The presence of the glyoxal in the distillate probably was due to the hydrolysis of the dimethyl semiacetal during the protracted contact of the latter with water.

The residual sirup, 2,3-monoacetone *d*-threose, was dissolved in absolute ethyl alcohol, the solution filtered with activated carbon and the filtrate evaporated *in vacuo* to a sirup (1.74 g.) which reduced Fehling's solution and had an initial specific rotation of 18.7° in water solution (*c*, 1.065) that changed after two days to 12.5°. The presence of the isopropylidene group was shown by an acetone estimation according to the method of Bell and Harrison.[18]

Conversion of 2,3-Monoacetone *d*-Threose into Potassium Acid *l*-Tartrate.—A solution of 1.7 g. of 2,3-monoacetone *d*-threose in 20 cc. of 10% acetic acid was heated on a water-bath until constant rotation was obtained (one hour). The solution had $[\alpha]^{20}D$ −10.5° which was in good agreement with the values (−10.7 to −12.0°) given by Hockett[19] for the rotation of *d*-threose. The acetic acid was removed by distillation of the solution *in vacuo*. A 70-mg. sample of the sirupy product gave a crystalline osazone with m. p. 159–160° (Hockett[19] reported m. p. 164°). The *d*-threose was then oxidized in 25 cc. of aqueous solution with 4 g. of bromine and the *d*-threonic acid formed was isolated in the usual manner. A clear sirup (0.95 g.) was obtained which had $[\alpha]^{20}D$ −26.1° in water solution (*c*, 1.645).

Anderson[20] gave rotations varying from −20 to −30°. From the threonic acid the brucine salt was obtained in a procedure similar to that of Ruff.[21] The salt crystallized from 85% ethyl alcohol in the form of fine needles which melted at 199° and had $[\alpha]^{20}D$ −37.2° in water solution (*c*, 1.340). Hockett[19] reported m. p. 197–198° and $[\alpha]^{20}D$ −36.8°.

Anal. Calcd. for $C_{27}H_{34}O_9N_4$: OCH_3, 11.69. Found: OCH_3, 11.60.

The *d*-threonic acid (0.7 g.) was oxidized with 3.5 cc. of nitric acid (*d*, 1.2) to *l*-tartaric acid which was converted into the acid potassium salt as described by Reichstein.[22] The crystalline product had $[\alpha]^{20}D$ −28.1° in

a 2% potassium hydroxide solution (*c*, 1.425). Hockett[19] recorded $[\alpha]^{24}D$ −29.7 in a 2% sodium hydroxide solution and Reichstein[22] gave $[\alpha]^{22}D$ −32.8° in a 2% potassium solution.

Summary

1. The "2,3-monoacetone galactosedibenzylmercaptal" of Pacsu and Löb was found to be a mixture of two isomeric monoacetone derivatives.

2. The chemical structure of the higher rotating isomer was investigated and it was proved that the isopropylidene group was attached on carbon atoms 4 and 5.

3. This conclusion was drawn from the results of a series of transformations in which the substance was first converted into the 4,5-monoacetone galactosedimethylacetal. On methylation the latter gave rise to the 2,3,6-trimethyl derivative which on hydrolysis and subsequent oxidation yielded crystalline 2,3,6-trimethyl γ-galactonolactone.

4. Oxidation by periodic acid of the monoacetone galactosedimethylacetal gave glyoxal and 2,3-acetone *d*-threose, which scission products could form only if the starting material had the isopropylidene group at carbon atoms 4 and 5.

5. The glyoxal was isolated as *bis*-phenylhydrazone, the 2,3-acetone threose was converted into *d*-threonic acid from which the acid potassium salt of *l*-tartaric acid was prepared.

Acidic Constituents of a California Straight-run Gasoline Distillate

BY KINNEY HANCOCK[1] AND H. L. LOCHTE

The acidic constituents of petroleum from various regions have been a source of rather extensive investigation. The isolation and identification of numerous individuals of the acyclic series have been reported. Among these are: formic and oxalic acids from Grosny distillates by Schidkoff[2]; palmitic, stearic, myristic, and arachidic acids from Ishikari distillates by Tanaka and Kuwata[3]; isoamylacetic and diethylpropionic acids from Baku petroleum by Chichibabin[4]; isovaleric, *n*-heptylic, *n*-octylic, and *n*-nonylic acids and ethyl mercaptan from a West Texas pressure distillate by Williams and Richter[5]; *n*-butyric and *n*-valeric acids and dimethylmaleic anhydride from a Texas distillate by Schutze[6]; and isocaproic acid from Rumanian petroleum by Nenitzescu and co-workers.[7]

As to the phenolic constituents, phenol, the three cresols, and several of the xylenols have been isolated.[5,7,8]

The isolation of numerous naphthenic acids, varying in complexity from cyclopentanecarboxylic acid to pentacosan-naphthenic acid, has been reported. Later investigation has proved that the majority of these acids were mixtures. Von Braun and co-workers[9] are given credit for the isolation of the first homogeneous naphthenic acid. These investigators isolated 3,3,4-trimethylcyclopentanone from the degradation products from mixtures of decanaphthenic acids from various sources. This ketone was then reconverted to 3,3,4-trimethylcyclopentylacetic acid.

Very recently Nenitzescu and co-workers[7] have reported the isolation, through selective amide formation, and identification of cyclopentanecarboxylic, cyclopentylacetic, and 3-methylcyclopentylacetic acids from Rumanian petroleum.

The material investigated in the present study was a complex mixture of crude petroleum acids from the sodium carbonate wash of Signal Hill straight-run gasoline.[10] The objectives of the investigation were: (1) to study and to improve methods of separation of acid mixtures, (2) to attempt to develop new methods of separation, (3) to attempt the isolation and identification of all of the aliphatic acids from formic through the pentanoic acids, and (4) to study the fractions in

the region of the nonanoic acids with a view to the isolation and identification of some of the individuals. The fractions in the region of the hexanoic, heptanoic, and octanoic acids are being investigated by another student in this Laboratory. The general procedure for the partial separation of this mixture is shown in the accompanying Flow Sheet.

In two runs, 70 l. of crude acids was distilled under reflux at 50 mm. from a 15-gallon steel still with a 110 cm. × 12 cm. column. Natural gas was used in the capillary in this case and in all subsequent vacuum distillations. The three fractions shown on the Flow Sheet were obtained. The two layers in the first fraction were separated, the top layer amounting to 2840 cc. and the bottom layer 760 cc.

By a series of distillations the 760-cc. portion was separated into 20 cc. of acids and 740 cc. of water solution of acids. The 20-cc. portion was returned to the top layer obtained originally. In this manner, the majority of dissolved acids of higher molecular weight than propionic acid were removed.

The 740-cc. portion was neutralized with 115 cc. of 3 *N* sodium carbonate, and an excess of 25 cc. was added. The basic solution was evaporated to dryness on a steam cone. The residue was pulverized and dried thoroughly at 20 mm. to obtain 29.1 g. of powder. One-half of this powder was distilled at 20 mm. with 25 cc. of phosphoric acid[11] (dried for twenty-four hours at 150–160° and 20 mm. with a capillary leak) to obtain 4.5 g. of acids.

Formic Acid.—Small portions of this mixture (I on Flow Sheet) reduced silver nitrate and mercuric chloride solutions.

The balance of the 4.5-g. portion was distilled with 23 cc. of methyl *n*-caproate[12] and 0.6 cc. of 18 *N* sulfuric acid to obtain 3.0 g. of dry methyl esters. The esters were fractionated under a high reflux ratio through a 70 cm. × 5 mm. column containing a spiral of chromel wire to obtain several fractions with $n^{24}D$ values: A1, 1.3560; A2, 1.3572; A3, 1.3609; A4, 1.3765; A5, 1.3780; residue, not detd.

Acetic Acid.—The $n^{20}D$ value reported for methyl acetate is 1.3619.[13] Fraction A3 yielded, after saponification, Duclaux values of 7.0, 7.5, and 8.0, respectively, for the first three 10% distillates. The Duclaux values for acetic acid given by Kamm[14] are: 6.8, 7.1, and 7.4.

The combined top layers (2860 cc.) amounted to 14.8 equivalents. A consideration of the differences in solubility and in K_a values for the lower acids expected in this mixture indicated the possibility of separation through fractional extraction with sodium hydroxide. The two experimental difficulties recognized were: loss of lower acids as a result of water solubility and solubility of the sodium salts in the free acid layer. The following procedure was designed to lower these factors to a minimum.

The whole portion (2860 cc.) was stirred effectively for six hours with 3 liters of normal sodium hydroxide. The top layer was stirred thoroughly for thirty minutes with three 500-cc. portions of water. The washes were combined with the bottom layer and the combination distilled to small volume. The residue was steam distilled until the distillate became neutral to litmus. All distillates were combined, made slightly basic with sodium hydroxide, evaporated to small volume, and the concentrated solution mixed with the top layer. The residue was concentrated further and an excess of 18 *N* sulfuric acid was added with cooling. The freed acids were separated and the heavy layer extracted three times with petroleum ether (30–60°). The solvent was removed and the acids dried at 100° and 20 mm.

(14) Kamm, "Qualitative Organic Analysis," 2d ed., John Wiley and Sons, Inc., New York, N. Y., 1938, p. 153.

This procedure was repeated four times, beginning each time with the mixture of the top layer and the combination of basic distillates which had been concentrated by evaporation. A stubborn emulsion resulted during the fourth extraction. This emulsion was broken through: (1) addition of water and extraction with petroleum ether (30–60°), and (2) steam distillation of the raffinate. This treatment yielded a fraction listed as 4a in Table A. After the fifth extraction, a small portion, insoluble in an excess of sodium hydroxide, was discarded.

TABLE A

	Wt., g.	$n^{20}D$	Equiv. wt.
1	284.0	1.4139	104.5
2	297.3	1.4204	115.6
3	342.7	1.4286	127.9
4	555.5	1.4367	144.3
4a	178.1	1.4410	159.0
5	252.8	1.4407	156.8

Fractions 1 and 2 (Table A) were extracted separately with three equal portions of normal sodium hydroxide as described above. No appreciable emulsion formation occurred in these cases due to the transfer of the weak, emulsifying acids to fractions 4, 4a, and 5 by the previous extraction.

TABLE B

	Wt., g.	$n^{20}D$	Equiv. wt.
1a	67.5	1.4155	90.6
1b	83.1	1.4103	98.0
1c	77.1	1.4147	109.0
2a	79.8	1.4135	107.0
2b	97.4	1.4181	113.1
2c	97.8	1.4273	126.5

Fractions 1a, 1b, 1c, and 2a (Table B) were converted separately to the methyl esters by refluxing for three hours with an equal volume of methanol containing 2% hydrogen chloride. The unchanged acids were recovered and esterified as before. The two portions of esters were combined. This general procedure was followed in all subsequent esterifications, except that in some cases the unchanged acids after the second operation were recovered and esterified as before to yield a third portion of esters. The yields in grams from fractions 1a, 1b, 1c, and 2a were: 57.9, 74.3, 79.8, and 77.8 (one esterification), respectively.

Dimethylmaleic Anhydride.[6]—A solid crystallized out when the unchanged acids recovered after the first esterification of 1a (Table B) were cooled with an ice–salt mixture. This solid melted at 94–95° after two recrystallizations from petroleum ether (60–68°). Treatment with resorcinol and sulfuric acid, followed by neutralization with sodium hydroxide, gave a yellow-green fluorescence.[15] This reaction is given by the anhydride ring group of phthalic anhydride. This same group is present in dimethylmaleic anhydride. The mixed melting point of the isolated acid with synthetic dimethylmaleic anhydride showed no depression. All of this anhydride had been concentrated in the fraction from which it was isolated. Schutze found the same substance in eight different fractions in his investigation of Texas petroleum acids.

(15) Mulliken, "The Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York, N. Y., 1st ed., Vol. I, 1905, p. 84.

The methyl esters of fractions 1a, 1b, 1c, and 2a were fractionated separately, under good reflux, from a 200-cc. still with a 130 cm. × 8 mm. (i. d.) column containing a spiral of chromel wire. The fractions obtained were combined on the basis of boiling points and indices of refraction. The combinations were subjected to four-fold refractionation and recombination, the esters with boiling points above that of methyl *n*-valerate being set aside each time. For the smaller combinations a 30-cc. still with a 75 cm. × 5 mm. (i. d.) column containing a spiral of small glass rod was used.

TABLE C

	Wt., g.	$n^{20}D$	B. p., °C.
1	0.35	1.3728	<79
2	2.54	1.3792	79– 80
3	1.2	1.3831	80– 91
4	7.44	1.3843	91– 92
5	5.0	1.3862	92–101
6	3.95	1.3885	101–102
7	8.7	1.3923	102–115
8	57.2	1.3942	115–116
9	11.9	1.3962	116–126
10	12.8	1.3983	126–127

Propionic, Isobutyric, *n*-Butyric, Isovaleric, and *n*-Valeric Acids.—Small portions of fractions 2, 4, 6, 8, and 10 (Table C) were saponified and the 2-alkylbenzimidazoles[16] of the recovered acids were prepared.

TABLE C-1

No.	B. p. of acid, °C.	$n^{20}D$ of acid	M. p. of 2-alkylbenzimidazole, °C. Synthetic	Isolated	Mixed
2	141–142	1.3872	174.5	178.5	176
4	153–154	1.3948	234	233.5	234
6	162–163	1.3982	159	158	158
8	175–176	1.4050	190.5	190	190
10	185–186	1.4090	154	153	153

The *p*-phenylphenacyl esters[17] of the acid from fraction 2 (Table C) and of propionic acid were also prepared: m. p., synthetic, 103°; isolated, 100.5°; mixed, 102°.

Attempts to isolate methylethylacetic and trimethylacetic acids were unsuccessful; in fact, there was very little indication, if any, of their presence in the mixture investigated.

In two runs, the 54-liter fraction (Flow Sheet) was distilled under reflux at 70 mm. from the 15-gallon still to obtain the four fractions shown on the Flow Sheet. The top fraction (22 liters) was combined with a similar fraction of 17 liters from an earlier distillation of 30 liters of crude acids. This combination was topped to 137° at 25 mm. from Claisen flasks. The tops were retopped to 137° at 25 mm. in the same manner. This procedure yielded the 11-liter and 28-liter fractions shown on the Flow Sheet.

The 28-liter fraction was combined with the 18-liter fraction (Flow Sheet) and the combination (1500-cc. charges) subjected to two-fold fractionation at 3 mm. under a high reflux ratio from a 2-liter still with a 145 cm. × 3.5 cm. (i. d.) glass marble-(7 mm. diam.)-filled column.

(16) Pool, Harwood and Ralston, THIS JOURNAL, **59**, 178 (1937).

(17) Drake and Bronitsky, *ibid.*, **52**, 3715 (1930).

After each fractionation similar fractions were combined on the basis of boiling points and indices of refraction. The combinations after the second fractionation were combined with similar fractions obtained from the two-fold fractionation (3 mm.) through the 145-cm. column of the 11-liter portion (b. p. < 137° at 25 mm.). These final combinations were then fractionated a third time through the 145-cm. column to obtain the following fractions.

TABLE D

6	1005	1.4405			

Menschutkin[18] has shown that primary, secondary, and tertiary aliphatic acids differ greatly in their velocities of esterification. His results suggested the possibility of separation of petroleum acids through fractional esterification.

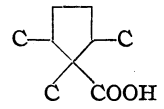
Two liters of fraction 4 (Table D) was fractionated at 3 mm. through the 145-cm. column to obtain a main fraction of 1614 cc.—the tops and bottoms were combined with similar fractions from the previous fractionation. The main fraction was fractionally esterified by refluxing each time for twelve hours with one-fourth of the calculated amount of methanol–2% hydrochloric acid. After each step the mixture of acids and esters was washed, dried and then fractionated at 25 mm. through the 145-cm. column until the distilling temperature rose abruptly. Corresponding fractions from the four series obtained showed very little difference in physical properties. Possibly, interchange between the acids and esters[12] may have occurred during the fractionation, although a detailed study of this type of reaction in this Laboratory with synthetic acids and esters indicated that the reaction would not occur except in the presence of a catalyst.

Fractionation of the unchanged acids remaining after the fourth step yielded a solid acid, m. p. 194–195° from dilute alcohol.

The balance of fraction 4 (Table D) was subjected to three-fold esterification. More of the solid acid was recovered from the unchanged acids remaining after the third esterification. A similar procedure with fraction 5 (Table D) yielded additional solid to total 62.5 g.

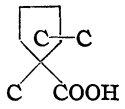
Data Determined on this Solid Acid.—(a) Qualitative analysis: negative for sulfur, nitrogen, and halogen. (b) M. p. 194–195° from dilute alcohol. (c) Equivalent weight: calcd. for $C_9H_{16}O_2$, 156.21; found, 156.33. (d) C and H. Calcd. for $C_9H_{16}O_2$: C, 69.20; H, 10.32. Found: C, 69.41; H, 10.02. (e) Unsaturation tests: negative. (f) 0.1047 g. of acid in 1.0021 g. of camphor melted at 177°, while camphor alone melted at 174°. (g) An electrometric titration proved that the acid is monobasic.

The behavior of the compound in the Rast molecular weight determination and the high melting point led us to suspect a tertiary acid closely related to camphor. A search of the literature on known $C_9H_{16}O_2$ acids and homologs of near the same molecular weight led us to predict that the isolated acid was either



1,2,5-Trimethylcyclopentanecarboxylic acid

or



Camphonanic acid

The former is unknown but Appel[19] in 1933 prepared camphonanic acid. Although his degradation from *d*-camphoric acid yields the dextrorotatory acid while the isolated acid is inactive or slightly levorotatory, his synthesis was repeated since only *d*-camphoric acid was available at the time. The constants of the acid obtained agreed with those of Appel's acid with the exception of the m. p., which was found to be 192–193° instead of 190–191°. In agreement with Appel, esterification by methanol and hydrochloric acid failed. The *p*-bromoanilides and *p*-toluidides of the *d*-camphonanic acid and of the isolated acid were prepared according to Kuehn and McElvain.[20] The melting points of the acids and of their derivatives are tabulated.

	dl-Camphonanic	Isolated	Mixed
Acid	192–193	194–194.5	193–194
p-Bromoanilide	102–103	119–120	111–115
p-Toluidide	114–115	110–111	111–112

Since none of the mixed melting points showed a depression, it appeared that the isolated acid was either pure *dl*-camphonanic acid and the slight rotation due to an error, or that the rotation was due to a small amount of an active acid. The *dl*-acid was then prepared from *dl*-camphor.

dl-Camphoric acid was prepared from *dl*-camphor according to Noyes.[21] The dibasic acid was degraded to *dl*-camphonanic acid by Appel's procedure. The *p*-bromoanilide and the *p*-toluidide were prepared as described above.

	dl-Camphonanic	Isolated	Mixed
Acid	193–194	194–194.5	193.5–194
p-Bromoanilide	119–120	119–120	119–120
p-Toluidide	110–111	110–111	110–111

This proves definitely that the isolated acid is *dl*-camphonanic acid—the first naphthenic acid isolated from American petroleum.

Summary

1. A mixture of crude petroleum acids has been partially separated through fractionation as acids, fractional extraction with sodium hydroxide, fractionation as methyl esters, and through differences in tendencies to esterify.

2. The separation of aliphatic acids of low molecular weight through systematic fractional extraction with sodium hydroxide is effective.

3. Fractional esterification of a particular mixture of acids by a batch procedure yielded very little separation.

4. Isolation of peculiar individual substances from the mixture of unchanged acids recovered after esterification has proved to be relatively simple.

5. Formic acid has been identified through qualitative tests. Dimethylmaleic anhydride and acetic, propionic, isobutyric, *n*-butyric, isovaleric, and *n*-valeric acids have been isolated and identified. Of these eight substances, acetic, propionic, and isobutyric acids have not been reported previously.

6. *dl*-Camphonanic acid has been isolated and identified as the first American naphthenic acid.

The Use of *n*-Butyl Chlorosulfonate and *n*-Butyl Chlorosulfite in the Friedel–Crafts Reaction

BY CHAS. BARKENBUS, RALPH L. HOPKINS AND J. FORREST ALLEN

Alkyl halides have been used for many years in the Friedel–Crafts reaction as a means of introducing alkyl groups into aromatic nuclei. More recently efforts to extend the scope of this reaction to permit use of a wider variety of alkylating agents have resulted in the use of many types of esters, both organic and inorganic, with widely varying results. Besides the esters of the fatty acids such inorganic derivatives as alkyl sulfates, orthosilicates, phosphates, hypochlorites,[1] borates,[2] and sulfites[3] have been used.

In a search for a more direct method of making alkyl benzenesulfonates, an investigation was made of the method described by Frèrejacque,[4] who claimed to have prepared the methyl sulfonates of benzene, toluene, naphthalene, and chlorobenzene by the action of methyl chlorosulfonate on the above compound. Using *n*-butyl chlorosulfonate and benzene no butylbenzene sulfonate could be obtained. However, a reaction took place at 60° with evolution of hydrogen chloride, and from the reaction mixture a small hydrocarbon residue was obtained, although most of the product was converted into an unworkable tar. All methods used in attempting to show that some sulfonates were produced failed. The addition of anhydrous aluminum chloride caused the ester to react extremely vigorously even at 0° with copious evolution of hydrogen chloride.

A study of this reaction under the most favorable conditions showed it to be principally one of alkylation with production of *s*-butylbenzene and *m*-di-*s*-butylbenzene. Chlorination also takes place, and chlorobenzene was recovered in quantity. Alkylation of toluene under similar conditions yielded *m*- and *p*-*s*-butyltoluenes and *o*-chlorotoluene along with smaller amounts of *p*-chlorotoluene and various side-chain chlorinated products. In both cases higher boiling hydrocarbon fractions were obtained.

The alkylating action of *n*-butyl chlorosulfite on benzene in the presence of anhydrous aluminum chloride was also investigated. Less high-boiling material is produced by this ester than was observed with the *n*-butyl chlorosulfonate, and chlorination does not take place, but an unstable sulfur compound of undetermined nature is produced, and unfavorably affects the quality of the yield.

Experimental

Reactions of *n*-Butyl Chlorosulfonate

Benzene.—A series of experiments was carried out to determine the most suitable reacting conditions and the proper proportions of reactants necessary for the maximum yield of *s*-butylbenzene. From these it was concluded that the temperature is best maintained between 0 and 5°. The most efficient proportion of aluminum chloride to ester is 2:1. The use of 9 moles of benzene with the

(4) Frèrejacque, *Compt. rend.*, **183**, 607 (1926).

above ratio increases the total yield and greatly facilitates stirring.

From the results of the foregoing conclusions two large-scale runs were made in each of which 3 moles of crude *n*-butyl chlorosulfonate prepared according to Barkenbus and Owen[5] and used without distillation was added slowly to 27 moles (2106 g.) of benzene (dried over sodium) and 6 moles (800 g.) of anhydrous aluminum chloride (technical) with stirring at 0–5°. After the elapse of three hours the mixture was poured onto 5 kg. of cracked ice, washed with concentrated hydrochloric acid and water and allowed to stand overnight with concentrated ammonium hydroxide, which readily removed labile chlorine compounds. The benzene was then washed repeatedly with 80% sulfuric acid until the acid no longer developed a color. This treatment removed unsaturated material, which has a tendency to decompose in distillation. No sulfonates could be isolated from this fraction. After washing with sodium hydroxide, drying over calcium chloride, and distillation of the excess benzene, a total residue of 652 g. remained.

Preliminary fractionation in a short column removed about 60 g. of chlorobenzene which boiled at 128–130° and was identified as *p*-nitrochlorobenzene by nitration. Much chlorine still remained and was removed by heating with sodium. Fractionation of the mixture on a large column similar to that described by Tongberg, Quiggle, and Fenske[6] was performed at 3 mm. and many small fractions were collected. By taking the index of refraction of each fraction and plotting against the amount distilled two main fractions of constant index were obtained. The first main fraction weighing 83 g. was identified as *s*-butylbenzene by the method of Reilly and Hickenbottom:[7] m. p. of acetamino derivative 124–125°; listed m. p. 125–126°; $n^{20}D$ 1.4910. Ipatieff[8] gives 1.4902. The second fraction weighing 165 g. was characterized as *m*-di-*s*-butylbenzene by oxidation to isophthalic acid and conversion of the latter to its methyl ester (m. p. 67–68°); $n^{20}D$ 1.4890; b. p. 88–92° at 3 mm. This fraction contained a trace of the ortho isomer as shown by the fluorescein test: yields, *s*-butylbenzene, 19%; *m*-di-*s*-butylbenzene 26.6%; chlorobenzene 11.2%.

Toluene.—Six moles of *n*-butyl chlorosulfonate was allowed to react with 12 moles of aluminum chloride and 54 moles (4968 g.) of toluene for three hours after addition of the ester at −2°. The product was washed and fractionated in a manner analogous to that used for benzene. The following products were separated and identified: *m*-*s*-butyltoluene 290 g. (32.4%); b. p. 193–197°; $n^{20}D$ 1.4957. This fraction was completely soluble in concd. sulfuric acid; *p*-*s*-butyltoluene 174 g. (19.6%); b. p. 201–202°; $n^{20}D$ 1.4950. Only a trace of this fraction was soluble in cold concd. sulfuric acid; *o*-chlorotoluene 83 g. (21.8%). The *o*-chlorotoluene and *p*-chlorotoluene fractions were not pure but were contaminated slightly with each other, due to the closeness of their boiling points. They were of sufficient purity to obtain readily *o*-chlorobenzoic and *p*-chlorobenzoic acid by oxidation of the respective fractions: *p*-chlorotoluene 23.5 g. (6.2%). A high boiling hydrocarbon residue of 170 g. also was obtained but the components were not identified. Considerable benzoic acid, probably derived from benzotrichloride, resulted from the sodium treatment and smaller amounts of other side-chain chlorinated products were present.

Summary

The action of *n*-butyl chlorosulfonate on benzene and toluene in the presence of anhydrous aluminum chloride has been investigated. The principal effect is one of alkylation accompanied by nuclear and side-chain chlorination.

n-Butyl chlorosulfite reacts with benzene and aluminum chloride to produce *s*-butylbenzene. The reaction is not accompanied by chlorination, but sulfur derivatives are produced.

Fractionation of the Hydrogen Isotopes in the Distillation of Ethyl Alcohol

BY ALEX H. WIDIGER AND WELDON G. BROWN

During the course of some experiments on hydrogen exchange reactions in deutero-alcohol in which it was necessary to recover the alcohol from the mixtures, for deuterium analysis, by careful fractional distillation under reduced pressure, using small laboratory columns, we had occasion to suspect that serious errors were being introduced as a result of fractionation of the hydrogen isotopes during the distillations. In view of the small mass difference between C_2H_5OD and C_2H_5OH, and the difficulty of accomplishing the desired separations (*e. g.*, phenylacetylene and alcohol) with our columns, the possibility of accounting for our results on this basis was not considered seriously until after a number of more obvious possible sources of error had been eliminated. It was nevertheless possible to show, by distillations of alcohol alone, that the degree of isotopic separation is fully capable of accounting for our results.

The first distillations were carried out with a vacuum-jacketed column, 4 mm. i. d., 45 cm. in length, containing a spiral nichrome wire packing. In a typical experiment, a sample of alcohol containing 17.8% C_2H_5OD was distilled at 40 mm. pressure, and the distillate, amounting to one-half of the total, was found to contain 14.8% C_2H_5OD. The boiler residue was correspondingly richer in deuterium and contained 21.1% C_2H_5OD. In order to compare this separation with that to be obtained on the distillation of water, a sample of water containing 3.06% D_2O was distilled under similar conditions and the distillate was found to contain 2.43% D_2O. These results would indicate that the fractionation of the hydroxyl hydrogen in alcohol takes place with very nearly the same efficiency as the fractionation of the isotopic forms of water. However, some allowance would have to be made for the fact that this column could not be made to operate smoothly in distillations of water.

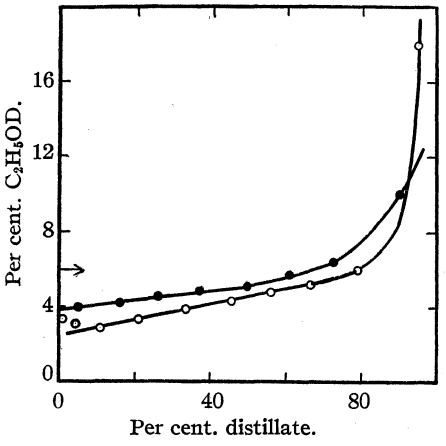

Fig. 1.—The distillation of 6% C_2H_5OD at atmospheric pressure (●) and at 80 mm. (○).

These results immediately suggested that the distillation of alcohol with the aid of high efficiency fractionating columns might prove to be a practicable method for the concentration of deuterium in quantity. The concentration of deuterium by the distillation of water has not thus far been a conspicuous success and it appears to be common experience that the efficiency of fractionating columns in such distillations does not approach that predicted on the basis of performance with organic liquids. The method of distilling alcohol offers a number of advantages from the standpoint of column operation and it was therefore of interest, although there is no intention of pursuing the project further at this time, to determine the degree of isotope separation obtainable with a more efficient column than that described above.

Subsequent distillations were carried out using a column packed with single-turn glass helices, packed length 2.2 m., internal diameter 18 mm. The theoretical plate equivalent of this column was estimated to be in the neighborhood of 25 plates, this estimate being based on its performance in the separation of active amyl and isoamyl alcohols.[1] The results of two distillations, one at atmospheric pressure (750 mm.), the other at 80 mm. pressure, of deutero-alcohol containing 6.0% C_2H_5OD initially are shown in Fig. 1. The isotopic separation obtained corresponds to a fractionation factor 1.6 for the distillation at atmospheric pressure, and a factor 2.4 for the distillation at 80 mm. pressure. Assuming a column efficiency of 25 plates, the enrichment factors for the vaporization process are as follows: at 750 mm. 1.019 and at 80 mm. pressure 1.035.

In a distillation at atmospheric pressure of water containing 0.330% D_2O, the first fraction of the distillate was found to contain 0.195% D_2O. Before this experiment was carried out the column was cleaned thoroughly by distilling nitric acid through it, in order to facilitate uniform wetting of the packing, and no difficulty was experienced in the subsequent operation of the column with pure water. The observed fractionation factor, 1.69, is slightly higher than that found in the distillation of alcohol, and if we again assume a column efficiency of 25 plates we obtain an enrichment factor, 1.021. This is appreciably lower than the value, 1.025, reported by Urey and Teal[2] and our estimate of the column efficiency was therefore, for this distillation at least, too high.

The fact that a partial separation of the hydrogen isotopes can be effected readily by the distillation of water has been known for some time[3] and consequently the possibility of errors arising from this source in work on exchange reactions in heavy water has been recognized almost from the beginning. It is now evident that effects of this type can be equally significant in work on exchange reactions in heavy alcohol and that the necessary precautions will have to be taken to minimize the resulting errors.

Summary

It has been shown, by distillations of alcohol in laboratory fractionating columns, that the isotopic forms, C_2H_5OH and C_2H_5OD, readily undergo a partial separation on distillation, the degree of isotopic separation being comparable with that observed in the distillation of water.

The Salts of Europium

BY HERBERT N. MCCOY

Although nearly forty years have passed since Demarçay[1] characterized europium as a distinct element, its compounds have been studied little. The only systematic study was that made by Sarkar,[2] who made and analyzed a dozen europic salts. Earlier workers[3–7] had made eight or ten other compounds but many of these had not been analyzed. Europous chloride and sulfate have been made and studied by several workers.[8–12]

With the more abundant supply of europium made available through newer methods[11] of separation and purification, it was deemed worth while to make further studies of the salts of this element. The analytical results are shown in Table I.

In a few cases the results of this study were at variance with earlier work. *m*-Nitrobenzenesulfonate, made by James and Robinson,[6] is said to have $3H_2O$; the analysis of my crystalline product, seemingly pure, indicates $6H_2O$. Europium citrate was made and analyzed by Sarkar,[2] whose figures indicate five molecules of water. My analyses lead to but four. That there are other salts of citric acid is indicated by the fact that only by following a definite procedure could this substance be obtained pure. When 4.0 g. of europium acetate in 30 cc. of cold water was mixed with 6.3 g. of citric acid in 15 cc. of cold water (one mole of each) a precipitate formed at once. This dissolved completely when the mixture was well stirred. When the solution was heated to 80° it gave an amorphous precipitate that changed to microscopic crystals. After two hours of stirring these were filtered out, washed, dried and analyzed. Sarkar's iodate is given the formula $Eu(IO_3)_3 \cdot 5^1/_2H_2O$. The results found here indicate four molecules of water.

The methods of preparation varied according to the nature of the acid and of the resulting salt. The formate, acetate, propionate, monochloroacetate, trichloroacetate, furoate, picrate, *p*-toluenesulfonate and *m*-nitrobenzenesulfonate were made by dissolving europium oxide in a hot aqueous solution of acid. These salts were all more soluble in hot than in cold water and crystallized well when their solutions were cooled.

The acetates of the cerium group of rare earths differ from europium acetate in having three molecules of water instead of four and in being less soluble in hot than in cold water.

Solutions of the sodium salts of the acids were treated with a solution of europium acetate or nitrate to prepare the maleate and fumarate. These salts are not much soluble in water. The former is soluble in cold dilute acetic acid. Other salts more or less difficultly soluble in water including the malonate, succinate, lactate, tartrate, pyruvate, citrate, benzoate, salicylate, cinnamate, benzilate, and basic sulfite could be made from a solution of europium acetate and the corresponding acid.

In several cases the salt did not separate at once but came down slowly when its solution was stirred and heated. This was true of the malonate, maleate, pyruvate, salicylate, lactate, citrate, acid tartrate and basic sulfite.

In general the salt, after its precipitation or crystallization, was filtered and washed well with water if it contained any foreign substance and afterward with methanol. It was dried in air or in a desiccator as necessary.

In the analyses when no complication occurred, the salt was simply ignited to the oxide, Eu_2O_3. In other cases europium was precipitated as oxalate and the latter ignited. The bromate and iodate were treated with potassium iodide and the liberated iodine titrated with thiosulfate. The sulfite could be titrated directly with iodine.

Several other euopric salts were made which were not analyzed either because they were extremely deliquescent, as the perchlorate, dichloroacetate, bromide and sulfamate or of doubtful purity or interest as *o*-chlorobenzoate, *p*-bromobenzoate, naphthol-6-sulfonate, fluosilicate, hypophosphate and chromate. In addition there were made a number of very definite and interesting europous salts which have not yet been obtained

Carbonate	$Eu_2(CO_3)_3 \cdot 3H_2O$	65.42	65.68		

entirely free from europic salts. These include the carbonate, oxalate, succinate, etc.

The fluoride, little soluble in water, oxidizes so fast in air that it sets fire to the filter paper after it has been washed with methanol.

Analysis of Europous Salts.—Soluble europous salts are quickly oxidized in air. The less soluble they are in water, the greater their permanence in air. Europous sulfate, $EuSO_4$, is the most stable so far found. It suffers little change in the course of a year. This very small solubility makes its titration with permanganate very slow and the results uncertain. A completely satisfactory procedure was found in the addition of ferric sulfate prior to the titration. The latter reacts quickly and quantitatively with the europous salt to form soluble europic sulfate and ferrous sulfate. Titration of the latter follows the well-known method with permanganate. Ten cc. of a solution containing 0.5 g. of ferric sulfate and 5 g. of sulfuric acid were used for 0.3 to 0.4 g. of europous sulfate.

This method of analysis was tried with a fresh lot of europous sulfate. Twenty-five cc. of purest europium chloride, of density 1.14, was reduced in a reductor containing 400 g. of ten-mesh amalgamated zinc and run slowly into 150 cc. of a solution containing 25 cc. of 6 *N* hydrochloric acid and 15 cc. of 6 *N* sulfuric acid at 40 to 50°. The β form of europous sulfate resulted. It was filtered, washed with water and methanol, dried at 150° for one hour and titrated. Calcd. for $EuSO_4$: Eu, 61.27. Found: Eu, 61.02, 61.06, corresponding to a purity of 99.54 and 99.62%.

The new volumetric method is also useful in the analysis of other europous compounds.

Summary

A number of europic salts have been made and analyzed. An improved method of titration of europous salts is described.

The Pressure–Volume–Temperature Relations for Gaseous Monomethylamine[1]

BY CHARLES T. KENNER WITH W. A. FELSING

Introduction

The possible and probable use of monomethylamine as the refrigerating fluid in the absorption type of refrigerating units has led to the determination of its thermodynamic properties in this Laboratory.[2] Since the chemical literature records no systematic investigation of the pressure–volume–temperature relations, such determinations constituted the experimental object of this study.

Leduc[3] has proposed an equation of state for monomethylamine, based *not* upon p–v–T relations, but derived by aid of the theory of corresponding states. Mehl[4] has proposed an equation of state of the Callendar–Mollier type based upon a knowledge of some specific gas volumes and of the heat-capacity ratio.

In this investigation an equation of state will be fitted to the observed p–v–T data.

The Proposed Method.—The method adopted for this investigation is the one that has been in common usage at the Research Laboratory of Physical Chemistry at the Massachusetts Institute of Technology, and which has been described in numerous papers.[5] The method, in essentials, consists of determining the pressures developed by a given mass of substance at different temperatures, the volume being held constant. Thus is obtained a series of pressure–temperature relations at different specific volumes.

From the experimental data thus obtained, an equation of state of the Keyes type[6] was derived; this relation reproduces the experimental values with satisfactory accuracy.

(6) Keyes, *Proc. Natl. Acad. Sci.*, **3**, 323 (1917).

The Apparatus

The apparatus was a development of the dead-weight piston type pressure gage devised by Amagat and which has been thoroughly described by Keyes and Brownlee,[5a] Keyes and Felsing,[5b] and in its present form by Beattie and Edel[5c] and by Keyes.[5d] No essential differences in design of the pressure measuring device existed. The accuracy attainable in pressure measurements alone is at least 1 part in 3000 at pressures below 10 atmospheres, 1 part in 10,000 or better for pressures 10 to 20 atmospheres, and 1 part in 20,000 for pressures above 20 atmospheres.

Temperatures were measured by a platinum resistance thermometer, calibrated by the National Bureau of Standards, in conjunction with a calibrated Mueller bridge and a high sensitivity galvanometer. The thermometer was calibrated again during the investigation at the ice-point, at the boiling point of water, and at the boiling point of mercury. The true boiling point temperatures of water and of mercury were evaluated from the observed data by means of the relations proposed by Beattie and Blaisdell[7] and by Beattie, Blaisdell and Kaminsky.[8] Temperatures could be measured readily with an accuracy of at least 0.001°.

The thermostat consisted of a large Pyrex dewar flask of about 10 inches (25 cm.) internal diameter and 24 inches (61 cm.) deep. The bath liquids were liquid paraffin, Crisco, or high melting paraffin, depending upon the temperature range. The temperature of the bath could be held constant to ±0.002° for fifteen- to twenty-minute intervals.

All necessary parts of the assembly were calibrated carefully with mercury before use. The piston was calibrated by the method of Bridgeman,[9] employing liquid carbon dioxide at 0°, where its vapor pressure is 26,144.7 mm. The average millimeter equivalent of 1 g. on the piston was 2.00107.

Preparation of Material

The best C. P. Eastman Kodak Co. monomethylamine hydrochloride was dried for several hours at 110°, followed by extended drying over sulfuric acid in a desiccator. This dried hydrochloride was extracted with highly purified, dry chloroform to remove any di- and trimethylamine hydrochlorides. The extracted salt was again dried at 110° and was kept over sulfuric acid.

After evacuation of the generating and drying system,[10] the methylamine gas was generated by treatment of the purified hydrochloride (mixed with a small amount of yellow mercuric oxide to remove any ammonia) with a 40–50% potassium hydroxide solution. The liberated gas passed through several long drying tubes filled with potas-

sium hydroxide pellets into a reservoir partially filled with sodium wire and cooled by a dry-ice–acetone mixture. The liquefied amine was allowed to remain in contact with the sodium for at least eight hours until a blue color developed in the solution; this blue color was caused, most probably, by the formation of solvated sodium ions and indicated that the amine was dry. During this period the system was "flushed out" several times by opening the connection to the vacuum system for short intervals, to remove the hydrogen formed. From this reservoir the amine was condensed into an evacuated glass reservoir surrounded by dry-ice; again this system was flushed repeatedly to remove any permanent gas. The amine finally was condensed into a metal reservoir for storage.

From this storage reservoir the amine was distilled in a vacuum into a calibrated three-bulb volumeter of the form described by Keyes and Felsing.[5b] The loading of the piezometer also followed their procedure, except that liquid air was used as the bath surrounding the piezometer during the loading process. This procedure ensured a negligible error in determining the amount of amine left in the volumeter and in the lines of the loading apparatus because of the extremely low vapor pressure of the amine at liquid air temperatures.[2a]

The Experimental Data

The experimental data, calculated to atmospheres, are presented in the table, together with the values of the pressure calculated by the equation of state fitted to the observed data, as shown in the section following.

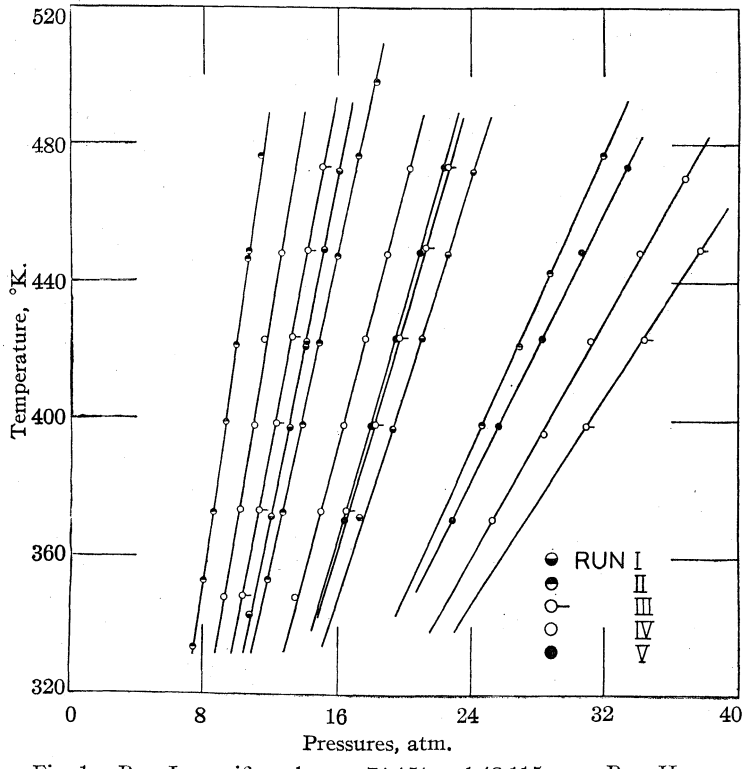

Fig. 1.—Run I, specific volumes, 74.151 and 48.115 cc.; Run II, spec. vol., 107.058, 69.726, and 35.796 cc.; Run III, spec. vol., 79.756, 51.753, and 26.583 cc.; Run IV, spec. vol., 90.253, 58.514, and 30.002 cc.; and Run V, 52.588 and 34.088 cc.

Treatment of Results

The observed pressures were plotted on a large scale as functions of the temperature at the various specific volumes (see figure). The lines were linear over the entire range, though, in several runs, the first and last points seem to indicate a slight curvature. For the purpose of evaluating an equation of state, it was considered sufficiently accurate to consider these isometrics to be linear. Values of $(\partial p/\partial T)_v$ were determined from these linear relations; these values are shown in the table.

It was decided to apply the Keyes equation[6] to the data of this investigation; this equation has the form

$$p = RT/(v - \delta) - A/(v - l)^2$$

where $\delta = f(T)$ and A and l are constants characteristic of the substance. On differentiation, this equation leads to the expression

$$(\partial p/\partial T)_v = R/(v - \delta) \text{ or } \delta = v - R/(\partial p/\partial T)_v$$

The values of $(\partial p/\partial T)_v$, as determined for each isometric, were used to calculate values of δ. A plot of $\log_{10} \delta$ as a function of $1/v$ yielded a linear relation between δ and the volume, v

$$\log_{10} \delta = 1.0548 - 6.120/v$$

which relation reproduces the observed δ values fairly well, except at large specific volumes.

The cohesive pressure term, ϕ, in the Keyes equation is

$$\phi = A/(v - l)^2 = \left(\frac{RT}{v - \delta}\right) - p$$

The values of ϕ are calculated readily from values of δ and of p at any given T. The values of ϕ were calculated for each individual measurement; the average of these closely agreeing values was taken as the correct ϕ for the particular specific volume. Since

$$\phi = A/(v - l)^2 \text{ and } v = (A^{1/2}/\phi^{1/2}) + l$$

a graphical representation of $1/\phi^{1/2}$ as a function of v yielded the linear relation $\phi = 17{,}940/(v + 1.759)^2$.

The Keyes type of equation, hence, for gaseous monomethylamine becomes

$$[p + 17{,}940/(v + 1.759)^2][v - \delta] = RT$$

where $\log_{10}\delta = 1.0548 - 6.120/v$. The units here are atmospheres, cc. per gram, and

$$T = 273.16 + t$$
$$R = 2.6421 \text{ cc.-atm.}$$

A comparison of the pressures calculated by this equation with the observed pressures is given in the table.

Summary

1. The pressure–volume–temperature relations for gaseous monomethylamine have been measured over a temperature range of 60 to 225°, a specific volume range of approximately 27 to 107 cc. per gram, and a pressure range of approximately 7.5 to 38 atmospheres.

2. An equation of the Keyes type has been fitted to these data; this equation is

$$p = \frac{RT}{(v-\delta)} - \frac{17{,}940}{(v+1.759)^2}$$

where $\log_{10}\delta = 1.0548 - 6.120/v$. This equation reproduces the observed pressures satisfactorily.

Some Properties of the Dioxane–Ethanol System

BY ROBERT N. HOPKINS, EARLE S. YERGER AND CECIL C. LYNCH

In recent years considerable attention has been given to the solvent dioxane, and the dioxane–water system.[1,2] It was believed that a study of the dioxane–ethanol system also should prove interesting. Accordingly some of the properties—densities, refractive indices, viscosities, and boiling points—of the dioxane–ethanol system have been determined.

Preparation of Materials. Dioxane.—Technical 1,4-dioxane from the Eastman Kodak Co. was purified by the method described by Eigenberger.[3] The product was kept over metallic sodium, from which it was distilled when needed.

Ethanol.—Commercial absolute ethanol was refluxed for twenty-four hours over lime and barium oxide, and distilled from the mixture. The product was treated with metallic sodium to remove remaining water and the redistilled product was used. This alcohol had a density at 25° of 0.7852.

Density Measurements.—All solutions were prepared by direct weighing in glass-stoppered flasks, and measurements were made on the freshly prepared mixtures. Two pycnometers of approximately 50 cc. each were employed. The pycnometers with solutions were allowed to reach equilibrium (requiring twenty to thirty minutes) at 25.00 ± 0.05° in a water thermostat. Each value is the result of four independent measurements; the precision ±0.02%. Data are given in Table I.

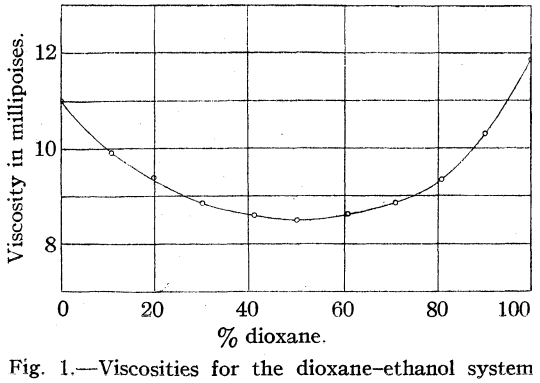

Fig. 1.—Viscosities for the dioxane–ethanol system at 25°.

Refractive Indices.—Solutions used were those prepared for the density measurements. An Abbe refractometer accurate to ±0.0002 unit of refractive index was employed using sodium light as a source of illumination. Each value is the mean of four measurements. Data are included in Table I.

Viscosity Measurements.—The solutions used were those prepared under density measurements. The Ostwald modification of the Poiseuille viscosimeter was used, care being taken to introduce the same volume (7 cc.) of liquid for each measurement. Timing was accurate to ±0.2 second. Each value given is the mean of at least five measurements. Data are given in Table I and in Fig. 1.

TABLE I

DENSITIES, REFRACTIVE INDICES, AND VISCOSITIES FOR THE DIOXANE–ETHANOL SYSTEM AT 25.00 ± 0.05°

% dioxane	Mole fraction dioxane	Refractive index, n_D	Density, d^{25}_4	Viscosity, millipoises

tion were introduced into the apparatus and runs were made until equilibrium had been established between liquid and vapor phases. This required three to four hours for each run. Temperatures were measured with a thermometer (0–110°) with 0.1° divisions, which was checked frequently for accuracy, the precision ±0.03°. Pressure correction to one atmosphere and stem corrections were made for all readings. The equilibrium residue and distillate were analyzed through refractive index. Data are given in Table II, and Fig. 2 shows the boiling point–composition diagram for the system.

TABLE II

BOILING POINT–COMPOSITION DATA FOR THE DIOXANE–ETHANOL SYSTEM AT ONE ATMOSPHERE

B. p., °C.	% dioxane Liquid	Vapor

94.89	96.3	85.0
97.99	98.7	92.5
99.05	98.8	94.8
101.07	Dioxane	

A minimum boiling point of 78.13° was observed for the composition 9.3% dioxane.

Summary

1. Density, refractive index and viscosity data for the dioxane–ethanol system have been presented. The viscosity curve apparently passes through a minimum in the vicinity of 50% dioxane.

2. Boiling points and the boiling point–composition diagram for the dioxane–ethanol system have been determined. A minimum boiling temperature of 78.13° was observed at 9.3% dioxane.

The Synthesis of 1,4-Dimethyl-6,7-dihydroxyphenanthrene from *para*-Xylylacetic Acid and 6-Nitroveratraldehyde by the Pschorr Reaction

BY JACK TARKINGTON CASSADAY[1] AND MARSTON TAYLOR BOGERT

Eddy[2] has reported that phenanthrene derivatives carrying a hydroxyl group on carbon no. 3 (no. 6 in our formula) are likely to possess analgesic properties in higher degree than when this group is in other positions on the phenanthrene nucleus.

Small, Eddy, Mosettig and Himmelsbach[3] state that: "No generalizations can be made as to the influence on pharmacological action of the entrance of another substituent in a given monosubstituted phenanthrene. The changes in pharmacological action are very likely dependent to some extent upon changes in chemical or physical properties, among others, differences in acidity or basicity, and in solubility. There was a decided increase in effectiveness from 3-hydroxyphenanthrene to 3,4-dihydroxyphenanthrene, but at the same time also, from 3-hydroxyphenanthrene to 3-hydroxy-4-aminophenanthrene."

So far as our examination of the literature has gone, the hydroxyphenanthrenes reported to date are all insoluble in water, and but few of them are appreciably soluble in cold olive oil.

We have therefore synthesized the 1,4-dimethyl-6,7-dihydroxyphenanthrene (V), in order that its physical, chemical, and pharmacological properties can be studied. It is a white crystalline solid, m. p. 164–164.5° (corr.), appreciably soluble in water, and dissolving in cold olive oil.

In a previous communication[4] from these Laboratories, we reported some unsuccessful attempts to obtain this compound by the hydrolysis of the 1,4-dimethyl-6,7-methylenedioxyphenan-

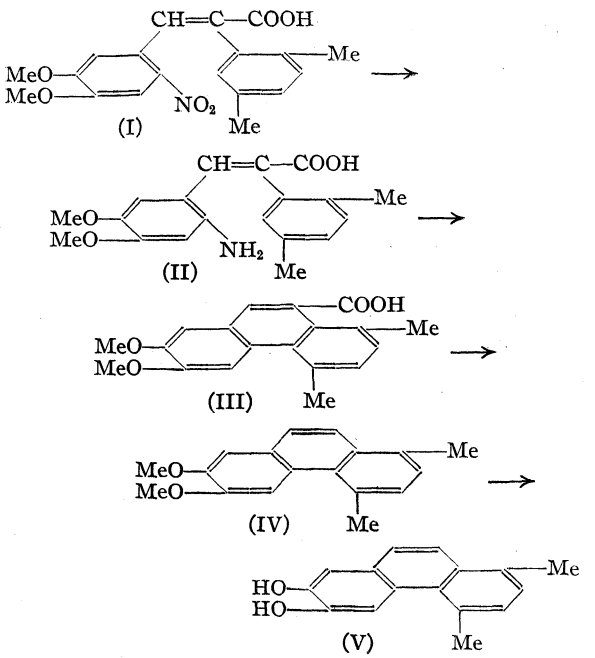
threne. Whereas the methylenedioxy group resisted our efforts at hydrolysis, the corresponding dimethoxy compound has been found to be more tractable, and yielded the desired dihydroxy derivative when digested with a mixture of glacial acetic and hydrobromic (48%) acids.

The synthesis followed the classical Pschorr lines, with a few modifications α-(*p*-xylyl)-6-nitrodimethylcaffeic acid (I), from *p*-xylylacetic acid and 6-nitroveratraldehyde, was reduced to the corresponding amine (II) by ferrous sulfate and ammonium hydroxide. Cyclization was accomplished, in dioxane solution containing some sulfuric acid, by the action of isoamyl nitrite, with the subsequent addition of copper powder and sodium hypophosphite. By refluxing the acid (III) with quinaldine and basic copper carbonate, it was decarboxylated, and the dimethoxy compound (IV) then hydrolyzed to the dihydroxy derivative (V). It was found possible also to accomplish a simultaneous decarboxylation and hydrolysis of the dimethoxy acid (III) to the dihydroxy hydrocarbon (V), but the yield of the latter was not very good.

Acknowledgments.—We are happy to have this opportunity of expressing our thanks to the Ella Sachs Plotz Foundation and to the National Academy of Sciences for financial assistance in the purchase of the necessary chemicals and apparatus to carry out this investigation, as well as to Mr. Saul Gottlieb for the analytical work.



Experimental

6-Nitroveratraldehyde was prepared as described by Marr and Bogert,[5] with certain modifications which increased the yield and reduced the time required.

To 300 cc. of concentrated nitric acid (sp. gr., 1.42), there was added in small portions 30 g. of finely pulverized veratraldehyde in thirty minutes, with vigorous mechanical stirring, maintaining the temperature of the mixture at 15–20°. After stirring for an additional half hour at 25–30°, the mixture was poured into about 9 liters of ice water, the precipitate collected, washed with an additional 9 liters of ice water, pressed dry on the filter, and immediately crystallized from ethyl alcohol without further drying; yield 87%, m. p. 132–133° (corr.) (lit.,[4] 133.5–134.5°, corr.). The nitrations and crystallizations can be conducted in artificial light without any appreciable reduction in yield.

α-(*p*-Xylyl)-6-nitrodimethylcaffeic Acid (I).—A solution of *p*-xylylacetic acid (156 g.), prepared according to the procedure of Akin, Stamatoff and Bogert,[6] and 6-nitroveratraldehyde (166.5 g.), in freshly distilled acetic anhydride (1110 cc.), was heated to 105–110° and stirred for eight hours under a reflux condenser carrying a calcium chloride guard tube. Excess of acetic anhydride was hydrolyzed by the addition of hot water, keeping the temperature of the mixture below 120°. It was then poured into a mixture (7 liters) of water, crushed ice, and a little hydrochloric acid. The tarry material which separated became crystalline on standing. It was removed, boiled with water (3–4 liters), to eliminate unchanged initial materials, and crystallized from dilute acetic acid. It separated as a pale tan solid, m. p. 221–224° (corr.), sufficiently pure for use in the next step; yield 61%. After three more crystallizations from the same solvent, it appeared as pale greenish crystals, m. p. 226–227° (corr.); yield 50–55%.

Anal. Calcd. for $C_{19}H_{19}O_6N$: C, 63.9; H, 5.3; N, 3.9. Found: C, 63.8; H, 5.7; N, 4.2.

α-(*p*-Xylyl)-6-aminodimethylcaffeic Acid (II).—A solution of 80 g. of the nitro acid (I) in dilute ammonium hydroxide solution was added, in the course of three to four minutes, to a boiling solution of 440 g. of ferrous sulfate heptahydrate and 100 cc. of ammonium hydroxide solution in 1275 cc. of water. During this addition and for the next half hour, 780 cc. of concentrated ammonium hydroxide solution was slowly run into the boiling mixture, followed by 200 cc. more of the ammonium hydroxide solution for the succeeding forty-five minutes. To prevent foaming, five drops of octyl alcohol was added. When the mixture had cooled, the upper portion was siphoned off through a filter, and the black residues extracted thrice with dilute ammonium hydroxide solution, filtered through Norite, and the combined filtrates poured into a slight excess of dilute acetic acid containing ice. The precipitated amino acid was collected, redissolved in ammonium hydroxide solution and reprecipitated, the mixture heated to boiling, cooled, and the amino acid filtered out; yield 76%, m. p. 185–186° (corr.). Recrystallized twice from benzene, it formed pale yellow crystals, m. p. 191–192° (corr.); yield, 65% or better.

(5) Marr and Bogert, THIS JOURNAL, **57**, 1329 (1935).

(6) Akin, Stamatoff and Bogert, THIS JOURNAL, **59**, 1268 (1937).

Anal. Calcd. for $C_{19}H_{21}O_4N$: C, 69.7; H, 6.4. Found: C, 69.6; H, 6.5.

1,4-Dimethyl-6,7-dimethoxyphenanthrene-10-carboxylic Acid (III).—In our experience with the Pschorr reaction, we have found that, in the cyclization of the *o*-aminocinnamic acids, hydroxy acids are formed often instead of the phenanthrene sought. By carrying out the diazotization in dioxane as the solvent, and using sodium hypophosphite as recommended by Ruggli and Staub,[7] in the second step of the reaction, it has been possible to effect the cyclization without this complication. In this particular series (II), a large excess of dioxane was found requisite to prevent the separation of solid oxonium compounds formed from the sulfuric acid and the dioxane. In other series, this trouble has not been encountered.

To a solution of 44 g. of the amino acid in 850 cc. of dioxane, there was added 10 cc. of concentrated sulfuric acid, followed by 25.2 cc. of isoamyl nitrite when the solution had cooled to room temperature. The nitrite used was washed with dilute sodium bicarbonate solution, followed by a saturated sodium chloride solution, and dried over sodium sulfate. The diazo solution solidified, after about thirty minutes of stirring at 25–30°. To a solution of 139 g. of sodium hypophosphite in 139 cc. of water, there was added some freshly prepared Gattermann copper powder. The mixture was heated to incipient ebullition, cooled to 50°, and the mush of diazo compound added during thirty minutes, while the temperature was kept at 40–50°. After all of the diazo compound had been added, the mixture was heated to 80° for a short time and then poured into six liters of water containing sufficient ammonium hydroxide to assure solution of the acid. The filtered solution was run into 15 liters of very dilute hydrochloric acid containing ice, the precipitated acid removed, and dried, first in the air and then at 105°; yield of crude acid, sufficiently pure for the next step, 83%. By recrystallization from methanol, or from dilute acetic acid, and decolorization with Norite, the acid was obtained in colorless crystals, m. p. 215.5–216.5° (corr.).

Anal. Calcd. for $C_{19}H_{18}O_4$: C, 73.5; H, 5.8. Found: C, 73.2; H, 6.1.

1,4-Dimethyl-6,7-dimethoxyphenanthrene (IV).—A mixture of 1 g. of the crude acid (III), 3 cc. of freshly distilled quinaldine, and 0.2 g. of basic copper carbonate, was refluxed for forty-five minutes, then cooled, extracted with ether, the ether solution washed first with dilute hydrochloric acid, to remove quinaldine, and then with dilute potassium hydroxide solution, to free it from unchanged acid. Glacial acetic acid was added, the ether distilled off, and the residual solution diluted with water. The gummy precipitate which separated, when crystallized from alcohol, yielded 45% of the pure dimethoxy hydrocarbon (IV). Recrystallized from alcohol, in the presence of Norite, it formed glistening white platelets, m. p. 175–176° (corr.).

(7) Ruggli and Staub, *Helv. Chim. Acta*, **20**, 37 (1937).

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.2; H, 6.8. Found: C, 80.9; H, 7.0.

1,4-Dimethyl-6,7-dihydroxyphenanthrene (V).—A mixture of 1.6 g. of the dimethoxy derivative (IV), 49 cc. of glacial acetic acid, and 49 cc. of hydrobromic acid (48%), was refluxed for two hours in an all-glass apparatus, and the cold green solution poured into 300–350 cc. of water. After the mixture had stood for fifteen to twenty minutes, the precipitate was collected and crystallized thrice from water, filtering the hot solutions through cotton and filter paper at first, to remove tarry contaminants. It also could be recrystallized from hot alcohol solution by the gradual addition of water. The pure compound formed white crystals, m. p. 164–164.5° (corr.); yield 35%. With ferric chloride solution, it gave an intense green, like catechol, which was changed to a pink or reddish color by the addition of sodium hydroxide or ammonium hydroxide solutions.

Anal. Calcd. for $C_{16}H_{14}O_2$: C, 80.7; H, 5.9. Found: C, 80.8; H, 6.0.

The same compound (mixed m. p., etc.) was secured in one operation from the dimethoxy acid (III), when 0.93 g. of it was refluxed for two hours in a mixture of 31 cc. of glacial acetic acid and 31 cc. of hydrobromic acid (48%), and the crude product purified as above, but the yield was only 10–15% in the different runs.

In 100 cc. of water, the solubility of the pure compound at various temperatures (±2°) was as follows: 100°, 0.038 g.; 37°, 0.007 g.; 0°, 0.003 g. The *p*H of the saturated aqueous solution was 6.4 (±0.2). In alcohol, glycol, or acetone, it was easily soluble, and dissolved also in cold olive oil.

Diacetyl Derivative.—From the dihydroxy derivative (V), acetic anhydride and fused sodium acetate, after repeated crystallization from dilute acetic acid, formed white crystals, m. p. 133–133.5° (corr.).

Anal. Calcd. for $C_{20}H_{18}O_4$: C, 74.5; H, 5.6. Found: C, 74.8; H, 5.9.

Summary

1. 1,4-Dimethyl-6,7-dihydroxyphenanthrene has been synthesized by the Pschorr reaction and found to be slightly soluble in water, and to dissolve also in cold olive oil.

2. In the application of the Pschorr reaction, dioxane has been found preferable to alcohol as a solvent for the diazotization.

3. 1,4-Dimethyl-6,7-dimethoxyphenanthrene-10-carboxylic acid can be hydrolyzed and decarboxylated simultaneously by refluxing with a mixture of glacial acetic and hydrobromic (48%) acids, but the yields are not very good.

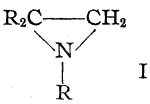
Attempts to Prepare Optically Active Ethyleneimine Derivatives Containing an Asymmetric Nitrogen Atom

BY ROGER ADAMS AND T. L. CAIRNS[1]

The fact that many oximes exist in stable *syn-* and *anti*-forms and that the oxime of cyclohexanone-4-carboxylic acid[2] can be resolved has led to the belief that, in these compounds, the nitrogen atom probably exists in a stable tetrahedral form. The work of Meisenheimer[3] has established that many substituted hydroxylamines of the type RR'NOH cannot be resolved and the investigations of many others have failed to find an optically-active compound of the type RR'R''N.

A factor which has been assumed to be responsible for the existence of a stable tetrahedral nitrogen atom thus resulting in stable *syn-* and *anti*-oximes is the strain of the carbon-to-nitrogen double bond. A molecule which reproduces this strain as closely as possible and, at the same time, is constituted so that the nitrogen atom is the only possible source of asymmetry in the molecule is represented by a substituted ethyleneimine of the type I.



I

This report deals with the preliminary work on the synthesis of such a molecule and the determination of whether or not it may exist in optically-active forms.

It was found that the *p*-bromobenzenesulfonyl derivative of 1-amino-2-methyl-2-propanol (II) can be converted into the corresponding chloro compound (III) by means of concentrated hydrochloric acid. The chloro compound, when treated with aqueous alkali, yielded a mixture of the ethyleneimine derivative (IV) and the alcohol (II).

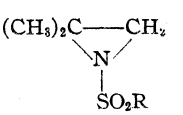
$(CH_3)_2COHCH_2NHSO_2R$

II

R = *p*-bromophenyl

$(CH_3)_2CClCH_2NHSO_2R$

III

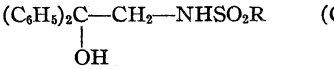


IV

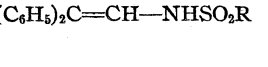
Attempts were made to prepare an optically-active amide analogous to II by the use of camphorsulfonyl chloride or α-bromocamphorsulfonyl chloride. Unfortunately, these derivatives proved to be oils which could not be purified and were consequently unsuitable for further study. The corresponding diphenyl compound, aminomethyldiphenylcarbinol, also gave no crystalline α-bromocamphorsulfonamide.

A comparison of the action of aqueous alkali, under similar conditions, upon the *p*-bromobenzenesulfonyl derivative of β-chloroethylamine and the dimethyl compound (III) was studied. The former gave merely hydrolysis with the formation of 2-*p*-bromobenzenesulfonamidoethanol, whereas the latter gave essentially equivalent amounts of the alcohol (II) and the ethyleneimine derivative (IV). This result might have been anticipated from a consideration of the work of Thorpe.[4] He showed that the *gem*-dimethyl group in place of two hydrogens alters the subtended angle between the valence bonds of carbon in such a manner that the ease of formation of a three-membered ring is increased.

Attempts to convert the *p*-bromobenzenesulfonyl derivative of aminomethyldiphenylcarbinol (V) into an ethyleneimine derivative proved fruitless. The corresponding chloride could not be made by the regular procedure using thionyl chloride or hydrochloric acid. The action of thionyl chloride resulted in the formation of 1-*p*-bromobenzenesulfon-2,2-diphenylvinylamide (VI). This same compound was produced in excellent yields by the action of phosphorus pentoxide on V.



V



VI

A reaction analogous to this has been reported by Krabbe[5] who found that similar products were formed by the action of certain acid chlorides or of phosphorus pentoxide on N-acyl derivatives of aminomethyldiphenylcarbinol.

The action of phosphorus pentoxide on 1-*p*-bromobenzene-sulfonamido-2-methyl-2-propanol (II) gave neither the ethyleneimine (IV) nor the

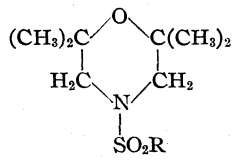
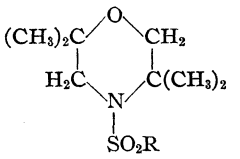
vinylamine derivative corresponding to VI. Instead, a substance was produced which, by analysis and properties appeared to be a morpholine of structure VII or VIII.



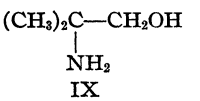
VII



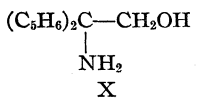
VIII

The action of sulfuric acid followed by alkali on ethanolamine has been reported to give ethyleneimine.[6] Upon treatment of 1-amino-2-methyl-2-propanol in a similar manner the reaction took a different course and β-methylallylamine was formed in good yields. Krabbe[5] found that aminomethyldiphenylcarbinol is converted by cold sulfuric acid into the corresponding vinylamine.

It is quite possible that the complications which have arisen in the formation of ethyleneimine derivatives may be avoided if the compounds IX and X are used. Under these conditions



IX



X

the possibility of dehydration to form an allylamine or a vinylamine derivative is unlikely and the synthesis of an ethyleneimine derivative should be possible.

During the preparation of this manuscript an article by Meisenheimer and Chou[7] has appeared describing attempts to prepare ethyleneimines for resolution studies. They were unsuccessful in obtaining the compounds desired, so that the possibility of resolving properly substituted ethyleneimines is still undetermined.

Experimental

2-*p*-Bromobenzenesulfonamidoethanol.—To a solution of 15 g. of ethanolamine in 150 cc. of water and 125 cc. of aqueous 10% sodium hydroxide solution, maintained at 50–70°, was added slowly 51 g. of *p*-bromobenzenesulfonyl chloride. Upon cooling the reaction mixture and acidification with hydrochloric acid an oil separated that solidified to a white crystalline solid. It was purified by recrystallization from dilute ethanol: white crystals, m. p. 93.5–95° (corr.); yield, 28 g. (59%).

Anal. Calcd. for $C_8H_{10}O_3BrNS$: C, 34.29; H, 3.57. Found: C, 34.59; H, 3.73.

2-*p*-Bromobenzenesulfonamido-1-chloroethane.—To 10 g. of 2-*p*-bromobenzenesulfonamidoethanol was added slowly 30 cc. of thionyl chloride and the mixture was then refluxed for thirty minutes. The solution was poured with rapid stirring into 300 cc. of crushed ice. The product was purified from methanol: white plates, m. p. 150–152.5° (corr.); yield, 3 g. (28%).

Anal. Calcd. for $C_8H_9O_2BrClNS$: C, 32.17; H, 3.01. Found: C, 32.12; H, 3.03.

When 3 g. of this product was shaken for fifteen minutes and then warmed on the steam cone for two hours with 200 cc. of water and 20 cc. of 10% aqueous potassium hydroxide hydrolysis took place. After filtration the filtrate, while still hot, was acidified with hydrochloric acid. White crystals of 2-*p*-bromobenzenesulfonamidoethanol separated.

1-*p*-Bromobenzenesulfonamido-2-methyl-2-propanol.—To a solution of 17.8 g. of 1-amino-2-methyl-2-propanol in 125 cc. of 10% aqueous sodium hydroxide, maintained at 50–80°, was added slowly 51 g. of *p*-bromobenzenesulfonyl chloride. The mixture was then cooled and acidified with dilute hydrochloric acid. After filtering and drying, the product was dissolved in 250–300 cc. of benzene and the solution distilled until a volume of 75–80 cc. remained. White crystals separated which were recrystallized from benzene, m. p. 96.5–98° (corr.); yield, 40 g. (96%).

Anal. Calcd. for $C_{10}H_{14}O_3BrNS$: C, 38.96; H, 4.58; N, 4.54. Found: C, 38.96; H, 4.50; N, 4.79.

When 6 g. of this product was heated under reflux for twenty minutes with 10 cc. of constant-boiling hydrobromic acid, a black oil separated. Steam distillation removed a small amount of a water-insoluble oil which was not identified. The residual solution in the distillation flask, after cooling, gave 4.5 g. (97%) of *p*-bromobenzenesulfonamide.

Action of Phosphorus Pentoxide upon 1-*p*-Bromobenzenesulfonamido-2-methyl-2-propanol, VII or VIII.—A solution of 5 g. of 1-*p*-bromobenzenesulfonyl-2-methyl-2-propanol in 100 cc. of dry benzene was refluxed for an hour with 20 g. of phosphorus pentoxide. The benzene was decanted and then steam distilled. The residual aqueous suspension was made up to a volume of 200 cc., boiled and filtered. A pale yellow solid (2.2 g.) was obtained which on crystallization from methanol gave white needles, m. p. 145–147° (corr.).

Anal. Calcd. for $C_{14}H_{20}O_3BrNS$: C, 46.4; H, 5.54; N, 3.87; S, 8.85. Found: C, 46.92; H, 5.53; N, 4.09; S, 8.95.

The filtrate from this product gave, on cooling, *p*-bromobenzenesulfonamide.

In attempting to prepare 1-*p*-bromobenzenesulfonamido-2-methyl-2-chloropropane from the alcohol by means of thionyl chloride, there was always obtained a small amount of the morpholine derivative as a by-product.

1-*p*-Bromobenzenesulfonamido-2-methyl-2-chloropropane.—A mixture of 24 g. of 1-*p*-bromobenzenesulfonamido-2-methyl-2-propanol was heated with 150 cc. of concentrated hydrochloric acid under reflux for ten minutes. Solution took place with simultaneous separation of a white solid. After dilution with one liter of water, the suspension was cooled and the product filtered and air-dried. It was purified by recrystallization from petroleum ether (b. p. 60–110°): white leaflets, m. p. 123–128° (corr.); yield, 21 g. (71%).

(7) Meisenheimer and Chou, *Ann.*, **539**, 70 (1939).

Anal. Calcd. for $C_{10}H_{13}O_2BrClNS$: C, 36.70; H, 3.98. Found: C, 36.99; H, 3.97.

1-*p*-Bromobenzenesulfon-2,2-dimethylethyleneimide.—A mixture of 80 cc. of 10% aqueous sodium hydroxide and 18 g. of 1-*p*-bromobenzenesulfonamido-2-methyl-2-chloropropane was shaken vigorously for one hour. It was then warmed on the steam-cone for fifteen minutes during which time the solid present melted and collected as a yellow oil. On cooling, it resolidified and was purified from a mixture of petroleum ether (b. p. 40–60°) and chloroform: white cubic crystals, m. p. 79.5–81.5° (corr.); yield, 7.5 g. (46%).

Anal. Calcd. for $C_{10}H_{12}O_2BrNS$: C, 41.37; H, 4.13; mol. wt., 290. Found: C, 41.50; H, 4.06; mol. wt. (b. p. $CHCl_3$), 274.

This product is insoluble in aqueous alkali, does not react with a chloroform solution of bromine or with aqueous potassium permanganate in the cold.

The filtrate from the preparation of this compound gave, upon acidification, 6 g. of 1-*p*-bromobenzenesulfonamido-2-methyl-2-propanol.

If the chloro compound was refluxed with alcoholic potash instead of aqueous, a yellow oil was obtained, insoluble in aqueous alkali, the constitution of which was not determined. In addition hydrolysis of the chloro compound to the alcohol took place.

β-Methylallylamine.[6]—A solution of 40 cc. of concentrated sulfuric acid in 100 cc. of water, cooled to below 10°, was poured into a cold solution of 70 g. of 1-amino-2-methyl-2-propanol in 100 cc. of water. The mixture was distilled at 30 mm. pressure until the temperature of the solution reached 120°; the distillation was continued at 5 mm. at a temperature of 145° for one hour. A brown viscous liquid remained. After cooling 400 cc. of aqueous 40% sodium hydroxide was added and the mixture distilled rapidly until the distillate became milky. The distillate was dried over solid sodium hydroxide and then distilled through a fractionating column. There was thus obtained 33 g. of β-methylallylamine; b. p., after fractionation, 76.7–77.7° at 746 mm.; $n^{20}D$ 1.4312.

Anal. Calcd. for C_4H_9N: N, 19.76. Found: N, 19.45.

β-Methylallylamine Hydrochloride.—This was prepared in dry ether and purified from a mixture of absolute ethanol and acetone; m. p. 190–191° (corr.).

Anal. Calcd. for $C_4H_{10}NCl$: N, 13.02. Found: N, 12.91.

β-Methylallylamine Picrate.—The picrate formed in ethanol solution and purified from dilute ethanol had a melting point of 202–206° (corr.).

Anal. Calcd. for $C_{10}H_{12}O_7N_4$: N, 18.66. Found: N, 18.48.

N-(β-Methylallyl)-*p*-bromobenzenesulfonamide.—This product was prepared from β-methylallylamine and *p*-bromobenzenesulfonyl chloride and formed white crystals from a mixture of petroleum ether (b. p. 40–60°) and chloroform; m. p. 74–76° (corr.).

Anal. Calcd. for $C_{10}H_{12}O_2BrNS$: C, 41.37; H, 4.13; N, 4.82. Found: C, 41.46; H, 4.13; N, 4.96.

N-Phenyl-N'-(β-methylallyl) Thiourea.—This product was prepared from phenyl isothiocyanate and β-methylallylamine and purified from dilute ethanol; white crystals, m. p. 78–79° (corr.).

Anal. Calcd. for $C_{11}H_{14}N_2S$: N, 13.59. Found: N, 13.34.

N-(β-Methylallyl)-phthalimide.—A mixture of 28 g. of potassium phthalimide and 18 g. of β-methylallyl chloride was heated in a sealed tube at 150° for three hours. The reaction product was transferred to a flask by treatment with benzene, and the benzene and excess β-methylallyl chloride were removed by steam distillation. The brown solid which remained behind was purified by crystallization from methanol with norite; white crystals, m. p. 88.5–90° (corr.).

Anal. Calcd. for $C_{12}H_{11}O_2N$: N, 6.96. Found: N, 6.90.

This product was hydrolyzed to β-methylallylamine as follows. A solution of 4 g. of N-(β-methylallyl)-phthalimide in 15 cc. of ethanol was allowed to stand for twenty-four hours with 2.5 g. of 40% aqueous solution of hydrazine hydrate. The solution was then acidified with hydrochloric acid and concentrated to a small volume. The precipitate of phthalyl hydrazide was filtered and the filtrate made basic with aqueous sodium hydroxide. Upon distillation β-methylallylamine was obtained. The product from the action of sulfuric acid upon 1-amino-2-methyl-2-propanol proved to be identical with it.

1-*p*-Bromobenzenesulfonamido-2,2-diphenyl-2-ethanol.—A solution of 9 g. of *p*-bromobenzenesulfonyl chloride in 75 cc. of boiling benzene was added slowly to a hot solution of 8 g. of aminomethyldiphenylcarbinol[8] in 75 cc. of benzene and 5 cc. of pyridine. The mixture was allowed to stand at room temperature for twelve hours, then 2.2 g. of potassium hydroxide in about 50 cc. of water was added. The benzene and most of the pyridine was removed by steam distillation and the pale yellow residue purified from dilute methanol: white crystals, m. p. 151–153° (corr.); yield, 16 g. (quantitative).

Anal. Calcd. for $C_{20}H_{18}O_3BrNS$: C, 55.55; H, 4.17. Found: C, 55.65; H, 4.16.

1-*p*-Bromobenzenesulfon-2,2-diphenylvinylamide.—A mixture of 50 cc. of thionyl chloride and 5 g. of 1-*p*-bromobenzenesulfonamido-2,2-diphenyl-2-ethanol was refluxed for thirty minutes. The solution was then poured into 400 cc. of ice. The 4.5 g. of brown gummy material was dissolved in acetone and precipitated with water after which it was extracted with petroleum ether (b. p. 60–110°). The petroleum ether insoluble residue was crystallized from dilute acetone; white plates, m. p. 197–198°.

Anal. Calcd. for $C_{20}H_{16}O_2BrNS$: C, 57.97; H, 3.87; S, 7.73; Br, 19.34. Found: C, 58.08; H, 3.93; S, 7.59; Br, 19.04.

The product also could be obtained by refluxing for thirty minutes 2 g. of 1-*p*-bromobenzenesulfonamido-2,2-diphenyl-2-ethanol in 200 cc. of benzene with 10 g. of phosphorus pentoxide.

The product was soluble in hot aqueous alkali.

By heating for one hour a mixture of 1 g. of this compound with 5 g. of chromic anhydride in 30 cc. of glacial acetic acid and then pouring into ice water, benzophenone

(8) Paal and Weidenkaff, *Ber.*, **38**, 1686 (1905).

was obtained. 1-*p*-Bromobenzenesulfon-2,2-diphenylvinylamide dissolved in chloroform reacted rapidly with a chloroform solution of bromine with the evolution of hydrogen bromide.

Summary

1. An investigation has been undertaken to determine whether ethyleneimine derivatives of the type $R_2C\text{—}CH_2\text{—}NR$ can be resolved.

2. Preliminary experiments have indicated that the *p*-bromobenzenesulfonyl derivatives of 1-amino-2-methyl-2-propanol can be converted to the chloride and then to the corresponding ethyleneimine. The replacement of the *p*-bromobenzenesulfonyl group with an optically active sulfonyl group has not yet been successful, since the compounds produced were oils and could not be purified. Corresponding treatment of the *p*-bromobenzenesulfonyl derivative of ethanolamine did not result in the formation of an ethyleneimine.

3. The *p*-bromobenzenesulfonyl derivative of aminomethyldiphenylcarbinol upon treatment with phosphorus pentoxide or thionyl chloride gave 1-*p*-bromobenzenesulfon-2,2-diphenylvinylamide. Similar treatment of 1-*p*-bromobenzenesulfonamido-2-methyl-2-propanol gave what appeared to be a morpholine derivative.

4. Action of sulfuric acid on 1-amino-2-methyl-2-propanol gave β-methylallylamine.

The Isolation of α-Spinasterol from Alfalfa

BY ERHARD FERNHOLZ AND MILDRED L. MOORE

In the course of experiments directed toward the isolation of vitamin K from alfalfa, small amounts of a crystalline sterol were obtained regularly. After a number of recrystallizations it melted at 168°. It was characterized as a sterol by the formation of a digitonide, and by positive Liebermann, Salkowski, and Tortelli-Jaffé reactions. The properties of this sterol suggested to us the possibility that it might be identical with α-spinasterol[1] which was first isolated from spinach,[1] and also has been found in senega root.[2] There is little doubt that the sterol isolated by Dam[3] from alfalfa under similar circumstances and called by him medicagosterol II is in fact α-spinasterol.

The constants observed by us, by Dam, and the latest values for α-spinasterol as recorded by Larsen and Heyl[4] are given in Table I.

TABLE I

	Fernholz and Moore alfalfa sterol		Dam, *et al.* medicagosterol II		Larsen and Heyl α-spinasterol	
	M. p., °C.	$[\alpha]_D$	M. p., °C.	$[\alpha]_D$	M. p., °C.	$[\alpha]_{5461}$
Sterol	168	±0	164	−2.4	172.5	−3.7
Acetate	183	−5	173	...	187	−5.8
m-Dinitrobenzoate	195	±0	195	...	...	...

The data agree well enough if one takes into consideration the difficulties of obtaining the sterol in pure form. The melting point reported for α-spinasterol has gone up steadily in successive publications.

Further evidence for the identity of our sterol with α-spinasterol was obtained by studying its catalytic hydrogenation. Our sterol also took up only one mole of hydrogen using Adams catalyst. The compound obtained was still unsaturated and the melting point and rotation of the dihydrosterol and its acetate agreed well with those reported for α-spinasterol and its acetate. Titrations with perbenzoic acid were carried out, and it was found that 3 atoms of oxygen were consumed by the sterol itself and 2 atoms by the hydrogenated sterol. In the literature, on the other hand, it has been reported[4] that 2 or 1 atom, respectively, is used up. We are unable to explain this difference, but have obtained the same result with authentic α-spinasterol,[5] while stigmasterol under the same conditions consumed a little less oxygen than is calculated for two double bonds. It is not rare, however, that sterols use more perbenzoic acid than the number of double bonds would indicate. A pertinent example is dihydro-

(4) Larsen and Heyl, THIS JOURNAL, **56**, 2663 (1934).
(5) We are greatly indebted to Dr. C. Donald Larsen, University of Rochester, for samples of α-spinasterol and its acetate. Mixed melting points with the corresponding derivatives of our sterol did not show a depression.

ergosterol[6] which contains two double bonds and which consumes 2.7 atoms of oxygen. Like α-spinasterol it also contains a double bond resistant to hydrogenation. We do not believe that our results should be interpreted to indicate the presence of three double bonds in α-spinasterol.

We have obtained 0.8 g. of α-spinasterol, m. p. 165°, from 3.8 kg. of alfalfa. Alfalfa meal is probably the most accessible source for this sterol.

Experimental

Isolation of α-Spinasterol.—By percolation with hexane 140 g. of an extract was obtained from 2.8 kg. of dehydrated alfalfa meal. This material was saponified by boiling for two hours with 50 g. of potassium hydroxide in 1 liter of alcohol. The unsaponifiable matter (28 g.) was isolated by ether extraction. It consisted of a dark brown waxy material. It was dissolved in 200 cc. of hot acetone, and the material coming out on cooling was removed by filtration and discarded. The filtrate was evaporated to dryness (20 g.), the residue dissolved in 200 cc. of hexane and washed five times in succession with 200 cc. of 95% methanol saturated with hexane. The combined methanol extracts left on evaporation a residue weighing 11 g. This residue was dissolved in 50 cc. of alcohol. After two days at room temperature the crystallized sterol was filtered and recrystallized from a mixture of alcohol and benzene; yield 0.8 g., m. p. 165°. It was recrystallized nine times more but the melting point could not be raised above 168°; melting point of a mixture with α-spinasterol (169–171°) 168–169°; $[\alpha]^{25}D \pm 0°$ (21.3 mg. in 2 cc. chloroform, $l = 1$ dm.). *Anal.* Calcd. for $C_{29}H_{48}O \cdot {}^1/_2H_2O$: C, 82.58; H, 11.70. Found: C, 82.70; H, 11.83.

α-Spinasteryl *m*-Dinitrobenzoate.—A sample of 0.1 g. of the above described α-spinasterol was heated on the steam-bath for one hour with 0.3 g. of dinitrobenzoyl chloride and 5 cc. of pyridine. The dinitrobenzoate was then isolated by means of ether and purified by crystallization from benzene by addition of alcohol as small white needles, m. p. 195°, $[\alpha]D \pm 0°$ (27.2 mg. in 2 cc. of chloroform, $l = 1$ dm.). *Anal.* Calcd. for $C_{36}H_{50}O_6N_2$: C, 71.24; H, 8.31. Found: C, 71.11; H, 8.39.

α-Spinasteryl acetate was prepared from the sterol isolated from alfalfa by refluxing with ten times the amount of acetic anhydride for one hour. The acetate crystallized out after cooling and was recrystallized from benzene by addition of alcohol, in which solvent it is but sparingly soluble; m. p. 183°, mixed with authentic material (184.5°) also 183°; $[\alpha]^{23}D - 5.3°$ (33.8 mg. in 2 cc. chloroform, $l = 1$ dm., $\alpha D - 0.09°$). *Anal.* Calcd. for $C_{31}H_{50}O_2$: C, 81.87; H, 11.09. Found: C, 81.74; H, 11.02.

α-Spinastenyl Acetate.—The acetate described above (0.5163 g.) was hydrogenated in acetic acid solution (50 cc.) at room temperature and ordinary pressure with a platinum oxide (0.1643 g.) the hydrogen consumption of which was known from a blank determination. The calculated amount of hydrogen (49.6 cc.) was absorbed within eighty minutes. The hydrogenation product was recrystallized from a benzene–alcohol mixture as large leaflets, m. p. 117°, $[\alpha]^{24}D + 15.3°$ (20.9 mg. in 2 cc. chloroform, $\alpha D + 0.16°$]. *Anal.* Calcd. for $C_{31}H_{52}O_2$: C, 81.58; H, 11.48. Found: C, 81.80; H, 11.74. The literature[4] reports m. p. 119°, $[\alpha]_{5461} + 12°$.

α-Spinastenol was obtained from the acetate by saponification with 5% alcoholic potassium hydroxide. It was purified by crystallization from methanol and obtained in the form of big leaflets. An air-dried sample melted on slow heating at 110°, a value also reported in the literature; immersion into a bath at 100° caused melting at that temperature. The compound thoroughly dried in a high vacuum at 80° melts at 112–114°. At times the compound crystallized in the form of small crystals of this melting point without having been dried at 80°; $[\alpha]^{24}D$ +26° (26.5 mg. in 2 cc. of chloroform, $l = 1$ dm., $\alpha D +$ 0.34). *Anal.* Calcd. for $C_{29}H_{50}O$: C, 83.98; H, 12.16. Found: C, 83.68; H, 12.35.

Titration with Perbenzoic Acid.—The chloroform solution of perbenzoic acid used in these determinations was several months old and contained approximately 3 mg. of active O per cc. The substance was dissolved in 2 cc. of chloroform and 2 cc. of the perbenzoic acid solution added. Blanks were made with the same amount of chloroform and perbenzoic acid. After standing at 0° for three days the samples were titrated and the consumption of oxygen determined by difference. α-Spinasterol from alfalfa: 41.3 mg. consumed 4.57 mg. O = 2.95 atoms; α-spinasterol from spinach: 31.5 mg. consumed 3.6 mg. O = 3.05 atoms; α-spinastenyl acetate: 25.8 mg. consumed 1.97 mg. O = 2.18 atoms; stigmasteryl acetate: 21.2 mg. consumed 1.38 mg. O = 1.81 atoms.

Summary

The isolation of a sterol from alfalfa has been described together with evidence showing its identity with α-spinasterol.

It has been pointed out that Dam's medicagosterol II also obtained from alfalfa is in all probability α-spinasterol.

The Effect of Temperature on the Nitration of *p*-Cymene The Synthesis of 6-Nitrocarvacrylamine and Certain Derivatives

BY GRANVIL C. KYKER[1] AND R. W. BOST

Recently a considerable quantity of 6-nitrocarvacrylamine was needed for certain studies which were in progress in this Laboratory. Much difficulty was experienced in obtaining good yields of pure 2,6-dinitro-*p*-cymene when the methods of Aschan[2] and of Wheeler and Harris[3] were followed.

Since *p*-cymene upon nitration yields 2,6-dinitro-*p*-cymene,[2,4] 2,4-dinitrotoluene,[5] *p*-nitrotoluene,[3] and various oxidation products, it seemed desirable to observe the reaction at carefully controlled, lower temperatures and to employ chemical methods for the separation of the nitrated products.

Early in this study it was noticed that small changes in the reaction temperature resulted in reaction products which were quite different in quality and quantity. The reaction temperature, previously defined as "below 0°C.,"[3] was herein studied at −3 to −5°, −5 to −7°, and −10 to −12°. With decreasing temperature, the quantity of solid product, its melting point, the ratio of 2,6-dinitro-*p*-cymene to nitrated toluene derivatives, and the reaction time were increased. Likewise, the degree of oxidation, color of product, and the quantity of oils decreased. Contrary to previous work,[3] the reaction product yielded no oil but in every case solidified when washed, dried, and refrigerated at 0°. Oils were obtained from the mother liquor when the product was crystallized.

The separation of 2,6-dinitro-*p*-cymene in pure form was improved by crystallization from a pure solvent instead of mixed solvents.[3] In the selection of a solvent, the following were tried: dioxane, ethyl ether, dichlorodiethyl ether, isopropyl ether, petroleum ether, heptane, toluene, carbon disulfide, chloroform, carbon tetrachloride, methyl alcohol, and ethyl alcohol. Methyl alcohol was the superior solvent both for yield and purity of product. After the third crystallization with methyl alcohol the 2,6-dinitro-*p*-cymene melted at 51–53° whereas it melted at 40–42° after the sixth crystallization with ethyl alcohol.[3] For use in this study, the purification of 2,6-dinitro-*p*-cymene by one crystallization from methyl alcohol followed by a chemical separation, as described below, proved to save both time and material. The results of the nitration studies are given in Table I.

TABLE I

THE DINITRATION OF 500 G. OF *p*-CYMENE

The reduction of impure 2,6-dinitrocymene with ammonium sulfide gave a reaction product from which 6-nitrocarvacrylamine was separated in pure form after one or two crystallizations. The reduction product was crystallized from dilute hydrochloric acid which yielded 6-nitrocarvacrylamine hydrochloride, m. p., 209°. The free base melted at 52° and the acetyl derivative at 114–115°. These constants confirm those reported by Wheeler and Harris[3] but in the case of the free base and of the acetyl derivative they disagree with those reported by Aschan[2] as 80–82 and 111°, respectively. When an excess of ammonia was added to the mother liquor, 2-nitro-*p*-toluidine separated and after repeated purifications with dilute alcohol it melted at 81°[6]; its benzoyl derivative melted at 174°.[7,8] This formation and identification of 2-nitro-*p*-toluidine confirm the positions of the nitro groups in the dinitrotoluene as proved by Alfthan,[5] who obtained 2,4-toluylenediamine by reduction of both nitro groups. The selective reduction of the para nitro group and not the ortho group agrees

with the work of Beilstein and Kuhlberg[9] on 2,4-dinitrotoluene.

By using the nitration product of *p*-cymene obtained at −10 to −12°, 6-nitrocarvacrylamine was prepared from *p*-cymene in a higher yield than that which has been reported previously for the nitration alone. The results of the studies on the reduction of impure 2,6-dinitrocymene with ammonium sulfide are listed in Table II.

TABLE II

THE REDUCTION OF 2,6-DINITRO-*p*-CYMENE

Temp., °C., of nitration	6-Nitrocarvacrylamine HCl From solid, g.	From oil, g.	Yield from cymene, %	2-Nitro-*p*-toluidine From solid, g.	Yield from cymene, %
− 3 to − 5	126	43	19.7	65	11.4
− 5 to − 7	216	40	29.8	56	9.9
−10 to −12	281	36	36.8	51	9.0

Experimental

2,6-Dinitro-*p*-cymene.—One kilogram of fuming nitric acid (sp. gr., 1.52) and 2 kg. of sulfuric acid (sp. gr., 1.84) were placed in a 3-liter three-necked balloon flask equipped with a dropping funnel, thermometer, and an efficient stirrer. After cooling to −15° in a well insulated ice–salt mixture, the addition of 500 g. of *p*-cymene (Eastman, terpene-free, fraction boiling at 176.5°) was regulated so that the temperature did not exceed −10° and was maintained from −12 to −10°. It was necessary to arrange the stirrer so as to prevent the collection of a hydrocarbon layer, since this induced localized heating, oxidation, and a lower yield. The addition of *p*-cymene required thirty-three hours and stirring was continued for an additional hour. The reaction product was poured over 8 liters of cracked ice, stirred vigorously for one hour and washed successively with six to eight 3-liter portions of water by working and removing the aqueous layer by a siphon, once with dilute sodium hydroxide, and again with water. The spongy, lemon yellow product melted at 25°; it was warmed to 35° and separated from the aqueous layer in a separatory funnel. The oil was dried by heating in a distilling flask at 100° and 20–25 mm. The dry oil, when refrigerated at 0°, solidified to a hard crystalline lemon-yellow mass which weighed 785 g. The solid was recrystallized from 750 ml. of methyl alcohol at 0°. Impure 2,6-dinitro-*p*-cymene separated, weighing 420 g., and melted at 38–40°. On evaporation the mother liquor gave 360 g. of heavy, reddish-yellow oil which did not yield a further crop of crystals. Without further purification, the 2,6-dinitro-*p*-cymene was used for the preparation of 6-nitrocarvacrylamine.

6-Nitrocarvacrylamine Hydrochloride.—Two hundred and fifty grams of 2,6-dinitro-*p*-cymene (impure, m. p. 38–40°) in 1 liter of alcohol was placed in a 3-liter flask equipped with an inlet tube and an outlet *via* a reflux condenser. To the flask was added 170 ml. of ammonium hydroxide (28%). Hydrogen sulfide was passed into the flask at a rapid rate until the contents of the flask were saturated and the hydrogen sulfide was continued another five minutes. The reaction mixture was refluxed for fifteen minutes. The process of cooling, saturating, and refluxing for fifteen minutes was carried out three times. After the saturation with hydrogen sulfide the fourth time, the condenser was turned down and the alcohol was removed until the distillate produced a turbidity when allowed to drop in water. The residue was boiled with 3 liters of dilute hydrochloric acid (containing 375 ml. of concd. hydrochloric acid) in three successive portions of 2000, 500, and 500 ml. and filtered after each extraction. The filtrate was boiled, charcoaled, filtered, and cooled slowly to 0°. Straw colored needles separated which weighed 167.5 g.; m. p. 208°; yield 65% (from *p*-cymene, 36.8%).

6-Nitrocarvacrylamine.—Ten grams of the hydrochloride was suspended in 100 ml. of water and ammonia was added in slight excess. The amine which precipitated was recrystallized from dilute alcohol below 45°; yellow needles; m. p. 52°; yield, practically the theoretical.

N-Acetyl-6-nitrocarvacrylamine.—Three grams of the free base was dissolved in 2 ml. of pyridine and treated cautiously with 2 ml. of acetyl chloride. After warming the mixture for ten to fifteen minutes on a steam-bath it was cooled, washed with water until it solidified, and then washed successively with dilute sodium hydroxide, water, dilute hydrochloric acid, and water. After recrystallization from dilute alcohol the melting point was 114–115°.

2-Nitro-*p*-toluidine.—The acid mother liquor from the crystallization of 6-nitrocarvacrylamine hydrochloride was neutralized with concentrated ammonium hydroxide. Fifty-five grams of impure amine separated. After recrystallizing several times with dilute alcohol it melted at 81°.
