CHARLES HOLMES HERTY

1867–1938

BY FRANK K. CAMERON

Charles Holmes Herty was born December 4, 1867, at Milledgeville, Georgia. His father, Bernard Richard Herty, was born in Milledgeville in 1844, the son of James Herty, a substantial citizen. Bernard Herty enlisted in the Confederate army at the age of 17 years and rose to the rank of Captain. After the war, he returned to Milledgeville to become the leading druggist of the region. Charles Herty's boyhood ambition, to be a druggist also, remained with him to his university days at Baltimore. He and a younger sister were orphaned at an early age, both parents dying before he was 11 years old. Left in somewhat straitened circumstances, Herty always acknowledged gratefully the particular care of an aunt, Miss Florence I. Holmes of Athens, Georgia, who survives him.

Surrounded by relatives and family friends, his boyhood was a happy one. He grew up keenly interested (and successful) in outdoor sports and games, the interest being maintained throughout his life. Graduating from the local school, the Georgia Military Academy, he went to the State University at Athens, taking a Ph.B. in 1886. He entered the Johns Hopkins University in the fall. It was a period of intense intellectual activity at that institution, with a relatively large body of graduate students and few undergraduates. The graduates almost completely dominated the extrascholastic activities and Herty was soon active in them, particularly in glee club and baseball. He was easily the most popular and best loved student of his time. He justified his extracurricular activities because he had now abandoned his ambitions to be a druggist in favor of a teaching career in chemistry and wished to have an appeal to his prospective students, independent of scholastic ability. In 1890 he attained his Ph.D. His dissertation entitled, "The Double Halides of Lead and the Alkali Metals," was a sound piece of work and he returned to a study of double halides later. At this time neither Gibbs' Principle, the phase rule, nor modern techniques were available for guidance. People spoke vaguely of molecular compounds as distinct from atomic compounds and suspected that persistent work in the field would give a clue to the meaning of the also vague concept of valency.

Herty became Assistant Chemist of the Georgia State Experiment Station in 1890 and a year later, 1891, instructor at the State University. He was advanced to Adjunct Professor in 1894 and held the appointment until 1902. In 1895 he married Miss Sophie Schaller of Athens and in 1899 real-

ized a long-time desire by going to Berlin with his wife and two young children. After a year in Berlin listening to Witt and Körner, he went to Zürich to renew his interest in valency by studying with Werner. Returning to Georgia in 1901, he made contact with the U. S. Bureau of Forestry, for Witt's caustic criticism of American methods of obtaining turpentine rankled in his memory and was confirmed by visits to the pine belt. The Naval Stores industry was languishing. Herty was concerned with possibilities for restoring it. His invention of the now universally used cup and accompanying technique was revolutionary, the old boxing method being quite abandoned, with a saving of many millions of dollars. In 1902 he became a regular member of the Forestry Bureau's staff, remaining to 1904. During the years 1904–05 he was with the Chattanooga Pottery Company in connection with the manufacture of his cup.

Financial security now attained, Herty welcomed a return to academic work with the call to head the Department of Chemistry at the University of North Carolina. He was a successful teacher, logical, persuasive and with a never-flagging enthusiasm. Venable and Baskerville had done noteworthy research on the rare earths, and Alvin S. Wheeler had started his long series of investigations on pine oils. Promptly Herty returned to a study of the double halides of platinum and potassium, going on to study the halides and thiocyanates of mercury and lead. While with Werner he had published on the cobalt-ammonia chlorides and he returned for a while to the study of coördination numbers. The reaction of ammonia with ethylphospho-platinic chloride was studied and the compound previouly found by Rosenheim was shown to have a formula strictly in accord with the Werner theory. This publication marked the culmination of Herty's contribution to theoretical or pure chemistry. Henceforward, all his interest in chemistry was as a means for improving the material conditions of people: specifically, to develop industry. He had been writing about turpentine, along the lines he developed in Bulletin No. 40 of the U. S. Bureau of Forestry, which became a classic in the literature of turpentine; and, in 1908, the same year in which his paper on coördination numbers appeared, he reported studies on pine products. He found little change in the optical properties of samples of turpentine gathered throughout the year; the turpentine from the black pine, *Pinus serotinus*, is little used, but was found to be rich in limonene and to absorb more oxygen than the turpentine from the common source, *Pinus heterophylla*. These were followed in the next few years by furher studies of pine products, cotton seed oil, soaps, leather, etc. Of particular interest is the paper delivered before the Eighth International Congress of Applied Chemistry on "The Past, Present and Future of the Naval Stores Industry," and his efforts to obtain isoprene from turpentine. He showed pinene and not dipentene to be the source. Herty served as Dean of the School of Applied Science at the University of North Carolina, 1908–11.

In 1915 Herty was president of the American Chemical Society. An important accomplishment in his administration was the census of American Chemists. In his first presidential address, at New Orleans, he called attention to the resources of the South in raw materials and man power. At Seattle he called attention to the need of more research to supply deficiencies created by the World War, and for coöperation between University laboratories and industry. He suggested acquisition of governmental supplies of raw materials and strong tariff protection. Again President in 1916, in his address in New York he stressed the importance of financial support to make the teaching of chemistry more attractive to competent instructors, the necessity of better training of students going into industry, the desirability of government stores of raw materials, investigation of fuel and potash resources, tariff protection of new American industries, and popularizing chemistry with the laity. In 1916, the A. C. S. News Service was inaugurated. Herty had become accustomed to a much wider audience than the University and was ready to accept the editor's chair in 1917 when expansion of the activities of the American Chemical Society brought a full-time editorship for the *Journal of Industrial and Engineering Chemistry*. He remained with the *Journal* for five years, making it the foremost in its field, and a monument to his talents.

Starting with the motto "Coöperation," a trenchant pen soon showed he could be otherwise than gentle and suave when occasion warranted, and editorials on a wide range of subjects had far-reaching effects on the American industry, particularly in the manufacture of dyes. It is impracticable to cite, much less discuss, the list of subjects. It was the strenuous post-war period. Chemi-

cal education policies, protective tariffs, stimulation of the manufacture of synthetic organic substances, the organization of the Chemical Warfare Service owe much to his incisive and logical editorials. During the war settlement period, September, 1919, he was sent abroad by President Wilson to arrange for the purchase of impounded dyestuffs. This led to the organization of the Textile Alliance for the protection of American purchasers and forming of a domestic dye industry. From it has come the Textile Foundation with its valuable support of research with the funds then accumulated.

In 1921, yielding to the plea that he was, definitely, the best equipped man for the place, he gave up his editorship to become president of the Synthetic Organic Chemical Manufacturers Association, a new organization he had been vigorously advocating. His familiarity with technical procedures coupled with highly developed national gifts were very successful in persuading federal legislation. He retained this position until 1926. His interest in questions of public import was undiminished and it was at this period that he took every practicable occasion to urge studies of synthetic and natural remedial agents for internal medicine, and to further the activities which finally led to the passage of the Ransdell bill, in 1930, assuring the establishment of the National Institute of Health. It was their mutual conviction of the need for a coöperative alignment of medicine and chemistry that brought Herty and Francis P. Garvan together about 1918 and led to that association so important for the coming years. In 1926, feeling that his personal task had been accomplished with the secure establishment of the dye and pharmaceutical industry in the United States, he retired from his administrative duties. He became advisor to the Chemical Foundation, and for two years was engaged in the promotion of research in chemotherapy. Still retaining a connection with the Chemical Foundation, he opened a consulting office in New York in 1928 and maintained it until 1935. His major effort was to direct attention of financial interests to the industrial possibilities of the South Atlantic States with their great resources in raw materials. The Naval Stores industry was prominently in mind and, inevitably, consideration of other uses of the huge cover of pines on the Atlantic littoral. The subject was not entirely new to American chemists. The possibilities of removing the resins yielding a raw material suitable for alcohol or cellulose products had been studied but without practical outcome. A considerable and growing production of Kraft paper existed.

Herty maintained that the secretion of turpentine and resins being a protective device of nature, young pines should be relatively free of them, and the wood as suitable for pulping as spruce or other commercially used woods. He found the resin content of young slash pine to be less than one per cent., comparing favorably in this respect with spruce. Moreover, pine makes a relatively rapid growth and at four to eight years of age compares favorably with spruce of perhaps fifty or sixty years growth. He maintained, further, that pine naturally reseeded itself and given favorable conditions would come in spontaneously in cut-over lands, thus assuring a continuing pine stand without cultivation. Other observers maintain there is a natural cycle of tree growth, hardwood following pine, and left to itself a long period elapses before pines again are the dominant growth. No one doubts, however, that with cultivation, pines will follow pine, and at moderate costs. To obtain consideration of industrialists and financiers, laboratory experimentation and pilot-plant demonstration were needed. These facilities became possible in 1931 with a grant of fifty thousand dollars from the Chemical Foundation, supplemented by twenty thousand a year for five years from the State of Georgia, and substantial support from the city of Savannah. Dr. Herty had been appointed director of research for paper and pulp of the Georgia State Department of Forestry and the Chemical Foundation equipped the establishment known as the Savannah Pulp and Paper Laboratory. In a few years it was shown that the slash and other pines of the South yielded a fine grade of white newsprint. On March 31, 1933, the *Soperton News*, a weekly, was printed on paper made by Herty. In October, 1933, with three refrigerator cars loaded with pulp and transported to Thorold, Canada, a carload of entirely satisfactory news-print was procured, without any untoward incident. Nine newspapers of Georgia used it in their editions of November 20. And this *tour de force* was followed in 1936 by organization of a company by Southern capital for the erection of a plant near Lufkin, Texas, and the manufacture of newsprint. Over a dozen plants for production of cellulose products from pine have recently been added to those al-

ready operating in the Southeast. Some of them frankly admit Herty's influence in bringing them into existence.

The Savannah laboratory has produced high-grade alpha-cellulose which has been made into rayon, and is now investigating the practicability of utilizing in this way gum tupelo and other southern trees as well as pines. Now known as the Herty Foundation Laboratory, it is hoped that means will be found to establish it on a permanent basis, because of its obviously great value to Southern industry, as well as the most fitting of monuments to Herty.

Following the formation of the concept of farm chemurgy by Dr. William J. Hale, in close association with Dr. Herty the Farm Chemurgic Council came into existence, largely because of financial support by the Chemical Foundation and more perhaps because of the enthusiastic support of the late Francis P. Garvan. By reason of the nature of his work with pines, Herty inevitably took a leading part in this work. His addresses and exhibits were striking features at all annual meetings. Chemurgic problems in general including dry alcohol, sweet potato starch and conservation policies, particularly fire control, found frequent and forceful references in a long series of addresses and magazine articles. He continued to answer calls to public service and by presidential appointment was associated with General Hugh Johnson in the early work of the NRA.

Busy with his varied interests, a tired heart rebelled. In July, 1938, he went to a Savannah hospital. After three weeks he seemed to be making a complete recovery. On July 28, it is reported that he ate a good breakfast, and chatted with some early visitor. A few hours later the end came to the long, useful and happy life. He was seventy years of age.

He is survived by his sons Dr. Charles Holmes Herty, Jr., of Bethlehem, Pa., member of the American Chemical Society and a recognized authority on the chemisty of steel making, and Frank Bernard Herty of Brooklyn, N. Y.; his daughter, Miss Sophie Dorothea Herty, of Savannah, Ga., well known plant physiologist; a sister, Mrs. W. D. Hooper of Athens, Ga.; an aunt, Miss Florence Holmes of Athens, Ga.; many relatives and a host of friends. Mrs. Herty died in 1929. His private charities were many. While a vestryman at Chapel Hill, he devised a pension system for retiring clergy; operating successfully in the diocese, the Episcopal Church used it as a model in 1917. He died a vestryman of St. John's, Savannah.

Aside from his professional work, his main interest was always in field sports. He is credited with introducing football to the South when he was on the faculty of the University of Georgia, and he served as Director of Athletics while at the University of North Carolina. On his many trips about the country he rarely missed an opportunity to attend a game of baseball. Adept at the traps in his younger years, he was always keenly interested in the hunting of upland game. He was an expert billiardist.

A recital of Herty's contributions, as here attempted, falls far short of a complete description of his many services, indirect as well as direct, to the cause of chemistry and industry in America. These services must await the perspective of time for adequate evaluation. But his memory long will remain green as it already bids fair to beome a tradition. We can be grateful that he lived and that, as contemporaries in the American Chemical Society, we have shared in some measure in his distinguished merits.

Herty received the medal of the American Institute of Chemists in 1932. In 1934 he received a medal from the Herty Society organized in his honor by the Georgia State College for Women at Milledgeville, in a roster of distinguished scientific workers. He was the Edgar Fahs Smith lecturer at the University of Pennsylvania for 1937 and the Joseph W. Richards Memorial Lecturer before the Electrochemical Society in 1938. Fellow of the American Association for the Advancement of Science, he was a member of the Institute of Chemists, Society of Foresters, the Forestry Association, Institute of Chemical Engineers, the Society of Chemical Industry, the Electrochemical Society, the Society of Engineering Education, the Philosophical Society, the Franklin Institute, the London Chemical Society, the Société de Chimie Industrielle and the Société Chimique de France.

Herty held the Sc.D. from Colgate and Oglethorpe, the Doctor of Chemistry from Pittsburgh. He was made an LL.D. by the University of Georgia in 1928, by the University of North Carolina in 1934, by the University of Florida in 1937, and by Duke University in 1938.

Relation Between Fluidity, Temperature and Chemical Constitution of Pure Liquids

BY E. C. BINGHAM AND S. D. STOOKEY

In a recent report[1] on the results of a general survey of the field of viscosity, the fact is made evident that there is so far apparently no simple equation expressing accurately a direct relationship between viscosity of liquids and temperature. With regard to the form of equations evidently considered best by the investigating committee, the statement is made (1): "As to the influence of temperature, it has been found that the characteristic decrease of the viscosity of a liquid with rising temperature can, with a fair amount of approximation, be described by the exponential formula $\eta = Ae^{B/RT}$."

Also, the committee makes the following statement (1): "In the homologous series of the aliphatic hydrocarbons, alcohols, fatty acids, etc., an increase of the viscosity generally seems to take place with the number of CH_2— groups of the chains, although even a merely rough proportionality or other regularity appears to be out of the question."

We believe that the equation to be discussed in this paper expresses, in a simple and accurate form, a definite relationship between temperature and viscosity; and that in addition it affords a "well defined regularity" in the viscosity–temperature functions of successive members of a homologous series of liquids.

The equation is

$$\varphi/T = a + bT + \ldots \qquad (1)$$

where φ denotes the fluidity in RHES (reciprocal poise) and T is temperature in degrees absolute.

It will be shown that for liquids whose molecules are not longer than nine or ten carbon atoms, equation (1) expresses the fluidity–temperature relationship very accurately without introducing higher terms.

Also, equation (1) shows a very definite and striking relationship between the fluidity–temperature functions of successive members of a homologous series, which will be discussed in section II. This relationship follows from the fact that the constant a in equation (1) is a function of the homologous series to which the compounds belong, and b a function of the molecular weights of the members of the series; so that an equation may be obtained containing constants which are functions only of the series concerned, and not of individual members of the series.

The modified equation is

$$\varphi/T = A_s + \alpha T 10^{(\beta/M - \gamma/M^2)} \qquad (2)$$

M denoting molecular weight, and α, β and γ being constants.

Equation (2) has been found to be almost as accurate as the simple one, equation (1), and so makes it possible to calculate quite precisely the fluidity of any member of the series (as high in the series as the two-constant form of equation (1) is valid), at any temperature at which the substance is in the liquid state, by the use of only four constants.

This paper will be divided into three sections: section I dealing with the application of equation (1) to individual compounds; section II, with the application of equation (2) to homologous series, and section III, with the anomalous behavior of the aliphatic acids, aliphatic alcohols, and water.

Section I: Application of Equation (1)

Procedure.—The best available viscosity data were used. The data consisted of the absolute viscosities measured at small temperature intervals from 0° to the boiling point of each liquid studied, or to 100°. An attempt was made to choose representative members of as many classes of liquids as possible for which reliable data could be obtained, so that each liquid for which data are given in Table I is typical of several to which the equation may be applied with accuracy. The major part of the viscosity measurements were made by Thorpe and Rodger.[2]

Values of the constants a and b in equation (1) were determined by the method of least squares. The fluidities were then calculated at various temperatures from these constants, and the deviation from the observed fluidities recorded.

Table I gives the values of the constants for a number of compounds, with the standard, or root

Discussion of Results.—Table I demonstrates that equation (1) is valid for a large number of classes of pure liquids, including straight and branched chain saturated aliphatic hydrocarbons, unsaturated hydrocarbons, aromatic hydrocarbons, alkyl bromides and iodides, ethers, aldehydes, ketones, anhydrides, esters, thioalcohols (normal and secondary), alkyl sulfides, and inorganic liquids, including elements and liquefied gases. The average root mean square deviation of the calculated fluidities from those observed is 0.15% for all the liquids in Table I.

This list does not exhaust the range of applicability of equation (1). The only class of liquids for which it is known to be invalid is the alcohols, which will be discussed in Section III.

Section II: Application of Equation 2

Procedure.—Upon examination of the constants a and b, it became evident that a is practically identical for all members of a non-associated homologous series (as high in the series as equation (1), without introduction of higher terms, is valid). That is, when the ratio φ/T is plotted against the absolute temperature, the straight lines representing the members of the series all converge at the absolute zero of temperature.

Also, it was found that the values of the constant b of equation (1) are an exponential function of the molecular weight within a given series, conforming to the equation

$$b = \alpha 10^{\beta/M - \gamma/M^2} \qquad (3)$$

M being the molecular weight, and α, β and γ constants.

These facts make it possible to express the fluidity–temperature relations of all the members of a series (within the above-stated limits) by means of equation (2) given above.

The individual values of the constant a were averaged to obtain the series constants "A_s" for each of six aliphatic series: normal hydrocarbons, isohydrocarbons, normal bromides, normal iodides, normal mercaptans, and secondary mercaptans.

The values of b were recalculated from the new series constants, and the fluidities redetermined.

Finally, the constants α, β and γ in equations (2) and (3) were calculated, and the fluidities redetermined with all restrictions, according to equation (2).

Figures 1 and 2 are graphs, φ/T *vs.* T, for a typical series, the alkyl bromides. In Fig. 1, successive lines represent successive members of

(3) A. R. Bayer, Master's Thesis, Lafayette College, 1933.

(4) E. C. Bingham and H. J. Fornwalt, *J. Rheol.*, **1**, 372 (1930).

the series, from ethyl bromide on the right to decyl bromide on the left. The numbers of the lines denote the number of carbon atoms. Figure 2 is identical with Fig. 1 except that the lines are extrapolated to absolute zero and decyl bromide is not represented.

In Table II, a and b are the constants of equation (1); b' is the new value of b calculated from the series constant A_s; and the equations contain all the series constants A_s, $-\alpha$, β and γ of equation (2). The last three columns of Table II contain the percentage standard deviation, or root mean square deviation (denoted by % S. D.) of the calculated fluidities from the observed. The first of the three columns represents the deviation of fluidity calculated from a and b; the second, that calculated from A_s and b'; and the last column, that calculated when equation (2), with all the series constants, is applied.

Figure 3 is a deviation chart, % deviation in fluidity *vs.* temperature for some representative aliphatic bromides.

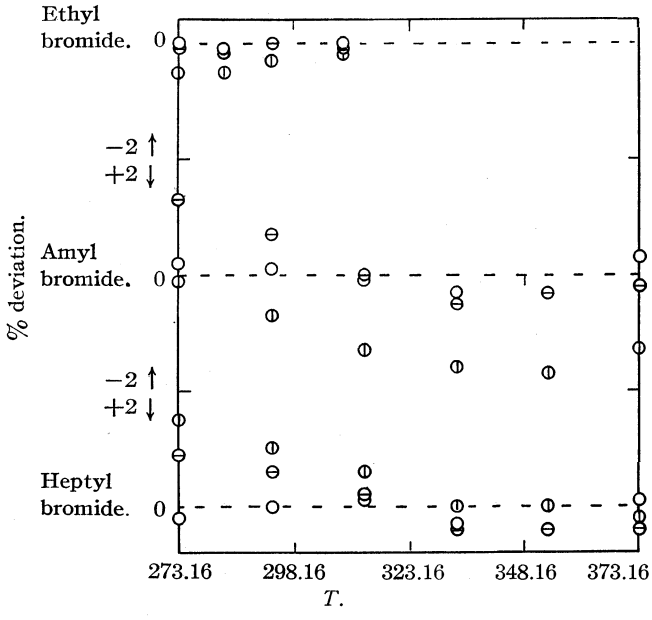

Fig. 3.—Deviation chart. Representative plot of the percentages of deviation of calculated fluidity from observed: open circles represent φ calculated by equation 1; circles with horizontal diameters, φ calculated from a_s (series constant) and b'; circles with vertical diameters, φ calculated by equation 2, with all series constants.

The fluidities of the higher members of the alkyl bromide series have been determined by Bayer[3] and are given at the end of this paper in Table IV.

TABLE IIIA

0–25	1.6439	0.0067635	0.3
25–100	1.9149	.007675	
		Max. dev.	0.5

TABLE IV

FLUIDITY OF ALKYL BROMIDES (3)

Bromide	Fluidity in rhes at given temperature, °C. 0.0	20.0	40.0	60.0	80.0	100.0
Butyl	122.0	154.4	192.3	230.8	271.8	321.2
Amyl	94.6	123.9	156.4	192.3	230.6	270.6
Hexyl	73.4	99.1	128.4	161.0	195.5	231.5
Heptyl	54.7	77.5	102.9	131.4	161.8	194.9
Octyl	41.4	61.2	84.0	108.9	136.7	166.5
Nonyl	31.7	48.9	69.2	92.3	117.4	144.5
Decyl	24.3	39.3	75.2	77.7	100.8	125.4

Discussion of Results.—The average standard deviation of the calculated fluidity from the observed, when equation (3) is applied to individual members of the series, is 0.4% for eight alkyl bromides, 0.1% for three alkyl iodides, 0.4% for six *n*-hydrocarbons, 0.2% for three isohydrocarbons, 0.45% for seven *n*-mercaptans, and 0.4% for six secondary mercaptans. The equation fits the data for higher members of the series than those given here with almost equal accuracy, but the percentage deviation increases gradually with increasing molecular weight, due, presumably, not to the increased weight of the molecules (since bromine obeys the equation) but to the effect of the long chains. The curvature is in a direction which shows that for longer molecules the fluidity increases more rapidly at higher temperatures than at low temperatures. Addition of a term of the power series in T of equation (1) corrects for this tendency, if desired.

When the individual values of a are averaged to give a series value A_s, the average standard deviation for bromides is 0.6%, iodides 0.4%, *n*-hydrocarbons 0.7%, isohydrocarbons 0.4%, *n*-mercaptans 1.3%, secondary mercaptans 0.8%.

Applying all restrictions, according to equation

(2), the average standard deviation for *n*-bromides is 1.4%, *n*-iodides 0.4%, *n*-hydrocarbons 1.2%, isohydrocarbons 0.4%, *n*-mercaptans 1.8%, secondary mercaptans 1.1%.

Section III: Anomalous Liquids

Procedure.—The only marked abnormalities noted thus far in the behavior of liquids with regard to equations (1) and (2) occur in compounds which contain a hydroxyl radical. The three abnormal types of liquids are the aliphatic acids, alcohols, and water. Each of the three exhibits a different sort of anomaly.

Table IIIA contains the values of a and b (equation 1) for the first four members of the aliphatic acid series, and the percentage standard deviations. Figure 4 shows the corresponding curves, φ/T *vs.* T, the curves being numbered according to the number of carbon atoms in the compound represented.

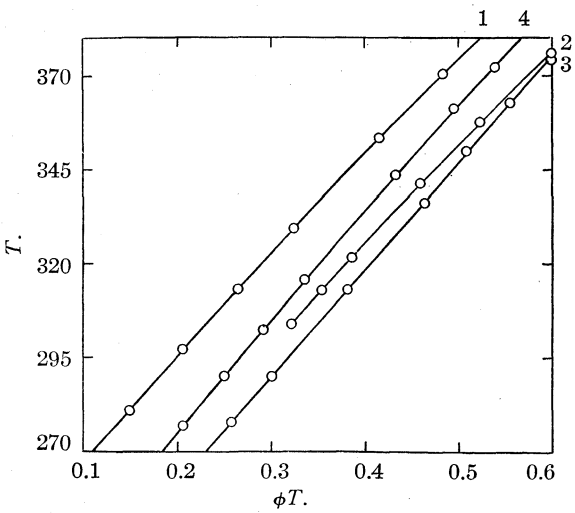

Fig. 4.—Aliphatic acids: the numerals denote the number of carbon atoms in the acids represented: formic, acetic, propionic and butyric. Note contrast between relative positions of curves as compared to Fig. 1.

Table IIIB gives the constants a and b for water; Fig. 5 shows the curve φ/T *vs.* T. The data used are an average of the observations of six observers.[5]

Discussion of Results.—The results show that the aliphatic acids obey equation (1) quite well, the average standard deviation being only 0.7%. In nearly every case, however, there is a definite though slight tendency toward curvature.

(5) E. C. Bingham, "Fluidity and Plasticity," McGraw-Hill Book Co., Inc., New York, N. Y., 1922, p. 339.

On the other hand, comparison of Fig. 4 with Fig. 1 makes very evident the contrast between the apparently random variation of the slopes and positions of the curves for acids, and the regular variation for a typical non-associated series.

The fact that the acids obey equation (1) may be explained by considering that they form nearly stable compounds in their association; for which there is evidence from X-ray measurements.[6]

The slight curvature then is probably caused by the slight instability of the associated liquids.

The φ/T *vs.* T curves of the alcohols all show very decided curvature. This may possibly be caused by the fact that the alcohols, although associated, form unstable compounds, and that the degree of association varies with temperature.

The φ/T *vs.* T curve for water (Fig. 5) is a straight line from 0 to 25°, and from 25 to 100°, curving slightly in the neighborhood of 25°. We have, therefore, applied equation (1) twice, and the two equations reproduce the observed fluidity with a standard deviation of 0.3%, the maximum deviation being 0.5%.

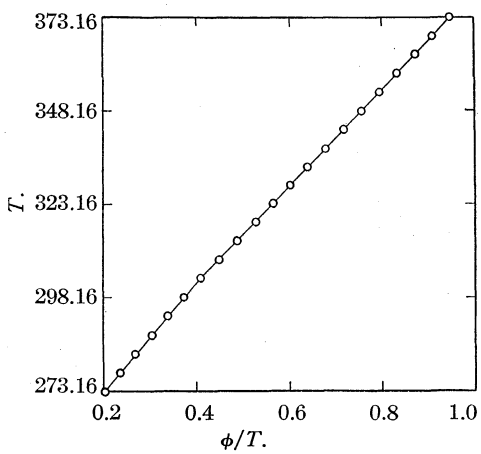

Fig. 5.—Water.

Summary

A simple equation relating fluidity directly to temperature has been shown to fit the data very accurately for a large number of liquids, apparently failing only for alcohols. The equation also shows a definite relation between the viscosity–temperature functions of successive members of a homologous series, making it possible to calculate the viscosity of any member of a non-associated series up to ten carbon atoms at any temperature by means of only four constants.

The fluidities of the aliphatic bromides from

(6) Müller, *J. Chem. Soc.*, **123**, 2054 (1923).

butyl bromide to decyl bromide between 0 and 100° as determined by Bayer, are given.

Note: Equation (1) has been found to apply to some types of solutions as accurately as to pure liquids. Further investigations are being made along this line.

The Mechanism of Solvolytic Reactions of Organic Halides and the Use of Activity Coefficients in the Equation for a Reaction Velocity

BY PAUL D. BARTLETT

Of the theories about the dependence of reaction velocity in solution upon the solvent, the two which have received the most attention in this century are those of van't Hoff[1] and of Brönsted,[2] later refined by other workers and commonly known, respectively, as the "activity-rate theory" and the "transition-state theory." It is consistent with both theories to regard the activated complex as a molecular species in equilibrium with the reactants. The activity-rate theory then demands that the rate of reaction shall be proportional to the fugacity of the activated complex, while the transition-state theory makes the rate proportional to the concentration of this complex.

For reactants forming nearly ideal solutions below their limits of solubility, the activity-rate theory predicts specific reaction rates inversely proportional to their solubilities in a series of solvents. This prediction was shown by von Halban[3] in 1913 to fall hopelessly short of the facts in the formation of *p*-nitrobenzyltrimethylammonium chloride. Here the introduction of corrections for solubility increased the range of observed velocity constants in eighteen solvents from 9300-fold to over 400,000-fold, when according to the theory it should have rendered the corrected rate independent of solvent.

It has thus long been evident that the activity-rate theory does not possess general validity. Since this is so, the success recently attained by Olson and Halford[4] in reviving this theory and applying it to the calculation of reaction rates in a graded series of methanol–water and ethanol–water mixtures is surprising. The rate of production of hydrogen chloride by *t*-butyl chloride in these series of solvents varies 100-fold for the former and 750-fold for the latter series, and these rates have been calculated in terms of the vapor pressures of the reactants within less than the uncertainty of the data employed in the calculation.

Such agreement cannot be entirely accidental, and from the standpoint of the theory of reaction velocity it is important to try to decide between two possibilities. Either (1) the activity-rate theory is fundamentally true for a solvolytic reaction in mixed solvents, while lacking general validity, or (2) it is not fundamentally true, but represents a useful approximation because of special relationships among the quantities appearing in the equations. It is the purpose of this paper to approach this question by inquiring whether the activity-rate theory fits the data of Olson and Halford uniquely, and to draw such conclusions as may be possible about the factors determining the rate of reaction and the mechanism of this particular reaction.

The liberation of hydrogen chloride from *t*-butyl chloride in these experiments proceeds with the formation of three organic products—*t*-butyl alcohol, methyl *t*-butyl ether, and isobutylene. The reaction is an unfortunate one for testing a kinetic formulation on account of the difficulty in making a convincing demonstration of what is going on. The reaction has been variously designated by Farinacci and Hammett[5] as polymolecular, by Olson and Halford[4] as bimolecular, and by Ingold, Hughes,[6] and their co-workers as unimolecular, depending upon the extent to which attention has been focussed upon the role of the solvent in the rate-determining step. In a recent note[7] the British workers have indicated that the difference between their "unimolecular" and Hammett's "polymolecular" is a matter of language

rather than point of view. There remains a difference between the original opinion of Olson and Halford and that of the other workers with regard to the point of attack of the solvent molecule on the chloride. Since the kinetics would be the same regardless of the form of the transition state, we shall postpone discussion of this point.

Olson and Halford[4] (p. 2647) say of their fugacity-rate equation: "This equation is in disagreement with the one obtained from transition state theory by Wynne-Jones and Eyring [*J. Chem. Phys.*, **3**, 492(1935)] unless we assume that the fugacity coefficient of each of the three complexes which we studied remains constant throughout the whole range of experimental conditions. This appears to us highly improbable." Examination of the equations shows that there is actually a less rigid condition than this for the simultaneous perfect applicability of the two equations, owing to the fact that an observed rate is being resolved into two rates governed by different activated complexes. If an approximate equation is used, a fit may under certain conditions be obtained without correctly assigning these contributing rates to their proper transition states. Denoting by k the observed rate constant in terms of mole fractions for the appearance of hydrogen chloride in a solution of *t*-butyl chloride in a mixture of water and alcohol, by f_W, f_A, f_X and f_Y the activity coefficients (expressed as Henry's law constants) of water, alcohol and the transition states involving them, respectively, by f_B the activity coefficient of *t*-butyl chloride, and by M_W and M_A the mole fractions of water and alcohol, and assuming the reaction to occur between one molecule of solvent and one of chloride, the transition-state theory gives the equation

$$k = k_W M_W \frac{f_W f_B}{f_X} + k_A M_A \frac{f_A f_B}{f_Y} \qquad (1)$$

while the activity-rate equation as used by Olson and Halford does not contain the activity coefficients of the transition states

$$k = k'_W M_W f_W f_B + k'_A M_A f_A f_B \qquad (2)$$

The condition that both these equations shall fit the same set of data exactly is found by eliminating k/f_B from Equations (1) and (2)

$$\left(k_W \frac{f_W}{f_X} - k'_W f_W\right) M_W = \left((k'_A f_A - k_A \frac{f_A}{f_Y}\right) M_A$$

This equation may of course be true by both sides being equal to zero, through a constancy of f_X and f_Y, as recognized by Olson and Halford. It may also be true as a result of other modes of dependence of f_X and f_Y upon solvent composition, in which case the quantities k'_W and k'_A will be composite constants. In addition to the functional relationships among the f's which can be seen to satisfy this equation, there are sure to be some others (possibly including the true one) which yield a close enough approximation to the condition of this equation to make both equations (1) and (2) fit the data.

A qualitative consideration of the probable form of the activated complex suggests a simple formulation which, if Equation (1) is correct, might be expected to yield as good an approximation as that of Equation (2). The solubility behavior of an aliphatic chloride is very similar to that of a hydrocarbon, the halogen atom making no characteristic contribution to its solubility in hydroxylic solvents. Any mechanism by which a water or alcohol molecule might attach itself to a *t*-butyl chloride molecule could only have the effect of making it much more alcoholic or aqueous in character. This suggests the provisional assumption that the activity coefficients of the transition states might be sufficiently like those of their hydroxylic components so that the two would approximately cancel, and we might write

$$k = k''_W M_W f_B + k''_A M_A f_B \qquad (3)$$

Like Equation (2), this can be derived from (1) by introducing a somewhat more flexible condition than the one which originally suggested the approximation. Equation (3) follows from (1) if

$$\left(k_W \frac{f_W}{f_X} - k''_W\right) M_W = \left(k_A - k_A \frac{f_A}{f_Y}\right) M_A$$

Equation (3) has been applied to the data of Olson and Halford for the reaction in water–methanol mixtures and the fit compared to that of Equation (2). To make this comparison, we determine the constants k_W and k_A which will give the lowest mean square percentage deviation of the calculated from the experimental rates by both these types of formulation. We assume that the percentage accuracy of the rate constants of Olson and Halford is about the same for the large and small values. To make the mean square percentage deviation a minimum in each case, Equations (2) and (3) are divided through by k and normal equations constructed from the resulting experimental equations. Table I shows the results of this comparison. The fit of Olson and Halford, not using this method, is also included.

TABLE I

Formulation	$(k'_W, k''_W) \times 10^6$	$(k'_A, k''_A) \times 10^6$	% mean deviation	% mean square deviation
O. and H.	0.393	0.0156	3.80	4.61
Least sq. Eq. (2)	0.379	0.01573	4.09	4.48
Least sq. Eq. (3)	11.54	2.07	2.86	3.78

Figure 1 shows this situation graphically. Equations (2) and (3) can be written in the form

$$\frac{a}{b}k'_W + k_A = \frac{k}{b} \qquad (4)$$

and

$$\frac{a'}{b'}k''_W + k''_A = \frac{k}{b'} \qquad (5)$$

wherein $a = M_W f_W f_B$, etc. Equations (4) and (5) demand, respectively, that k/b plotted against a/b, and k/b' against a'/b', should yield straight lines, and from the graphs it is apparent that this is true in both cases.

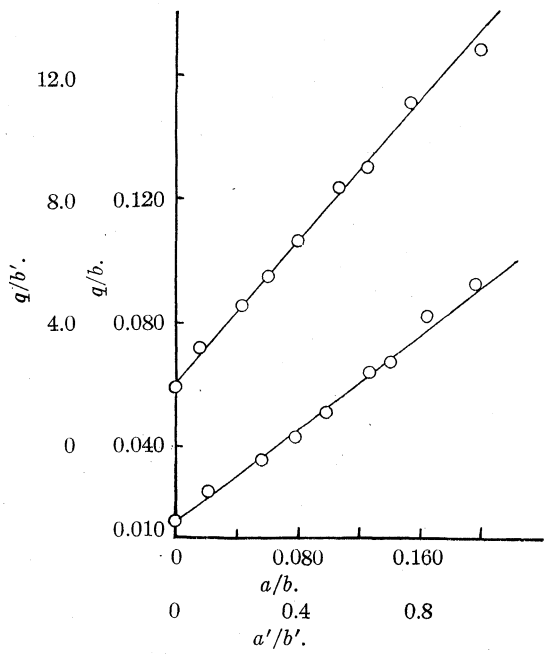

Fig. 1.—Plots of Equation (4) (lower curve) and Equation (5) (upper curve) for the reaction of *t*-butyl chloride with methanol–water mixtures (data of Olson and Halford).

The recalculation by Olson and Halford of Hughes' kinetic data on the solvolysis of *t*-butyl chloride in mixtures of water and ethyl alcohol is impressive for the wide range of velocity which it covers, but the agreement between calculated and observed rates is quite inferior to that in the methanol–water mixtures. The signs of the deviations also suggest a distinct curvature to the points, and the plots of Equations (4) and (5) in Figs. 2 and 3 for the water–ethanol system bear this out. The point at $a/b = 0$, obtained by Olson and Halford by extrapolation of the data of Hughes, is included in this plot but not in the least squares solutions, since it is not an experimental point. One of the points in the plots is so badly out of line that I have carried through the

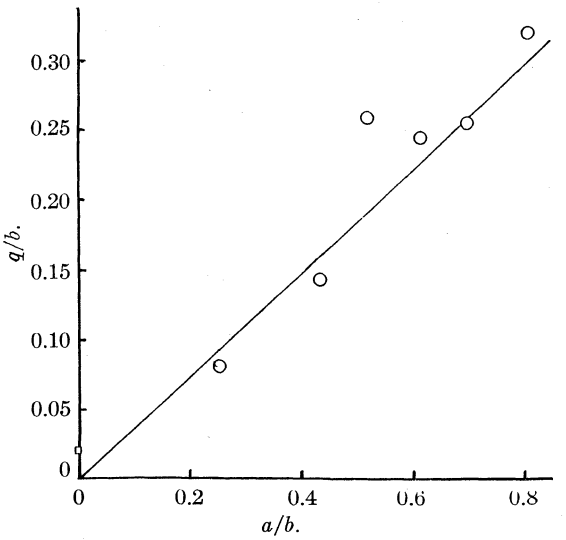

Fig. 2.—Plot of Equation (4) for the reaction of *t*-butyl chloride with ethanol–water mixtures (data of Hughes).

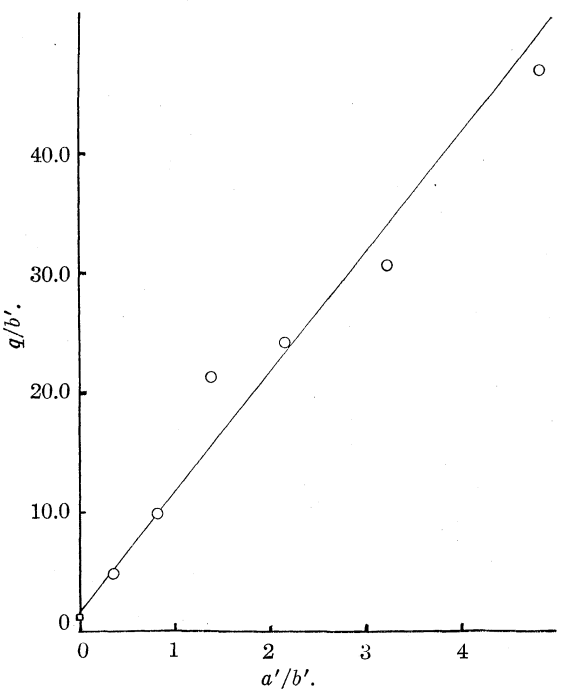

Fig. 3.—Plot of Equation (5) for the reaction of *t*-butyl chloride with ethanol–water mixtures (data of Hughes).

fits both with and without it. The conclusions in both cases are substantially the same.

In this system the Henry's law constants of water vary 79%, and those of alcohol 151%, over the range of solvent composition employed, compared with 27 and 10% in the methanol case. It is therefore to be expected that the two imperfect approximations to the correct formula which we are considering will both fit the facts less well than in the case of water–methanol mixtures. In fact, if we ignore the extrapolated point for pure ethanol, introduced by Olson and Halford, and consider only the experimental points, the best straight line through the points of Equation (4) (the activity equation) intersects the axis of ordinates at a negative value, making $k'_A = -0.0296 \times 10^{-6}$ if we include the suspicious point with the large deviation, and -0.0259×10^{-6} if we reject this point. A negative rate constant is permissible if k' is a composite quantity, but not if it has the fundamental significance attributed to it by Olson and Halford. In such a case, the closest fit that can be made of Equation (4) which has any physical meaning is to assume $k_A = 0$, and that all reaction is due to the water present. Table II shows a comparison of this best allowable fit with the best fit of Equation (5) to the data, both with and without the doubtful point.

TABLE II

No. of points	Formulation	$(k'_W, k''_W) \times 10^6$	$(k'_A, k''_A) \times 10^6$	% mean deviation	% mean sq. dev.
7	O. and H.	0.393	0.021	18.1	24.4
6	Eq. (2)	0.3688	0	11.4	13.91
6	Eq. (3)	10.05	1.63	9.05	10.15
5	Eq. (2)	0.35547	0	8.40	9.00
5	Eq. (3)	9.317	2.029	4.81	5.66

Here again the formulation employing mole fractions of water and alcohol fits the data fully as well as that employing vapor pressures.

Olson and Halford did not test any mechanism involving the participation of more than a single molecule of solvent in the rate-determining step. Since their data are now found to be fitted by different rate equations, it is of interest to see whether they may also be fitted by an equation which postulates three concurrent rate-determining steps in which the chloride collides with two water molecules, a water and an alcohol molecule, or two alcohol molecules. Such an equation would be written

$$k = k'_{WW} p_W^2 f_B + k'_{WA} p_W p_A f_B + k'_{AA} p_A^2 f_B \quad (6)$$

or

$$k = k''_{WW} M_W^2 f_B + k''_{WA} M_W M_A f_B + k''_{AA} M_A^2 f_B \quad (7)$$

depending upon whether vapor pressures or mole fractions of the solvent components were used in the equations. Equation (6) fits the data of Olson and Halford with a root mean square deviation of 3.85% when the following constants are used

$$k'_{WW} = 0.0155 \times 10^{-6}$$
$$k'_{WA} = 0.00299 \times 10^{-6}$$
$$k'_{AA} = 0.000127 \times 10^{-6}$$

Equation (7) fits the same data with a root mean square deviation of 3.12% using the constants

$$k''_{WW} = 9.28 \times 10^{-6}$$
$$k''_{WA} = 14.98 \times 10^{-6}$$
$$k''_{AA} = 2.02 \times 10^{-6}$$

Thus, not only do these data not serve to establish an activity-rate law, but they also afford no proof of the order of the reaction with respect to solvent molecules.

Although the equations using mole fractions seem in general a better approximation than those using vapor pressures, it should be pointed out that all these formulations fit the data better than the accuracy of the data themselves would lead us to expect.[8] Under these circumstances it would appear that errors in the values of f_B (the quantity known with least certainty) must have considerable regularity, if indeed they are as large as supposed. In any event, no weight is to be given to small differences in the fits of different equations.

Table III compares the calculated rates of hydrolysis of *t*-butyl chloride in water–dioxane and water–acetone mixtures by equations (2), (3), (6), and (7).

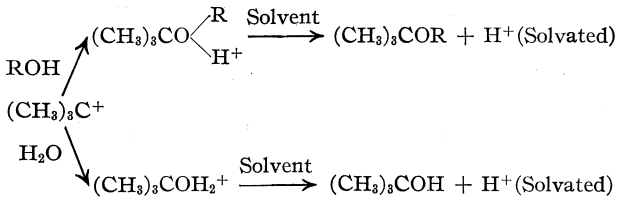
TABLE III

Method of calcn.	Dioxane k	Dioxane % dev.	Acetone k	Acetone % dev.
Observed	644		6.90	
Olson and Halford	745	15.6	11.6	68.1
Equation (2)	720	11.8	11.1	60.8
Equation (3)	927	43.9	9.58	38.8
Equation (6)	581	9.78	8.11	1.73
Equation (7)	404	37.2	2.53	63.3

In a recent paper Bateman, Hughes and Ingold[7] approve the activity formulation of Olson and Halford, but show that the lack of agreement between the predicted and found ratio of alcohol and ether in the products invalidates any idea that

(8) Professor Olson has emphasized in a private communication that the Henry's law constants of *t*-butyl chloride may be in error by as much as 25% or even more.

the solvolysis could be a one-step bimolecular replacement process. This argument stands also if Equation (3) is adopted. The second step of the ionization mechanism of Bateman, Hughes and Ingold



is subject to an activity formulation according to both of the above methods. The data of these authors and of Olson and Halford can be used to test these formulations. The relative amounts of alcohol and ether in the product, so long as the solvent composition remains constant, are supposed to be the result of simple competition between the water and the alcohol in reaction with the *t*-butyl cation. There may be some question of the reversibility of the association step, but it can scarcely be as mobile as the acid–base interchanges among the oxygen-containing compounds, and hence, if, as found by Bateman, Hughes and Ingold, the products resulting from a run are not in equilibrium, the relative forward rates of the association steps between the *t*-butyl ion and the solvent molecules should completely determine the ratio of alcohol and ether in the product. According to the activity-rate theory, the ratio of alcohol to ether in the product should remain proportional to the ratio of vapor pressures of water and alcohol in the solvent. The transition-state theory divides this latter ratio by that of activity coefficients of transition states resembling in appearance the proton alcoholate and etherate in the equation.

In Table IV Column I records the ratio of vapor pressures of water to alcohol in the solvents of Bateman, Hughes and Ingold; II is the ratio of alcohol to ether in the product; and III is the ratio of moles of water to moles of alcohol in the solvent. It is seen that II/I is far from constant as it ought to be according to the activity-rate theory. II/III is more nearly constant, although this would scarcely be demanded by the transition state theory. It may be that no energy of activation is required in the combination of the butyl cation with a water or alcohol molecule, the ion pair representing a plateau of energy from which a change means a direct descent. In this case the near constancy of the ratio II/III would be expected.

TABLE IV

I	II	III	II/I	II/III
	Ethanol–Water Mixtures			
0.611	4.61	2.15	7.5	2.14
.432	2.07	0.808	4.8	2.56
.255	0.90	.359	3.5	2.50
	Methanol–Water Mixtures			
.192	1.53	0.961	8.0	1.59
.099	0.474	.397	4.8	1.19
.0525	.206	.196	3.9	1.05

As has been pointed out repeatedly by Ingold, Hughes, and their collaborators, the two-step nature of the solvolytic process is indicated not alone by the seeming independence of rates and product compositions, but also by the inability of the strongly basic ions, hydroxyl and alkoxyl, to influence the rate of reaction of the secondary and tertiary halides. Any mechanism which allowed a direct attack of a solvent molecule upon the central carbon atom of the halide to take part in the rate-controlling step would be attributing something like a basic function to this solvent molecule and would be at a loss to explain the failure of the far more basic ions to participate in this same manner.

Miss Ethel M. Holmes has given valuable help in these calculations by carrying through the least squares application of Equations (6) and (7) and checking all the other results.

Summary

Evidence of long standing is recalled which shows that the rate of a chemical reaction is not generally proportional to the fugacity of the reactants and to that of the transition state, as apparently found by Olson and Halford for the hydrolysis and alcoholysis of *t*-butyl chloride in mixtures of water and alcohol. A recalculation of their kinetic results and those of Hughes shows that these results are no more consistent with the activity-rate theory than with the Brönsted–Polanyi–Eyring theory of the transition state, supplemented with a not unreasonable assumption about the activity coefficients of the transition states. A special case of the assumed relationship is that the transition state involving water has a water-like activity coefficient and that involving alcohol has an alcohol-like activity coefficient.

This leads to an approximate rate equation in

which vapor pressures of the chloride are used, but mole fractions of water and alcohol. The probability is discussed that the equation of Olson and Halford is, like this, a special approximation and does not represent a fundamental rate law.

Contrary to the conclusions of Olson and Halford, their results do not prove that the hydrolysis and alcoholysis of *t*-butyl chloride in mixed solvents is a bimolecular reaction, for the rates can also be accurately calculated on the assumption of a termolecular transition state by either of the two approximate kinetic equations.

It is shown that the product composition exhibits a dependence on solvent composition which is consistent with the view that the rate-determining step is an ionization, the solvent serving to solvate the anion, and that the solvent components then compete for the cation in rough proportion to their mole fractions.

The Solvolysis of *t*-Butyl Chloride. Solvolytic Reactions and the Walden Inversion

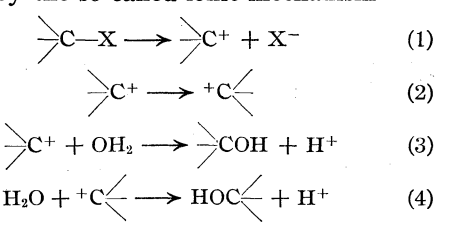
BY SAUL WINSTEIN

A serious problem at the present time is the exact interpretation of first-order solvolytic reactions of organic halides. Ingold and collaborators[1] suppose that these reactions proceed by an ionic mechanism, S_N1

$$RX \xrightarrow{\text{slow}} R^+ + X^-$$
$$R^+ + R'OH \xrightarrow{\text{fast}} ROR' + H^+ \qquad S_N1$$

in which the halide RX ionizes, the cation R^+ reacting rapidly with solvent molecules. Hammett and co-workers[2] believe these solvolytic reactions to be polymolecular, while Olson and Halford[3] and Taylor[4] have presented evidence that they are bimolecular. It is the purpose of the author to present in the following paragraphs evidence and discussion in favor of the polymolecular interpretation of solvolytic reactions of halides and opposed to the ionic mechanism, and to discuss the polymolecular mechanism from the standpoint of the steric results obtained using optically active halides.

Objections to the Ionic Mechanism.—It may be satisfactory for some purposes to speak of solvolytic reactions as involving an ionization with stress placed on the role of solvation in the ionization. But unless solvation is considered explicitly, it is impossible to discuss logically the steric results and product compositions (if mixed solvents are used) from solvolytic reactions of halides. To see this clearly let us formulate the first-order hydrolysis of a halide as involving an ionization of this halide, first without including any mention of solvation in the reaction equations and then allowing for solvation of the organic cation. First let us consider reactions 1–4, which relate to the hydrolysis of a halide molecule by the so-called ionic mechanism



without being explicit about solvation of the organic cation. Reaction 1 represents the ionization process and reaction 2 the process of flattening-out of the cation, permitting it to react to give products with either one of two enantiomorphic configurations, as shown by reactions 3 and 4. One would predict that if the life of the cation were long enough to permit one to speak of the existence of the cation, reaction 2 would be fast enough to give rise to a racemic alcohol from an optically active halide.

Ingold and collaborators[5] explain the usual steric result[2a,6] of solvolytic reactions (predominant inversion with more or less racemization) by the argument that usually X^- will shield R^+ sufficiently so that reaction occurs more easily from the side away from X^- than from the side toward

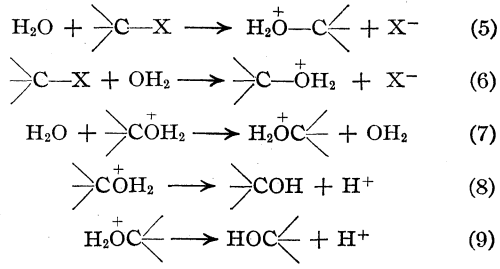
X^-, so that inversion predominates. In certain cases, such as the solvolysis of α-bromopropionate ion,[7] these workers expect[5] and find complete retention of configuration. It is believed by them that the intermediate zwitterion in this case is stabilized in a pyramidal form and a solvent molecule reacts with it at the place left vacant by bromide ion.

The above arguments do not seem to me to be at all reasonable. It would seem that if ionization were complete enough to permit the reaction to be called unimolecular, then the ion R^+ would be free enough from shielding effects so that a completely racemic product would result from the reaction of R^+ with solvent molecules.

Further, it is my opinion that the correct explanation of the retention of configuration in the first-order solvolysis of α-bromopropionate ion is not that the reaction proceeds by mechanism S_N1 with stabilization of the intermediate zwitter ion, but that instead the carboxylate ion group substitutes for the bromine atom by an intramolecular variety of the usual bimolecular exchange leading to Walden inversion.[8] The formation of the α-lactone is assumed to be the rate-determining step. The α-lactone then rapidly reacts with solvent molecules with a second inversion in the manner of epoxides[9] or β-lactones[10] under some conditions.[11]

If we continue to describe the first-order hydrolysis of a halide as involving an ionization of the halide but now consider solvation explicitly we must admit that only through solvation does the activation energy of such a reaction become low enough to give rise to a reasonable rate for the process of hydrolysis. Thus, as Ogg and Polanyi[12] have pointed out, the hydrate of the carbonium ion and not a bare cation is to be expected from any ionization of a halide in water. Reactions 1–4 are now replaced by 5–9. Reactions 5 and 6 represent the formation of two optically different cation hydrates, depending on the mode of reaction. These cation hydrates we recognize as



oxonium compounds of alcohols. Reaction 2 is replaced by 7, which represents a racemization brought about by a water exchange. Reactions 8 and 9 represent the loss of protons by the oxonium compounds. When the reaction is represented in this way it seems desirable not to speak of an ionization mechanism but rather to regard the solvent as a reactant. One has no reason to suppose that reaction 7 is rapid, so that the steric result of the hydrolysis is determined with the formation of the oxonium compounds. Ogg and Polanyi suggested that ionization goes only by reaction 5, but the considerable racemization accompanying most solvolytic reactions[2a,6] indicates the occurrence of both reactions 5 and 6. How water is able to enter into both reactions 5 and 6 will be seen later.

Hydrolysis and Alcoholysis of *t*-Butyl Chloride.—If, as is discussed above, we regard the solvent as a reactant, further insight into the nature of solvolytic reactions of halides can be gained by studying the solvolyses in mixed solvents. In the case of the first order hydrolysis and alcoholysis of tertiary butyl chloride in mixtures of water with either methyl or ethyl alcohol, considerable data are at hand.[3,13] Olson and Halford[3] have suggested that rates of hydrolysis and alcoholysis of *t*-butyl chloride in binary solvents should be proportional to the fugacities of halide and water or alcohol. Thus the total rate of hydrolysis plus alcoholysis is given by equation 10, where k_m is the measured first-order specific reaction rate constant for the

$$k_m = (k_w p_w + k_a p_a)(p/N)_{RCl} \qquad (10)$$

formation of hydrogen chloride, p_w and p_a are vapor pressures of water and alcohol, respectively, k_w and k_a are constants characteristic of pure water and alcohol, respectively, and $(p/N)_{RCl}$ is the Henry's law constant for the halide in a given solvent. P_A, the mole per cent. of the reaction product which is *t*-butyl alcohol and not its

(11) Recently[9] it has been found that 3-bromo-2-butanol reacts with hydrobromic acid with complete retention of configuration. In this case an argument based on stabilization of an intermediate carbonium ion in a pyramidal form is not possible but a role for the bromine atom similar to the role of the negative oxygen in α-bromopropionate ion can be and has been formulated.

alkyl ether, is thus predicted by equation 11

$$P_A = (100/k_m)(k_w p_w)(p/N)_{RCl} \quad (11)$$

Olson and Halford were able to fit exceedingly well the rates of hydrogen chloride formation in water–methyl alcohol and water–ethyl alcohol mixtures with equation 10, k_w being identical in both cases. This same k_w predicted quite well the rates in a water–acetone mixture and a water–dioxane mixture where only *t*-butyl alcohol and no ether results. These facts caused Olson and Halford to conclude that the reaction between *t*-butyl chloride and water or alcohol is bimolecular and not unimolecular.

Olson and Halford neglected to analyze the product of the reaction to see whether the composition agreed with equation 11. Bateman, Hughes, and Ingold[13b] did this and found serious disagreement between observed compositions and those expected from equation 11. These authors felt that this was evidence in favor of the unimolecular (S_N1) mechanism; that is, they assume that solvent plays a significant role in the ionization of the halide but the product composition is given by the inaccessible rate constants for the reactions of R^+ with water or alcohol.

However, the failure of equation 11 to predict the composition of the product does not necessarily indicate that the unimolecular mechanism is the correct one. Alternative explanations are that the solvolysis is not bimolecular but of a higher order or that a fugacity equation such as equation 10 is not applicable. While full justification for the use of fugacity rate expressions is still lacking, nevertheless the suggestion that fugacities should be used instead of concentrations for treating rates in binary solvents where association and solvation occur seems a sensible one. The validity of the use of fugacity rate expressions is assumed in the following discussion.

I have found that equation 12

$$k_m = (k_{w^2} p_w^2 + k_{wa} p_w p_a + k_{a^2} p_a^2)\,(p/N)_{RCl} \quad (12)$$

corresponding to the reaction of tertiary butyl chloride with two solvent molecules, fits the data of Olson and Halford[3] and Hughes[13] as well as equation 10. Here $k_{w^2} p_w^2$ is the term representing reaction involving two water molecules and giving rise to *t*-butyl alcohol, $k_{wa} p_w p_a$ is the term representing reaction with one water molecule and one alcohol molecule and giving rise to either *t*-butyl alcohol or *t*-butyl alkyl ether, and $k_{a^2} p_a^2$ is the term representing reaction with two alcohol molecules and giving rise to ether. The value of k_{w^2} was determined from the data on the water–acetone mixture and the water–dioxane mixture as is shown in Table I, that of k_{a^2} from

TABLE I

DETERMINATION OF k_w FROM DATA ON THE HYDROLYSIS OF *t*-BUTYL CHLORIDE IN ACETONE–WATER AND DIOXANE–WATER MIXTURES[3]

Solvent	Acetone–H_2O	Dioxane–H_2O	Mean
Mole % H_2O	50.3	83.2	
p_w (mm.)	17.8	19.7	
k_m	6.90×10^{-3}	644×10^{-3}	
$(p/N)_{RCl}$ (mm.)	1.65×10^3	96.5×10^3	
$k_{w^2} \times 10^8$	1.319	1.719	1.519
$k_{w^3} \times 10^{10}$	7.41	8.73	8.07
$k_{w^4} \times 10^{11}$	4.16	4.43	4.30

the rate in pure methyl or ethyl alcohol, and that of k_{wa} from the rate in the alcohol solution containing the most water. Tables II and III give a comparison between observed values of k_m and those calculated by Olson and Halford from equation 10 and by the author from equation 12. Values in parentheses are those used in obtaining the constants (k_{wa}, etc.). It is evident that equation 12 fits the data fully as well as equation 10.

In the case of the data in methyl alcohol–water mixtures still another fugacity equation was tried.

$$k_m = (k_{w^3} p_w^3 + k_{w^2 a} p_w^2 p_a + k_{w a^2} p_w p_a^2 + k_{a^3} p_a^3)\,(p/N)_{RCl} \quad (13)$$

It was found that equation 13 fits the data just as well as equation 10 or 12. Equation 13 represents the reaction of *t*-butyl chloride with three solvent molecules, all of water, all of alcohol, or some of each. The value of k_{w^3} was determined from the data on the water–acetone mixture and the water–dioxane mixture as is shown in Table I, and the other constants were evaluated as described for equation 12. Table II lists the values of k_m calculated from equation 13; it is obvious that the equation represents k_m satisfactorily.

Whereas the product compositions were not well predicted by equations 10 and 11, treatment of the data with the aid of equations 12 and 13 leads to satisfactory agreement between predicted and obtained product compositions if one makes reasonable assumptions regarding the terms which lead to a mixture of products. Thus, in the case of equation 12, P_A in the methyl alcohol study is given satisfactorily by equation 14 and

$$P_A = (100/k_m)(k_{w^2} p_w^2 + 0.11\, k_{wa} p_w p_a)\,(p/N)_{RCl} \quad (14)$$

in the ethyl alcohol study by equation 15. On

$$P_A = (100/k_m)(k_{w^2} p_w^2 + 0.01\, k_{wa} p_w p_a)\,(p/N)_{RCl} \quad (15)$$

treating the methyl alcohol–water data with equation 13, it turns out that product compositions are given satisfactorily by equation 16.

$$P_A = (100/k_m)(k_{w^3}p_w^3 + 0.61k_{w^2a}\,p_w^2p_a + 0.01\,k_{wa^2}p_wp_a^2)\,(p/N)_{RCl} \quad (16)$$

The comparison between observed[14] values of P_A and those predicted by equations 11, 14, 15 and 16 is shown in Table IV. It is clear that equations 14, 15, and 16 are satisfactory and equation 11 is not.

Thus, if one assumes the validity of rate equations based on fugacities, one obtains evidence that the solvolysis of *t*-butyl chloride in water–alcohol mixtures involves two or more solvent molecules. It is apparent that the data available do not permit a more definite statement to be made; any treatment involving two or more solvent molecules is satisfactory.

(14) In writing down the values of P_A (observed) in Table IV it is necessary to take into account the small amount of olefin produced[13b] in the reaction. In the case of the methyl alcohol–water data Dr. P. D. Bartlett has pointed out to the author that the amount of olefin is proportional to the amount of ether in the reaction product and therefore that the olefin is to be regarded as ether which has been sidetracked. In the case of the ethyl alcohol–water data it would appear that the olefin arises from the sidetracking of both ether and alcohol. A reasonable assumption appears to be that the amount of ether which has been sidetracked amounts to about 40% of the observed ether.

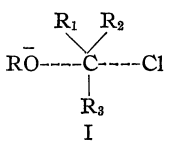
The Polymolecular Mechanism.—Hammett and co-workers already have proposed,[2] in connection with solvolyses of benzhydryl chloride

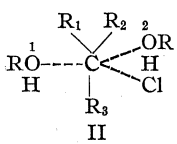
and α-phenylethyl chloride, that solvolytic reaction is a polymolecular one and takes place within a solvation complex. These workers noted that small amounts of water catalyze the alcoholysis of benzhydryl chloride linearly without diverting very much material to benzhydrol, and, also, that small amounts of hydroxylic solvent in acetone are ineffective in hydrolyzing or alcoholyzing benzhydryl chloride. Bateman, Hughes, and Ingold[15] have noted recently that the benzhydryl chloride data of Farinacci and Hammett cannot be treated by equations 10 (but assuming $(p/N)_{RCl}$ is constant) and 11 to predict product compositions and have felt again that the ionic mechanism is indicated. The situation here is similar to that for *t*-butyl chloride. Actually, the data in the case of benzhydryl chloride cover only a narrow range of solvent composition and Henry's law constants for the halide are unknown, so further calculations with vapor pressure rate equations cannot be carried out.

The author agrees essentially with Hammett and co-workers[2] concerning the nature of solvolytic reactions of halides and feels that the difference in steric results obtained from solvolytic reactions and from bimolecular exchanges[8] can be discussed as is done below.

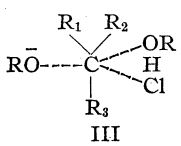
In the case of an ordinary bimolecular substitution of RO^- for Cl^- a transition state[5] such as I is imagined. RO^- is oriented away from the chlorine and clean-cut inversion is the result of reaction through transition state I.



I



II

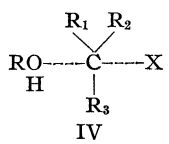


III

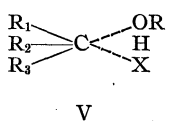
In the case of a solvolytic reaction, let us for the sake of convenience write only two solvent molecules into the transition state II, one in back of the carbon–chlorine dipole and one, due to the tendency toward hydrogen-bond formation to the halogen, on the same side as the chlorine. Products can be obtained from II in two ways, either with inversion, if solvent molecule 1 becomes bonded to the central carbon atom and solvent molecule 2 leaves as part of the solvation sphere of the chloride ion, or with retention of configuration, if solvent molecule 2 becomes bonded to the central carbon atom. From the usual steric results of solvolytic reactions of halides, we would say that solvent molecule 2 competes more or less successfully with solvent molecule 1 for electron donation to the central carbon atom, the predominating process being the one in which solvent molecule 2 leaves as part of the solvation sphere of the chloride ion with solvent molecule 1 becoming bonded to the central carbon atom.

It might be argued that transition state I is an oversimplification and that transition state III should be considered when RO^- replaces a chlorine atom. We see, however, that a solvent molecule would have little success in competition with a negative ion in the same transition state, since a negative ion is a much better electron donator than a solvent molecule. Thus, with reaction going through transition state III we would still expect clean-cut inversion, the solvent molecule always leaving as part of the solvation sphere of the chloride ion.

When a solvolytic reaction is carried out in an inert solvent containing smaller and smaller concentrations of hydroxylic compound, a bimolecular mechanism should be reached. Transition states of the type IV and V seem possible. If the



IV



V

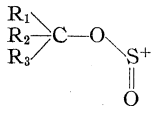
solvent can aid in removing halide ion mechanism IV with inversion is possible. Mechanism V[16] with retention of configuration is possible even when the solvent cannot aid in removing halide ion. Actually, the hydrolysis of *t*-butyl bromide seems to approach a bimolecular mechanism at very low concentrations of water in acetone.[4] More work in this direction and the investigation of the steric result of reactions of this sort under conditions where the mechanism is definitely second-order would serve to yield information about the relative extent of operation of mechanisms IV and V.

Other First-Order Reactions of Halides.—In other first-order reactions of halides more detailed attention should be given to the role of sol-

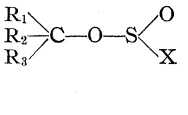
(15) Bateman, Hughes and Ingold, THIS JOURNAL, **60**, 3080 (1938).

(16) Mechanism V has been suggested by Taylor, *J. Chem. Soc.*, 1962 (1937), and is similar to some suggested in other connections.[5]

vent. For example, the conductivity of halides in sulfur dioxide,[17] and the first-order reactions in sulfur dioxide[13b,18] are explained by ionization of the halide. It might be better to remark that sulfur dioxide is a reactant forming a cation–sulfur dioxide ion[19] VI and halide ion, the ion VI undergoing racemization or reaction with reagents.



VI



VII

One recognizes VI as the product obtained by reaction of thionyl halide with one molecule of alcohol and ionization of the remaining halogen atom from the intermediate ester VII. VI can presumably give VII by reaction with halide ion. VII can presumably give halide and sulfur dioxide with or without inversion.[5] In the formation of VI inversion or retention may be the steric result. Thus, only after careful scrutiny of the role of the solvent, sulfur dioxide, may one hope to understand the steric results of reactions in this solvent.

The author acknowledges with pleasure the help and advice of Dr. Linus Pauling in connection with the ideas presented in this paper and in the preparation of the manuscript.

Summary

A recalculation of the data on the solvolysis of *t*-butyl chloride in alcohol–water mixtures using fugacity rate equations of the type suggested by Olson and Halford shows that the rates and product compositions can be explained assuming that the reaction between *t*-butyl chloride and solvent involves two or more solvent molecules.

The ionic mechanism of Ingold and collaborators for the first-order solvolytic reaction of halides and the explanation of the usual steric result of these reactions on the basis of shielding of the carbonium ion by the ionizing halogen atom is rejected in favor of an interpretation which regards the solvent as a reactant.

The author agrees essentially with Hammett and co-workers on a polymolecular interpretation for solvolytic reactions of halides. The difference in steric results obtained in solvolytic reactions and in exchanges involving attack by negative ions is discussed from the standpoint of possible transition states and competition between different solvent molecules or between a solvent molecule and a negative ion in the transition state.

Investigations on the Stereoisomerism of Unsaturated Compounds. IV. The Identification of *cis-trans* Isomers by Rate Studies[1]

BY WILLIAM G. YOUNG, DAVID PRESSMAN AND CHARLES D. CORYELL[2]

Introduction.—The determination of the configuration of *cis-trans* isomers of the ethylene type is a difficult problem in spite of the many modes of approach which have been suggested. None of the generally accepted[3] chemical methods of identification such as ring opening or ring formation, are applicable in all cases and the most reliable physical methods require special equipment which is not available in most laboratories. Consequently, it is particularly desirable to develop chemical methods of establishing the configuration of *cis–trans* isomers which can be applied easily and which will give dependable results.

A study of the rates of reaction of the stereoisomeric ethylene dibromides with potassium iodide in 99% methanol was the most promising method considered. The reaction[4] involved is

$$RCHBrCHBrR' + 3I^- \rightarrow RCH{=}CHR' + I_3^- + 2Br^- \quad (1)$$

for which the rate is first order with respect to

both the dibromide and iodide concentrations. It has been shown in the case of two pairs of stereoisomers, fumaric and maleic acids,[5] and *cis*- and *trans*-2-butenes,[6] that the *meso* dibromides (from the *trans* compounds) react more rapidly than the corresponding *d,l*-dibromides (from the *cis* compounds). It is the purpose of this paper to present the experimental results obtained with the dibromides of several more pairs of geometrical stereoisomers in which two hydrogen atoms are adjacent to the double bond, and the other two groups are identical or similar. In every case the dibromide from the *trans* isomer had the larger second-order specific reaction rate constant both at 75° and 60°, and the smaller Arrhenius heat of activation.

Nomenclature.—A convenient nomenclature has been adopted for this work which emphasizes the relationship between the parent unsaturated compound and the product of normal bromine addition (*trans* addition) by naming the product as the dibromide of the parent compound. This nomenclature is especially useful in referring to dibromides of unsymmetrical stereoisomers. *cis*- and *trans*-2-pentenes both give racemic mixtures of 2,3-dibromopentanes which are different from each other. The names *trans*- and *cis*-2-pentene dibromide clearly show this difference by referring to the structure of the parent compound.

Experimental Procedure

Measurement of Reaction Rates

Technique.—The following procedure was used to follow the rate of reaction of the various dibromides with potassium iodide: a solution containing the dibromide, approx. 0.025 molal, and potassium iodide, approx. 0.25 molal, in 99% methanol was prepared at 20°. Eight or ten 20.00-ml. aliquot portions of this solution were then sealed in test-tubes and placed in a thermostat at 75 or 60°. For any given run the temperature was constant to within 0.03°. Tubes were removed at measured intervals and quenched in ice water, broken in an acidified aqueous solution of potassium iodide, and titrated for iodine with 0.015 *N* sodium thiosulfate solution.

Due to the very slight solubility of the *trans*-stilbene dibromide in methanol, it was necessary to use acetone to make a comparison of the isomeric stilbene dibromides. The *trans*-dibromide, 0.003 *M*, liberated iodine from sodium iodide, 0.125 *M*, at an appreciable rate at room temperature and had reacted completely in eighteen hours, whereas the *cis*-dibromide under the same conditions liberated only 5% of the theoretical quantity in eighteen hours.

Calculation of the Rate Constants.—An analysis of equation (1) for the reaction first order with respect to both dibromide and iodide concentrations leads to the following equation connecting initial iodide concentration a, initial dibromide concentration b, fraction φ of the dibromide consumed, and t, time in hours

$$\mathrm{d}\log_{10}\frac{1-3b\varphi/a}{1-\varphi}\Big/\mathrm{d}t=\frac{a-3b}{2.303}k_{\mathrm{obsd.}} \qquad (2)$$

Values of $\log_{10}(1-(3b\varphi/a)/(1-\varphi)$ corresponding to the various samples of a run were plotted as ordinates against the corresponding values of time t, and the best straight line was drawn through the points. The slope of this line was multiplied by the value of $2.303/(a-3b)$ for the run to give $k_{\mathrm{obsd.}}$. This method does not give undue weight to the first analysis made, and the value of k is not affected by the small time necessary to bring the solution to temperature, which would lead to a small positive intercept on the abscissa axis.

As a matter of fact, the best straight lines for many runs did not pass through the origin, but formed small positive intercepts on the ordinate axis. For a given compound, the intercepts for different runs were nearly the same regardless of temperature. Figure 1 is a plot of two runs with *cis*-3-hexene dibromide at 74.90°, which are selected as representative cases showing clearly the existence of the intercept. In a few cases the value of the intercept was uncertain because the measurements had been made within a time interval which was shorter than that used in most runs. In those cases the average intercept obtained with the other runs on the same compound was assumed and the best line was drawn through the points to this assumed intercept. This pro-

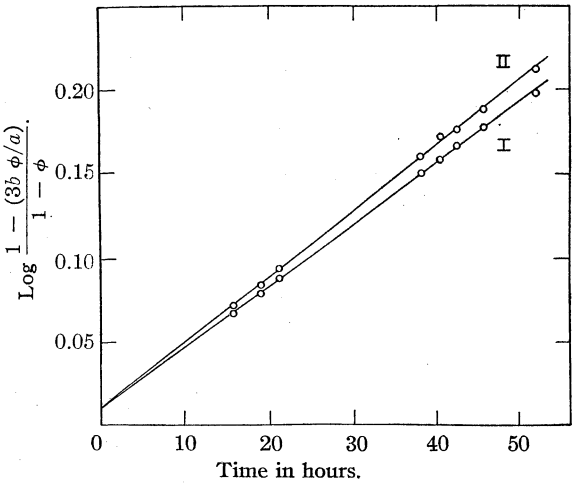

Fig. 1.—Treatment of the runs with *cis*-3-hexene dibromide at 74.90°.

[a] Natural methanol, rates 7% lower than synthetic methanol I (the standard for this work). [b] Synthetic methanol II, rates 2% lower than on methanol I. [c] Synthetic methanol III, rates same as methanol I. [d] The constants have been corrected for reactivity of solvent, solvent expansion and to the temperatures 75.00 or 60.00°. [e] These calculations were made using the data reported by Dillon;[4] correction has not been made for potassium iodide effect.

cedure gave satisfactory agreement with rate constants calculated from the runs made over longer time intervals. Table I presents the data for all runs made on the compounds to be discussed in this paper. Column 2 lists $k_{obsd.}$ while column 6 lists the intercepts found, with parentheses enclosing assumed values.

In most of the previous work in this field an integrated form of a rate equation has been used. The existence of an ordinate intercept such as was frequently found in this study would lead to calculated constants exhibiting a tendency to fall off. This behavior has been observed by Davis and Heggie,[7] who report that propene dibromide and 1-pentene dibromide give steadily decreasing constants. The data presented by Dillon, Young and Lucas[6] and Dillon[4] gave no evidence of drift in constants.

The intercepts obtained when the data are treated by our method and the drifts obtained by use of an integrated equation may be accounted for chemically on the assumption that with some compounds the reaction starts out abnormally fast

(7) Davis and Heggie, *J. Org. Chem.*, **2**, 470 (1937).

as though catalyzed but very soon becomes normal through destruction of the catalyst. In rare cases this initial liberation of iodine was observable during operations at room temperature.

Effect of Solvent on the Rate Constants.—Due to the fact that the different preparations of 99% methanol exhibited slightly different rates for the same compound, all of the rates involving methanol preparations were corrected to the value they would have exhibited in the first preparation of methanol used in this set of experiments. This was accomplished by comparing the rate constant of a standard substance, some of the original preparation of 1-butene dibromide used by Dillon, Young and Lucas,[6] in the three different solvent preparations used in this work, as suggested by Young and Winstein.[8] The first and third preparations gave identical rate constants while the second preparation gave a rate constant 2% smaller. Accordingly, all of the rate constants determined in solvent II were increased by 2% to afford a comparison with those determined in solvents I and II (see references to column 2, Table I).

Correction of Rate Constants to Standard Temperature.—Since different reactions were studied at slightly different temperatures in the neighborhood of 75.00 and 60.00°, all of the rate constants were corrected to correspond to those temperatures by the use of the experimentally determined temperature coefficients calculated for each compound.

Correction of Rate Constant for Solvent Expansion.—A positive error is made in volume concentrations of substances in methanol at temperatures above 20° due to the thermal expansion of the solvent between the temperature at which the tubes are made up and the temperatures at which the reaction rate is followed. Because the rate constant for a second order reaction has units reciprocal in concentration and time, there is introduced a negative error in the directly calculated values of the rate constant with increasing temperature due to the use of the 20° volume concentrations. Hence a small negative error in the apparent temperature coefficient of the rate constant is introduced. In order to correct for this error the constants at 60° were increased by 4.8% and those at 75° were increased by 6.8% in accord with the measurements[9] on the density of methanol at 20, 60 and 75°. The rate constants corrected for effect of solvent, temperature and alcohol expansion are listed in Table I, column 7.

Correction of Rate Constant for Salt Effect.—Although the reproducibility of the constants listed in column 7 of Table I was fairly satisfactory, there were a few isolated cases with unexpectedly large percentage deviations, in which a high constant seemed to be correlated with high potassium iodide concentration. The data of all pairs of runs in which the iodide concentrations differed by 0.03 *M* or greater are presented in Table II. Column 2 gives the constants from col. 7, Table I, while col. 3 lists the corresponding iodide concentrations. Column 4 shows the percentage increase in the constant associated with the increase in molality of potassium iodide listed in col. 5. Column 6 gives the percentage increase in the constant per mole increase in iodide concentration for each compound, assuming a linear relation between the constant and the iodide concentration. The average increase is 57 ± 6% regardless of the compound or temperature. We have deemed it advisable to correct all of the constants of Table I to a constant iodide concentration (0.25 *M*) before calculating heats of activation (col. 8). These pairs of constants show an average average deviation of 0.55% and a maximum average deviation of 1.3%.

TABLE II

THE EFFECT OF SALT CONCENTRATION ON THE RATE CONSTANTS

Dibromide	*k* corr.	Molal concn. of KI	$\frac{100\,\Delta k}{\text{av. } k}$	Δ KI	$\frac{100\,\Delta k}{k\,\Delta \text{KI}}$

[a] Although the study of the *cis*- and *trans*-crotonic acid dibromides is not included in this paper, these data on the *trans* isomer are given to show the consistency of the salt effect with different types of dibromides.

Preparation of Materials

All dibromides used contained the correct percentage of bromine as shown by Carius analyses.

(8) Young and Winstein, THIS JOURNAL, **58**, 102 (1936).

(9) Landolt–Börnstein, "Tabellen," Verlag von Julius Springer, Berlin, 1923, Vol. I, p. 278.

cis- and trans-2-Pentene Dibromides.—These compounds were kindly supplied by Professor H. J. Lucas[10] of the California Institute of Technology.

cis- and trans-3-Hexene Dibromides.—These compounds were prepared by the action of hydrobromic acid on the diacetates of the *meso*-and *d,l*-diethyl glycols.[11] The physical properties of the *cis*-3-hexene dibromide (*d,l*) were b. p. (9 mm.) 80.4–80.6°, d^{25}_4 1.5896, $n^{25}D$ 1.5031, and those of the *trans*-3-hexene dibromide (*meso*) were, b. p. (9 mm.) 79.0–79.2°, d^{25}_4 1.5940, $n^{25}D$ 1.5048.

cis- and trans-4-Octene Dibromides.—The dibromide of *cis*-4-octene was synthesized by Mr. Zene Jasaitis by the action of hydrobromic acid on *meso*-dipropylglycol diacetate[12]: b. p. (4 mm.) 84.0–84.5°, $n^{20}D$ 1.4981, d^{20}_4 1.4569.

trans-4-Octene dibromide was obtained from a mixture of 4,4-dibromooctane and *meso*-3,4-dibromooctane which had been prepared by Mr. Leo Levanas from the racemic dipropylglycol and hydrogen bromide in the presence of zinc bromide.[12] The dibromide mixture was converted into a mixture of octane and *trans*-4-octene by reduction with zinc in alcohol. The hydrocarbon mixture, freed from alcohol, came over through a 30-cm. column of glass helices, at 119–120.3°. This distillate was treated dropwise with bromine at 0°, and the product washed with sodium bisulfite solution and with sodium bicarbonate solution and dried with calcium chloride. Fractionation through a Weston column yielded *n*-octane and a constant-boiling *trans*-4-octene dibromide, b. p. (8 mm.) 103°, $n^{25}D$ 1.4965.

cis- and trans-Stilbene Dibromides.—A mixture of the *cis*- and *trans*-stilbene dibromides was prepared by the action of bromine on freshly distilled stilbene in carbon disulfide in the dark at 0°.[13] The *trans*-stilbene dibromide which separated out was recrystallized twice from benzene, and dried over paraffin in a vacuum. The crystals melted with decomposition at 230–237° (reported m. p. 237°). The *cis*-stilbene dibromide was obtained from the carbon disulfide mother liquor by evaporating the solvent. The residual solid was twice recrystallized from ethanol, yielding a product melting at 109.5–111° (reported m. p. 110°).

Fumaric and Maleic Acid Dibromides.—Fumaric acid was brominated in the presence of water at 100° and the product[14] melted at 270–273° after two recrystallizations from water.

Maleic anhydride and bromine were refluxed at 60–70° for two hours. The colorless reaction mixture was warmed with water, the crystals of fumaric acid dibromide were removed by filtration and the filtrate was concentrated. The first crop of crystals, m. p. 160–162°, was discarded but the second crop which formed after several weeks at room temperature (m. p. 164–167°, reported m. p. 166–167°)[15] was used in this work.

Discussion of Results.—The specific reaction rate constants and the Arrhenius heats of activation for the reactions of the dibromides of several pairs of *cis–trans* isomers with potassium iodide in 99% methanol are listed in cols. 9 and 11 of Table I. In these cases in which the parent unsaturated compounds have two hydrogen atoms adjacent to the double bond and the other two groups are identical or similar the dibromide from the *trans* compound gives a greater rate constant and a smaller heat of activation than the dibromide from the *cis* isomer.[16] It would appear that rate studies of this character offer a valuable method of identifying the isomers of alkene hydrocarbons which cannot be identified readily by the usual methods applied when carboxyl, amino, hydroxyl, etc., groups are present in the molecule. Until data to the contrary are obtained, therefore, it will be assumed that rate constants alone are sufficient for identifying the dibromides from *cis–trans* isomers of the type herein reported. Work on other types of stereoisomeric dibromides now in process should make it possible to establish generalizations regarding the effect of radicals on the rate constants and heats of activation.

The authors are indebted to Professor H. J. Lucas for his generosity in furnishing the *cis*- and *trans*-2-pentenes.

Summary

The reaction of potassium iodide with several pairs of stereoisomeric alkene dibromides in 99% methanol has been investigated at 75 and 60°. A qualitative comparison of *trans*- and *cis*-stilbene dibromides in acetone indicated that the *trans* derivative reacted over a hundred times as rapidly as the *cis* derivative.

In five cases where quantitative comparisons have been made the dibromide from the *trans* parent compound of the type RHC=CHR′ gave a larger rate constant and smaller heat of activation than the dibromide of the *cis* parent compound. The groups R and R′ were identical or similar. Rate studies of this type have been suggested as a means of identifying *cis–trans* isomers.

(16) Although Davis and Heggie[7] have pointed out that a reversal of the relative magnitude of rate constants might be observed when the reaction is carried out at different temperatures, it should be noted that the compounds which they cite, the dibromides of ethyl acrylate and maleic acid, do not possess a similarity in structure comparable to that of the stereoisomeric pairs reported in this paper. A study of the action coefficients for these and other reactions which is now almost complete will indicate whether such reversals are ever likely when dealing with stereoisomeric pairs.

Investigations on the Stereoisomerism of Unsaturated Compounds. V. A Mechanism for the Formation of Butenes from 2,3-Dibromobutanes by the Action of Iodide Ion

BY SAUL WINSTEIN, DAVID PRESSMAN AND WILLIAM G. YOUNG

The reaction of 1,2-dihalides with inorganic iodides to yield unsaturated compounds has been studied from a kinetic standpoint[1] and has been recommended as a method for synthesis of ethylenic compounds.[2] In spite of the considerable attention paid the reaction, the steric result of the elimination of halogen by iodide ion has remained uncertain[1d] until the present time. The question as to whether bromine is eliminated *trans* or *cis* to give pure products or by both of these processes to give a mixed product is of importance from the theoretical standpoint in formulating a mechanism for the reaction and from a practical standpoint for deciding the applicability of the reaction to syntheses of stereoisomeric olefin derivatives. It is the purpose of this paper to show that the removal of bromine from 2,3-dibromobutanes by iodide ion involves almost entirely *trans* elimination at moderate temperatures and that at a higher temperature considerable rearrangement accompanies the reaction. The mechanism of the reaction is discussed on the basis of the experiments presented here and of the previous kinetic results.

The nature of the elimination of bromine from 2,3-dibromobutanes by iodide was investigated by treating pure 2,3-dibromobutanes or a mixture of them with iodide ion either in aqueous propanol at approximately 95° or in diethylene glycol at approximately 200°. The generated butenes were converted to dibromobutanes and analyzed be measuring the rate of reaction of the final dibromide with potassium iodide in methyl alcohol.[1e,3] Table I summarizes the results obtained. Inspection of the table discloses that in propyl alcohol at the lower temperature *meso*-2,3-dibromobutane gives rise to a butene which is 96% *trans*, and *dl*-2,3-dibromobutane gives a butene which is 91% *cis*. Also the ratio of isomers in a mixed dibromide is essentially unchanged by the successive elimination and addition of bromine. These results show that *trans* elimination is by far the predominating reaction. However, in diethylene glycol at the higher temperature *dl*-2,3-dibromobutane gives a butene mixture showing that considerable rearrangement occurs, but even here the elimination is largely *trans*. The small changes in composition of the dibromides at the lower temperature and the considerable change at the higher temperature may be due to the isomerizing effect of the iodine on the butenes[4] or possibly the participation of a mechanism other than the predominating one.

The Mechanism of the Reaction.—The facts that: (a) the elimination of halogen from 1,2-diiodoethane, 1-bromo-2-iodoethane, and 1,2-dibromides, in general, is first order with respect to the dihalide and iodide ion concentrations[1]; (b) elimination of halogen is induced by reducing agents such as iodide ion or zinc; and (c) the elimination of bromine by iodide ion is *trans* suggest a general mechanism (equations (1), (2) and (3)) for the elimination of iodide ion which is in part the reverse of Ogg's[5] negative mechanism for the addition of halogen to the ethylenic linkage.

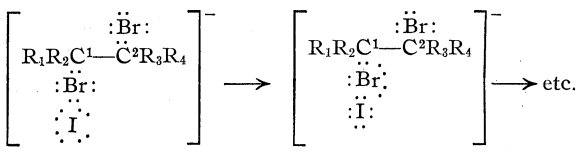
4	.0298	100	0	$C_4H_{10}O_3$	200	.0394	64	36

trons[6] to one of the bromine atoms of the dibromide giving iodine bromide and the intermediate, $R_1R_2C^-$—$CBrR_3R_4$. The unshared pair of electrons on carbon atom 1 then rapidly attacks the carbon face opposite the remaining bromine atom, freeing bromide ion with inversion of carbon atom C^2. A double bond has thus been formed between carbon atoms C^1 and C^2 and the whole process is then a *trans* elimination of bromine. The iodine bromide formulated as a product immediately reacts with iodide ions to give triiodide and bromide ions.



I

It is thought that the life of the $R_1R_2C^-$—$CBrR_3R_4$ intermediate is exceedingly short, because otherwise reaction with solvent and racemization[7] about carbon atom C^1 would be serious. The decomposition of $R_1R_2C^-$—$CBrR_3R_4$ is thought to occur essentially simultaneously with the breaking of the C—Br bond of carbon atom C^1. Thus, we have here a process quite analogous to the usual bimolecular exchange leading to Walden inversion.[8] In the usual bimolecular exchange involving a negative ion, this ion presents a pair of electrons to an atom, another substituent being expelled with a pair of electrons previously shared. In our process an electron transfer has been brought about but through a longer chain of atoms.

Figure 1 depicts the structure of the 1,2-dibromide as being one with the two bromine atoms *trans* to each other, enabling the electron transfer discussed above to take place. The *trans* configuration with respect to the two bromine atoms is reasonable because this structure may be essentially the normal state of affairs in dihalides[9] or it may tend to be assumed on the approach of the iodide ion.

One might have assumed that the first step in the reaction of iodide ion with a dihalide is a bimolecular exchange of iodide for bromide (with inversion of the carbon atom concerned) with subsequent rapid reaction of the iodobromide. But then for the reaction of the iodobromide with iodide ion only a mechanism such as that proposed by us seems plausible. Thus a total of two Walden inversions would be present in the process and *cis* elimination instead of *trans* elimination would be its result. We feel, therefore, that exchange of iodide for bromide is at most only a subsidiary reaction at low temperatures, but that it may explain part of the deviations from clean-cut *trans* elimination of bromine by iodide ion.

Experimental

Preparation of *meso*-2,3-Dibromobutane.—*trans*-2-Butene was prepared by a modification of the method of Wislicenus, Talbot, Henze and Schmidt[10] in which tiglic acid hydrobromide instead of tiglic acid hydriodide[11] was used.

A solution of 70 g. (0.66 mole) of sodium carbonate in 700 ml. of water was cooled to 0° and added to 60 g. (0.33 mole) of tiglic acid hydrobromide in a flask equipped with a mercury-sealed stirrer and a gas delivery tube. The mixture was warmed slowly. At 30° a slow evolution of gas began. The gas was washed with sodium hydroxide solution, dried with anhydrous calcium chloride and condensed in an ampoule cooled with a solid carbon dioxide–alcohol bath. The temperature of the reaction mixture was raised to 70° over a period of two and one-half hours. The gas evolved at this temperature was soluble in sodium hydroxide and presumably was carbon dioxide. The yield of olefin was 80%. When the reaction was completed in one and one-half hours only 65% yield was obtained. The butene was converted to dibromide by the method previously described.[11]

The tiglic acid hydrobromide was prepared by Mr. Zene Jasaitis by the action of dry hydrogen bromide on a solution of tiglic acid in chloroform.

(6) Professor Linus Pauling has suggested to one of us that perhaps a complex ion, I, is formed which then undergoes the electron transfer to be outlined.

Preparation of *dl*-2,3-Dibromobutane.—*dl*-2,3-Dibromobutane was prepared from *meso*-2,3-butanediol by the synthesis outlined by Wilson and Lucas.[12]

Reaction of 2,3-Dibromobutanes with Sodium Iodide in Propanol.—Seventy grams (0.46 mole) of sodium iodide was dissolved in a warm mixture of 75 ml. of *n*-propanol and 25 ml. of water. Then 20 g. (0.093 mole) of 2,3-dibromobutane was added. Two liquid phases were present initially but a homogeneous solution resulted upon further heating. The mixture was refluxed gently, the evolved gas being washed with water, dried with calcium chloride and collected in a cold ampoule at −78°. In the reaction flask, iodine was liberated and a white precipitate of sodium bromide formed. After four hours of refluxing, the rate of butene evolution was slow and the reaction was stopped, the apparatus being flushed out with air. The crude yield of hydrocarbon was 87% of the theoretical from *meso*-2,3-dibromobutane, 80% from *dl*-2,3-dibromobutane and 81% from a mixed dibromobutane.

Reaction of 2,3-Dibromobutane with Potassium Iodide in Diethylene Glycol.—Forty grams (0.185 mole) of *dl*-dibromobutane was added dropwise to a hot solution of 80 g. (0.48 mole) of potassium iodide in 300 g. of diethylene glycol. The butene which was evolved continuously during the course of the reaction was washed with a dilute sodium hydroxide solution and dried over anhydrous calcium chloride before being condensed in an ampoule. The temperature of the reaction mixture started at 245° and gradually dropped to 165° at the finish. The yield of butene was 85%.

Analysis of Butene Mixtures.—The butene mixtures were analyzed according to the method previously outlined.[1e] The second order reaction rate constants of the original and final dibromobutanes with potassium iodide in 99% methanol are listed in Table I together with the corresponding compositions of butenes which they represent.

(12) Wilson and Lucas, THIS JOURNAL, **58**, 2396 (1936).

Summary

The elimination of bromine from *dl*- and *meso*-2,3-dibromobutanes by iodide ion has been found to be an almost complete *trans* removal of halogen at moderate temperatures. A mechanism for the process has been proposed. It is thought that iodide ion removes a positive bromine atom and essentially simultaneously with this removal the electron pair which is left unshared by this removal attacks the carbon face opposite the remaining bromine atom forming a double bond and liberating bromide ion.

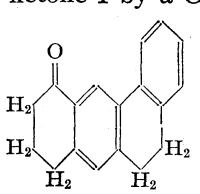
Syntheses in the 1,2-Benzanthracene and Chrysene Series

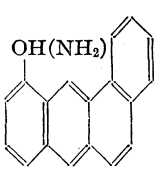
BY LOUIS F. FIESER AND WILLIAM S. JOHNSON[1]

Having developed a satisfactory method for the synthesis of pure 8-methyl-1,2-benzanthracene[2] from the keto acid resulting in nearly quantitative yield from the succinoylation of 9,10-dihydrophenanthrene,[3] we have utilized some of the same intermediates for the synthesis of certain other compounds which seemed of interest to the problem of hydrocarbon carcinogenesis.

8-Ethyl-1,2-benzanthracene was prepared from the ketone I by a Grignard reaction followed by



I



II (III, NH_2)

sulfur dehydrogenation of the low-melting but crystalline tetrahydride obtained on distillation of the resulting carbinol. Like the lower homolog,[2] the completely aromatized hydrocarbon shows a characteristic double melting point when pure. For the preparation of the phenol II, required for comparison with the weakly carcinogenic 3-isomer,[4] the dehydrogenation of 8-keto-hexahydrophenanthrene (I) by the method of Mosettig and Duval[5] using Adams catalyst in naphthalene solution was tried without success. 8-Hydroxy-1,2-benzanthracene, however, can be obtained satisfactorily by dehydrogenation with sulfur,[6] and the phenol was converted into the amine III by the Bucherer reaction.

In view of the enhancement of carcinogenic potency noted with certain combinations of *meso*- and α-methyl groups[4] (5,10-, 5,9-, 9,10-), it seemed important to obtain the di-α-substituted 5,8-dimethyl-1,2-benzanthracene (XII).

The introduction of a methyl group at a point corresponding to the 5-position was accomplished by the action of methylmagnesium iodide on methyl β-(9,10-dihydro-2-phenanthroyl)-propionate (IV). Haworth and co-workers[7] conducted similar reactions with the esters of a number of β-aroylpropionic acids and obtained from the acidic fractions unsaturated acids of the type indicated by formula V. While these acids were obtained in yields up to 50–75%, the neutral fractions apparently were not investigated. In an earlier paper Rupe and Steinbach[8] report the preparation of an unsaturated acid from ethyl β-(*p*-toluyl)-propionate in fair yield, and state, without giving details, that the neutral fraction contained a mixture of unchanged starting material and the ester of the unsaturated acid. They also describe the lactonization of the unsaturated acid with dilute mineral acid. In view of the high yields obtained in the methylation of *o*-aroylbenzoic acids by the procedure[9] of adding Grignard reagent in excess to a suspension of the free keto acid, this method was tried in the present case. When treated with a large excess of methylmagnesium bromide, however, the dihydrophenanthroylpropionic acid was converted largely into an unsaponifiable oil, and the result seemed so unpromising that we turned to the use of the ester. When the ester (IV) was treated with methylmagnesium iodide or bromide in only slight excess and the solution refluxed for about two hours the chief product (64%) was the unsaturated acid V. Material satisfactory for the reduction step but apparently consisting of a mixture of stereoisomers can be obtained easily on one crystallization (53% yield). When the Grignard reaction was moderated by operating at a lower temperature, the yield of the crude unsaturated acid V dropped to 32% and the neutral fraction afforded the corresponding lactone VI in 35% yield. The lactone was isolated from this source in a crystalline condition and it was also prepared by boiling the unsaturated acid with 10% sulfuric acid. By dissolving the lactone in hot alkali and carefully neutralizing the cooled solution the unstable γ-hydroxy acid VII was also isolated in a pure, crystalline condition.

A few attempts were made to reduce the lactone VI with zinc and alkali or by the Clemmen-

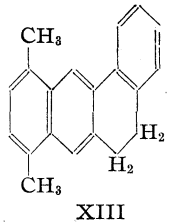
sen method, but the results were not promising. The easily obtainable unsaturated acid, however, can be hydrogenated smoothly in acetic acid solution to the γ-dihydrophenanthrylvaleric acid VIII. Cyclization to 5-methyl-8-keto-3,4,5,6,7,-8-hexahydro-1,2-benzanthracene (IX) was accomplished most satisfactorily by the action of liquid anhydrous hydrogen fluoride,[10] the pure material being obtained in 81.5% yield. An identical product was obtained in 64% yield by the PCl_5–$AlCl_3$ method in benzene. Cyclization in each case seems to occur exclusively in one direction, and that the product is a benzanthracene rather than a chrysene derivative was established by conversion of the ketone on Clemmensen reduction and dehydrogenation into a hydrocarbon identical with a sample of 5-methyl-1,2-benzanthracene (X) prepared by a different synthesis.[9]

5,8-Dimethyl-1,2-benzanthracene (XII) was prepared from the ketone IX by a Grignard reaction, dehydration of the carbinol, and dehydrogenation with sulfur. Purified through the picrate and by chromatographic adsorption, the dimethyl compound gave evidence from the melting point characteristics of the existence of two polymorphic forms, as noted for other compounds of the 8-series. The intermediate tetrahydride (XI) was not isolated. While the 8-methyl tetrahydride[2] was obtained crystalline in good yield, the oil resulting from the distillation of the carbinol of the 5,8-dimethyl series solidified only partially and the small amount of recrystallized product isolated had the composition of a dihydride. Of the possible structures that of 5,8-dimethyl-3,4-dihydro-1,2-benzanthracene (XIII) is clearly indicated by the



XIII

ultraviolet absorption spectrum (in absolute alcohol) kindly determined by Dr. R. Norman Jones. The curve (Fig. 1) is characteristic of an alkylated β-phenylnaphthalene and is practically identical with that for the similarly constituted 6,7-dihydromethylcholanthrene[11] (dotted line).

(10) Fieser and Hershberg, THIS JOURNAL, **61**, 1272 (1939).

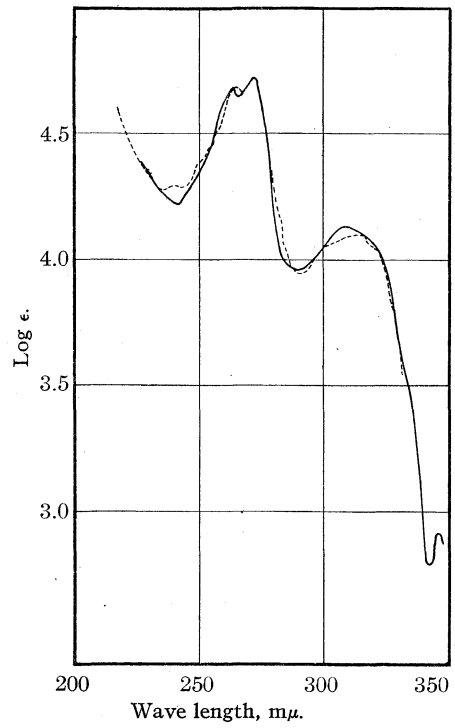

Fig. 1.—Solid line, 5,8-dimethyl-3,4-dihydro-1,2-benzanthracene; dotted line, 6,7-dihydro-20-methylcholanthrene.

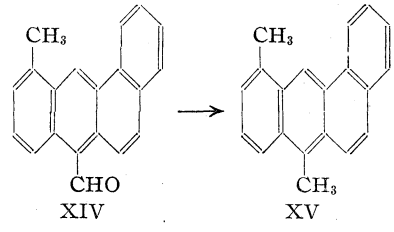
Another hydrocarbon of interest for the investigation of the combined influence of *meso*- and α-methyl groups was obtained by condensing 8-methyl-1,2-benzanthracene with methylformanilide and reducing the resulting aldehyde by the Wolff–Kishner method. The dimethyl com-



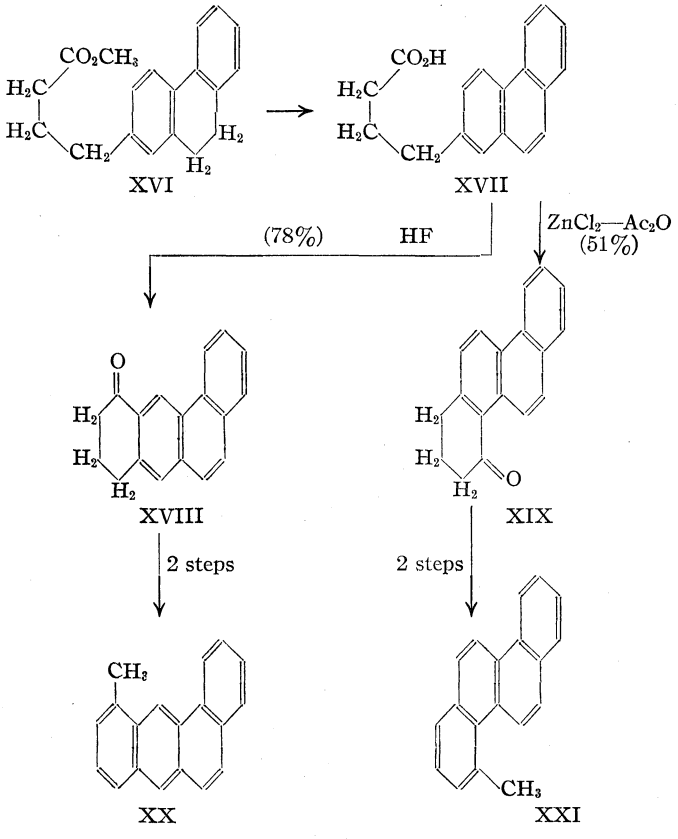
XIV XV

pound is different from the above 5,8-isomer and, since the aldehyde reaction is specific for structures of limited types and is known[12] to give the 10-derivative of 1,2-benzanthracene but to fail with 1,2,5,6-dibenzanthracene, the substance can be regarded with considerable assurance as 8,10-dimethyl-1,2-benzanthracene (XV). Some confirmation of the structure has been obtained by Dr. Jones in a study of the absorption spectra of this and related hydrocarbons which will be reported shortly. The introduction of a 10-methyl group is accompanied by a slight but definite dis-

(12) Fieser and Hartwell, *ibid.*, **60**, 2555 (1938).

placement of the most intense absorption band to longer wave lengths, specific to the *meso* positions.

The starting material for the above work served as well for the synthesis of 4-methylchrysene (XXI), required[13] as a possible model for the highly carcinogenic 3,4-benzpyrene. γ-(9,10-Dihydro-2-phenanthryl)-butyric acid (reduction of IV as acid) was dehydrogenated with sulfur in the form of the ester XVI giving, after saponification, γ-(2-phenanthryl)-butyric acid, XVII. Haworth and Mavin[14] previously prepared this acid from the less accessible 2-acetylphenanthrene and found that on cyclization with 85% sulfuric acid it yielded a mixture of isomeric ketones from which pure 4-keto-1,2,3,4-tetrahydrochrysene (XIX) was isolated in unspecified yield. Our experience was



much the same and the yield of pure XIX, m. p. 125°, was 23%. Ring closure by the hydrogen fluoride procedure[10] gave a high yield of total ketone which consisted almost entirely of the hitherto unknown isomer 8-keto-5,6,7,8-tetrahydro-1,2-benzanthracene (XVIII), m. p. 118°, which was obtained pure in 78% yield. For identification the ketone was converted to 8-methyl-1,2-benzanthracene through a crystalline dihydride. When the acid XVII was cyclized with zinc chloride[15] (0.65 equivalent) in acetic acid-anhydride the distilled and twice crystallized total ketone amounted to 51% and consisted of the pure chrysene derivative XIX. With the ketone available by this convenient process the synthesis of 4-methylchrysene, through a crystalline dihydride, was easily completed.

The sharp contrast in the direction of cyclization with hydrogen fluoride and with zinc chloride is quite striking and of obvious practical significance. The Friedel and Crafts procedure gave mixtures of the two ketones in which the benzanthracene derivative XVIII predominated. This isomer constituted about two-thirds of the total using benzene as the solvent, and a still higher proportion was produced in nitrobenzene solution. These results with γ-(2-phenanthryl)-butyric acid contrast with those reported for the cyclization of β-(2-phenanthryl)-butyric acid[16] and β-(2-phenanthryl)-propionic acid[17] in the Friedel and Crafts reaction and with stannic chloride, for these acids undergo ring closure exclusively at the 1-position.

Experimental Part[18]

8 - Ethyl - 3,4,5,6 - tetrahydro - 1,2 - benzanthracene.—An ethereal solution of 6 g. of 8-keto-3,4,5,6,7,8-hexahydro-1,2-benzanthracene[2] (I) was added with stirring to a cooled Grignard solution from 2 g. of magnesium and 7 g. of ethyl bromide. After refluxing for several hours the product was recovered as usual, heated to effect dehydration, and distilled, b. p. about 185° (1 mm.). The colorless oil (5.55 g., 88.5%) crystallized with difficulty in a solid carbon dioxide bath; a portion purified by several crystallizations from methanol formed large, elongated, highly fluorescent prisms, m. p. 65–67°.

Anal. Calcd. for $C_{20}H_{20}$: C, 92.26; H, 7.74. Found: C, 92.53; H, 7.63.

8-Ethyl-1,2-benzanthracene.—The distilled tetrahydride (1.33 g.) was dehydrogenated by heating with sulfur (0.33 g.) at 210–255° for twenty-five minutes. After very brief heating with a little zinc dust the product was distilled in vacuum, and after decolorizing the yellow oil in ether–alcohol picric acid (1.2 g.) was added. A dark red picrate separated on cooling (1.2 g., m. p. 148.5–149.5°) and an additional quantity (0.25 g.)

was obtained on concentration; total yield, 58.5%. Recrystallized from alcohol the picrate formed deep red blades, m. p. 149.5–150°.

Anal.[19] Calcd. for $C_{26}H_{19}O_7N_3$: N, 8.65. Found: N, 8.73.

The picrate (0.7 g.) was decomposed by passing a benzene solution through a tower of alumina; on adding alcohol to the concentrated filtrate the hydrocarbon crystallized in very faintly yellow, glistening needles, m. p. 82–83.5° (0.31 g., 84%). Recrystallization from petroleum ether gave a lower-melting form, m. p. 78–79°, which remelted after solidification at 82.5–83°.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.71; H, 6.29. Found: C, 93.51; H, 6.36.

8-Hydroxy-1,2-benzanthracene was prepared by heating the ketone I (2 g.) with 0.52 g. of sulfur at 230–255° for twenty-seven minutes and distilling the product at the oil pump vacuum. Crystallization from benzene–ligroin gave 1.1 g. of ringlets of small yellow needles, m. p. 138–148°; a second crystallization yielded 0.88 g. (45%) of product, m. p. 149–151°. The further purified phenol formed bright yellow rods, m. p. 151.3–151.8°.

Anal. Calcd. for $C_{18}H_{12}O$: C, 88.50; H, 4.95. Found: C, 88.55; H, 5.21.

The acetate, prepared using pyridine as catalyst, after three crystallizations from ligroin formed light buff colored needles, m. p. 133–133.6°.

Anal. Calcd. for $C_{20}H_{14}O_2$: C, 83.89; H, 4.93. Found: C, 83.86; H, 5.08.

8-Amino-1,2-benzanthracene.—A mixture of 0.5 g. of the hydroxy compound, 2.5 cc. of dioxane, 5 cc. of concentrated ammonia solution, and 2.5 g. of sodium bisulfite in 5 cc. of water was heated in a sealed tube at 190–200° for ten hours. The addition of dilute alkali precipitated a yellow oil which solidified on scratching. This crystallized from benzene–ligroin (Norite) in beautiful, long yellow needles (0.13 g., 26%), m. p. 201.7–202.3° dec. (no change on recrystallization).

Anal.[19] Calcd. for $C_{18}H_{13}N$: N, 5.76. Found: N, 5.49.

Methyl β-(9,10-Dihydro-2-phenanthroyl)-propionate (IV) was prepared by esterification of the keto acid (100 g.) in methanol (1400 cc.) saturated with hydrogen chloride. The ester was washed in ether with soda solution, dried, and distilled, b. p. about 250° (1–2 mm.). One crystallization from methanol gave 88 g. (84%), m. p. 76–78°. A recrystallized sample formed almost colorless prisms, m. p. 77–78°.

Anal. Calcd. for $C_{19}H_{18}O_3$: C, 77.53; H, 6.16. Found: C, 77.65; H, 6.28.

γ-Methyl-γ-(9,10-dihydro-2-phenanthryl)-vinylacetic Acid (V).—The reagent from 3.7 g. of magnesium and 22 g. of methyl iodide in 100 cc. of ether was added with cooling and stirring to a solution of 30 g. of the above ester IV in 500 cc. of benzene. After boiling the mixture under reflux for one and one-half hours the oily intermediate was decomposed with ice and acid. The organic layer was washed with acid and extracted with 10% soda solution. No saponifiable material was found in the neutral fraction. On acidifying the soda solution the unsaturated acid V separated in an almost colorless condition; yield, 18.2 g. (64%). One crystallization from benzene–ligroin gave 15.1 g. (53%) of pale yellow prisms, m. p. 117–125° (mixture of stereoisomers?), suitable for the next step. Eight recrystallizations were required to obtain a sample of the constant m. p. 137–138°, dec. (pale yellow plates).

Anal. Calcd. for $C_{19}H_{18}O_2$: C, 81.98; H, 6.53. Found: C, 82.08; H, 6.41.

γ-(9,10-Dihydro-2-phenanthryl)-γ-valerolactone (VI). (a) **From the Grignard Reaction.**—The ester IV (20 g.) in benzene (75 cc.) was treated with the reagent from 1.8 g. of magnesium and excess methyl bromide and the mixture was warmed gently on the steam-bath for one hour without refluxing. After hydrolysis with 10% sulfuric acid, extraction with soda afforded 4.5 g. (32%) of the crude vinylacetic acid derivative V. Evaporation of the solution containing the neutral fraction gave an oil which largely dissolved in hot alkali. On acidifying the alkaline solution an oil precipitated. This was taken up in ether, and after extracting a small amount of acidic material with soda, drying and evaporating the solution, the lactone VI distilled at about 240° (2 mm.). The colorless distillate was obtained crystalline from ligroin, forming large, colorless prisms, m. p. 60–65°, identical with material prepared in (b); yield, 5 g. (35%).

A second run identical with the above except that the Grignard reaction mixture was refluxed vigorously for two hours gave 9 g. (63%) of the crude vinylacetic acid V and only a small amount of the lactone.

(b) **From the Unsaturated Acid V.**—The crude vinylacetic acid V (4.5 g.) was boiled with 50 cc. of 10% sulfuric acid for four hours and the oily product washed in ether with water and extracted with soda, which removed 2 g. of unchanged acid. After evaporation of the ether the lactone distilled as a colorless oil which slowly crystallized as large, colorless prisms, m. p. 60–68° (1.3 g., 52% based on acid consumed). Further purification gave prisms melting largely at 61.5–63° but giving a clear liquid only at 70°.

Anal. Calcd. for $C_{19}H_{18}O_2$: C, 81.98; H, 6.53. Found: C, 81.91; H, 6.56.

γ-Hydroxy-γ-(9,10-dihydro-2-phenanthryl)-valeric acid (VII) was prepared by acidifying a cooled solution prepared by dissolving the lactone VI in boiling aqueous alkali. The hydroxy acid easily reverts to the lactone, but by careful crystallization from ether it was obtained as small, colorless needles, m. p. 95–97°, dec.

Anal. Calcd. for $C_{19}H_{20}O_3$: C, 77.00; H, 6.80. Found: C, 76.89; H, 6.83.

γ-(9,10-Dihydro-2-phenanthryl)-valeric Acid (VIII).—A solution of 12.1 g. of the vinylacetic acid V in 200 cc. of glacial acetic acid in the presence of Adams catalyst absorbed one mole of hydrogen rapidly at room temperature. The solvent was removed from the filtered solution and the product distilled at about 250° (1 mm.). The saturated acid was obtained in nearly quantitative yield as a colorless oil which set to a glass and, in the course of some time, crystallized. The distilled product was suitable for the next step. A sample of the solid material

(19) Microanalysis by Herbert S. Wight.

when purified by crystallization from ether–petroleum ether formed colorless prisms, m. p. 77.5–78.5°.

Anal. Calcd. for $C_{19}H_{20}O_2$: C, 81.40; H, 7.19. Found: C, 81.16; H, 6.87.

5 - Methyl - 8 - keto - 3,4,5,6,7,8 - hexahydrophenanthrene (IX). (a) Hydrogen Fluoride Procedure.—The valeric acid VIII (11 g.) was treated with 150 g. of chilled liquid anhydrous hydrogen fluoride in a platinum vessel and the solution allowed to stand at room temperature for three hours. After evaporating the reagent, warming the residue with soda solution and cooling, the product solidified. It was washed and dried in benzene and distilled in vacuum, giving a colorless solid. One crystallization from methanol yielded 8.4 g. (81.5%) of flat needles, m. p. 127.2–128.4°; recrystallized, m. p. 127.9–128.4°.

Anal. Calcd. for $C_{19}H_{18}O$: C, 86.98; H, 6.92. Found: C, 86.97; H, 6.83.

(b) **Friedel and Crafts Reaction.**—A mixture of the valeric acid (10 g.) and phosphorus pentachloride (9.5 g.) in 150 cc. of benzene was refluxed for one hour and the solution was cooled and treated under stirring with 9.5 g. of aluminum chloride. After standing two and one-half hours at room temperature and refluxing for one and one-half hours the mixture was poured onto ice and acid and the benzene layer washed and dried. Distillation in vacuum and one crystallization from methanol yielded 6 g. (64%) of colorless needles of the ketone, m. p. 126–127.5°.

5-Methyl-1,2-benzanthracene.—The ketone IX (5.7 g.) was reduced by the Clemmensen–Martin method using 25 g. of amalgamated zinc, 25 cc. of toluene, 1 cc. of glacial acetic acid, 18 cc. of water, and 45 cc. of concentrated hydrochloric acid. Refluxing was continued for forty-eight hours with the addition of a second charge of zinc and a total of 100 cc. of concentrated hydrochloric acid. As the reduction progressed the toluene layer became fluorescent in ultraviolet light. After separation of the layers and extraction with benzene the washed and dried solution was filtered through a tower of alumina to remove any ketone and concentrated. The residual colorless oil (5 g.) was heated with sulfur (1.93 g.) at 200–255° for one hour and the product distilled in vacuum from a pinch of zinc dust and redistilled, giving 2.6 g. (49.5%, from the ketone) of yellowish hydrocarbon, m. p. 140–150°. A 0.25-g. portion treated in alcohol with 0.5 g. of picric acid gave red needles of the **picrate** (0.37 g.), m. p. 164.5–165°; recrystallized from 5% picric acid solution it melted at 165.5–166° (Fieser and Newman,[9] 165.8–166.3°). Recovered by cleavage of the picrate in benzene with an alumina tower, the hydrocarbon crystallized from benzene–alcohol in yellowish plates (0.17 g., 68% from crude hydrocarbon), m. p. 158–159.4°. No depression in m. p. was observed on mixing with an authentic sample of 5-methyl-1,2-benzanthracene,[9] m. p. 158.5–159.1°.

5,8 - Dimethyl - 3,4 - dihydro - 1,2 - benzanthracene (XIII).—The ketone IX (3 g.) in benzene was added with cooling and stirring to the Grignard reagent from 0.55 g. of magnesium and excess methyl chloride. After stirring for one and one-half hours the mixture was refluxed for about two hours. After adding acid the organic layer was washed with dilute acid, water, and sodium chloride solution, dried over sodium sulfate and concentrated. The oil was dehydrated at 250° for one hour and distilled, giving a yellowish oil from which only 0.27 g. of crystalline product, m. p. 75.5–78.5°, separated. Purified by crystallization from alcohol to constant m. p., this formed glistening, colorless needles, m. p. 82.2–82.8°.

Anal. Calcd. for $C_{20}H_{18}$: C, 92.98; H, 7.02. Found: C, 93.07; H, 6.99.

The principal absorption maxima (Fig. 1) are at 271.5 mμ (log ε = 4.72) and 309.0 mμ (log ε = 4.13).

5,8-Dimethyl-1,2-benzanthracene.—The oily hydrocarbon mixture (2 g.) remaining in the above experiment after removal of the crystalline XIII was heated with sulfur (0.49 g.) at 210–215° for twenty minutes, and then for fifteen minutes while raising the temperature to 235°. A yellow product solidified on distillation in vacuum and the color was largely removed by adsorption from benzene on alumina. Addition of alcohol to the concentrated filtrate caused the separation of 0.8 g. of crude hydrocarbon; this was converted into the picrate in benzene–ligroin; yield 1.5 g. (27% from the ketone), m. p. 170–173°. Recrystallized from alcohol the picrate formed dark red needles, m. p. 174.5–175°.

Anal.[20] Calcd. for $C_{26}H_{19}O_7N_3$: N, 8.65. Found: N, 8.82.

The hydrocarbon mother liquor treated with picric acid gave 0.85 g. of light red needles melting at about 114–118° and probably containing incompletely dehydrogenated material.

A sample of purified picrate (0.65 g.) was cleaved in benzene with an alumina tower and on adding alcohol to the concentrated filtrate 0.31 g. of glistening needles of the 5,8-dimethyl compound separated in a pure condition (constant m. p.). The hydrocarbon forms colorless needles melting first at 131.2–131.4°, and remelting at 134.4–134.7°.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.71; H, 6.29. Found: C, 93.59; H, 6.04.

8 - Methyl - 1,2 - benzanthracene - 10 - aldehyde (XIV).—A mixture of 0.79 g. of 8-methyl-1,2-benzanthracene,[2] 0.92 g. of methylformanilide, 0.92 g. of phosphorus oxychloride, and 0.8 cc. of *o*-dichlorobenzene was heated on the steam-bath for two hours and the dark red solution poured into an aqueous solution of 5 g. of sodium acetate. After steam distillation the residual oil was washed and dried in benzene and the product crystallized from benzene–ligroin; the mother liquor on evaporation and addition of alcohol gave 0.3 g. of unchanged hydrocarbon (yellow). The crystallizate was submitted to chromatographic adsorption on alumina. Some unreacted hydrocarbon passed into the filtrate (fluorescence, 0.06 g. collected) and the aldehyde was adsorbed in a bright yellow zone. This was sectioned and eluted with benzene containing a few drops of methanol, and the recovered material was crystallized from benzene–ligroin in yellow needles, m. p. 125–140°. Crystallization from glacial acetic acid gave 0.2 g. (42% based on hydrocarbon consumed), m. p. 145–147°. On further crystallization from benzene–ligroin the aldehyde separated both as large yellow needles, melting at 147.5–148° and remelting

(20) Microanalysis by Lyon Southworth.

at 151.5–152°, and as clusters of fine yellow needles, m. p. 151.5–152°.

Anal.[19] Calcd. for $C_{20}H_{14}O$: C, 88.86; H, 5.22. Found: C, 88.94; H, 5.40.

The hydrazone was obtained by adding 0.5 cc. of hydrazine hydrate to 0.16 g. of aldehyde suspended in 15 cc. of boiling alcohol. After adding a trace of acetic acid the aldehyde dissolved, and presently the hydrazone began to separate as fine, light yellow needles. After boiling for ten minutes and cooling there was obtained 0.15 g. (89%) of product, m. p. 181–181.5°, dec. Recrystallization from alcohol did not change the m. p.

Anal.[19] Calcd. for $C_{20}H_{16}N_2$: N, 9.85. Found: N, 9.71.

8,10-Dimethyl-1,2-benzanthracene was prepared by heating 0.14 g. of the hydrazone with a solution from 0.05 g. of sodium and 2.5 cc. of absolute alcohol in a sealed tube at 195–208° for ten hours. After adding dilute acetic acid the crystalline product was collected. Filtration through alumina in benzene removed a trace of color and the highly fluorescent filtrate when concentrated, diluted with alcohol, and cooled yielded 0.11 g. (87%) of colorless needles, m. p. 145.5–146.5°. Recrystallization from benzene–alcohol did not alter the m. p.

Anal.[19] Calcd. for $C_{20}H_{16}$: C, 93.71; H, 6.29. Found: C, 93.56; H, 6.53.

The **picrate** formed deep red needles from alcohol or benzene–ligroin, m. p. 165.5–166°.

Anal.[19] Calcd. for $C_{20}H_{16}\cdot C_6H_3O_7N_3$: N, 8.65. Found: N, 8.62.

γ-(2-Phenanthryl)-butyric Acid (XVII).—γ-(9,10-Dihydro-2-phenanthryl)-butyric acid[2,3] (33 g.) was esterified by refluxing for four hours with 500 cc. of methanol saturated with hydrogen chloride. After adding water the ester was extracted with ether, washed with soda solution, dried with potassium carbonate, and distilled at about 230° (4–5 mm.) as a colorless liquid; yield 32 g. (92%). For dehydrogenation 31 g. of the ester was heated with 3.6 g. of sulfur at 232–255° for one hour. After adding 2 g. of zinc dust and heating for five minutes longer, distillation at about 240° (4 mm.) gave 28 g. of straw colored oil. This was boiled for one hour with 200 cc. of alcohol containing 7 g. of potassium hydroxide, and on concentrating the solution, adding acetone and cooling, the potassium salt of XVII crystallized in beautiful needles. Washed with acetone, the salt was obtained in a completely colorless condition (22 g.). Acidification of a solution in hot water gave colorless, granular acid, m. p. 131–133°; yield, 17.3 g. (53%). One crystallization from benzene–ligroin gave colorless plates, m. p. 134–135.5° (Haworth and Mavin,[14] 134–135°).

8 - Keto - 5,6,7,8 - tetrahydro - 1,2 - benzanthracene (XVIII).—A mixture of 4.8 g. of γ-(2-phenanthryl)-butyric acid and 100 g. of hydrogen fluoride was allowed to stand overnight and the remaining reagent was largely evaporated on the steam-bath. Soda solution was added and the product extracted with benzene. After washing with saturated sodium chloride solution and drying, the ketone was distilled and crystallized from alcohol (Norite); 3.8 g., m. p. 110–115°. Two more crystallizations from alcohol gave colorless blades, m. p. 117–118°; yield 3.5 g. (78%). On further purification the ketone melted at 117.8–118.5°.

Anal. Calcd. for $C_{18}H_{14}O$: C, 87.77; H, 5.73. Found: C, 87.83; H, 5.94.

8 - Methyl - 5,6 - dihydro - 1,2 - benzanthracene.—The above ketone XVIII (2.5 g.) was treated with methylmagnesium chloride in the usual way and the product dehydrated by distillation in vacuum from a trace of potassium bisulfate. The almost colorless distillate set to a solid (2.3 g., 93%), m. p. 70–76°. A sample for analysis formed glistening, colorless plates from alcohol or from petroleum ether, m. p. 80–80.6° (picrate, m. p. 151–152°, dec.).

Anal. Calcd. for $C_{19}H_{16}$: C, 93.40; H, 6.60. Found: C, 93.71; H, 6.35.

8-Methyl-1,2-benzanthracene was obtained by heating the above dihydride (0.53 g.) with sulfur (0.07 g.) at 205–245° for fifteen minutes, followed by treatment with zinc, distillation, adsorption of colored impurities on alumina, and crystallization from alcohol. There was obtained 0.5 g. (95%) of colorless plates, m. p. 117–118° and remelting at 113.5–114°. This did not depress the m. p. of the sample previously described.[2]

4-Keto-1,2,3,4-tetrahydrochrysene (XIX).—γ-(2-Phenanthryl)-butyric acid (7 g.) was refluxed for seventy minutes with 26 cc. of glacial acetic acid, 17.5 cc. of acetic anhydride, and 2.33 g. of freshly fused zinc chloride. Water was dropped into the hot, dark solution, cautiously at first and then to the point of incipient cloudiness. The crude ketone which crystallized was quite dark; it was washed in benzene with soda solution, water, and salt solution, dried, concentrated and diluted with ligroin. Brownish prisms separated on cooling (4 g.), and distillation at about 245° (3–4 mm.) gave an almost colorless product. On crystallization from benzene–ligroin and then from alcohol the ketone formed colorless prisms or prismatic needles, m. p. 124–125° (Haworth and Mavin,[14] 124–125°); yield 3.3 g. (51%). The purest sample obtained had the m. p. 125–125.5°.

Cyclization of γ-(2-Phenanthryl)-butyric Acid by Other Methods.—(a) On repeating the experiment of Haworth and Mavin[14] (85% sulfuric acid at 100° for fifty minutes), 2 g. of the acid yielded 0.44 g. (23%) of the ketone XIX, m. p. 123–125°.

(b) In another experiment 5 g. of the acid was refluxed in 75 cc. of dry benzene with 5 g. of phosphorus pentachloride, 4.5 g. of aluminum chloride was added after chilling, and after standing overnight the mixture containing a yellow precipitate was refluxed for two and one-half hours. On working up the mixture 0.1 g. of crude starting material was recovered and the distilled neutral fraction on slow crystallization from benzene–ligroin yielded a mixture of blades and prisms. These were largely separated by hand and each substance was separately purified and identified by mixed melting point determination (a mixture of the two ketones gives a marked depression). There was collected 1.65 g. (⅔ of total) of blades of 8-keto-5,6,7,8-tetrahydro-1,2-benzanthracene, m. p. 115–116.5°, and 0.8 g. of prisms of 4-keto-1,2,3,4-tetrahydrochrysene, m. p. 122–125°; total yield 52.5%.

(c) Another variation was to treat the acid (2 g.) in

nitrobenzene (25 cc.) with phosphorus pentachloride (steam-bath) and add a solution of aluminum chloride (1.85 g.) in nitrobenzene (30 cc.) to the solution of the acid chloride under stirring in a salt–ice bath. A mustard colored complex separated. After stirring for five hours in the freezing bath and standing overnight at room temperature the ketonic product was collected in the usual way and the components separated as in (b). The crude 8-ketotetrahydro-1,2-benzanthracene collected amounted to 0.95 g., and 0.1 g. of crude 4-ketotetrahydrochrysene was isolated and identified.

4-Methylchrysene (XXI).—Condensation of the ketone XIX (2.5 g.) with methylmagnesium chloride was conducted as in the examples described above, and vacuum distillation gave 2.23 g. (90%) of solid product suitable for dehydrogenation. This crystallized from alcohol in colorless plates, but the melting point rose steadily on repeating the process, probably as the result of disproportionation. The crude dihydride (1.2 g.) was heated with sulfur (0.16 g.) at 215–245° for thirty minutes, followed by vacuum distillation from a little zinc dust. The yellow solid was sublimed at 190–200° (1–2 mm.) and crystallized from benzene–alcohol (Norite), giving 0.6 g. of colorless plates, m. p. 140–146°. Three crystallizations from benzene–alcohol gave 0.38 g. of highly fluorescent hydrocarbon of the constant m. p. 151–151.5°.

Anal. Calcd. for $C_{19}H_{14}$: C, 94.18; H, 5.82. Found: C, 94.00; H, 5.94.

The material in the mother liquors was converted to the red picrate; 0.25 g., m. p. 132–136°. This substance sublimed nicely at 110–120° (1 mm.), and the sublimate on crystallization from benzene–ligroin separated in either of two forms. One of these appeared as bright red needles which melted at 135–135.5° and remelted at 137.5–138°; the other separated as light orange needles, m. p. 137.5–138°. The orange form changes to the red form on standing in contact with the mother liquor.

Anal.[19] Calcd. for $C_{19}H_{14}\cdot C_6H_3O_7N_3$: N, 8.91. Found: N, 8.88.

A sample of 4-methylchrysene recovered (alumina tower) from the purified picrate melted at 151–151.5° as before and differed from the above sample only in showing a more intense fluorescence, the colorless crystals appearing violet in daylight.

Summary

In extension of previous work 8-keto-3,4,5,6,7,8-hexahydro-1,2-benzanthracene has been employed as an intermediate for the synthesis of the 8-ethyl, 8-hydroxy, and 8-amino derivatives of 1,2-benzanthracene. The 5-methyl and 5,8-dimethyl derivatives of the hydrocarbon have been synthesized from β-(9,10-dihydro-2-phenanthroyl)-propionic acid through the unsaturated acid resulting from the condensation of the ester of the keto acid with methylmagnesium halide. It is shown that this reaction can be conducted in such a way as to yield the lactone as well as the unsaturated acid, and the α-hydroxy acid has also been isolated. Another hydrocarbon of interest for its possible carcinogenic activity has been prepared by conversion of 8-methyl-1,2-benzanthracene into the 10-aldehyde, followed by Wolff–Kishner reduction. 4-Methylchrysene has been synthesized starting with γ-(2-phenanthryl)-butyric acid, conveniently prepared from the product of the succinoylation of 9,10-dihydrophenanthrene. This acid can be cyclized exclusively either to the chrysene derivative, using zinc chloride in acetic acid–anhydride, or to the isomeric ketotetrahydro-1,2-benzanthracene, using liquid hydrogen fluoride. Cyclization with 85% sulfuric acid or by the Friedel and Crafts reaction gives mixtures of the isomers.

The Synthesis of D-Mannoheptulose, and the Preparation of Some of its Derivatives[1]

BY EDNA M. MONTGOMERY AND C. S. HUDSON

F. B. LaForge reported in 1917 that the avocado (the fruit of *Persea gratissima*, Gaertn.) contains a seven carbon atom ketone sugar in the free state. The ketose was isolated in crystalline form, characterized, and its structure and configuration established as those of D-mannoheptulose.[2] The present paper describes the synthesis of D-mannoheptulose from D-α-mannoheptose (D-manno-D-gala-heptose), a transformation which would be expected to occur because of the configuration assigned to the ketose by LaForge.

The Lobry de Bruyn rearrangement was applied to D-manno-D-gala-heptose under the mild conditions[3] used previously in the synthesis of lactulose from lactose.[4] After equilibrium had

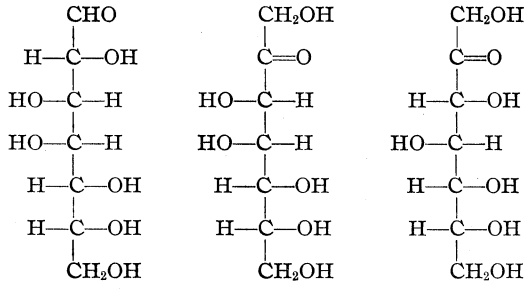
been established, as judged from the constancy of rotation, the aldose components were removed by oxidation with bromine water and subsequent precipitation of the barium aldonates. Crystallization of the ketose portion produced D-mannoheptulose in 25% yield, and D-glucoheptulose[5] in 13% yield. The formation of two ketone sugars from D-manno-D-gala-heptose is not unexpected if we compare this heptose with D-galactose with which it is identical in the configuration of the first four asymmetric carbon atoms, and which it resembles closely in physical and chemical properties. Thus, from the rearrangement of D-galactose with dilute potassium hydroxide, de Bruyn and van Ekenstein[6] were able to isolate not only D-tagatose but also the epimeric ketose, D-sorbose.

The less drastic rearrangement of D-manno-D-gala-heptose in pyridine solution,[7] followed by oxidation of the aldose components, resulted in the recovery of 72% as barium heptonates, and the separation of 21% of pure D-mannoheptulose. No D-glucoheptulose was detected in this case.



D-Manno-D-gala-heptose D-Mannoheptulose D-Glucoheptulose

Glycoside formation with the ketose occurred readily in 0.25 *N* methyl alcoholic hydrochloric acid at room temperature, and a constant rotation[8] of +71.3° was reached in three hours; practically the same rotation was attained when the reaction was carried out at the boiling point of the solution. The product was isolated in 68% yield. From its rotation of +69° in water it is to be designated as α-methyl-D-mannoheptuloside. From the similarity between its rotation and the rotation of the equilibrium solution from which it was obtained, it seems probable that the α-glycoside is formed almost exclusively. In this respect, D-mannoheptulose resembles the configurationally related aldoses, D-mannose and D-lyxose, each of which produces mainly the α-glycoside.

Acetylation of D-mannoheptulose with cold acetic anhydride and pyridine produced a crystalline hexaacetate in an 85% yield. The rotation, +39.0° in chloroform, indicates that it is the α-hexaacetate. Treatment of this acetate with glacial acetic acid saturated with gaseous hydrobromic acid resulted in a crystalline acetobromo-D-mannoheptulose, rotating +104° in chloroform; accordingly, it also is to be designated an α-form. Replacement of the bromine atom through the agency of silver oxide and methyl alcohol yielded a crystalline pentaacetyl-α-methyl-D-mannoheptuloside, rotating +49.5° in chloroform; the same compound is generated by the acetylation of α-methyl-D-mannoheptuloside; deacetylation regenerates the original glycoside. Thus, all the known derivatives of D-mannoheptulose appear as α-forms, and no evidence for a β-form has yet been discovered. The ketose itself shows no mutarotation, and presumably is the pure α-isomer. It is noteworthy that there is no Walden inversion in the passage from the acetobromo compound to the acetylated methylglycoside.

Although D-mannoheptulose is converted to its α-methylglycoside at 20° with the rapidity considered to be characteristic of furanoside formation in the aldose series, nevertheless it seems likely that methyl mannoheptuloside is a pyranoside. Evidence for this belief comes from the data in Table I, in which are compared the rotations of D-mannoheptulose and its derivatives with the rotations of D-mannose and its derivatives, both furanoside and pyranoside. Since the configurations of the asymmetric carbon atoms in the two sugars are identical, it would not be unreasonable to expect a certain similarity in rotations between compounds with the same ring systems. Although the α-mannoheptuloside is formed rapidly at room temperature with acidic methyl alcohol, it also is produced as the principal product when the solution is heated, showing that it is the stable end-product of the reaction and therefore, in all probability, a pyranoside.

Corresponding to the rapid glycoside formation from D-mannoheptulose in methyl alcoholic hydrochloric acid, there is a rapid hydrolysis of the

This value was obtained at 25°. [f] Haworth and Porter, *ibid.*, 650 (1930). [g] Dale, THIS JOURNAL, **46**, 1048 (1924). [h] Haworth, Hirst and Webb, *J. Chem. Soc.*, 656 (1930).

glycoside in dilute aqueous hydrochloric acid. In 0.005 *N* acid at 98°, the hydrolysis constant *k*, expressed in minutes and decimal logarithms, is 0.050. Although this value is very much larger than the constants obtained in the hydrolysis of aldopyranosides, and even for aldofuranosides,[9] yet the recent work of Purves and Hudson[10] has shown that the "glycosides of the keto sugar fructose differ from those of the aldoses in that both ring types possess very nearly the same slight stability toward aqueous acid." A similar conclusion has been reached by Schlubach and Graefe[11] in their study of the sorbosides. In conclusion it may be stated that, although α-methyl-D-mannoheptuloside is hydrolyzed about twice as rapidly as sucrose,[9] a fructofuranoside, no evidence for the size of the ring can be adduced from this behavior.

Experimental

D-Mannoheptulose from D-Manno-D-gala-heptose.—A solution containing 20 g. of D-manno-D-gala-heptose in 200 cc. of 0.05 *N* aqueous barium hydroxide was kept at 35° until the Lobry de Bruyn rearrangement was completed as judged from the changes in rotation. The values observed were +68.6° after fifteen minutes, +49.0° after twenty-four hours, +34.6° after forty-eight hours, and +25.4° (constant) after seventy-two hours. The solution remained clear, and developed only a slight yellow color during the course of five days. At the end of that period sufficient bromine and barium benzoate[12] were added to oxidize the aldehyde sugars to the corresponding aldonic acids; excess bromine, barium, and benzoic acid were removed, and the barium aldonates precipitated with alcohol in the usual way. The filtrate was concentrated *in vacuo* to a sirup which, upon solution in ten volumes of hot methyl alcohol and cooling, deposited 4.2 g. of ketose rotating +60.0° in water. One recrystallization produced 2.6 g. of sugar melting at 170–174° and rotating +66.9° in water (*c*, 2); these data are in accord with the melting point 171–174° and rotation +67.5° in water (*c*, 2.5) reported by Austin for D-glucoheptulose.[5] The combined mother liquors, concentrated in a desiccator over calcium chloride, furnished 6.3 g. of crude ketose, from which was separated 5.1 g. of D-mannoheptulose. The melting point 152° and rotation +29.2° in water (*c*, 2) are in agreement with the values recorded by LaForge.[2] A mixture of the synthetic and natural sugars melted at 152° also. The identification was completed by the "mixed solubility" method;[13] thus, 10 cc. of 80% alcohol at 3° was found to contain 0.3870, 0.3865, and 0.3868 g. from undersaturation, and 0.3860, 0.3862, and 0.3871 g. from supersaturation, of the synthetic, natural, and mixed D-mannoheptuloses, respectively.

The rearrangement of D-manno-D-gala-heptose according to Danilow's procedure was carried out by refluxing a solution of 25 g. of the dried sugar in 250 cc. of pyridine for four and one-half hours. The pyridine was removed by distillation *in vacuo*, and the residue, with rotation +54.5° in water (*c*, 25), treated with bromine and barium benzoate to remove aldehyde sugars as in the preceding experiment. The barium salts weighed 25.3 g., and represented about 72% of the original heptose. From the mother liquor was obtained 5.2 g. of pure, recrystallized D-mannoheptulose melting at 152° and rotating +29.2° in water (*c*, 2).

D-Mannoheptulose from the Avocado.—A number of varieties of avocado were examined but none was found to contain as much ketose as the Trapp variety recommended by LaForge. His procedure was modified somewhat, as follows. The crushed pulp was mixed thoroughly with sufficient 20% ethyl alcohol to make a thin soup, and left overnight. The mixture was heated on a steam-bath until the pulp was well coagulated and then filtered by gravity through folded filters or run through a fruit press. The following morning the filtrate was siphoned from any oil which had collected at the surface of the liquid. The solution was clarified and decolorized by heating to 95° with activated carbon, filtered through carbon, and concentrated *in vacuo* to a thin sirup which was poured into eight volumes of methyl alcohol. The precipitated gum separated in small flakes, showing only a slight reducing action toward Fehling solution. The filtered solution was concentrated *in vacuo* to a thick sirup, which was dissolved in four volumes of methyl alcohol and cooled to 5°. Crystalline perseitol separated first, and was filtered after three hours. The mother liquor, allowed to stand for several days in the ice-box, deposited mannoheptulose contaminated with perseitol. The latter was removed by dissolving each 50-g. portion of the powdered crude sugar in 200 cc. of hot 80% methyl alcohol, and allowing the perseitol to crystallize overnight in the ice-box. The filtered solution was concen-

(9) See for example Haworth and Hirst, *J. Chem. Soc.*, 2625 (1930).

(13) Montgomery and Hudson, *ibid.*, **52**, 2105 (1930).

trated *in vacuo;* the sirup, dissolved in methyl alcohol and cooled, deposited practically pure D-mannoheptulose, melting at 152°, and rotating +29.1° in water (*c*, 2). From 21 kg. of pulp, from 36 avocados, there was obtained 315 g. of pure D-mannoheptulose and 75 g. of perseitol, plus 400 g. of non-reducing gum and 310 g. of a final sirup containing 80% solids.

α-Methyl-D-mannoheptuloside.—Glycoside formation occurred readily when a 1% solution of the ketose in absolute methyl alcohol was made 0.25 *N* in hydrogen chloride (see Fig. 1). The rotation, +34.7° after one minute, changed rapidly to +47.5° at the end of four minutes, remained constant during the next three minutes,[14] and then increased slowly to a constant value +71.3° at the end of three hours.[15] The reducing power of the solution was negligible after thirty minutes. An equilibrated solution from 10 g. of ketose was neutralized with silver oxide, the excess silver removed with hydrogen sulfide, and the filtrate concentrated *in vacuo* to a sirup which crystallized after two weeks. The product weighed 7.2 g. It showed no reducing power toward Fehling solution. It is readily soluble in water, methyl alcohol, and ethyl alcohol, sparingly soluble in ethyl acetate, insoluble in ether. Recrystallized from methyl alcohol, as small prisms, it melted at 142°, and showed a constant rotation of +69.0° in water (*c*, 2).

Anal. Calcd. for $C_8H_{16}O_7$: C, 42.83; H, 7.19; OCH_3, 13.84. Found: C, 42.9; H, 7.17; OCH_3, 13.7.

Hydrolysis of α-Methyl-D-mannoheptuloside.—The hydrolysis of a 4.2% solution of the heptuloside in 0.005 *N* aqueous hydrochloric acid at 98° was followed polarimetrically, the samples being cooled rapidly to 20° for measurement. The observed readings, in circular degrees, were +2.82° at zero time, +2.35° after three minutes, +1.72° after ten minutes, +1.43° after fifteen minutes, and a final constant value of +1.17°. The average hydrolysis constant in terms of minutes and decimal logarithms, $k = \frac{1}{t} \log \frac{(r_0 - r_\infty)}{(r - r_\infty)}$, is 0.050. The final reading +1.17°, calculated on the basis of complete hydrolysis, corresponds to a specific rotation of +29.7° as compared with the value +29.2° for the pure mannoheptulose.

D-Mannoheptulose α-Hexaacetate.—The acetylation of 10 g. of pure D-mannoheptulose was accomplished by dissolving the sugar in a mixture of 50 cc. of acetic anhydride and 50 cc. of pyridine at 0°. The solution was kept at that temperature for forty-eight hours, then poured into ice water; the chloroform extract was washed, dried, and concentrated in the usual manner. The resulting sirup crystallized readily. By recrystallization from warm ether there was obtained 18.8 g. (85%) of large prisms, melting at 110°, and rotating +39.0° in chloroform (*c*, 2).

Anal. Calcd. for $C_{19}H_{26}O_{13}$: C, 49.35; H, 5.67; acetyl, 13.00 cc. of 0.1 *N* NaOH per 100 mg. Found: C, 49.26; H, 5.70; acetyl, 13.03 cc.

(14) This plateau may be an indication of extremely rapid furanoside formation, and the subsequent rearrangement to the pyranoside form.

(15) The final rotation for glycoside formation at the boiling point of the solution was +73.5°. Calculated as methylmannoheptuloside, the rotations become +66.9° and 68.9°, respectively.

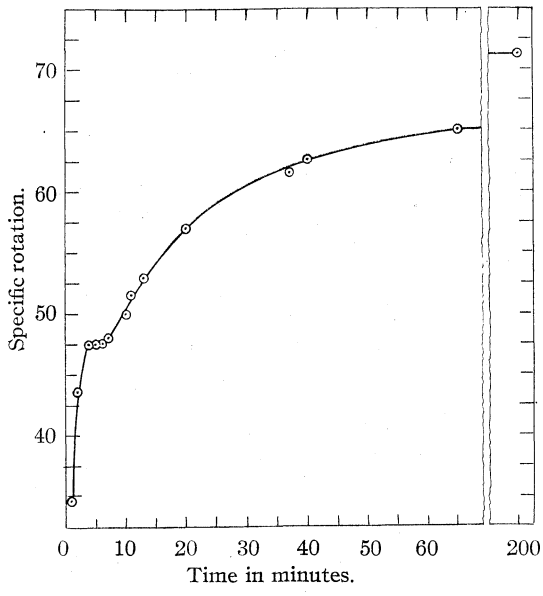

Fig. 1.—Change in rotation of a 1% solution of D-mannoheptulose in 0.25 *N* methyl alcoholic hydrochloric acid at 20°.

α-Acetobromo-D-mannoheptulose.—A paste of 10 g. of crystalline D-mannoheptulose α-hexaacetate and 5 cc. of glacial acetic acid, cooled to 0°, was dissolved at that temperature in 30 cc. of glacial acetic acid which had been saturated previously with gaseous hydrobromic acid. After two hours in an ice-bath the solution was poured into ice water and extracted with chloroform. The chloroform solution was washed, dried, and concentrated *in vacuo;* the resulting sirup, taken up in anhydrous ether, deposited 5.3 g. (50%) of rosets of prisms, melting at 92°. The recrystallized acetobromo-D-mannoheptulose rotated +104.0° in chloroform (*c*, 2).

Anal. Calcd. for $C_{17}H_{23}O_{11}Br$: Br, 16.55. Found: Br, 16.28.

Pentaacetyl-α-methyl-D-mannoheptuloside from α-Methyl-D-mannoheptuloside.—A 3-g. portion of the pure glycoside was acetylated at 0° with a mixture of 30 cc. each of acetic anhydride and pyridine. The product, isolated in the customary manner, weighed 5.3 g. Upon recrystallization from ether it separated in clusters of radiating needle-like prisms melting at 64° and rotating +49.5° in chloroform (*c*, 2). Deacetylation regenerated the original glycoside.

Anal. Calcd. for $C_{18}H_{26}O_{12}$: C, 49.74; H, 6.03; OCH_3, 7.14; acetyl, 11.51 cc. of 0.1 *N* NaOH per 100 mg. Found: C, 49.74; H, 5.90; OCH_3, 7.10; acetyl, 11.48 cc.

Pentaacetyl - α - methyl - D - mannoheptuloside from α-Acetobromo-D-mannoheptulose.—A solution of 4 g. of the pure acetobromo compound in 30 cc. of anhydrous methyl alcohol was shaken with 4 g. of silver oxide for five minutes. The halogen-free filtrate from the silver residues was concentrated *in vacuo* and the sirup dissolved in ether. The 1.5 g. of pentaacetyl-α-methyl-D-mannoheptuloside thus obtained had the same melting point, 64°, and the same rotation, +49.5°, as the sample prepared by acetylation of the α-methyl-D-mannoheptuloside

Summary

1. D-Mannoheptulose has been obtained by the rearrangement of D-α-mannoheptose (D-manno-D-gala-heptose) in dilute barium hydroxide solution, and also in pyridine solution.

2. D-Mannoheptulose α-hexaacetate, α-acetobromo-D-mannoheptulose, α-methyl-D-mannoheptuloside, and pentaacetyl-α-methyl-D-mannoheptuloside have been described.

3. A comparison of the rotations of these mannoheptulose derivatives with the rotations of the corresponding derivatives of D-mannose indicates a pyranoid ring in the mannoheptulose compounds.

4. α-Methyl-D-mannoheptuloside is very readily formed and very readily hydrolyzed; this behavior has been shown not to be inconsistent with the ketopyranoside formulation.

Relations between Rotatory Power and Structure in the Sugar Group. XXXIII. The Alpha and Beta Methyl Pyranosides of L-Fucose (L-Galactomethylose) and their Triacetates[1]

BY R. C. HOCKETT, F. P. PHELPS AND C. S. HUDSON

In 1925 one of us[2] reported two independent calculations of the specific rotation of α-methyl-L-fucoside, based upon its relationship to α-methyl-D-galactoside and to α-L-fucose, respectively; the values so predicted were −188 and −190. The deviation from the value (−122) that had been observed by Tadokoro and Nakamura[3] was so great that the purity of their product appeared doubtful; its rotation indicated that it might be a mixture of α- and β-forms. We undertook the preparation of the pure forms and soon found that the α-isomer is purified readily by recrystallization; its specific rotation was observed to be −196.9 as the average value of eleven preparations. It was then sought to obtain the pure β-form from the mother liquors of the other; the fractionation proved to be very slow and difficult because the isomers form mixed crystals over a wide range of composition, but it was learned that the β-form is certainly dextrorotatory. In 1930 Votoček and Valentin[4] reported the specific rotation of α-methyl-rhodeoside (α-methyl-D-fucoside) as +190. We then reinvestigated the purification of α-methyl-L-fucoside, confirmed our higher value and prepared the β-methyl-L-fucoside by fractional crystallization from the mother liquors of the α-form, obtaining a product of specific rotation +14, which was not changed by further recrystallization of the substance. In 1932 Minsaas[5] reported the values −197 and +16 for the specific rotations of the α- and β-methyl-L-fucosides, respectively, and Schlubach and Wagenitz[6] found the value −14 for β-methyl-D-fucoside (prepared by synthesis from D-galactose) and −5.9 for its triacetate. It was then discovered[7] that the β-L-fucoside forms a crystalline molecular compound with potassium acetate, but that the α-isomer does not, which enabled us to obtain the β-isomer readily in definite purity; its rotation confirmed the value +14. In 1937 Minsaas[8] reported the preparation of the triacetates of α- and β-methyl-L-fucosides (α-form, m. p. 74°, $[\alpha]^{20}D$ −151; β-form, m. p. 99°, $[\alpha]^{20}D$ +7.0). We have prepared both of these substances and find for the α-form, m. p. 67 and $[\alpha]^{20}D$ −149.7, and for the β-form, m. p. 96–97° and $[\alpha]^{20}D$ +7.1; by deacetylating them we have confirmed the purity of the original fucosides of rotations −197 and +14, respectively. It is evident that the value −197 which Minsaas found for the α-fucoside is substantially correct and that the α-methyl-D-fucoside (rhodeoside) of Votoček (+190) was an impure preparation containing some of the β-isomer. Our data con-

(1) Publication authorized by the Director of the National Bureau of Standards and by the Surgeon General, U. S. Public Health Service. The research was begun in 1926 at the National Bureau of Standards (F. P. P. and C. S. H.) and completed at the National Institute of Health (R.C.H. and C. S. H.). No. XXXII was published in THIS JOURNAL, **61**, 1525 (1939).

(6) Schlubach and Wagenitz, *Ber.*, **65**, 304 (1932).

(7) Watters, Hockett and Hudson, THIS JOURNAL, **56**, 2199 (1934).

(8) Minsaas, *Rec. trav. chim.*, **56**, 623 (1937). On p. 624 the rotations of β-methyl-L-fucoside and its triacetate are recorded as negative, obviously through a misprint because the context shows that the substances are dextrorotatory.

firm Minsaas' rotations except in the case of β-methyl-L-fucoside, for which his value (+16) appears to be about two degrees too large, due doubtless to the smallness of his observed reading (0.41°). The rotational data from our work are recorded in Table I. It is seen that the difference for the methyl fucosides (−37,600) agrees well with values found previously[9] from five other pairs of methyl glycosides; the difference for the acetylated methyl fucosides (−45,150) is decidedly less than would be expected (about −53,500). In an accompanying article[10] it is shown from the oxidation of these fucosides by periodic acid that they are pyranosides and that their alpha and beta classification, which has been made on the basis of their rotations, is correct from the standpoint of the configurations of carbon atom one.

TABLE I

THE ROTATIONS OF THE α- AND β-FORMS OF METHYL-L-FUCOPYRANOSIDE AND THEIR TRIACETATES

Substance	Mol. wt.	$[\alpha]^{20}D$	$[M]D$	Difference
α-Methyl-L-fucopyranoside	178	−197[a]	−35070	−37600
β-Methyl-L-fucopyranoside	178	+ 14.2[a]	+ 2530	
Triacetates of				
α-Methyl-L-fucopyranoside	288	−149.7[b]	−43110	−45150
β-Methyl-L-fucopyranoside	288	+ 7.1[b]	+ 2040	

[a] In water. [b] In chloroform.

Experimental

Preparation of L-Fucose from Seaweed (Hockett and Hudson).[11]—The seaweed (*Ascophyllum nodosum*) is cleaned by soaking it for several days in 3% hydrochloric acid, washing free of chlorides and drying on wire bottomed trays over a radiator until brittle; it is then broken into small pieces and stored.[12] A typical sample lost 12.6% moisture when dried at 110° to constant weight. A kilogram of air-dried seaweed (12.6% moisture) is hydrolyzed by boiling under reflux with 5 liters of 2% sulfuric acid for four hours. The cooled solution is filtered from insoluble material on a large porcelain filter, and the filtrate is neutralized to litmus with 110 g. of calcium carbonate (using a few drops of capryl alcohol to control foaming), followed by the addition of the necessary amount of calcium hydroxide. Seventy grams of decolorizing carbon is added and the mixture allowed to stand overnight. The solids are then removed by decantation and filtration, and the nearly colorless solution is concentrated *in vacuo* to about 2.5 liters, filtered from precipitated calcium sulfate, and further concentrated to 200 cc. Warm methyl alcohol (900 cc.) precipitates a granular material, which is filtered off and washed with three portions, 100 cc. each, of the same solvent. Further impurity is removed by adding 500 cc. of ether to the alcoholic filtrate and filtering again. The solution is now concentrated to a sirup of honey-like consistency, which is dissolved in absolute alcohol to a volume of about 200 cc. At this stage one may proceed to crystallize a portion of the fucose or to prepare the crystalline phenylhydrazone. To follow the first procedure, the 200-cc. solution is reconcentrated to a thick sirup (to reduce the water content), which is then dissolved in about 75 cc. of absolute alcohol and the solution seeded; the yield of crystalline fucose ranges from 13 to 25 g., and the remainder may be recovered from the mother liquor through the phenylhydrazone. To follow the second procedure, there is added to the 200 cc. of alcoholic solution 70 cc. of phenylhydrazine; fucose phenylhydrazone soon crystallizes and the mixture becomes solid. After standing overnight the hydrazone is filtered, washed thrice with absolute alcohol and dried at 50° (wt. 65 to 100 g., corresponding to 43–63 g. of fucose, which represents 5 to 7% of the dry seaweed). The fucose phenylhydrazone is readily converted to the sugar by heating 75 g. of it at 90° for one-half hour with 1800 cc. of water and 36 g. of benzaldehyde, with frequent stirring; an additional 10 g. of benzaldehyde is then added, and the heating and stirring are continued for fifteen minutes. The solution is cooled to 0° and the benzaldehyde hydrazone filtered off through a layer of decolorizing carbon; the filtrate is extracted three times with 100 cc. of chloroform (to remove benzoic acid and excess benzaldehyde) and concentrated to a sirup, which is dissolved in 50 cc. of hot absolute alcohol. Crystallization of fucose begins promptly and is allowed to continue overnight in a refrigerator. The yield of crystalline fucose, after filtration, washing with absolute alcohol and drying at 60° two hours, is about 40 g. The sugar is recrystallized (70% yield) by dissolving in 3 parts of water, concentrating to a sirup *in vacuo* and taking up with 3 volumes of absolute alcohol; the m. p. was 140–141° and the equilibrium $[\alpha]^{20}D$ was −74.9. The rotation of L-fucose, after several recrystallizations to constancy, was $[\alpha]^{20}D$ −76.0. The sugar may also be recrystallized from its solution in absolute methyl alcohol, prepared by refluxing the dry sugar with the solvent. The yield of crystalline fucose from 1 kg. of moisture-free cleaned seaweed through the phenylhydrazone procedure has ranged between 39 and 60 g.

The α- and β-Forms of Methyl-L-fucopyranoside. (a) (Experiments by Phelps).—The fucoside was obtained readily by refluxing 15 g. of fucose for six hours with methyl alcohol containing 1% hydrochloric acid, removing the acid as silver chloride, concentrating *in vacuo* to a sirup and crystallizing from ethyl acetate; yield 7.3 g. After one recrystallization from methyl alcohol and ethyl acetate the plate-like crystals showed $[\alpha]^{20}D$ −197.0 in water. The mother liquor deposited material which proved to be mixed crystals of the α- and β-fucosides. The pure β-form is difficult to obtain from these mixed crystals, but by working with larger quantities and fractionating repeatedly it was finally obtained pure; it showed $[\alpha]^{20}D$ +14.0 ± 0.3 in water (*c*, 4). It crystallizes from methyl or ethyl alcohol and ethyl acetate as long slender almost thread-like needles, which are anhydrous;

(9) Dale and Hudson, THIS JOURNAL, **52**, 2534 (1930).

(10) Maclay, Hann and Hudson, *ibid.*, **61**, 1660 (1939).

(11) These directions follow in general, but with some modifications, those of E. P. Clark, *J. Biol. Chem.*, **54**, 65 (1922).

(12) Grinding the seaweed is not necessary; its dust seems to be harmful to some persons.

from water it forms rather long thick prismatic crystals, which are a monohydrate that is stable in air but which soon becomes anhydrous in a desiccator over lime, passing to a white powder.

(b) (**Experiments by Hockett**).—α-Methyl-L-fucoside, prepared by refluxing fucose with 1% hydrochloric acid in methanol for twelve hours and isolated as described above, was recrystallized from methanol–ethyl acetate to constant properties readily. The pure substance shows m. p. 154° (corr.) and $[\alpha]^{20}D$ −197.1 (*c*, 3.42; 4-dm. tube); a sample which was prepared by deacetylation of its purified triacetate (described below) showed the rotation −197.0 (*c*, 4.16; 4-dm. tube). Analyses for carbon, hydrogen and methoxyl gave the expected values (the substance has been analyzed by previous investigators). The mother liquor from the α-form was treated in absolute alcoholic solution with double the theoretical quantity of dried potassium acetate (CH_3COOK) dissolved in absolute alcohol; silky needles of the 1:1 molecular compound of the β-fucoside separated at once and they were recrystallized from hot absolute alcohol. The β-fucoside was obtained by preparing its triacetate from this molecular compound (as described below) and deacetylating the triacetate with barium methylate, the over-all yield of the two steps being nearly quantitative. The pure β-L-fucoside showed m. p. 121–123° and $[\alpha]^{20}D$ +14.2 (*c*, 3.9; 4-dm. tube) in water.

The α- and β-Forms of Triacetyl-methyl-L-fucopyranoside.—Two grams of the pure α-fucoside was acetylated by heating for thirty minutes on the steam-bath with 12 cc. of acetic anhydride and 6 cc. of pyridine, followed by isolation according to standard procedure; yield 85%. The substance was recrystallized from hot water; a further recrystallization from aqueous methyl alcohol did not change its rotation, which was $[\alpha]^{23}D$ −149.1 (*c*, 0.9) in chloroform (Phelps). The pure α-fucoside was also acetylated by heating with 5 parts of acetic anhydride and one-quarter part of fused sodium acetate; the triacetate was isolated by standard procedure and recrystallized from absolute alcohol, as brilliant plates, which gave the correct analyses (previously reported by Minsaas) for methoxyl, acetyl, carbon and hydrogen, melted at 67° and showed $[\alpha]^{20}D$ −149.7 (*c*, 1.8) in chloroform (Hockett). The β-methyl-L-fucoside triacetate was prepared by heating 5 g. of its pure potassium acetate compound for one hour on the steam-bath with 20 cc. of acetic anhydride, and isolating the substance through standard procedure (yield, quantitative); by recrystallization from absolute alcohol, from which it separates in clear tablets, it is readily brought to constant properties, m. p. 96–97° and $[\alpha]^{20}D$ +7.1 (*c*, 4.5; 4-dm. tube) in chloroform (Hockett). Its analysis showed the correct values for carbon, hydrogen, methoxyl and acetyl, confirming Minsaas' reported analysis for the substance.

Summary

The α- and β-methylpyranosides of L-fucose (L-galacto-methylose) and their triacetates, previously reported by Minsaas, have been reprepared and their purity carefully controlled. The results confirm Minsaas' rotations except in the case of β-methyl-L-fucoside, the rotation of which is found to be +14.2 instead of +16.0. Some modifications of E. P. Clark's directions for preparing crystalline fucose from seaweed are presented. The difference of rotations of the glycosides shows the normal value; the difference for their triacetates is decidedly lower than would be expected.

The Cleavage of the Carbon Chains of Some Methyl Aldohexomethylo-pyranosides by Oxidation with Periodic Acid[1]

BY W. DAYTON MACLAY, RAYMOND M. HANN AND C. S. HUDSON

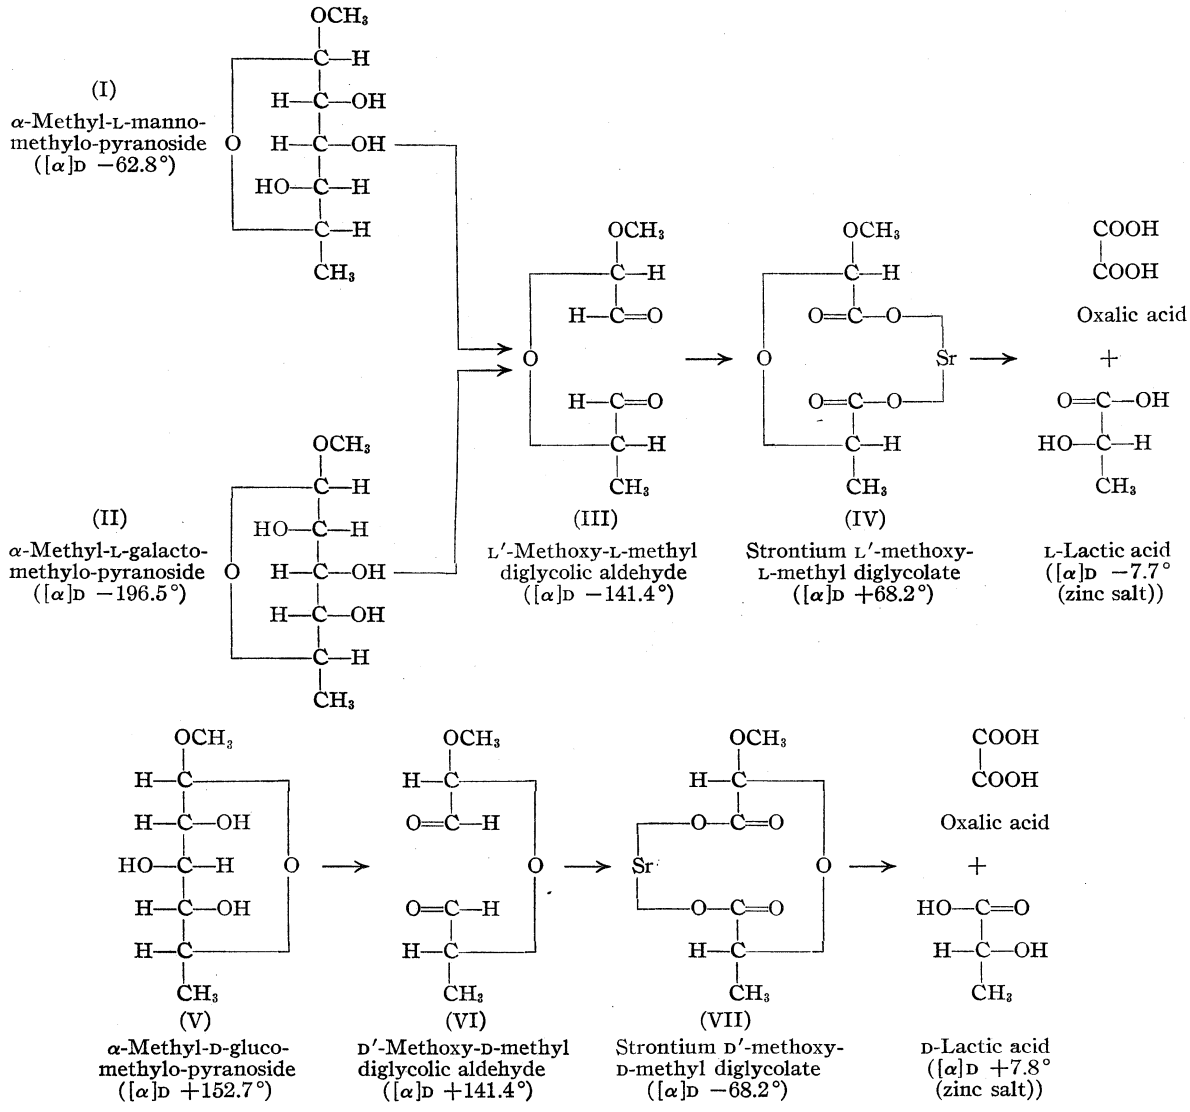
Jackson and Hudson[2] have described the crystalline dialdehyde (III) that results from the oxidation of α-methyl-L-mannomethylo-pyranoside[3] (I) with periodic acid. We have now obtained this same dialdehyde by the similar oxidation of α-methyl-L-galactomethylo-pyranoside (II), and by oxidation of this dialdehyde with bromine water in the presence of strontium carbonate have obtained the crystalline strontium salt of the corresponding dibasic acid (IV). In like manner it has been found that the periodic acid oxidation of α-methyl-D-glucomethylo-pyranoside (V) yields the crystalline enantiomorphous dialdehyde (VI), from which in turn has been prepared the crystalline strontium salt of the corresponding dibasic acid (VII), the enantiomorph of (IV). The hydrolysis of the dibasic acid formed from the strontium salt (IV) yields L-lactic acid[4] in optical

(1) Publication authorized by the Surgeon General, U. S. Public Health Service.

(2) Jackson and Hudson, THIS JOURNAL, **59**, 994 (1937).

(3) We use the nomenclature for methyl pentoses that was suggested by Votoček: L-mannomethylose = L-rhamnose, L-galactomethylose = L-fucose, D-glucomethylose = D-isorhamnose (syn. D-epirhamnose). The D and L symbols refer throughout to configuration.

(4) In the case of the optically active lactic acids and their zinc salts the L-lactic acid is dextrorotatory and its zinc L-lactate levorotatory, while the D-lactic acid is levorotatory and its zinc D-lactate dextrorotatory. D-Lactic acid has the configuration $CH_3—\overset{H}{\underset{OH}{C}}—COOH$.

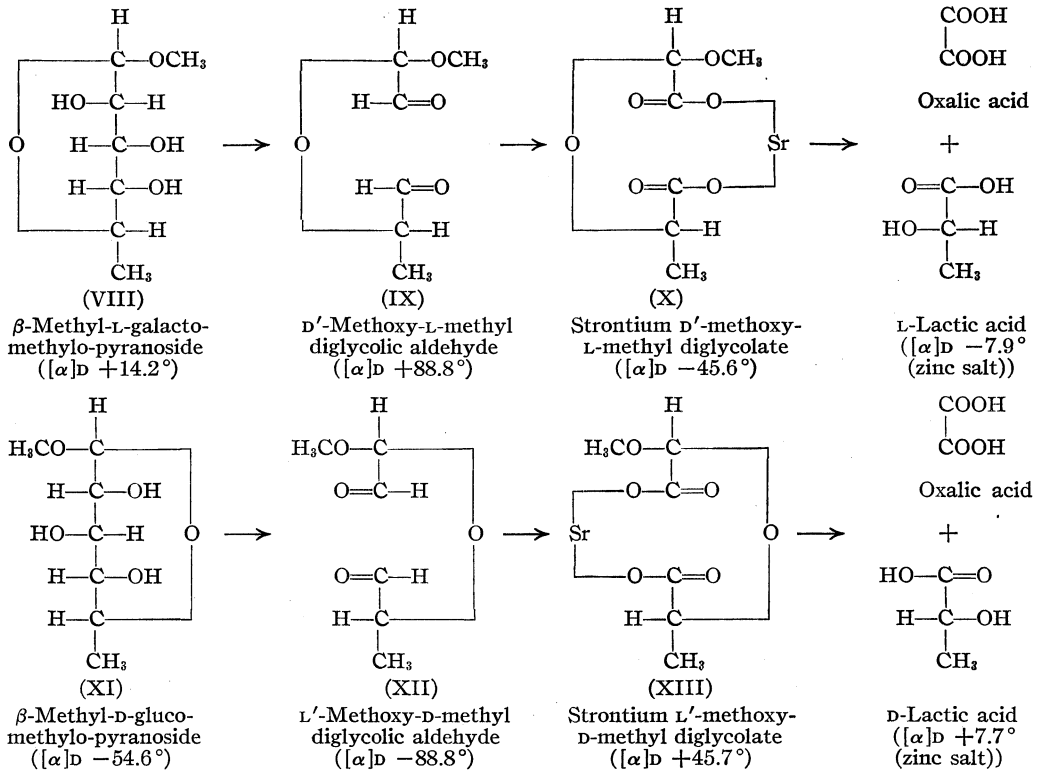


purity, and like treatment of the dibasic acid formed from the strontium salt (VII) yields D-lactic acid. The presence of lactic acid proves that all of these glycosides are pyranosides, and the correlation of the enantiomorphous forms of lactic acid with the known sugar configurations of Fischer proves the configurations of the lactic acids. We believe that this is the most simple and direct way of bringing the lactic acids into Fischer's system of configurations; it supplements the recent proof[2] of the configurations of the forms of glyceric acid that was obtained from the oxidation of the methyl-aldohexopyranosides with periodic acid. The results also prove that the two methylosides, α-methyl-L-mannomethyloside and α-methyl-L-galactomethyloside, have the same configuration for carbon atom one, enantiomorphous to the configuration for carbon atom one in α-methyl-D-glucomethyloside, both configurations having been designated alpha (*i. e.*, α-L- and α-D, respectively) in the past from rotatory considerations. The preparation of α-methyl-D-glucomethylo-pyranoside from α-methyl-D-gluco-pyranoside, by Helferich, Klein and Schafer[5] and by Compton[6] (see experimental part) furnishes the structural proof of the alpha classification of the three methylo-pyranosides.

The oxidation of β-methyl-L-galactomethylo-pyranoside (VIII) with periodic acid has yielded a new dialdehyde (IX) which is also crystalline and passes on bromine oxidation to a new dibasic acid, the strontium salt (X) of which

(5) Helferich, Klein and Schafer, *Ber.*, **59**, 84 (1926); *Ann.*, **447**, 19 (1926).

(6) Compton, THIS JOURNAL, **60**, 398 (1938).

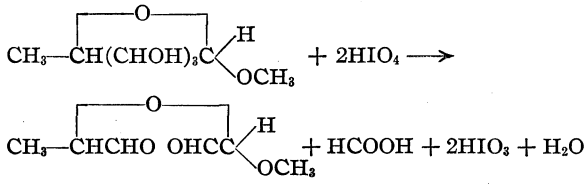


is crystalline. The similar oxidation of β-methyl-D-glucomethylo-pyranoside (XI) has yielded in crystalline state the dialdehyde (XII), which is the enantiomorph of (IX), and the strontium salt (XIII), which is the enantiomorph of (X). Hydrolysis of the dibasic acid of (X) yields L-lactic acid and that of the acid of (XIII) yields D-lactic acid. The two β-glycosides are therefore pyranosides and possess enantiomorphous configurations for carbon atom one, which are the opposites of the configurations for the corresponding α-glycosides. Since β-methyl-D-glucomethylo-pyranoside has been correlated as regards carbon atom one with β-methyl-D-glucoside,[7] the present results prove that the customary α- and β-designations of these methylosides are correct from the stereo-structural standpoint. It is also evident from the rotatory data of column 3, Table III, and Fig. 1 that these methylosides are pure substances, no one of them being a crystalline molecular combination of α- and β-forms.[8]

The four crystalline dialdehydes (two enantiomorphous pairs) and the four corresponding crystalline strontium salts are reference substances which can be employed to learn the ring structure and the α- or β-classification of any methyl pyranoside of the remaining aldohexomethyloses or of any methyl furanoside of the aldopentomethyloses.

The rotational relationships of the aldohexomethylo-pyranosides and their products of oxidation are shown in Table I.

The oxidation of these aldohexomethylo-pyranosides by periodic acid is practically quantitative, one mole of the glycoside consuming 2 moles of periodic acid according to the reaction equation



The distinction between a pyranoside and a furanoside probably can be made very readily in the aldohexomethylose series, since a mole of the pyranoside consumes 2 moles of periodic acid and generates one mole of formic acid, but a mole of the furanoside can be expected to consume only one mole of the acid and produce no formic acid.

It has been known in the past from methylation data[9] and some correlations that three of the

substances here studied (α-methyl-L-mannomethylo-pyranoside and α- and β-methyl-D-glucomethylo-pyranosides) are pyranosides; the present work confirms these ring allocations, extends the proof of the pyranoside structure to the two other glycosides (α- and β-methyl-L-galactomethylo-pyranosides) and proves the α- and β-classification by structural correlation.

We are indebted to Dr. A. E. Knauf for preparing the α- and β-methyl-D-glucomethylosides used in the present investigation. We also express our appreciation to Dr. W. T. Haskins for performing the micro-analyses in connection with this work.

Experimental

Preparation of the Methyl Aldohexomethylo-pyranosides.—The α- and β-methyl-L-galactomethylo-pyranosides were prepared from L-galactomethylose and methyl alcohol containing 1.5% of dry hydrochloric acid gas according to Hockett, Phelps and Hudson.[10] The α-methyloside melted at 157–158° (corr.) and rotated −196.5 ± 0.5°[11] in water, and the β-isomer melted at 122° (corr.) and rotated +14.2° in water.

The α-methyl-D-glucomethylo-pyranoside was obtained by deacetylation of its triacetate, which was prepared by Compton's[6] procedure of tosylation and acetylation of α-methyl-D-glucopyranoside and subsequent iodination and reduction of the terminal carbon atom. The purified triacetate melted at 78–79° (corr.) and rotated +153.4° in chloroform, in good agreement with Compton's values of 77–78° and +153.6°; Helferich, Klein and Schafer[5] reported a melting point of 75° and a rotation of +159.2° in chloroform for the triacetate, which they prepared by reduction of α-methyl-6-bromo-gluco-pyranoside triacetate. Pure α-methyl-D-glucomethylo-pyranoside was found to melt at 98–99°, in agreement with Helferich and his co-workers; the rotation, which apparently has not been recorded, was found to be +152.7° (c, 1.75; l, 4) in water.

The β-methyl-D-glucomethylo-pyranoside was prepared from levoglucosan by way of levoglucosan triacetate, 1,6-dibromo-glucose triacetate, β-methyl-6-bromo-glucoside triacetate and β-methyl-D-glucomethyloside triacetate followed by deacetylation. The purified substance melted at 131–132° (corr.) and rotated −54.6° in water, in agreement with the values of 131–132° and −55.1° reported by Fischer and Zach.[7]

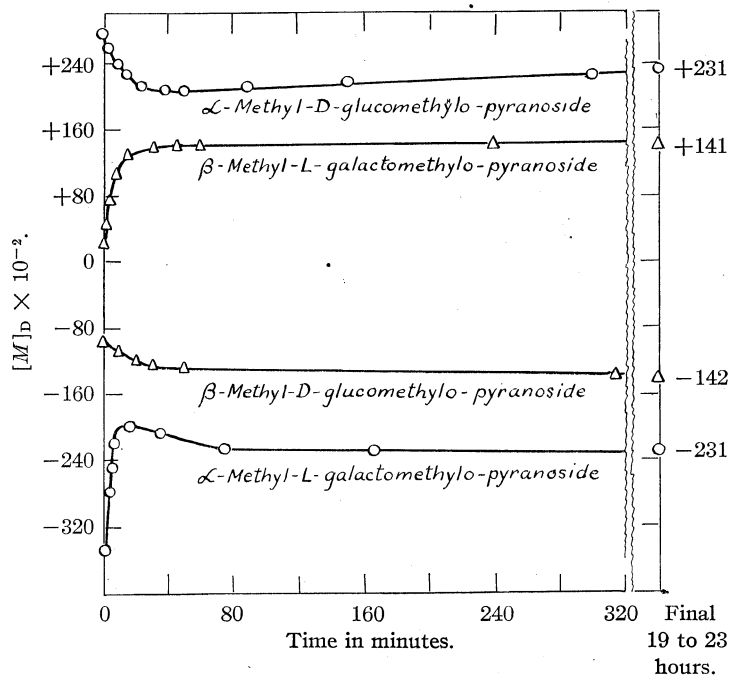

Fig. 1.—Rotatory changes during the oxidation of the methyl aldohexomethylo-pyranosides.

Rotatory Changes during the Oxidation of the Methyl Aldohexomethylo-pyranosides.—To a solution of 0.25 g. of the methyloside in 20 cc. of water was added 4.83 cc. of 0.610 M periodic acid (2.1 molecular equivalents). As quickly as possible the solution was diluted to 25 cc., thoroughly shaken, transferred to a 4-dm. tube and the rotatory changes observed. The solution was kept in a 20° room during the course of the reaction. The rotatory changes during the oxidation are recorded in Table II, and shown in Fig. 1. When the rotation of the solution had become constant, 5 cc. of it was analyzed for periodic acid.[12] The results showed that one mole of the aldohexomethylo-pyranosides (in the order listed in Table II)

(10) Hockett, Phelps and Hudson, THIS JOURNAL, **61**, 1658 (1939).

(11) Unless otherwise stated all rotations are constant specific rotations at 20° for sodium light.

(12) Fleury and Lange, *J. pharm. chim.*, [8] **17**, 107 (1933).

had consumed 1.99, 1.98, 1.99 and 1.99 moles, respectively, of periodic acid. This conforms with the equation previously stated.

hrs.		hrs.		hrs.		hrs.	

[a] Minutes after addition of the periodic acid. [b] Although the solutions were kept in a 20° room throughout the course of the reactions, there were temperature changes in the solutions due to the heat evolved in the oxidation reactions. [c] Calculated from the specific rotations in water of the methyl hexomethylo-pyranosides (mol. wt. 178.1) in the order listed: −196.5 ± 0.5°, +152.7°, +14.2°, −54.6°.

Isolation of the Dialdehydes.—The oxidation of β-methyl-D-glucomethylo-pyranoside and the subsequent isolation of crystalline L′-methoxy-D-methyl diglycolic aldehyde will be described as typical of the procedures used in the oxidation of the four glycosides and the isolation of the corresponding dialdehydes. To a solution of 5.0 g. of pure β-methyl-D-glucomethylo-pyranoside in 148 cc. of water in a 250-cc. volumetric flask was added 99.1 cc. of 0.595 *M* periodic acid (2.1 molecular equivalents). The solution was kept in a 20° room for eighteen hours; it was then made up exactly to 250 cc. with water and its rotatory power determined, which was found to be in agreement with the end-value recorded in Table II for the oxidation of this glycoside. The solution was neutralized to methyl red with a 10% solution of hot strontium hydroxide, and the strontium iodate and periodate salts that precipitated were filtered and washed with water. One gram of strontium carbonate was added and the solution concentrated *in vacuo* to 100 cc. in a water-bath at 50–60°. The strontium carbonate was filtered off and the concentration continued to dryness, partial crystallization of the dialdehyde taking place. The dry residue was extracted with two 50-cc. and two 25-cc. volumes of absolute ethanol, complete extraction being confirmed by the absence of optical activity of an aqueous solution of the crystalline salts remaining after the extraction. The alcoholic extract was concentrated *in vacuo* to a dry sirup which was dissolved in 20 cc. of ether; after shaking for a few minutes, crystals of the dialdehyde began to separate. Twenty-five cubic centimeters of petroleum ether was then added and on standing at room temperature for sixteen hours 2.55 g. of crystalline dialdehyde was obtained. The mother liquor was concentrated to dryness and dissolved in 8 cc. of ethyl acetate, yielding an additional 1.0 g. of crystals. The yield of crystalline product was 3.55 g. (77%) and the rotation of the mother liquor indicated an over-all yield of 95%. Recrystallized from 5 parts of ethyl acetate the L′-methoxy-D-methyl diglycolic aldehyde monohydrate separates in the form of long needles melting at 101–102° (corr.) and rotating −88.8° (*c*, 0.71; *l*, 4) in water.

The four crystalline dialdehydes resulting from the oxidation of their respective parent glycosides form two sets of enantiomorphs. Not only are the properties of the members of each enantiomorphous pair similar in nature, as would be expected of course, but a marked similarity is also found in the properties of the two pairs. Thus, the melting points are nearly the same and the four compounds are readily crystallizable from 5 parts of ethyl acetate or by dissolving them in 10 parts of ether and adding an equal volume of petroleum ether, separating from these solvents as needle-like crystals. Analysis of each of the compounds corresponds to the monohydrate and on heating at 65° over anhydrone in a vacuum (Hyvac pump) they readily sublime without loss of water, which therefore is to be regarded as water of constitution. The yields of crystalline products were 70–80% with overall yields of 90–95%. The rotations, melting points and analyses of these dialdehydes are listed in Table III. The crystallization of the four dialdehydes presents the first opportunity to test an assumption which was made by Jackson and Hudson[2] that the rotation of the non-crystallizable dialdehydes from the periodic acid oxidation of alpha methyl mannopyranoside, etc., is closely given by the constant end rotation of the oxidized solution. In the present case the specific rotations of the dialdehyde monohydrates (mol. wt. 164), as found from the constant end rotations of Table II, are ±23100/164 = ±140.9 and ±14150/164 = ±86.3, in satisfactory agreement with the data of Table III.

Oxidation of the Dialdehydes.—The oxidation of L′-methoxy-D-methyl diglycolic aldehyde to L′-methoxy-D-methyl diglycolic acid and the isolation of the latter in the form of its strontium salt will be described as typical of the technique employed in the oxidation of the four diglycolic aldehydes.

To 10.0 g. of L′-methoxy-D-methyl diglycolic aldehyde monohydrate in 800 cc. of water was added 80 g. of strontium carbonate and 10 cc. of bromine. The oxidation mixture was shaken intermittently for two hours and allowed to stand for an additional fifteen hours. The excess bromine was removed by aeration, the strontium carbonate filtered off and the bromide ions precipitated by shaking with 80 g. of silver carbonate. The silver ions were removed with hydrogen sulfide and the excess hydrogen sulfide by aeration. The solution was concentrated *in vacuo* in a water-bath at 60–70° to a volume of 40 cc. A volume of 40 cc. of absolute ethanol was added and the crystallization of the strontium salt began in a few minutes. After standing in a refrigerator for sixteen hours 11.6 g. of strontium L′-methoxy-D-methyl diglycolate had separated and an additional 0.9 g. was obtained by concentrating the mother liquor to 15 cc. and adding ethanol to saturation; total yield, 12.5 g.

TABLE III

ROTATIONS, MELTING POINTS AND ANALYSES OF THE DIALDEHYDES

Methylo-pyranoside oxidized	Diglycolic aldehyde formed	$[\alpha]^{20}D$[a] (monohydrate)	M. p., °C.	$C_6H_{10}O_4 \cdot H_2O$ C (Calcd. 43.88)	H 7.37	OCH_3 18.91)

TABLE IV

ROTATIONS AND ANALYSES OF THE ANHYDROUS STRONTIUM SALTS

Diglycolic aldehyde oxidized	Strontium-diglycolate formed	$[\alpha]^{20}D$[a]	$C_6H_8O_6Sr$ C (Calcd. 27.30	H 3.06	OCH_3 11.76	Sr 33.23)
L′-Methoxy-L-methyl-	L′-Methoxy-L-methyl-	+68.2°	27.29	3.20	11.66	33.24
D′-Methoxy-D-methyl-	D′-Methoxy-D-methyl-	−68.2°	27.45	3.25	11.81	33.33
D′-Methoxy-L-methyl-	D′-Methoxy-L-methyl-	−45.6°	27.37	3.25	11.60	33.03
L′-Methoxy-D-methyl-	L′-Methoxy-D-methyl-	+45.7°	27.20	3.18	11.93	33.06

[a] (*c*, 1.2–1.5; *l*, 4) in water.

(80%). The compound may be recrystallized in a yield of 80% by dissolving in 10 parts of water and adding a like volume of warm 95% ethanol, separating in the form of plate-like crystals rotating +45.7° (*c*, 1.3; *l*, 4) in water. Strontium L′-methoxy-D-methyl diglycolate and its enantiomorph, strontium-D′-methoxy-L-methyl diglycolate, crystallize in the anhydrous form while strontium L′-methoxy-L-methyl diglycolate and its enantiomorph, strontium D′-methoxy-D-methyl diglycolate, when recrystallized by dissolving in 4 parts of warm water and adding 5 parts of warm 95% ethanol, separate in the form of hydrated rhomboid crystals. Although the latter two salts, after being air-dried at room temperature for forty-eight to seventy-two hours, give reproducible specific rotations of +56.3 and −56.2°, respectively, analyses show the substances to contain a small amount of ethyl alcohol in addition to water of hydration. The salts become anhydrous and free of alcohol on heating *in vacuo* (Hyvac pump) over anhydrone at 138° for six hours. The yields of crystalline strontium salts from the oxidations were 80–90%. Rotatory and analytical data concerning them are listed in Table IV.

Hydrolysis of the Acids from the Strontium Salts.—To a solution of 11.2 g. of strontium L′-methoxy-D-methyl diglycolate in 272 cc. of water was added 42.26 cc. of 2.01 *N* sulfuric acid to balance exactly the strontium ions. A volume of 314 cc. of 95% ethanol was added and after standing for eighteen hours the strontium sulfate was filtered off and washed with 50% ethanol. The filtrate was concentrated *in vacuo* to 50 cc. and diluted with 50 cc. of 95% ethanol. The mixture was filtered and the filtrate concentrated to a thick sirup. The sirup was dissolved in 20 cc. of water and reconcentrated to dryness to remove alcohol. The L′-methoxy-D-methyl diglycolic acid sirup was dissolved in 100 cc. of water and heated on a steam-bath for three hours, the rotatory power of the solution becoming constant at the end of two hours. The hydrolyzed solution was diluted to 275 cc., 4 cc. of bromine was added and the reaction mixture allowed to stand for forty-eight hours. The excess bromine was removed by aeration and the oxalic acid precipitated as barium oxalate by neutralizing the solution to phenolphthalein with 0.45 *N* barium hydroxide. The dried barium oxalate (5.0 g., yield 52%) was dissolved in hot dilute hydrochloric acid and the barium ions precipitated with sulfuric acid. On concentration of the filtrate to a small volume the oxalic acid dihydrate crystallized. After recrystallization from water the oxalic acid was identified by its m. p. and its titration with alkali.

The filtrate from the barium oxalate precipitate was balanced with sulfuric acid to remove the barium ions and then shaken with 50 g. of silver carbonate to remove the bromide ions. The silver was removed by precipitation with hydrogen sulfide and the hydrogen sulfide by aeration. The solution was concentrated to 250 cc. and boiled for three minutes with 3 g. of zinc hydroxide. The excess zinc hydroxide was filtered off and the filtrate concentrated *in vacuo* at 60° to a volume of 20 cc. On standing for sixteen hours, 3.2 g. of zinc D-lactate dihydrate separated (yield 59%). Recrystallized from 4 parts of water the zinc D-lactate separated in the form of needle-like crystals and rotated +7.7° (*c*, 3.2; *l*, 4) in water.

Each of the other three strontium salts was treated in the same manner; in each case oxalic acid and an optically active form of zinc lactate were isolated in like yields. The rotations and analyses of the zinc lactates isolated are listed in Table V.

Zinc D-Lactate from Morphine D-Lactate.—The zinc lactates prepared from the four strontium salts exhibited larger rotations (see Table V) than those recorded by Irvine[13] ($[\alpha]D_{15}$ +6.84° (*c*, 5.6) for zinc D-lactate; $[\alpha]D_{20}$ −6.83° (*c*, 7) for zinc L-lactate) for the same compounds which were obtained from racemic lactic acid by resolution with morphine. In order to further establish the rotational values for the optically active zinc lactates a sample of the D-salt was prepared from pure morphine D-lactate. A quantity of morphine D-lactate prepared according to the directions of Irvine[13] was furnished the authors by Dr. E. L. Jackson. Recrystallized twice from 4 parts of 50% ethanol, morphine D-lactate rotates

(13) Irvine, *J. Chem. Soc.*, **89**, 935 (1906).

TABLE V

ROTATIONS AND ANALYSES OF ZINC LACTATES FROM THE STRONTIUM SALTS

Strontium diglycolate	Zinc lactate isolated	$[\alpha]^{20}D^{a}$	$C_6H_{10}O_6Zn \cdot 2H_2O$ C (Calcd. 25.75	H 5.05	Zn 23.39)
L′-Methoxy-L-methyl-	Zinc L-lactate	−7.7°	25.66	5.06	23.30
D′-Methoxy-D-methyl-	Zinc D-lactate	+7.8°	25.73	5.10	23.54
D′-Methoxy-L-methyl-	Zinc L-lactate	−7.9°	25.66	5.12	23.31
L′-Methoxy-D-methyl-	Zinc D-lactate	+7.7°	25.75	5.16	23.56

[a] (*c*, 3.0–3.8; *l*, 4) in water.

−92.2° (*c*, 5.0) in water, in good agreement with the value of −91.8° (*c*, 5) reported by Irvine for this substance. In order to eliminate the possibility of partial racemization by conversion of the D-lactic acid into its calcium salt as done by Irvine, the morphine D-lactate was decomposed and the resultant D-lactic acid isolated according to the directions of Freudenberg and Rhino.[14] To a solution of 9.7 g. of pure morphine D-lactate in 100 cc. of water was added 5 cc. of concentrated ammonium hydroxide. The precipitated morphine was filtered and the filtrate made acid to congo red by the addition of 7.2 cc. of 5.85 *N* sulfuric acid. The solution was then extracted successively with twenty 100-cc. and a like number of 50-cc. volumes of ether. The ethereal extracts were combined, concentrated to a dry sirup and the zinc D-lactate prepared and isolated in a yield of 1.2 g. in the same manner as the zinc lactates obtained from the strontium salts. Recrystallized from 4 parts of water, the zinc D-lactate rotated +7.9° (*c*, 3.2; *l*, 4) in water, in good agreement with the rotational values of the zinc D-lactates obtained from the strontium salts. The specific rotation was the same in a concentration of 5.2.

Summary

The oxidation of α-methyl-L-galactomethylo-pyranoside with periodic acid yields the same crystalline dialdehyde as Jackson and Hudson obtained from the oxidation of α-methyl-L-mannomethylo-pyranoside by the same reagent. A crystalline enantiomorphous dialdehyde is obtained from the periodic acid oxidation of α-methyl-D-glucomethylo-pyranoside. These two dialdehydes, on oxidation by bromine water in the presence of strontium carbonate, form crystalline enantiomorphous strontium salts, derivatives of L′-methoxy-L-methyl diglycolic and D′-methoxy-D-methyl diglycolic acids, respectively. Hydrolysis of these dibasic acids yields L-lactic acid from the former and D-lactic acid from the latter, proving these aldohexomethylosides to be pyranosides and establishing the configurations of the lactic acids through correlation with the known sugar configurations of Fischer. The designation of these three glycosides as α-forms, based in the past upon rotatory considerations, is now proved conclusively through their oxidation by periodic acid.

In like manner, the periodic acid oxidation of β-methyl-L-galactomethylo-pyranoside and β-methyl-D-glucomethylo-pyranoside yields two crystalline enantiomorphous dialdehydes which, in turn, yield two crystalline strontium salts, derivatives of D′-methoxy-L-methyl diglycolic and L′-methoxy-D-methyl diglycolic acids, respectively. Hydrolysis of these dibasic acids yields L-lactic acid from the former and D-lactic acid from the latter, proving the two β-aldohexomethylosides to be pyranosides and their designation as β-forms to be correct from the stereostructural standpoint.

Rotatory data of the oxidation of the four aldohexomethylo-pyranosides show them to be pure substances and not crystalline molecular combinations of α- and β-forms.

The four crystalline dialdehydes and the four corresponding crystalline strontium salts are reference substances which can be employed to learn the ring structure and the α- or β-classification of any methyl pyranoside of the remaining aldohexomethyloses or of any methyl furanoside of the aldopentomethyloses.

The Oxidation of Certain Glycosides by Lead Tetraacetate[1]

BY R. C. HOCKETT AND W. S. MCCLENAHAN[2]

In a previous paper[3] we stated that a number of methyl pyranosides, when dissolved in certain non-aqueous solvents, rapidly consume two molecular equivalents of lead tetraacetate. Evidence was presented that the two stages of the oxidation are (1) cleavage of a carbon–carbon bond between two adjacent, free carbinol groups with formation of a dialdehyde (II) and (2) subsequent elimination of one carbon atom to produce a second dialdehyde (IV).

Since the pyranosides all contain three adjacent unprotected carbinol groups (I), there are obviously two alternative positions in each compound at which the initial cleavage may occur. The isolated final products of the reaction do not, of course, by their structure provide any information regarding the position of initial attack (IV). Criegee,[4] however, has accumulated considerable evidence to the effect that *cis* glycols are oxidized more rapidly than *trans* glycols. Among the glycosides under investigation there may exist three possible types of configuration since the three carbinol groups inside the ring may be considered as forming two overlapping pairs: these types may be designated *cis–cis*, *cis–trans* (I), or *trans–trans*. No compounds of the first type were available during this study, but several *cis–trans* and *trans–trans* glycosides have been investigated. If Criegee's observation with respect to rates of oxidation is of general application it would be predicted that all those glycosides which contain no *cis* glycol configuration would consume their first mole of lead tetraacetate less rapidly than those which contain at least one *cis* pair of hydroxyls.[5] This relation has been verified in all the cases studied. Figure 1 shows a significant gap between the curve representing the oxidation of the slowest *cis–trans* glycoside (α-methyl-1-fucopyranoside) and that of the fastest *trans–trans* glycoside (β-methyl-*d*-xylopyranoside). The correlation between configurations and rates suggests that the *cis* positions are those initially attacked.

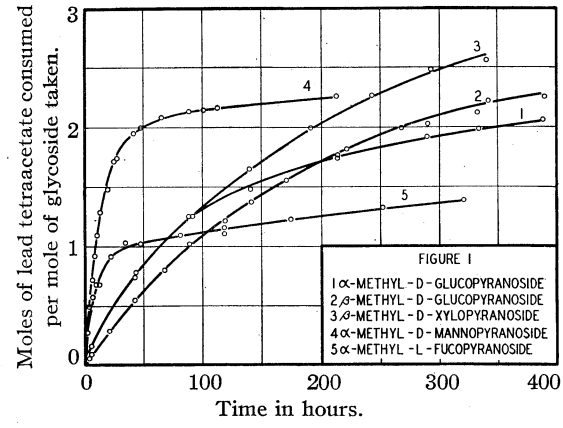

Fig. 1.

The second objective of the present study was to discover what effect upon the rates of oxidation would result from changing the substituent upon the reducing group from methyl to benzyl. In the two cases examined (α-methyl- and α-benzyl-fructofuranoside, β-methyl- and β-benzyl-fructopyranoside,[6(a)] this alteration in structure was found to have very little effect (Fig. 2).

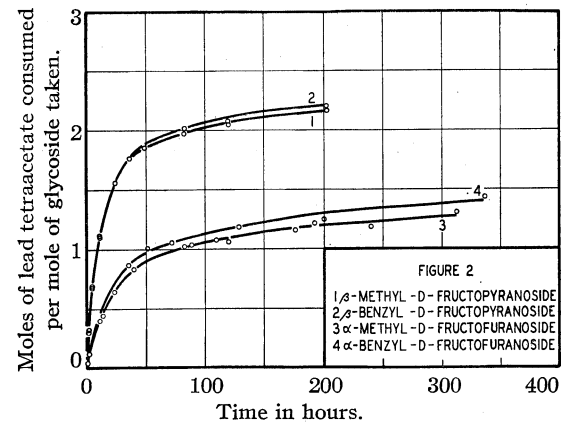

Fig. 2.

(5) Similar considerations have been employed by Freudenberg and Rogers, THIS JOURNAL, **59**, 1602 (1937), in establishing the configurations of the anhydrohexitols, styracitol and polygalitol.

(6) (a) Purves and Hudson, THIS JOURNAL, **59**, 49, 1170 (1937); (b) Pacsu, *ibid.*, **57**, 745 (1935).

A third objective was to learn whether reversing the configuration of the groups about the reducing carbon would alter the oxidation rates. In the few cases where an α- and β-pair were available for testing, their curves belonged to the same family (Figs. 3 and 4).

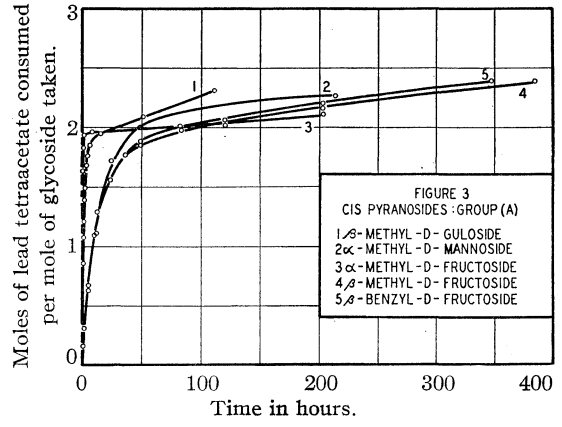

Fig. 3.

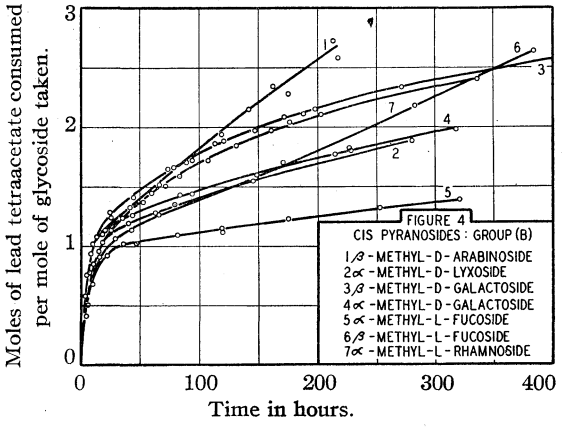

Fig. 4.

The fourth objective was to gain some information concerning the rates of consumption of the second mole of oxidant. The observation of Criegee[7] that glycerol consumes two moles of lead tetraacetate is presumptive evidence that hydroxyaldehydes are attacked by this reagent since glycolaldehyde should be the product of oxidation by the first mole. We found experimentally that the *cis* glycosides studied can be divided sharply into two groups according to whether (A) (Fig. 3) the consumption of oxidant slows down significantly only after the absorption of two moles or whether (B) (Fig. 4) it slows down after use of one mole. It has been found possible to correlate these differences by means of a simple hypothesis. All the glycosides of the first type (A) are so constituted that after initial fission at the *cis* glycol position, the resulting product would be a γ-hydroxyaldehyde (*e. g.*, II). According to the observations of Helferich,[8] hydroxyaldehydes of this nature readily form cyclic hemiacetals; such rearrangement would produce a five-membered ring structure (III) containing a new pair of adjacent carbinol groups which presumably would be attacked readily by the oxidant.[9] The glycosides of the first type (A) are so constituted that after initial fission at the *cis* glycol position, the resulting product would be a γ-hydroxyaldehyde (*e. g.*, II). According to the observations of Helferich,[8] hydroxyaldehydes of this nature readily form cyclic hemiacetals; such rearrangement would produce a five-membered ring structure (III) containing a new pair of adjacent carbinol groups which presumably would be attacked readily by the oxidant.[9] The glycosides of the first type (A) are so constituted that after initial fission at the *cis* glycol position, the resulting product would be a γ-hydroxyaldehyde (*e. g.*, II). According to the observations of Helferich,[8] hydroxyaldehydes of this nature readily form cyclic hemiacetals; such rearrangement would produce a five-membered ring structure (III) containing a new pair of adjacent carbinol groups which presumably would be attacked readily by the oxidant.[9] The gly-

(7) Criegee, *Ann.*, **495**, 211 (1932).

(8) Helferich, *Ber.*, **64**, 104 (1931).

(9) (a) More exactly, the dialdehyde probably would be in equilibrium with two cyclic hemiacetals in which the new glycol groups would be *cis* and *trans*, respectively. Criegee[4b,c] has shown that *cis* glycols in a five-membered ring system frequently are oxidized very rapidly; the concentration of the *cis* form would tend to maintain itself through a shift in the equilibrium.

(b) Oxidation of such a hemiacetal should yield a formic acid ester similar to that formulated by Felton and Freudenberg, THIS JOURNAL, **57**, 1637 (1935).

(c) A similar hypothesis was advanced by Criegee[7] to explain why α-methyl-mannofuranoside and 1-mannono-γ-lactone produced little formaldehyde when oxidized by lead tetraacetate. In these cases, if initial fission occurs between carbons two and three, cyclic hemiacetal formation would destroy the remaining glycol structure and *prevent* further oxidation (VII, VIII and IX).

cosides of type (B) if initially cleaved at the *cis* position yield products whose structures are unfavorable to hemiacetal formation (unless bimolecularly) and hence may be expected to react further less readily.

The most striking case of this difference is represented by the pair: α-methyl-*d*-mannopyranoside (I) and α-methyl-*l*-rhamnopyranoside (V). These substances would be enantiomorphs save for the lack of oxygen on carbon six of the latter. The former rapidly consumes *two* moles of lead tetraacetate while the latter, although initially attacked at nearly the same rate, slows down a great deal after use of one mole. To gain additional evidence concerning the function of the sixth hydroxyl in promoting the second stage of the reaction, through hemiacetalization, the behavior of 6-trityl-α-methyl-*d*-mannoside (VI) was studied. It was first ascertained that this substituent was stable toward the reaction medium (glacial acetic acid) and then it was found that the rate of oxidation closely paralleled that of the methyl rhamnoside (Fig. 5).

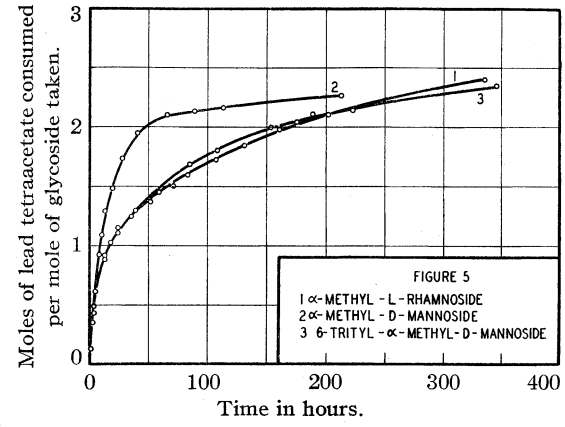

Fig. 5.

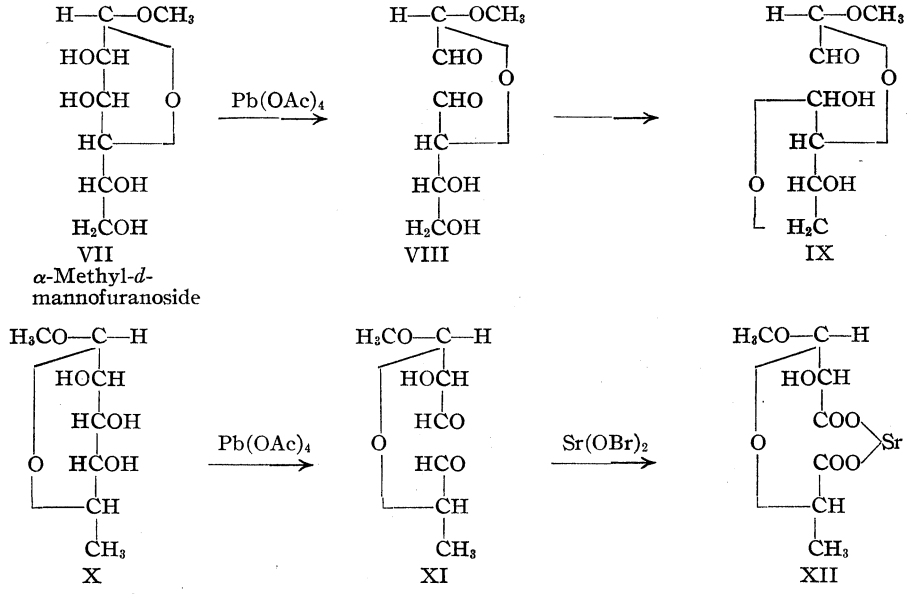
previous publication.[3] There was isolated, as its strontium salt, a dibasic acid which seems to contain all the original carbon of the glycoside and therefore probably is represented correctly by formula XII.

The consumption of only one mole of oxidant by this glycoside would have suggested the presence of a furanoside structure but for the rate of this reaction which is characteristic of a *cis*-hydroxyl pair. That α-methyl-*d*-fucoside (−197°) is a pyranoside has been established beyond question by Maclay, Hann and Hudson[11] through oxidation by periodic acid. Hence the very low rate of attack of the dialdehyde initially formed appears attributable to the unfavorable structure



It was also noted from the rate curve that α-methyl-*l*-fucoside (of rotation[10] −197°) is only slowly attacked after oxidation by one mole of oxidant. A sample of this glycoside was therefore treated with an equimolar quantity of lead tetraacetate by the technique described in the

(10) All rotations stated in this paper refer to specific rotations of sodium light at 20°.

(11) Maclay, Hann and Hudson, THIS JOURNAL, **61**, 1660 (1939).

of this substance in accordance with the hypothesis given. The data obtained for several miscellaneous compounds are illustrated in Fig. 6. From this it appears that the oxygen bridge in fructose is stable even after cleavage of the carbon chain has occurred.

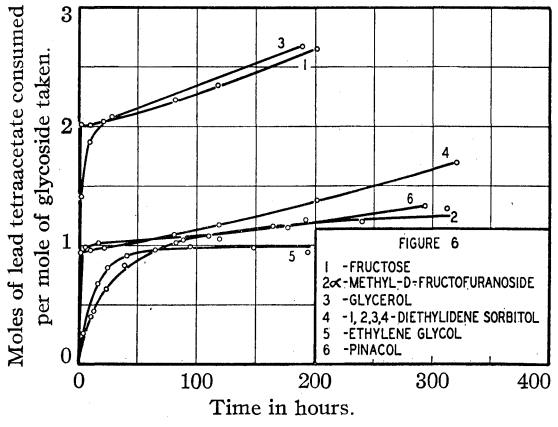


Fig. 6.

In the rate studies the molar concentrations of the glycosides were uniform throughout. A ratio of six and one-half moles of oxidant to one of glycoside was used. That this was virtually equivalent to an infinite excess is indicated by the observation that doubling the ratio in certain cases caused practically no change in rate.

We wish cordially to thank Professor C. B. Purves of this Laboratory for the fructosides employed, Dr. H. S. Isbell of the National Bureau of Standards for samples of α- and β-methyl-*d*-gulopyranosides, and Dr. Paul Arthur, Jr., of this Laboratory for valuable suggestions in the interpretation of the data.

Experimental

Standard Lead Tetraacetate Solution.—The salt prepared as previously described[3] was recrystallized from glacial acetic acid and was made up to a normality of 0.1315 in aldehyde-free acetic acid (29 g. per liter) by dissolving the requisite weight in hot acid, pouring the solution into cool acid and filtering the mixture. The solution was standardized under the conditions used in the rate determinations. It was found to deteriorate gradually over a period of several months.

Rate Determinations.—To 49 cc. of aldehyde-free acetic acid in a 100-cc. glass-stoppered volumetric flask was added 0.0005 mole (0.001 equivalent) of the dry glycoside which had been purified until its rotation agreed with recorded values. Warming on the steam-bath was necessary in a few cases. After cooling the solution to 20°, the time was noted and 50 cc. of standard lead tetraacetate solution at 20° was added from a pipet. The mixture was made up rapidly to 100 cc., mixed and placed in a constant temperature room maintained at 20–21°. At noted intervals, 10-cc. samples were withdrawn and run into 20 cc. of aqueous buffer solution containing 20 g. of reagent sodium or potassium iodide and 250 g. of sodium acetate per liter; the liberated iodine[12] was titrated with 0.02 *N* sodium thiosulfate solution.

The method was employed successfully upon as little as 0.000125 mole (24 mg.) of glycoside by making proportionate reductions in all the quantities given above.

α-Methyl-*l*-rhamnopyranoside.—A 3-g. sample of triacetyl-α-methyl-*l*-rhamnopyranoside melting at 86–87° (corr.), showing a rotation of −54.65° in acetylene tetrachloride (*c*, 3.2112; *l*, 4) and −60.34° in chloroform (*c*, 3.2100; *l*, 4) was deacetylated with barium methylate.[13] The concentration of the resulting aqueous solution was calculated from its optical rotation, the solvent was removed by distillation under reduced pressure and remaining traces of water by several redistillations in the presence of glacial acetic acid. The sirup was made up to 250 cc. with acetic acid and aliquots containing 0.0005 mole of methyl rhamnoside were withdrawn for oxidation experiments.

6 - Trityl - α - methyl - *d* - mannopyranoside.—This substance, prepared by the method of Watters, Hockett and Hudson,[14] who also proved the structure, rotated +22.1 (*c*, 1.4680; *l*, 2; $CHCl_3$) after drying to constant weight *in vacuo* at 65°.

α- and β-Methyl-*l*-fucosides.—Fucose, extracted from *Ascophyllum nodosum*, was converted to the glycosides as described by Hockett, Phelps and Hudson,[15] using precipitation with potassium acetate to separate the β-isomer from the predominating α-form.[16]

Oxidation of α-Methyl-*l*-fucopyranoside.—Two grams (0.011 mole) of the fucoside was oxidized in 150 cc. of chloroform with 5 g. (0.011 mole) of lead tetraacetate according to the method previously described.[3] After removing lead and acetic acid, the rotation of an aqueous solution was observed, and a specific rotation of approximately −80° was calculated assuming that the oxidation had been complete and that only one product had been formed. A titration by the Cajori[17] method revealed that approximately two equivalents of aldehyde had been formed per mole of lead tetraacetate consumed. In a two-stage oxidation, the same quantity of aldehyde would be produced by two moles of oxidant. After oxidation with strontium hypobromite, 2.5 g. (71%) of very fine crystals of a strontium salt was obtained. The rotation was unchanged by recrystallization after a value of +29.80° in water (*c*, 0.6924; *l*, 4) was reached. The free acid liberated by an equivalent quantity of hydrochloric acid rotated −13.2° (*c*, 0.2650; *l*, 4); after adding 3 drops more of concd. hydrochloric acid, −16.8°.

(12) An experiment was made which indicated that the aldehydes formed in the oxidation of the glycosides probably do not react appreciably with the liberated iodine in the *acid* solution: 5-cc. of standard lead tetraacetate solution was added to a mixture of 5 cc. of acetic acid and 20 cc. of buffer solution. Then 0.5 g. of glucose was added. After five minutes, the titer with sodium thiosulfate was found to be the same as with a blank.

Anal. Calcd. for $C_7H_{10}O_7Sr \cdot 2H_2O$: H_2O, 10.93. Found: loss in wt. at 105°, *in vacuo*, 10.18, 11.0. Calcd. for $C_7H_{10}O_7Sr$: Sr, 29.84. Found: 29.40, 29.25. Calcd. for $C_6H_8O_6Sr$: Sr, 33.23.[18]

Summary

1. The rates of oxidation of a number of glycosides by lead tetraacetate in glacial acetic acid have been measured.

2. All the glycosides which contain a *cis* glycol structure consumed the first mole of lead tetraacetate much more rapidly than those which contain only *trans* glycol structures, suggesting that the initial attack is at the *cis* position when such is present.

3. In two cases, substitution of benzyl for methyl on the first carbon has no effect upon the oxidation rates.

4. In several cases, α- and β-isomers have been found to show a general similarity in the oxidation experiments.

5. The glycosides containing glycol structures have been separated by experimental study into two groups: (A) those which consume a second mole of oxidant with a speed comparable to that at which the first is consumed, and those (B) which consume the second mole at a distinctly lower rate, and a hypothesis has been proposed to explain this difference.

6. The substitution of a trityl radical at carbon six of α-methyl-*d*-mannopyranoside is shown to shift this glycoside from group (A) to group (B) in accord with the prediction of the hypothesis.

7. α-Methyl-*l*-fucoside (−197°) has been oxidized by one mole of lead tetraacetate in chloroform solution and by strontium hypobromite to a dibasic acid containing all the carbon of the original substance.

CAMBRIDGE, MASS. RECEIVED APRIL 5, 1939

(18) The physical properties of our salt also differ markedly from those of the strontium salt obtained by Maclay and Hudson (ref. 11) which contains one carbinol group less.

Glycofuranosides and Thioglycofuranosides. VI. Preparation of Dimethyl Acetal and Methylfuranosides from *d*-Fructosediethylmercaptal

BY EUGENE PACSU

In a preliminary communication[1] it was reported that the application of the furanoside synthesis developed[2] in this Laboratory to *d*-fructosediethylmercaptal had resulted in the unexpected formation of *d*-fructosedimethylacetal. This was the second observed case where a sugar acetal had been formed from a starting material that contained all of its hydroxyl groups unprotected, the first case being that of the *l*-rhamnosedimethylacetal.[2e] The starting material, fructosediethylmercaptal, could not be obtained directly from fructose and mercaptan. Since Emil Fischer showed[3] that his general method for the preparation of sugar mercaptals had failed in the case of fructose and sorbose, it appeared as though the ketose mercaptals could not exist at all. However, Brigl and Schinle found[4] that the benzoyl analog of pentaacetyl-*keto*-fructose, for which the open-chain structure with a free carbonyl group was previously established[5] by Pacsu and Rich, gave readily a mercaptal derivative on treatment of the substance with ethyl mercaptan and dry hydrogen chloride. Subsequently, Wolfrom and Thompson reported[6] the formation of pentaacetyl fructosediethylmercaptal from pentaacetyl-*keto*-fructose and ethyl mercaptan in the presence of zinc chloride. From the acetylated mercaptal, on deacetylation with ammonia in methyl alcoholic solution, the authors obtained fructosediethylmercaptal in about 78% yield. It has now been found that the yield of the latter compound can be increased almost to that required by the theory, if the deacetylation be carried out at room temperature in methyl alcoholic solution in the presence of a small quantity of barium methylate.

The reaction between sugar mercaptals and mercuric chloride in neutral alcoholic solution was hitherto believed[2b] only to proceed through the following two stages

(1) Pacsu, THIS JOURNAL, **60**, 2277 (1938).

(2) (a) Pacsu and Green, *ibid.*, **58**, 1823 (1936); (b) Green and Pacsu, *ibid.*, **59**, 1205 (1937); (c) Green and Pacsu, *ibid.*, **59**, 2569 (1937); (d) Green and Pacsu, *ibid.*, **60**, 2056 (1938); (e) Green and Pacsu, *ibid.*, **60**, 2288 (1938); (f) Pacsu and Scattergood, *ibid.*, **61**, 534 (1939).

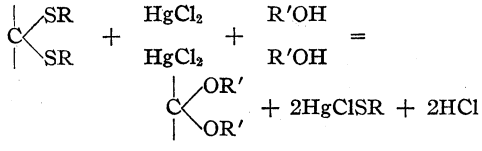
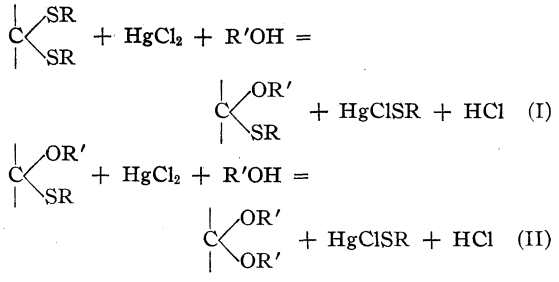
Usually, the final products of the reaction were found to be the more negative rotating forms of the furanosides admixed to a much smaller quantity of the diastereomers. Only in the case of glucose mercaptals was it possible to isolate the intermediate thiofuranosides, because the latter type of compounds, with the exception of the thioglucofuranosides, evidently reacted faster with mercuric chloride than the sugar mercaptals themselves. However, the reaction between *l*-rhamnose ethylmercaptal and methyl alcoholic mercuric chloride was shown recently[2e] to give rise to rhamnosedimethylacetal beside a large quantity of a sirupy product which undoubtedly was a mixture of the methyl rhamnofuranosides. Now it has been found that fructose ethylmercaptal reacts with mercuric chloride in methyl alcohol to yield almost exclusively the dimethylacetal, provided that the reaction is carried out at a very low temperature (−80°). In the formation of dimethylacetals the reaction must have proceeded either directly, according to the following general equation

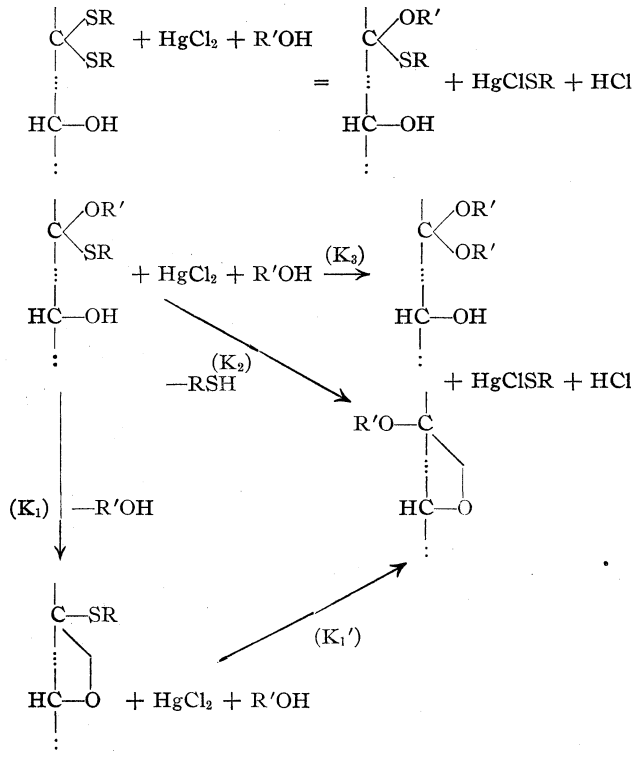


or in two stages, through the mixed acetal, as follows



Since it has not been possible to isolate the postulated intermediate product, the mixed acetal, it is to be concluded that if the dimethylacetal formation took place indirectly, according to the latter equations, then the velocity of the second stage of the reaction must have been very much faster than that of the first phase of the process. In the light of this interpretation the acetal formation in either direct or indirect way from a mercaptal appears to be a distinct reaction, which, depending upon unknown factors, may or may not occur as a side-reaction accompanying the usual conversion of the sugar mercaptals into furanosides and thiofuranosides.

However, it should be pointed out that it is entirely possible to consider all the observed products of the reaction, namely, thioglycofuranosides, glycofuranosides and acetals as being derived from one common intermediate, the mixed acetal. This view is best illustrated by the following diagram



According to this conception, the mixed acetal may undergo three distinct transformations: (1) loss of one mole of alcohol results in the formation of thioglycosides (K_1) which usually react further (K_1') to give rise to furanosides; (2) intramolecular loss (K_2) of one mole of mercaptan

yields furanosides; (3) intermolecular loss (K_3) of one mole of mercaptan produces acetals. Of course, the yields of the final product or products will depend upon the relative rates of the single stages. Until the mixed acetal can be isolated and the rates of its different transformations studied, this interpretation appears to be the most plausible for the mechanism of the complex reaction of sugar mercaptals with alcoholic mercuric chloride.

By the preparation of fructosedimethylacetal, it became quite definite that Purves and Hudson's[7] "gamma-methylfructoside (a)" is not identical with this acetal. From the results of analysis of gamma-methylfructoside mixtures by means of invertase the authors concluded that the constituent hydrolyzed by invertase and fermented by yeast must have a specific rotation of $-52 \pm 2°$, calculated for a true methylfructoside of molecular weight 194. Since this "gamma-methylfructoside (a)" has never been isolated and analyzed in substance, it could have represented the acetal, the hemiacetal or the β-methylfructofuranoside. In fact, its specific rotation ($-54°$) if calculated for a dimethyl acetal of molecular weight 226, becomes $-46.3°$, whereas the crystalline fructosedimethylacetal was found to have $[\alpha]^{20}D$ $-46.5°$. It was, therefore, of great interest to investigate the behavior of the crystalline acetal toward invertase and yeast.

On the addition of a powerful invertase solution the rotation of the crystalline acetal was found to remain unchanged for several hours in an unbuffered solution and dropped very slowly in a solution buffered to *p*H 4.5. Under identical conditions the same invertase solution hydrolyzed 75.7% of a 1.28% sucrose solution at *p*H 4.5 in thirty minutes. Furthermore, it partially hydrolyzed in thirty-five minutes the gamma-methylfructoside mixture prepared according to Purves and Hudson,[7a] the time of hydrolysis and final rotation being practically the same as those reported by the authors. The negative action of the invertase solution on the acetal was not due to inactivation, since the mixture rapidly inverted sucrose or hydrolyzed the gamma-methylfructoside mixture. The very slow change of rotation observed in the acetal-enzyme solution at *p*H 4.5 subsequently was found to be caused by the slow hydrolysis of the acetal due to the hydrogen ions, since it also occurred in the absence of invertase.

(7) Purves and Hudson, (a) THIS JOURNAL, **56**, 702 (1934); (b) **56**, 708 (1934).

Experiments carried out in fermentation saccharimeters showed that the acetal was fermented by yeast in distilled water, as measured by the volume of the carbon dioxide generated, about four times slower (twenty-three hours) than sucrose under identical conditions (six hours). However, yeast was without any effect on the acetal in a citric acid–disodium phosphate buffer solution of *p*H 7, while sucrose reacted in about twenty hours under similar conditions. When the hydrogen-ion concentration of the former solution was afterward adjusted to *p*H 5.6, a very slow fermentation began, the carbon dioxide generation reaching the end in about one week. These results clearly indicated that the action of yeast on the acetal in an unbuffered solution was due to the fermentation of fructose liberated from the acetal by the acid content of the yeast and that it was not a genuine enzymotic effect. They also suggested that the acetal must be extremely sensitive toward acid, a fact which subsequently was found to be the case, since the substance was hydrolyzed at room temperature in a 0.08 *N* hydrochloric acid within two minutes, and in a 0.00089 *N* acid in about six hours.

In a preliminary experiment carried out in anhydrous methyl alcoholic solution containing 0.84% hydrogen chloride, the specific rotation of the acetal was found to change in one hour from the initial rotation of $-63°$ to a dextrorotatory maximum of 14° calculated for methylfructoside. This transformation followed a unimolecular course with the velocity constant of $10^4 K = 347 \pm 20$. After the point of maximum rotation had been reached the rotation diminished very slowly, but the solution was still non-reducing. A detailed study is being made of the behavior of the acetal in acid media to discover the nature of substances present in the equilibrium mixture.

The reaction between fructose diethylmercaptal and methyl alcoholic chloride does not always give rise to the acetal exclusively. The acetal was found to be the single product only when the temperature had been kept very low during the reaction. At 0° or at higher temperature the reaction also proceeded in other directions and, beside the acetal, it gave rise to a considerable amount of a non-reducing, sirupy mixture. On systematic extractions with acetone and ethyl acetate, this mixture was finally separated into a crystalline product and a liquid fraction. The former was identified as the "crystalline gamma-

methylfructoside" of Purves and Hudson,[7b] showing the correct m. p. 69° and $[\alpha]^{20}D$ 93.0° in water solution. The liquid fraction has not yet been obtained in sufficient purity, but its specific rotation and especially the fact that invertase hydrolyzes it rapidly, lend support to the view that it represents the assumed "gamma-methylfructoside (a)" of Purves and Hudson. Attempts are being made to obtain this interesting substance in pure form.

Experimental

Preparation of *d*-Fructosediethylmercaptal.—Pentaacetyl-*keto*-fructose prepared according to Cramer and Pacsu[8] was converted into its ethyl mercaptal by the procedure of Wolfrom and Thompson.[6] The deacetylation was best carried out in small portions and the crude products obtained were united and recrystallized from methyl alcohol and ether. In a typical experiment 0.5 cc. 0.33 *N* barium methylate solution, prepared by refluxing barium oxide in anhydrous methyl alcohol for thirty minutes, was added to 5 g. of the acetylated mercaptal dissolved in 15 cc. of anhydrous methyl alcohol. After sixteen to twenty hours of standing at room temperature, one drop of the solution remained clear on addition of water, indicating that the reaction was completed. The residue obtained from the solution was crystallized from a small amount of methyl alcohol containing twice the volume of ether; yield, almost quantitative; m. p. and specific rotation in methyl alcohol agreed with the values given by Wolfrom and Thompson. The specific rotation of the mercaptal in water solution was found to be $[\alpha]^{20}D$ 16.5°; $[\alpha]^{20}_{6568}$ 12.9°; $[\alpha]^{20}_{5463}$ 20.2°; $[\alpha]^{20}_{61}$ 27.4° (*c*, 2.174).

Preparation of *d*-Fructosedimethylacetal.—To 11.4 g. of the mercaptal in 100 cc. of anhydrous methyl alcohol 17 g. of yellow mercuric oxide was added in a three-necked flask equipped with a mercury-sealed mechanical stirrer, a separatory funnel and a reflux condenser. The apparatus was placed in a Dewar flask containing an acetone–carbon dioxide mixture and the flask was immersed in an ice–salt bath. Under vigorous stirring a solution of 21.8 g. of mercuric chloride (2 moles) in 60 cc. of anhydrous methyl alcohol was added in about fifteen minutes to the mercaptal through the separatory funnel. After seventeen hours of continuous stirring at the freezing mixture's temperature, a filtered sample failed to produce $HgCl\text{-}SC_2H_5$ precipitate on heating, an indication that the reaction was completed. Then the reaction mixture was filtered and 5 cc. of pyridine was added to the filtrate for the removal of the excess of mercuric chloride. After two hours' standing at 0° the solution was filtered from the mercuric chloride–pyridine precipitate and evaporated *in vacuo* to a sirup. In order to remove the last traces of the pyridine salt the sirup was dissolved in ice cold water and the solution filtered with carbon. The filtrate was then made alkaline to phenolphthalein with a few drops of dilute alkali and evaporated *in vacuo* to a sirup. This was dissolved in methyl alcohol, filtered with carbon, if necessary, and the solution evaporated under diminished pressure to a colorless, non-reducing sirup, which gradually changed into a mass of diamond-shaped crystals. The substance crystallized from hot *n*-propyl alcohol in beautifully developed prisms. After a final recrystallization from absolute ethyl alcohol it had m. p. 107–108°; $[\alpha]^{20}D$ −45.6°; $[\alpha]^{20}_{6563}$ −35.6° and $[\alpha]^{20}_{5463}$ −53.6° in water solution (0.2977 g. of substance, 10 cc. of solution; 2-dm. tube; rotations, 2.71, 2.12 and 3.19° to the left, respectively); yield, 7 g. In methyl alcohol solution the acetal had $[\alpha]^{20}D$ −63.0°, $[\alpha]^{20}_{6563}$ −50.0° and $[\alpha]^{20}_{5463}$ −76.1° (*c*, 1.15).

Anal. Calcd. for $C_8H_{18}O_7$: OCH_3, 27.4. Found: OCH_3, 27.1.

Preparation of Pentaacetyl *d*-Fructosedimethylacetal.—One gram of the acetal was acetylated at 100° with acetic anhydride containing 5% of anhydrous sodium acetate. After the solution was evaporated *in vacuo*, a sirupy residue was obtained which, on addition of water, changed at once into crystals. On recrystallization from absolute alcohol, the substance was obtained in well-developed prisms with m. p. 109° and $[\alpha]^{20}D$ 0° in chloroform solution. In an acetyl estimation 0.1453 g. of the compound required 16.4 cc. of 0.1 *N* sodium hydroxide solution. The value calculated for the hydrolysis of five acetyl groups is 16.6.

Action of Methyl Alcoholic Mercuric Chloride on *d*-Fructosediethylmercaptal at 0° and Higher Temperature.—The experiment described for the preparation of fructosedimethylacetal was repeated with the modification that the apparatus was kept in ice cold water and the mercuric chloride solution was added to the mercaptal in about two hours. After eighteen hours of continuous stirring at 0° the reaction mixture was worked up in the usual manner. There was obtained 6.3 g. of a sirupy material which, on seeding with acetal crystals, gradually changed into a crystalline mass. Crystallization from *n*-propyl alcohol yielded 1.8 g. of pure acetal.

In another experiment the mercuric oxide was added to the methyl alcoholic mercuric chloride solution which was kept boiling gently. Then the mercaptal solution was added drop by drop in one hour to the mixture which was refluxed for an additional hour. After standing at room temperature for several days, the sirupy product obtained from this experiment changed into a partly crystalline mass, from which about 2 g. of pure acetal was isolated by crystallization from *n*-propyl alcohol.

From the residue of the united mother liquors of the crystalline acetal obtained in these two experiments a non-reducing, sirupy product with $[\alpha]^{20}D$ 6.4 was isolated by extraction with hot ethyl acetate and evaporation of the solution. This product was separated by treatment with hot acetone into an acetone-soluble (sp. rot. +14°) and an acetone-insoluble (−15.7°) fraction. From the +14° fraction hot ethyl acetate dissolved a portion which had +35°, while the part insoluble in ethyl acetate deposited from its acetone solution a small quantity of the crystalline acetal. Then the +35° and the −15.7° fractions were united and extracted with hot ethyl acetate giving a solution (A) and an insoluble sirup (B). Solution (A) was cooled to 0° and, after it had cleared up, it was decanted from an insoluble sirup. On prolonged standing at room temperature the solution deposited a small amount of crystalline acetal, which was removed by filtration. In

(8) Cramer and Pacsu, THIS JOURNAL, **59**, 1148 (1937).

the filtrate, on standing at room temperature, well-shaped, pointed prisms commenced to form which, after recrystallization from methyl alcohol containing a little amyl alcohol, had m. p. 69° and $[\alpha]^{20}D$ 92.8° in water solution. The substance was, therefore, identical with Purves and Hudson's "crystalline gamma-methylfructoside." The ethyl acetate-insoluble substance (B) was again extracted with hot ethyl acetate and the aqueous solution of the insoluble portion was tested with invertase solution. The initial rotation (−35.2°) of the nonreducing solution then dropped rapidly to −64.4° and the solution became strongly reducing. The substance, therefore, must represent the "gamma-methylfructoside (a)" postulated by Purves and Hudson.

Acknowledgment is made to Dr. C. S. Hudson for the invertase samples used in this investigation. The author also wishes to thank Messrs. Walter J. Kauzmann and E. Justin Wilson, Jr., for their helpful assistance in the experimental work.

Summary

1. *d*-Fructosediethylmercaptal reacted at −80° with methyl alcoholic mercuric chloride to give crystalline *d*-fructosedimethylacetal in excellent yield.

2. The same reaction when carried out at 0° or higher temperature gave rise to a partly crystalline material, from which, beside the acetal, the "crystalline gamma-methylfructoside" of Purves and Hudson was isolated. Another constituent obtained from the mixture represented the "gamma-methylfructoside (a)," whose presence in the liquid gamma-methylfructoside mixtures was postulated by the same authors. This substance was hydrolyzed rapidly by invertase.

3. The apparent reaction of the acetal with invertase and yeast was found to be due to the hydrolyzing effect of the acidic media rather than to a genuine enzymotic effect. In solutions buffered to *p*H 7 the action of both invertase and yeast was found to be completely negative.

4. A new mechanism for the reaction of sugar mercaptals with alcoholic mercuric chloride was suggested.

5. Crystalline pentaacetyl *d*-fructosedimethylacetal was prepared.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

Hydrogenation of Hydroxyamides

BY JAMES D. D'IANNI[1] AND HOMER ADKINS

The multiplicity of reactions that may occur when a hydroxyamide reacts with hydrogen under the influence of copper chromite[2] made it seem desirable to investigate rather carefully the nature of the products in the hydrogenation of representative compounds of this type.[3] Oeda failed to obtain amino alcohols by the hydrogenation of α-hydroxyamides.[4]

Monohydroxy Amides.—Five hydroxyamides, in which hydroxyl was in the α, β, γ, δ or ε position with respect to the N-pentamethylenecarbonamido or —C(O)NC_5H_{10} group, were submitted to hydrogenation over copper chromite. The detailed results are given in Table I. A typical reaction was

$$CH_3CHOH(CH_2)_2C(O)NC_5H_{10} \longrightarrow CH_3CHOH(CH_2)_2CH_2NC_5H_{10} + H_2O$$

The yields of the corresponding hydroxyamines were as follows: α, 51%, β, 0%, γ, 79%, δ, 76%, ε, 60%.

In the case of the β-hydroxybutyramide the chief product was N-*n*-butylpiperidine in 78% yield, formed according to the reaction

$$CH_3CHOHCH_2C(O)NC_5H_{10} \longrightarrow CH_3(CH_2)_2CH_2NC_5H_{10} + 2H_2O$$

This reaction is in accord with the well-established labilizing effect toward hydrogenolysis of nitrogen or oxygen substituents in the β-position with respect to each other.[5] A 4% yield of propylpiperidine from a lactamide was also isolated and presumably was formed by the same type of reaction.

Evidence for another type of hydrogenolysis

(1) This investigation was carried out in part while Dr. D'Ianni was a teaching assistant of the University and in part while he was a Procter and Gamble Fellow in 1937–1938.

(2) Groger first prepared the compound $CuCr_2O_4$ which he called copper chromite [Groger, *Z. anorg. Chem.*, **58**, 412 (1908); **76**, 30 (1912). When this compound was first reported by Connor, Folkers and Adkins as a catalyst for hydrogenation (for references on its early use see Adkins, *Ind. Eng. Chem., News Ed.*, **15**, 548 (1937)], it was referred to by the same name. In later papers from this Laboratory the catalyst has been called "copper-chromium oxide," since in some cases, a change in composition occurred during the course of a hydrogenation. However, W. A. Lazier and others prefer the use of the more convenient term, copper chromite (Lazier, U. S. Patents 1,746,782, 1,746,783 (1930), 1,964,000 (1934)).

TABLE I

HYDROGENATION OF AMIDES[a]

Amide	G. catalyst (moles amide)	%	% yield of products
N-Pentamethylenelactamide	6 $CuCr_2O_4$ (0.2)	51	1-Piperidinopropanol-2
		10	1,2-Di-piperidinopropane
		10	Propanediol-1,2
		10	Piperidine
		4	N-*n*-Propylpiperidine
	3 Ni(R) (0.1)	27	1-Piperidinopropanol-2
		18	Propanediol-1,2
		38	Piperidine
		23	Unchanged amide
N-Pentamethylene-β-hydroxy butyramide	3 $CuCr_2O_4$ (0.1)	78	N-*n*-Butylpiperidine
		12	Piperidine
	3 Ni(R) (0.1)	86	N-Pentamethylenebutyramide
		12	Piperidine
N-Pentamethylene-γ-hydroxy valeramide	4 $CuCr_2O_4$ (0.1)	79	5-Piperidinopentanol-2
		6	1,4-Dipiperidinopentane
		7	Piperidine
	5 Ni(R) (0.15)	15	5-Piperidinopentanol-2
		58	γ-Valerolactone
		44	Piperidine
		18	Unchanged amide
N-Pentamethylene-Δ-hydroxy caproamide	4 $CuCr_2O_4$ (0.1)	76	6-Piperidinohexanol-2
		14	1,4-Dipiperidinohexane
		4	Piperidine
	3 Ni(R) (0.1)	34	6-Piperidinohexanol-2
		29	Piperidine
		15	Δ-Caprolactone
		14	Unchanged amide
N-Pentamethylene-ε-hydroxy heptanoamide	2 $CuCr_2O_4$ (0.05)	60	7-Piperidinoheptanol-2
		26	Heptanediol-1,6
		14	1,6-Dipiperidinoheptane
		9	Piperidine
N-Pentamethylene caproamide	3 Ni(R) (0.1)	83	Unchanged amide
		7	Piperidine
		5	Hexanol-1
		6	N-*n*-Hexylpiperidine
Di-N-*n*-amylmalamide	16 $CuCr_2O_4$ (0.4)	32	N-*n*-Amylpyrrolidone
		30	Di-*n*-amylamine
		14	N-*n*-Amylsuccinimide
		12	Di-N-*n*-amylsuccinamide
		9	N-*n*-Amylpyrrolidine
		7	*n*-Amylamine
Di-N-*n*-amyltartaramide	15 $CuCr_2O_4$ (0.25)	20	Di-*n*-amylamine
		11	N-*n*-Amylpyrrolidine
		8	*n*-Amylamine
2,2-Dimethyl-5-phenyl-4-oxazolidone	5 $CuCr_2O_4$ (0.15)	35	Mandelamide
		29	Phenylethylene glycol
		3	Phenethyl alcohol
		47	Diisopropylamine (as hydrochloride)

[a] The hydrogenations were made at 225° with the nickel catalyst and at 250–260° for copper chromite, except for the oxazolidone, for which 210–215° was used. The hydrogenations were made in dioxane solution (0.1 mole of amide, 40 ml. of dioxane), the time of reaction for nickel being five to eight hours and with copper chromite one to four hours.

was found in the glycols from each of the five amides, *i. e.*

$$CH_3CHOHC(O)NC_5H_{10} \longrightarrow CH_3CHOHCH_2OH + C_5H_{10}NH$$

Piperidine was isolated from each of the reaction mixtures and the glycol was isolated from the products of two of the amides. It is possible that this type of hydrogenolysis is the primary reaction with all the amides and that the hydroxyamine is actually formed by the interaction of the amine and the glycol, *i. e.*

$$CH_3CHOHCH_2OH + C_5H_{10}NH \longrightarrow CH_3CHOHCH_2NC_5H_{10} + H_2O$$

There exist no data, so far as we know, which show conclusively the course of the reaction or reactions by which an amine is formed from an amide.

Diamines were isolated in yields of 6 to 14% from the products of three amides. These presumably were formed by a reaction similar to that given just above.

$$CH_3CHOHCH_2NC_5H_{10} + C_5H_{20}NH \longrightarrow CH_3CH(NC_5H_{10})CH_2NC_5H_{10} + H_2O$$

Raney nickel, as compared to copper chromite, is relatively inactive for the hydrogenation of amides to amines. A fair comparison between the catalysts has not been made, as copper chromite has been used at 250 to 260° while Raney nickel has been used at 225°. Raney nickel in one case brought about a rather violent reaction between dioxane and hydrogen at 250° so that we have since hesitated to run hydrogenations with Raney nickel in dioxane above 225°. However, even at 225° Raney nickel has induced a considerable hydrogenation of the hydroxyamides. The yields of amino alcohols were in three cases 15, 27 and 34%, as compared with 79, 51 and 76% when copper chromite was used with the same amides at 250°. In each of the cases with Raney nickel, considerable amounts of unchanged amide remained in the reaction mixture, even after periods of reaction two or three times as long as required for complete hydrogenation with copper chromite.

The greater ease of hydrogenation over nickel of hydroxyamides, as compared with amides containing no hydroxyl group, is shown by the fact that 83% of the caproamide and only 14% of the Δ-hydroxycaproamide were recovered after each was hydrogenated for eight hours. A similar difference in the rate of reaction of the amides over copper chromite does not exist.

The real value of Raney nickel in the hydrogenation of amides is indicated by the result of its use with the β-hydroxyamide. The hydroxyl group was removed and the amide group was unchanged, *i. e.*

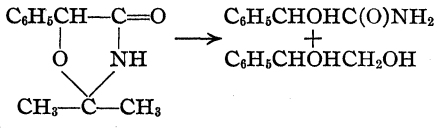
$$CH_3CHOHCH_2C(O)NC_5H_{10} \longrightarrow CH_3CH_2CH_2C(O)NC_5H_{10} + H_2O$$

The butyramide was obtained in 86% yield while with copper chromite, as noted above, the amide group was also hydrogenated and butylpiperidine obtained in 78% yield.

Another difference between the products isolated from a hydrogenation over nickel as compared with those over copper chromite, is the presence of lactones from the γ- and Δ-hydroxyamides. This may be due to the longer period of heating necessary with nickel or to the activity of copper chromite for the hydrogenation of lactones to glycols.

Hydroxy Diamides.—Hydrogenation of N-amylmalamides and N-amyltartaramides over copper chromite gave a mixture. Six products were isolated from the malamide while only three of the many formed were isolated from the tartaramide. The general course of the reactions is rather clearly indicated by the products from the malamide. The first step is apparently the loss of the hydroxy group to give a succinamide. The latter then goes to a succinimide, a pyrrolidone and a pyrrolidine, as reported by Paden,[6] with incidental formation of amyl- and diamylamines.

The hydrogenation of the cyclic amide, 2,2-dimethyl-5-phenyl-4-oxazolidone, over copper chromite gave interesting results, for the oxazolidone ring was cleaved at three different linkages, *i. e.*



Mandelamide and the glycol were formed in similar amounts, the latter was in part converted to phenethyl alcohol. Almost one-half of the isopropyl groups were recovered as diisopropylamine.

An amide derived from a tetrahydroxy acid such as mucic acid offers the possibility of many different reactions involving hydrogenation and hydrogenolysis. Twelve different products have actually been characterized, as listed in Table II. Attempts were made in early experiments to hydrogenate the compound with Raney nickel at 175–200° and with copper chromite at 225–235°. Acetylpiperidine, 1,4-dipiperidinobutane and piperidine were isolated from these experiments. The weight of these three products obtained from 34 g. of the amide was 7 g. after hydrogenation for ten hours over Raney nickel or 8 g. after four to five hours over copper chromite. Since the larger share of the products so obtained could not be separated or characterized, subsequent hydrogenations were made at 250° for five hours over copper chromite.

XI	1,6-Di-piperidinohexanediol-2,5	16	150–160	1	1.4990
XII	Di-N-pentamethyleneadipamide	11	160–170	1	1.5021

[a] These figures represent the weights of the various fractions obtained from the products of the hydrogenation of 1 mole of the amide (344 g.). As shown in the experimental part these figures do not represent pure compounds. Ninety-nine grams of water was formed. The intermediate fractions and mechanical losses during fractionation amounted to 77 g. The hydrogenations were made at 250–260° under 200–350 atm. during periods of five hours each using 40 g. of copper chromite with 0.5 mole of amide dissolved in 400 ml. of dioxane. One mole of amide took up 6.5 moles of hydrogen.

A reasonable scheme for the formation of the various products identified is given in Fig. 1. The formulas of two hypothetical intermediates not isolated are indicated in brackets.

The carbon chain of mucamide is broken between carbon atoms 2 and 3. In no case was a product isolated which contained an uneven number of carbon atoms from the acid radical. That is to say, rupture did not occur between carbons 1 and 2, or 3 and 4. This is a striking fact for in the hydrogenolysis of sugars the change occurs very largely between carbons 3 and 4, with small amounts of one and two carbon fragments.[7] The yield of products (0.24 mole) containing two carbon atoms was almost exactly equal to the yield of products containing four carbon atoms (0.25 mole). The yield of products (0.29 mole) containing the uncleaved chain of six carbon atoms was a little greater than the yield of cleavage products of either of the two types.

As a result of hydrogenolysis between carbon

(7) Zartman and Adkins, THIS JOURNAL, **55**, 4559 (1933). *Cf.* for example Horst and Balle, German Patent 624,443, January 21, 1936.

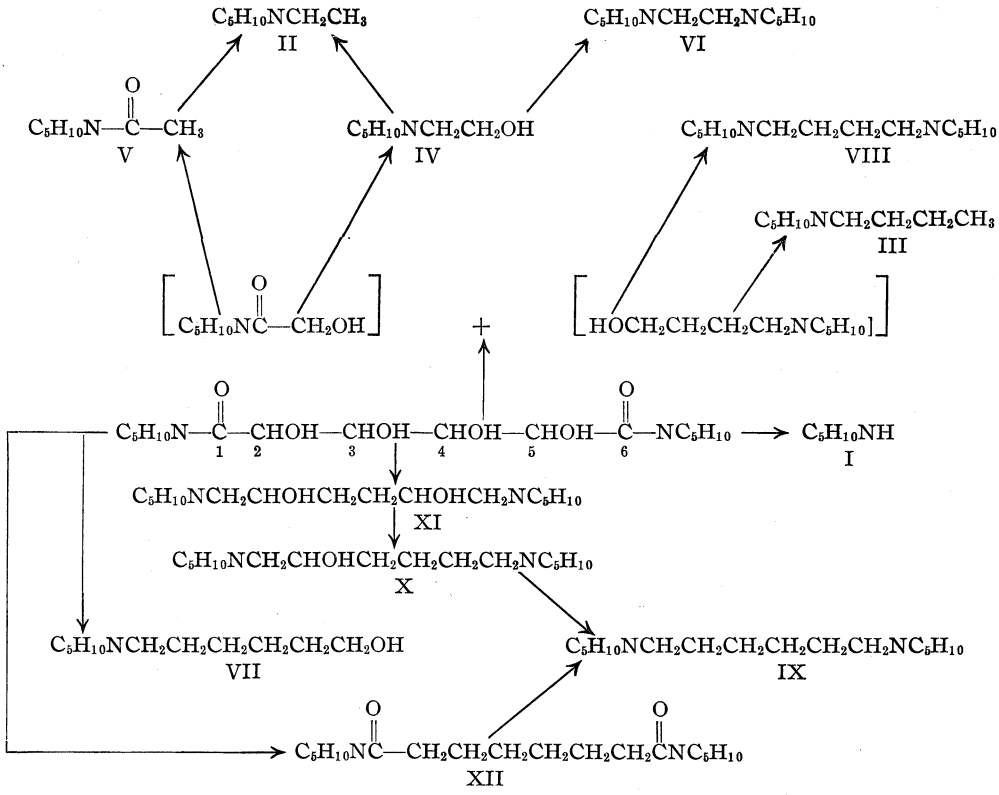

Fig. 1.—Hydrogenolysis of N-pentamethylenemucamide.

atoms 2 and 3 of the mucamide, acetylpiperidine, V, ethylpiperidine, II, and β-hydroxylethylpiperidine, IV, would be formed readily by hydrogenation. The reaction of IV with piperidine would give dipiperidinoethane, VI. Piperidine, I, as has been shown above, is a normal product of the hydrogenolysis of pentamethylene substituted amides. The fragment containing carbon atoms 3, 4, 5 and 6 would by similar transformations give butylpiperidine, III, and dipiperidinobutane, VIII. The compounds listed as VII to XII inclusive would result from the hydrogenolysis of oxygen or piperidino groups from the six carbon chain of the amide. There is no conclusive evidence for the position of the hydroxyl groups shown in XI and X. The hydroxyls are believed to be situated as shown for these are the positions in which hydroxyl groups are most stable toward hydrogenolysis.[5] Compounds would not be expected in which hydroxyl groups were beta to each other or to an amino group. Hydroxyls would therefore be found on carbon atoms 2 and (or) 5.

Experimental Part

The hydrogenations usually were made either in a vessel having a void of 270 ml. or one having a void of 1880 ml. The preparation of catalysts and procedure have been previously described.[5]

The separation of products was based upon fractional distillation of the products. In most cases a "modified Widmer" column having a spiral 15 cm. in length with 12 turns of the helix was used.[8] Spirals with greater or less pitch in the helix were occasionally advantageous. The usual rate of fractionation was 6 to 9 g. per hour, the conduct of the fractionation being as previously described.[8] In general it has been found advantageous to make a rough separation of the products into fractions boiling over 20 or 30° and then carefully fractionate the fractions so obtained. This was particularly important in separating the products from the mucamide.

Amines distilling over with dioxane were recovered as hydrochlorides and in most cases were then converted to the free amines and again fractionated. The same procedure was used for separating amines from glycols or amides having similar boiling points. Amines were characterized by boiling points, neutral equivalents and the formation of solid derivatives (see Table III). In a few cases it was not feasible to separate the components in the quantity of a mixture available. In these cases the proportion of the components of a mixture was estimated from the results of titration with acid, and the presence of each component established by the formation of solid derivatives.

Many of the compounds referred to in this paper have not hitherto been described in the literature. The ana-

(8) Martha E. Smith and Adkins, THIS JOURNAL, **60**, 657 (1938).

lytical data and certain physical properties for thirty such compounds are given in Table III.

Certain derivatives have been described previously: 1-piperidinopropanol-2, b. p. 67–68° (7 mm.), $n^{25}D$ 1.4586, and its methiodide, m. p. 147° (from dry ethanol–ether);[9] 1,2-dipiperidinopropane, b. p. 120–123° (7 mm.);[10] picrate of N-*n*-butylpiperidine, m. p. 132–133°;[11] 3,5-dinitrobenzoate of hexanol-1, m. p. 59–60°;[12] picrate of N-*n*-hexylpiperidine, m. p. 108–109° (from ethanol);[13] N-*n*-amylpyrrolidine, b. p. 76–82° (25 mm.), and its picrate, m. p. 119–120° (from ethanol);[14] chloroplatinate of N-*n*-amylpyrrolidine, m. p. 150° (from ethanol);[15] hydrochloride of diisopropylamine, m. p. 209–211°;[16] phenylethylene glycol, b. p. 115–125° (1 mm.), m. p. 69–70° (from benzene), dibenzoate of phenylethylene glycol, m. p. 95–96° (from dilute alcohol);[17] α-naphthylurethan of phenethyl alcohol, m. p. 118–119° (from petroleum ether).[18]

N-*n*-Butylpiperidine (3 g., b. p. 165–175° at 740 mm.) was prepared by the hydrogenation of N-pentamethylenebutyramide (4.7 g.) in 15 ml. of dioxane, with copper chromite at 260° under 300 atm. within one hundred minutes. 7-Piperidinoheptanol-2 (1.2 g.) and 1,6-dipiperidinoheptane (1.1 g., b. p. 127–130°) were obtained by hydrogenating N-pentamethylene-ε-hydroxyheptanoamide (3 g.) with piperidine (2.6 g.) in 14 ml. of dioxane and 1 g. of copper chromite at 260° for 4.3 hours under 300 atm. The picrate of the diamine (m. p. 203–205° dec.) (from ethanol) was made. 1,4-Dipiperidinopentane (1.4 g., b. p. 118–119° at 1 mm., $n^{25}D$ 1.4806) was obtained by heating 5-piperidinopentanol-2 (2.0 g.) with piperidine (1.7 g.) in 10 ml. of dioxane and 1 g. of copper chromite for three and one-half hours at 250° under a pressure of 150 atm. of hydrogen. The picrate, m. p. 168–169° (from ethanol), as well as those given above were used for comparison and mixed melting points.

The fractions listed in Table II were characterized and estimated as follows: I. The neut. equiv. was 98 (calcd. 85). Piperidine was characterized by its addition product with carbon bisulfide, m. p. 170°. II. The neut. equiv. was 110 (calcd. 113) and the amine gave a picrate, m. p. 173–174°, which showed no lowering when the compound was mixed with an authentic sample.[19] III. The neut. equiv. was 156 (calcd. 141) with a picrate of m. p. 130–131°. IV. The neut. equiv. was 154 (calcd. 129) and the compound gave a hydrochloride of the benzoate, m. p. 173–174° (from absolute alcohol–ether), which was compared with an authentic sample.[20,21] The amine could not be separated by fractionation from the acetylpiperidine with which it formed a constant boiling mixture. The separation was made after acidifying the mixture with hydrochloric acid using congo red as an indicator. The amide, acid and water were then evaporated under 10 to 20 mm., the amine recovered from the salt showed a b. p. of 69–70° (9 mm.), $n^{25}D$ 1.4700. V. As indicated above acetylpiperidine could not be separated by fractionation from piperidinoethanol. Fraction V contained about 20% of the amine. The purest sample of the amide had a b. p. 90–91° (8 mm.), $n^{25}D$ 1.4775, and was characterized by hydrolysis to piperidine and acetic acid which were characterized in the usual way. VI. The neutral equivalent indicated that this fraction was quite impure, *i. e.*, 147 compared with 98. The dipiperidinoethane was converted into its methiodide, m. p. 246°, a hydrochloride of the correct analysis, m. p. over 323°,[22] and a picrate, m. p. 225–227° (dec.), were also obtained.[23] VII. The fraction showed the correct analysis for nitrogen and approximately the correct neutral equivalent (181 compared with 185). Solid derivatives could not be obtained. VIII. A sample purified from this fraction had a b. p. 98–99° (1 mm.) and $n^{25}D$ 1.4826, and neut. equiv. of 114 (calcd. 112). A hydrochloride, m. p. 309°, was compared with an authentic sample. The m. p. of picrate was 185–186° (from alcohol).[24] IX. A sample purified from this fraction had a b. p. 114–118° (1 mm.), $n^{25}D$ 1.4859 and a neut. equiv. of 131 (calcd. 126). The methiodide, m. p. 250–253°, showed the correct analysis.[25] X. A sample purified from this fraction, b. p. 125–130° (1 mm.), $n^{25}D$ 1.4949, showed a high neut. equiv. (150 as compared with 134), but gave 1.04 and 1.09 moles of methane in a Zerevitinoff analysis. A picrate, m. p. 138–139°, and a hydrochloride, m. p. 189–191°, were obtained. XI. The neutral equivalent of this fraction indicated the presence of a neutral compound to the extent of 30%. This impurity was presumably dipentamethyleneadipamide. The fraction was therefore hydrogenated in dioxane at 250° over copper chromite. The product, b. p. 150–160° (1 mm.), $n^{25}D$ 1.4943, showed a neut. equiv. of 148 (calcd. 142) and gave a dipicrate, m. p. 170–173° (from alcohol). There was also obtained 1,6-dipiperidinohexane. b. p. 110–120° (1 mm.), resulting from the hydrogenation of the dipentamethyleneadipamide. XII. This fraction was approximately equal parts amide and the glycol of XI, so that it was hydrogenated as above and the resulting 1,6-dipiperidinohexane characterized as the dimethiodide, m. p. 250–253° (from alcohol and ether).

Preparation of Esters.—Diethyl mucate,[26] m. p. 167–168° after one recrystallization from ethanol, was obtained in yields of 76 to 90% through the reaction of mucic acid (50 g.) and dry ethanol (800 ml.). Hydrogen chloride was passed in for three to four hours, the mixture refluxed with stirring, filtered hot and the ester allowed to crystallize out. The higher yields were obtained using four times the quantities selected above, and making allowance for the recovered acid.

Diethyl tartrate (b. p. 150–155° at 13 mm.)[27] in yields of 55 to 67% was made similarly except that the product was distilled.

Diethyl malate[28] (471 g., b. p. 120–130° at 13 mm. from 500 g. acid) was prepared similarly except that about 60% of the volume of the alcohol used was distilled off, replaced with dry ethanol and the esterification repeated.

Ethyl lactate (80 g., b. p. 83–84° at 50 mm.) was made through the reaction of dry ethanol (500 ml.), lactic acid (250 g. of 85% acid) in carbon tetrachloride (250 ml.) for twenty-four hours using an automatic separator which returned the heavier liquid to the flask. Additional ethanol was added and the refluxing continued as long as water was formed.

Ethyl β-hydroxybutyrate (b. p. 64–65° at 7 mm.), ethyl γ-hydroxyvalerate (b. p. 55–60° at 0.5 mm.), ethyl ε-hydroxyheptoate (b. p. 89–91.5° at 0.5 mm., $n^{25}D$ 1.4309) and Δ-caprolactone (b. p. 95–97° at 8 mm., $n^{25}D$ 1.4470) were made by the hydrogenation in ethanol of the corresponding keto esters.[29] Copper chromite at 150° was used for acetoacetic ester while Raney nickel at 125–130° was used in the other cases.

Ethyl ε-ketoheptoate (18 g., b. p. 110–113° at 7 mm., $n^{25}D$ 1.4385) was prepared by the hydrolysis of α-acetyl-Δ-cyanovaleric ester (33.5 g.) during eight hours of refluxing with 20% hydrochloric acid (175 ml.). The solution was cooled, saturated with ammonium sulfate, extracted nine times with ether, the solution dried over anhydrous sodium sulfate and the ether distilled. The residue was taken up in 200 ml. of dry ethanol and filtered. The crude acid was esterified in 100 ml. of carbon tetrachloride for twelve hours using an automatic separator, and the ester separated by fractionation.

The α-acetyl-Δ-cyanovaleric ester (b. p. 85–91° at 1 mm.) used in the above preparation was prepared as by Derick and Hess[30] but the yields were about one-fourth that reported by these investigators.

Ethyl Δ-ketocaproate[31] (161 g., b. p. 98–99° at 9 mm.) was made from α-acetylglutaric ester (274 g.) by refluxing with 500 ml. of 4 *N* hydrochloric acid for nine to ten hours. The Δ-ketocaproic acid (142 g., b. p. 103–107° at 1 mm.) obtained by fractionation was esterified in 250 ml. of ethanol and 125 ml. of carbon tetrachloride for six hours as in the preparation of the ethyl ε-ketoheptoate.

Preparation of Amides.—The N-pentamethylene amides of β-hydroxybutyric and ε-hydroxyheptanoic acids were made in 60% yields by heating the corresponding

(28) Wislicenus, *Ber.*, **25**, 2448 (1892).

(29) Connor, Cramer and Adkins, THIS JOURNAL, **52**, 5192 (1930

(30) Derick and Hess, *ibid.*, **40**, 547 (1918).

(31) Isbell, Wojcik and Adkins, *ibid.*, **54**, 3685 (1932).

ethyl esters (0.5 mole) with piperidine (1.0 mole) for four hours at 200° under hydrogen. N-Pentamethylene-Δ-hydroxycaproamide was made in the same way in 86% yield except that caprolactone was used instead of an ethyl ester. The b. p. and refractive index of the pentamethylene β-hydroxybutyramide are b. p. 118–123° (7 mm.), and $n^{25}D$ 1.5065, and not as previously given.[32]

N-Pentamethylene lactamide, di-N-*n*-amyl malamide, and di-N-*n*-amyl tartaramide were made by refluxing the ethyl ester of the acid (0.5 mole) with a 10% excess of piperidine or amylamine. The yields of the lactamide were 70 to 80% after twenty hours, 87% after three hours for the malamide and 98% after five hours for the tartaramide. The amides were recrystallized from dilute alcohol.

Di-N-pentamethylene mucamide (m. p. 231 dec.) was obtained in quantitative yield by gently heating and stirring a mixture of diethyl mucate (57 g.) with piperidine (40 g.) for a few minutes. The product was washed with ether and alcohol but was not recrystallized.

N-Pentamethylene caproamide (b. p. 95–99° at 1 mm., $n^{25}D$ 1.4725) was made in 81% yield by heating caproic acid (29 g.) and piperidine (21 g.) in dioxane (48 ml.) for three hours at 250° under hydrogen.

Attempts to distil N-pentamethylene-γ-hydroxy-valeramide (prepared by the reaction for four hours of 72 g. of the ester and 85 g. of piperidine at 200° under hydrogen) gave caprolactone. Therefore the crude amide was subjected to hydrogenation without purification.

2,2-Dimethyl-5-phenyl-4-oxazolidone (80 g., m. p. 127°) was obtained by the reaction of mandelamide (160 g.) with acetone (600 ml.).[33] The product was refluxed with Raney nickel in ethanol for thirty minutes and then crystallized from ethanol.

Refluxing ethyl β-hydroxybutyrate (100 g.) for four hours with piperidine (77 g.) gave only 19 g. of the desired amide. There was also obtained 46 g. of a compound, b. p. 105–110° at 1 mm., $n^{25}D$ 1.4896, which gave the correct analysis for N-pentamethylene-β-(β′-hydroxybutyryl)-hydroxybutyramide. Similarly when ethyl α-hydroxyisobutyrate (132 g.) was heated, for four hours at 200° under hydrogen, with piperidine (170 g.) the desired amide was not obtained. Instead a compound (56 g.), b. p. 108° at 1 mm., $n^{25}D$ 1.4651, was obtained which showed the correct analysis for N-pentamethylene-α-(α′-hydroxyisobutyryl)-hydroxyisobutyramide. The formation of these products is analogous to those formed in the hydrogenation of β-keto esters in the absence of a solvent.[29]

Summary

Various N-pentamethylene amides having a hydroxyl group in the α, β, γ, δ or ε position have been submitted to hydrogenation over copper chromite. The corresponding amino alcohols have been obtained in yields of 51 to 79%, except from the amide having the hydroxyl group in the β-position, in which case the hydroxyl group was eliminated and the chief product was the alkylpiperidine. Glycols and diamines were also obtained in low yields from certain of the hydroxy amides.

Raney nickel catalyzed the same types of reaction with hydroxyamides as did copper chromite. However, reaction was not so rapid and the yields of piperidino alcohols were much lower than with copper chromite.

Raney nickel with $CH_3CHOHCH_2C(O)NC_5H_{10}$ gave the amide $CH_3CH_2CH_2C(O)NC_5H_{10}$ while copper chromite also catalyzed the hydrogenation of the carbonyl group giving the amine $CH_3CH_2CH_2CH_2NC_5H_{10}$.

The action of hydrogen over copper chromite upon di-N-pentamethylene mucamide gave twelve products as listed in Table II. It is a striking fact that cleavage of the six carbon chain occurred exclusively between carbon atoms 2 and 3 and never between carbon atoms 3 and 4, as in the hydrogenolysis of the six carbon sugars and the corresponding alcohols.

The hydrogenolysis of amides derived from malic, tartaric and mandelic acids has also been studied.

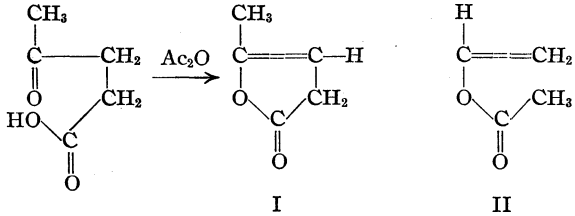
The Structure of Vinyl Polymers. III.[1] The Polymer from α-Angelica Lactone

BY C. S. MARVEL AND CHARLES L. LEVESQUE[2]

α-Angelica lactone (I), readily prepared by the action of acetic anhydride on levulinic acid,[3] may be regarded as a disubstituted vinyl acetate (II)



I II

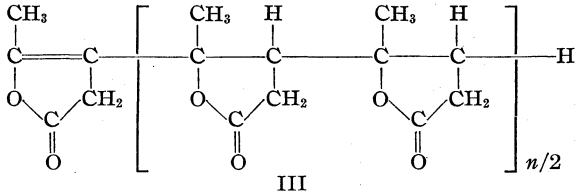
type. Such esters, with terminal substituents on the vinyl group, do not polymerize readily, but it seemed possible that the strain due to the lactone ring structure might activate the double bond in this case. Although peroxides, the usual catalysts for vinyl polymerization, are ineffective, α-angelica lactone is easily polymerized by the boron fluoride–ether complex. The product is a tacky, dark red solid. Attempts to remove the color have been unsuccessful.

Long irradiation of α-angelica lactone with ultraviolet light also produces a polymer. Although less highly colored than the product obtained by the use of boron fluoride, it is also of lower molecular weight, since it shows an appreciable cold flow. Only the polymer formed by the boron fluoride catalyst was used in the investigations reported below.

Cryoscopic determinations in benzophenone and bromine titration of the residual double bonds gave values of 800–900 for the average molecular weight of the polymer. This corresponds to a chain of eight to nine units. The relatively low value of the molecular weight, and the presence of one double bond per molecule indicate a stepwise polymerization related to the Friedel–Crafts reaction, rather than the chain mechanism frequently encountered in other vinyl polymerizations. The double bond is probably in a terminal unit.

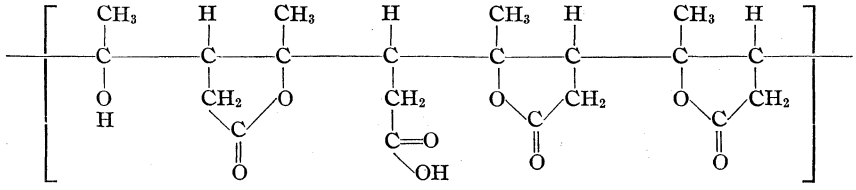
Most of the lactone groups are retained in the polymer, since it dissolves only slowly in aqueous sodium hydroxide, reacts with ammonia to produce a polylactam, and with phenyllithium to give a polyalcohol. As is frequently the case with polymers, the two latter reactions do not proceed to completion. Analysis indicates that in the lactam, 80%, and in the alcohol, 90% of the carbonyl groups have undergone reaction.

Analyses of the original polymer demonstrated that approximately every fourth lactone unit had added a molecule of water. If a "head to tail" structure (III, $n = 7$ or 8) is assumed for the polymer, this result is readily explained.



III

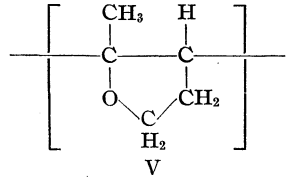
Boron fluoride is a *trans* esterification catalyst, and a *trans* esterification of a polymer such as III would result in the liberation of some hydroxyl and carboxyl groups. Since *trans* esterification is a random reaction certain of these groups will become isolated (IV).



IV

Since this reaction would tend to approach equilibrium, the number of unesterified groups cannot be calculated by Flory's statistical method.[4] The value found, however, is quite consistent with the "head to tail" formulation.

When an attempt was made to hydrogenate the lactone units to tetrahydrofuran units (V) at 250°



V

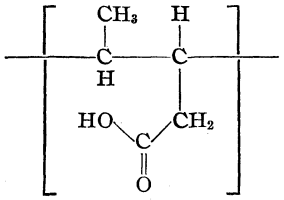
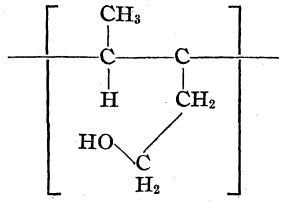
and 400 atm. over copper–chromium oxide,[5] the amount of hydrogen absorbed was nearly twice that calculated for this reaction alone. The polymeric material isolated weighed only 70% as much as the starting material, and had a much lower average molecular weight. Analysis of this product showed that reactions other than simple hydrogenation of the carbonyl groups had occurred. These facts also pointed to the "head to tail" structure (III), since this structure contains the grouping –O–C–C–C–O. It has been shown[6] that in this group, common to 1,3-glycols and their ethers, 1,3-diketones, β-keto esters, etc., the carbon–oxygen bonds and the carbon–carbon bonds are especially sensitive to cleavage by hydrogen at high pressure and temperature over copper–chromium oxide. Under the conditions used in our reduction experiment, in addition to tetrahydrofuran units (V), the polymer III would also produce units of VI and VII,



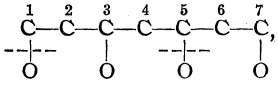
VI



VII

formed by hydrogenolysis of the carbon–oxygen bond both before and after reduction of the carbonyl group. The analytical results may be explained on the basis that a mixture of these structural units (V, VI and VII) is produced. Hydrogenolysis of the carbon–carbon bonds would account for the lower molecular weight, and the losses.

To test this hypothesis, the original polymer was treated with hydrogen at 175° and 400 atm. over copper–chromium oxide. From certain of the data of Connor and Adkins,[6] it seemed possible that at this temperature, cleavage of the carbon–oxygen bonds might take place to a much greater extent than cleavage of the carbon–carbon bonds. It is obvious that the former cleavage can never be quantitative. In the group



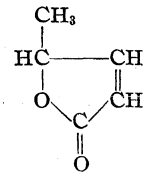
for example, cleavage of the bonds, as indicated at carbon atoms 1 and 5, would destroy the 1,3-glycol character of the carbon–oxygen bond at carbon atom 3. Hence this bond would not cleave. Applying the methods of Flory,[4] and assuming no carbon–carbon cleavage, it may be calculated that for a 1,3-type polymer of n units, the following relation holds

$$S_n = \frac{2}{n}\left(1 + \frac{3}{3} + \frac{4}{3} + \frac{5}{3} + \cdots \frac{n}{3}\right) = \frac{n+1}{3}$$

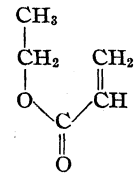
S_n is the number of carbon–oxygen bonds per molecule not cleaved. For an octamer $S_8 = 3$. Hence only 62.5% of the carbon–oxygen bonds should be cleaved, and the polymer will take up 0.625 molecule of hydrogen per unit. Since there is also one double bond for every eight units, another 0.125 molecule of hydrogen per unit will be taken up, making the total amount of hydrogen absorbed 0.75 molecule per unit.

This figure agrees satisfactorily with the experimental result. The polymer absorbed 0.84 ± 0.05 molecule of hydrogen per unit to give a quantitative yield of a polyacid. The analysis of the material obtained agreed with that calculated on the assumptions above, and a determination of the molecular weight showed that little carbon–carbon cleavage had taken place.

We have considered the possibility that isomerization of the α-form to β-angelica lactone (VIII)[7] might have taken place before polymerization. This β-lactone is a substituted ethyl acrylate (IX) type. However, neither of the two

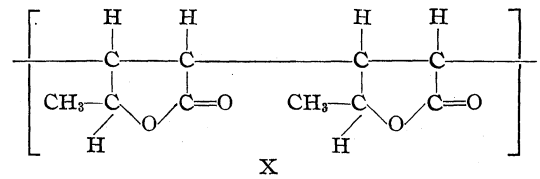


VIII

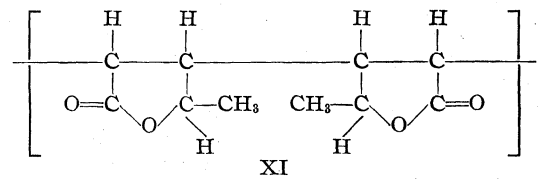


IX

possible structures for a β-angelica lactone polymer (X, XI) would have the 1,3-glycol grouping



X



XI

which has been shown to be present in our polymer.

(5) Connor, Folkers and Adkins, THIS JOURNAL, **54**, 1138 (1932).
(6) Connor and Adkins, *ibid.*, **54**, 4678 (1932).
(7) Thiele, Tischbein and Lossow, *Ann.*, **319**, 188 (1901); Auwers, *Ber.*, **56**, 1672 (1923).

From these data, the polymer produced from α-angelica lactone is a polylactone having a "head to tail" structure, and containing about 25% free carboxyl and hydroxyl groups (IV).

Experimental

Polymerization of α-Angelica Lactone by the Boron Fluoride–Ether Complex.—To a solution of 15 g. of α-angelica lactone[3] in 40 cc. of carbon disulfide was added 0.4 cc. of the boron fluoride–ether complex. The solution was refluxed gently for five hours. The colorless supernatant layer was decanted from the viscous red polymer layer which was then washed by decantation with several portions of ether, and freed of volatile matter by heating slowly (one and a half hours) to 80° at 2 mm. There remained 14.7 g. of a dark red solid, tacky, but showing no cold flow. It was readily soluble in acetone, dioxane, cellosolve, ethyl alcohol and butyl alcohol, slowly soluble in aqueous sodium hydroxide, insoluble in water, ether, benzene and ligroin.

Mol. wt. (benzophenone): 845. Bromine titration: 3.030 g. of polymer in ethanol–chloroform required 17.3 cc. of 0.214 *N* bromine in carbon tetrachloride; eq. wt., 818. The polymer may also be prepared in ether solution, though in lower yields.

Anal. Calcd. for $(C_6H_8O_2)_4 \cdot H_2O$: C, 58.4; H, 6.40. Found: C, 58.17, 58.19, 58.38; H, 6.64, 6.89, 6.56.

Polymerization of α-Angelica Lactone by Ultraviolet Light.—Five cubic centimeters of α-angelica lactone in a quartz test-tube was irradiated for two weeks with light from a mercury vapor arc. At the end of this time, the lactone had polymerized to a very viscous orange liquid. The liquid had the same solubility characteristics as the boron fluoride catalyzed polymer.

Poly-α-angelica Lactam.—A solution of 6.0 g. of polylactone in 50 cc. of dioxane was placed in a glass-lined steel bomb, cooled in dry-ice, and 20 cc. of liquid ammonia added. The bomb was sealed, and heated at 150–160° for three hours, then allowed to cool to room temperature overnight. The glass liner containing the reaction mixture was removed, the supernatant liquid decanted and the precipitated polymer washed with dioxane and ligroin. After drying *in vacuo* over concentrated sulfuric acid 4.0 g. of brittle, red-brown solid remained. It was readily soluble in water.

Anal. Found: N, 11.59.

Assuming the free carboxyl groups (IV) are converted to ammonium salt groups, this analysis shows that 84% of the lactone groups have been converted to lactam groups.

Reaction of Polylactone with Phenyllithium.—A solution of phenyllithium in ether was prepared under nitrogen from 2.3 g. of lithium and 25 g. of bromobenzene, and the ether displaced by toluene. To this was added a solution of 6.0 g. of the polylactone in a mixture of 50 cc. of dimethyl ether of ethylene glycol and 50 cc. of toluene. Heat was evolved and a reddish-brown, flocculent precipitate formed. The mixture was stirred and heated on a steam cone for sixteen hours then 50 cc. of water was added cautiously and steam passed through the mixture for two hours to remove solvents and diphenyl. Fifteen cubic centimeters of concentrated hydrochloric acid was added, and the steam distillation continued for one hour. The hot polymer, which had collected as a heavy, oily liquid, was thoroughly washed with several portions of hot water. After cooling, and drying *in vacuo* over sulfuric acid, 10.0 g. of plastic, chocolate brown solid remained. It was soluble in alcohol, and insoluble in aqueous sodium hydroxide.

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.2; H, 7.14. Found: C, 78.15; H, 6.85.

Hydrogenation of the Polymer at 250°.—A solution of 10 g. of the polylactone in 135 cc. of butanol was twice refluxed over Raney nickel, and filtered into a 280-cc. steel bomb. Five grams of copper–chromium oxide catalyst[5] was added and the bomb filled with hydrogen at 3325 lb. (222 atm.) and 25°. After shaking at 250° for ten and a half hours, the pressure drop (after cooling) was 900 ± 20 pounds, equivalent to 3.92 ± 0.05 moles of hydrogen per mole of polymer unit. The reaction mixture was filtered, centrifuged, and the solvent removed *in vacuo* in a stream of nitrogen. The residual liquid was washed into an evaporating dish with a little alcohol and, after drying *in vacuo* over sulfuric acid, left 7 g. of a light brown, viscous liquid.

Anal. Calcd. for C_5H_8O: C, 71.5; H, 9.6; $C_5H_{10}O$: C, 69.8; H, 11.8; $C_5H_8O_2$: C, 60.0; H, 8.06. Found: C, 67.54; H, 9.94; mol. wt. (benzophenone), 351.

Hydrogenation of the Polylactone at 175°.—Fourteen and eight-tenths grams of polymer was dissolved in 140 cc. of dioxane which previously had been treated with hydrogen and copper–chromium oxide. The solution was twice refluxed over Raney nickel and then filtered into a 280-cc. steel bomb containing 5.0 g. of copper–chromium oxide. Hydrogen at 4100 lb. (273 atm.) and 25° was admitted and the bomb shaken at 175° until absorption of hydrogen ceased (twenty hours). The pressure drop (cold) was 320 ± 20 pounds, equivalent to 0.84 ± 0.05 mole of hydrogen per mole of polymer unit. The product was isolated as before, giving 15.1 g. of a very viscous brown polymer, insoluble in water, but readily soluble in aqueous sodium bicarbonate.

Anal. Calcd. for 75% $C_5H_8O_2$ + 25% $C_5H_6O_2$: C, 60.31; H, 7.58. Found: C, 60.20; H, 7.24; mol. wt. (benzophenone), 767.

Summary

The polymer prepared by the action of boron fluoride–ether complex on α-angelica lactone has been shown to be a polylactone having the "head to tail" structure.

The Preparation and Reactions of Some Triphenyllead Derivatives

BY LAURENCE S. FOSTER, WILLIAM M. DIX AND IRVING J. GRUNTFEST

Introduction

By taking advantage of the reducing properties of solutions of the alkali metals in liquid ammonia and related solvents, it is possible to prepare some types of organo-metallic compounds which elude preparation in any other way. The method has had striking success in studying the organo-metallic compounds of the elements in Group 4B of the periodic table.[1] Until very recently no work on lead compounds from this viewpoint had been reported,[2] and the purpose of this investigation was to extend the earlier studies to the triphenyllead derivatives.[3]

In all of their properties the triphenyllead derivatives are found to follow the trends observed with the corresponding derivatives of the other elements in Group 4B. In passing from lead to carbon, the strength of the bond between the phenyl group and the metallic element becomes continually greater and, except for carbon, the same is true of the metal-to-metal bond in the dimeric form of the "free group." The high degree of dissociation of hexaphenylethane is decidedly abnormal, but the apparent partial dissociation of hexaphenyldilead, $(C_6H_5)_3Pb—Pb(C_6H_5)_3$, observed in dilute benzene solutions, is not unexpected.

The halides of triphenyllead and triphenyltin are stable in liquid ammonia, but those of the germanium and silicon derivatives are irreversibly and completely ammonolyzed. Triphenylmethyl halides undergo partial ammonolysis, but the reaction is reversible and the compounds may be used in preparations in ammonia without much side reaction.

With all of the Group 4B elements, the alkali metal salts of the triphenyl derivatives are stable in liquid ammonia at $-33.4°$. There is, however, a marked deepening of the color of their solutions in proceeding from lead to carbon. A solution of sodium triphenylplumbide, $NaPb(C_6H_5)_3$, is colorless when dilute and pale yellow when concentrated, but a solution of potassium triphenylmethide, $KC(C_6H_5)_3$, is an intense red even when dilute. The solutions of the corresponding salts of the intervening metals are intermediate in color. In these salts the triphenylmetal anion becomes progressively more electronegative in the same order When, for example, sodium triphenylgermanide is allowed to react with an ammonium salt, the anion, $(C_6H_5)_3Ge^{1-}$, takes on a proton and triphenylgermane is precipitated. This reaction is characteristic of the entire group with the exception of the lead analog. No hydride is formed when ammonium bromide is added to a solution of sodium triphenylplumbide in ammonia, but the solution appears to contain ammonium triphenylplumbide as a highly ionized salt. Evidently the triphenylplumbide ion, $(C_6H_5)_3Pb^{1-}$, is not basic enough to remove the proton from the ammonium ion, and the normal group reaction is not observed, even in the presence of great excess of ammonium salt.

Experimental

Preparation of Tetraphenyllead.—The method followed was that of Gilman and Robinson,[4] in which carefully dried lead dichloride is allowed to react with phenylmagnesium bromide, but with the substitution of xylene for benzene to increase the temperature of refluxing. The yields were sometimes as high as 81% (based upon the amount of lead dichloride used) but the results were not uniform.

Preparation of Triphenyllead Chloride.—Dry hydrogen chloride was passed into a solution of tetraphenyllead in chloroform, according to the method of Gilman and Robinson,[5] and the yield of 75% of the theoretical agreed with their observations.

Preparation[6] and Purification of Triphenyllead Iodide.—The preparation of triphenyllead chloride is not entirely satisfactory, so the iodide was investigated. It was found that it could be made easily and in addition the iodide proved to be a superior reagent for the syntheses undertaken. A solution of iodine in chloroform was stirred vigorously into a suspension of an equivalent quantity of tetraphenyllead in chloroform. The solvent and the iodobenzene formed in the reaction were removed by vacuum distillation at 100°. The yellow crystalline residue was extracted with methyl alcohol to separate the product from the diphenyllead diiodide also formed and from the unreacted tetraphenyllead. Crude triphenyllead iodide

(6) The preparation was carried out by H. I. Boynton as a part of a senior research problem, 1933.

was crystallized from the extract in an amount representing 97% of the theoretical yield. Even after several recrystallizations, the product still had a light yellow color, and melted over a range from 138° to 141°.[7] It was found that the colored impurity could be removed by dissolving the iodide in ether and allowing the solution to stand over metallic sodium or silver for two days. From the ether, pure white crystals of the iodide were recovered which melted sharply at 142° (uncorr.).[8]

Preparation of Hexaphenyldilead (Triphenyllead).—Krause and Reissaus[7b] (p. 894) prepared hexaphenyldilead by the reaction of phenylmagnesium bromide and lead dichloride in absolute ether, where it is an intermediate product in the formation of tetraphenyllead. Austin[9] reported that it is isolated as a by-product of the reaction between phenyllithium and lead dichloride, when the mixture is not heated to too high a temperature. It may be prepared most simply and practically quantitatively by reducing triphenyllead iodide by means of an equivalent amount of sodium in dry liquid ammonia. After the reaction is completed and the ammonia has evaporated, the residue is extracted with chloroform, filtered and concentrated by distillation until the solution is nearly saturated. Cold ethyl alcohol is added to precipitate the hexaphenyldilead. It is recrystallized in the same way, *i. e.*, from chloroform solution by the addition of ethyl alcohol. The amount of the purified product is above 90% of the theoretical yield.

Use of Tetrasodium Nonaplumbide, Na_4Pb_9, as a Reducing Agent.—If triphenyllead chloride is used in place of the iodide in the preparation of triphenyllead, the reaction does not proceed so smoothly, evidently due to the lower solubility of the chloride in ammonia. It was found feasible, however, to carry out the reduction of the chloride by means of tetrasodium nonaplumbide, Na_4Pb_9,[10] which evidently is a much weaker reducing agent than sodium and permits the reduction to proceed without cleavage of phenyl groups from the triphenyllead radical. The equations for the reactions involved in the preparation of hexaphenyldilead by means of this reducing agent are

$$9PbCl_2 + 22Na = Na_4Pb_9 + 18NaCl$$
$$Na_4Pb_9 + 4(C_6H_5)_3PbCl = 2[(C_6H_5)_3Pb]_2 + 4NaCl + 9Pb$$

Lead dichloride is placed in a reaction tube immersed in a bath of liquid ammonia at −33.4°. When ammonia is condensed upon the lead halide, it swells tremendously, due to the formation of ammines,[11] and partly dissolves. Sodium is added in several pieces. The tetrasodium nonaplumbide formed is soluble and the solution is practically opaque. Triphenyllead chloride in powdered form is added slowly from an attached tube and hexaphenyldilead precipitates. The color of the solution disappears and a curdy mass (Pb) rapidly settles to the bottom of the tube. After the ammonia has evaporated, hexaphenyldilead is extracted from the residue and recrystallized. The yield of the purified product is above 90% of the theoretical.

Properties of Hexaphenyldilead. (a) **Stability.**—Krause and Reissaus[7b] report that when it is heated, hexaphenyldilead decomposes at 155° with the deposition of lead and finally melts at 225°, the melting point of tetraphenyllead. We have observed that different samples vary in their behavior. One exploded at 173°, turned black and melted at 225°. Frequently the blackening appears at 170°. If the determination is carried out very slowly in an open sample tube, no blackening is observed, due to the oxidation of the deposited lead, but melting occurs invariably at 225°. If the sample tube is evacuated, decomposition may occur from 5 to 10° below 170° but the blackening is always observed. The characteristic pyrolytic behavior may be used in confirming the identity of the material.

Hexaphenyldilead becomes yellow and infusible when kept for six months in a loosely corked, colorless bottle in the normal illumination of the laboratory, but samples have been kept for five years in the dark without change. From a solution of hexaphenyldilead in alcohol, kept for two months in the dark, the substance was recovered without change in its properties, but when it was dissolved in benzene, it underwent reaction, especially if the solution was kept warm. These observations are not entirely compatible with those of Krause and Reissaus, and may explain the anomalous molecular weight data discussed in a later section.

(b) **Solubility.**—Hexaphenyldilead is very soluble in carbon tetrachloride and chloroform, moderately soluble in benzene and acetone, and very slightly soluble in liquid ammonia, methyl and ethyl alcohols, ethyl ether and petroleum ether. It is insoluble in water.

(c) **Molecular Weight.**—Krause and Reissaus[7b] present evidence to show that hexaphenyldilead is highly dissociated into the monomeric form in dilute solutions in benzene. Three cryoscopic determinations made at different concentrations confirm their findings. At the concentrations stated below, expressed in grams of hexaphenyldilead per 1000 g. of benzene, the apparent molecular weight is seen to be less than 876, the theoretical value for the dimer: 9.53 g., 768; 18.71 g., 773; and 29.94 g., 791. While in both these results and those of Krause and Reissaus there is a steady rise in molecular weight with concentration increase, no mass action constant could be calculated for either set of data. At present it is not possible to offer any explanation for the observations.

Preparation of Sodium Triphenylplumbide.—This substance may be made in ammonia solution by reducing triphenyllead chloride or iodide or hexaphenyldilead by means of sodium or tetrasodium nonaplumbide. To prepare the pure salt, however, the reaction between sodium and hexaphenyldilead must be adopted. Due to side reactions, finely divided lead may appear as a precipitate, but if great care is exercised to prevent the concentration of sodium from becoming high at any time, not enough lead is formed to lower the yield appreciably. If the temperature is allowed to rise as the ammonia evaporates ammonolysis occurs, yielding unknown products. By removing the ammonia under reduced pressure at −33.4° or lower, the salt crystallizes from a faintly yellow saturated solution as a solid with a rather intense lemon-yellow color. The color

(11) Biltz and Fischer, *Z. anorg. allgem. Chem.*, **124**, 230 (1922).

fades as the residual ammonia is withdrawn, and the dry, cream-colored salt formed is stable at room temperature.

Preparation of Triphenylethyllead.—Since the properties of triphenylethyllead had been established previously,[12] its preparation was undertaken to demonstrate the existence of the triphenylplumbide ion in the ammonia solution of the sodium salt. An excess of ethyl bromide was admitted to the reaction vessel and white crystals of triphenylethyllead were precipitated. A pure product was obtained by dissolving the crude material in a small quantity of ethyl ether, adding about twice the quantity of methyl alcohol and evaporating the solution *in vacuo* at room temperature. The material precipitated in white curds, which when dried *in vacuo* formed a fine white powder. The melting point was 39° and molecular weight determinations and analyses for lead identified it as triphenylethyllead. It is very soluble in ether, acetone, carbon tetrachloride and petroleum ether, less soluble in methyl alcohol and only very slightly soluble in ammonia.

Ammonium Triphenylplumbide.—When an ammonium salt,[13] in equivalent amount, is added to a liquid ammonia solution of sodium triphenylplumbide, no reaction is observed. If a small excess is added, no change in appearance of the solution is apparent, but in the presence of great excess, complete destruction of the triphenylplumbide radical results, accompanied by the separation of metallic lead in large, heavy, black curds and the production of benzene.

When the solution containing sodium and ammonium triphenylplumbides is evaporated at low temperatures under reduced pressure, crystals do not appear until it has become very concentrated and no indication of reaction between the ammonium ion and the triphenylplumbide ion is detectable. If ethyl bromide is added to the dilute solution, a white precipitate of triphenylethyllead separates, indicating that the triphenylplumbide ion remains unchanged. Ammonium triphenylplumbide appears to be stable and very soluble in liquid ammonia at −33.4°.

Reaction of Sodium Triphenylplumbide with Methylene Chloride.—Sodium triphenylplumbide, freed of ammonia at −33.4°, was allowed to react with an excess of dry methylene chloride. The salt dissolved at first to form a yellow solution, but the color gradually faded, due presumably to reaction. A soft, waxy solid of indefinite melting point and soluble in petroleum ether was isolated from the product. A single molecular weight determination gave a value of 640, suggesting that the product might contain two triphenyllead radicals, comparable to the product of the reaction of sodium triphenylgermanide with methylene chloride.[14] No similar product was detected, however, when the reaction was carried out in liquid ammonia solution. Since no pure, well characterized product could be obtained, this reaction was not investigated further.

Summary

1. Methods for the preparation of tetraphenyllead, triphenyllead iodide, hexaphenyldilead, sodium triphenylplumbide and triphenylethyllead are described and some of the reactions and properties of these compounds are recorded.

2. Use is made of tetrasodium nonaplumbide, Na_4Pb_9, as a mild reducing agent in liquid ammonia solutions.

3. The existence of ammonium triphenylplumbide as a fairly stable and soluble salt in liquid ammonia has been indicated, but triphenylplumbane does not appear to be formed.

Ammino Compounds of Triphenyllead Chloride

BY LAURENCE S. FOSTER, IRVING J. GRUNTFEST AND LINTON A. FLUCK

When ammonia is condensed upon crystalline triphenyllead chloride at the boiling point of liquid ammonia, the volume of the solid increases greatly, indicating that a reaction occurs. It has been shown that a series of ammino compounds exists, none of which is stable at room temperature. Two methods have been employed in an attempt to establish the composition of the solid phases: in the first, method I, which was entirely volumetric, the amount of ammonia which was added or withdrawn from the reaction chamber was measured by means of a gas buret; and in the second, method II, the gas buret was used to make small, definite adjustments in the amount of ammonia in the system, but the composition of the phase under investigation was determined by decomposing it and absorbing and weighing the ammonia evolved. Method I was found to be useful for a preliminary exploration of the system, but since the errors in the volume measurements were cumulative, it did not prove to be entirely satisfactory. Method II was used in determining the composition of the highest ammino compound only, and had the advantage that it was much more rapid.

Using the volumetric method (I), two runs

were carried out, each taking about three months, due to the slowness with which equilibrium is established between the solid phases. The results were not in very good agreement, and from the data it was not possible to determine the ratio of the number of moles of ammonia per mole of triphenyllead chloride with an error of less than 10%. The results are shown graphically in Fig. 1, where the equilibrium pressures are plotted against the number of moles of ammonia per mole of triphenyllead chloride present in the condensed phase. There are indications of the existence of at least four ammino compounds which have the following approximate compositions

Vapor pressure, mm.	400	160	100	50
Moles NH_3	9.65	2.7	1.8	1.3

The vertical line in the graph, corresponding to 9.72 moles of ammonia, was drawn from the data obtained using method II. The existence of a metastable compound with a vapor pressure of 415 mm. is suggested, but its composition was not established.

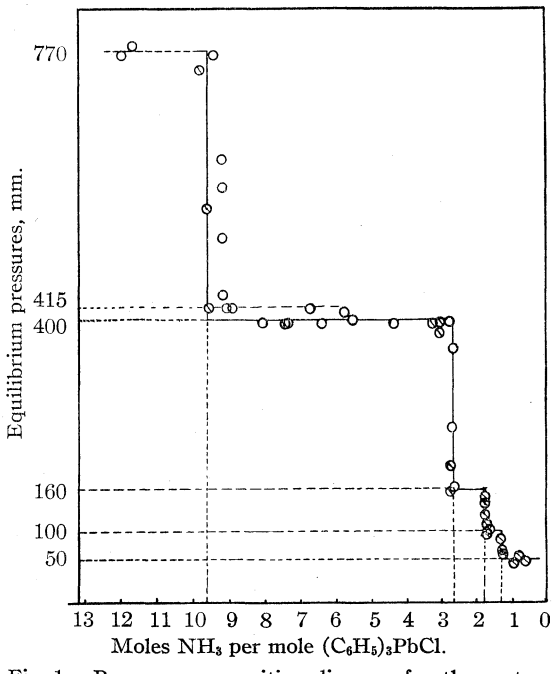

Fig. 1.—Pressure–composition diagram for the system $(C_6H_5)_3PbCl$–NH_3 at −33.4°.

Due to the uncertainties of the results, it was decided to repeat part of the work, focusing the attention upon the compound containing the largest amount of ammonia, since it could be prepared readily in equilibrium with the saturated solution and analyzed conveniently by the use of method II. The experiments were performed independently by two operators who used different equipment and different preparations of triphenyllead chloride. The results of eight experiments gave an average composition of 9.72 moles of ammonia per mole of triphenyllead chloride, and the deviations of the individual results from the mean were less than 1%. The composition for this single compound is in fair agreement, thus, with that obtained through the use of the first method.

While it is not usual for the numbers of molecules in complex ammino compounds to be so far from a ratio of small whole numbers, it appears that the tentative conclusion must be drawn that with triphenyllead chloride the ratio of the number of moles of ammonia per mole of chloride, in the highest complex, has a value of about 29 to 3 or 68 to 7. Additional information concerning the structure will be needed before a formula can be assigned. The experimental data for the other ammino compounds are so inaccurate that no statement concerning their compositions is justified at this time.

Few studies have been made of the compounds formed between organo-metallic substances and neutral molecules, like those described here. In the index of the treatise by Krause and von Grosse,[1] out of the 6000 organo-metallic compounds listed only two dozen ammino or similar complex derivatives are catalogued, and none of them show any irregularities. It may be noted, however, that Biltz and Fischer[2] found that several ammino compounds are formed by the lead dihalides, the compositions of some of which do not correspond to ratios of small whole numbers; *e. g.*, $4PbCl_2 \cdot 13NH_3$ and $2PbCl_2 \cdot 11NH_3$. They postulated that these compounds consist of mixtures of simpler ammines, but until structure determinations have been made the question as to their formulas also remains unanswered.

Experimental

Preparation of Triphenyllead Chloride.—The starting material was tetraphenyllead and it was converted to triphenyllead chloride by the method of Gilman and Robinson.[3] The samples used were shown to be pure by the melting point, 206°, and by analysis for chlorine. The material is stable toward ammonia; the weights and melt-

ing points of the samples remained unaltered, even though the outward appearance was considerably changed during the formation and decomposition of the complexes. Triphenyllead chloride is stable toward air and atmospheric moisture.

Apparatus and Procedure.—The sample of triphenyllead chloride was sealed in a "Pyrex" glass bulb (vol., 17 ml.) attached to a long stem of capillary tubing, a stopcock and one part of a ground joint. The reaction bulb thus could be removed from the system and weighed. It was cooled to −33.4° in a bath of liquid ammonia. In addition to connections to the source of purified and redistilled ammonia and to a "Hyvac" vacuum pump, the remaining apparatus consisted of a mercury manometer; a removable bulb, similar to the reaction bulb, holding anhydrous calcium chloride for absorbing and weighing the ammonia evolved upon decomposition of the compounds; and a jacketed gas-measuring buret[4] equipped with a Pettersson compensator set for 760 mm. and 0°,[5] so that the number of moles of gaseous ammonia added or withdrawn from the reaction vessel could be determined without laborious calculations. The volumes of the connecting tubes were determined so that it was possible to compute at any time, from the total amount of ammonia in the system, the amount of ammonia held in the condensed phase.

Since the vapor pressures of the solid compounds were found not to vary appreciably with small temperature fluctuations, no attempt was made to maintain the boiling point of the bath ammonia at a strictly constant temperature. The vapor pressure of the saturated solution of triphenyllead chloride, on the other hand, did vary considerably with temperature, and it seemed advisable, prior to recording significant vapor pressure values, to replace the ammonia in the bath with a fresh supply and to allow it to evaporate against a definite pressure, to ensure that the temperature was −33.4°.

Sufficient ammonia was condensed in the reaction tube to form a saturated solution of triphenyllead chloride in equilibrium with the highest ammino complex. After the crystals had been allowed to remain in contact with the solution for several days, ammonia was withdrawn, either in measured quantities by means of the gas buret (method I) or more rapidly by means of the vacuum pump (method II). In either case, when the sample was nearly dry the remaining excess ammonia was taken off slowly by means of the buret, and when it was established that the dry salt was in equilibrium with the vapor, the pressure was recorded and the composition of the complex compound was determined.

Using method I, additional ammonia was removed in known decrements and the system was allowed to return to equilibrium after each removal. In this way the equilibrium pressure–composition diagram, shown in Fig. 1, was arrived at.

In method II, once the ammino compound was formed, in the manner just described, it was decomposed by allowing it to warm to room temperature and the ammonia evolved was absorbed in the weighing tube containing calcium chloride, cooled to −33.4°. By subtracting the amount of ammonia computed to be in the gas phase in the reaction bulb, at −33.4°, the amount of ammonia held in the solid phase was obtained. The data are given in Table I, expressed in moles of reactants.

In Table II the data are given from which the values of the equilibrium pressures were estimated. It will be noted that in most cases it was possible to approach the equilibrium from both sides.

Summary

The compounds formed between ammonia and triphenyllead chloride have been investigated and their vapor pressures measured at −33.4°. Several compounds were detected, but the composition of only one was determined accurately. In this compound the number of moles of ammonia per mole of triphenyllead chloride cannot be expressed as the ratio of small whole numbers.

The Standardization of Strong Oxidizing Agents with Potassium Iodide by the Acetone Method

BY I. M. KOLTHOFF AND H. A. LAITINEN

Lewis[1] attributes the low results obtained by us[2] in the standardization of potassium permanganate with pure potassium iodide by the acetone method of Berg[3] to the use of too low an acidity. The acidity used in our work was 0.9 *N*, while Berg used 2.0–2.5 *N* with potassium iodate as the oxidant. According to his comments the most suitable acidity seems to vary with the oxidant which is being standardized. In order to determine whether our low results were caused by too low an acidity, we have extended our experiments over a range of varying concentrations of acid. The same sample of pure potassium iodide as described previously[2] was used. An accurately weighed amount of the pure iodide was dissolved in water, 50 ml. of acetone, water and varying amounts of 9 *M* sulfuric acid were added to make a volume of 200 ml. One tenth normal potassium permanganate, standardized by the accurate method previously described, was added from a weight buret to within about 1% of the end-point (40 to 50 ml.) and the titration was then finished with 0.01 *N* permanganate which was added from an ordinary buret. The results were found to be independent of the acidity when the initial sulfuric acid concentration lay between 0.5 and 4 *N*. The results were always low, but depended upon the speed with which the 0.01 *N* permanganate was added in the immediate vicinity of the end-point. When it was added at a rate of about ten seconds per drop the results were 1.0%, low; on the other hand, if the permanganate was added rapidly until the color change persisted for thirty seconds, the results were 0.2% low. The speed of addition of the permanganate up to 0.5% before the equivalence point did not affect the results. Apparently, the low results have to be attributed to the fact that part of the 0.01 *N* permanganate added in the immediate vicinity of the end-point reacts with the acetone and the iodoacetone and is withdrawn from reaction with iodide. If the titration was carried out and finished with 0.1 *N* permanganate, which was added either from a weight or a volume buret, the results were found to be close to the theoretical value but always slightly low. This is evident from the experiments reported in Table I which were carried out at varying acidity. In all these experiments 25 ml. of acetone was used in an initial volume of 100 ml.

TABLE I

STANDARDIZATION OF 0.1 *N* PERMANGANATE WITH POTASSIUM IODIDE BY BERG'S METHOD. THEORETICAL VOLUME OF PERMANGANATE 47.70 ML.

Initial normality of H_2SO_4	0.25	0.5	1.0	2.0	3.0	4.0
0.1 *N* permanganate used	[a]	47.69[b]	47.68[b]	47.67	47.62	47.63
Error, %		−0.02	−0.04	−0.06	−0.16	−0.14

[a] Reaction velocity too small to allow titration.
[b] Average of two to three titrations.

Under the specified conditions the titration yields excellent results, particularly when the initial acidity is between 0.5 and 2 *N* and the titration is carried out with 0.1 *N* permanganate. It was found that the amount of acetone in the initial volume of 100 ml. could be changed between 10 and 50 ml. without changing the results

more than 0.05%. From the practical point of view the use of the following procedure for the standardization of 0.1 *N* permanganate is to be preferred over the standardization with sodium oxalate.

Procedure for the Standardization of 0.1 *N* Permanganate (and 0.1 *N* Ceric Sulfate).—Weigh out approximately 0.35 g. of pure potassium iodide, dissolve in 75 ml. of water, add 5 ml. of 18 *N* sulfuric acid, 3 drops of 0.025 *N* ferrous phenanthroline sulfate solution and 20 to 25 ml. of C. P. acetone. Mix and titrate with 0.1 *N* permanganate until the end-point color change from red to practically colorless persists for thirty seconds.

In his experiments, Lewis used a C. P. Mallinckrodt product of potassium iodide and found results which agreed within 0.1 to 0.2% with the normality obtained with sodium oxalate. Using our precise methods[2] we determine the purity of a C. P. Mallinckrodt product of potassium iodide. After drying at 250° we found a potassium iodide content of 99.94% as compared to 100.00% for our pure product. Thus, for most practical purposes the standardization can be made with the dried Mallinckrodt product.

A limitation of the method is that the procedure described gives low normalities in the standardization of 0.01 *N* permanganate. Under the most favorable conditions (fast titration close to the end-point), the results were found to be 0.8 to 1% low.

The experiments described above were repeated with ceric sulfate. The results obtained were strictly comparable with those obtained with permanganate. The procedure given for the standardization of 0.1 *N* permanganate gives equally good results in the standardization of 0.1 *N* ceric sulfate, but again yields 0.8 to 1% low results in the standardization of 0.01 *N* ceric sulfate.

A separate investigation has been made of the cause of the low results obtained in the slow titrations with 0.01 *N* permanganate in the vicinity of the end-point. In the following experiments 5 ml. of 0.1 *N* permanganate was added to a mixture of 25 ml. of C. P. acetone in 100 ml. of dilute sulfuric acid. After standing for fifteen minutes at room temperature, the excess of permanganate was determined by adding an excess of standard iodide and titrating with 0.1 *N* permanganate according to the procedure described above. From the results given in Table II it is evident that the amount of permanganate which has reacted is proportional to the acidity of the solution.

TABLE II

REACTION OF PERMANGANATE WITH ACETONE IN ACID MEDIUM AFTER FIFTEEN MINUTES

Sulfuric acid, *N*	0.5	1.0	2.0	3.0	4.0
MnO_4^- reduced, %	17	34	70	98	100

Since the reduction of the permanganate may be attributed to impurities in the acetone, we have repeated the experiments with purified samples. The original C. P. sample was refluxed for several hours with an excess of permanganate and distilled. In other experiments the original sample was purified by making the sodium iodide addition compound from which the purified product was obtained by distillation.[4] The purified products behaved similarly to the original sample. Particularly immediately after addition of the permanganate the reaction velocity was found to be relatively great, the relative rate being greater with 0.01 *N* than with 0.1 *N* permanganate. A few figures given in Table III illustrate the behavior. The latter only partly accounts for the low results obtained in slowly titrating with 0.01 *N* permanganate near the end-point. Part of the error must be attributed to the fact that the presence of iodo-acetone increases the rate of reduction of permanganate. This rate was found to increase with increasing concentrations of iodoacetone.

The conditions under which the experiments of Table III were carried out were chosen so as to correspond closely to those in the neighborhood of the end-point in the titration. To a solution of 25 ml. of acetone in 140 ml. of 1.3 *N* sulfuric acid were added the indicated reagents and 2.90 ml. of permanganate. After various periods of standing at room temperature the amount of permanganate left was determined as described before.

TABLE III

RATE OF REACTION OF PERMANGANATE WITH ACETONE UNDER VARYING CONDITIONS

[a] Unpurified C. P. acetone. [b] Purified by the sodium iodide addition compound. [c] Purified by refluxing and distilling from neutral permanganate.

Acknowledgment.—We wish to express our appreciation to the Graduate School of the University of Minnesota for a grant which enabled us to carry out this investigation.

Summary

1. A simple procedure is given for the standardization of 0.1 *N* permanganate and 0.1 *N* ceric sulfate by Berg's method using potassium iodide as a primary standard.

2. The method gives 0.8 to 1% low results in the standardization of 0.01 *N* solutions.

3. Low results are shown to be due to a reduction of the oxidizing agent by the acetone and the iodoacetone in the close neighborhood of the end-point.

The Action of Liquid Ammonia Solutions of Sodium, Potassium, and Potassium Amide upon Bismuth Oxyiodide[1]

BY GEORGE W. WATT[2] AND W. CONARD FERNELIUS

The successful removal of halogen from organic combination and the reduction of inorganic halides by the action of the alkali and alkaline earth metals in liquid ammonia solution[3] suggests the possibility of obtaining sub-oxides of certain metals by the reduction of oxyhalides such as bismuth oxyiodide, BiOI. The experiments described below, however, show that the compound is reduced completely in that both iodine and oxygen are removed by the alkali metal. It might be expected that the amide ion, NH_2^-, would be more selective, since it has been shown to be a mild reducing agent.[4] However, KNH_2 undergoes simple metathesis to form $BiONH_2$.

Experimental

The Action of Sodium and Potassium in Liquid Ammonia on Bismuth Oxyiodide

When 0.500 g. of bismuth oxyiodide (Merck C. P.) was treated with a solution of sodium or potassium (0–25°) in liquid ammonia,[5] the light red color of the oxyhalide was discharged immediately, the solid phase changed to a grayish-black color, and a small amount of a somewhat flocculent white precipitate appeared. A blue color, indicative of an excess of alkali metal, persisted for a short time when it was replaced either by a pale yellow color (3 equivalents of potassium) or by violet colors (all other cases). In every instance a small and variable amount of a water-insoluble gas (hydrogen) was formed during the reaction.

Upon completion of the reaction, the insoluble reaction product was washed with liquid ammonia until colorless washings were obtained, or until the intensity of the color of the washings showed no visible decrease upon repeated washing. The solvent was then allowed to evaporate and the tube was opened for analysis.

Data relevant to these reactions are presented in Table I. The values representing analyses are the average of two or more determinations.

TABLE I

Expt.	Alkali metal	Alkali metal used, g.	Analysis of insol. reaction product: Sample, g.	Found, %: Bi	Alkali metal	N	%I[a] recovered from washings
			Three equivalents alkali metal				
2	K	0.333	0.5888	82.7	12.2	0.6	97.4[b]
3	K	.333	.6834	84.8	8.6	.5	97.7[b]
1	Na	.196	.5912	73.7	18.4	...	...
4	Na	.196	.3840	73.1	18.6	.5	100
			Six equivalents alkali metal				
5	K	0.666	0.7270	68.1	26.6	.3	99.2
8	K	.666	.6640	63.4	28.9	Trace	99.2
6	Na	.392	.6512	63.3	29.3	Trace	99.5
9	Na	.392	.9136	62.5	30.2	0.6	99.4

[a] Based on iodine used as BiOI. [b] Some iodine inadvertently lost prior to analysis.

Discussion

The data of Table I indicate that the following reactions are involved

$$BiOI + 3M \longrightarrow Bi + MI + M_2O \quad (1)$$
$$2NH_3 + 2M \longrightarrow 2MNH_2 + H_2 \quad (2)$$
$$M_2O + NH_3 \longrightarrow MOH + MNH_2 \quad (3)$$
$$3M + Bi \longrightarrow M_3Bi \text{ (insoluble)} \quad (4)$$
$$M_3Bi + xBi \longrightarrow M_3Bi{\cdot}Bi_x \text{ (soluble)} \quad (5)$$

The analyses of the washings for iodide ion show clearly that ammonia solutions of sodium and potassium quantitatively remove the iodine from bismuth oxyiodide (reaction 1). The evolution of hydrogen accompanying the reduction is due to the reaction between the metal and solvent, probably catalyzed by the liberated bismuth metal (reaction 2). The occurrence of reactions 2 and 3 accounts for the appearance of nitrogen (as MNH_2) in the washings.

Alkali monoxides (indicated in reaction 1) are not stable in liquid ammonia but are ammonolyzed to hydroxides (reaction 3),[6] thereby ex-

plaining the white precipitate observed. Further, the analysis of the insoluble products indicates the presence of alkali hydroxide.

The composition of the insoluble products depends upon the nature of the alkali metal and the number of equivalents used. The pale yellow color (KNH_2) of the ammonia solution at the end of the reaction with three equivalents of potassium as well as the analytical data indicate that no insoluble bismuthide was formed. If the potassium in the insoluble product is assumed to be in the form of potassium hydroxide (in expt. 2, 12.2% potassium corresponds to 17.5% potassium hydroxide, the total analysis (100.8%) accounts for all of the sample.

When three equivalents of sodium are used, the color of the washings indicates the presence of bismuthides (reactions 4 and 5) which are sufficiently soluble to impart intense colors to the liquid ammonia.[7] The presence of an insoluble bismuthide is indicated by the following considerations. If all of the sodium in the insoluble products is assumed to be in the form of sodium hydroxide, the total of the analysis is several per cent. above 100 (expt. 4, 18.6% Na is equivalent to 32.3% sodium hydroxide and the total then equals 105.9%).[8]

When six equivalents of sodium or potassium are used, the solutions above the solids are strongly colored (violet for potassium and blue-violet for sodium). These colors grow less intense but persist throughout the washing process. The amount of bismuth present in the washings and the amount of alkali metal in the insoluble products are greater for the experiments involving six equivalents of alkali metal. A simple calculation shows that all of the alkali metal cannot be present as hydroxide (in expt. 6, 29.3% sodium is equivalent to 50.9% sodium hydroxide, and the total of the analysis would be 114.2%; in expt. 5, 26.6% potassium is equivalent to 38.2% potassium hydroxide, and the total of the analysis would be 106.6%). These data show that with excess alkali metal, bismuthides are formed and that the tendency to form bismuthides is greater for sodium than for potassium.

(7) E. Zintl, J. Goubeau and W. Dullenkopf, *Z. physik. Chem.*, **A154**, 1–46 (1931), give the following data: Na_3Bi, insoluble black solid; Na_3Bi_3, deep violet solution in liquid ammonia; Na_3Bi_5, brown solution.

(8) While it might be argued that the use of *exactly* three equivalents of sodium would lead to the production of metallic bismuth only, such a situation would be difficult to realize experimentally because in each reaction there is a variable quantity of alkali metal converted to amide by reaction with the solvent.

Experimental

The Action of Potassium Amide in Liquid Ammonia on Bismuth Oxyiodide

Preliminary experiments showed that bismuth oxyiodide reacts with a molar equivalent of potassium amide in liquid ammonia at or near room temperature to form a very dark red solid which decomposes slowly in the presence of liquid ammonia with liberation of elementary bismuth and which explodes violently when exposed to the air. When an excess of potassium amide is used, an identical product is obtained.

One-half gram of bismuth oxyiodide was brought into reaction with the potassium amide from 0.32 g. (large excess) of potassium. After standing for one hour, during which there was no further change, the ammonia solution was decanted and the solid (dark red with traces of black) was washed free of ammonia-soluble impurities. The ammonia was allowed to escape, the tube sealed off, evacuated, and the insoluble reaction product hydrolyzed *in vacuo* by the vapors from dilute hydrochloric acid. A clear solution and a small amount of a black insoluble solid (Bi) resulted.

Anal. Found (independent experiments), N, 5.7, 5.8. Calcd. for $BiONH_2$: N, 5.80; for BiN, N, 6.28. Analysis of the washings for iodine gave values of 99.8 and 99.7% (based on the weight of iodine in the BiOI used), thus showing conclusively that the oxyiodide was quantitatively dehalogenated.

Discussion

In view of the similarity of the properties of the product described above with those of bismuth nitride, BiN,[9] one might suspect that the following reaction had occurred

$$BiOI + KNH_2 \longrightarrow BiN + KI + H_2O$$

Water thus formed, however, would lead to the production of white ammonia-insoluble potassium hydroxide by interaction with the excess potassium amide

$$KNH_2 + H_2O \longrightarrow KOH + NH_3$$

There was no evidence whatever of the appearance of potassium hydroxide among the products of the reactions under consideration. Furthermore, the analyses for nitrogen show that the product must be bismuth oxyamide rather than bismuth nitride. Accordingly, the reaction must be one of simple metathesis

$$BiOI + KNH_2 \longrightarrow BiONH_2 + KI$$

Summary

1. Bismuth oxyiodide is reduced by liquid ammonia solutions of sodium and potassium at room temperature in accordance with the equation $BiOI + 3M + NH_3 \longrightarrow Bi + MI + MOH + MNH_2$.

2. With excess alkali metal, bismuthides are formed.

3. The reaction between potassium amide

(9) E. C. Franklin, THIS JOURNAL, **27**, 847 (1905).

and bismuth oxyiodide in liquid ammonia at room temperature may be represented by the equation $BiOI + KNH_2 \longrightarrow BiONH_2 + KI$.

The Ternary System: Ethyl Alcohol, Toluene and Water at 25°

BY E. ROGER WASHBURN, ALBERT E. BEGUIN AND ORVILLE C. BECKORD

In order to have solubility and distribution data for this system at 25° to compare with the systems already studied[1] and others which are soon to be described, it has been found necessary to carry out this investigation. Ormandy and Craven[2] and Tarasenkov and Poloznintzeva[3] have studied this system but their studies did not include determinations of the distribution of alcohol between the toluene-rich and water-rich layers or refractive indices of the saturated solutions, and the temperatures at which they worked were not those at which our earlier studies have been made.

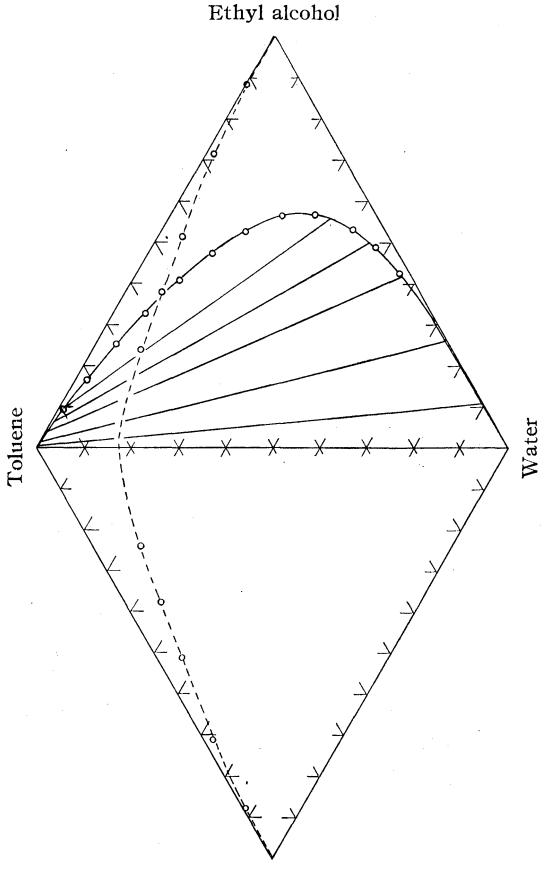

Fig. 1.—Solubility and conjugation curves at 25.0°.

Materials.—Carefully purified water was used. It was distilled from alkaline permanganate and collected while hot. A commercial grade of absolute ethyl alcohol was refluxed over lime for many hours and carefully fractionated. Its specific gravity d^{25}_4 was 0.7851 ± 0.0001, while its refractive index $n^{25}D$ was 1.35940 ± 0.00001.

Toluene of "analytical reagent grade" was dried over sodium and fractionated. This material had a specific gravity d^{25}_4 of 0.8608 ± 0.0002 and an index of refraction

$n^{25}D$ of 1.49371 ± 0.00001. Although this specific gravity is almost identical with that listed in the "International Critical Tables,"[4] we have reason to believe that the value is a little too low for toluene of highest purity. A small portion of what we believe to be a more nearly pure toluene was used in part of the work. It had a specific gravity d^{25}_4 of 0.86221 ± 0.00003 and a refractive index of 1.49375 ± 0.00003. We were not able to detect any difference in the solubility results obtained with the two grades of toluene.

Procedure.—The solubility curve was determined at 25.0 ± 0.1° in a constant temperature bath by a titration method not greatly different from that previously described.[1] The refractive indices were measured with an Abbe refractometer at the same temperature. An immersion refractometer was used in obtaining the constants for the pure liquids. Large scale curves were plotted for the refractive indices *versus* concentration of each of the three components in the saturated solutions. These curves were used in determining the composition of the conjugate solutions formed when alcohol in insufficient amounts to bring about homogeneity was added to two liquid phase mixtures of water and toluene. Samples were removed from each of the layers, after equilibrium had been reached, for the determination of refractive index. The results are given in Tables I and II. The values marked with a (*) were used in plotting the solubility curve with its tie lines as shown in Fig. 1. The conjugation curve (4) (p. 398), is also indicated. Its intersection with the solubility curve locates the plait point.

(4) "International Critical Tables," Vol. III, p. 29.

Summary

The solubility curve for the ternary system ethyl alcohol, toluene and water has been determined at 25.0°. The refractive indices of the saturated solutions have been recorded. The compositions of various conjugate solutions throughout a large range of concentrations have been measured.

LINCOLN, NEBRASKA RECEIVED APRIL 26, 1939

Molecular Freedom and Melting in Alkyl Halides

BY WILLIAM O. BAKER AND CHARLES P. SMYTH

In the course of an investigation relating the structure of organic molecules to their rotational mobility in the solid state, dielectric constant and apparent conductance measurements over a range of temperature and frequency were made on liquid and solid *i*-propyl and *n*-amyl bromides. The crystalline phases were also examined with the polarizing microscope. The *n*-amyl bromide molecule was chosen as less rod-like than long chain compounds,[1] but more anisotropic than the *i*-amyl, *i*-butyl and *i*-propyl derivatives. The latter was selected as intermediate in symmetry between the nearly spherical *t*-butyl halides[2] and the isobromides.[3]

The dielectric measurements with a capacity bridge involved the general procedure previously employed.[4] The usual precautions of pumping off dissolved gases from the liquids, and of slow freezing to reduce void formation, were observed. Temperatures were determined with a platinum resistance thermometer. A small unsilvered dewar tube with a liquid air cooling device was mounted on the microscope stage for observations between crossed nicols.

Purifications of Materials

Final purification was fractionation through a packed jacketed 80 × 2 cm. Pyrex column with still head equipped for variable reflux ratio. Boiling points were measured with Anschütz type short range thermometers calibrated by the Bureau of Standards, and the surface for liquid–vapor equilibrium to give true boiling temperatures was increased by use of a mercury well in the column top. Refractive indices were determined with a Pulfrich refractometer.

***i*-Propyl Bromide.**—Material from the Eastman Kodak Co., dried over pure calcium bromide for several weeks, was twice fractionally distilled; b. p. 59.5°; f. p. −90.8°; $n^{20.0}D$ 1.42476. "International Critical Tables" values are: b. p. 59.6°; $n^{20}D$ 1.4251, while Skau and McCullough[5] give b. p. 59.41° and f. p. −90.0°. As with the *i*-amyl bromide, the absence of Maxwell-Wagner interfacial polarization on freezing and the low apparent specific conductance values for the liquid assured purity.

***i*-Amyl Bromide.**—The Eastman product was dried over calcium bromide for two weeks and twice fractionated; b. p. 128.6°; m. p. −88.7°; $n^{20.0}D$ 1.44455; "International Critical Tables" values are: b. p. 127.9°; $n^{20.0}D$ 1.4444; whereas Skau and McCullough[5] gave b. p. 129.6°, m. p. −87.9°, and Deese[6] reports m. p. −88.0°.

Experimental Results

The dielectric constants, ϵ, and specific conductances k (ohm^{-1} cm.$^{-1}$) form Table I, in which, also, the temperatures are given in the first column, and the appropriate frequencies in kilocycles are indicated for the other data. Many measurements at intermediate temperatures have

been omitted, but those given are often selected from different runs to demonstrate reproducibility. The imaginary part of the dielectric constant $\epsilon'' = 1.8 \times 10^9\ k/f$, in which f, the frequency in kilocycles, is given for *i*-propyl bromide. The apparent values of ϵ'' just below the freezing point are too high because of a certain amount of direct current conductance. In the dielectric constant values for amyl bromide between 97.4 and 96.9°, the apparent decrease with decreasing frequency arises from the fact that the readings were taken in the order of decreasing frequency. Although the temperature changed by less than 0.01° during the readings at the three frequencies, the rapid crystallization with consequent setting of the dipoles caused a decrease in dielectric constant which was not influenced by the frequency.

Discussion of Results

Figure 1 represents the general immobilizing of the dipoles of *i*-propyl bromide upon freezing, after

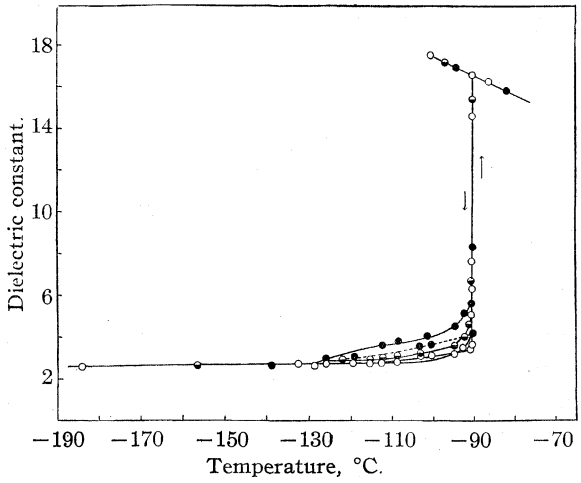

Fig. 1.—Temperature dependence of the dielectric constant of *i*-propyl bromide. (Filled circles represent values at 0.5 kc., half-filled circles values at 5 kc., and hollow circles values at 50 kc.)

slight supercooling, with hindered rotational freedom extending to about −131°. Below this temperature, dispersion has disappeared, and the dielectric constant is nearly the square of the refractive index, as electron polarization alone would require. The polarizing microscope shows pronounced double refraction in the crystals, hence anisotropy, on solidification, so the rotation is probably not about all axes. The cubic, or, occasionally, the hexagonal, class is characteristic of molecular crystals in which rotational molecular freedom comparable to that in the liquid obtains.[2,7] The sharp reduction of the dielectric constant at the freezing point suggests that rotation around any axis perpendicular to the C–Br line ceases at this temperature, while the gradual fall of the dielectric constant accompanied by anomalous dispersion from this temperature down to about −131° indicates the possibility of a decreasing hindered rotation about this axis or one nearly parallel to it, a behavior undetectable in many structures.

Although beginning at the same temperature as that at which it ends on cooling, the dispersion is more pronounced on warming, and a coöperative loosening, like rotational premelting, may occur.[1,8,9] Inspection of Table I confirms the idea of hindered rotation with no transition in that the dielectric loss as indicated by ϵ'' shows only a steady decline after solidification.

The *i*-propyl bromide molecule is sufficiently symmetrical to pack with an economy of free volume in the liquid, but its anisotropic lattice implies that the liquid arrangement is not of cubic-packed spheres. Hence, some supercooling is expected,[3] but soon, on cooling, the thermodynamic potential, probably with the aid of short relaxation times, is able to effect crystallization with free energy diminution, unlike the cases of the more anisotropic *i*-butyl and *i*-amyl compounds. Further, standard theories that supercooling proceeds in the complete absence of nuclei are supported by the exact continuity of the supercooled ϵ curve with that for the liquid in Fig. 1. Minute crystallites would cause a sharp change in the dielectric constant.[4,10]

Figure 2 shows the dielectric behavior of *n*-amyl bromide on cooling and warming. Like diethyl ether,[11,12] it evidently possesses a monotropic transition resulting in a low temperature form which melts at −88.7°, about 5.9° higher than the phase which first apears on freezing. This transformation had appeared in thermal studies on *n*-amyl bromide[6] for, about 25° below the melting point, the calorimeter was found suddenly to heat up 5° against a 10° shield gradient. Skau and McCullough[5] confirmed the presence of two forms, an unstable one melting at −94.6° (a value close to −94.5°, our higher freezing point indicated on Fig. 2), and a stable one melting at −87.9°. They quote Simon[13] as reporting a

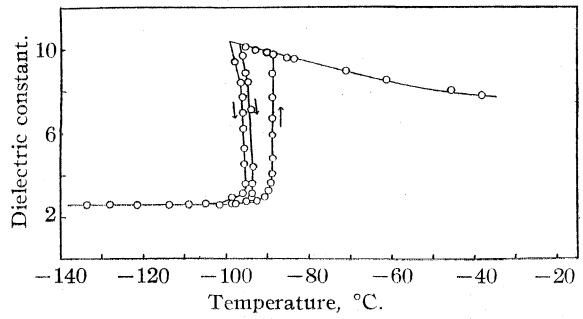

Fig. 2.—Temperature dependence of the dielectric constant of *n*-amyl bromide.

freezing point of −95.25°, a value close to the lower freezing temperature, −95.9°, on Fig. 2. The dielectric measurements, tracing the mechanical behavior of the polar molecules, reveal that, although their anisotropy prevents much supercooling, crystallization either does not pro-

ceed rapidly enough, or does not release sufficient latent heat, completely to return the system to a "true" freezing point. This would seem to explain the divergent data of previous investigators, for the freezing point will appear to vary with the bath gradient.

Many polymorphic transitions involving only anisotropic lattices, as the polarizing microscope showed both forms of *n*-amyl bromide to be, are found to involve rotational freedom about at least one molecular axis.[1] However, Fig. 2 resembles similar data for diethyl ether[12] in indicating, after occasional orientation just below the freezing point has ceased, that only electronic and atomic polarizations are contributing to the dielectric constant. An X-ray analysis of the transformation would seem desirable, as discovery of a mode of motion not involving librations in the rearrangement of a molecular lattice might result.

Optical examination gave direct evidence of the transition. The initial crystals were strongly anisotropic, but the double refraction increased when a given sample was held at a low temperature. When the sample was frozen, cooled briefly about 30° below the melting point, and then allowed to warm up quite rapidly, sharp melting of the unstable form was first observed. However, distributed through the liquid were tabular, strongly doubly-refracting crystals which did not themselves melt until a distinctly higher temperature. The latter were the so-called stable form. On prolonged standing at low temperature, the transformation was complete, and only one melting process was observed under the microscope.

The observation that *i*-propyl bromide melted at nearly the same temperature as *n*-amyl bromide, and about 20° higher than *n*-propyl bromide, coupled with data from other work,[2,3] led to examination of the melting properties of simple alkyl halides. The mono-halides, and especially the bromides, were chiefly considered, because they have closely similar polarizabilities and permanent moments, obey Trouton's rule well as shown by available data,[14] and exhibit no extensive liquid association. They should thus have comparable behavior in condensed phases. Also, the dimensions of the molecules should be little altered by interchanges of methyl and bromo groups, since the same method of measurement yields 2.0 and 1.9 Å., respectively, for their radii.[15] Even a chlorine atom with radius of 1.65 Å. approximates the methyl group in size. Hence, it is not surprising that the relationships noted below apply to the isomeric hydrocarbons as well as to the isomeric halides.

Writers on the theories of fusion and of liquids have considered the thermodynamic and statistical changes accompanying melting.[16-18] Hirschfelder, Stevenson and Eyring explained the low entropies of fusion of substances which gained non-translational degrees of freedom in the solid state (as by rotational transitions) as arising from the communal sharing of free volume possible on liquefaction. They have shown that if complete communal sharing immediately occurs,[19] the entropy of fusion, ΔS_f, should be 2 e. u. for a substance already possessed of rotational freedom, as found for *t*-butyl chloride.

Relationships among the entropies of fusion of structurally similar compounds also have been sought,[20-22] but without definite reference to structure. Melting points are often regarded as constitutive properties of organic compounds[23] and an empirical equation connecting them with molecular weights has been suggested.[24] The linear relation between number of C atoms and melting points for odd or even members, respectively, of an homologous series, has been long known,[23] and it has been observed without explanation that isomers often deviate from such straight lines.

Thermal and viscosity data are listed in Table II, under the headings m. p., melting point; ΔS_f, entropy of fusion; t. p., transition point; ΔS_t, entropy of transition; $\Delta t°_{liq.}$, liquid interval under normal conditions, in degrees; $\Delta E_{vis.}$, the activation energy for viscous flow, in calories per mole; and $\Delta E_{vap.}$, the energy of vaporization in calories per mole.

Figure 3 demonstrates, as shown by the data of Table II, that nearly spherical molecules, which have rotational transitions in the solid, melt far

above the "normal" temperature, as t-butyl bromide melts at 255.4°K., 95° above n-butyl bromide. Further, those molecules of somewhat lower symmetry, which can still acquire some rotational freedom before melting, like that found above for i-propyl bromide, will still melt significantly higher and with correspondingly lower entropies of fusion than their non-rotating isomers. This agrees with the position of i-propyl bromide on Fig. 3, and, conversely, the normal location of the n-amyl bromide point confirms the dielectric results in deciding against rotational freedom in the solid.

The abnormal positions of methyl chloride and bromide probably do not mean exceptional librational freedom, although rotation about the C–X axis would not be detected by dielectric measurements, which, for methyl bromide, yield a solid state polarization only slightly higher than the molecular refraction.[25] However, the methyl halide lattices contain a high concentration of dipoles, and might be expected to have greater lattice energies than the higher homologs, in which the dipoles are diluted by the hydrocarbon residues.

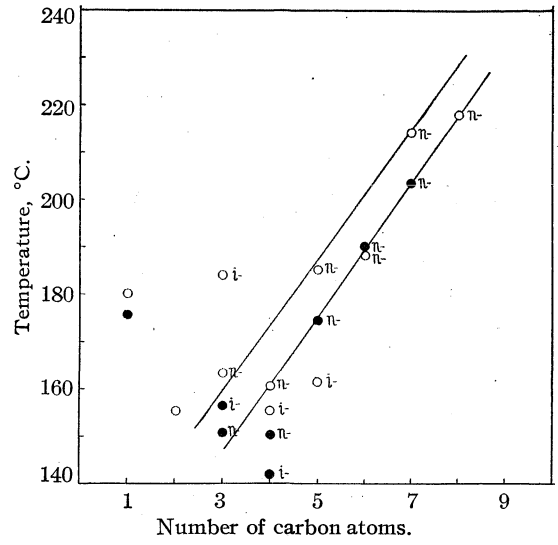

Fig. 3.—Graph of melting point against number of carbon atoms in alkyl chlorides and bromides. (Filled circles ● represent chlorides, hollow circles ○ bromides.)

The following proposals indicate agreement between the thermodynamic and mechanical interpretations of melting properties. The trend toward equilibrium in a system under given conditions involves an increase in entropy while maintaining the minimum free energy feasible.

At a given temperature, a solid can acquire entropy with small change of free energy by going over into the liquid, so melting occurs, and, at a still higher temperature, the boiling point, complete transition to the gas, the most disordered and hence highest entropy state of all, takes place. If, however, the symmetry of a molecule is such that its interaction with neighbors in a lattice does not vary much with its orientation, thermal agitation may give it sufficient kinetic energy to acquire, by means of a polymorphic transition, or simply a gradual loosening, a degree of rotational freedom approaching that in the liquid. A satisfying degree of disorder or increase in entropy has been introduced, and the actual melting can be economically postponed to a higher temperature, when the tendency to increase the entropy still further, by gaining translational freedom, finally causes liquefaction. That a lattice whose molecules possess orientational freedom should have a reduced entropy of fusion is shown in another way by

$$\Delta S_t = R \ln (W_l/W_s)$$

where W_l = number of ways of realizing the liquid state, W_s = number of ways of realizing the solid state; the order of magnitude is given by a W_l/W_s ratio of 2 in which $R \ln 2 = \sim 1.4$ cal./mole/°,[26] for example.

From their approximate obedience to Trouton's rule, most normal liquids are found to have the same entropy of vaporization at their boiling points. Hence, from the above argument, one would expect those molecules which gain extra entropy in the solid, and thus melt higher than is normal, to have liquid ranges much shorter than similar but less symmetrical molecules behaving normally in the solid. This is borne out in Table II, where *n*-butyl bromide has a liquid range of 214° and *t*-butyl bromide is a liquid for only 91°. Striking examples of very symmetrical molecules with solid transitions, that gain so little entropy on melting that they go over into the vapor almost immediately, are hexamethylethane, with 2.8° of liquid interval, and hexachloroethane, which, like iodine, forms no liquid under normal conditions. X-Ray studies have shown the onset of rotational freedom in these two molecules,[27,28] as their non-polarity precludes dielectric investigation. The recorded ΔS_f of hexachloroethane, which would be the entropy change on sublimation less that of vaporization, is little more than half the entropy of transition, so a vanishingly small liquid range is suggested.

i-Butyl and *i*-amyl bromides, which vitrified readily, appear on Fig. 3 to melt too low, possibly because of the efficiency of their packing in the liquid as indicated by glass formation. However, since the dielectric studies showed that the molecules could not rotate in the crystalline solids,[3] it would appear that the conditions of a small change in internal energy accompanied by a large, desirable entropy increase would lower the melting temperature.

The *t*-butylethylene data are included to provide another example besides carbon tetrabromide of an entropy of fusion less than the 2 units to be expected from communal volume sharing. Although its liquid range 160° is greater than those of the alkyl halides which have transitions, it is still a bit shorter than that of the unbranched butylethylene.

Data for six of the isomeric heptanes, at the bottom of Table II, further illustrate the generalizations. As the symmetry of the molecule finally reaches the maximum possible in 2,2,3-trimethylbutane, the melting point rises from a normal one around 150 to 247.7°K., and, correspondingly, the liquid interval drops from an average of over 200 to 106.3°. Parks and Huffman[29] observed that increased branching in a paraffin hydrocarbon leads to a marked decrease in ΔS_f. This behavior is understandable in the light of the present results, where the additional symmetry to be derived from branching may produce librational freedom in the solid.

The applicability of the explanation of the melting point variation among isomers may be further examined in the camphor compounds. Camphor has a rotational transition in the solid state,[30,31] and is a symmetrical molecule, as may be seen from kinetic theory models. If it is made unsymmetrical and the solid transition thus eliminated by moving the two methyl groups from the inner bridge to the outer ring, fenchone results, which should, by the above concept, have a lower melting point and a longer liquid interval than camphor. This is well confirmed by the comparison: α-camphor, m. p. 451.8°K., liquid interval, 30.4°; fenchone, m. p. 278.1°K., liquid in-

terval, 188°. Similar considerations may be extended through the camphor series, where other rotational transitions are known.[30,31] Hence, the size of the molecules involved would not seem to limit the validity of the principle.

An independent index of the symmetry a molecule is likely to exhibit in condensed phases, and hence of its properties arising therefrom, comes from an examination of the activation energy of viscous flow, interpreted by the modern theory of viscosity.[32,33] Eyring has shown that to make a hole the size of a molecule in a liquid requires the same energy as to vaporize the molecule. Further, the mechanism of viscous flow involves an activation process which, apparently, requires extra volume, on the part of the flowing molecules, perhaps that swept out by a rotating couple. For nearly spherical molecules, this needed free volume is about one-third the size of a molecule, that is, the ratio $\Delta E_{\text{vap.}}/\Delta E_{\text{vis.}}$ is 2.5 to 3.[33] For rod-like molecules, however, the flow process seemingly goes in the most economical way, say by the couple's rotation about an axis parallel to the chain axes. Then, the $\Delta E_{\text{vap.}}/\Delta E_{\text{vis.}}$ ratio is about 4,[32] as rods rotating by each other require relatively less extra volume than spheres. This idea agrees with the independent calculations of the activation energies for orientation of *i*-butyl and *i*-amyl bromides.[3] The activation energies for viscous flow listed in Table II were calculated from the data in the Landolt–Börnstein "Tabellen." Perfectly straight lines for the plots of log η against $1/T$ were obtained. The $\Delta E_{\text{vap.}}$ values are from $\Delta H_{\text{vap.}} - (pV)_{\text{vap.}}$. The ratios are very approximate, but are consistent with the rest of the scheme in showing that a molecule which requires a large fraction of the energy of vaporization for the process of viscous flow will, in general, have a sufficiently symmetrical force field to gain vibrational degrees of freedom in the solid, and hence exhibit a reduced ΔS_{f}. An alternative method of statement is that molecules whose force fields interact nearly equally in all orientations with those of surrounding molecules in condensed phases will have no preferred arrangements in the flow process, and $\Delta E_{\text{vap.}}/\Delta E_{\text{vis.}}$ will be 2.5 to 3. However, molecules whose interaction potentials vary greatly with orientation will possess $\Delta E_{\text{vap.}}/\Delta E_{\text{vis.}}$ ratios of 4 or more indicating definite relative positions during flow, and, further, will be unlikely to show rotational freedom in the solid. Exceptions to this latter class are certain of the long chain compounds,[1] but, here, the mode of motion in the solid, about one axis only, is very like that found to be easiest in the flow process.

It may thus be concluded from fusion data, coupled with dielectric and crystallographic results, that members of a homologous aliphatic series (including isomers) melting above the normal temperatures indicated by the graph of melting point against number of carbon atoms have gained entropy by rotational freedom in the solid. Hence, since fewer than the normal degrees of freedom are gained on fusion, these compounds will have abnormally short liquid intervals. Viscosity results agree with the other structural data in assigning this behavior to symmetrical molecules.

Summary

Dielectric constant and dipole loss measurements over a range of temperature and frequency on liquid and solid *i*-propyl bromide reveal a small hindered rotational freedom of the molecules in the anisotropic molecular lattice over a 40° interval below the freezing point. Similar studies on *n*-amyl bromide show that its already-known monotropic transition, which results in a melting point (−88.7°) 5.9° higher than the freezing point, does not involve detectable rotational freedom. These results, together with measurements on *t*-butyl halides as well as other data in the literature, lead to a correlation of the melting points, heats and entropies of fusion, and liquid intervals of alkyl halides with the shapes and mobilities of their molecules in the crystals.

Energy Relations in Transformations from Three to Two-Dimensional Systems. I. The Latent Heat and Entropy of Spreading of Myristic and Pentadecylic Acids

BY WILLIAM D. HARKINS AND G. C. NUTTING

1. Introduction. Heats of Spreading and Freezing

By the application of a Clapeyron equation in the form

$$\Delta H = \lambda_{S \rightarrow F} = T(\partial f/\partial T)(a_F - a_S) \qquad (1)$$

it is possible to determine the latent heat of spreading $\lambda_{S \rightarrow F}$ of a solid S to form a film F upon an aqueous subsolution. Here f is the film pressure at equilibrium between the crystals and the film and a the area of the surface involved. In practice a_S may be made sufficiently small to be negligible.

Since the values of the temperature required to give the same molecular area at equilibrium in a monolayer of either the 14 or the 15 carbon atom acid are not very different, it is apparent that the differences in the latent heats of spreading, at any given value of a_F, are almost entirely determined by the value $\partial f/\partial T$ of the slope of the f, T curve.

Values of these slopes have been determined by Cary and Rideal,[1] who find $\partial f/\partial T$ to be practically the same for both myristic and pentadecylic acid, that is the f, T curves are parallel, which is not in agreement with our data as presented later. The values of the latent heats of solidification or "settling" of these acids have been determined by King and Garner,[2] and these are, in kcal. per mole, 10.7 for the even (14 C) and 10.30 for the odd (15 C) acid if the solid is in the α-form. The transformation $\alpha \rightarrow \beta$ of the odd acid evolves 1.20 kcal. per mole in addition.

Thus the tightness of binding of the molecules of the even (14 C) acid may be said to be 10.7 kcal. per mole greater in the crystals than in the three dimensional liquid, while for the odd (15 C) acid the value is 10.3 or 11.5 as has been stated. The effects of the small changes of volume are neglected.

All of the monolayers formed by these two acids are liquids in the ranges of T, f, and a considered here. They may be classified as: I, Liquid, condensed; II, Liquid, intermediate (or transition); and III, Liquid, expanded.

(1) A. Cary and E. W. Rideal, *Proc. Roy. Soc.* (London), **A109**, 328 (1925).

(2) Annie M. King and M. E. Garner, *J. Chem. Soc.*, 578 (1931).

In these liquid monolayers the energy of molecular binding may be assumed to be greater than in the three dimensional liquid on the basis of the orientation theory, which assumes intimate contact between the carboxyl groups and water molecules, both of which have powerful dipoles. On the basis of the reasoning given above the energy added as heat (Q_F) to produce a spreading of the material from the crystals over the surface of the liquid should for any of the solids be less than the heat of melting (Q_M), or (1) $Q_F < Q_M$.

2. Apparatus and Methods.—The film balance used for the measurement of film pressure, an improved form of that described by Harkins and Myers,[3] was of the general Adam–Jessop type, and was built in such a way as to give a high degree of accuracy in the measurements. For the determination of $\partial f/\partial T$ it is essential to have more accurate temperature control. The use of an air thermostat alone is not sufficient to determine closely enough the temperature of the film. The trough of stainless steel used to contain the subsolution was 80 × 25 × 0.5 cm. with the bottom of the trough hollow, and water from a thermostat was circulated through the shallow reservoir in this bottom, so that the subsolution came rapidly to the thermostat temperature. Water from the thermostat was also circulated through the top of the metal box which inclosed the trough and underneath the trough, and the box was surrounded by an air thermostat.

In performing the experiments, two or three hundred small crystals of fatty acid, supplied by Drs. E. E. Reid and Jane D. Meyer, were placed on a clean surface of 0.01 N sulfuric acid and the temperature of the air and the subsolution were equalized. Temperatures were read by means of thermocouples placed just above and just below the film-covered surface. The air within the film balance case was kept saturated with water vapor. This precaution was necessary for two reasons. At the higher temperatures if the air is not kept saturated, evaporation is rapid and the level of the subsolution in the film trough drops considerably in the course of an experiment, which introduces a proportionate error in the film pressures. Also rapid evaporation produces in the film-covered surface a temperature lower (by an unknown amount) than that measured with the thermocouples. The area included between the float and barrier of the film balance, which was available for spreading, was about 100 sq. cm. The criterion of equilibrium was constancy of film pressure within 0.1 dyne per cm. for ten to fifteen minutes. Attainment of equilibrium below 20° required about two hours but the time became rapidly less as the temperature was raised.

Since a considerable number of investigators

$(\lambda_{S_\beta \rightarrow L} = 11.5)$								

have used the ring method in an attempt to determine the surface tension of a subsolution covered with an insoluble film, and since this method was applied by Cary and Rideal to determine the pressures of films in equilibrium with crystals of myristic, pentadecylic, and other acids, it is important to point out why this method fails. The film pressure is given by the equation

$$f = \gamma_S - \gamma_F$$

where γ_S is the surface tension of the clean surface of the subsolution, and γ_F the value when the film is present. However, at least with rings of the size in use, the ring method does not measure γ_F. This is due to the fact that, in order to meet the conditions of the theory of the method, the ring must be pulled completely from the liquid, and the maximum pull exerted gives the surface tension. Now at the instant when the maximum pull is exerted, the area of the surface inside the ring is much greater than when the surface is plane. Thus unless crystals of the solid are kept on the surface inside the ring, the surface tension found will be higher than the true tension for the film. The film pressure as determined will thus be too low; much too low if the film is initially condensed, considerably if expanded, and not very much if the film is in the intermediate (transition) state just above the pressure of the transition Intermediate → Expanded. Even if crystals are present inside the ring the time which elapses during the pulling of the ring from the surface is often insufficient to give equilibrium. In addition the weight of the crystals must be negligible or the method is inaccurate.

Values of the variable correction factor, which is essential if the pull on the ring is to be transformed into a surface tension, had not been determined at the time of Cary and Rideal's work. The corrections cannot now be made because of insufficient data on the dimensions of the ring which they used.

The Wilhelmy method, used as a film balance in the form recommended by Harkins and Anderson,[4] should give fully as accurate results as those which we report in this paper, and this method is much more adaptable if temperatures much higher than 45° are to be used.

3. Latent Heat and Entropy of Spreading of Monolayers

For myristic acid the magnitude of the slope $\partial f/\partial T$ as taken from Fig. 1 was found to be 0.662, while pentadecylic acid exhibited a much smaller value (0.517), or the difference between the two is 27% of the latter magnitude. The corresponding slopes found by Cary and Rideal are 0.568 and 0.552, so their work fails to exhibit a difference between the slopes.

The values of the entropy and of the latent heat of spreading are given in Table I. Pressure–area measurements on myristic and pentadecylic acids at several temperatures have been reported in another paper.[5] The areas given in Column 2 of Table I have been taken from the data of that paper for pressures read from the curves of Fig. 1. The relation between the latent heat and the molecular area of the film in equilibrium with the solid, is exhibited in Fig. 2, and is seen to be nearly linear. The complete relationship involves a three dimensional plot, since the temperature is also involved. The entropy of spreading increases with the molecular area, that is, with

(4) W. D. Harkins and T. F. Anderson, THIS JOURNAL, **59**, 2189 (1937).

(5) G. C. Nutting and W. D. Harkins, *ibid.*, **61**, 1180 (1939).

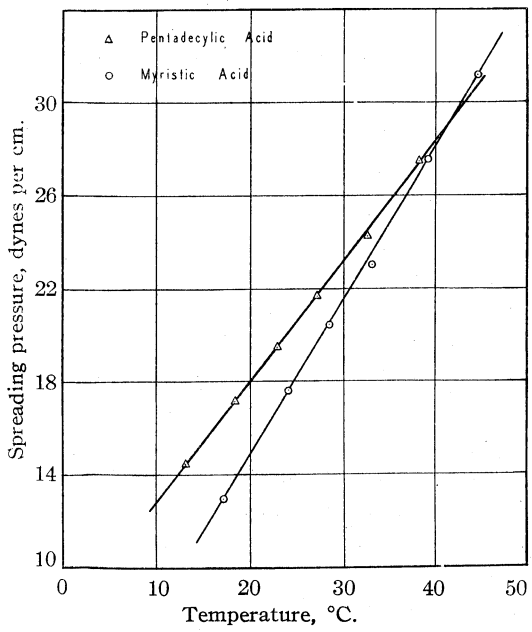

Fig. 1.—Equilibrium spreading pressures of crystals of myristic and pentadecylic acid on an aqueous subsolution at pH 2.

the two dimensional "dilution" of the film. This is similar to the relation found in the vaporization of a liquid, since the entropy of vaporization increases as the concentration of the equilibrium vapor decreases.

The latent heat of spreading involves a work term $\int f\,da$ and, if this is subtracted, the internal latent heat is obtained. This gives the increment in molecular energy (λ_i) involved. Thus

$$\Delta E = \Delta H - W = \lambda_i = \lambda - f(a_F - a_S) = \left(T\frac{\partial f}{\partial T} - f\right)(a_F - a_S) \quad (2)$$

The values for myristic acid given in Column 9 of the table show that λ_i in calories per mole changes from 5800 at an area of 22.3 to 7500 at an area of 28.9 sq. Å. per molecule.

The entropy of spreading is found to vary from 14.5 to 19 $\times 10^{-16}$ ergs per degree per molecule for myristic acid at areas from 22.3 to 28.9 sq. Å. per molecule. This would give, if a linear extrapolation is justified, about 26 $\times 10^{-16}$ ergs per molecule per degree at 40° . With pentadecylic acid the entropy is about 11 at an area of 21 in the above units. These values may be compared with those for the entropy of vaporization of a normal liquid which follows Hildebrand's relation. Thus, for example, the values are 15.7 ergs per degree per molecule if the concentration of the vapor is 0.0201

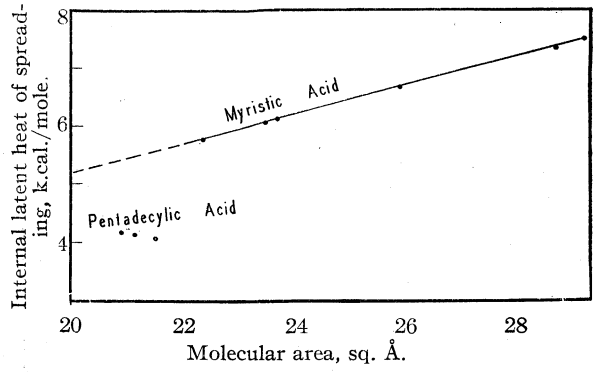

Fig. 2.—Internal latent heat of transformation from three-dimensional crystals to two-dimensional films on an aqueous subsolution at pH 2. The values for pentadecylic acid are in such a limited range of areas that the slope is uncertain, but it is certain that the values increase with molecular area as in the case of myristic acid.

mole per liter,[6] and 18.8 if the concentration is 0.00507. These have been chosen at concentrations of the vapor which are associated with entropy values of the same order as those for spreading as cited above. From the rate at which the heat of spreading increases with the temperature it seems that at the melting point the value must still be below the heat of fusion. This means that the spreading of the material from a liquid lens gives off heat instead of absorbing it.

4. Summary

1. By the use of the equation $\Delta h = \lambda_{S \rightarrow F} = T(\partial f/\partial T)_a\,(a_F - a_S)$, the latent heats of spreading of crystals of myristic and pentadecylic acid to form a monolayer on 0.01 N sulfuric acid have been determined. The measurements involved are the determination of the pressures of the film in equilibrium with the crystals at various temperatures, and that of the molecular area at each temperature and pressure.

2. The latent heats of spreading for myristic acid are found to increase with molecular area in an almost linear way, and rise from 6020 cal. per mole at 22.1 sq. Å. per molecule to 8060 cal. per mole at 28.7 sq. Å. The corresponding increase of entropy is from 14.5 to 18.9 $\times 10^{-16}$ ergs per degree per molecule.

3. The latent heat of spreading is of the order of a thousand calories per mole less for pentadecylic (15 C) than for myristic (14 C) acid.

A New Synthesis of Acetals of Chloroacetaldehyde and Bromoacetaldehyde

BY EDWARD M. FILACHIONE[1]

A variety of methods for the preparation of the acetals of chloroacetaldehyde and of bromoacetaldehyde has been reported. These may be summarized briefly as follows: (a) chlorination of ethyl alcohol[2,3]; (b) the reaction of the α,β-dihalogenated ethyl ether with sodium ethylate[4-7] or with ethyl alcohol[8]; (c) halogenation of the acetal[9] preferably in the presence of calcium carbonate[10-12] or sodium ethylate[13] and (d) the halogenation of paraldehyde followed by treatment with ethyl alcohol.[14-16]

Except for the process mentioned in the patent literature,[13] the yields, where reported, were not highly satisfactory. A synthetic method from a readily available starting material, easily carried out, and resulting in good yields was the purpose of the present work.

There is described in the patent literature[17] the addition of halogens to vinyl acetate yielding α,β-dihaloethyl acetate.

$$CH_2{=}CH{-}O{-}COCH_3 + X_2 \longrightarrow CH_2(X){-}CH(X){-}OCOCH_3$$

An inspection of this dihalide shows that it contains a very reactive halogen atom as well as an ester grouping that should undergo alcoholysis almost completely. Hence it is reasonable to expect the halogen and the acetoxy group to be replaced by alkoxyl groups merely by treatment with the alcohol.

Such was found to be the case. Vinyl acetate dibromide was prepared by the addition of bromine to vinyl acetate. This was then mixed with ethyl alcohol. On standing they reacted and bromoacetal was formed. Ethyl acetate and hydrogen bromide were also among the products. In actual practice it was found more efficient to pass the halogen into a solution of vinyl acetate in the alcohol. The addition of halogen to the double bond is so rapid that halogenation of the alcohol is not extensive.

In any mechanism written, undoubtedly the first step is addition of halogen to the double bond.

$$CH_2{=}CH{-}OAc + X_2 \longrightarrow CH_2(X){-}CH(X){-}OAc \qquad (1)$$

The acetal may result from this by several paths which may be indicated as follows

$$CH_2(X){-}CH(X){-}OAc + C_2H_5OH \overset{HX}{\rightleftharpoons} CH_2(X){-}CH(X){-}OH + C_2H_5OAc \qquad (2)$$

$$CH_2(X){-}CH(X){-}OH \rightleftharpoons CH_2(X){-}CHO + HX$$

$$CH_2(X){-}CHO + 2C_2H_5OH \overset{HX}{\rightleftharpoons} CH_2(X){-}CH(OC_2H_5)_2 + H_2O \qquad (3)$$

or the following may represent the course of reaction

$$CH_2(X){-}CH(X){-}OAc + C_2H_5OH \rightleftharpoons CH_2(X){-}CH(OC_2H_5){-}OAc + HX \qquad (2a)$$

$$CH_2(X){-}CH(OC_2H_5){-}OAc + 2C_2H_5OH \overset{HX}{\rightleftharpoons} CH_2(X){-}CH(OC_2H_5)_2 + C_2H_5OAc + H_2O \qquad (3a)$$

Reactions (2) and (3) are slow and do not occur at the low temperature of the halogen addition. By using methyl alcohol in place of ethyl alcohol, the methyl haloacetal is formed.

Experimental

Purification of Vinyl Acetate.—The practical grade vinyl acetate (purchased from Eastman Kodak Co.) was distilled and the fraction boiling at 69–71° was collected. Distillation gives an anhydrous ester since the water comes

over in the first portion. Care was taken not to distill to dryness in case peroxides were present.

Synthesis of the Acetals

Ethyl Chloroacetal.—A solution of 43 g. (0.5 mole) of vinyl acetate in 150 cc. (2.5 mole) of absolute ethyl alcohol was placed in a 3-necked flask and the flask immersed in a crock containing dry ice–acetone cooling mixture. The flask, where exposed to light, was wrapped with black cloth. Accompanied by vigorous stirring, a stream of dry chlorine, flowing at the rate of 0.4 g. per minute, was bubbled into the solution for ninety minutes, *i. e.*, till the theoretical amount had been added. The mixture was next allowed to warm to room temperature and then stand overnight. It was then poured into an equal volume of iced water, and the ethyl chloroacetal, which separated as an oil, was taken up with ether. The ether solution was washed twice with cold water, then with sodium bicarbonate solution until the ether layer showed no acid reaction to moist litmus, then washed once more with cold water, and finally dried with anhydrous calcium chloride. The ether was removed by distillation from a water-bath, and the residual ethyl chloroacetal was fractionated *in vacuo*. The yield was 62 g. (83% yield) of ethyl chloroacetal boiling at 53–54° (16 mm.); d^{20}_{20} 1.017; $n^{20}D$ 1.4171; M_D 37.7 (calculated 38.1); Cl, 23.38 (theoretical 23.23).

Further proof of the identity of this compound was obtained by hydrolysis. Ethyl alcohol was identified in the hydrolyzate through its 3,5-dinitrobenzoate, m. p. 92°. Chloroacetaldehyde was identified in the hydrolyzate by oxidation with hydrogen peroxide to chloroacetic acid, m. p. 60°.

An experiment identical to the above except that the chlorine was passed in at a higher temperature (−10 to −5°) resulted in a 70% yield of ethyl chloroacetal.

Methyl Chloroacetal.—This preparation was carried out exactly as above. From 86 g. (1 mole) of vinyl acetate in 200 cc. (5 moles) of methyl alcohol, there resulted 66 g. (53% yield) of methyl chloroacetal boiling at 124.5–126.5° (atmospheric pressure); d^{20}_{20} 1.094; $n^{20}_{20}D$ 1.4150; M_D 28.5 (calcd. 28.8).

Anal. Calcd. for $C_4H_9O_2Cl$: Cl, 28.48. Found: Cl, 28.47.

Hydrolysis of this acetal gave an hydrolyzate in which methyl alcohol was shown to be present by isolation of its 3,5-dinitrobenzoate, m. p. 106°. Hydrolysis followed by oxidation with hydrogen peroxide gave chloroacetic acid, m. p. 62°, showing the presence of chloroacetaldehyde.

Ethyl Bromoacetal.—Air was passed over the surface of 12.5 cc. (0.25 mole) of bromine, and the bromine laden stream of air was led into a solution of 21.5 g. (0.25 mole) of vinyl acetate in 75 cc. (1.3 moles) of absolute ethyl alcohol. During this addition (one and one-half hours) the solution was stirred. Cooling was effected by a freezing mixture (about −10°). The resulting solution was worked up exactly as above. The yield was 33 g., or 68% of the theoretical, of ethyl bromoacetal boiling at 62–63° (15 mm.); d^{20}_{20} 1.276; $n^{20}D$ 1.4395; M_D 40.7 (calcd. 41.0).

Another experiment similar to the above except that liquid bromine was added dropwise to the ethyl alcohol solution of vinyl acetate gave a 58% yield of ethyl bromoacetal. This substance is a good lachrymator.

This acetal was characterized as above. Hydrolysis gave ethyl alcohol, identified through its 3,5-dinitrobenzoate, and bromoacetaldehyde, identified by oxidation with hydrogen peroxide to bromoacetic acid, m. p. 45°.

Methyl Bromoacetal.—A solution of 64.5 g. (0.75 mole) of vinyl acetate in 150 cc. (3.7 moles) of methyl alcohol was cooled in a dry ice–acetone mixture. To this was added, with stirring, a solution of 120 g. (38.5 cc., 0.75 mole) of bromine in 100 cc. of chloroform. (It was necessary to use a solution of bromine since liquid bromine solidified in the stem of the dropping funnel.) The addition required two hours, during which time the reaction mixture remained below −40°. The resulting solution was worked up as the others. Thus there was obtained 59 g. (a yield of 46%) of methyl bromoacetal boiling at 48–51° (18 mm.); d^{20}_{20} 1.467; $n^{20}D$ 1.4475; M_D 30.8 (calcd. 31.7). This compound is also lachrymatory.

As in the above cases, this acetal was characterized by its products of hydrolysis. These were shown to be methyl alcohol and bromoacetaldehyde.

Summary

A new synthesis of acetals of chloroacetaldehyde and bromoacetaldehyde has been investigated. The addition of chlorine to vinyl acetate in the presence of ethyl alcohol or in the presence of methyl alcohol resulted in good yields of the acetals, ethyl chloroacetal and methyl chloroacetal, respectively. Similarly, addition of bromine to vinyl acetate in the presence of methyl or ethyl alcohol formed the corresponding bromoacetals. The yields of the ethyl haloacetals were considerably higher than the yields of the corresponding methyl haloacetals.

As for the mechanism, undoubtedly the halogen first adds to the vinyl acetate, resulting in the α,β-dihaloethyl acetate, which subsequently reacts with the alcohol present in the mixture, giving rise to the acetal of the α-haloacetaldehyde.

Saponins and Sapogenins. X. The Isolation of Gitogenin from Chlorogalum Pomeridianum

BY C. R. NOLLER, L. H. GOODSON AND MARTIN SYNERHOLM

In a recent paper Marker and Rohrmann[1] state that they "have isolated from the acid hydrolysis extracts of *Chlorogalum pomeridianum* in addition to chlorogenin and tigogenin a substance which appears to be identical with gitogenin." This interest of other workers in *Chlorogalum* as a source of steroid sapogenins prompts us to report the observations in regard to their isolation which we have made since our original publication.[2]

Hydrolysis of the alcoholic extracts of the ground bulbs or of the partially purified saponins followed by separation of the sapogenins by crystallization always has yielded an intermediate fraction melting between 230 and 255° which could be made to melt over the comparatively narrow range of 235–240°.[3] Oxidation of this material with Kiliani's mixture[7] gave an acid fraction which appeared to be identical with gitogenic acid. Three possibilities seemed likely: (1) that the material was a molecular compound of chlorogenin and tigogenin, the gitogenic acid being formed by oxidation of the latter; (2) that it was a new sapogenin which also gave gitogenic acid on oxidation; (3) that it contained gitogenin possibly as a molecular compound with chlorogenin or tigogenin. Melting point determinations of mixtures of pure tigogenin and chlorogenin eliminated the first possibility as shown in Fig. 1.[4] Moreover, an analysis checked almost exactly for the composition $C_{27}H_{44}O_4$. This could result from an equimolar mixture of tigogenin, $C_{27}H_{44}O_3$, and a trihydroxy compound, $C_{27}H_{44}O_5$, or from a mixture of the isomeric substances gitogenin and chlorogenin.

Further attempts to separate the mixture by crystallization of the sapogenins were without encouraging results. While the material crystallized well from benzene, carbon tetrachloride, ethylene chloride, and dioxane, there was no more evidence that a separation was taking place than when crystallized from methyl, ethyl or isopropyl alcohol. Separation was effected readily, however, after conversion to the benzoates or acetates. The mixed esters were extracted with ether in which one isomer is much more soluble than the other and this was followed by systematic crystallization of the two portions to constant melting point. The less soluble benzoate, its saponification product and the acetate had melting points almost identical with those of authentic samples of gitogenin dibenzoate, gitogenin and gitogenin diacetate.[5] Mixtures of the corresponding compounds gave slight but definitely observable depressions or elevations over that for the components even when present in the same bath, which, until a satisfactory explanation is found, is a disturbing fact. The specific rotations, however, of the two sapogenins and of their acetates were identical within experimental error and in spite of the melting behavior of the mixtures we feel certain that the two sapogenins are identical.

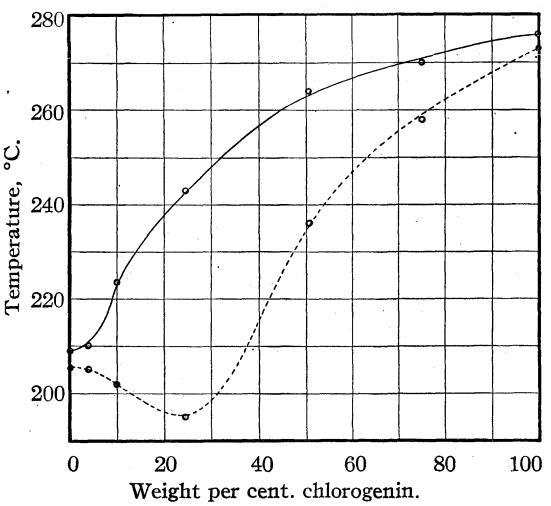

Fig. 1.—Melting point diagram for mixtures of tigogenin and chlorogenin.[4]

The more soluble benzoate, its saponification product and the acetate proved to have the same

(4) In all of the melting point diagrams, the dotted curve represents the temperature at which the mixture first wets the walls of the capillary tube while the solid line gives the temperature at which the melt is entirely clear. In Figs. 1 and 3 the melting point diagram indicates that the components form a continuous series of solid solutions with the melting point passing through a minimum. The fact that the temperature at which the melt is clear does not pass through a minimum as does the softening point is probably caused by the system not being in equilibrium.

(5) The authors are greatly indebted to Dr. W. A. Jacobs of the Rockefeller Institute for Medical Research for a generous sample of gitogenin from *Digitalis* leaves.

melting points, respectively, as chlorogenin dibenzoate, chlorogenin and chlorogenin diacetate and the specific rotations of the sapogenins were identical within experimental error. Here again the mixture of the benzoates and of the acetates melted slightly lower than either component, while the mixture of the sapogenins melted higher. The fact that these phenomena occur with the chlorogenin fraction of the mixture supports our belief that they do not indicate non-identity and that the other component is indeed gitogenin.

The melting point curve for mixtures of gitogenin and chlorogenin given in Fig. 2 shows that the two components do not form a continuous series of solid solutions, but form a eutectic. This

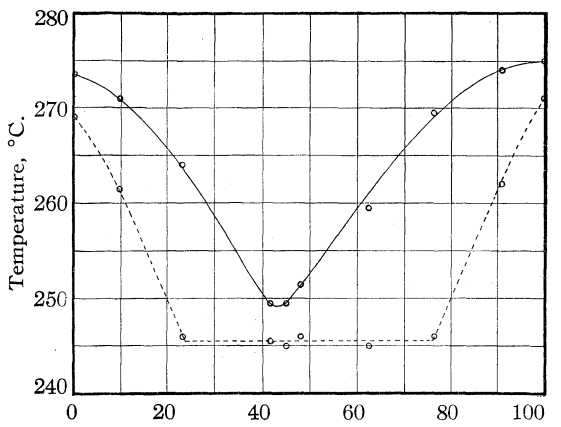

Fig. 2.—Melting point diagram for mixtures of gitogenin and chlorogenin.[4]

eutectic is the cause of the relatively sharp melting point of approximately equimolar quantities of gitogenin and chlorogenin. Apparently the solubility of the gitogenin and chlorogenin in the solvents used is practically identical and the solubility of the eutectic mixture is greater than that of either of the pure components with the result that with an excess of chlorogenin, crystallization leads to a separation of pure chlorogenin and the eutectic. One discrepancy in this explanation is the fact that the melting point of 235–240° commonly encountered in isolating the sapogenins is about 10° lower than that of the eutectic as determined by the mixed melting point curves. It is possible that the natural mixture contains some tigogenin which may lower the melting point of the eutectic.

Figure 3 gives the melting point diagram of mixtures of tigogenin and gitogenin which is very similar to Fig. 1 except that the lowering of the softening point of tigogenin by gitogenin is less than in the case of tigogenin and chlorogenin.

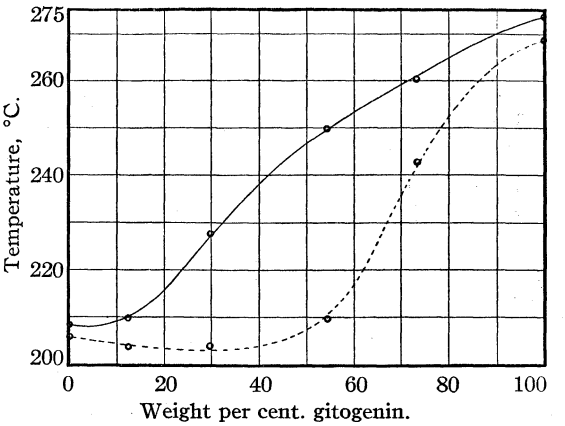

Fig. 3.—Melting point diagram for mixtures of tigogenin and gitogenin.[4]

The general procedure for the isolation of the sapogenins has been improved considerably over the method originally published[2] and our present procedure is recorded in the experimental part. The identity of tigogenin from *Chlorogalum* with that from *Digitalis* has been confirmed further by conversion into tigogenin acetate, tigogenone, tigogenone oxime, the C_{22} lactone acetate obtained by oxidation and the C_{22} hydroxy lactone, the melting points of which all checked with those recorded in the literature for derivatives of tigogenin isolated from *Digitalis purpurea* or *Digitalis lanata*.

Experimental

Isolation of the Mixed Sapogenins.—Several hundred pounds of bulbs of *Chlorogalum pomeridianum* from which the outer husks had been removed were put through a power food grinder at the San José plant of the California Prune and Apricot Growers Association. The resultant mash was mixed thoroughly with about an equal volume of methyl alcohol to act as a preservative and the saponin extracted as opportunity and facilities permitted. Addition of the methyl alcohol caused a thickening of the mash presumably due to a precipitation of plant gums by the alcohol. For isolating the saponins the mixture of ground bulb and methyl alcohol was pressed in a cider press. The expressed liquid yielded very little sapogenin on hydrolysis so that it was hardly profitable to work it up other than to recover the methyl alcohol. The press cake was extracted in 12-liter flasks with boiling methyl alcohol, the hot solution filtered and allowed to cool overnight. The saponins which separated were filtered and stored moist in tightly stoppered wide-mouthed bottles. The extraction with hot methyl alcohol was repeated until no saponin separated on standing overnight. Each of the mother liquors was concentrated and additional crops of saponin were obtained.

For hydrolysis a saturated solution of the saponins in hot methyl alcohol was prepared and an equal volume of 10% aqueous hydrochloric acid added. A flocculent precipitate formed which after twelve hours of refluxing became crystalline and was filtered. The advantage of using the saponins which have been isolated as above rather than the crude extracts is that about half the time is required for hydrolysis, and the hydrolysis product is light colored and almost pure sapogenins, very little residue being left after exhaustive extraction with hot carbon tetrachloride.

It was found that a partial separation of the sapogenins could be obtained in the next step, the extraction of the crude hydrolysis product with carbon tetrachloride. Extraction was carried out in Soxhlet extractors until a copious crop of crystals had formed in the boiling flask. These were filtered and the extraction continued and crops removed until no more sapogenin separated. The carbon tetrachloride was then concentrated and successive crops of crystals removed. The melting point of each crop was taken and the various crops combined into three groups: those melting below 230°, those melting between 230 and 245° and those melting above 245°.

Isolation of Tigogenin.—The combined fractions melting below 230° were extracted in a Soxhlet extractor with a petroleum hexane fraction (Viking Distributing Company, b. p. 60–70°), separating crops of crystals until the rate of extraction is relatively slow. The crops melting up to 220° could be purified readily by several crystallizations from isopropyl alcohol when they melted at 203–208°. Concentration of the hexane mother liquors gave material melting as low as 180–186°. This low melting point was found to be caused by the presence of a non-crystallizable oil. The melting point of these fractions readily could be brought to that of tigogenin by one crystallization from hexane, in which the oil is very soluble, followed by recrystallization from isopropyl alcohol.

A special effort was made to obtain a sample of tigogenin of maximum purity. A sample that had been purified by crystallization from isopropyl alcohol was converted to the acetate by means of acetic anhydride and pyridine. After two crystallizations from ethyl alcohol the acetate melted at 202–208° while Jacobs and Fleck[6] report 200–202°. Saponification of the acetate and two crystallizations from isopropyl alcohol brought the melting point of tigogenin to 206.5–209° which could not be raised nor the range narrowed by subsequent recrystallizations. This value compares favorably with the 206.5–210° previously reported.[2]

Oxidation of a less pure sample of tigogenin, m. p. 199–204°, gave tigogenone which after two crystallizations from acetone melted at 203–205°. This was converted to the oxime, which after three crystallizations from acetone melted at 256–258°.

Isolation of Chlorogenin.—The crude fractions melting above 245° readily gave pure chlorogenin by repeated crystallization from methyl alcohol. The purest sample of chlorogenin that we have obtained was prepared by crystallizing a product, m. p. 270–275°, once from methyl alcohol, twice from dioxane and twice from methyl alcohol, after which it melted at 273–276°. No change in the melting point was observed during the last three crystallizations.

(6) Jacobs and Fleck, *J. Biol. Chem.*, **88**, 546 (1930).

Separation of Gitogenin and Chlorogenin.—All attempts to separate the crude fraction melting between 230 and 245° into its components by crystallization or partial extraction with hot solvents failed. The solvents tried were benzene, dioxane, ethylene dichloride, carbon tetrachloride, methyl alcohol and 95% ethyl alcohol. While there were minor changes in the melting point, such as spreading or narrowing of the range, successive crops of the dissolved and undissolved portions would melt at so nearly the same temperatures that no practical separation could be made.

A fraction having the narrow melting range of 235–239° occasionally was obtained, usually when using carbon tetrachloride as a solvent. Five grams of this fraction on oxidation at room temperature by the procedure of Kiliani and Merk[7] gave 4 g. of crude oxidation product. This was extracted with cold benzene, giving 1.5 g. of insoluble material. The benzene extract after washing with 10% sodium carbonate solution and evaporation of the benzene gave 0.72 g. of neutral product. The sodium carbonate extracts on acidification gave 1.3 g. of acidic material. The benzene insoluble material was completely soluble in sodium carbonate solution. This behavior on oxidation is in marked contrast to that of chlorogenin[8] which yields very little acidic material. The benzene insoluble acid was crystallized eight times from glacial acetic acid, the melting point then remaining constant at 243–245°. Windaus and Schneckenburger[9] report the melting point of gitogenic acid as 242–243° and Jacobs and Simpson[10] as 244° with preliminary sintering.

The remainder of the sapogenin sample, m. p. 235–239°, was recrystallized for analysis.

Anal. Calcd. for $C_{27}H_{44}O_4$: C, 74.96; H, 10.25. Found: C, 74.77; H, 10.24.

The separation of the mixture was first effected through the benzoates. A mixture of 9 g. of material, m. p. 230–240°, 17 g. of benzoyl chloride, 9.5 g. of pyridine and 500 cc. of benzene was refluxed for fifteen minutes, allowed to stand at room temperature for three hours and the benzene distilled from a steam-bath until a sirup remained. The residue was rubbed up with 6 *N* hydrochloric acid and then three times with 25-cc. portions of 80% ethyl alcohol, decanting from the residue. The product is still pasty at this point but, on the addition of 25 cc. of ether, a portion goes into solution leaving a solid which can be filtered. The undissolved portion weighed 4 g. and melted at 211–227°. It was only slightly soluble in hot methyl alcohol, 95% ethyl alcohol or hexane, very soluble in dioxane and could be crystallized from isopropyl alcohol, ethyl acetate or acetone. After two crystallizations from each of the last three solvents, the product melted at 223–228°.

Anal. Calcd. for $C_{41}H_{52}O_6$: C, 76.84; H, 8.18. Found: C, 76.89; H, 8.22.

A mixture with an equal amount of gitogenin benzoate, m. p. 223–227°, melted at 222–227°. All three samples were placed at the same time in a Hershberg[11] apparatus so that the lowering though slight was definitely observable. The specific rotation for the dibenzoate isolated from the

(11) Hershberg, *Ind. Eng. Chem., Anal. Ed.*, **8**, 312 (1936)

mixture was $[\alpha]^{25}D$ −75.9° in pyridine. The sample of gitogenin benzoate available was not sufficiently large for a determination of its rotation.

The dibenzoate was saponified by refluxing 1.8 g. with 0.8 g. of potassium hydroxide in 60 cc. of ethyl alcohol for three hours. The sapogenin was precipitated by the addition of water and crystallized twice from 95% ethyl alcohol and three times from 90% ethyl alcohol, when it melted at 269–274°. A recrystallized sample of gitogenin melted at 270–274.5° and a mixture of equal amounts of the two preparations melted at 271–275°. Here again all three tubes were in the same melting point bath. The specific rotation for the sample from *Chlorogalum* was $[\alpha]^{25}D$ −61.3° in pyridine, while that for gitogenin was $[\alpha]^{25}D$ −60.9°.

The sapogenin was converted to the diacetate by heating 0.2 g. with 1 cc. of acetic anhydride and 1 cc. of pyridine on the steam-bath for two hours and allowing to stand overnight. After precipitation with water the product was crystallized from methyl alcohol when it melted at 239–244°. This sample was not used for determination of the specific rotation or a mixed melting point with gitogenin diacetate, the sample obtained below from the acetylation of the mixed sapogenins being used for this purpose.

The filtrate from the above ether extraction of the crude benzoate gave on evaporation an oil which partially solidified on cooling. On rubbing up with 25 cc. of 80% ethyl alcohol, the mass solidified sufficiently to be pulverized and filtered. The product, which weighed 8 g. and melted at 130–165°, probably contained considerable benzoic acid. Two crystallizations from isopropyl alcohol and one from ethyl acetate raised the melting point to 180–197° and two more crystallizations from acetone brought it to 196–203.5°.

Anal. Calcd. for $C_{41}H_{52}O_6$: C, 76.84; H, 8.18. Found: C, 76.72; H. 8.27.

When mixed with an equal amount of chlorogenin dibenzoate, m. p. 203.5–207.5°, the melting point was 195.5–205.5°, a slight but noticeable depression.

Saponification gave the sapogenin which after two crystallizations from methyl alcohol melted at 268–274°. A mixture with an equal part of chlorogenin, m. p. 268–275°, melted at 269–276°, a slight but definite elevation. The specific rotation of the sapogenin was $[\alpha]^{25}D$ −47.7° in dioxane while that for pure chlorogenin was $[\alpha]^{25}D$ −46.3°.

Conversion to the acetate by acetic anhydride and pyridine and crystallization from methyl alcohol gave a product, m. p. 154–156°. A mixture with an equal part of chlorogenin diacetate, m. p. 153.5–156.5°, melted at 152.5–155°.

The extreme solubility of chlorogenin diacetate and the slight solubility of gitogenin diacetate in hot methyl alcohol suggested that the mixture could be separated more conveniently through the acetates. A mixture of 10 g. of the mixed sapogenins, m. p. 230–245°, with 50 cc. of acetic anhydride and 80 cc. of pyridine was heated on a hot-plate until completely homogeneous and then allowed to stand overnight. Decomposition with an excess of water and filtering gave 11.5 g. of air-dried product. This was rubbed up with 50 cc. of ether and filtered. The air-dried insoluble portion weighed 5 g. and melted at 225–235°. It was recrystallized five times from methanol when it melted at 239–243°. No change in melting point took place during the last two crystallizations. A mixture with a sample of gitogenin, m. p. 239–243°, melted at the same temperature as far as measurement with the thermometer indicated, although the mixture appeared to shrink just before the individual samples and was definitely clear before them. The specific rotation of the acetate separated from the mixture was $[\alpha]^{25}D$ −80.2° in pyridine compared with −80.7° for an authentic sample of gitogenin diacetate.

The ether extract contained the chlorogenin diacetate contaminated by a small amount of gitogenin diacetate which was difficult to remove by crystallization because of its insolubility. This is true also when separating through the benzoates and the best procedure is to saponify the partially purified esters and continue the purification by crystallization of the chlorogenin.

Determination of Melting Point Diagrams for Mixtures.—The fact that some decomposition takes place at the melting point and that only limited amounts of material were available made it necessary to mix the components mechanically and to take the melting points in capillary tubes. Only slightly more material was weighed out than was necessary to fill the capillary tube in order to ensure adequate mixing. The data used in Fig. 1 were obtained on samples carefully mixed mechanically with a small spatula. It was later found more convenient to dissolve the sample in a few drops of dioxane, allow the solvent to evaporate and to grind the residue with a spatula, this method being used for the data of Fig. 2 and Fig. 3. Melting points in this and the previously recorded work were taken in a Hershberg melting point apparatus[11] with completely immersed calibrated Anschütz thermometers having 0.2° scale divisions. The points of the lower curves are the temperatures at which the sample first wet the sides of the capillary tubes while those of the upper curves represent the temperatures at which the melts were completely clear. The rate of rise of temperature was less than 1° per minute in the neighborhood of the melting point. In spite of the precautions taken it is obvious that this procedure could not be expected to give more than roughly quantitative results.

Summary

1. An improved procedure is given for the isolation of steroid sapogenins from *Chlorogalum pomeridianum*.

2. Besides the previously reported tigogenin and chlorogenin a third sapogenin has been isolated which has been shown beyond reasonable doubt to be identical with gitogenin from *Digitalis* in spite of an unexplainable behavior of mixed melting point determinations.

3. Melting point diagrams for mixtures of tigogenin and chlorogenin and for tigogenin and gitogenin indicate that these pairs form a continuous series of solid solutions, while mixtures of gitogenin and chlorogenin form a eutectic at approximately 42% gitogenin.

The Peroxide Effect in the Addition of Reagents to Unsaturated Compounds. XX. The Addition of Hydrogen Bromide to 2-Butyne and 2-Bromo-2-butene

BY CHEVES WALLING,[1] M. S. KHARASCH AND F. R. MAYO

Since the report in 1933 of the reversal by certain catalysts, notably oxygen and organic peroxides, of the direction of addition of hydrogen bromide to olefins,[2] investigation in this Laboratory and elsewhere has disclosed some thirty olefins which undergo such a reversal of the direction of addition.[3] In all of these, addition occurs to a terminal double bond, while with a number of other olefins with non-terminal double bonds, no such reversal has been observed. Accordingly, it has become of increasing interest to know whether the presence of a terminal double bond is essential for this phenomenon.

The addition of the second of two molecules of hydrogen bromide to 2-butyne[4] appeared as a likely subject for investigation for two reasons. In the first place, the unsymmetrical distribution of substituents about the double bond in 2-bromo-2-butene would be expected to yield only one product of normal addition. Secondly, it has been observed in this Laboratory that halogen atoms attached to a molecule favor abnormal addition by retarding the normal reaction.

Addition of hydrogen bromide was carried out under the conditions specified in Table I, 5.4 g. of butyne being used in every instance. In the experiments marked "vacuum" the usual technique developed in this Laboratory was employed,[2] with evacuation to a pressure of 10^{-4} to 10^{-5} mm. After addition, the reaction mixture was first distilled at 5–10 mm. directly from the tubes in which the reaction took place into a trap at −80°, and the yield was determined at this point. In the case of additions in pentane the solvent was evaporated before distillation, while in experiments carried out in acetic acid the products were washed with water. All products were then distilled at 30 mm. in a Podbielniak column, and the index of the main fraction was taken. The first few drops of distillate and material which did not distill were rejected, but loss by this method rarely exceeded 2 g.

(2) Kharasch and Mayo, THIS JOURNAL, **55**, 2468 (1933).

(3) See Kharasch, Engelmann and Mayo, *J. Org. Chem.*, **2**, 288 (1937), for references to the subject.

(4) As the product of the addition of one molecule of hydrogen bromide to 2-butyne is necessarily 2-bromo-2-butene under all conditions, no necessity of isolating this intermediate arises. There is no reason to expect that the *cis* and *trans* isomers would give rise to different products (see ref. 7).

Experimental Part

2-Butyne was prepared from sodium acetylide, sodamide, and dimethyl sulfate in liquid ammonia by the method of Bried and Hennion[5] except that the reaction was carried out in a flask cooled in a bath of solid carbon dioxide and acetone. In this way the temperature of the reaction mixture was held at −70 to −60° during the addition of the dimethyl sulfate. The products were distilled through water to remove ammonia, and collected in a vessel cooled in ice water. Loss of product from the receiver was prevented by a trap maintained at −80°. With the use of a 2-liter flask containing about 1 liter of ammonia, 2 moles of sodium acetylide and other reagents in proportion could be handled with ease. The product was fractionated through a Podbielniak column. The yield from four moles of sodium acetylide was 88 g. (41%) of 2-butyne; b. p. 27.0–4° (754 mm.); m. p. −28° to −27°; $n^{20}D$ 1.3920.

Identification of Products.—Analysis was by index of refraction, checked by the boiling range of the products. The wide difference in index and boiling point of the two products makes the analyses certain to at least 5%. The most probable index of 2,2-dibromobutane was determined as $n^{20}D$ 1.5015 by measurements, after another fractionation, on the combined products of the experiments showing normal addition. The material was definitely identified by conversion to the 2,4-dinitrophenylhydrazone of methyl ethyl ketone (m. p. 111–112°; melting point of mixture with known sample 111–112°). The racemic 2,3-dibromobutane was identified by boiling point and index of refraction.

As the meso and racemic forms of 2,3-dibromobutane have different indices of refraction ($n^{20}D$ 1.5116 and 1.5147, respectively),[6] the question naturally arises as to whether variations in the index of the abnormal products are due to variations in the ratios of the isomeric 2,3-dibromobutanes or to the presence of small quantities of 2,2-dibromobutane. To answer this question, the products of all experiments giving the abnormal product were combined and carefully fractionated through a Podbielniak column.[7] While the first portion had an index of 1.5108, indicating it to be largely 2,2-dibromobutane, the remaining 80% had an index of 1.5145–7. Thus, the abnormal product appears to be entirely the racemic isomer, and the percentages of normal and abnormal product are calculated on this basis.

Discussion of Results

The results of our experiments are summarized in Table I. It will be noted that under most con-

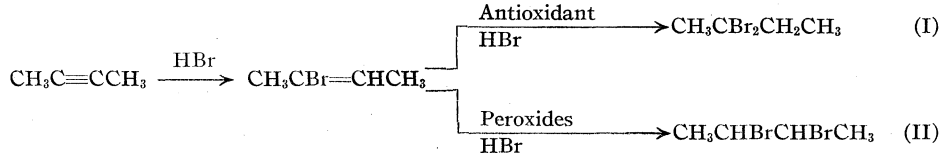
[a] In moles per mole of 2-butyne. [b] Considerable 2-bromo-2-butene in product. [c] Sample of 2-butyne employed gave very strong test for peroxide. [d] Not including 10–20% of dark, non-volatile material obtained. [e] Indices used in analysis: 2,2-dibromobutane, $n^{20}D$ 1.5015; racemic 2,3-dibromobutane $n^{20}D$ 1.5147.

ditions described in Table I the product is exclusively normal, namely, 2,2-dibromobutane,[8] and that even the addition of 3 mole per cent. of ascaridole fails to reverse the addition completely. However, when the normal addition is retarded by dilution with pentane, the product is almost exclusively abnormal. In acetic acid solution, addition is normal (expt. X) except when the 2-butyne has a high peroxide content (expts. II and VII).



The discovery of a case of abnormal addition to a non-terminal double bond considerably increases the number of compounds which may be expected to undergo this reaction. In fact, it now seems likely that, with certain exceptions, abnormal addition to any ethylenic bond may be observed. The exceptions appear to be as follows. (1) Compounds in which symmetrical substitution by groups of the same order of electronegativity results in a double bond of low polarity. Compounds such as 2-pentene[9] and 9-undecenoic acid[10] give an equimolecular mixture of two addition products in the presence or absence of peroxides, and it cannot be determined whether or not reversal takes place. A border-line case is that of 2-bromopropene, which gives a 2:1 mixture on normal addition and a single product in the presence of oxygen or peroxides.[3] (2) Compounds in which double bonds are conjugated with carboxyl and similar groups. (3) Compounds for which abnormal addition is masked by a very rapid normal reaction. All known cases of failure to obtain a reversal of the direction of addition of hydrogen bromide in the presence of peroxides seem to fall into one of these three classes.

The effect of a rapid normal addition in the abnormal reaction is clearly demonstrated in the case of 2-butyne. Here, the normal reaction is comparatively rapid (almost complete in two hours at 0°), with the result that only upon dilution does the abnormal reaction become important. The abnormal reaction, being presumably a chain reaction,[3] is not retarded greatly by dilution with an inert solvent.

The principle of preferential retardation of the normal reaction by dilution appears to be a valuable tool, and it is now being employed in this Laboratory in attempts to detect abnormal addition in the addition of hydrogen bromide to several olefins which show a rapid normal reaction.

Summary

1. 2-Butyne adds hydrogen bromide in the

(8) This is the product reported by Wislicenus and Hölz, *Ann.*, **250**, 232 (1889).

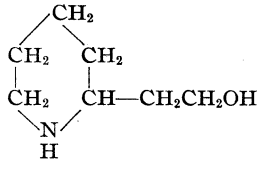
Local Anesthetics from β-(2-Piperidyl)-ethanol

BY L. A. WALTER AND RUSSEL J. FOSBINDER

The recent publication of Tullock and MacElvain[1] on anesthetics derived from α-picoline prompts submission of the following paper.

A series of substituted benzoic esters of β-



(2-piperidyl)-ethanol was prepared by refluxing one equivalent of the hydrochloride of the amino alcohol with one equivalent of acid chloride in dry chloroform. The amino ester hydrochlorides were purified by crystallization from absolute alcohol or from absolute alcohol–ether mixture. The N-phenylurethan and the cinnamate were prepared similarly from phenyl isocyanate and cinnamoyl chloride, respectively. The hydrochlorides of the nitro esters were reduced to the amino compounds with platinum and hydrogen in glacial acetic acid.

Pure β-(2-pyridyl)-ethanol is best prepared by heating α-picoline with twice its weight of 40% formaldehyde in a sealed tube at 120° for sixteen to twenty hours. The mixture is then fractionally distilled at a pressure sufficiently reduced so that the temperature of the mixture never rises above 130°. The yields are only 15 to 20% but the product is not contaminated with the β-(2-pyridyl)-allyl alcohol which is formed by dehydration of β-(2-pyridyl)-propylene glycol at higher temperatures. Some of the latter compound is formed from two moles of formaldehyde and one of picoline even at 120°.

The pyridyl alcohol was reduced to the piperidyl alcohol with sodium and absolute alcohol.[2]

The properties of the compounds are recorded in the following table. They are all nicely crystalline and non-hygroscopic without exception.

TABLE I

	β-(2-Piperidyl)-ethanol ester hydrochloride	Formula	M. p., °C., corr.	Analyses, %Cl Calcd.	Found
I	Benzoate	$C_{14}H_{20}O_2NCl$	189–191[a]	13.14	13.08

(2) Marvel and Shelton, *ibid.*, **51**, 915 (1929).

Their action as topical anesthetics is shown in Table II.

However, such data alone does not necessarily give a true idea of relative anesthetic usefulness. The compounds have been subject to extensive pharmacologic investigation the results of which will be published elsewhere.

Several members of a similar series of esters have been prepared from β-(2-piperidyl)-propanol, γ-(2-piperidyl)-propanol, and (2-piperidyl)-isopropanol. The last two alcohols are prepared readily from the corresponding pyridine compounds, which, in turn, are easily prepared in 40% yields by treating lithium picolyl with ethylene oxide, and with acetaldehyde, respectively. This will be the subject of a future communication.

Summary

A series of substituted benzoic esters of β-(2-piperidyl)-ethanol hydrochloride has been prepared and their local anesthetic properties determined.

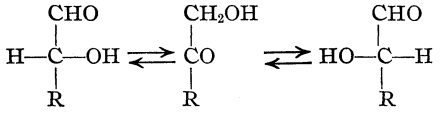
The Rearrangement of α-Hydroxy Carbonyl Compounds

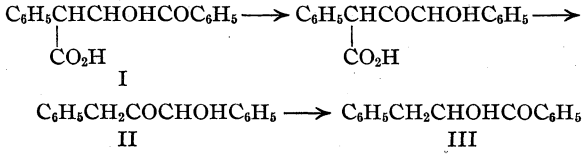
BY PHILIP G. STEVENS

The first case of the rearrangement of α-hydroxy carbonyl compounds was that studied by Lobry de Bruyn,[1] wherein glucose, fructose, and mannose were shown to be in equilibrium with one another in alkaline solutions. The essential change is a shift of the carbonyl and hydroxyl groups, presumably through a dienol intermediate

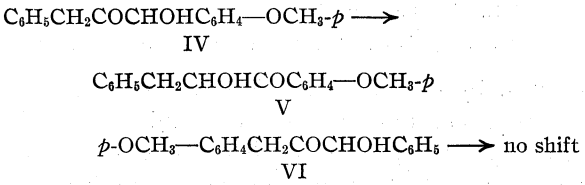


Wohl[2] found that in all probability the same equilibrium existed between certain trioses, namely, glyceric aldehyde and dihydroxyacetone, because in alkaline solutions both compounds yielded the same β-acrose. This view was supported later by Fischer's discovery[3] that glyceric aldehyde could be converted into dihydroxyacetone by mere boiling with pyridine. Still later a similar shift of the carbonyl and hydroxyl groups has been reported by Shoppee[4] with highly substituted cyclic α-hydroxy ketones.

More recently Kohler and Kimball[5] observed the same shift in alkaline media with derivatives of diphenylpropane. Thus α-phenyl-β-hydroxy-β-benzoylpropionic acid I with alkalies lost carbon dioxide spontaneously, forming α-hydroxy-dibenzyl ketone II; and this in turn could be converted to its isomer α-hydroxy-benzylacetophenone III. The conversion of II into III convinced them that the mechanism of the formation of II from I involved a similar shift



Later Kohler and Leers[6] found the same shift in the *p*-methoxy substituted series. The position of the substitute was, however, of importance, for while both mono-*p*-methoxy-substituted acids formed hydroxy ketones corresponding to II, only one of these would undergo further shift to that corresponding to III



Although neither III, V, nor VI was altered by further treatment with alkalies, Kohler and Kimball believed that an equilibrium existed between the two isomers, but offered no evidence as proof, for in no case was the shift —CH_2—CHOH—CO— → CH_2—CO—CHOH— observed.

This paper deals with the observation of such a reverse shift with the *p*-chloro analog of IV

$C_6H_5CH_2CHOHCOC_6H_4Cl\text{-}p$ ⟶
VII
$C_6H_5CH_2COCHOHC_6H_4Cl\text{-}p$
VIII

Henze[7] likewise observed a reverse shift in a similar system in the presence of sodium ethylate, but did not report the existence of an equilibrium between the two substances

$CH_3COCH_2CHOHCOC_6H_5$ ⟶ $CH_3COCH_2COCHOHC_6H_5$

If these intramolecular shifts are to be classed with that of Lobry de Bruyn, it is essential to establish the existence of an equilibrium in alkaline media between the two isomeric hydroxy ketones. This it has been possible to do in the case of VII and VIII, for each has been transformed into the other by means of weak alkali. The reaction should then be written VII ⇄ VIII.

It is quite likely then that all α-hydroxy carbonyl compounds are in equilibrium with their dismutation isomers, and that the failure to observe this equilibrium may be due merely to the position of the equilibrium being almost entirely on one side or the other—or due to the unfavorable physical or chemical properties of one of the isomers, making its isolation difficult.

The establishment of this equilibrium lends support to the new mechanism recently advanced by Hibbert[8] for the formation of lignin from guaiacol and pyruvic aldehyde. This system is closely related to that reported in this paper, and hence it is quite probable that an equilibrium actually exists

$CH_3COCHO + C_6H_4(OH)(OCH_3)$ ⟶
$CH_3COCHOHC_6H_3(OH\text{-}p)(OCH_3\text{-}m)$ ⇄
$CH_3CHOHCOC_6H_3(OH\text{-}p)(OCH_3\text{-}m)$ ⟶ lignin

The mechanism of the interconversion of these hydroxy carbonyl compounds very probably involves a dienol intermediate. This is consistent with the existence of an equilibrium, since alkaline media favor enolization. Acid media being proton donors likewise favor enolization, and should also cause an equilibrium to be established. Favorsky[9] has shown already that similar interconversions occur under the influence of acids, and hence it is probable that here, too, an equilibrium exists between the two isomeric substances.

In the work here, it unfortunately was impossible to determine the position of the equilibrium between VII and VIII, because of the unstable character of both isomers, as well as the unfavorable physical properties of one of them, VII.

The sensitive character of VIII for example was shown by its behavior with strong alkalies, whereby large amounts of oxidation and reduction products appeared. These would be expected if a dienol intermediate were formed, since dienols are peculiarly active hydrogen donors.[10] The following scheme, in part suggested earlier by Kohler and Kimball, indicates a possible course of the reaction with strong alkalies

$C_6H_5CH_2COCHOHC_6H_4Cl\text{-}p$ (VIII) ⇄ $(C_6H_5CH_2C(OH)=C(OH)C_6H_4Cl\text{-}p)$ ⇄ $C_6H_5CH_2CHOHCOC_6H_4Cl\text{-}p$ (VII)

Oxidation and reduction

$(C_6H_5CH_2COCOC_6H_4Cl\text{-}p) + (C_6H_5CH_2CH_2COC_6H_4Cl\text{-}p)$ not isolated

Cleavage: $p\text{-}ClC_6H_4CO_2H$

Benzilic acid rearrangement: $C_6H_5CH_2C(OH)(C_6H_4Cl\text{-}p)(CO_2H)$

This work was done under the direction of Professor Kohler, in partial fulfilment for the degree of Doctor of Philosophy, Harvard University, 1929. Some time before his death, Professor Kohler kindly gave the author permission to publish the work independently.

Experimental Part

α-Hydroxy-*p*-chlorobenzyl Benzyl Ketone, VIII.—This α-hydroxy ketone was prepared both from α-phenyl-

β-hydroxy-*p*-chlorobenzoylpropionic acid, previously reported by Kohler and Shohan,[11] and by synthesis from *p*-chlorobenzaldehyde cyanhydrin and benzylmagnesium chloride. The ketone crystallized from 95% alcohol as needles, melting at 125.5–126°.

Anal. Calcd. for $C_{15}H_{13}O_2Cl$: C, 69.1; H, 5.0. Found: C, 69.0; H, 5.0.

Action of Alkalies on the α-Hydroxy Ketone, VIII.—In contrast to the α-hydroxy ketones II and IV, this ketone yielded with strong alkalies non-crystallizing oils, from which only secondary products could be isolated, namely, *p*-chlorobenzoic acid, and α-hydroxy-α-*p*-chlorophenyl-β-phenylpropionic acid. These acids result from cleavage and benzilic acid rearrangement respectively, of the intermediate α-diketone, formed presumably from the dienol intermediate by intermolecular oxidation and reduction. The latter acid crystallized from ether and ligroin, and melted at 201–202° with decomposition.

Anal. Calcd. for $C_{15}H_{13}O_3Cl$: C, 65.1; H, 4.7. Found: C, 64.9; H, 4.9.

It was further identified by synthesis from α-phenyl-α'-*p*-chlorobenzoylethylene oxide by means of alkalies according to the method of Bodforss[12] and Jörlander,[13,14] and also by oxidation with sodium dichromate in acetic acid to *p*-chlorodesoxybenzoin. This ketone crystallized from ligroin as plates melting at 104.5–105.2°.

Anal. Calcd. for $C_{14}H_{11}OCl$: C, 72.9; H, 4.8. Found: C, 73.2; H, 4.7.

This difference in reaction between these α-hydroxy ketones is probably due to the much greater solubility of the isomeric ketone VII. It was only by using weak alkalies that it was possible to isolate VII, and then only with difficulty and in very poor yields. Five grams of VIII was dissolved in 75 cc. of hot 95% alcohol; 50 cc. of water was added, and an excess of solid sodium carbonate. The solution turned orange at once. After thirty minutes of boiling, the solution was made faintly acid, and then evaporated to one-half its volume. On cooling 2.7 g. of VIII precipitated unchanged. The filtrate was evaporated further until it become cloudy, and was then allowed to stand overnight. The oil which had precipitated was now extracted with chloroform and ligroin mixture. More water was then added, precipitating more oil (about 0.2 g.). This finally crystallized on standing for four days at 0°, and melted at 39–42°. A mixed melting point with the isomeric ketone VII, m. p. 43–44°, was 41–44°.

Benzyl-*p*-chloroacetophenone.—This saturated ketone, prepared easily by reduction of benzal-*p*-chloroacetophenone with Adams platinum oxide catalyst in methyl alcohol solution, crystallized from ligroin as plates, melting at 75–76°.

Anal. Calcd. for $C_{15}H_{13}OCl$: C, 73.2; H, 5.3. Found: C, 72.5; H, 5.0.

Benzyl-α-bromo-*p*-chloroacetophenone.—The ketone brominated easily in chloroform solution, yielding a crystalline α-bromo ketone, melting at 92–93°.

Anal. Calcd. for $C_{15}H_{12}OClBr$: C, 55.6; H, 3.7. Found: C, 55.6; H, 3.9.

Benzyl-α-hydroxy-*p*-chloroacetophenone, VII.—Seventeen grams of the bromo ketone was dissolved in 500 cc. of hot 95% alcohol, and water was added until the boiling solution just remained clear. Then 4.2 g. of sodium bicarbonate was added, and the mixture boiled for 40 minutes. The solution became yellowish. On cooling, 3.3 g. of the bromide precipitated unchanged, and was filtered out. The filtrate was poured into water, extracted with ether, and dried. Addition of ligroin deposited an oil which slowly crystallized at −10–15°. Thus 3.7 g. of the hydroxy ketone was obtained, which after several recrystallizations from chloroform and ligroin melted at 43–44°. The ketone was very soluble in all solvents save ligroin and water, and is far more soluble than its isomer VIII.

Anal. Calcd. for $C_{15}H_{13}O_2Cl$: C, 69.1; H, 5.0. Found: C, 69.0; H, 5.3.

Action of Alkalies on the α-Hydroxy Ketone, VII.—One-fifth gram of VII was dissolved in 10 cc. of 95% alcohol. An excess of sodium carbonate was now added, and the mixture boiled for one hour. The solution was then neutralized, and the volume reduced to 5 cc. On cooling, the isomeric α-hydroxy ketone VIII crystallized out pure, melting at 125–126°, and identified by comparison with an authentic sample.

Summary

1. Two isomeric α-hydroxy ketones, derived from *sym*-diphenylpropane, have been shown to be in equilibrium in alkaline solution.

2. The presence of this equilibrium lends support to Hibbert's theory of lignin formation.

The Isomerization of Cyclohexane and Methylcyclopentane[1]

BY A. L. GLASEBROOK AND W. G. LOVELL

Recently Montgomery, McAteer, and Franke[2] reported a reversible isomerization of the butanes occurring in the presence of aluminum bromide. Since the isomerization was unaccompanied by side reactions, it offered a method for experimentally determining the equilibrium constant.

In view of Montgomery's success, we decided to study the reversible isomerization of cyclohexane and methylcyclopentane reported by Nenitzescu and Cantuniari.[3] These investigators found cyclohexane or methylcyclopentane to rearrange in the presence of moisture-containing aluminum chloride to give an equilibrium mixture containing approximately 22% methyl cyclopentane. In addition, a small amount of saturated hydrocarbon, suspected to be *n*-hexane, was produced. Other investigators have not found the reaction products of aluminum chloride and cyclohexane to be as simple as reported by Nenitzescu. In addition to methylcyclopentane, Zelinsky[4] also reports dimethylcyclobutane as one of the reaction products. Ipatieff and Komarewsky[5] also found methylcyclopentane among the reaction products of cyclohexane and aluminum chloride, but 34% of the reaction products boiled higher than cyclohexane and consisted of 34% dimethylcyclohexane and 66% of a mixture containing dicyclohexyl and dimethyldicyclopentyl. These experiments, however, were carried out in closed autoclaves at 150°, and represent quite severe conditions.

In general, our results at lower temperatures confirm the findings of Nenitzescu. The anhydrous aluminum chloride was inert toward the hydrocarbons and the addition of water or hydrogen chloride was required to effect reaction. The reactions were remarkably clean, and the gas and tar which usually characterize the action of aluminum chloride on hydrocarbons were completely absent, even in experiments lasting as long as seven weeks. Also, the aluminum chloride remained clean and powdery and only a slight discoloration occurred. However, when aluminum bromide was substituted for aluminum chloride, a tarry lower layer was formed and isobutane was evolved.

Distillation of relatively large amounts of the reaction products in an 80-plate column showed them to consist almost exclusively of a mixture of cyclohexane and methylcyclopentane; refractive index measurements of the initial distillate and distillation residue indicated only traces of other products to be present. Fractionation of 15 liters of cyclohexane–aluminum chloride reaction product indicated that not more than about 5% of the cyclohexane reacting is consumed in side reactions which accompany the isomerization. Branched chain hexanes, methylcyclohexane, 1,3-dimethylcyclohexane, dicyclohexyl, and dimethyldicyclopentyl are the probable products of the side reactions.

Since isomerization appeared to be practically the sole reaction, experimental determination of the equilibrium constant and the effect of temperature on it were next studied. Experiments were carried over the temperature range 25 to 77.4° (boiling temperature) at 10° intervals, in which the equilibrium was approached from both sides. The course of the reaction was followed by the change in the refractive index. The data obtained are shown in Table I and Fig. 1.

TABLE I

EQUILIBRIUM CONCENTRATIONS OF METHYLCYCLOPENTANE

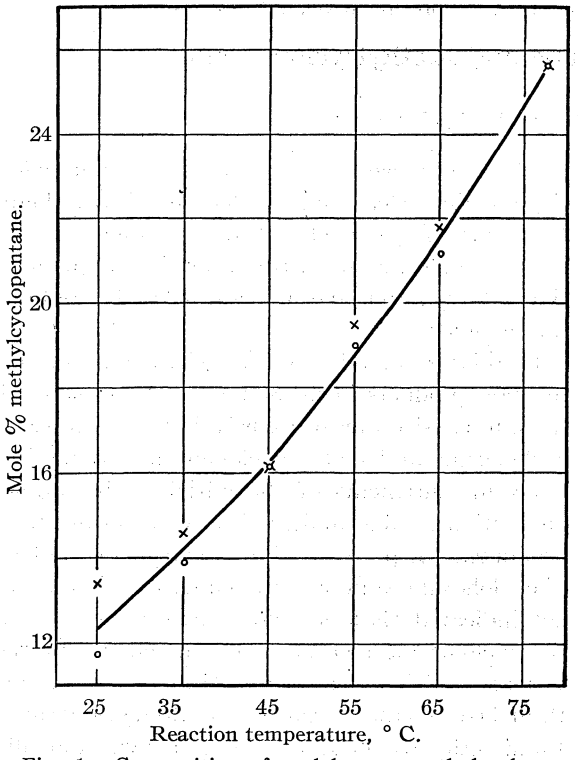

Fig. 1.—Composition of cyclohexane–methylcyclopentane equilibrium mixtures. X, Equilibrium approached from methylcyclopentane side; O, Equilibrium approached from cyclohexane side.

liquid phase reaction: cyclohexane → methylcyclopentane. These results are shown in Table II.

TABLE II

EQUILIBRIUM BETWEEN CYCLOHEXANE AND METHYLCYCLOPENTANE

Reaction temp., °C.	K	$\Delta F°$
25	0.143	1150
35	.170	1085
45	.193	1040
55	.238	936
65	.272	875
77.4	.344	743

The values of $\Delta F°$ and K were used to calculate the heat of reaction and the entropy change. The heat of reaction was calculated by the use of the van't Hoff equation, $d(-R \ln K)/d(1/T) = \Delta H$, and the entropy change calculated from the equation $\Delta F = \Delta H - T\Delta S$. The thermodynamic constants obtained from the equilibrium measurements are summarized in Table III and compared with the results of Parks.[6]

(6) Parks and Huffman, "The Free Energies of Some Organic Compounds," A. C. S. Monograph Series No. 60, The Chemical Catalog Co., New York, 1932; Huffman, Parks and Barmore, THIS JOURNAL, **53**, 3876 (1931); Parks, Huffman, and Thomas, *ibid.*, **52**, 1032 (1930); Parks, paper presented at the Washington meeting of the Am. Chem. Soc., 1933.

TABLE III

THERMODYNAMIC CONSTANTS FOR THE REACTION: CYCLOHEXANE (liq., 25°) ⟶ METHYLCYCLOPENTANE (liq., 25°)

	Calcd. from equilibrium measurements	Calcd. from third law by Parks
ΔH, cal.	3510	−1100
ΔS, e. u.	7.9	10
$\Delta F°$, cal.	1150	−4100

With the exception of ΔS, the constants obtained by the different methods are in rather poor agreement. Parks' value for ΔH is based on earlier work[7] on the heats of combustion of the two hydrocarbons. The combustion data, particularly that of methylcyclopentane, are rather uncertain and considering the magnitudes of the heats of combustion, it is probable that their small difference, or ΔH, contains considerable error. With Parks' method of calculation any error in ΔH is, of course, carried over to $\Delta F°$.

Experimental

Materials and Analytical Methods.—The cyclohexane used in the experiments for the identification of the reaction products was a C. P. grade manufactured by the Eastman Kodak Company. Distillation of this material indicated a negligible quantity of higher-boiling impurity. The cyclohexane used for the study of the equilibrium constants was a constant boiling fraction distilled from the Eastman Kodak Company material and had a refractive index of 1.4262 at 20°. The methylcyclopentane was prepared by the action of aluminum chloride on cyclohexane. Only the constant boiling fraction having a refractive index of 1.4100 at 20° was used. Baker C. P. anhydrous aluminum chloride was used throughout without further purification. The aluminum bromide was prepared by the action of bromine on aluminum.

Unless otherwise stated, the fractionating column used throughout this work was a spiral-packed, vacuum-jacketed, automatic recording and controlled column having 80 theoretical plates and a low holdup (40 cc.).

A series of methylcyclopentane–cyclohexane mixtures were prepared and the refractive indices determined with an Abbe–Zeiss refractometer, with temperature control within 0.2° by an independent cooling and circulating system. A plot of the data given in Table IV was used to obtain refractive index analyses.

TABLE IV

REFRACTIVE INDICES OF METHYL CYCLOPENTANE–CYCLOHEXANE MIXTURES

Mole % methylcyclopentane	7.19	13.26	19.89	24.91	29.95	35.01
$n^{20}D$	1.4250	1.4238	1.4227	1.4219	1.4210	1.4200

The Action of Aluminum Chloride on Methylcyclopentane.—For a quantitative experiment, 750 cc. of methylcyclopentane, 150 g. of anhydrous aluminum chloride, and 5 cc. of water were placed in a 2-liter flask equipped with a reflux condenser connected to a gas receiver. The

(7) Kharasch, *Bur. Stds. J. Research*, **2**, 374 (1929).

reaction mixture was boiled for three hours, the reaction flask was then cooled, the liquid decanted, and washed with water. Tar and gas were not formed in this experiment. After drying, 650 cc. of product remained, indicating a loss of 100 cc. Absorption of the liquid by the aluminum chloride and the drying agent probably accounts for the principal part of the loss, washing and handling account for the remainder. The dried product had a refractive index of 1.4220 at 20°, which, according to the data of Table IV, indicates the presence of 24.0 mole % methylcyclopentane.

For the distillation analysis, 600 cc. of the product was used. The distillation curve obtained is shown in Fig. 2. Altogether 536.8 cc. was distilled, leaving a residue of 58 cc. with a refractive index of 1.4282 at 20°, indicating that part of the residue consisted of material boiling higher than cyclohexane. The first 11 cc. of distillate also had a refractive index 0.0022 lower than pure methylcyclopentane. However, the products of the side reactions are relatively small in quantity and the mixture can be considered as consisting solely of methylcyclopentane and cyclohexane. The distillation curve shows 151.5 cc. methylcyclopentane and 448.5 cc. cyclohexane. Converting to mole % gives 24.6 mole % methylcyclopentane, a figure which compares favorably with the 24.0 mole % found by refractive index measurements.

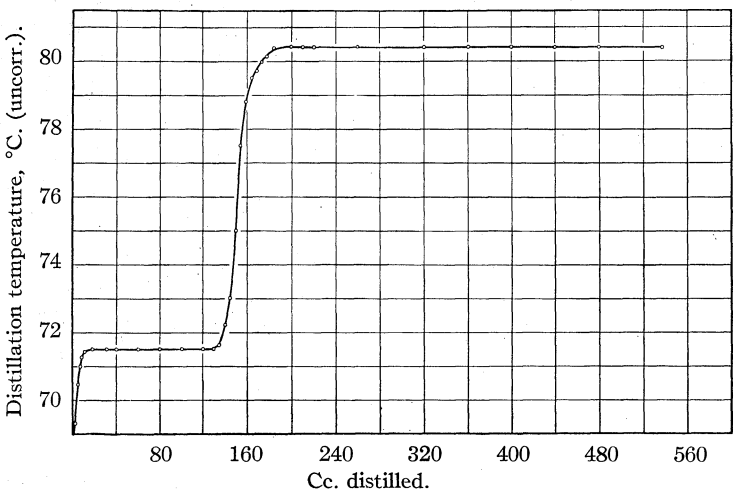

Fig. 2.—Distillation of 600 cc. methylcyclopentane–aluminum chloride reaction mixture. Distillation residue, 58 cc.

The Action of Aluminum Chloride on Cyclohexane.—Preliminary experiments indicated similarity between the cyclohexane–aluminum chloride and methylcyclopentane–aluminum chloride reactions. The addition of water to the anhydrous aluminum chloride was found to be necessary to promote reaction and the reaction products were free of tar and gas.

A quantitative experiment was made to discover the reaction products and to test the feasibility of using refractive index measurements as a method of analysis: 1500 cc. of cyclohexane, 300 g. of aluminum chloride, and 6.5 cc. of water were boiled for three hours in the same apparatus as used in the methylcyclopentane experiment. The reaction product was then cooled, the clear liquid decanted, washed, and dried; 1270 cc. of dried material was recovered having a refractive index of 1.4225 at 20°. The data of Table IV show this to be equivalent to 21.0 mole % methylcyclopentane. Distillation of 1200 cc. of this material gave a curve similar to that shown in Fig. 2, and showed the mixture to contain 250 cc. of methylcyclopentane and 950 cc. of cyclohexane. These volumes correspond to 20.2 mole % methylcyclopentane which compares favorably with the 21.0 mole % found by refractive index measurements. In this distillation, the first 30 cc. of distillate had a refractive index of 1.4087 at 20° and the 508 cc. of residue had a refractive index of 1.4266 at 20°, indicating that side reactions had occurred to a slight extent.

The products and extent of the side reactions were determined in a similar type of experiment in which a total of approximately 15 l. of cyclohexane was treated with aluminum chloride. Distillation in an 80-plate column gave 2.5 l. of pure methylcyclopentane, 50 cc. of material boiling below methylcyclopentane, and 97 cc. of material boiling above cyclohexane. Redistillation of the lower boiling material in a 28-plate column and refractive index measurements suggested the presence of only paraffinic constituents. The bulk of the material distilled in one plateau at 61°. The $n^{20}D$ of this material was 1.3756, and it was probably a mixture of isomeric hexanes; however, the small amount did not allow complete separation. No trace of *n*-hexane could be detected. Redistillation of the higher boiling material revealed three plateaus: 20 cc. boiled at 99.5°, 25 cc. at 119.5°, and 30 cc. from 208 to 220°. The 99.5° material is probably methylcyclohexane, although the refractive index of 1.4212 at 20° is somewhat low. The 119.5° material had a refractive index of 1.4237 and is probably 1,3-dimethylcyclohexane, since a product with these constants has been identified as such by Ipatieff.[5] The material boiling from 208 to 220° and having a refractive index of 1.4680 to 1.4703 undoubtedly consists of dimethyldicyclopentyl and dicyclohexyl, as reported by Ipatieff[5] and Nenitzescu.[8] On the basis of this experiment, not more than about 5% of the cyclohexane reacting is consumed in side reactions which accompany the isomerization.

The Action of Aluminum Bromide on Cyclohexane.—Previous work[9] with paraffins suggested that aluminum bromide could be substituted advantageously for the chloride. However, when the bromide was used with cyclohexane, tar formation and gas evolution resulted. Also, appreciable quantities of paraffins boiling lower than methylcyclopentane were formed. Isobutane, isopentane, and the isomeric hexanes were among the reaction products.

The Cyclohexane–Methylcyclopentane Equilibrium.—The apparatus used in these experiments consisted of a 200-cc. reaction flask fitted with a reflux condenser. The top of the condenser connected to a drying tube, the other end of which was open to the atmosphere. The reaction

(8) Nenitzescu and Ionescu, *Ann.*, **491**, 189 (1931).

(9) Glasebrook, Phillips and Lovell, THIS JOURNAL, **58**, 1944 (1936).

flasks were immersed in a constant temperature bath which maintained the temperature within 0.5°.

Although experiments had shown the equilibrium to be independent of catalyst concentration, nevertheless, uniform quantities, consisting of 100 cc. of hydrocarbon, 30 g. of aluminum chloride, and 1 cc. of water, were used in each experiment. At each temperature studied, simultaneous experiments were made to approach the equilibrium from both sides.

In the preliminary experiments it was also noted that the reaction undergoes an induction period. If the aluminum chloride, water, and hydrocarbon are mixed and allowed to stand at room temperature, refractive index measurements indicate very little reaction, even after several days of standing. If, however, the reaction mixture was heated to boiling, reaction started within fifteen minutes. In view of this fact, the reaction flasks were always boiled for a few minutes after the reactants were mixed to initiate the reaction. Samples were withdrawn at the end of the boiling period, and refractive index measurements made to make certain that the reaction mixtures were still far removed from the probable equilibrium. The reaction flasks then were placed in the constant temperature bath. Periodically, samples of the reaction mixture were withdrawn by inserting a glass tube down through the reflux condenser. The samples immediately were washed, dried, and analyzed by means of refractive index measurements. The reactions were continued until the refractive indices reached and maintained a constant value. Constant values were reached in about two hours at the boiling point, but three or four weeks were required at the lower temperatures.

The data obtained are presented in Table I.

Summary

1. The reaction of cyclohexane or methylcyclopentane in the presence of anhydrous aluminum chloride promoted by water results in an equilibrium mixture consisting principally of the two hydrocarbons. In the case of cyclohexane, the side reactions amount to approximately 5% based on the quantity of cyclohexane isomerized.

2. The equilibrium constants for the isomerization reaction have been determined at 10° intervals from 25° to the boiling temperature (77.4°).

3. From these data, values of the free energy change, heat of reaction, and entropy change for the isomerization reaction have been computed and compared with values calculated from heat capacity data.

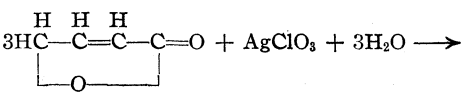
The Reduction of *dl*-Erythronic Lactone to *dl*-Erythrose[1]

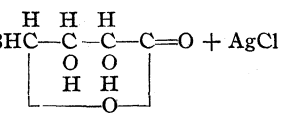
BY J. W. E. GLATTFELD AND B. D. KRIBBEN

For some years past, work on the preparation and study of the eleven C_4-saccharinic acids has been carried on in these Laboratories.[2] The work, which is now completed, was done in order to provide data on the constants and properties of these acids that might be useful in detecting them in, and separating them from, reaction mixtures produced by the action of alkalies on the tetroses.

The next step in the program is the synthesis of the *dl*-tetroses themselves. A source of one of these tetroses, *dl*-erythrose, has been found in *dl*-erythronic lactone which is prepared by the oxidation of the lactone of γ-hydroxy-isocrotonic acid, obtained as a by-product in the synthesis of one of the C_4-saccharinic acids.[3] The oxidation is achieved with osmium tetroxide-activated silver chlorate[4] according to the equation



Lactone of γ-hydroxy-isocrotonic acid



dl-Erythronic lactone

Some success has been attained in the conversion of the *dl*-erythronic lactone so obtained into *dl*-erythrose. This paper gives an account of the work.

The optically active forms of the aldotetroses seem to be fairly well known, the constants of the threoses[5] resting, perhaps, on a somewhat firmer

basis than those of the erythroses.[6] As far as the authors are aware there is found in the literature only one report of the isolation of these sugars in the racemic form.[6a]

Two previous attempts to reduce *dl*-erythronic lactone to *dl*-erythrose in this Laboratory proved to be unsuccessful. Hutton[7] tried sodium and other amalgams and reported a maximum yield of 2.5% of the aldehyde. Miss Stack[8] attempted the reduction of both the lactone and the butyl ester, with hydrogen in the presence of platinum black. At both high and low pressures she obtained 60–70% yields of erythritol and found no evidence of aldehyde formation. These results indicate: (a) the rate of reduction of the aldehyde to erythritol is so much faster than the rate of formation of the aldehyde, that the concentration of the latter in the mixture is always very small; or (b) that, under the conditions of the experiment, the formation of the aldehyde is not a step in the mechanism by which the alcohol is formed. The former assumption seems the more probable in view of the high reactivity of the furanose type of aldose in general.

A more circuitous method of reducing sugar acids to aldehydes has been reported recently by Cook and Major.[9] They prepared pentaacetylgluconic acid, converted it to the acid chloride and successfully reduced the latter to pentaacetylglucose by means of hydrogen in the presence of palladinized barium sulfate according to the procedure of Rosenmund.[10] The yield was almost quantitative. Mochel[11] and Straitiff[12] have recently applied this procedure to the reduction of two of the C_4-saccharinic acids to the corresponding aldehydes and the method showed promise of being adaptable to the reduction of *dl*-erythronic lactone to *dl*-erythrose.

The first step to be accomplished was the preparation of *dl*-triacetyl-erythronic acid. Nef[13] had prepared the diacetyl and dibenzoyl derivatives of *dl*-erythronic lactone, the former as a sirup and the latter as a crystalline solid. During the course of the work herewith reported, the diacetyl lactone was obtained in almost quantitative yield as a crystalline solid which melted at 52.0–52.5°. It was hoped that, by the use of catalysts or higher temperatures, the lactone bond could be opened during acetylation and the triacetyl acid obtained. The use of acetic anhydride with pyridine, zinc chloride and hydrochloric acid as catalysts in the acetylation procedures did not bring this about. This failure showed that it would be necessary to break the bond previous to acetylation attempts, if the triacetyl acid was to be obtained. The simplest method for breaking the lactone bond proved to be conversion to a salt.

The calcium salt was prepared according to the method of Snoddy[14] but attempts to acetylate it proved unsuccessful. The sodium and potassium salts were then prepared. Attempts to crystallize these salts from water were unsuccessful. However, when the lactone was dissolved in absolute methyl alcohol and the solution treated with alcoholic alkali at low temperatures, white crystalline products were obtained. The sodium salt was very hygroscopic; the potassium salt much less so.

The sodium salt reacted with acetylating agents with great violence but the potassium salt was acetylated smoothly at low temperatures by means of acetyl chloride. Potassium chloride precipitated during the reaction with the potassium salt. After removal of this salt and the excess acetyl chloride, followed by concentration of the solution, there remained an almost colorless sirup that could neither be distilled without decomposition nor induced to crystallize. The neutralization equivalent of this sirup indicated that it was composed to a large extent of the triacetylated *dl*-erythronic acid. This conclusion was confirmed by the preparation and analysis of the calcium salt. The triacetylated acid, upon treatment with highly purified thionyl chloride, was converted into the acid chloride. It is interesting to note that some workers[11] have reported difficulties in the preparation of the acid chlorides by means of thionyl chloride and have, therefore, preferred phosphorus pentachloride as the chlorinating agent. These difficulties were encountered in this work, when a supposedly pure commercial grade of thionyl chloride was used. However, carefully purified thionyl chloride proved to be satisfactory.

The reduction of the triacetyl acid chloride was

carried out in a manner prescribed by Rosenmund.[10] Hydrogen was bubbled into a xylene solution of the acid chloride in which was suspended palladinized barium sulfate. After a short induction period, the evolution of hydrogen chloride began, and the reaction proceeded smoothly until it was about 85% completed when the rate became extremely slow. The course of the reaction was followed by determination of the amount of volatile acid and chloride entrained by the excess hydrogen as it bubbled through the reaction mixture (see Experimental Part). Both the acid and chloride were determined because it was found that hydrogen chloride was not the only volatile acid produced and the true extent of the reduction could be ascertained only by the determination of the chloride content of the effluent gases. The results of these analyses are given in the table below.

TABLE I

REDUCTION OF THE ACID CHLORIDE

Acid chloride 30.0 g.

Calcd.	107.2	107.2		

After removal of the catalyst and the xylene, the reaction mixture was fractionated at reduced pressure. The analysis of the main fraction which boiled at 126–129° at 2 mm. showed that reduction of the acid chloride to the aldehyde had been accomplished but that a diacetyl- instead of a triacetyl-erythrose had been produced. This unexpected result was verified by the preparation and analysis of the 2,4-dinitrophenylhydrazine derivative of the product. The compound produced was apparently the dinitrophenylhydrazone of neither triacetyl- nor diacetyl-erythrose. It contained 45.70% of carbon and 14.82% nitrogen instead of the 45.07% carbon and 13.15% nitrogen which are theoretical for the dinitrophenylhydrazone of triacetyl-erythrose and the 43.75% carbon and 14.58% nitrogen which are theoretical for the dinitrophenylhydrazone of diacetyl-erythrose. While these results are not close enough to either set of figures to prove the identity of the compound, they do indicate that one acetyl group was lost either in the reduction step or the subsequent fractionation. That this loss took place in the reduction step is indicated by the fact that acetaldehyde was present in the alkali solutions through which the hydrogen was passed after it left the reaction flask.

But the loss of one acetyl group and replacement by a hydrogen atom alone would not give a product of the correct composition for an analysis such as was obtained for this dinitrophenylhydrazine derivative. This change together with the loss of one molecule of water, however, would do so as the data in the following table show. The agreement in the nitrogen figure is not good but, because of the difficulties

THE DINITROPHENYLHYDRAZINE DERIVATIVE

	A Triacetyl-dinitro-phenyl-hydrazone $C_{16}H_{18}N_4O_{10}$	B Diacetyl-dinitro-phenyl-hydrazone $C_{14}H_{16}N_4O_8$	B-H_2O $C_{14}H_{14}N_4O_9$	Found

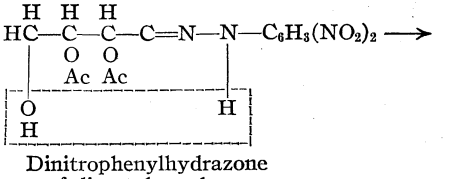
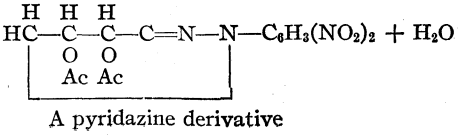
inherent in nitrogen determinations by the combustion method in compounds of this type, the low figure obtained is perhaps not surprising.

The structure of the compound under discussion has not been determined. Mr. E. M. May of this Laboratory has suggested that the loss of a molecule of water might have occurred as indicated.



Dinitrophenylhydrazone of diacetyl-erythrose



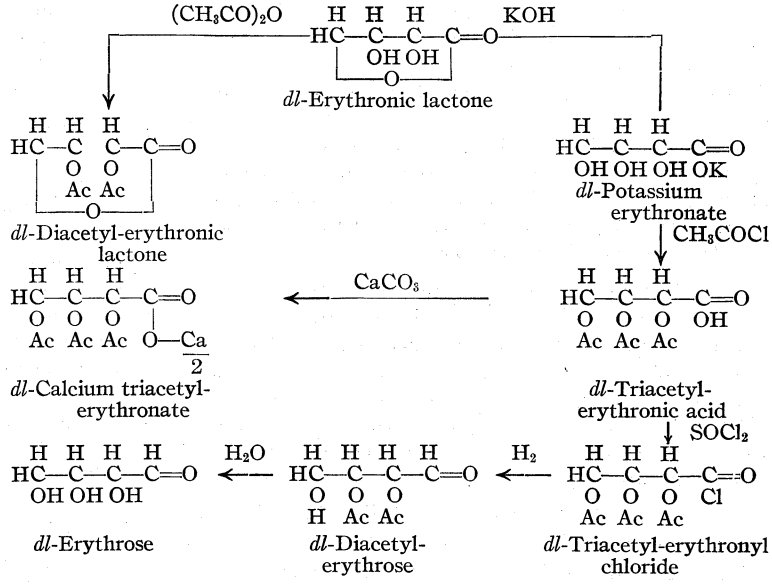
A pyridazine derivative

The structure indicated has been accepted tentatively. An attempt to prepare a derivative of the diacetyl-erythrose with phenylhydrazine resulted in the formation of an oil that could not be crystallized.

The hydrolysis of the diacetyl-erythrose was accomplished by warming a mixture of it with an equal volume of water to 70° and holding the mixture at that temperature until the compound had dissolved. If either alkali or acid was added or if the temperature was raised to hasten the reaction, the solution rapidly turned brown. The acetic acid formed during the hydrolysis was removed to a large extent by repeated extraction with chloroform. The distribution coefficient for acetic acid in chloroform–water mixtures is unfavorable to removal of acetic acid by this process at low concentrations of acetic acid and the separation was not very complete. Evaporation of the extracted solution at reduced pressure over phosphorus pentoxide left a light yellow sirup. Attempts to crystallize this product from methyl and ethyl alcohols proved to be unsuccessful. The sirup reduced cold Fehling's solution and, upon condensation with phenylhydrazine in the usual manner, gave a small yield of an osazone which, after recrystallization from benzene, melted at 162–165°. Fischer,[15] who prepared *dl*-erythrosazone by treatment with phenylhydrazine of a reaction mixture obtained by the oxidation of erythritol, reports a melting range of 166–168°.

The chart scheme summarizes the work reported in this paper beginning with the starting product *dl*-erythronic lactone. It shows the compounds new to the literature that were prepared in the course of the work and indicates how they were prepared.

NEW PRODUCTS FROM *dl*-ERYTHRONIC LACTONE



Experimental Part

Preparation of *dl*-Diacetyl-erythronic Lactone.—Seventy-five grams of freshly-distilled acetic anhydride was poured into a Claisen flask. Dry hydrogen chloride was passed into the liquid until an increase in weight of 2 g. was observed. The flask was stoppered and fitted with a calcium chloride tube at the side-arm. The contents were cooled in ice and, when a temperature of 0° was attained, 20 g. of *dl*-erythronic lactone was added. The mixture was shaken intermittently and allowed to warm to about 20°. After the lactone had dissolved, the solution was allowed to stand at room temperature for three hours. The excess acetic anhydride was removed by distillation under reduced pressure finally at 100°, the temperature of the bath raised to 200° and the residue fractionated. The major portion distilled between 172–176° at 9–10 mm. Upon standing this fraction slowly crystallized; yield 31.5 g., 93% of the theoretical, calculated as the diacetyl-lactone.

The crude material melted at 47–50°. After two recrystallizations from hot water the melting point of the product was found to be 52.5–53°.

Anal. Calcd. for diacetyl-erythronic lactone, $C_8H_{10}O_6$: C, 47.50; H, 4.98; neut. equiv., 67.3. Found: C, 47.48; H, 5.06; neut. equiv., 67.5.

In the preparation of the diacetyl lactone, acetyl chloride may be substituted for the acetic anhydride–hydrogen chloride solution with equivalent yields. The pure product obtained by either method is an odorless, white, stable, crystalline material. It is readily soluble in alcohol and ether and may be recrystallized from water. A water solution of the diacetyl lactone slowly develops the odor of acetic acid.

The use of other catalysts such as zinc chloride, sodium acetate, or pyridine did not cause the opening of the lactone bond. In every case, the only product recovered was the diacetyl lactone. The presence of these catalysts made the recovery of the diacetyl derivative more difficult.

The Preparation of *dl*-Potassium Erythronate.—A solution of 118 g. (1 mole) of *dl*-erythronic lactone in 350 cc. of methyl alcohol was poured into a large evaporating dish and cooled to 5°. Fifty-six and one-tenth grams (1 mole) of pure potassium hydroxide dissolved in 400 cc. of methyl alcohol was added slowly to the lactone solution, with constant stirring, and at such a rate that the temperature of the solution did not rise above 10°. After all the

(15) Fischer, *Ber.*, **20**, 1090 (1887).

alkali had been added a gummy precipitate began to separate. The gum was triturated in the solution until it hardened to a cake. After about two hours the precipitation seemed to be complete. Most of the reaction solution was decanted, the cake was loosened from the sides of the dish and ground to a paste in the presence of a small amount of the solution. The paste was transferred to a Büchner funnel, the solid washed thoroughly with methyl alcohol, and dried in a vacuum desiccator: yield 132 g. of a stable white crystalline powder, 76% of the theoretical calculated as potassium erythronate.

Anal. Calcd. for $C_4H_7O_5K$: C, 27.56; H, 4.05; K, 22.45. Found: C, 27.76; H, 4.03; K, 22.47.

The Preparation of *dl*-Sodium Erythronate.—This salt was prepared in exactly the same manner as the potassium salt. The yield in the case of this salt was lower, about 60%. The product was a very hygroscopic white powder. Unless it was kept in a desiccator it soon turned into a greenish-brown sirup.

Anal. Calcd. for $C_4H_7O_5Na$: C, 30.38; H, 4.43; Na, 14.46. Found: C, 30.52; H, 4.48; Na, 14.37.

The Preparation of *dl*-Triacetyl-erythronic Acid (hereinafter called the triacetyl acid).—To 245 g. of freshly distilled acetyl chloride in a wide-mouthed Erlenmeyer flask was added, in small portions, 100 g. of potassium erythronate. Hydrogen chloride was evolved copiously and time was allowed between additions for the foam to subside. After all the potassium salt had been added and the evolution of hydrogen chloride had practically ceased, the flask was attached to a reflux condenser and the reaction mixture was heated on a boiling water-bath for one hour. At this point the mixture was a viscous sirup in which the potassium chloride was held in colloidal suspension. Addition to the sirup of six volumes of dry ether caused the coagulation and precipitation of the salt. The precipitate was removed by filtration and the filtrate treated with 2 g. of activated carbon. After removal of the carbon, the ether solution was evaporated at reduced pressure to a viscous, almost colorless sirup. The sirup was moderately soluble in water, quite soluble in ether and alcohol, and insoluble in chloroform, ligroin, and benzene. It did not crystallize from any of these solvents: yield 128 g., or 74%.

Anal. Calcd. for the triacetyl acid, $C_{10}H_{14}O_8$: neut. equiv., 65.5. Found: neut. equiv., 66.1.

Attempts to distil the sirup at 2 mm. resulted in rapid decomposition. A small fraction was recovered between 156–160° and later identified as the diacetyl lactone. Acetic anhydride was shown to be present in the distillate. Most of the material in the distilling flask was converted into a black tar.

The Preparation of *dl*-Calcium Triacetyl-erythronate.—Fifteen grams of the triacetyl acid dissolved in 40 cc. of 80% methyl alcohol was warmed to 40° and 2 g. of calcium carbonate added. After the evolution of carbon dioxide had ceased the solution was cooled, the precipitate was allowed to settle, and the supernatant liquid decanted. The precipitate was dried on a water-bath and thoroughly washed with ether to remove any unchanged acid. The precipitate was then treated with 50 cc. of water and the excess calcium carbonate removed by filtration. The calcium salt in the filtrate was again precipitated by the addition of 50 cc. of methyl alcohol. The precipitate was removed by filtration, washed with ether, and dried over phosphorus pentoxide; yield 6.3 g. or 37%. The product was a stable white powder moderately soluble in water.

Anal. Calcd. for calcium triacetyl-erythronate $C_{20}H_{26}O_{16}Ca$: C, 42.66; H, 4.62; Ca, 7.13. Found: C, 42.60; H, 4.66; Ca, 7.21.

The Preparation of *dl*-Triacetyl-erythronyl Chloride.—Twenty-five grams of the triacetyl acid and 25 g. of purified thionyl chloride (see below) were mixed and the mixture allowed to stand overnight in a flask fitted with a reflux condenser and protected from atmospheric moisture with a calcium chloride tube. The following day the mixture was refluxed on a water-bath until the evolution of hydrogen chloride had practically ceased (about four hours). Very cold water was circulated through the reflux condenser to prevent the loss of thionyl chloride. The residue was distilled at reduced pressure. The main fraction boiled between 115–130° at 2 mm. This fraction was again distilled at 2 mm. and from it there was obtained 21 g. of a mobile colorless liquid which boiled at 114–116°; a 79% yield calculated as triacetyl acid chloride. The substance fumed in moist air and possessed a sharp odor similar to that of hydrogen chloride.

Anal. Calcd. for the triacetyl acid chloride, $C_{10}H_{13}O_7Cl$: C, 42.77; H, 4.67; Cl, 12.64; neut. equiv., 55.9. Found: C, 42.77; H, 4.43; Cl, 12.77; neut. equiv., 56.1.

The Purification of Thionyl Chloride.[16,17]—Two hundred grams of thionyl chloride was mixed with 30 g. of quinoline and distilled through a Schneider column. The fraction which boiled at 74–78° was mixed with 30 g. of boiled linseed oil and again distilled through the Schneider column. The fraction which boiled at 75–76° was colorless and remained so when kept in the dark. It was this fraction which was used in the preparation of the acid chloride.

The Reduction of *dl*-Triacetyl-erythronyl Chloride.—Thirty grams of the acid chloride was dissolved in 100 cc. of dry xylene and 2 g. of palladinized barium sulfate (5% Pd) catalyst added.[18] The flask which contained the solution was attached to a reflux condenser and the mixture was heated to 135° in an oil-bath. Hydrogen, purified and dried by passage through 5% solutions of silver nitrate and potassium permanganate, then through concentrated sulfuric acid and copper gauze at dull red heat and finally through soda lime and phosphorus pentoxide, was introduced into the solution at such a rate as to keep the catalyst in uniform suspension. After a few minutes the evolution of hydrogen chloride began and proceeded smoothly, gradually lessening as the reaction approached completion. The effluent gases from the reflux condenser were conducted into a solution which contained a known amount of alkali and a few drops of phenolphthalein. When the alkali solution changed color, the effluent gases were conducted immediately into another solution of known alkali content. By noting the time at each color change and consequently the time required for the production of a known quantity of hydrogen chloride, both the rate and extent of the reduc-

(17) H. Meyer and K. Schlegl, *ibid.*, **34**, 569 (1913).

(18) Gattermann and Wieland, "Laboratory Methods of Organic Chemistry," 22d edition, The Macmillan Co., New York, N. Y., 1934, pp. 369–370.

tion of the acid chloride were followed (see Table I). The chloride in these solutions was estimated by titration with a normal solution of silver nitrate with dichlorofluorescein as the indicator. The chloride content of the solutions, calculated as hydrogen chloride, did not account for all of the acid present. Attempts were made to identify this additional volatile acid but they were unsuccessful. It was noticed that the solutions used for the estimation of the chloride had a distinct odor of acetaldehyde. This aldehyde probably was produced by the reduction of the acetyl group that was lost from the triacetyl acid chloride during the reduction process (see analysis below). When the chloride determination indicated that the reduction was 85% complete, the rate of reaction had become very slow and the reduction was discontinued in order to prevent thermal decomposition of the product obtained.

The xylene was removed by the introduction of the reaction solution dropwise into a small Claisen flask, evacuated to 10 mm. and heated to 100°. Attempts to distil the reaction mixture at reduced pressure in the ordinary manner caused so much foaming that serious mechanical loss resulted. The residue was fractionated at 2 mm. A small fraction which distilled between 114–120° proved to be unchanged acid chloride. The main fraction distilled between 125–140°. A second fractionation of this portion yielded 14.5 g. of a mobile, colorless liquid which boiled at 126–129° at 2 mm., a yield of 20% calculated as diacetyl-erythrose. The product possessed a mild aromatic odor and gave no test for chloride. It quickly reduced boiling Fehling's solution.

Anal. Calcd. for diacetyl-erythrose, $C_8H_{12}O_6$: C, 47.03; H, 5.92; neut. equiv., 102. Found: C, 47.20; H, 5.80; neut. equiv., 99.3.

The Reaction of *dl*-Diacetyl-erythrose with 2,4-Dinitrophenylhydrazine.—Two grams of the diacetyl-erythrose was dissolved in 50 cc. of a saturated solution of 2,4-dinitrophenylhydrazine in ethyl alcohol and the mixture was boiled for two minutes. Upon the addition of 5 drops of concentrated hydrochloric acid the solution immediately turned from orange to bright yellow. The solution was stored overnight in the icebox during which time a crop of bright yellow, needle-like crystals formed; yield 0.3 g. These were removed by filtration and recrystallized twice from a small quantity of methyl alcohol; m. p. 172–173°. Further recrystallization did not raise the melting point.

Anal. Calcd. for $C_{14}H_{14}N_4O_8$ (see above): C, 45.90; H, 3.83; N, 15.30. Found: C, 45.70; H, 3.62; N, 14.82.

The Hydrolysis of *dl*-Diacetyl-erythrose.—A mixture of 10 g. of the diacetyl-erythrose and 10 cc. of water was heated to 70° and held at that temperature until all the aldehyde had dissolved. The solution was extracted with ten 10-cc. portions of chloroform to remove the acetic acid formed during the hydrolysis. It was then evaporated over phosphorus pentoxide in a vacuum desiccator to a light colored viscous sirup; yield 2.4 g. or 41%. The odor of acetic acid was still quite noticeable in the sirup but attempts to remove it by further extraction with chloroform were unsuccessful. The sirup readily reduced cold Fehling's solution.

Preparation of *dl*-Erythrose Phenylosazone.—To a solution of 2 g. of the sirupy *dl*-erythrose in 3 cc. of 95% ethyl alcohol were added 2 g. of freshly-distilled phenylhydrazine and 2 g. of glacial acetic acid. The solution was allowed to stand in the dark for twelve hours. During this time a small quantity of brownish-yellow crystals had formed. They were separated by filtration and recrystallized from benzene; m. p. 162–165°.

Summary

1. *dl*-Diacetyl-erythronic lactone was prepared in almost quantitative yield by the acetylation of the lactone. It was a crystalline solid which melted at 52.5–53°. It has been reported heretofore only as a sirup.

2. The potassium and sodium salts of *dl*-erythronic acid as well as *dl*-triacetyl-erythronic acid and its calcium salt are reported for the first time.

3. Triacetyl-erythronic acid was converted into the corresponding acid chloride in high yield. This acid chloride was reduced according to the method of Rosenmund as modified by Cook and Major. Diacetyl-erythrose, instead of the expected triacetyl-erythrose, was obtained.

4. A crystalline product was obtained by the action of 2,4-dinitrophenylhydrazine upon the *dl*-diacetyl-erythrose. The analytical data showed that two molecules of water had been eliminated in the course of the reaction and the compound has been characterized tentatively as a pyridazine derivative.

5. *dl*-Diacetyl-erythrose was hydrolyzed to *dl*-erythrose, which was recovered as a light yellow sirup.

Heats of Combustion of Some Mono- and Disaccharides

BY THEODORE H. CLARKE[1,2] AND GEBHARD STEGEMAN

A program has been instituted at this Laboratory for obtaining the thermal data on compounds of physiological interest. Studies are being carried out on carbohydrates and glycerides, and in this paper are presented the combustion data on six carbohydrates.

Method and Apparatus.—Since the proposed course of study will involve only liquids and solids, the "bomb calorimeter" method has been adopted. The determinations were made isothermally, that is, the rise in temperature of the calorimeter is observed while the temperature of the jacket is kept constant.

The calorimeter system was patterned after that of Dickinson.[3] A hollow removable head was so arranged that the calorimeter could be surrounded completely by a well-stirred water-bath kept constant to within ±0.002°. Two ball-bearing mounted stirrers driven by constant speed motors were employed to circulate the water in the jacket and to pump water through the head. The jacket also was provided with a cooling coil for use in warm weather. The calorimeter proper had a stirrer mounted in a side-tube and connected by means of a hard rubber connector to a shaft extending through the head. This stirrer was driven by a belt to the main stirrer shaft.

An "Emerson double-valved bomb" of 516-ml. capacity was used throughout the investigation. Gold-plated electrodes with threaded binding posts, gold-plated crucible support, and gold-plated inner linings for the bomb were employed to eliminate any corrosion. The material to be burned was placed in a platinum cup.

The temperature measuring system consisted of a Bureau of Standards calibrated platinum resistance thermometer, a White double potentiometer, and a type H. S. galvanometer, all supplied by Leeds and Northrup Co. A shunt of seventy ohms was placed across the galvanometer which then had a sensitivity of 0.000005 ohm (0.00005 C) per 0.1 mm. deflection and was quite stable. The galvanometer was used as a deflection instrument.

Burgess–Parr oxygen bomb fuse wire was used to ignite the sample. As the same length of wire and the same source of energy for its ignition were used throughout all the determinations, the heat evolved by the ignition of the wire was included in the heat equivalent of the calorimeter. As in general sugars tend to melt rather than to ignite, a small disk of filter paper was placed on top of the sample to start the combustion. Whatman's No. 42 ashless filter paper, kept in a constant humidity container, having a determined heat of combustion of 3999.2 cal./g. was used. The error for the size of filter paper disk was less than 0.1 cal.

The mass of the calorimeter and water was determined to ±0.05 g. by means of a large capacity balance having a sensitivity of ±0.01 g. The mass of the sample was determined to ±0.00002 g. by means of a good analytical balance. Weighings were made on both arms of the balance to eliminate any differences in the arms of the balance.

The bomb was first evacuated and then filled with commercial oxygen to a pressure of 30 atm.; 3 g. of water was placed in the bomb for each determination.

Units.—The unit of energy used throughout this paper is the defined conventional calorie which has been derived from the international joule by the factor 1 cal. = 4.1833 int. j.[4,5] The unit of mass is the "gram true mass" which is derived from the mass in air against gold-plated brass weights by the use of a suitable conversion factor.

Errors.—In the calculation of the precision of these determinations the procedure proposed by Rossini[5] has been used. The errors are defined: "assigned error" on the standardizing substance, ± e%; error on the standardization or "calibration error" ± c%; error on the actual determination or "reaction error," ± b%; and the final precision error, ± p. e.%. This procedure gives an error larger than the usual "probable error" but as Rossini states, "it seems better because it yields an 'error' which is conservative and reasonable."

Calibration of the Calorimeter

The energy equivalent of the calorimeter was determined by burning benzoic acid (sample No. 39e) supplied by the Bureau of Standards. Benzoic acid has been chosen as the primary standard for combustion calorimetry and the value for the isothermal heat of combustion of this sample is given as 26.419 international kilojoules per gram mass.[6] In Table I are presented a series of values of the energy equivalent of the calorimeter as determined from the heat of combustion of benzoic acid.[7] It was not always possible to obtain complete combustion of benzoic acid, but in the cases where carbon appeared it was present in such small quantities as to be impossible to weigh. Any uncertainty due to this effect appears to be within the experimental error.

From the results in Table I, the energy equivalent of the calorimeter has been assigned the value of 2769.1 ± 0.3 cal. per °C. at 25°.

Preparation of Samples

As the procedure developed was somewhat similar in the case of all the sugars investigated, only a general discussion of the method will be given and the specific conditions for each sample tabulated at the end of this discussion (Table II). The sugar under investigation was dissolved in sufficient water to make a fluid liquid and filtered through best grade filter paper to remove any carbon, silica, etc., carried through from the manufacturer's filters. The water was then evaporated under vacuum (in order to avoid heating the sample in excess of 35–40°) until the amount of water remaining equaled the water necessary to form the aqueous fraction of the water–ethyl alcohol mixture used for recrystallization of a single isomeric form. The sample was allowed to stand for a given period of time in contact with this alcohol solution to ensure that only one isomer was present in the solid phase. This is the procedure developed by Hudson.[8] The sam-

drate, α-*d*-galactose, β-*d*-levulose, β-maltose monohydrate. β-Lactose and *l*-sorbose were treated similarly with the exception of the alcohol treatment.

The number of filtrations varied with the sample and are tabulated. The pressure varied between 1–3 mm. Samples were kept for ten to fourteen days over calcium chloride, were bottled and stored over calcium chloride while being used.

As standards of purity of the samples used, the following criteria were adopted: agreement in optical rotation values with those of Hudson and others and the checking of results on samples from different sources or in some cases the checking of results on samples from the same source secured from different batches. In this way it is believed that the possibility of error caused by poor samples has been practically eliminated.

Heats of Combustion.—In Table IV the experimental results of the combustions on these six compounds are listed with the errors stated as discussed earlier in this paper.

Calculated Values.—In addition to the results in Table IV we have calculated the value of $-\Delta U_B$, the heat evolved in the bomb process in kcal. per gram formula weight; $-\Delta U_R$, the decrease in energy for the chemical reaction at the standard state as defined by Washburn[10]; and $-\Delta H^\circ_{298.16}$, the heat of formation of the compound from the elements by the use of −68,318.1[11] and −94,029.8 cal.[12] for the heats of formation of water and carbon dioxide. A summary of the derived values is given in Table V.

Discussion of Results

The values determined here along with those on sucrose[3] and glucose[13] complete the combustion data on the three physiologically most important disaccharides (maltose, lactose, sucrose) and their component monosaccharides (levulose, galactose, glucose). Investigations on the specific heats of these compounds are being carried on in this Laboratory and the values for the free energy of formation of these sugars will be reported at a future date.

The assignment of the precision errors to our measurements is a mathematical process without assumptions, but a statement of the limits of accuracy involves factors difficult to evaluate. Optical rotation as a criterion of purity is not extremely accurate; but by its use and the method of checking samples from different sources and batches, it is believed that the absolute errors due to purity of sample have been nearly eliminated. A conservative estimate might place the accuracy error as 0.025–0.035%.

No error is stated for the value of $-\Delta H^\circ_{292.16}$ as this would involve the errors on the determination of the heats of formation of water and carbon dioxide. Since in the comparison of values the influence of the errors on water and carbon dioxide would be constant, the uncertainties are probably those of the heats of combustion of the compounds.

Galactose was burned by Stohmann[14] and anhydrous lactose by Stohmann,[14] and by Karrer and Fioroni,[15] whose results are higher by several tenths of one per cent. than the values here reported. The reported values for the hydrated form of lactose[14,16,17] and maltose[14,16] lie as much

(17) Van Rechenberg, *J. prakt. Chem.*, [2] **22**, 11 (1880).

as 1% lower than our values. The authors believe, however, that due to the higher precision attainable today, preparation of the samples by the method of Hudson,[8] and carefully controlled drying conditions, the reported values are worthy of consideration.

Summary

1. A brief description of a precise calorimetric system for measuring heats of combustion and the standardization of the apparatus with a precision of 0.009% have been presented.

2. The heats of combustion, reduced to the standard state $-\Delta U_R$, are reported as: *l*-sorbose, −670.30; *β*-*d*-levulose, −671.70; *α*-*d*-galactose, −666.76; *β*-lactose, −1345.47; *β*-maltose monohydrate, −1360.50; *α*-lactose monohydrate, −1354.66 kcal. per mole for the constant pressure process at 25°.

3. A comparison of these results with older values in the literature shows discrepancies of from 0.1–1%.

Equilibria of Mercuric Oxide in Solutions of Dilute Nitric Acid. Evidence for Stepwise Dissociation of Bases

BY A. B. GARRETT AND W. W. HOWELL

Equilibrium data for mercuric oxide in alkali[1] showed no minimum in the mercuric oxide–alkali graph and showed only a very low degree of dissociation for mercuric hydroxide as an acid. This paper presents equilibrium data in *acid* solutions; such data make possible the determination of (1) the position of minimum solubility of mercuric hydroxide, (2) the equilibrium constants of mercuric hydroxide as a base, and (3) the direct evidence for stepwise dissociation of bases. In addition to this, these data, together with the equilibrium data of mercuric oxide in alkali, give the complete record of the behavior of mercuric oxide in dilute solutions of nitric acid and sodium hydroxide.

Procedure.—The general procedure in the determination of the solubility of mercuric oxide in acid was similar to that described by Garrett and Hirschler.[1] The red mercuric oxide used was prepared by the calcination of mercuric nitrate which had been prepared from especially purified mercury and nitric acid. The yellow mercuric oxide was Merck Reagent Quality Mercuric Oxide. The nitric acid was C. P. quality acid. Conductivity water was used for all solutions. All preparations were made in an atmosphere of nitrogen. The temperature was 25.00 ± 0.02°.

The equilibrium periods, sedimentation periods, method of filtration, and determination of the mercury content of the samples were the same as those described by Garrett and Hirschler.[1]

(1) Garrett and Hirschler, THIS JOURNAL, **60**, 299 (1938).

The concentration of acid was determined by preparing the samples with standard solutions of the acid used. The acidity was corrected for the amount of acid used to react with the oxide. The *p*H value of each of the solutions was determined (after equilibrium was established) by means of a glass electrode.

The Data.—The data are given in Tables I and II and in Figs. 1, 2, 3, and 4. All of the data are expressed in moles of mercuric oxide and moles of acid per 1000 g. of water. In most of these data is given the average value of a pair of samples one of which approached equilibrium from undersaturation (u) and the other from supersaturation (s). Several samples, for which the mate was lost, are marked (u) or (s) to indicate the approach to equilibrium.

The data were calculated on the assumption of the following reactions

$$HgO + H_2O \rightleftharpoons Hg(OH)_2 \quad (1)$$

$$HgO + H^+ \rightleftharpoons Hg(OH)^+ \quad (2)$$

$$K_2 = \frac{m_{Hg(OH)^+}\gamma_{Hg(OH)^+}}{m_{H^+}\gamma_{H^+}}$$

$$HgO + 2H^+ \rightleftharpoons Hg^{++} + H_2O \quad (3)$$

$$K_3 = \frac{m_{Hg^{++}}\gamma_{Hg^{++}}}{m^2_{H^+}\gamma^2_{H^+}}\, a_{H_2O}$$

The acidity of the standard solutions of which the samples were made was corrected for the acid used in reactions indicated in equations (2) and (3). The curvature of the mercuric oxide–acid graph (Figs. 1, 3, and 4) indicates that reaction (3) is appreciable. While no direct method is

readily available to determine $m_{Hg^{++}}$ it can be determined together with the $m_{Hg(OH)^+}$ by a method of approximation with the aid of a relationship of activity coefficients similar to that derived for the dissociation of copper hydroxide.[2] Assuming that the total solubility of the mercuric oxide (S_{HgO}) is expressed by the equation

$$S_{HgO} = m_{Hg(OH)_2} + m_{Hg(OH)^+} + m_{Hg^{++}} \qquad (4)$$

where $m_{Hg(OH)_2}$ is the undissociated mercuric hydroxide (essentially water solubility since $Hg(OH)_2$ is only slightly dissociated[1])

$$m_{Hg(OH)^+} = K_2 \frac{m_{H^+}\gamma_{H^+}}{\gamma_{Hg(OH)^+}}$$

(2) Johnston and McDowell, THIS JOURNAL, **58**, 2009 (1936). The use of this relationship is necessary here since $\gamma_{Hg^{++}}$ has not been determined. An alternative procedure at this point would be to use the value of the activity coefficient for an ion similar to Hg^{++}. A probable choice would be $\gamma_{Pb^{++}}$ from the data of $\gamma_{Pb(NO_3)_2}$ given by Randall and Vanselow, *ibid.*, **46**, 2448 (1924).

and

$$m_{Hg^{++}} = K_3 \frac{m^2_{H^+}\gamma^2_{H^+}}{\gamma_{Hg^{++}}} \times \frac{1}{a_{H_2O}}$$

Then

$$S_{HgO} = m_{Hg(OH)_2} + K_2 \frac{m_{H^+}\gamma_{H^+}}{\gamma_{Hg(OH)^+}} + K_3 \frac{m^2_{H^+}\gamma^2_{H^+}}{\gamma_{Hg^{++}}} \times \frac{1}{a_{H_2O}} \quad (5)$$

which can be simplified to the following equation with the aid of the relationship of activity coefficients referred to above and also assuming $\gamma_{H^+}/\gamma_{Hg(OH)^+} = 1$ at low and moderate values of the ionic strength.

$$S_{HgO} = m_{Hg(OH)_2} + K_2 m_{H^+} + K_3 m^2_{H^+} \left(\frac{1}{\gamma^2_{HNO_3}}\right)\left(\frac{1}{a_{H_2O}}\right) \quad (6)$$

The terms in parentheses (equation 6) can be evaluated from reliable data[3] and from Raoult's law, respectively.

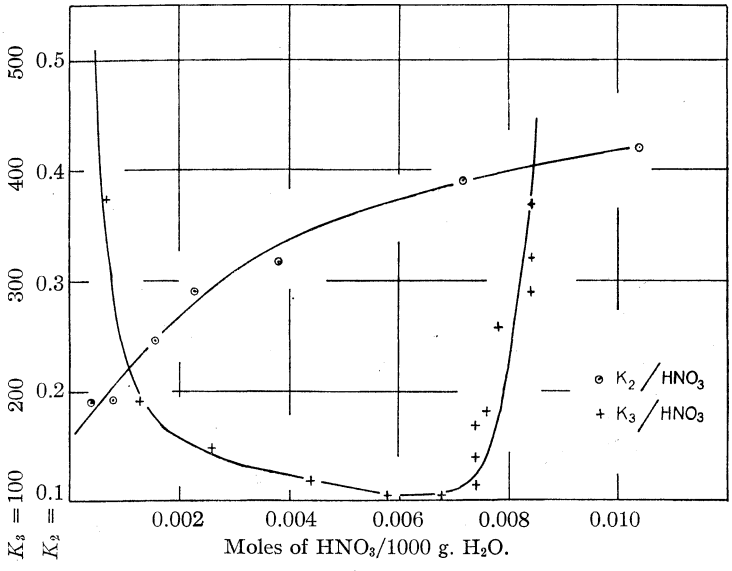

Fig. 2.

The values of K_2 and K_3 were first determined by assuming as first approximation that reactions (2) and (3) proceed to the same extent; the acid concentrations were corrected for the amount used in the reactions with HgO; K_2 and K_3 were then evaluated by solution of simultaneous equations (using equation 6). This procedure was repeated until constant values of K_2 and K_3 were obtained. As a critical test of this method, this whole procedure was again repeated on the assumption that reaction (2) was the only effective reaction and the value of the acidity was corrected accordingly. This method gave approximately the same values of K_2 and K_3 as the first procedure.

An indication of the limiting value of K_2 and K_3 was obtained by the independent calculation of K_2 and K_3 assuming, in the calculation of K_2, that reaction (3) did not take place, and, in the calculation of K_3, that reaction (2) did not take place. These values of K_2 and K_3 were then plotted against the concentration of acid (see Fig. 2). It is obvious that at low concentrations the ratio of K_2/m_{HNO_3} should be constant. Extrapolation of the K_2/m_{HNO_3} graph indicates a value of $K_2 > 0.1$ and < 0.2 at $m_{HNO_3} = 0$. This justifies the magnitude of the value of $K_2 = 0.17$ determined by the method of approximations described above. The value of K_3 could not be determined graphically as readily as that of K_2 due to an apparent theoretical buffering action occurring at approximately $m_{HNO_3} = 0.008$ (see Fig. 2). This graph does indicate the limits of acid concentration through which the value of K_2 and K_3 can be calculated reliably; furthermore, it suggests a limiting value in the magnitude of 100 for K_3 which is in agreement with the value of $K_3 = 53$ from the method of approximations. Additional information given by Fig. 2 is the fact that the drift in the values of K_2 and K_3 indicates clearly that neither reaction (2) alone nor reaction (3) alone is sufficient to account for the solubility of mercuric oxide in nitric acid. The alternative is that the dissociation of mercuric hydroxide must be a stepwise dissociation process; such a process was suggested by Kolthoff,[4] who observed from data in cell reactions that "Wanneer nu de dissociatie van het kwikhydroxyde totaal volgens folgende vergelijking plaats had: $Hg(OH)_2 = Hg^{++} + 2OH^-$, zou $[Hg^{++}] = {}^1/_2[OH^-]$ zijn.

"Uit de genoemde waarden blijkt daarentegen, dat $[Hg^{++}]$ veel kleiner is, en dat de dissociatie, die wel is waar zeer gering is, hoofdzakelijk a.v. plaats heeft: $Hg(OH)_2 = Hg(OH)^+ + OH^-$."

"If now the total dissociation of $Hg(OH)_2$ took place according to the following equation $Hg(OH)_2 \rightleftarrows Hg^{++} + 2OH^-$ then $[Hg^{++}]$ should be equal to ${}^1/_2(OH)^-$ but from the values given it is evident on the other hand that the Hg^{++} is much

(3) Abel, Redlich and Lengyel, *Z. physik. Chem.*, **132**, 189 (1928).

(4) Kolthoff, *Chem. Weekblad*, **14**, 1016 (1917).

smaller and that the dissociation, which is probably very small, takes place chiefly as follows

$$Hg(OH)_2 \rightleftharpoons Hg(OH)^+ + OH^-$$

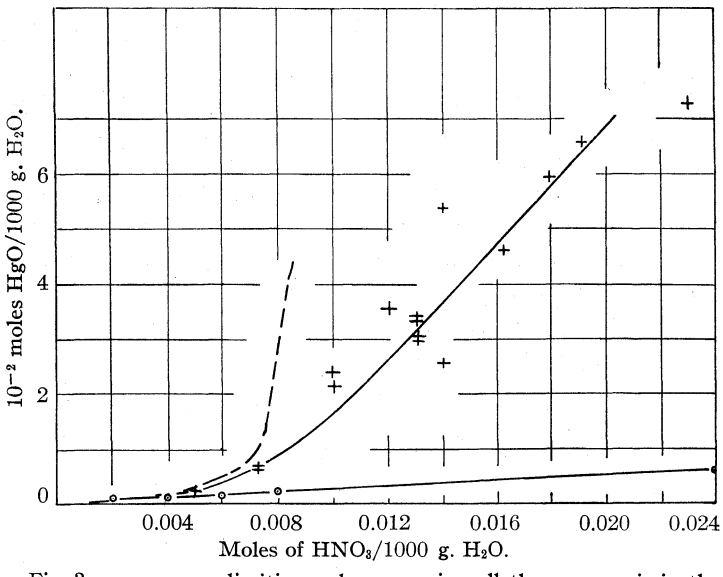

Fig. 3.— — — — , limiting value assuming all the mercury is in the form of Hg^{++} [see equation (3)]; +, glass electrode values; ⊙, values from concentration of standard acid with which the samples were made up.

Our method of treatment of the data, however, gives *direct* evidence of a stepwise dissociation process for bases. Figure 1 shows the agreement between the calculated values of nitric acid and those measured by means of the glass electrode. This graph also shows the limiting value of m_{HgO}/m_{HNO_3} assuming that all of the mercuric oxide may be in the form Hg^{++}. Figure 3 gives a similar comparison of this limiting value with that obtained by glass electrode measurements at higher concentrations. These graphs (Figs. 1 and 3) are direct evidence of the fact that mercuric hydroxide dissociates in a stepwise manner.

The calculated values of nitric acid (calculated from K_2 and K_3) show excellent agreement with the glass electrode values to m_{HNO_3} = 0.008 (see Fig. 1). Efforts to obtain values of K_2 and K_3 to fit the curve above this value were fruitless. This may be due to too small a value of K_3—however, a larger value of K_3 disturbed the agreement of the data at the low concentration where the limiting law would be most applicable. It may well be assumed that above $m_{HNO_3} = 0.008$ the solubility of the mercuric oxide becomes so high that the activity coefficient relationship[2] used to simplify the expression for K_3 is no longer valid; also the assumption that the ratio $\gamma_{H^+}/\gamma_{Hg(OH)^+} = 1$ may not be valid in this high solubility range. If, however, the lack of fit is due to an incorrect value of K_3, it can be observed here that the value of K_3 *could not* be greater than 100 nor less than 53. We believe the former reason is the more probable explanation.[5]

The values of K_2 and K_3 can be converted to the respective ion products and ionization constants by the use of the ion product of water and the value of $a_{Hg(OH)_2} = 2.4 \times 10^{-4}$ (see Ref. 1), and will give the following values for the reactions

$$Hg(OH)_2 \rightleftharpoons Hg(OH)^+ + OH^- \quad (4)$$
$$K_4 = a_{Hg(OH)^+} a_{OH^-} = 1.7 \times 10^{-15}$$

and

$$K_4' = \frac{a_{Hg(OH)^+} a_{OH^-}}{a_{Hg(OH)_2}} = 7.1 \times 10^{-12}$$

and

$$Hg(OH)_2 \rightleftharpoons Hg^{++} + 2OH^- \quad (5)$$
$$K_5 = a_{Hg^{++}} a_{OH^-}^2 = 5.3 \times 10^{-27}$$

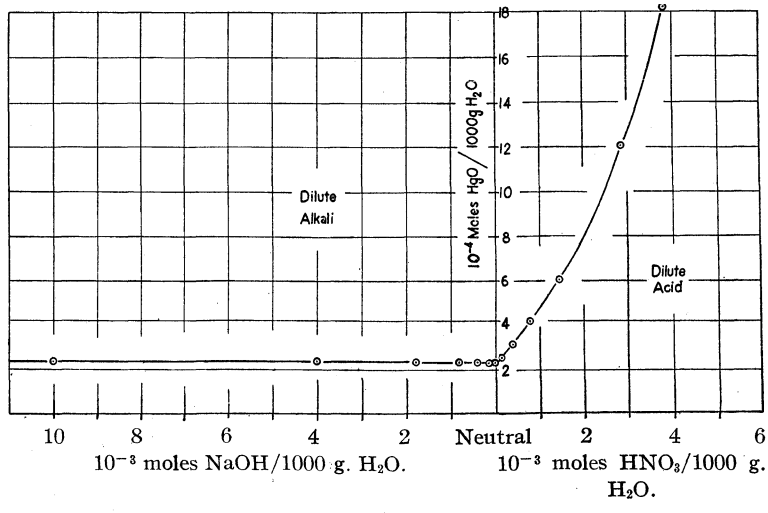

Fig. 4.

and

$$K_5' = \frac{a_{Hg^{++}} a_{OH^-}^2}{a_{Hg(OH)_2}} = 2.2 \times 10^{-23}$$

(5) Another possible explanation is that another equilibrium may be involved in addition to those considered here. This is possible due to the notoriously unpredictable characteristics of mercury compounds. The more probable explanation, however, lies in the uncertainty of the value of the activity coefficients.

The corresponding values calculated by Kolthoff at 18° are

$$K_4' = 5.35 \times 10^{-11}$$
$$K_5' = 7.38 \times 10^{-23}$$

An interesting fact with respect to mercuric oxide is that the position of minimum solubility appears to be that in water solution (see Fig. 4 which includes data given by Garrett and Hirschler[1]). This is to be expected since Kolthoff has indicated that the *p*H of water solutions of mercuric oxide at 18° is approximately 7.2. It is also to be observed that the value[1] of K_6 for the reaction

$$H_2HgO_2 \rightleftharpoons H^+ + HHgO_2^- \qquad (6)$$

is

$$K_6 = 1.4 \times 10^{-15}$$

and the ion product is 3.4×10^{-19}; while the value of K_4' for the reaction

$$Hg(OH)_2 = Hg(OH)^+ + OH^- \qquad (4)$$

is

$$K' = 7.1 \times 10^{-12}$$

and the ion product is 1.7×10^{-15}. The similar magnitude of K_4' and K_6 and of the ion products of these two reactions is further evidence of a nearly neutral hydroxide and therefore one which would be expected to give its minimum solubility at approximately *p*H = 7. In fact both the m_{H^+} and the m_{OH^-} contributed by the mercuric hydroxide are less than the concentration of these ions produced by water; however, the $m_{OH^-} > m_{H^+}$. This indicates the minimum solubility might be expected to be slightly on the basic side. These very low values of m_{H^+} and m_{OH^-} contributed by the dissociation of mercuric hydroxide serve to explain the fact that the conductivity of aqueous solutions of mercuric oxide is about that of the solvent itself.

The character of the solid phase was established by analysis for the nitrate ion and for the mercury content, respectively. This was particularly necessary at the high acid concentration where one might expect basic salt formation. The solid phase was separated from the mother liquor by filtration; it was washed quickly in the filter crucible with two small portions of water to remove adsorbed nitric acid and analyzed with standard potassium iodide solution. All samples except one analyzed to mercuric oxide and gave negative nitrate tests.

Summary

The solubility of mercuric oxide has been determined in nitric acid solutions ranging from 0.00005 to 0.16 molal. The constants for the dissociation of mercuric hydroxide have been evaluated from these data. The values of these constants are in good agreement with the fact that mercuric hydroxide solutions have a very low conductivity and give a *p*H value of approximately 7. They are also in agreement with similar constants obtained from e. m. f. measurements (Kolthoff). The data indicate that the minimum solubility is in water solutions, that mercuric hydroxide dissociates in a stepwise manner, and that the H^+ and OH^- contributed by mercuric hydroxide in water solution are less than those contributed by the solvent.

The Viscosity Function. II.[1] Viscosity and Constitution

BY ERNEST P. IRANY

The graphical method of analyzing viscosity data by means of functional viscosity scales has revealed a great number of general regularities in the dependency of viscosity on temperature, volume (ideal dilution) and pressure. One may reasonably expect some relation between viscosity and chemical constitution to be derivable by the same or analogous means.

However, before this can be attempted it is important to realize the difficulties arising from the uncertainty which still surrounds the concepts to be dealt with. We are not yet able to define the liquid state or to recognize the real meaning of constitution within it. Molecules, as described by their chemical formula, exist in gases but not in the crystal lattices of solid bodies; all that can be said about liquids is that their molecules must be in some intermediate condition: neither as mobile and independent as in gases nor as fixed and diffused as in solids. Precisely what

(1) The first paper on the subject appeared in THIS JOURNAL, **60**, 2106 (1938).

the physical units of liquid constitution are—single molecules, more or less permanent and more or less well-defined groups of molecules, or even some kind of organized structure—remains a matter of speculation.

Association, Intermolecular Forces.—When considering the existence in liquids of units composed of several molecules or molecular structures of some kind, strong binding forces must be assumed. The problem of viscosity now divides itself, for, should viscosity be correlated with the intensity of these intermolecular forces or with the association of molecular volumes which they may bring about? The forces as well as the volumes partake of constitution, whatever it be.

This distinction is very decisive for the approach to the problem of constitutional viscosity. Most modern authorities still prefer to connect viscosity with variously defined additive volumes or weights which are held to be a property of certain atoms or atomic groups. Often the disregard of the intermolecular forces is very explicitly stated.[2] However, as shown in the following, volume or weight association of the physical units does not as such provide a valid interpretation of constitutive viscosity.

Association Factors.—The paraffin hydrocarbons are known to be "non-polar" or "non-associated"—in their case the controversial aspects of constitution are absent. They are available in a very long and unbroken series of homologs and, as a matter of course, they are always chosen as the first objects of study in the verification of a new rule of constitutional additivity. It is mostly very easy to show regular increments in no matter what terms, but agreement usually fails as soon as the new formula is applied to other types of liquids which, presumably, are more "polar" or "associated." If the latter view is adhered to, agreement with facts may be enforced by specifying "association factors" which are supposed to denote a bodily enlargement of the molecular unit. These factors disagree widely, depending on their source; whether they possess real significance or whether they merely reflect the inadequacy of the original premises can only be decided by independent evidence.

Such proof can be found in the viscosity–temperature functions of polar as well as non-polar liquids of various types. If represented in the functional ϕ scale, all appear as perfectly straight lines. This accord in linearity can only mean that all liquids except some, such as the lower alcohols and fatty acids, are either non-associated or that their state of association is entirely independent of temperature. The suggested association factors are fractional numbers, indicating the liquids to be mixtures of several species of multiple molecular size; that such equilibria should be unaffected by large temperature changes is, however, barely conceivable. Hence: *The association factors as deduced from empirical rules of constitutionally additive viscosity are not real; most liquids are not associated and the rules thus amended are wrong.*

If, then, association of molecules does not suffice to explain liquid constitution in its relation to viscosity, the whole basis must be altered. The intermolecular forces must be included in the concept of constitution, without implying that they actually cause associative combinations. These forces, the resultants of equilibria within the molecules, cannot be computed—least of all as mere sums of some atomic constants. However, where variable association occurs, it can be recognized by the graphical method of functional scales; it reveals itself in deviations from linearity.

The Equation of the Liquid State.—The explicit mathematical or graphical statement of nature and physical behavior of a liquid would be its equation of state. Without argument on its exact form, it may be said that this basic function correlates the three variables of condition—volume, pressure and temperature; it must contain general constants and also various specific material constants—parameters in which the nature of the substance, in other words, its constitutive elements, are expressed. Among the latter the regularities must be detected which govern viscosity.

The three viscosity functions (that of volume (dilution), that of temperature and that of pressure) are, in combination, a complete expression of the equation of state in parameter form. The functional scales employed in the graphical method of generalization are common to all normal liquids and, hence, embody the general constants of the equation of state; the individually descriptive constants must appear as intercepts or gradients of the straight lines which record and distinguish the function of each substance. The

(2) Bingham, "Fluidity and Plasticity," 1922, p. 148, etc.; McLeod, *Trans. Faraday Soc.*, **21**, 151 (1925); Staudinger and Heuer, *Ber.*, **63**, 222 (1930).

question now arises as to how many of these constitutive elements of viscosity are necessary and sufficient.

Number of Material Factors.—One given viscosity measurement determines one point in each of the three functional diagrams; in order to determine a line, another point must be given in each figure—which brings the total to four (Fig. 1). However, two of the functional scales—that of ideal mixture (volume) and that of temperature—are identical; in other words, volume and temperature are of the same relevance with respect to constitution. (The temperature function may be considered a special case of dilution, *i. e.*, with a solvent of no viscosity or a void.) Accordingly, the number of independent constitutional factors reduces from four to three.

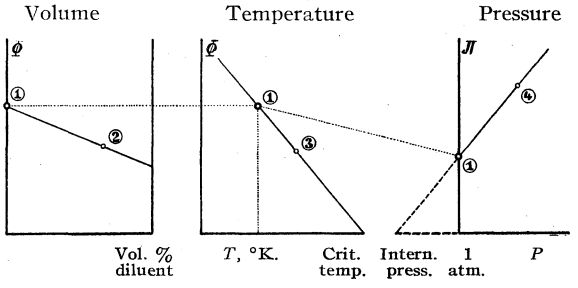

Fig. 1.—Constitutive parameters of the viscosity functions.

The viscosity of liquids is not appreciably affected by pressures of several atmospheres. It is entirely correct to assume that, ordinarily, viscosity measurements are compared under strictly "corresponding" conditions with regard to pressure—at the external pressure nil. This dispenses with another material constant, leaving only two. Further simplification is not possible. Hence: *No rule of constitutive viscosity can be generally valid unless it postulates two independent parameters of different computation.*

To recognize the necessity of two constitutional constants is one step, but to define them in such a way that they become additive in terms of atomic values is another, far more difficult one, which cannot be attempted here. This problem is most complex with the most simple chemical compounds because among them every structural difference is large enough to obscure all physical relationship. Additive increments can only be expected in certain series of homologous substances in which the intermolecular forces are either negligible or constant for all members: for example, (a) homologous series of non-polar substances, (b) polymer-homologous series of substances which are composed of a large and variable number of identical polar groupings.

The former are represented by the normal paraffin hydrocarbons, the latter by various polyvinyl derivatives. In both cases one of the two constitutive parameters becomes a serial constant; the other is, therefore, uniquely descriptive of the individual member and additive in any terms of structure, such as molecular volume, molecular weight, number of constituent groupings, degree of polymerization—all of which become synonymous. It must be kept in mind, however, that this final simplification applies only within series of the above description; the absence of this limitation is the common error which invalidates the numerous single-parameter rules of additive viscosity and the supplementary association factors.

Paraffin Hydrocarbons.—If the viscosities are plotted in ϕ scale against reduced absolute temperatures, T/Θ,[1] (Fig. 9) the lines of the members of this series coincide almost completely. Hence, $\phi = CT/\Theta$, where C is a serial constant, and Θ, the critical temperature, appears as the constitutive parameter. The problem resolves to that of the critical temperature and its additivity; reversely, the critical temperature of a hydrocarbon can be computed from a single viscosity measurement. That the whole series—though not absolutely "non-polar"—is distinguished by very weak intermolecular forces which are the same for each member, can be proved in the functional viscosity–pressure diagram (II scale); the extrapolated internal pressures have a constant value of about 1200 kg./cm.^{2} (Fig. 11[1]).

Polymer Homologs.—Since most of these substances are high-molecular colloids, the distinction by critical temperatures is meaningless; the constitutive parameters must be defined

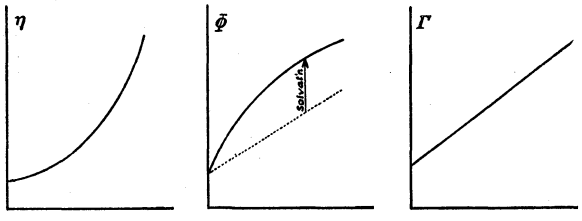

Fig. 2.—Polyvinyl acetate solution.

through the viscosity–concentration function of solutions. The series of polyvinyl acetates may serve as an example.

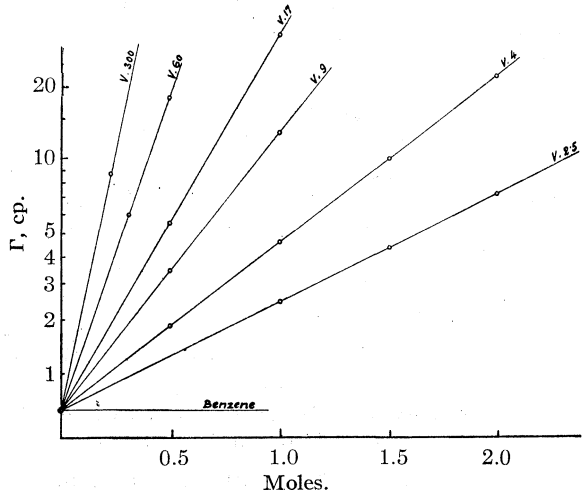

Fig. 3.—Polyvinyl acetates, benzene solutions.

If the viscosities of polyvinyl acetate solutions are plotted in ϕ scale against concentration, no straight lines appear, but curves whose trend indicates strong associative or solvating effects between solute and solvents of various description (Fig. 2). Since all polyvinyl acetates consist of regularly repeated identical groupings, the disposition of their intermolecular forces must be the same and characteristic of the whole series. The polar effects which cause the deviations from linearity in the ϕ scale diagram can, therefore, be expressed as a single serial constant which may be incorporated into the viscosity scale. This can be done by the same graphical method as that applied in the construction of the ϕ scale itself (Fig. 2[1]), except that in the present case not an "ideal" mixture but, specifically, a polyvinyl acetate solution is used as a standard. The resulting viscosity scale Γ embodies the serial polarity as well as the concentration effects of *all* polyvinyl acetates in a given solvent, *e. g.*, benzene (Fig. 3). The lines shown in the diagram are perfectly straight and differ only in their gradients; the latter represent the individual constitutive parameter—the degree of polymerization.[3]

Analogous viscosity scales can be constructed for other solvents, such as ethyl acetate, butyl acetate, pyridine, dioxane, chloroform, tetrachloroethane, acetic acid. In each case accurate linearity for polyvinyl acetates of every degree of polymerization is obtained. These scales are, by precept, specific for each solvent. However, it is most significant that, actually, a majority of them have been found one and the same. It must be concluded that all solvents of this group induce the same state of solvation, that they respond to a certain normal polarity of the solute, revealing a characteristic regularity in the associative tendencies of polyvinyl acetates.

If the gradients of the lines in the various diagrams represent, as concluded, the respective degrees of polymerization, they should appear in proportions fixed by the nature of the samples. That this is true with the greatest precision is

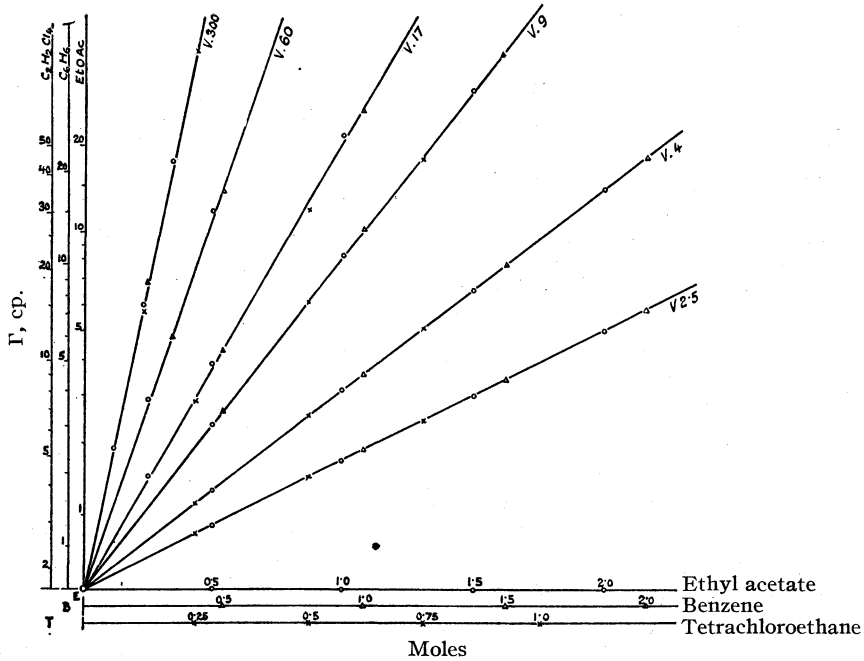

Fig. 4.—Polyvinyl acetates (Gelva).

(3) Polyvinyl acetates ("Gelva," manufactured by Shawinigan Chemicals, Ltd.) are mixtures of high and low polymers over a wide range. The mean degree of polymerization is indicated in the figures by "V ..." which is the viscosity of the sample in one-molar (86 g./l.) benzene solution at 20°.

shown in Fig. 4, where the viscosities of one specimen ("V.4") in three solvents, *viz.*, ethyl acetate, benzene and tetrachloroethane, are plotted on the same straight line. The origin of this line represents the viscosities of the respective pure solvents, and the scales are adjusted accordingly. As a result, the lines of the three solutions of each sample coincide; the complete Γ diagrams of ethyl acetate, benzene and tetrachloroethane solutions of polyvinyl acetates register exactly when superimposed. Hence, the gradients are independent of the solvent but descriptive of the solute.

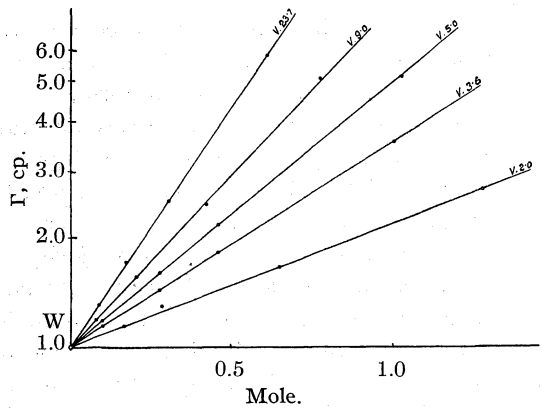

Fig. 5.—Polyvinyl alcohols in water.

That the same regularities exist in the solutions of all true polymer homologs can be shown by many other examples, such as the water-soluble polyvinyl alcohols (Fig. 5),[4] the polyisobutylenes (Fig. 6),[5] various cellulose derivatives (Fig. 7). All these substances give linear concentration functions in their own characteristic viscosity scales which compensate for association and solvation effects common to all members. In some series these effects are absent; they, therefore, appear linear in the ideal ϕ scale. Examples of these are indene resins, toluene sulfonamide resins, colophony, chlorinated diphenyl resins, etc. (Fig. 8). In order to illustrate the deviations of the specific Γ scales from ideality, an ideal mixture is plotted in the diagrams which appears strongly curved in all cases except Fig. 8.

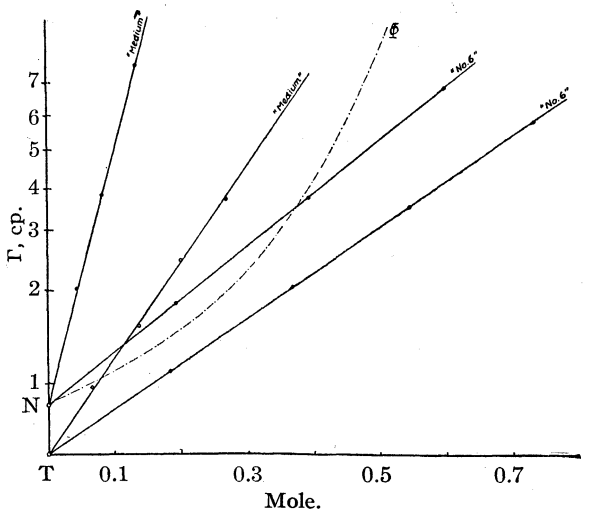

Fig. 6.—Poly-butylenes ("Vistanex") in V. M. naphtha (N) and in toluene (T).

Molecular Weights.—That the gradients of the lines in the Γ diagrams appear in the proportions of the molecular weights of the solutes can be made clear by analogy to Staudinger's "viscosity law."[6] The latter is based upon a formula by Einstein[7] which expresses the viscous resistance in an ideal case—that of spherical, rigid and non-polar particles dispersed in a viscous liquid—but without assumption of mutual attractions. Because of the disregard of the latter, the formula is not applicable to real solutions, but under

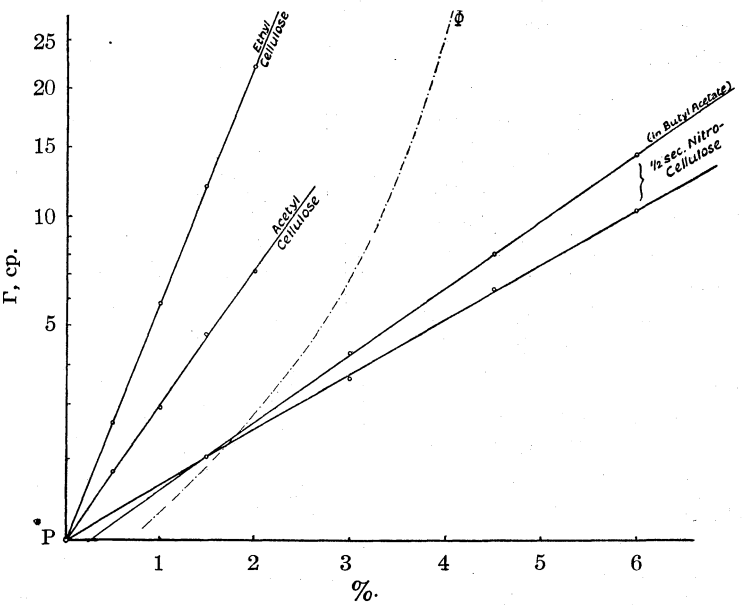

Fig. 7.—Cellulose derivatives in pyridine.

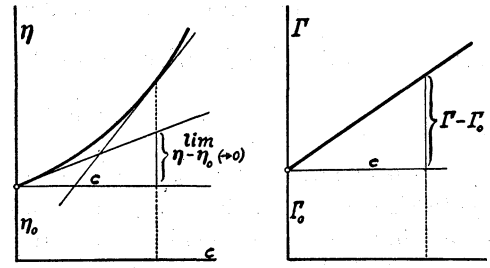
(4) "Solvar" (Shawinigan Chemicals, Ltd.).
(5) "Vistanex" (Advance Solvents & Chemical Corp.).
(6) Staudinger, "Die hochmolekularen Verbindungen," Verlag J. Springer, Berlin, 1932.
(7) Einstein, *Ann. Physik*, **19**, 289 (1906).

the limitation of minimum concentration, Staudinger transformed it into

$$\eta_{sp} = \lim_{c=0} \frac{\eta - \eta_0}{\eta_0} = K_m Mc \qquad \lim_{c=0} \frac{\eta - \eta_0}{c} = (\eta_0 K_m) M$$

where η_{sp} is termed "specific viscosity," K_m is a constant valid for a given polymer-homologous series in a given solvent, M the molecular weight and c the concentration.

In a diagram where absolute viscosity is plotted against concentration, the term $(\eta - \eta_0)/c$ appears as the gradient of the curve in the vicinity of the origin (Fig. 9). The same figure, drawn in Γ parallel to the viscosity axis, the intercepts on it are in proportion of the molecular weights of the solutes, or, more correctly, their individual constitutive parameters which may be expressed equally well in terms of molecular weights, volumes, chain lengths, number of constituent units, etc.



Staudinger's law. Gamma function.

Fig. 9.—Molecular weight of polymer homologs.

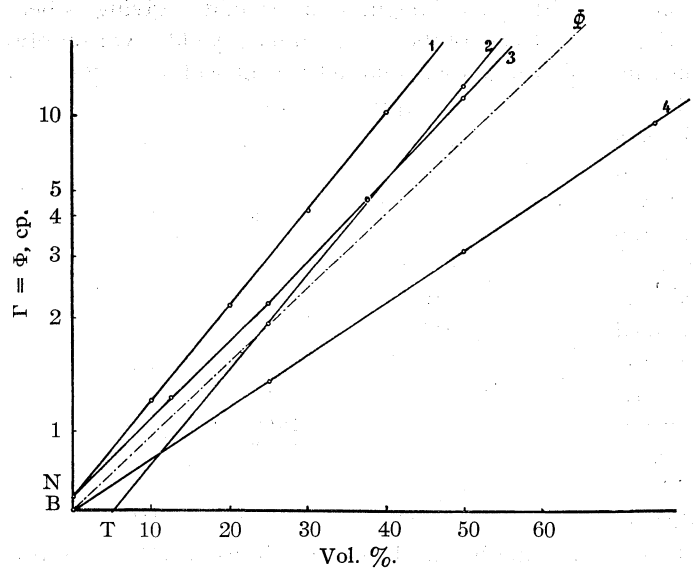


Fig. 8.—No solvation: 1, indene resin (Nevindene) in butyl acetate; 2, toluene sulfonamide resin (Santolite MHP) in toluene; 3, rosin in butyl acetate; 4, chlorinated diphenyl (Aroclor) in V. M. naphtha.

scale, represents the curve as a straight line of constant gradient; there is no need to limit the rule to low concentrations. Accepting the reasoning that led from Einstein's formula to that of Staudinger as substantially correct, the substitution of Γ for η would, according to definition, compensate for the effects of intermolecular forces at *any* concentration

$$\Gamma_{sp} = \frac{\Gamma - \Gamma_0}{\Gamma_0} = K_m Mc$$

Γ_{sp}/c, now to be termed "specific viscosity function," is the gradient of the straight line in the Γ diagram. In other words, if a line is drawn

Summary

Graphical analysis of viscosity data shows that most pure chemical compounds are unassociated in the liquid state. The association factors which, while derived from empirical rules of constitutionally additive viscosity, are necessary to uphold their validity, have no meaning.

It can be proved that the general viscosity function contains not less than two independent constitutive parameters. It therefore appears impossible to specify single atomic constants supposed to be additive in terms of viscosity.

The best approach to the problem is not through the study of the most simple chemical compounds, but that of truly polymer-homologous series of high-molecular substances. In the latter case, one parameter, expressing the polar character common to all members of the series, is constant and the second parameter becomes constitutionally additive. This has been proved by graphical evidence on various such series.

The method of analysis is an extension of the principle of the functional viscosity scales reported in a preceding paper to which reference is made.

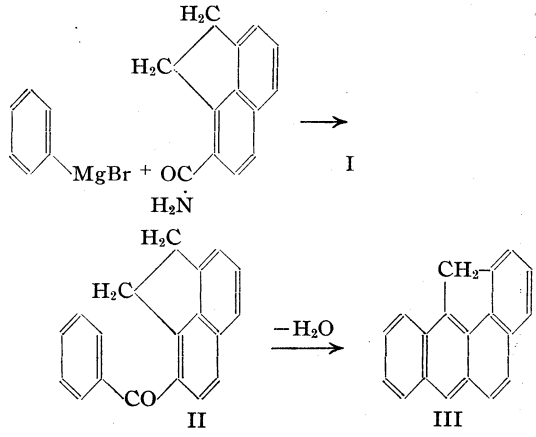
Synthesis of 1′,9-Methylene-1,2-benzanthracene and Related Hydrocarbons

BY LOUIS F. FIESER AND JAMES CASON[1]

It seemed of interest for a number of reasons to synthesize 1′,9-methylene-1,2-benzanthracene (III) and investigate its chemical properties and possible biological actions. Like the as yet unknown[2] 1′,9-dimethyl compound, the hydrocarbon may constitute a simplified model of the highly reactive and powerfully carcinogenic 3,4-benzpyrene, and the presence of a methylene group at the meso position 9 may confer upon the substance some of the special properties of the cholanthrenes[3] or of 8,9-dimethylene-1,2-benzanthracene.[4] It is also interesting to learn whether the 1′,9-methylene derivative, considered as a simple alkylated 1,2-benzanthracene, is associated in biological properties with the moderately carcinogenic[3] 9-methyl compound[5] or with the inactive[3] 1′-methyl derivative.[2,6] While 1′,9-methylene-1,2,5,6-dibenzanthracene[7] gives a moderate yield of tumors in mice only after a very extended induction period,[3] the relationship between the inactive 9,10-dimethyl-1,2,5,6-dibenzanthracene[8] and the highly potent 9,10-dimethyl-1,2-benzanthracene[9] suggests that the simpler 1′,9-methylene compound is well worthy of investigation.

One possible route to the desired hydrocarbon involved the synthesis and pyrolysis of 1-benzoylacenaphthene (II). A small quantity of this ketone was obtained in preliminary work by M. E. Gross from 3-acenaphthylmagnesium iodide and benzonitrile, but this route was temporarily abandoned because of the difficulty of obtaining adequate quantities of the required 3-iodoacenaphthene from the rather inaccessible 3-nitro compound (literature, ref. 7). The situation is considerably altered, however, by the recent observation that 3-acetoacenaphthene can be prepared very easily by the acetylation of the hydrocarbon in the presence of anhydrous hydrogen fluoride.[10] In a large-scale preparation the yield of satisfactory 3-isomer was 29%, and the hypohalite oxidation to 3-acenaphthoic acid proceeded very smoothly. In one trial the Friedel and Crafts condensation of the acid chloride with benzene took an abnormal course and gave a sparingly soluble yellow product. The amide (I), obtainable from the acid with little loss, condensed very smoothly if slowly with phenylmagnesium bromide, giving 1-benzoylacenaphthene (II) in 95% yield. On pyrolysis the ketone suffered loss of water at 425° and



1′,9-methylene-1,2-benzanthracene (III) was isolated in a satisfactory condition in 13% yield. The Elbs reaction proceeds about as expected, the difficulty of ring closure into a benzenoid nucleus being offset by the favorable utilization of a methylene group of an alicyclic ring. The hydrocarbon (m. p. 123°) has a faint greenish-yellow color which was retained on purification through the picrate, by chromatographic adsorption, and treatment with maleic anhydride. Like methylcholanthrene and 3,4-benzpyrene, and in contrast to 1′,9-methylene-1,2,5,6-dibenzanthracene, it couples rapidly (deep color in five minutes) with *p*-nitrobenzenediazonium chloride in acetic acid solution.[11] The hydrocarbon is attacked rather readily by lead tetraacetate and apparently is converted into a mixture of products. The condensation with methylformanilide was tried with unpromising results, for at 0° a part of the material was recovered unchanged and a part converted into tars.

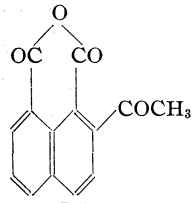
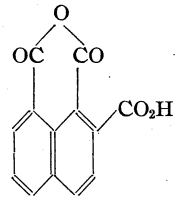
In preparing the starting material some further study was made of the reaction between acenaphthene and acetic acid in the presence of hydrogen fluoride. The yield and the ratio of isomers was the same when acetyl chloride was used in place of the free acid. It was ascertained also that neither 1- nor 3-acetoacenaphthene suffers rearrangement under the conditions of the acylation. 3-Acetoacenaphthene picrate was found to exist in two polymorphic forms of the same melting point, one separating as orange prisms and the other appearing as yellow needles. 1-Acetoacenaphthene was converted into two new reference compounds of the naphthalene series. Oxidation with sodium dichromate in acetic acid solution gave 2-aceto-1,8-naphthalic anhydride (IV), and



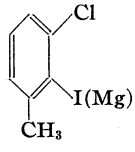
IV



V

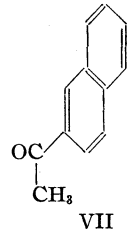
oxidation of 1-acenaphthoic acid by the same method gave 2-carboxy-1,8-naphthalic anhydride (V).

Some further synthetic experiments may be reported. A satisfactory procedure was worked out for the preparation of 2-iodo-3-chlorotoluene (VI) from 2-iodo-3-nitrotoluene and attempts were made to condense the Grignard reagent from the dihalide with β-acetonaphthalene, in the hope of



VI

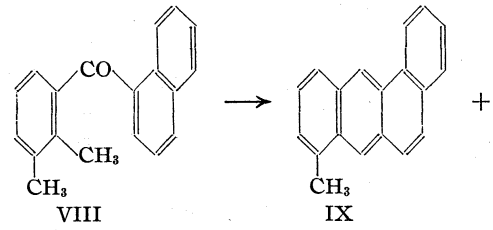
+



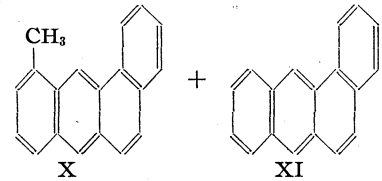
VII

obtaining a ketone which might be convertible into 5,10-dimethyl-1,2-benzanthracene[12] by the synthetic method employed for the 3,9-isomer.[13] The reaction proceeded very poorly and the small amount of product obtained after dehydration contained considerably less than the expected amount of chlorine and could not be hydrogenated. Condensation with β-naphthonitrile also gave poor results, and the difficulty is thus attributable to the hindered character of the more reactive halogen substituent, and perhaps to the opportunity for some interaction with the *o*-chloro atom.

As a possible route to the known 5-methyl-1,2-benzanthracene,[12,14,15,16] *vic.*-*o*-xylyl α-naphthyl ketone (VIII) was synthesized from *vic.*-cyano-*o*-xylene and α-naphthylmagnesium bromide and submitted to pyrolysis at 425–430°. There was

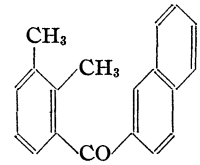


VIII IX

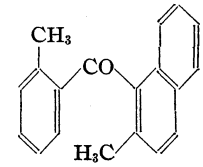


X XI

obtained a mixture of hydrocarbons found to contain the 5-methyl compound IX, the 8-methyl isomer[17] X, and 1,2-benzanthracene (XI). The formation of 8-methyl-1,2-benzanthracene evidently is the result of a rearrangement, presumably involving the migration of the xyloyl group of the ketone VIII from the α- to the β-position in the naphthalene nucleus, as postulated for the formation of 1,2,5,6-dibenzanthracene on pyrolysis of 1-(α-naphthoyl)-2-methylnaphthalene.[18] The isomeric *vic.*-*o*-xylyl β-naphthyl ketone (XII) was prepared for comparison and pyrolyzed.



XII



XIII

The hydrocarbon mixture resulting in fairly good yield was found to consist in large part of 8-methyl-1,2-benzanthracene, identified as the quinone, and no 1,2-benzanthracene was noted. Because of the difficulty of isolating a pure product from the mixture, this is not a practical preparative method. The observation that a methyl group is in part retained at position 8 is of interest because of the contrasting result obtained by

Cook[18] on pyrolysis of 1-*o*-toluyl-2-methylnaphthalene (XIII). With this ketone, where ring closure involved condensation into a benzenoid nucleus, the sole product was 1,2-benzanthracene. With the isomer XII, in which the more reactive naphthalene nucleus is involved in the cyclization, the pyrolysis proceeds more smoothly, for the second methyl group is largely retained. This is in line with the high yield of 1,2-benzanthracene from *o*-tolyl β-naphthyl ketone,[19] in contrast to the low yield from the isomeric 1-benzoyl-2-methylnaphthalene.[20] The observation that methyl groups in the α-positions 5 and 8 of the benzanthracene system withstand to some extent the drastic conditions of the Elbs reaction substantiates previous comments[21] on the subject.

Experimental Part[22]

1-Acetoacenaphthene was prepared as described[10] from 154 g. of powdered acenaphthene, 65 g. of acetic acid, and 750 g. of anhydrous hydrogen fluoride, allowed to stand in a copper flask for forty-eight hours with occasional stirring. After adding soda solution and benzene, filtering, separating the green benzene layer and distilling, there was obtained 182 g. of total ketone, b. p. 193–195° at 8 mm. Successive crystallizations of the top fraction from 400 cc., 500 cc., and 650 cc. of methanol gave 53 g. of the 1-isomer, m. p. 104–105°, and 4.5 g. more of the pure material was obtained from the final mother liquor; yield 29%.

When acetyl chloride (added slowly) was used in place of acetic acid neither the total yield nor the ratio of isomers was affected. To test the stability of the ketone under the conditions of the acylation, 5 g. of 1-acetoacenaphthene was treated with 200 g. of anhydrous hydrogen fluoride and the solution allowed to stand for forty-two hours. The recovered and distilled product on crystallization from methanol gave 4 g. of starting material, m. p. 104.5–105°, and 0.6 g. of the corresponding picrate, m. p. 114–114.5°, was obtained from the mother liquor.

The picrate crystallized from methanol as light yellow needles, m. p. 114.5–115°.

Anal. Calcd. for $C_{20}H_{15}O_8N_3$: N, 9.88. Found: N, 9.97.

The trinitrobenzene derivative, which is considerably less soluble, formed bright yellow plates from alcohol, m. p. 113.5–114°.

Anal. Calcd. for $C_{20}H_{15}O_7N_3$: N, 10.27. Found: N, 10.12.

3-Acetoacenaphthene was separated as the picrate from the mother liquors from the first two crystallizations of the 1-isomer. After several crystallizations from methanol a total of 39 g. of satisfactory product, m. p. 97–97.5°, was collected. Treated with ammonia, this afforded 16 g. of 3-acetoacenaphthene, m. p. 69–69.5°; after melting and freezing several times the polymorphic form, m. p. 56.5–57.5°, was obtained. The 3-ketone (5 g.) was recovered unchanged (4 g., m. p. 69.2–69.6°) after standing for forty-two hours in hydrogen fluoride solution.

The picrate was found to exist both in the orange-prism form previously described[10] and in the form of long, fine, yellow needles of the same m. p. If the yellow modification is introduced to a bath preheated to 93° it melts at once, but when heated gradually the m. p. is 97–97.5°. The orange picrate separates as cubic or elongated prisms when crystallization occurs at or above room temperature, while the **yellow picrate** crystallizes from a colder, more dilute solution. The transition temperature seems to be about 20–25°. If the temperature is lowered after the orange form has started to separate, yellow needles are deposited from the same solution. The picrates are interconvertible and yield the same ketone.

Anal. (yellow picrate). Calcd. for $C_{20}H_{15}O_8N_3$: N, 9.88. Found: N, 9.75.

2-Aceto-1,8-naphthalic Anhydride (IV).—A mixture of 1 g. of 1-acetoacenaphthene and 8 g. of sodium dichromate in 20 cc. of acetic acid was heated at 55–65° for one hour, boiled for three minutes, and poured (cold) into 100 cc. of water. The tan precipitate was crystallized twice from acetic acid containing a few drops of acetic anhydride (Norite), giving 90 mg. of almost colorless, diamond-shaped plates of the constant m. p. 219–219.3°.

Anal. Calcd. for $C_{14}H_8O_4$: C, 70.00; H, 3.38. Found: C, 69.86; H, 3.54.

1-Acenaphthoic Acid.[10]—A stirred solution of 15 g. of 1-acetoacenaphthene in 300 cc. of dioxane (purified with sodium) was treated in the course of twenty minutes with a hypochlorite solution[23] from 48 g. of HTH, 34 g. of potassium carbonate, 9.6 g. of potassium hydroxide, and 300 cc. of water. After an initial exothermic reaction (to 75°), the temperature was maintained at 60° with stirring for one-half hour (one hour for a 50-g. run). Excess reagent was destroyed with bisulfite, the solution was cooled, diluted with 1 l. of water, filtered from a slight sediment, and acidified. The precipitate was coagulated by boiling, collected and washed; yield, 14.5 g. (95.5%), m. p. 254–256°. No further purification is required for the following reactions.

2-Carboxy-1,8-naphthalic Anhydride (V).—To a solution of 1 g. of 1-acenaphthoic acid in 30 cc. of acetic acid at 90°, 6 g. of sodium dichromate was added gradually at such a rate as to maintain a temperature of 90–95°. After forty minutes at this temperature and boiling for five minutes the solution was poured into 100 cc. of water containing 10 cc. of concentrated hydrochloric acid. After boiling for a few minutes and cooling, the product slowly separated as light yellow crystals (260 mg.). Two crystallizations from acetic acid containing a little acetic anhydride gave colorless plates melting constantly at 297.5–298.5°.

Anal. Calcd. for $C_{13}H_6O_5$: C, 64.46; H, 2.48. Found: C, 64.48; H, 2.65.

The methyl ester, prepared with diazomethane in ether

suspension, crystallized from acetic acid–anhydride as small, nearly colorless plates, m. p. 191–192°.

Anal. Calcd. for $C_{14}H_8O_5$: C, 65.63; H, 3.15. Found: C, 65.80; H, 3.29.

1-Acenaphthoyl Chloride.—The precipitated acid (1 g.) was refluxed with purified thionyl chloride (2 cc.) for two hours, the excess reagent evaporated at reduced pressure, and the solidified residue crystallized from benzene–ligroin (Norite). This gave tan needles, m. p. 109.5–110.5°; yield 0.85 g. (82%). A recrystallized sample melted at 110–111°.

Anal. Calcd. for $C_{13}H_9OCl$: C, 72.02; H, 4.20. Found: C, 71.85; H, 4.40.

When a good grade of commercial thionyl chloride was used without purification with quinoline and linseed oil, both the acid chloride and the amide obtained from it contained impurities which persisted after numerous crystallizations.

On treatment of the acid chloride (3.8 g.) in benzene (30 cc.) with aluminum chloride (2.9 g.) at the refluxing temperature there was obtained a yellow substance which is not altered by prolonged boiling with dilute acid, is sparingly soluble in organic solvents, decomposes above 200°, and leaves an ash on ignition.

1-Acenaphthamide.—The crude acid chloride from 12 g. of 1-acenaphthoic acid was dissolved in 150 cc. of warm dioxane and the solution was added rapidly to 120 cc. of well-stirred, cold, concentrated aqueous ammonia solution. After thirty minutes 500 cc. of water was added, and after stirring for fifteen minutes longer the precipitated amide was collected. The yield of light tan powder melting at 219–222° and suitable for the Grignard reaction was 12 g. (quantitative). A sample recrystallized from alcohol formed colorless, short needles, m. p. 227–228° (constant).

Anal. Calcd. for $C_{13}H_{11}ON$: N, 7.11. Found: N, 6.96.

1-Benzoylacenaphthene.—Ten grams of the solid, precipitated amide was added to the Grignard reagent from 5.1 g. of magnesium and 32 g. of bromobenzene in 200 cc. of ether and the mixture was refluxed with stirring for seventy-two hours. The complex, which separated as a solid, was decomposed with ice (50 g.) and concentrated hydrochloric acid (25 cc.), giving the ketimine hydrochloride as a light yellow solid insoluble in either the water or ether layer. The ether was evaporated and after adding 35 cc. each of concentrated hydrochloric acid, glacial acetic acid and toluene the mixture was refluxed two hours for hydrolysis. The toluene layer was separated, washed with water and bicarbonate solution, dried and distilled. The ketone distilled as a light yellow oil, b. p. 210–215° at 1 mm., which crystallized at once on cooling. The yield of distilled material suitable for pyrolysis was 12.4 g. (95%). A sample crystallized for analysis from methanol formed colorless needles, m. p. 91.5–92°.

Anal. Calcd. for $C_{19}H_{14}O_4$: C, 88.34; H, 5.46. Found: C, 88.02; H, 5.48.

The ketone was also prepared by M. E. Gross starting with 1-nitroacenaphthene (19.8% yield in the nitration), through the amine (88%) and iodide (yield about 45%, in two experiments the material completely decomposed on vacuum distillation). The condensation of benzonitrile with the lithium derivative was tried without success; with the Grignard reagent the yield of distilled ketone was 15%. A purified sample melted at 93–94°, uncorr. (found: C, 88.23; H, 5.32).

1′,9-Methylene-1,2-benzanthracene.—A 9.9-g. charge of distilled 1-benzoylacenaphthene was heated in a bath at 420–425° for forty minutes and the hydrocarbon distilled at 1 mm. and a bath temperature of 250–350°. The solidified distillate was dissolved in 100 cc. of alcohol, 3.5 g. of picric acid was added, and after concentrating to a volume of about 50 cc. there separated on slow cooling 2.75 g. of dark red picrate. A solution of this in 40 cc. of benzene was put through a tower of alumina and the hydrocarbon, which showed a bright blue fluorescence in ultraviolet light, was washed through until a lighter blue fluorescent zone reached the bottom of the tower. The benzene was evaporated and the hydrocarbon was crystallized from 50 cc. of alcohol, giving light yellow plates, m. p. 121.5–122°; yield, 1.2 g. (12.9%). After three further crystallizations the hydrocarbon (0.85 g.) melted at 122.5–123°; a sample which had been crystallized repeatedly as the trinitrobenzene derivative melted at 122.7–123.1°. The purified material (plates) has a faint fluorescent greenish-yellow color not removed by purification as above, crystallization of the picrate, chromatographic adsorption, or treatment with maleic anhydride.

Anal. Calcd. for $C_{19}H_{12}$: C, 94.96; H, 5.04. Found: C, 94.92; H, 5.08.

The **picrate** crystallizes from alcohol in the presence of excess picric acid as dark red needles, m. p. 141.5–142°.

Anal. Calcd. for $C_{25}H_{15}O_7N_3$: N, 8.95. Found: N, 8.51.

The **trinitrobenzene derivative** separates from alcohol in bright orange needles, m. p. 162.5–163°.

Anal. Calcd. for $C_{25}H_{15}O_6N_3$: N, 9.27. Found: N, 9.21.

2-Iodo-3-chlorotoluene.—**2-Iodo-*m*-toluidine** was prepared by the hydrogenation of 2-iodo-3-nitrotoluene (30 g.) in acetic acid (100 cc.) in the presence of Adams catalyst (0.3 g.), absorption being complete in ten hours. The filtered solution was treated with 20 cc. of 12 *N* sulfuric acid and 1 l. of ether and the precipitated salt collected (35.5 g., 94%). For conversion to the amine this salt was dissolved by warming in 400 cc. of water containing 4 cc. of 12 *N* sulfuric acid, the solution was filtered from a little dark material (colorless filtrate), and neutralized carefully at 0° with cold ammonium hydroxide. The amine separated in a colorless, crystalline condition, m. p. 40–40.6° (compare 41–42°[24]); yield 21.7 g. (82% from the nitro compound).

For conversion to the iodochlorotoluene it is best to omit isolation of the amine or its salt. The acetic acid solution from the hydrogenation of 20 g. of the nitro compound was diluted with 290 cc. of water and 58 cc. of concentrated hydrochloric acid and cooled to −5° with stirring. To the resulting suspension of the hydrochloride a cooled solution of 6.3 g. of sodium nitrite in 35 cc. of water was added all at once. After stirring for thirty

(24) Wheeler and Liddle, *Am. Chem. J.*, **42**, 452 (1909).

minutes below 0°, 10 g. of urea was added; after twenty minutes more the cold (unfiltered) solution was added to a stirred solution of 9.1 g. of cuprous chloride in 43 cc. of concentrated hydrochloric acid and 11 cc. of water. The complex began to decompose at once, and a dark oil began to separate. After stirring for one-half hour below 0° and for one hour longer after removal from the cooling bath, the mixture was steam distilled. The heavy oil, which distilled slowly, was extracted with ether, washed with alkali, acid, and water, dried and distilled. This gave a nearly colorless oil, b. p. 123–125° at 14 mm.; yield 14.3 g. (74.5%, from the nitro compound). The product solidified at about 24° and melted at 25.5–26.5°; recrystallized from methanol it formed colorless plates, m. p. 27.3–27.6°.

Anal. Calcd. for C_7H_6ClI: C, 33.28; H, 2.38. Found: C, 33.02; H, 2.64.

Long and Dains[25] report the preparation of the dihalide as a yellow oil which darkened on standing and solidified at −26°.

The dihalide formed a Grignard reagent readily, but no acid was obtained on attempted carbonation with solid carbon dioxide. From the reaction with β-acetonaphthalene there was obtained after dehydration a small yield (30%) of product which contained only about three-quarters of the expected amount of halogen and which could not be hydrogenated in the presence of Adams catalyst in acetic acid or, at high pressure, using copper chromite or Raney nickel. The reaction with β-naphthonitrile also gave a low yield (30%) of non-homogeneous oil.

***vic.*-Cyano-*o*-xylene.**—*vic.*-*o*-Xylidine was prepared (first experiments by T. G. Webber, Jr.) by reduction of the nitro compound with iron and water according to James, Snell and Weissberger,[26] but in better yield (91.5%; b. p. 98–100° at 11 mm., 118–119° at 25 mm.). Catalytic reduction also proceeded smoothly (92%) but was less convenient. The amine (20 g.) in water (140 cc.) and concentrated hydrochloric acid (54 cc.) was diazotized at −5° with sodium nitrite (13.7 g.) in water (85 cc.), the solution was neutralized with solid sodium carbonate, and the dark solution was added to a cold solution prepared from 29 g. of sodium cyanide and 20 g. of cuprous chloride in 130 cc. of water. A dark yellow complex separated and began to decompose on allowing the mixture to come to room temperature. After steam distillation the nitrile was extracted with ether, washed with alkali and water, dried and distilled, giving a colorless oil, b. p. 105–107° at 11 mm.; yield 8.6 g. (40%). Brunner, Hofer and Stein[27] obtained about the same yield by a different procedure.

***vic.*-*o*-Xylyl α-Naphthyl Ketone (VIII)** was prepared by adding 5.5 g. of *vic.*-cyano-*o*-xylene in 35 cc. of benzene to the reagent from 10.5 g. of α-bromonaphthalene and 1.3 g. of magnesium in 40 cc. of ether and 10 cc. of benzene. After most of the ether had been distilled, the mixture was refluxed with stirring overnight. After adding 40 g. of ice and 20 cc. of concentrated hydrochloric acid and removing the solvent with steam, 30 cc. more hydrochloric acid was added together with 30 cc. of acetic acid and 40 cc. of toluene. After refluxing for six hours the collected product distilled, after a fore-run containing naphthalene, as a viscous yellow oil, b. p. 190–195° at 1 mm.; yield 9.7 g. (89%). The ketone was not obtained crystalline.

Anal. Calcd. for $C_{19}H_{16}O$: C, 87.66; H, 6.19. Found: C, 88.24; H, 6.18.

Pyrolysis of VIII.—In one experiment 2.2 g. of *vic.*-*o*-xylyl α-naphthyl ketone was heated with 0.25 g. of zinc dust at 425–430° for two hours. Distillation at 1 mm. gave 1 g. of crystalline yellow solid, and after a prolonged process of fractionation of the hydrocarbon from alcohol and of its picrate from benzene–hexane there was obtained 10 mg. of **5-methyl-1,2-benzanthracene,** m. p. 154–156°. A mixture with a known sample[12] melted at 156–158°; there was a large depression on admixture with 1,2-benzanthracene.

In another experiment, conducted as above except that no zinc dust was used, there was isolated a small quantity of **1,2-benzanthracene,** m. p. 154–157°, mixed m. p. 155–157°. A picrate fraction (1 g., m. p. 153–154°) which had been crystallized repeatedly from alcohol and then put through an adsorption tower in benzene gave a hydrocarbon mixture melting below 125° and apparently containing 8-methyl-1,2-benzanthracene. Since a pure product could not be isolated, the material was oxidized to the quinone as described by Fieser and Johnson.[17a] The yellow zone in the tower was eluted with benzene–methanol, and the material was fractionally crystallized from acetone. One fraction was obtained as long, light yellow needles of **8-methyl-1,2-benzanthraquinone,** m. p. 194.5–196°, mixed m. p. 195–196° (sample, ref. 17a). Another small fraction formed fluffy yellow needles, m. p. 171–172.5°, and probably was 5-methyl-1,2-benzanthraquinone.

***vic.*-*o*-Xylyl β-naphthyl ketone (XII)** was obtained as described for the isomer in 87% yield as a yellow oil which slowly solidified. A sample crystallized several times from methanol formed colorless prisms, m. p. 62–63°.

Anal. Calcd. for $C_{19}H_{16}O$: C, 87.66; H, 6.19. Found: C, 87.93; H, 6.19.

Pyrolysis of XII.—Pyrolysis of 2.6 g. of the β-naphthyl ketone with 0.5 g. of zinc dust at 420–425° for one and one-half hours gave 1.8 g. of distilled product. No pure hydrocarbon could be isolated by crystallization as the hydrocarbon, picrate, or trinitrobenzene derivative; the best sample of hydrocarbon melted at 110–112°, and a mixture with 8-methyl-1,2-benzanthracene[17a] melted at 114–116°. A 1 1-g. sample of hydrocarbon mixture, m. p. 98–108°, was oxidized to the quinone and after adsorption on alumina and crystallization from acetone there was obtained 45 mg. of **8-methyl-1,2-benzanthraquinone,** m. p. 196–196.5°, and 130 mg., m. p. 192–195°. This showed no depression with an authentic sample.[17a] The amount of this quinone was about three-quarters of that obtained from the pure hydrocarbon by Fieser and Johnson.[17a] The mother liquors contained another quinone which was not isolated in a pure condition but which melted at 162–164° and showed a large depression when mixed with 1,2-benzanthraquinone.

Summary

1-Benzoylacenaphthene, obtained conveniently from the available 1-aceto compound by a phenyl Grignard reaction on the corresponding amide, gives 1′,9-methylene-1,2-benzanthracene on pyrolysis in 13% yield.

Further data are given on the preparation of 1-acetoacenaphthene by the hydrogen fluoride procedure and on the characterization and oxidation of the ketone.

A study of the pyrolysis of *vic.-o*-xylyl α- and β-naphthyl ketones shows that methyl groups in the α-positions 5 and 8 of the 1,2-benzanthracene molecule withstand to some extent the conditions of the Elbs reaction but that with the α-naphthyl isomer there appears to be both migration of the aroyl group and partial elimination of the methyl substituent.

Diffusion Velocity and Molecular Weight. I. The Limits of Validity of the Stokes–Einstein Diffusion Equation

BY LEO FRIEDMAN AND PAUL G. CARPENTER[1]

Considerable interest has been evidenced in recent years in the use of diffusion velocity studies as a means of determining molecular weights.[2–4] Some results have been obtained that are in excellent agreement with results yielded by other methods.[3] On the other hand, the results of Northrop and Anson on hemoglobin[2,5] have been discouraging, as were the results of one of the authors on gelatin (to be reported in a later paper of this series).

In the use of diffusion velocity as a means of determining molecular weights, too little attention has been paid to the concentration of the diffusate. Since the Stokes–Einstein diffusion equation makes no provision for change in concentration and is derived on the assumption of free diffusion, it would appear that the diffusion coefficient to be used for the calculation of molecular weight should be determined at infinite dilution.

In a classical paper on this subject Sutherland[6] made an effort to apply the Stokes–Sutherland–Einstein equation to the evaluation from diffusion data of the molecular weights of a number of non-electrolytes ranging in molecular weight from methyl alcohol to raffinose. Undoubtedly his failure to obtain closer agreement between diffusion data and molecular weight was due to inaccuracy of data available at that time. In this paper he also gives a general empirical equation for use as the molecular weight becomes small.

Attempt to Evaluate Molecular Weights of Non-Electrolytes from their Diffusion Coefficients.—Examination of the diffusion data for non-electrolytes to be found in the "International Critical Tables" shows that the diffusion coefficient varies considerably with the concentration of the diffusate. Calculations of the molecular weights of these non-electrolytes have been made by use of the Stokes–Einstein diffusion equation

$$D = \frac{RT}{N}\frac{1}{6\pi\eta r}$$

combined with the relationship

$$M = {}^4/_3\pi r^3 dN$$

Results of several of these calculations are given in Table I. In the case of each non-electrolyte, the last value of the diffusion coefficient labeled 0 concentration has been calculated from the molecular weight of the substance. It is to be observed in each case that the value so obtained is not unreasonable when compared with the experimental values reported in the "International Critical Tables."

If the results of Table I are represented graphically by plotting the diffusion coefficient against the square root of the concentration of the diffusate, it is possible to draw a straight line from the theoretically calculated diffusion coefficient through the experimental points taken from the

"International Critical Tables." When the circles used to represent the experimental values are so drawn that they represent the probable experimental error of each point, the straight line will pass through each circle, although it must be admitted that one could not determine where to draw this line from the experimental points alone. The data in the "International Critical Tables" are too limited to make this possible.

Experimental Studies on the Diffusion of Glucose.—Since the diffusion values found in the "International Critical Tables" are relatively few and are not so exact as can now be obtained with newer methods of studying diffusion, a study of the diffusion velocity of glucose has been made. The apparatus used consisted of glass cells of the type employed by Northrop and Anson,[2] and McBain and his co-workers.[3,4] The experimental procedure used by McBain and co-workers was followed. Because of the extremely low concentrations resulting in the outside solution, this method effectively measures diffusion against water. Cell constants were calculated from the diffusion coefficient of potassium chloride as listed in the "International Critical Tables" from the work of Öholm. The glucose concentrations were measured by determining the amount of potassium iodate needed for complete oxidation of a sample.[7]

All experiments on glucose were carried out at 25° and several determinations of diffusion velocities were made at each concentration. The results of this study are given in Table II, in the third column of which the apparent molecular weight of glucose has been calculated from the diffusion coefficient obtained at each concentration.

when sufficiently accurate diffusion data are obtained, it is possible by plotting diffusion coefficient against square root of the concentration to extrapolate to infinite dilution and thus obtain the value of diffusion coefficient that will yield the correct molecular weight when substituted in the Stokes–Einstein diffusion equation.

Even more striking is the fact that this relationship holds for a substance of molecular weight of 180 whereas most investigators have felt that the Einstein relationship could not be applied to substances of such low molecular weight.

Published with the approval of the Monographs Publications Committee, Oregon State College, as Research Paper No. 19, School of Science, Department of Chemistry.

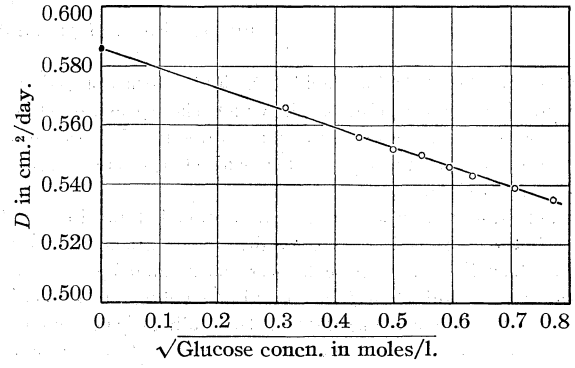

Fig. 2.—Diffusion of glucose at 25°.

Summary

It has been shown that molecular weights of simple non-electrolytes can be calculated from diffusion coefficients determined at infinite dilution, (1) by an examination of the values of diffusion coefficient to be found in the "International Critical Tables," and (2) by experimental study of the diffusion velocity of glucose.

Diffusion Velocity and Molecular Weight. II. The Effect of *p*H upon Particle Size in Gelatin Solutions

BY LEO FRIEDMAN AND KARL KLEMM[1]

Change of hydrogen ion concentration of a gelatin solution brings about marked changes in many of the properties of the solution. In seeking explanations of these changes, some investigators have attributed them to increased or decreased hydration with changing *p*H or to increased or decreased particle size with changing *p*H. Investigators of diffusion of colloidal materials have observed marked changes in diffusion velocity with changing *p*H.[2-4]

Experimental

In order to investigate the effect of *p*H upon particle size in gelatin solutions, diffusion experiments have been carried out using 3% solutions of Eastman Kodak Co. electrodialyzed gelatin, adjusted to various *p*H's by the

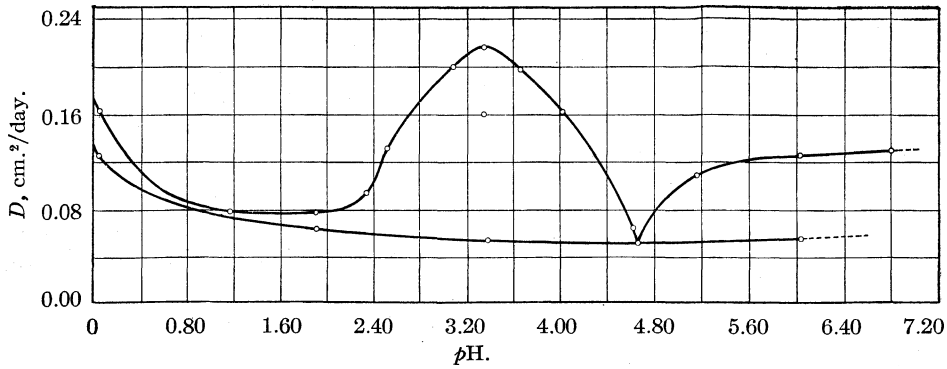

Fig. 1.—Effect of *p*H on diffusion velocity of gelatin.

addition of hydrochloric acid. A similar series of experiments has been carried out in which there was added to the above solutions a sufficient amount of potassium chloride to eliminate the electrical charge effect upon diffusion velocity.[4]

Diffusion coefficients were determined following the method and technique of McBain and co-workers[4,5] with the exceptions that the cells were suspended by a metal rod from a universal joint, making leveling of the cells easier and more certain, and that the sealing of the systems to prevent evaporation between the cell and the outside beaker was improved. Diffusion cells containing fused-in sintered Jena glass membranes (G_4) were used. The cells were calibrated with 0.1 *N* potassium chloride solutions using values from Öholm as listed in the "International Critical Tables." All diffusion measurements were made at 35° and extended over twenty-five hours. Gelatin concentrations after diffusion were determined by the colorimetric micro-method of Koch and McMeekin,[6] with the following modification. After the digestion, the material was diluted to 25 ml. instead of 100 ml., which allowed use of samples containing 0.1 to 0.25 mg. of nitrogen. This permitted shorter diffusion times. All nitrogen determinations were made in quadruplicate.

Since the source of the material and the previous history, especially thermal treatment, have such a marked effect upon the properties of gelatin solutions, these factors were controlled carefully and conditions were duplicated as nearly as possible in all determinations.

The results are given in Table I and are shown graphically in Fig. 1.

Discussion

A study of the two graphs shown in Fig. 1 reveals the cause of the abnormally high values of diffusion coefficient obtained by many investigators of lyophilic systems.[2,3] The lower curve reveals the cause of the large decreases in value of diffusion coefficient frequently found by investigators upon the addition of salts to lyophilic solutions.[2,3] The lower curve also reveals the effect of *p*H upon the aggregation–deaggregation equilibrium of 3% gelatin solution at 35° within the *p*H range of 0.05 to 6.40. Below *p*H 2, the values of *D* indicate a rapid disintegregation or deaggregation of the gelatin micellae, whereas if *p*H is above 2 since *D* remains nearly constant, there is a much smaller change in the particle size in gelatin solutions with changing *p*H. The point at *p*H 3.34, $D = 0.160$, shows that the addition of an insufficient amount of salt to a system of given concentration and *p*H will decrease the value of *D*, but will not reduce it to the minimum value for that *p*H.

An excellent explanation for the shape of the upper curve has been presented by McBain, Dawson, and Barker[4] in discussing their results obtained in the study of the diffusion of egg albumin. The results obtained in this study are an excellent corroboration of their work.

It is quite evident from the above results that any investigations of the diffusion of lyophilic colloidal substances must be carried out at the iso-

electric point or the solutions must contain a sufficient amount of salt, if the results are to be used for the calculation of particle size.

Published with the approval of the Monographs Publications Committee, Oregon State College, as Research Paper No. 20, School of Science, Department of Chemistry.

Summary

The effect of *p*H upon diffusion velocity of gelatin solutions has been measured over the *p*H range 0.05 to 6.4.

The effect of added potassium chloride at the various *p*H's upon the diffusion coefficient has been measured.

Results obtained indicate that between *p*H's 2 and 6.4 only a small change in particle size takes place in 3% gelatin solution at 35°, but below *p*H 2, there is a rapid decrease in particle size.

The Effect of Non-electrolytes upon the Time of Setting of Gelatin Gels

BY LEO FRIEDMAN AND W. N. SHEARER[1]

In an earlier investigation[2] a study was made of the effect of non-electrolytes upon diffusion velocity in gelatin gels. Interpretations of the results obtained involved the hypothesis that non-electrolytes present in gelatin gels actually influenced gel structure. With the view to further investigate this possible influence the following study of the setting of gelatin gels was undertaken.

Experimental.—Gelatin solutions containing 25 g. of electrodialyzed calfskin gelatin in 475 ml. of water were made up. The gelatin was first placed in 200 ml. of water in a one-liter flask and permitted to stand for twenty-two hours in a thermostat at 25°, after which 275 ml. of water was added and the solution heated to 55° until the gelatin was dissolved completely. This solution was then cooled to 25° in the thermostat.

Varying amounts of the non-electrolytes to be used were dissolved in enough water to make up 10 g. of solution. These non-electrolyte solutions were then placed in wide-mouthed bottles, approximately 6.3 cm. in diameter, and 90 ml. of the gelatin solution was poured into each bottle. The bottles were placed immediately in the thermostat and tightly stoppered.

In order to determine when the gels had set a penetrometer was used. The penetrometer consisted of a glass tube about 45 cm. long and 8 mm. in diameter sealed and rounded on the end which was used to test the gel. At the other end of the glass tube was fastened a larger glass tube 18 cm. long and 12.5 mm. in diameter. Around the first tube was a coil consisting of 25 loops of steel wire 0.035 mm. in diameter so fastened that the spring resisted the movement of the smaller glass tube into the larger. As an indication that a gel had set the following criterion was followed.

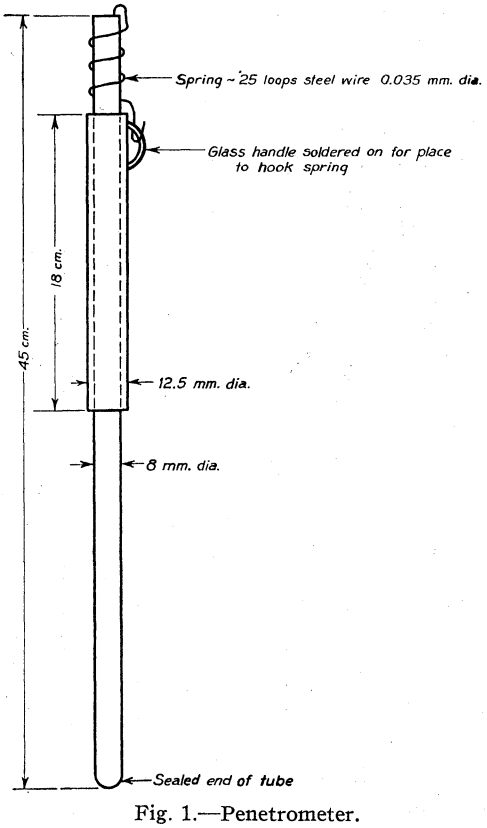

Fig. 1.—Penetrometer.

When a gel had set enough so that the tube would go into the gel far enough to stretch the spring to the 2.6 cm. mark from the starting point without

breaking the surface of the gel, it was considered to have completely set. This empirical method and home-made penetrometer were found to be very accurate and convenient in testing gels.

Table I gives the results obtained in the study of the time of setting of gelatin gels in the presence of sucrose, urea, and levulose. It is to be noted that up to a concentration of 0.02 to 0.03 molar non-electrolyte setting time was increased, but this effect became less marked at higher concentrations and finally at concentrations of 0.2 molar, setting times had been decreased by more than 20%.

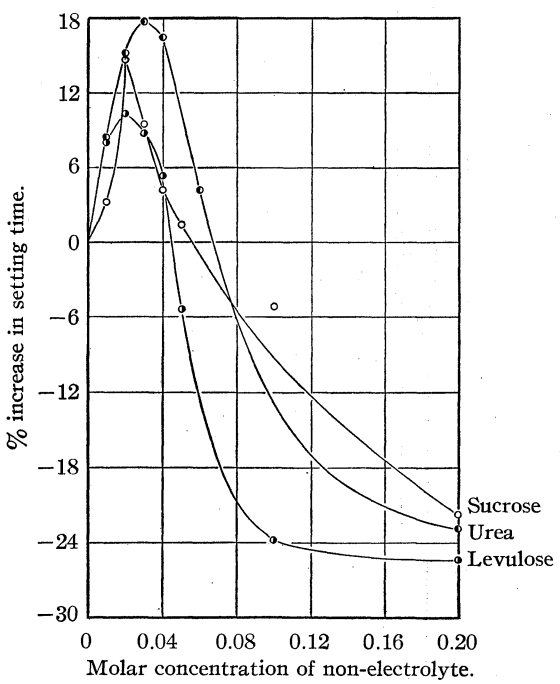

Fig. 2.—Effect of non-electrolytes on setting of gelatin gels.

Discussion

In the investigation of the effect of non-electrolytes upon diffusion velocity in gelatin gels,[2] it was found that low concentrations of non-electrolyte brought about an increase in diffusion velocity, this effect reaching a maximum at concentrations below 0.04 molar. At higher concentrations of non-electrolyte the diffusion velocity was increased less and at concentrations above 0.08 to 0.18 molar for the various non-electrolytes used the diffusion velocity was slower than in the absence of any non-electrolyte. These results were explained by assuming that non-electrolytes influence diffusion in gels in two ways: (1) by increasing the radii of the pores within the gel due to a decrease in the hydration of the solid phase, and (2) by increasing the viscosity of the medium through which diffusion takes place.

As early as 1900, Hardy[3] observed that the rate of setting influenced the structure of gels, and that gels which had been cooled rapidly had a "finer structure." In an earlier investigation by one of the authors[4] on diffusion of non-electrolytes in gelatin gels, it was observed that when gels were set at low temperatures, which results in rapid setting, gels were formed through which diffusion was more rapid than through gels set at higher temperatures.

On the other hand those concentrations of non-electrolytes which through their presence slow down gel formation yield gels through which diffusion is more rapid than through those gels that have set more rapidly due to the presence of higher concentrations of non-electrolytes. When rate of setting is influenced by foreign substances, it appears that slow setting yields gels with a more open structure, since diffusion velocity in gels[2] varied directly with time of setting.

Summary

A study of the effect of non-electrolytes upon the rate of setting of gelatin gels has been carried out.

Small concentrations of non-electrolytes increase setting time, this effect becoming a maximum at 0.02–0.03 molar.

Concentrations of non-electrolyte exceeding 0.1 molar cause gels to set more rapidly than in the absence of non-electrolytes.

Comparison with results of diffusion experiments leads to the conclusion that the slower setting gels have a more open structure.

Catalytic Dehydration of C_6–C_8 Aliphatic Alcohols

BY SEYMORE GOLDWASSER AND HUGH S. TAYLOR

An apparatus for the study of vaporized hydrocarbons and its application to the dehydrogenation of cyclooctene were described in a previous paper.[1] In seeking a good source of aliphatic hydrocarbons, it was found that certain alcohols were available in comparatively large quantities. Catalytic dehydration of these alcohols in this same apparatus proved to be an excellent source of alkenes and provided certain information concerning the mechanisms of dehydration and isomerization.

The separation of the pure isomers resulting from the dehydration of an alcohol was accomplished by the use of a modification of the Podbielniak column together with a special head which permits controlled reflux ratio.

Apparatus.—The column proper is shown in Fig. 1. It consists simply of a Pyrex tube, A, 1.5 meters long and 4.5 mm. i.d., flared at both ends to fit in a 1.8-meter long 16-mm. tube, B, which has a 16-mm. ground joint at one end and is ring-sealed at 1 and 2 at both ends. The space between the two tubes is evacuated through a side tube with the column at about 150°, the necessary heat being provided electrically with 12.2 meters of no. 20 chromel wire wound externally. About 6.1 meters of no. 20 chromel are wound spirally on a rod of such size that, when the spiral is stretched to six or seven turns per inch (2.5 cm.), it fits snugly inside the center tube of the column. This is the Podbielniak type packing. It does not allow reflux liquid to run down the column but causes it to travel down in a spiral path. More time is thus afforded for equilibrium to be set up and separation is excellent. The hold-up is small and the amount of liquid reaching the head without flooding is much larger than can be secured with the helical glass packing. A 200° thermometer, C, graduated in tenths of one degree is tied with asbestos directly to the column so that the bulb of the thermometer touches the evacuated jacket about one-third from the bottom. Just above the ground joint and also 1.5 meters up the column are wound asbestos strips so that the column is tightly supported inside a 1.5-meter 35-mm. Pyrex tube.

The head, D, which is described by J. H. Simons,[2] is sealed on just above the outermost insulating jacket and fitted with a thermometer, E, which is calibrated at 0, 56.7 and 100°. This head is a total condensing variable take-off type and has the advantage that it will accurately control reflux ratio, that it allows accurate and direct temperature measurement, and that hot hydrocarbon vapors can in no way come in contact with any contaminating surfaces. It can be adjusted for total return so that, in adjusting the column for operation, there is no loss.

Heating of the liquid is supplied by a small electrical heater, F. Either a 100-cc. or 200-cc. flask, G, with interchangeable ground joints may be used. The receivers are 30 cm. long 12-mm. tubes immersed in an ice-bath so that the outlet tube, H, from the head is at a lower level than the

surface of the ice, eliminating as far as is possible loss from evaporation during a distillation.

The catalytic apparatus used in this study of dehydration is identical with that previously described.[1] When the rate of passage of alcohol was 20 cc. per hour or more, the central buret tube used was 12 mm. o.d.

Materials.—The alcohols used were commercial products supplied by E. I. du Pont de Nemours and Company and by Carbon and Carbide Chemical Corporation. They were purified by careful distillation in the column described. The maximum impurity in any one of the alcohols proved to be about 3%. The heptanol-4 used was synthesized as follows.

A manganous oxide was prepared by passing methanol vapors over manganous carbonate *in situ* at 400°. The temperature was then raised to 450° and butyric acid passed over it. The heptanone-4 formed was separated by fractional distillation. This was then reduced by passing its vapors mixed with hydrogen over a nickel catalyst at 150°. Repetition of passage and distillation gave a pure heptanol-4; sp. gr. d^{20}_4 0.820, refractive index $n^{20}D$ 1.4325, b. p. (760 mm.) 155.4°.

The properties of the other purified alcohols were:

	Sp. gr. d^{20}_4	n_D	B. p., °C. (760 mm.)
Hexanol-1	0.8189	1.4161	156.4
2-Ethylbutanol-1	.8328	1.421	148.9
2,4-Dimethylpentanol-1	.819		157
2,4-Dimethylpentanol-3	.8288	1.4226	140
2-Ethylhexanol-1	.833		184.6

The catalysts used in the investigation were alumina, chromic oxide gel and thoria. Uranium oxide was found to be inactive for dehydration. The preparation of chromic oxide gel has been described previously. Alumina was prepared by precipitating aluminum hydroxide from a 1.5 *N* aluminum nitrate solution with concentrated ammonia, vigorously stirred and filtered on a Büchner funnel. When dried at 100° the particles obtained were glassy, large and non-crumbling. Several other methods were tried for this preparation, including precipitation from dilute solutions and heating before filtration. The method cited proved to be the most convenient in preparation and handling, and also the most active in dehydration. The thoria catalyst used was prepared by the method of Kramer and Reid.[3] It consists of thoria supported on pumice in the proportion 1:3 and is prepared by the ignition of thorium nitrate under carefully controlled conditions.

Procedure.—The procedure for the passage of an alcohol over a catalyst is identical with the procedure described for the dehydrogenation of cycloöctene. It is very convenient to collect the product in a pig of 100-cc. capacity, used only for the alcohols. The liquid condensed separates into two layers, water and hydrocarbon. To determine extent of dehydration, the water layer is drawn off and weighed, and the volume of the hydrocarbon layer measured. The specific gravity of the alcohols is about 0.82, the hydrocarbon about 0.69. For 100 cc. of alcohol dehydrated, there should be 96 cc. of hydrocarbon and 14.1 cc. of water. This method of estimation is quite accurate. The hydrocarbon is then dried over calcium chloride for two hours, then placed over a new batch of calcium chloride in a second flask and allowed to stand for twelve hours. This eliminates any unchanged alcohol as well as water. Traces of water show up as a cloudiness in the first drops refluxing in the fractionation. When this occurs, the column must be opened and dried thoroughly.

For the fractionation of the dry hydrocarbon mixture, the procedure will be described in detail. The mixture is placed in a 200-cc. flask fitted with a ground joint and attached to the column. The heater is placed under the flask and its temperature adjusted so that the liquid will begin to boil in about half an hour. The valve in the head is turned so that all vapors will pass to the non-exit side and the condenser on the other side adjusted so that all condensate will return to the column. The rheostats in series with the heating coil around the vacuum jacket are adjusted from time to time so that the temperature shown by the thermometer in the outer jacket keeps pace exactly with that in the head. The purpose of this and the vacuum jacket is to make the column as adiabatic as possible, so that heat exchange will take place only between the refluxing liquid and the vapors coming up the column. As soon as the column is operating properly, that is, about 30 drops of liquid are returning to the column every five seconds, with no flooding, the condenser on the exit side is adjusted so that one drop is collected in the receiver every five seconds. As the distillation is in progress, a plot is made with the number of drops as the abscissa and the temperature of the head as ordinate. The receiver is changed at the beginning and end of each horizontal part of the curve, there resulting two portions of liquid for each constant boiling fraction, one of a nearly pure hexene isomer, the other of a mixture consisting of the two isomers between the boiling points of which the mixture distils. Total reflux is used for five minutes at the end of each horizontal part in order to make the break sharper. Throughout the distillation, outer jacket temperature must be the same as, or 1° lower than, the temperature of the head. The receivers are of known volume and the amount of each fraction may be ascertained without undue transfer of liquid.

Specific gravities, correct to the third decimal place, and Hanus numbers are taken for each fraction. The Hanus number determination is used to determine the purity of the fraction with respect to non-olefins, and the fraction corresponding to a horizontal part of the curve is then identified by comparison with a table of boiling points and specific gravities of hydrocarbons, as described in the next section. The absolute amount of the various isomers in a mixture is determined by extrapolation of the horizontal and rising parts of the curve. The meeting point of the lines gives the amount of the pure fraction. The slopes of the vertical lines are those of the tangents to the distillation curve at the points of inflection. It must be understood that, even for the fractions corresponding to the horizontal parts of the curve, absolute purity is not obtained. The main constituent of a given fraction is present, however, in amounts greater than 95%. The fractionation, from which the data in Table II are taken, is shown in abbreviated form in Fig. 2, and demonstrates

(3) Kramer and Reid, THIS JOURNAL, **43**, 880 (1921).

the method of extrapolation. The validity of the method was checked by the fractionation of known mixtures, in which case complete substantiation was found.

The amount of the liquid to be placed in the distilling flask was determined by that component of the mixture which was present in smallest amounts, since to get a good flat in the curve required about 0.75 cc. In all cases, 100 cc. of an alcohol or more was dehydrated, and 100 cc. of the dry hydrocarbon mixture fractionated, so that, as a rule, volumes were equal to percentages. In certain cases where material was scarce and the composition of the resultant mixtures was known qualitatively by previous experience, a 20-cc. sample was sufficient, and a 10-cc. sample of a two-component mixture was sometimes sufficient.

Identification of Fractions.—The first satisfactory compilation of the physical properties of pure hydrocarbons has appeared only recently. The compilation was made by G. L. Eaton.[4] The table is comprehensive and lists specific gravities, etc., for every pure hydrocarbon known. No complete tabulation of octene isomers is available.

To illustrate difficulty in identification, the following may be cited. Fractionations continuously gave a cut at 65.6–65.7° and no further cut to 66.2°. There appeared to be no isomer boiling at the lower temperature recorded in the literature. However, one of the isomers of 3-methylpentene-2 was reported as boiling at 65.7–66.2°. By the elimination of the fractions which were known with some certainty, it was decided that the fraction boiling at 65.7° must be 3-methylpentene-2 and further work was carried out on this basis. A paper by van Risseghem,[5] which has appeared recently, in which was described the isolation of several pure hexene isomers identified by chemical means and checked with infrared spectra, records that the isomer variously reported as boiling at 65.7–66.2° is *trans*-3-methylpentene-2 and that its true boiling point is 65.7°. This concordance may be used to emphasize the confidence that may be placed in the fractionations obtained.

While most boiling points reported are uncorrected, transformations of values found at one pressure to another pressure for purposes of comparison are necessary. According to an article on conversion factors in the same treatise,[4] the following facts are found.

B. p. at 760 mm., ° C.	0	50	100	150
Corr. per mm. for b. p. at 760 ± 50 mm.	0.035	0.040	0.046	0.051

Moxt hexene isomers boil in the range 60 to 70°. The correction on a normal day will amount to 0.4°, which is as much as the difference between two isomers to be separated. Pressure variations corresponding to as much as 0.6° have been found in interrupted distillations of a given cut.

With a distillation curve corrected to 760 mm., it was found that the sequence of the fractions together with their boiling points could be correlated readily with the

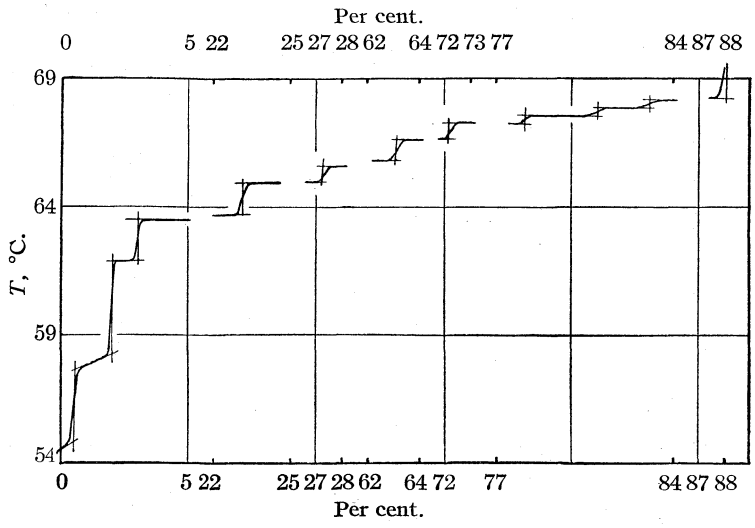

Fig. 2.

boiling point sequence of the isomeric olefins in question. A correlation with specific gravities served as additional check. If the specific gravities fell in the sequence which the fractions required when the identifications were made from the boiling point, identification was assumed to be adequate for the purposes of the present study, a procedure which is common in other work of this type. Accordingly, we have, in the succeeding data, labelled the respective cuts with the name of the alkene having the corresponding boiling point. Substances of a type other than hydrocarbon can confuse identification, but the use of specific gravities eliminates this possibility. In certain cases, where there was a good quantity of isomer available, dibromo derivatives were prepared as a further check. For example, the dibromo derivative prepared from the hexene identified as hexene-1, gave a product: b. p. 77–77.5° (15 mm.) and sp. gr.$^{13.5}_4$ 1.596, whereas the literature shows this derivative to have: b. p. 77–78° (15 mm.) and sp. gr.$^{13.5}_4$ 1.59625.

The possibility of the formation of azeotropic mixtures was considered. In sixty or more fractionations of mixtures of pure hexene isomers, containing every possible combination of such isomers, save one to be mentioned, no fractions were found which did not correspond exactly with tabulated isomers in all properties. Only in one case, with mixtures containing both hexene-1, b. p. 63.5–64.0°, and *trans*-3-methylpentene-2, b. p. 65.7–66.0°, was there evidence for a constant boiling mixture at 65.0°. However, no more than 4% of the total multicomponent mixture came off in this form.

Table Ia was used for the identification of the hexenes. Similar tables, Tables Ib and Ic, were used for the heptenes and the octenes.

Table II shows a typical fractionation. The

(5) H. van Risseghem, *Bull. soc. chim. Belg.*, **47**, 47 (1938)

percentage data given are deduced from Fig. 2, by the method of extrapolation given. All percentages in the tables following are deduced in a similar manner from the fractionation curves (see Figs. 3–7). The close checks found for the observed and the calculated values of specific gravities and unsaturation attest both the purity and the correctness of method.

flow was controlled to 1%. The results are recorded in Table III, together with a set of data for a 10% UO_2–90% Al_2O_3 catalyst available from other work.

(1) The first and most obvious thing about Table III is that the primary products are shown to be hexene-1, 2-methylpentene-1, 4-methylpentene-2, and, surprisingly, a small amount of 2-methylpentane. (2) As the rate becomes slower, the actual amount of hexene in the mixture increases at the expense of unchanged hexanol. The hexene-1 in turn decreases and other hexene isomers appear. That this is due to direct

isomerization of hexene-1 on the alumina surface will be shown in a later paper. The same is the case with 2-methylpentene-2, as is shown in the table. (3) The faster the passage, the more unchanged hexanol and polymer is found. An ether is found in the polymer only in the case of most rapid passage. Slower passage allows any ethers formed to decompose. (4) Correcting for unchanged hexanol, it is seen that the amount of polymer formed is a function of the unchanged hexanol. The amount of hexene formed does not change, but slower rate allows its isomerization. (5) The results found for 10% uranyl on alumina lie between the results from the two slowest rates on pure alumina. This is due to a screening of alumina surface by inactive uranyl, as will be shown.

The polymer discussed is a yellow oily liquid with a boiling range of 200–250°. This and the specific gravity point to a dodecalene. A Hanus number determination corresponds exactly with that calculated for a dodecalene.

(B) Effect of Catalyst on Products of Dehydration.—

Hexanol					100	

This table yields the following conclusions. (1) Mode of preparation of aluminum oxide does not significantly change dehydration. Four different pure aluminas were tried. (2) Isomerization proceeds much more rapidly on thoria. All intermediate isomers have disappeared. All hexene-1 has isomerized to 3-methylpentene-2. (This will be elaborated in a later paper.) (3) 100% uranium oxide produces no dehydration, either at 400 or at 500°. The catalyst preparation

proved to be active for dehydrogenation, however. No preparation of pure uranium dioxide was found that dehydrated. (4) As was shown in section (A), the 10% uranyl catalyst on alumina gives products which are the same as though a faster rate were used over pure alumina. (5) The reaction with chromic oxide is a different type from the others. Not only is there dehydration but dehydrogenation. Benzene is formed from the hexene-1 and some of the olefins formed are hydrogenated at this comparatively low temperature. Water vapor when mixed with olefin over chromic oxide causes oxidation of the olefin so that considerable carbon dioxide is evolved.

The effect of rise of temperature is slight, except to decrease decomposition. In the case of chromic oxide, however, an increase to 460° gives excellent dehydrogenating conditions. The ma-

jor product is benzene, and the saturates drop to 5%. There is no water in the exit gas, it being entirely converted to hydrogen and carbon dioxide.

To determine whether there are analogous effects with change in rate of passage with other alcohols, the primary products of decomposition were determined in the cases of several other alcohols.

Table V gives the percentage decomposition of the hydrocarbon layer resulting from the dehydration of several alcohols at a slow and a rapid rate. Figures 3, 4, 5, 6 and 7 record the distillation curves obtained with the products from the six-, seven- and eight-carbon alcohols indicated. The correlation of the "flats" in the curves and the specific gravities is made with data, for the isomer indicated, obtained from Tables Ia, b, and c. In every case, save for the two unidentified octenes, this correlation leads to the designation of the isomer as given below each curve. It is from such distillation curves that the data in Table V were deduced.

From Table V, it is seen that the following are the primary products of dehydration on alumina gel.

(1) Hexanol-1: hexene-1; 2-methylpentene-1; 4-methylpentene-2.

(2) 2-Ethylbutanol-1: hexene-1; 3-methylpentene-2; 2-ethylbutene-1; 2-methylpentene-2; hexene-3.

(3) Heptanol-4: heptene-3; 2-ethylpentene-1; 2-methylhexene-2.

(4) 2,4-Dimethylpentanol-1: 4-methylhexene-2; 2,4-dimethylpentene-2; 3,4-dimethylpentene-2.

(5) 2,4-Dimethylpentanol-3: 2-methylhexene-3; 2,4-dimethylpentene-2; 3,4-dimethylpentene-2.

(6) 2-Ethylhexanol-1: 2-methylheptene-2; 3-methylheptene-2; 4-methylheptene-4; octene-3.

The only one of these cases in which there is any doubt as to the primary products is that of hexanol-1 on thoria. The fastest rate used still gave 100% dehydration.

Analysis of Results

Production of Oily Polymer.—The polymer is produced in larger quantity at the faster rates. This is the case with both alumina and thoria. As was pointed out in the detailed table of effect of rate of passage on the products of hexanol dehydration, the amount of polymer depends on the amount of hexanol in the vapor. Although the concentration of hexene-1 is as large at 11.2 cc./hour as at 22 cc./hour, the amount of polymer has fallen sharply and there is no hexanol left unchanged. To confirm this, purified hexene-1 was passed over a thoroughly dry alumina. Although every other condition was the same, there was no polymer formed. Water vapor mixed with hexene-1 likewise had no effect. This points definitely to an intermediate in the dehydration reaction which can either polymerize or give olefin. Evaporation without drying shows that the amount of polymer is not changed by calcium chloride used in drying.

Formation of Ethers.—Ethers are known to be very unstable on dehydration catalysts at temperatures over 350°. The presence of an ether was found only in the products from the two most rapid passages of hexanol-1.

Distribution of Products.—Table III in section (A) shows that isomerization occurs as passage of alcohol becomes slower, the olefins having both greater availability of surface and more time on the surface. The straight chain olefin, hexene-1, seems to be the least stable at the temperature and passes to the various isomers tabulated. The other primary products are more stable, 2-methylpentene-2 also tending to disappear, however. This, also, is confirmed by passage of the pure isomer. The isomer 3-methylpentene-2-*trans* seems to be the most stable and the percentage of this increases as the rate decreases further. In the rapid dehydration of 2-ethylbutanol-1 (Table V), 3-methylpentene-2-*cis* appears as the major primary product. In the slower passage the same effects of isomerization appear. Again 2-methylpentene-2 and the straight chain hexene-1 disappear, as does the major product. Again, 3-methylpentene-2-*trans* appears as the major secondary product. In the dehydration of hexanol-1 on thoria, it is evident that both dehydration and isomerization occur much more rapidly than on alumina since, even at the fastest rate, there is no unchanged alcohol and the major products appear to be 3-methylpentene-2 and hexene-1. All the hexene-1 which has isomerized has gone to this 3-methylpentene-2 isomer and at the slower rate there is nothing in addition but polymer.

The three 7-carbon alcohols dehydrated show somewhat similar behavior. Heptene-3, the straight chain major product from heptanol-4, isomerizes to branched chain isomers which in turn give 3-methylhexene-2, while 2-methylhexene-2 goes directly to 3-methylhexene-2-*trans*, as is shown if the pure isomer is passed over alumina at various rates of speed. This is exactly analogous to hexanol-1. The other two 7-carbon

alcohols are different in that there is no straight chain primary product. The migration of a methyl group across a double bond toward the center of the molecule, which is the trend observed above, is prevented for either of two reasons. The length of the hydrocarbon chain is such that either the double bond is one carbon removed from the side chain or migration across the bond makes the side chain no more central. For both 2,4-dimethylpentanol-1 and 2,4-dimethylpentanol-3 the primary and secondary products are the same, the percentages changing with the amount of unchanged alcohol in the vapor.

Amount of Unchanged Alcohol.—From the results on alumina, it would seem that ease of dehydration is in the order:

	2-Ethylbutanol-1	>	heptanol-4	>	hexanol-1	>	2,4-dimethylpentanol-1	>	2,4-dimethylpentanol-3
Unchanged alcohol	*3* (primary)		*5* (secondary)		*20* (primary)		*20* (primary)		*40* (secondary)

where the numbers are the amount of unchanged alcohol resulting from dehydration under comparable conditions.

While it has generally been found that the comparative rates of dehydration of alcohols are in the order primary, secondary, tertiary, this does not hold here.

Discussion.—From the results above, it is possible to derive a mechanism which affords a very convenient picture and proves itself useful in understanding dehydration of higher alcohols.

Mechanism.—Models for the above five alcohols were constructed to scale. To investigate what possible hydrogens could be involved with the hydroxyl group in dehydration, the models were contorted in every way possible. Those hydrogens which could actually touch the oxygen of the hydroxyl group were taken as possibilities. The hydrogens on carbons 3, 4 and 5 of heptanol-4 are inaccessible, but the hydrogens on 1, 2, 6, and 7, are all equally accessible. In hexanol-1, only the hydrogens on carbon 2 are inaccessible, those in fact which are usually supposed to be involved. In the case of 2,4-dimethylpentanol-1 only the hydrogens on carbon 2 are entirely inaccessible. Similarly with the others. Assuming that by elimination of water in these various possible ways, there is formed a sort of activated ring involving 3, 4, 5 or 6 carbons, as the case may be, a series of reactions may be predicted. The predictions are made in the following manner.

Each bond in the hypothetical ring is in turn broken and a free radical intermediate indicated which satisfies its valence requirements internally, giving rise to an olefin. That such predictions are valid is shown by Egloff in his book "Reactions of Pure Hydrocarbons,"[6] in which are enumerated the reactions of many cyclic hydrocarbons under various conditions, together with the products formed. While the reactions of such hydrocarbons at high temperatures may produce a bewildering array of products, such a method of prediction accounts for all in an orderly fashion. The formation of 5- and 6-membered rings in any quantity was early ruled out because catalytic pyrolysis of such substances produces characteristic products: comparatively high boiling homologs of cyclohexene in the case of the 6-membered ring; various gaseous hydrocarbons from the 5-membered ring. Both of these cases could have been detected easily but were found in none of the investigations under discussion.

The reason for this non-formation of the larger, more stable, rings may lie in the fact that the alcohols used were too short-chained to allow such rings to be formed except by the reaction of the hydroxyl group with primary hydrogens. The great difference in reactivity between primary and secondary hydrogens is well exemplified by the cyclization of the hydrocarbons on chromic oxide. *n*-Octane, when dehydrogenated on chromic oxide, does not give ethylbenzene as the major product as might be supposed, but according to Moldavski,[7] gives 90% *o*-xylene and only 10% ethylbenzene. This together with the facts that octane is easier to aromaticize than heptane and heptane than hexane means that two secondary hydrogens are removed more easily than one primary and one secondary, while one primary and one secondary are removed more easily than two primary hydrogens.

Forming the hypothetical 4- and 3- membered rings with the five alcohols discussed, certain conclusions result. It will be noted that 2,4-dimethylpentanol-3 does not allow the formation of a 4-membered ring, while 2,4-dimethylpentanol-1 allows two different 3-membered rings,

	2,2-Dimethylpentene-3 2,4-Dimethylpentene-2	 2,4-Dimethylpentene-2 2,3-Dimethylpentene-3 4-Methylhexene-2	 2,4-Dimethylpentene-2 2,3-Dimethylpentene-3 4-Methylhexene-2	3	2	0	0	1
2,4-Dimethylpentanol-3	Impossible			12	0	0	0	0
		4-Methylhexene-2 2,3-Dimethylpentene-3 2,4-Dimethylpentene-2	2-Methylhexene-3 2,3-Dimethylpentene-3 2,4-Dimethylpentene-2					

only one of which involves a secondary hydrogen, however. It also may be seen that, when only one carbon in the 3- or 4-membered ring is substituted, there are only two scissions which are different; when two carbons are substituted, there are three; if the two substitutions in the 4-membered ring are different, there are three. It will be remembered that if these rings were actually formed, the momentary presence of the oxygen and a hydrogen atom in the ring makes 3- and 4-membered rings into 5- and 6-membered rings, respectively.

While, in general, the products are similar from both types of ring, they are different enough in some cases to allow discrimination. The case of butanol-1 is a good example. The 4-membered ring allows formation only of butene-1 and butene-2. The 3-membered ring allows these two and also isobutene. This latter actually is found as one of the products of dehydration with iodine[8] as catalyst. This also points to the comparative ease of removal of a secondary hydrogen as compared with a primary.

Table VI shows the assumed 3- and 4-membered rings and their products for the five alcohols discussed. Under the alcohol considered are shown the hypothetical 3- and 4-membered rings resulting from dehydration together with the products to be expected from them. The column "Found" gives the primary products actually found. The column "Hydrogens available" indicates the number of hydrogens bound to carbon available for the formation of each ring and the class of hydrogen: primary, secondary and tertiary.

The exact agreement of the primary products found and those predicted from the 3-membered ring is apparent. In hexanol-1, there is one product which is not accounted for in either way, but the 3-membered ring still gives the better agreement. The tabulation of the hydrogens available brings to light an important corollary.

(8) F. C. Whitmore, "Organic Chemistry," D. Van Nostrand Co., New York, N. Y., 1937, p. 40.

Ease of Dehydration.—Under the discussion of the amount of unchanged alcohol, it was shown that the order of ease of dehydration was not that expected. In Table VII are listed the number of hydrogens available in the same order as found for ease of dehydration.

TABLE VII

	2-Ethyl-butanol-1	Hep-tanol-4	Hex-anol-1	2,4-Di-methyl-pentanol-1	2,4-Di-methyl-pentanol-3
Order found	3	5	20	20	40
3 ring, s	4	4	2	2	0
3 ring, p	0	0	0	3	12
4 ring, s	0	0	2	0	0
4 ring, p	6	6	0	0	0

Table VII shows the exact correlation between the number of secondary hydrogens available for the formation of the 3-membered ring by the elimination of water, and the ease of dehydration. The most difficult to dehydrate is 2,4-dimethylpentanol-3, as is shown by the large amount of unchanged alcohol after a passage. There are no hydrogens available except primary ones, in a position for 3-ring formation. At the slower passage, dehydration involving the primary hydrogens takes place, and complete dehydration is made possible by the large number of such hydrogens available.

The products of dehydration as reported by other workers conform to this proposed mechanism of dehydration. To be noted in this connection is the paper by Cramer and Glasebrook[9] which has appeared since the completion of the work in this paper. The dehydration of 2,2-dimethylbutanol-3 was found to give several products, namely, 2,2-dimethylbutene-3, 2,3-dimethylbutene-1 and 2,3-dimethylbutene-2, which are the products to be expected from the mechanism proposed above.

Conclusion

Evidence from three sources thus points to an activated intermediate stage having the configuration corresponding to a 3-membered ring. (1) The most strongly adsorbed substance in the system involved in the dehydration of an alcohol is the alcohol itself, by reason of its hydroxyl group. The formation of larger amounts of polymer when alcohol vapor is present in larger quantities indicates that the alcohol is flushing something from the surface. This substance, which produces olefins if allowed to remain on the surface, may be displaced as polymer by alcohol or, displaced as active intermediate, may polymerize in the vapor phase. The presence of some polymer even at the slowest rates indicates that flushing by alcohol still exists on a portion of the catalyst, probably at the point of entrance to the catalyst. Pure olefin, with or without water vapor, gives no polymer whatsoever on alumina and thoria surfaces.

(2) Ease of dehydration is shown to be correlated with the number of secondary hydrogens on the carbon second from that having the hydroxyl group. The elimination of water in this position causes the formation of an activated intermediate stage with the configuration of a 3-membered ring, and this in turn breaks down.

(3) The products which are predicted from the reactions of pure hydrocarbons, assuming that this activated cyclopropane configuration is formed, correspond exactly with those found to be the actual primary products of dehydration. The effects of various catalysts on the products may be summarized as follows. Alumina tends to break all the bonds of the ring more or less indiscriminately and to give all the products possible. The proportions of the various products give the relative frequency of the various scissions. This fits with other observations that alumina opens bonds in those rings which are strained. Thoria is less general in its action and tends to break one bond selectively. This is illustrated in the alcohols studied by other workers. Chromium oxide introduces the further complication of dehydrogenation. The olefin gives aromatization instead of isomerization, but, in this case, poisoning of the catalyst prevents ready determination of the nature of the olefin products.

Summary

1. An apparatus and a procedure have been described which allow the separation of isomers resulting from the dehydration of an alcohol.

2. The effects of rate of passage and change of catalyst have been investigated and interpreted.

3. Ease of dehydration and structure of the alcohol have been correlated and ease shown to be dependent on the availability of secondary hydrogen atoms on the carbon beta to that with the hydroxyl group.

4. The conclusion is derived that there is an activated intermediate stage in dehydration that has the configuration corresponding to a 3-membered ring.

Isomerization of Alkenes on Alumina and Thoria

BY SEYMORE GOLDWASSER AND HUGH S. TAYLOR

Investigation of catalytic dehydration of C_6–C_8 alcohols has shown it to be an excellent method for the production of alkene hydrocarbons for the catalytic study of their vapors.[1] One of the facts brought out by this investigation is that olefins isomerize extensively when allowed to remain in contact with the active surfaces studied. Further work with the purified olefins themselves was thought desirable.

The apparatus for the catalytic studies[2] and for fractionation of the liquid products[1] have been described already. The procedures both for the passage of olefin and the separation and identification of the products were identical with those described. No drying of the hydrocarbons over calcium chloride was necessary, however, in the runs with pure olefins. The olefins used in the study of isomerization were the purified fractions resulting from the dehydrations and the isomerizations themselves. The catalysts used were prepared as previously noted.

Experimental Results.—To determine whether results on different samples of a catalyst can be compared with each other, ten different preparations of pure alumina were made. These were as follows: solutions of aluminum nitrate were prepared in the five strengths—1.5, 1, 0.5, 0.3 and 0.1 *N*. Aluminum hydroxide was precipitated by the addition of 15 *N* ammonia, rapidly and without stirring in the case of the 1.5 *N* aluminum nitrate solution (catalyst a), 0.1 *N* ammonia slowly with rapid stirring in the case of the 0.1 *N* solution of aluminum nitrate (catalyst b). The others were graded between. Two samples of each catalyst were made, one was heated to boiling before filtration, the other filtered and dried at 80° before final drying. The only effect found was on the particle size and appearance of the alumina itself. Isomerization was not affected. The results found for the two most contrasting catalysts are as follows.

TABLE I

Al_2O_3: Temperature 398°, Rate 3.1 cc./hr./10 g.

The runs were in the order hexanol-1 (a), hexene-1 (a), hexanol-1 (b), hexene-1 (b). The catalyst was dried by passing dry nitrogen over it for 12 hours. This was done between hexanol-1 and hexene-1 the first time only. The second time the catalyst was allowed to be wet. Fractionation of products of hexanol-1 dehydration without any drying on calcium chloride show the same proportion of polymer. In this case it is impossible to separate the fractions because of azeotropic mixtures of water and hydrocarbons. The polymer is easily separated, because it has a much higher boiling point.

	Hexanol-1 (a)	Hexanol-1 (b)	Hexene-1 (a)	Hexene-1 (b)
4-Methylpentene-2	2%	2%		
2-Methylpentene-1	1.1	1.5		
Hexene-1	22.0	23.7	5.9	6.3
3-Methylpentene-2-*t*	38.0	36.8	9.8	10.2
2-Ethylbutene-1	9.0	8.5	38.7	38.3
2-Methylpentene-2	6.0	6.2	27.7	27.9
Hexene-3	3.0	3.2	11.3	10.6
3-Methylpentene-2-*c*	2.0	1.8	5.3	5.2
Hexene-2	5.0	4.1		
Polymer	12.0	13.0	0	0

It may be seen that the mode of preparation of the pure alumina catalyst has no appreciable effect on the distribution of products. Catalyst (a) is made up of large glossy translucent chunks; (b) crumbles and is white. To be specially noted is the fact that there is no polymer formed in the runs with pure hexene-1, wet or dry. After two runs, the alumina is jet black from carbonization. This has no effect on the distribution of products. The products are found to be the same immediately after burning off the carbon with oxygen-bearing nitrogen and after ten runs without burning off the carbon.

Comparison of the products of dehydration of hexanol-1 and isomerization of hexene-1 at comparable rates of passage shows that the change of products from the dehydration with increase in rate is the result of progressive isomerization of the primary product hexene-1, and not to a change of mechanism of dehydration. Table II demonstrates this.

Hexene-1 shows the same products at 11.2 cc./hr. as hexanol-1 shows at 3.1; the same holds true for hexene at 22.5 cc. and hexanol-1 at 11.2 cc./hr./10 g. At the higher rates, hexene-1 tends to remain unchanged. The conclusion is that the alcohol is more strongly adsorbed than the olefin so that, at the faster rates, the proportion of material adsorbed changes so that the olefin does not remain on the surface long enough to isomerize.

(1) S. Goldwasser and H. S. Taylor, THIS JOURNAL, **61**, 1751 (1939).
(2) S. Goldwasser and H. S. Taylor, *ibid.*, **61**, 1260 (1939).

At the slower rates, hexene-1 isomerizes more rapidly than the hexene-1 mixed with the alcohol since no surface is taken up by the alcohol or the product water. However, it is clear that the additional isomers produced at the slower rate of passage of alcohol are due to isomerization of the major primary product, hexene-1.

The course of isomerization as related to the structure of the olefin is summarized in Table III.

Analysis of Results.—(1) The first and most obvious conclusion concerning isomerization to be drawn from this table is that the straight chain olefin is the most unstable at these temperatures. Hexene-1 and heptene-1 give a large number of isomers on alumina. No other isomer gives any straight chain substance, however.

(2) On alumina at 398°, equilibrium is not reached from either the 2-methylpentene-2 side or the 3-methylpentene-2 side, since the per-

2-Ethylpentene-1			90	87	3	61.8 (93.1–93.2); 18.3 (93.9–94.0); 2.6 (94.4–94.5); 4.3 (over 160).

centages of products resulting are not the same from the two isomerizations. The same holds true for 2-methylhexene-2 and 3-methylhexene-2. On thoria, however, the composition of the isomerized liquid is practically the same starting from either the 2- or 3-methyl isomer. Therefore, isomerization is faster on thoria than on alumina. This agrees with the comparative rates of dehydration found for these two catalysts. That there is still some straight chain isomer left after passage over alumina and none over thoria also points to this conclusion. It is also to be noticed that the 7-carbon olefins isomerize slightly faster than the 6-carbon ones, as is evidenced by the fact that the isomers are closer to the composition found on thoria under the same conditions.

(3) The main isomerization observed is the migration of a methyl group across a double bond. The more stable of the two positions is the more centralized one. All 2-methyl compounds give the corresponding 3-methyl compounds in large quantities. The reverse migration occurs only to a small extent.

(4) The isomer 2-ethylbutene-1 is the result of migration, not of a methyl group but of the double bond. The methyl group is in the same relative position as in the stable 3-methylpentene-2. Both 2-ethylbutene-1 and 2-ethylpentene-1 give the same composition of products over thoria as the 2- and the 3-methyl compounds. The similarity in composition of the products from isomerization of all these hydrocarbons indicates a reaction path conforming to a specific pattern.

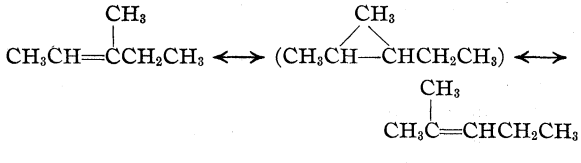
(5) Rise in temperature to 440° causes the double bond to shift to the end of the chain and considerable 2-methylpentene-1 and 2-methylhexene-1 are found. Decomposition has been enough to allow some hydrogenation of olefin. The same is true for both chromium and thorium oxides.

(6) Contrary to the findings concerning the

formation of polymer in the isomerization of a pure straight chain olefin, it is seen here that, while the straight chain olefin does not give any polymer on isomerization, there is some formed in all other cases.

(7) The formation of benzene from the 2-methylpentenes and 3-methylpentenes with chromic oxide catalyst points to the fact that there must be some isomerization to the straight chain taking place with consequent ring closure of the olefin. The only olefin for which any isomerization to the straight chain seems likely is the 2-methylpentene-1 isomer. If only a trace of hexene-1 or hexene-2 is formed from this isomer, benzene is formed immediately on the catalyst and the 2-methylpentene-1:hexene-1 equilibrium is displaced to the straight chain side. The results at 440° on thoria and alumina show the extent to which 2-methylpentene-1 is formed at higher temperatures. The fact that there is only 32% aromatic yield from the methylpentenes as compared with 95 to 100% from the hexenes is evidence of the comparative slowness of the isomerization to straight chain olefins even at the higher temperature of 474°.

Mechanism.—A mechanism which brings together several of the above findings concerning isomerization is, as in the case of the dehydration of alcohols described in a previous paper, the formation of an activated intermediate stage having the configuration corresponding to a 3-membered ring. That is, it is assumed that, on the surface of the catalyst, the following takes place



If this occurs, the products may be predicted exactly as in the case of the alcohols, and are found to agree exactly with those found. The formation of polymer in the isomerization of the branched olefin points to the same type of activated intermediate found with the alcohols. That no compound such as 4-methylpentene-2 is found, as well as that 4-methylpentene-2 and its analogs do not isomerize, indicates that methyl groups migrate across double bonds only under these conditions.

At higher temperatures, where migration of a double bond is found to take place, 2-methylpentene-1 is formed from 2-methylpentene-2 by the same mechanism. The methyl group is again on the inside of the double bond. It is this type of reaction which gives hexene-1 as a product, which then immediately aromaticizes on chromium oxide.

Summary

1. Two different preparations of the same alumina catalyst have been shown to be comparable as to their effects on isomerization of alkenes.

2. Change in distribution of isomers produced with change in rate of passage of an alcohol over a dehydrating catalyst has been shown to be due to isomerization of the olefin products themselves.

3. The products of isomerization at 400° have been determined for several olefins and comparative rates of isomerization on thoria and alumina studied.

4. A mechanism postulating an intermediate 3-carbon ring structure similar to that proposed for the dehydration of alcohols has been found to account for the products of isomerization.

5. The order of stability of some olefins at 400° is as follows: 3-methylpentene-2-*t* > 2-ethylbutene-1 > 3-methylpentene-2-*c* > 2-methylpentene-2 > 2-methylpentene-1 > hexene-1. 3-Methylhexene-2-*t* > 2-ethylpentene-1 > 3-methylhexene-2-*c* > 2-methylhexene-2 > 2-methylhexene-1 > heptene-1.

Aromatization of Heptane, Heptene and Hexene Isomers on Chromic Oxide

BY SEYMORE GOLDWASSER AND HUGH S. TAYLOR

Aliphatic alcohols containing six to eight carbon atoms have been found to be good sources of various aliphatic alkenes.[1] A convenient mechanism for the interpretation of the course of isomerization of these olefins on active non-dehydrogenating surfaces having been formulated, further work was undertaken on dehydrogenation. The present paper records a study of the effects of structure and rate of passage of hydrocarbons on the reactions involved in ring closure and aromatization.

Apparatus.—The apparatus and procedure were the same as described for the dehydrogenation of cycloöctene.[2] Samples of pure cyclohexene and 1,3-cyclohexadiene were kindly sent us from the Harvard Laboratories. Pure *n*-heptane, sulfur-free, was obtained from the California Chemical Company. All the other materials were prepared by dehydration of alcohols.

Analysis.—Because chromium oxide catalysts poison too quickly to give sufficient material for ready determination of composition by fractionation, a different method of analysis had to be used. Specific gravities and Hanus numbers were first determined for each sample. The spread of physical properties between aromatics and naphthenes, naphthenes and olefins, olefins and saturates, allowed the composition to be calculated fairly well from these determinations alone. The assumption is made that there are no substances present which do not belong to these classes. The compositions found were often checked both by calculation from off-gas volume and composition and from analysis of the liquids by means of dimethyl sulfate and bromination. There was never any disagreement between the various methods of checking. Fractionation of the liquid products from certain catalysts which do not poison over long periods of time gave still another check of the validity of the calculations used.

Experimental Results

Cyclohexene and Cyclohexadiene.—The results obtained are given in Table I.

Cyclohexene is observed to give a quantitative yield of hydrogen at 390° and the evolution of hydrogen ceases completely only below 300°. The cyclohexene continues to give benzene, however, to temperatures as low as 200° by a self reduction–oxidation on the surface. When temperatures below that causing evolution of hydrogen are used, raising the temperature of the catalyst does not cause evolution of hydrogen from fresh cyclohexene, but the value for conversion to benzene remains that of the lowest temperature used. After getting 0.9% benzene at 163°, a rise to 316° gave only 1% as compared with 20% at 305° after revivifying. Revivification by oxidation in the standard manner always restored full activity. It seems therefore that, at lower temperature, the cycloölefin, with a longer life on the surface than at higher temperatures, poisons the catalyst and remains on the surface, possibly as a hydrocarbon fragment desorbable only with difficulty.

Non-catalytically at 500°, cyclohexane has been shown to give as products 25% benzene, 40% hydrogen and 22% ethane. In not one of the runs tabulated was there any decomposition. Even at 500°, although the catalyst had never been heated above 490°, the water vapor which must have come off had no effect on the cycloölefin, although it oxidized *n*-heptane and other aliphatic hydrocarbons. Here, with cyclohexene and a dehydrogenating catalyst, the production of ben-

Al_2O_3 (act.)	540	3	9	.4	42	2	80	18

zene is so rapid that there is little chance for decomposition.

Cyclohexadiene is exactly similar to cyclohexene except that the lowest temperature at which hydrogen evolution occurs is 175° instead of 300°. Rise of temperature gives no hydrogen with new cyclohexadiene as with cyclohexene. At 95°, just a little above the boiling point of benzene, there is still 33% yield of benzene with 17% cyclohexadiene hydrogenated and 50% unchanged. This small yield is not the result of permanent poisoning as is shown by revivification and repetition at the low temperature without any intervening run.

***n*-Heptane.**—The effect of rate on the conversion of *n*-heptane to toluene is shown in Table II.

The fastest rate at which complete conversion to toluene is found is 9 cc. per hour, with the vapor in contact with the catalyst for three minutes. At a rate three times this, conversion in one passage is still 69%.

The results with thoria and pure alumina show the normal amount of unsaturation which accompanies thermal decomposition. There is no aromatization. At 540°, small amounts of aromatic normally appear in thermal decompositions of hydrocarbons. The second alumina cited in the table has a small iron content and is sufficiently dehydrogenating to give some aromatization. The great difference between a dehydrogenating and an isomerizing catalyst is evident. The rate of poisoning or fall in the evolution of hydrogen with time decreases with increase of rate. Anything that decreases the life of an olefin on the active surface decreases the rate of poisoning.

Olefins.—The influence of structure of an olefin on aromatization is shown in Table III, which presents some typical results found with various olefins. After each run there was a ten to twenty-four hour period of revivification, an eight to ten hour reduction period and a four to eight hour period for the flushing of hydrogen from the surface by the use of purified nitrogen as described in the procedure of the first paper in this series. The order of experiment is as listed.

The results obtained may be summarized as follows. (*1*) *Effect of Rate on Conversion of Olefin.*—Heptene-1 at 474° shows complete conversion at the slowest rate tried, but poisoning is more rapid than at high rates. In the experiments at the rapid rate, where poisoning takes place more slowly, a lower rate of aromatization than is the case for heptane is found. This indicates that the olefin is on the surface for a shorter time interval.

(*2*) *Effect of Temperature on Conversion.*—A rise in temperature of 50° doubles the percentage of heptene-1 converted to toluene and causes the time for half-way poisoning to be tripled. The heptene spends less time on the surface and is more readily dehydrogenated at the higher temperature. Aromatics do not poison the catalyst.

The effect of rise of temperature on the amount of conversion of the methylpentene is less marked, although the poisoning changes qualitatively in the same way. This smaller temperature effect reflects the fact that the necessary isomerization does not have as large a temperature coefficient as dehydrogenation, and that the slow process in the over-all reaction to benzene is the isomerization of the branched hexene to the straight chain hexene.

(3) *Effect of Structure on Conversion.*—(a) 7-Carbon olefin: the position of the double bond in the straight chain heptene does not cause any

TABLE III

OLEFINS ON CHROMIC OXIDE GEL

Rate: 3.1 cc./hr./15 g.

The data given are for the first five minutes of the run. The last run carried out was a heptane run in order to make sure that the catalyst had not changed activity during many runs. Several of the above were repeated on fresh catalysts with no change in results. The heptene runs were done in the order tabulated to test reproducibility of results.

marked difference in the rate of conversion to an aromatic. The rate is also that of 5-methylhexene. As was seen in the work on isomerization, the branched chain olefin is formed with great rapidity from the straight chain. 5-Methylhexene-2 is readily cyclicized and dehydrogenated. (b) 6-Carbon olefin: unless methylcyclopentane is first formed and then ring enlargement to cyclohexane occurs, any branched chain 6-carbon olefin must isomerize to the straight chain olefin before ring closure takes place. At 474°, the three isomers tried showed identical properties over chromium oxide. There is 32% conversion and the same amount of decomposition and poisoning for each. At 424°, 2-methylpentene-2 shows somewhat the higher rate of conversion to benzene, gas evolution is higher but it is of the same composition. 2-Ethylbutene-1 and 3-methylpentene-2-*t* are equal in conversion and poisoning rates, but are slower than the 2-methylpentene.

(4) *Effect of Structure on Poisoning.*—The slower the conversion to aromatics, the faster the poisoning becomes. Branched chain olefins are found to poison the catalyst more rapidly than straight chain. Again it is seen that increase of life of an olefin on the surface of a catalyst increases the rate of poisoning.

Discussion.—The conclusions to be drawn from the cycloölefin experiments are several. Once a 6-membered ring is formed on chromic oxide catalyst, the ring is not broken again at these temperatures. If the temperature is high enough to dehydrogenate an olefin, or cyclohexane or its homologs, the temperature is already too high to allow the presence of more than minute amounts of cyclohexene and even less cyclohexadiene. When cyclohexene is dehydrogenated, no cyclohexadiene intermediate can be expected to be isolated since, as has been shown, cyclohexadiene yields its hydrogen quantitatively at a temperature 100° below the lowest temperature at which cyclohexene evolves the gas. Indeed, the temperature is 25° below the temperature at which cyclohexene poisons the catalyst so that there is even no disproportionation. Although only a small amount of cyclohexene may be formed in a given reaction, the subsequent reactions to cyclohexadiene and to benzene are so rapid and complete at the higher temperatures, that the total reaction is far displaced and in some cases even 100% conversion is found.

It is evident that, for aromatization of an aliphatic hydrocarbon, dehydrogenating conditions are required which improve the chance that cyclohexene or its homologs may be formed. That there is a small but definite chance of this

happening without any special catalyst is shown by the fact that the same reaction occurs to a small extent in a Pyrex vessel and, as shown, on alumina and thoria. The reaction goes to a larger extent when dehydrogenating conditions are present. Save for the cracking reactions, the conversion of heptane to toluene is quantitative on chromic oxide gel with sufficient contact time.[3]

The data on the aromatization of the olefins agree with the results from isomerization experiments. The 6-carbon branched chain olefins, while giving only 32% aromatics as compared with 90% for the straight chain compound under the same conditions, are all quite similar. It has been shown that isomerization from one branched olefin to another is rapid at this temperature with the methyl group tending to centralize. The reason for the comparatively low yield must be the necessary isomerization to and low concentration of the straight chain olefin. This is further borne out at the lower temperature where isomerization is slower, and the differences of structure of the starting materials have more influence. The 2-methylpentene-2 isomer gives a better conversion to benzene than does either 2-ethylbutene-1 or 3-methylpentene-2-*t*, two isomers which have been shown to be about equal in rate of reaction on an active surface. The reason seems to be that there is one step less to the straight chain from the 2-methyl than from the 3-methyl isomer.

The other properties of the olefins can be summarized similarly. Both liquid and gaseous products show the occurrence of disproportionation at the lower temperatures. As the evolution of hydrogen decreases with decreasing temperature, hydrogenation to saturates begins and poisoning increases. The olefin content of the off-gas at lower temperatures is small and the liquid products have a higher concentration of saturates.

(3) Moldavski and Kamusher, *Bull. Soc. Acad. Sci., U. S. S. R. (N. S.)*, 1936, have shown that *n*-heptane, *n*-octane, and *n*-hexane cyclicize on chromic oxide gel but not on thoria, alumina, uranium oxide, zinc oxide, nickel chromate and floridin. Subsequent work by the present writers will show that cyclization actually does occur on special preparations of uranium oxide which have marked dehydrogenation properties.

Summary

1. The dehydrogenation of cyclohexene and 1,3-cyclohexadiene on chromic oxide gel surfaces has been investigated.

2. The influence of character of catalyst on aromatization has been shown. For the conversion of aliphatic hydrocarbons to aromatic hydrocarbons, a dehydrogenating catalyst must be used.

3. The influence of structure of olefin on poisoning, aromatization and disproportionation has been demonstrated.

4. Conclusions concerning isomerization drawn from these experiments agree with those found on other catalysts.

The Electron Diffraction Investigation of the Structure of Benzene, Pyridine, Pyrazine, Butadiene-1,3, Cyclopentadiene, Furan, Pyrrole, and Thiophene

BY V. SCHOMAKER AND L. PAULING

The determination of values of interatomic distances in molecules has been found to provide much information regarding electronic structure, especially in the case of substances which resonate among two or more valence-bond structures. The interpretation of interatomic distances in terms of the types of bonds involved is made with use of an empirical function formulated originally for single bond–double bond resonance of the carbon–carbon bond.[1] There are given in this paper the results of the determination of the configurations of two molecules involving Kekulé resonance, pyridine and pyrazine, of two molecules with conjugated double bonds, butadiene and cyclopentadiene, and of three five-membered heterocyclic molecules, furan, pyrrole, and thiophene, together with the conclusions regarding their electronic structures reached by application of the bond type–interatomic distance function. In addition, because of the improvement in electron diffraction technique since the study of benzene in these Laboratories four years

ago[2] and because of its similarity to pyridine and pyrazine, this substance was re-investigated.

Experimental Method.—The diffraction photographs were prepared with the apparatus and technique described by Brockway.[3] Ten or more photographs were made for each substance, the electron wave length used being about 0.0613 Å. and the camera distance 10.83 cm. The values of $s_0 = 4\pi(\sin\theta/2)/\lambda$ given in the tables are averages of the values found by visual measurement of ring diameters for ten or more films.

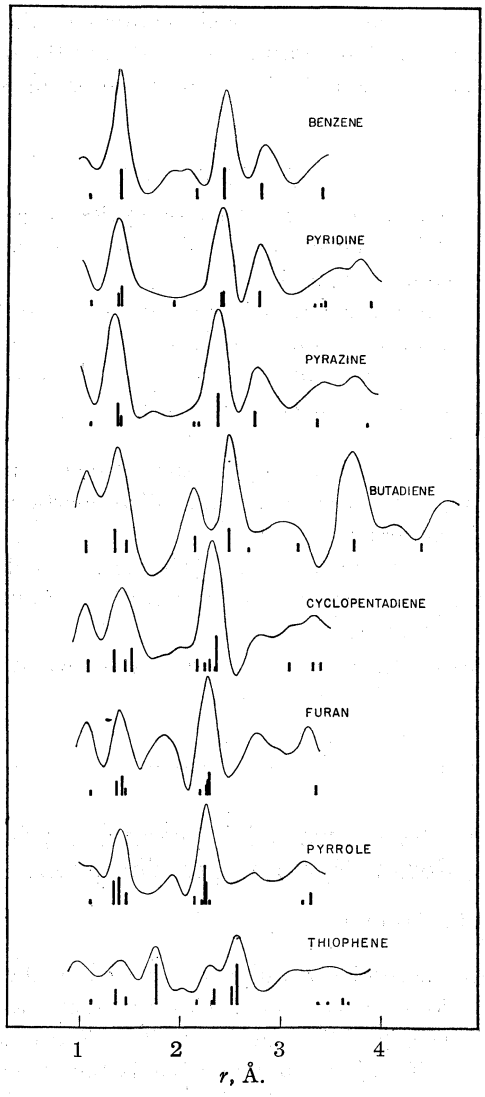

Fig. 1.—Radial distribution curves.

The radial distribution treatment,[4] with refinements soon to be described in THIS JOURNAL, was applied as the first step in the interpretation of the data for each substance. Further selection from among the small range of molecular models compatible with the radial distribution curve for each substance was then made by the usual visual method, involving comparison with simplified theoretical intensity curves for the models under discussion.

The sample of benzene used was prepared by redistilling thiophene-free benzene and rejecting the first and last portions. A similar treatment was given to pyridine (Kahlbaum), pyrrole (Eastman), and thiophene (Eastman). Butadiene was prepared by treating tetrabromobutane in ethyl alcohol solution with granulated zinc and redistilling the product several times. Cyclopentadiene was prepared by distilling dicyclopentadiene; in order that appreciable repolymerization should not take place in the sample the diffraction photographs were made immediately after the distillation (within one hour). Furan was prepared by the decarboxylation of furoic acid and purified by fractional distillation. A sample of pyrazine kindly given us by Professor F. W. Bergstrom was used without further purification.

Benzene, Pyridine, and Pyrazine.—New photographs of benzene were obtained showing four more measurable rings than those used in the

earlier investigation in these Laboratories. The radial distribution curve calculated with the C and s values of Table I (Fig. 1) shows three principal peaks, at 1.37 Å., 2.43 Å. (= $\sqrt{3} \times$ 1.40 Å.), and 2.83 Å. (= 2 × 1.415 Å.), representing the C–C separations for a regular hexagon with edge about 1.39 Å. The small peaks do not provide reliable information about the C–H bond distance. In order to make an approximate evaluation of this distance, intensity curves were calculated for plane hexagonal models with C–C = 1.39 Å. and C–H varying between 1.00 and 1.18 Å. at intervals of 0.03 Å. These curves (Fig. 2) differ significantly only in the region from the third to the sixth ring. (Note that in the tables a feature of the photographs is for convenience designated by "max." or "min." even though it appears to be a shelf or the inner edge of a shelf, respectively, and that in the text the numbers assigned to the rings correspond to those for maxima in the tables.) The visual intensity estimates for the third and fourth rings have the ratio $^4/_3$; this is not in accordance with the curves with C–H = 1.12 Å. or more, which make the fourth ring as strong as the third. Moreover, the 1.03 curve (as well as the 1.00 curve) shows only a very poorly defined shelf in place of the fourth ring. The 1.06 and 1.09 curves satisfactorily reproduce all of the features observed on the photographs, including the fifth and sixth rings. The quantitative comparison of observed s values with those calculated for C–C′ = 1.39 Å. and C–H = 1.075 Å. (the mean for the 1.06 and 1.09 curves), given in Table I, leads to C–C = 1.393 ± 0.02 Å. and C–H = 1.08 ± 0.04 Å. This value for the C–H distance agrees well with the value C–H = 1.090 ± 0.005 Å. which may be inferred from the C–H stretching frequencies and our knowledge of the relation of these frequencies to C–H bond distances.[5]

Wierl[6] and Pauling and Brockway[2] have previously reported C–C = 1.39 Å. in benzene. Jones[7] has reported the values C–C = 1.40 ± 0.01 Å. and C–H = 1.14 ± 0.01 Å. It seems probable that the latter value is in error.

An intensity curve was calculated also for a plane trigonal model, with C–H = 1.09 Å., C–C = 1.36 and 1.42 Å. alternately around the ring, the angles C–C–C = 120°, and the angles H–C–C = 123 and 117°, corresponding to quite incomplete resonance between the Kekulé structures. This curve is practically indistinguishable from that for the corresponding plane hexagonal model with C–H = 1.09 Å. and C–C = 1.39 Å. The electron diffraction method is accordingly unable to add to the existing theoretical and experimental evidence[8] for complete resonance in the benzene molecule.

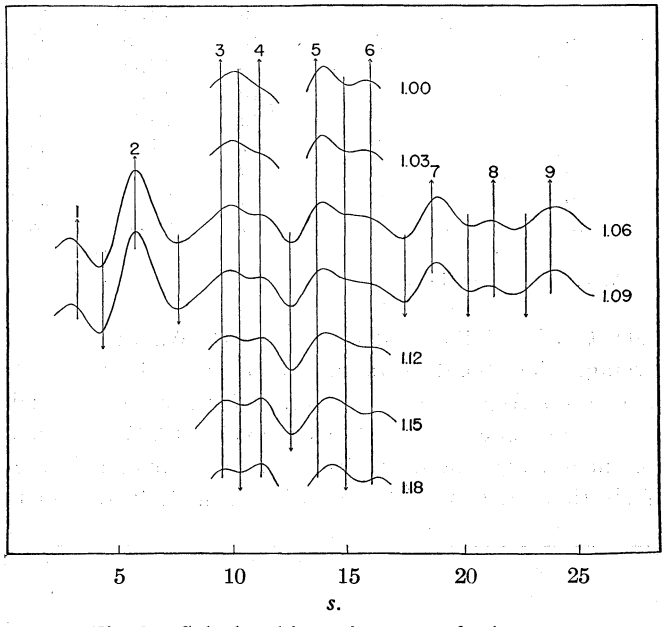

Fig. 2.—Calculated intensity curves for benzene.

The photographs obtained for pyridine and pyrazine are so closely similar to those of benzene as to leave no doubt that the three molecules have nearly identical structures. The radial distribution curve for pyridine (Fig. 1) calculated from the data given in Table II has well-defined peaks at 1.38, 2.39 (= $\sqrt{3} \times$ 1.38), and 2.76 (= 2 × 1.38) Å. The sharpness of the 2.39 peak indicates that the six meta distances in the ring are nearly equal. The calculated intensity curve for the model with C–C = 1.39 Å., C–N = 1.33 Å., C–H = 1.08 Å., the angle C–N–C = 119° and the angles C–C–C = 121°, and having nearly equal "meta" and "para" distances, is shown in Fig. 3. The comparison of s_0 and s values for this model (Table II) leads to the values C–H =

[a] Models described in text.

1.09, C–C = 1.405, and C–N = 1.344 Å., with average ring bond distance 1.385 ± 0.01 Å. The comparison with the s values for a regular hexagonal model leads to the same value 1.385 Å. for the average ring bond distance. It seems unlikely that the C–C distance differs from 1.39 Å., and the results accordingly suggest that the C–N distance is about 1.37 ± 0.03 Å.

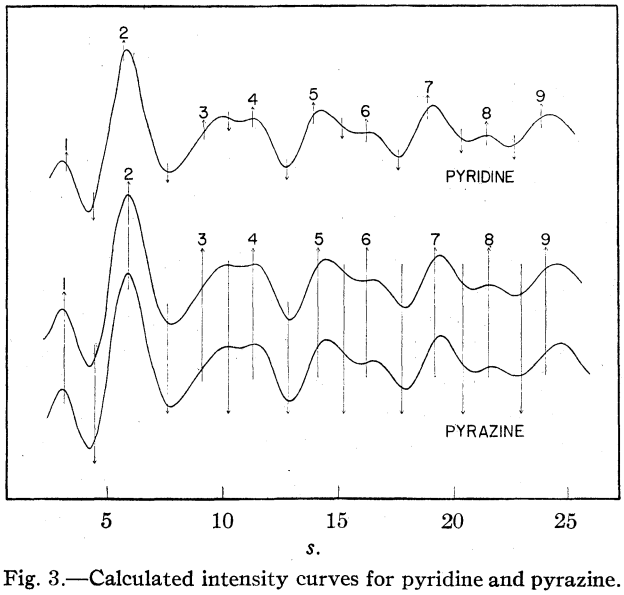

Fig. 3.—Calculated intensity curves for pyridine and pyrazine.

The principal peaks on the radial distribution curve for pyrazine (Fig. 1) lie at 1.36, 2.37 ($= \sqrt{3} \times 1.37$), and 2.76 ($= 2 \times 1.38$ Å.). Intensity curves for model I, with C–C = 1.39 Å., C–N = 1.33 Å., C–H = 1.09 Å., and all ring angles 120°, and for model III, with the same bond distances but with the ring angles at nitrogen 123° and at carbon 118°30′, making the meta distances equal, are shown in Fig. 3. These curves, as well as the benzene curve (representing a regular hexagonal model), agree qualitatively with the photographs. The quantitative comparison for all three leads to the value 1.366 ± 0.01 Å. for the average ring bond distance. With C–C = 1.39 Å., this corresponds to C–N = 1.35 ± 0.02 Å.

Butadiene-1,3 and Cyclopentadiene.—The photographs of butadiene which were obtained are diffuse and were measured only with difficulty, so that the determination of the configuration of the molecule is less precise than usual. Thirteen rings could be seen, with the s_0 and I values given in Table IV. These correspond to the radial distribution curve shown in Fig. 1, with peaks at 1.07, 1.38, 2.12, 2.48, (3.0), 3.71, (4.13), and (4.65) Å., the values in parentheses being unreliable. The carbon–carbon peak at 1.38 Å. represents the mean of the values for the two double bonds and the intervening single bond, which has some double bond character. If the double bonds have about the normal distance 1.34 Å. found in ethylene and allene,[1b,5] the value 1.46 Å. is indicated for the conjugated single bond. The peak

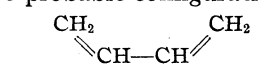
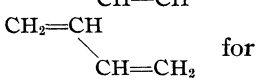
[a] Models described in text. [b] The theoretical curve does not show a measured feature at this point.

at 2.48 Å. corresponds to the 1,3 and 2,4 carbon–carbon distances; this value leads to about 125° for the C=C—C bond angle.

Of the two probable configurations *cis*



and *trans*



for the molecule, the latter is suggested by the presence of a large radial distribution peak at 3.71 Å., which is just the value calculated for the *trans* model. The small radial distribution peak at 3.0 Å. is probably without significance.

The intensity curves I, II, III, and IV of Fig. 4 are calculated for coplanar *trans* models with C–H = 1.06 Å., the angle H—C=C = 115°, and the angle H—C—H = 109.5°. Although these hydrogen parameters are so chosen as to agree as well as possible with minor peaks of the radial distribution function, no great reliance can be placed on them, and indeed it is likely that for this molecule the C–H bond distance is 1.09 Å. The models have the following additional parameters

Model	C=C	C—C	Angle C=C—C
I	1.38 Å.	1.38	126°10′
II	1.36	1.44	124°40′
III	1.34	1.48	123°5′
IV	1.32	1.54	120°10′

The average of the carbon–carbon bond distances has for each model approximately the radial distribution value 1.38 Å. and the angle C=C—C is such as to give the radial distribution value 2.48 Å. for the 1,3- and 2,4-distances. The agreement with the photographs is reasonably satisfactory for curves II and III, but not for I and IV. For example, the relative intensities of rings 9 and 10 are not well reproduced by curve IV, and those of rings 11 and 12 are not given satisfactorily by either curve I or curve IV. The appearance on the photographs of a doublet (rings 6 and 7) rather than a single ring may be due to an inflection in curves II and III in this region; otherwise the agreement is excellent. Curves were also calculated for about ten models differing slightly from these, with no improvement.

It is concluded that the butadiene molecule has the configuration described by the following parameter values: C–H = 1.06 Å. (assumed), C=C = 1.35 ± 0.02 Å., C–C = 1.46 ± 0.03 Å., angle C=C—C = 124 ± 2°. The configuration is probably essentially coplanar and *trans;* the evidence for this view provided by the radial distribution function is not conclusive inasmuch as it is not supported by a strong dependence of the theoretical intensity curves on the relative rotation of the vinyl groups of the butadiene model. The electron diffraction data are not incompatible with a mixture of *cis* and (predominantly) *trans* molecules. However, other experimental evidence (reviewed by Mulliken[9]) together with theoretical

(9) R. S. Mulliken, *J. Chem. Phys.*, **7**, 121 (1939). See, however, **7**, 373 (1939).

considerations[10] indicates that butadiene molecules must be essentially coplanar and *trans*.

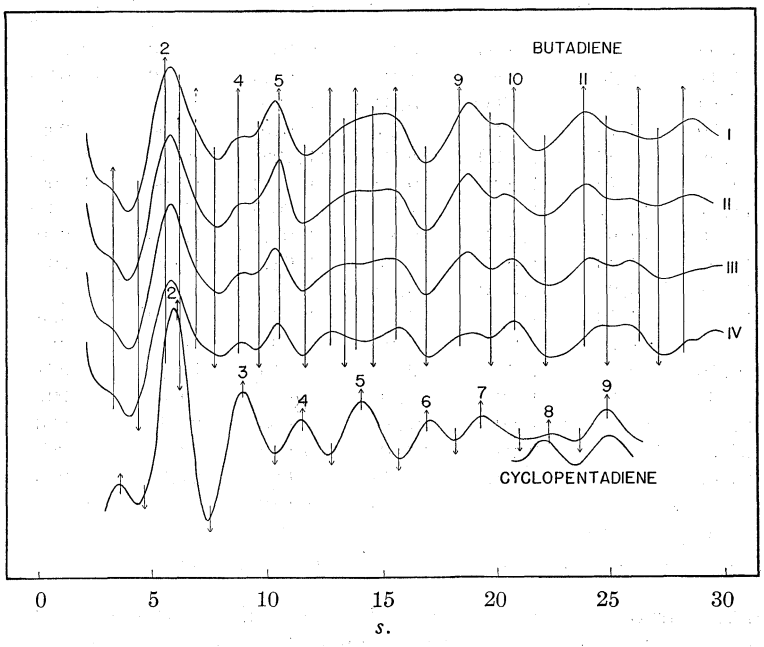


Fig. 4.—Calculated intensity curves for butadiene and cyclopentadiene.

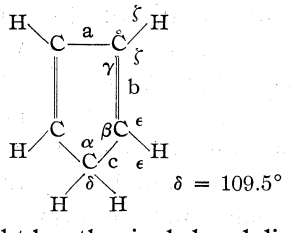
The spectroscopic conclusion of Bartholomé and Karweil[11] that in butadiene there is essentially free rotation about the C–C bond with a barrier not greater than 200 cal./mole is almost certainly incorrect.

Data for the excellent photographs of cyclopentadiene, showing nine rings, are given in Table V. The corresponding radial distribution curve (Fig. 1) has peaks at 1.06, 1.42, and 2.33 Å. The number of parameters determining the structure of this molecule is so great as to prevent their independent evaluation. The molecule



without doubt has the single bond distance *c* equal to about 1.53 Å., as in the cycloparaffins, and the double bond distance *b* equal to about 1.35 Å., as in butadiene. The conjugated single bond *a* is probably about 1.46 Å. Many models with approximately these values for the carbon–carbon distances, with various ring angles, and with C–H = 1.09 Å. were found to give calculated curves showing by their qualitative appearance that $\alpha = 101 \pm \sim 3°$ and leading on quantitative comparison to the value 1.445 ± 0.01 Å. for the average ring bond distance. This is exactly the average of the values suggested above. Assuming the average of the values of *b* and *c* to be reliable, we write C–C = 1.46 ± 0.04 Å. as the value determined for the conjugated double bond. The curve shown in Fig. 4, with *s* values given in Table V, is that for the model with the values *a* = 1.44, *b* = 1.34, and *c* = 1.54 Å., and the angles $\alpha = 101°$, $\beta = 109°$, $\gamma = 110°$. While this curve is slightly better than any of the others we have calculated, it is not possible to base a satisfactory determination of the relative values of the bond distances on the qualitative appearance of the diffraction pattern. The curve gives an excellent representation of the appearance of the photographs except that the fourth minimum of the curve is much too deep relative to the fifth minimum, and the eighth maximum is much too weak. On the films the eighth ring appears to be as strong as the ninth. These discrepancies arise from ignoring the temperature effect,[12] that is, the effect on the diffraction pattern of the variation of the interatomic distances resulting from molecular vibrations. We have found that when probable variations of the various interatomic distances are considered, the slight trouble of the fourth and fifth minima is resolved, as is the greater difficulty of the eighth maximum. This is illustrated for the region of the eighth maximum by the last curve of Fig. 4, which has been plotted for the best cyclopentadiene model (C–C = 1.53, 1.46; C=C = 1.35; $\alpha = 101°$), with the carbon–hydrogen interactions omitted as an approximation to the effect at large diffraction angles of the temperature factor corresponding to the large amplitudes of vibration of the hydrogen atoms.

(10) L. Pauling and J. Sherman, *J. Chem. Phys.*, **1**, 679 (1933); W. G. Penney, *Proc. Roy. Soc.* (London), **A158**, 306 (1937).

(11) E. Bartholomé and J. Karweil, *Z. physik. Chem.*, **B35**, 442 (1937).

(12) L. O. Brockway, *Rev. Modern Phys.*, **8**, 238 (1936). The temperature effect may be somewhat significant also for the other molecules discussed in the paper. Its dominating importance for cyclopentadiene is perhaps coincidental. We expect to investigate this question further.

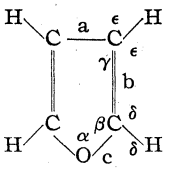
[a] Model XIX: C–O = 1.41, C=C = 1.35, C—C = 1.46, α = 105°, β = 110.8°, γ = 106.7°.

Furan, Pyrrole, and Thiophene.—The data for furan (Table VI) lead to a radial distribution curve (Fig. 1) with principal peaks at 1.39 and 2.26 Å., indicating an average ring bond distance

of 1.39 Å. This is substantiated by comparison with calculated intensity curves, which gives 1.395 ± 0.01 Å. for this average.

If the assumption be made that in the molecule



the values of a and b are 1.46 and 1.35 Å., respectively, as in butadiene and cyclopentadiene, it is found that there is excellent qualitative and quantitative agreement between the photographs and models with C–H = 1.09 Å., c = 1.41 ± 0.02 Å., α = 107 ± 4°, β = 109 ± 3°, and γ = 107 ± 2°, as is illustrated for model XIX by Fig. 5 and Table VI. The quantitative agreement is impaired by change in c, and the qualitative agreement by change in α (with corresponding changes in β and γ). It is interesting to note that the value of c is only slightly less than the single bond C–O value, 1.43 Å.

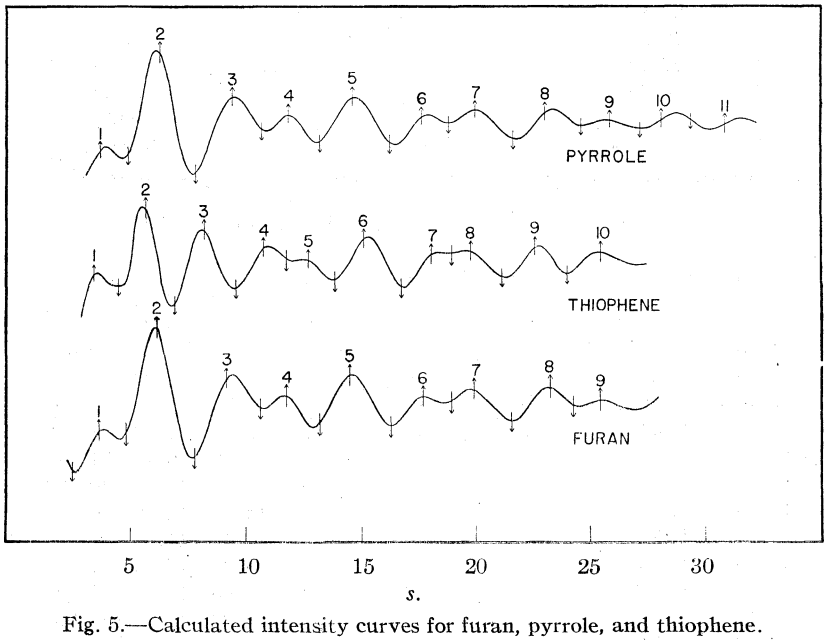


Fig. 5.—Calculated intensity curves for furan, pyrrole, and thiophene.

The curve for model XIX represents the appearance of the photographs very well, except that the sixth and seventh maxima actually appear to be equally strong. Several of the twenty theoretical curves calculated for furan are nearly as satisfactory, and one, for the model with C—O = 1.42, C=C = 1.34, C—C = 1.44, and α = 104°, is somewhat better, the sixth and seventh maxima on it being equally high. This improvement is probably not significant, especially since the temperature effect may here play a role as with cyclopentadiene. We find that it is not possible to determine the relative values of the bond distances in the heterocyclic molecules containing only light atoms within reasonable limits by the qualitative comparison, and we have accordingly assumed appropriate values for C=C and C—C. For any reasonable given set of ring bond distances qualitative agreement is obtained only when the bond angles are so chosen as to make the cross-ring distances equal to within a few hundredths of an ångström unit.

The photographs for pyrrole are very closely similar to those for furan, and lead to the same value, 1.395 ± 0.01 Å., for the average ring bond distance. The radial distribution function shown in Fig. 1 has important sharp peaks at 1.40 and 2.25 Å. With a = 1.46 and b = 1.35 Å., the average ring bond distance leads to c = 1.41 Å., which is 0.06 Å. less than the C–N single bond value. In accordance with the discussion given below, it seems probable that this decrease, indicating double bond character, is accompanied by further decrease in a, and that the values in the molecule are C—H = 1.09 Å. (assumed), a = 1.44 Å. (assumed), b = 1.35 Å. (assumed), and c = 1.42 ± 0.02 Å. The angles have the values α = 105 ± 4°, β = 110 ± 3°, and γ = 108 ± 2°. The agreement of the photographs with a model falling within this range is shown in Fig. 5 and Table VIII. Other models give the same average ring bond distance.

The data from the photographs of thiophene, showing ten rings (Table VIII), lead to the radial distribution curve of Fig. 1, with peaks at 1.40 Å. (C–C), 1.74 Å. (S–C), 2.29 Å. (C–C, meta), and 2.55 Å. (S—C). If the values C—C = 1.44 and C=C = 1.35 Å. be assumed in this molecule, as in pyrrole, the radial distribution curve leads to the configuration with S—C = 1.74 ± 0.03 Å., angle C—S—C = 91 ± 4°, angle S—C=C = 112 ± 3°, and angle C=C—C = 113 ± 3°. The curve calculated for this model (with C—H = 1.09 Å.) agrees very well with the photographs, as shown in Fig. 5 and Table VIII.

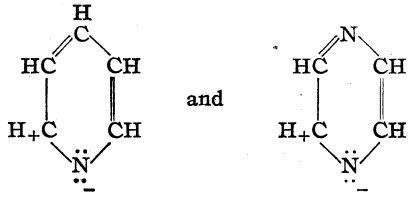
[a] Model described in text. [b] Many of the features of the thiophene photographs are of types known to be difficult to measure. Here the inner rings and the components of the two doublets have been thrown out of the average, since measurements of both types of features are known to be unreliable. The effect of the choice of rings to be thrown out is here somewhat greater than usual and may amount to ±0.005 in s/s_0.

for the C–N Kekulé-type bond distance in pyridine and pyrazine, 1.37 ± 0.03 Å. and 1.35 ± 0.02 Å., respectively, are somewhat larger than the expected value 1.33 Å. for 50% double bond character. It is possible that this is the result of the large electronegativity of the nitrogen atom, leading to significant additional resonance with ionic structures such as



Probably the effect on the C–N distance is greater for pyridine than for pyrazine because in pyridine there are three structures giving the nitrogen atom a negative formal charge and only single bonds, while in pyrazine there are four such structures of which only two affect a given one of the nitrogen atoms. Investigations of the C–N distances in related compounds such as pyridazine, pyrimidine, and cyanuric and cyameluric[13] derivatives would be of interest in this connection.

(13) L. Pauling and J. H. Sturdivant, *Proc. Natl. Acad. Sci.*, **23**, 615 (1937), have discussed the cyanuric and cyameluric derivatives.

It may be mentioned that this interpretation is in agreement with the deactivating and β directing influence of nitrogen in pyridine and its analogs[14] with respect to substitution reactions.

Butadiene-1,3 and Cyclopentadiene.—The value 1.46 Å. for the single bond between conjugated double bonds in butadiene-1,3 and cyclopentadiene has been discussed already in connection with the values found in other hydrocarbons containing conjugated systems.[15] Penney's[10] predicted value for the conjugated bond in butadiene, 1.43 Å., appears to be a little too low.

Furan, Pyrrole, and Thiophene.—The carbon–heteroatom distances found in furan, pyrrole, and thiophene correspond to 5 ± 5%, 12 ± 6%, and 17 ± 10% double-bond character, respectively. Resonance of the normal structure I with structures of the types II and III (X = O, NH, S) is assumed to be responsible for this double-bond character, while excited structures characteristic

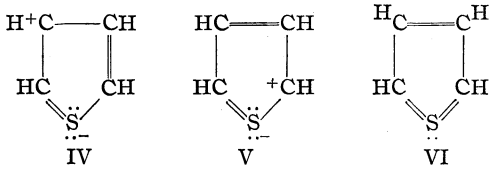
I II III

of the conjugated system  together with structures of the type III lead to the shortening of the C—C bond and the lengthening of the C=C bond. The C–C distance is assumed to be 1.46 Å. for furan and 1.44 Å. for pyrrole and thiophene, corresponding approximately to the expected contributions of various structures in these molecules. Besides those already mentioned, we may write for thiophene further reasonably stable structures, of types IV, V, and VI, involving the violation of the octet rule by sulfur, and contributing to the shortening of the C–S and C–C bonds. The



IV V VI

extent of their contribution is discussed below.

It is of interest to compare our results regarding furan, pyrrole, and thiophene with other information about these molecules. First of all, it is understandable that the very electronegative oxygen atom should not like to assume the positive charge of the excited structures written for furan, and that in consequence resonance with these structures should be less important than in pyrrole and thiophene, where the less electronegative atoms nitrogen and sulfur are involved. The values of the stabilizing resonance energy 21, 23, and 31 kcal./mole, respectively, for furan, pyrrole, and thiophene reported by Pauling and Sherman[16] are not in agreement with the great difference of degree of resonance in furan and pyrrole indicated by the electron diffraction investigation. We have recalculated values of the resonance energy from combustion data[17] for several furan and pyrrole derivatives; these values are listed in Table IX, together with our estimates of that part of the resonance energy which is to be attributed to the heterocyclic nuclei, obtained by subtracting the following corrections: 39 kcal./mole for benzene resonance, 6 kcal./mole for conjugation with phenyl, vinyl, or aldehyde group, 1.5 kcal./mole for conjugation with methyl or ethyl group, and 3 kcal./mole for conjugation with a hydroxyl group. These values[18] indicate that the resonance energy of the pyrrole nucleus is actually greater than that of the furan nucleus by about 8 kcal./mole, the probable values being approximately 23 and 31 kcal./mole, respectively. It accordingly seems likely that the value given in the literature for the heat of combustion of pyrrole is about 8 kcal./mole high.

TABLE IX

VALUES OF RESONANCE ENERGY OF DERIVATIVES OF FURAN AND PYRROLE

Substance	Resonance energy, kcal./mole	Resonance energy of nucleus, kcal./mole
Furan	23	23
Furfural	29.5	23.5
Furylethylene	28	22
Furfuryl alcohol	32	29
Pyrrole	23	23
Pyrrole aldehyde	40	34
N-Phenylpyrrole	76	31
2,4,5-Trimethyl-3-ethylpyrrole	33.5	27.5
2,4-Dimethyl-3-ethylpyrrole aldehyde	42.4	32

The new value for the resonance energy of pyrrole is just equal to that for thiophene. Unfortunately we have been unable to find combustion data for derivatives of thiophene to use in verifying the thiophene value. The interatomic distance data indicate greater resonance for thiophene than for pyrrole, which presumably would be accompanied by greater resonance energy; it is possible, however, that the magnitude of the resonance integrals for a molecule involving a heavier atom (sulfur) is less than for molecules containing only light atoms, and that the resonance energies of thiophene and pyrrole cannot be directly compared to obtain the relative amounts of resonance in the two molecules.

The electric dipole moments in units 1×10^{-18} e. s. u. of these molecules and their derivatives by hydrogenation measured[19] in benzene solution are the following: furan, 0.670; 2,5-dihydrofuran, 1.53; tetrahydrofuran, 1.68; pyrrole, 1.80; pyrroline, 1.42; pyrrolidine, 1.57; thiophene, 0.54; and tetrahydrothiophene, 1.87. We now give a very rough interpretation of these quantities based on the bond moments given

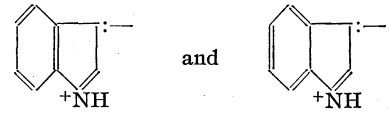
[a] Probably coplanar *trans* configuration.

by Smyth[20] and on the usual approximate treatment[21] of the effect on electric dipole moment of resonance with polar structures. A simple calculation suggests that the difference 0.15 *D* in moment between the dihydro and tetrahydro derivatives of furan and pyrrole may be accounted for as the result of change in the direction and number of C–H bonds having moments of about 0.4 *D*. The differences of moments of tetrahydrofuran and furan, and tetrahydrothiophene and thiophene, which are 1.01 and 1.33 *D*, respectively, consist of contributions of 0.05 to 0.10 *D* due to the change of C–H moments, combined with resonance moments, in the same direction, of about 0.95 and 1.25 *D*, respectively, the effects of changing the angles in the ring being neglected. The interpretation of the moments of the pyrroles is complicated by uncertainty regarding the orientation of the N–H bond in these molecules. It seems to be impossible to make a reliable estimate of the resonance moment for pyrrole; various methods of making the calculation give values lying between 1.0 and 2.5 *D*, with 1.5 *D* the most probable value. These resonance moments, 0.95 *D* for furan, 1.5 *D* for pyrrole, and 1.25 *D* for thiophene, correspond to approximately the following total contribution of structures of Types II and III (assumed to be equally important): furan 15%, pyrrole 23%, and thiophene 16%, while the assumed C–X distances correspond to total contributions by excited structures of 10, 24, and 34%, respectively. The agreement of the estimates made in the two ways is reasonably good for furan and pyrrole. The low value found for thiophene by the dipole moment calculation indicates that structures of types IV, V, and VI are of considerable significance; the consideration of the data suggests about 10% contribution by these structures, involving more than eight electrons in the outer shell of the sulfur atom, and 20% by the structures of types II and III.

Finally, it may be said that the general chemical behavior of furan, pyrrole, and thiophene indicates this order of increasing stability and aromatic character, in agreement with this discussion. An interesting example which seems to support this conclusion is the reaction[22] with maleic anhydride of furan to give (by the Diels-Alder reaction) a product which does not contain the furan nucleus, and that of pyrrole[23] to give in part by a simple condensation a compound in which the pyrrole nucleus is retained. The α directing influence on substitution reactions of the hetero atoms in furan, pyrrole, and thiophene indicates that excited structures of type III predominate over those of type II, as would be expected from their smaller charge separation. It is interesting to note that β-substitution occurs in indole; this is the result of the fact that of the ionic excited structures, two



place a negative charge on the β-carbon atom, whereas only one such structure occurs for each of the other carbon atoms. This striking difference between pyrrole and indole thus has a simple explanation in terms of resonance.

We wish to thank Professor F. W. Bergstrom for the sample of pyrazine, Dr. W. E. Vaughan for that of tetrabromobutane, Dr. K. J. Palmer for his help with experimental work, Dr. Sidney Weinbaum for assistance in the preparation of the figures, and Dr. E. R. Buchman for discussion of the chemical properties of the substances. We are especially indebted to Professor L. O.

Brockway for checking our measurements of the photographs, for general assistance, and for many helpful discussions.

Summary

The results of the electron diffraction investigation reported in this paper are collected in Table X. The re-investigation of benzene confirms the value 1.39 Å. for the C–C distance and provides a rough experimental value for the C–H distance. In pyridine and pyrazine the C–N distance is greater than expected for Kekulé resonance; the effect is attributed to extra resonance with ionic structures. The electron diffraction results, electric dipole moment data, resonance energies, chemical information, and simple theoretical considerations indicate, almost uniformly, the order furan < pyrrole < thiophene for the degree of resonance stabilization of these molecules. The contributions of excited structures, other than those characteristic of the conjugated double bonds, are about 10, 24, and 34%, respectively. Part of the resonance of thiophene is with structures with ten electrons in the valence shell of the sulfur atom.

[CONTRIBUTION FROM THE COLLEGE OF PHARMACY, UNIVERSITY OF MICHIGAN]

Naphthylaminoalkanes

BY F. F. BLICKE AND CHARLES E. MAXWELL[1]

A number of phenyl and hydroxyphenyl substitution products of aminoethane and aminopropane such as epinephrine, neosynephrin, ephedrine and benzedrine have found extensive use as therapeutic agents.

Since there seems to be little information in the literature relative to the pharmacological activity of naphthyl analogs of compounds such as are mentioned above, we have prepared six naphthylaminoalkanes which, with the exception of α-naphthylaminomethane, have been examined in the form of their hydrochlorides by Mr. L. W. Rowe of Parke, Davis and Company. It was found that the amines exhibited only a slight pressor activity upon initial intravenous injection in dogs with the development of tolerance to succeeding injections. An interesting property shown by the whole group is the production of a "cross tolerance," that is, little or no effect on blood pressure is produced by the administration of ephedrine if the injection of the latter is preceded by an injection of one of the naphthylaminoalkanes.

It seems that more effective compounds might be obtained by the introduction of hydroxyl groups into the naphthalene nucleus; however, Windaus and Bernthsen-Buchner[2] stated that α-[1-(4-hydroxynaphthyl)]-β-aminoethane exhibits only slight pharmacological activity.

α-Naphthylaminomethane, α-$C_{10}H_7CH_2NH_2$ (I), was obtained by interaction of α-naphthylmethyl chloride and hexamethylenetetramine in chloroform.[3]

In order to obtain 1-(α-naphthyl)-1-aminoethane, α-$C_{10}H_7CH(NH_2)CH_3$ (II), 1-(α-naphthyl)-1-aminopropane, α-$C_{10}H_7CH(NH_2)CH_2CH_3$ (IV) and 1-(α-naphthyl)-1-aminobutane, α-$C_{10}H_7CH(NH_2)CH_2CH_2CH_3$ (VI), α-naphthylmagnesium bromide was allowed to react with aceto-, propio- and butyronitrile, respectively. The ketones, prepared in this manner, were converted into the oximes and the latter reduced to the amines with sodium and alcohol.

1-(β-Naphthyl)-1-aminoethane, β-$C_{10}H_7CH(NH_2)CH_3$ (III), was synthesized by reduction of β-acetonaphthone oxime.

The naphthyl analog of benzedrine, 1-(α-naphthyl-2-aminopropane), α-$C_{10}H_7CH_2CH(NH_2)CH_3$ (V), was obtained by the following series of reactions: diethyl malonate ⟶ diethyl α-naphthylmethylmalonate ⟶ diethyl methyl-α-naphthylmethylmalonate ⟶ methyl-α-naphthylmethylmalonic acid ⟶ β-(α-naphthyl)-isobutyric acid ⟶ β-(α-naphthyl)-isobutyramide ⟶ 1-(α-naphthyl)-2-aminopropane.

β-(α-Naphthyl)-isobutyric acid (IX) was prepared by a second method according to which α-naphthaldehyde was condensed with methyl ethyl

(1) This paper represents part of a dissertation to be submitted to the Horace H. Rackham School of Graduate Studies by C. E. Maxwell in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the University of Michigan.

(3) For a discussion of this interesting reaction see Heidelberger, "An Advanced Laboratory Manual of Organic Chemistry," The Chemical Catalog Company, New York, N. Y., 1923, p. 24.

ketone to yield methyl α-methyl-β-(α-naphthyl)-vinyl ketone (VII). The latter was oxidized with sodium hypobromite to α-methyl-β-(α-naphthyl)-acrylic acid (VIII). Upon reduction of the acrylic acid with sodium amalgam there was obtained β-(α-naphthyl)-isobutyric acid.

$$C_{10}H_7—CHO + CH_3—CH_2—CO—CH_3 = C_{10}H_7—CH=C(CH_3)—CO—CH_3 \quad (VII)$$

$$C_{10}H_7—CH=C(CH_3)—COOH \quad (VIII)$$

$$C_{10}H_7—CH_2—CH(CH_3)—COOH \quad (IX)$$

Incidentally, diethyl methyl-α-naphthylmethylmalonate was condensed with urea to form methyl-α-naphthylmethylbarbituric acid.

Experimental Part

α-Naphthylmethylamine (I).—A mixture of 19.4 g. (0.11 mole) of α-naphthylmethyl chloride,[4] 14 g. (0.10 mole) of finely powdered hexamethylenetetramine and 50 cc. of chloroform was heated until the compounds began to react, the heat removed for a short time and the mixture then refluxed for one-half hour. The slightly turbid solution was cooled, 150 cc. of petroleum ether (30–60°) added and the gummy precipitate, which soon became solid, filtered and dried; yield 35 g. The material was placed in a distillation flask, 82 cc. of alcohol and 30 cc. of concd. hydrochloric acid added and the mixture distilled until about one-third of the liquid had been removed. The residue was cooled, the solid product filtered, dissolved in water, the solution made alkaline with concd. alkali and the amine extracted with ether; yield 11.5 g.; b. p. 200–205° (30 mm.).[5]

An ether solution of the amine, treated with hydrogen chloride, yielded the hydrochloride; m. p. 260–262°.[6]

1-(α-Naphthyl)-1-aminoethane (II).—To α-naphthylmagnesium bromide, prepared from 103 g. of α-bromonaphthalene, 12 g. of magnesium and 300 cc. of ether, there was added, during the course of one-half hour, 21 g. of acetonitrile, dissolved in 100 cc. of ether. The mixture was refluxed for one-half hour, cooled, stirred and 150 cc. of 10% hydrochloric acid added slowly, followed by the addition of 25 cc. of concd. hydrochloric acid. The ether layer was separated, dried, the solvent removed and the α-acetonaphthone distilled; yield 62 g.; b. p. 145–147° (6 mm.).[7]

The oxime was formed in practically quantitative yield when 5 moles of sodium hydroxide was added, slowly, to one mole of the ketone, 1.5 moles of hydroxylamine hydrochloride, 360 cc. of alcohol and 75 cc. of water and the mixture refluxed for five minutes. The latter was poured into 550 cc. of concd. hydrochloric acid, diluted with 3600 cc. of water, the oxime filtered and recrystallized from dilute alcohol; m. p. 134–135°.[8]

Twenty-five grams of the oxime was reduced with sodium and alcohol,[9] the alcohol removed under reduced pressure and the amine extracted with ether. The solution was dried with stick sodium hydroxide. The amine boiled at 141–142° (5 mm.)[10]; yield 15 g.

Hydrogen chloride was passed into an ether solution of the amine and the precipitated hydrochloride recrystallized from alcohol; m. p. 236–237°.[11]

Anal. Calcd. for $C_{12}H_{14}NCl$: N, 6.75; Cl, 17.08. Found: N, 6.68; Cl, 17.02.

1-(β-Naphthyl)-1-aminoethane (III).—β-Acetonaphthone[8b] was converted into its oxime as described above; m. p. 142–143°.[12] Eight and one-half grams of the oxime, reduced with sodium and alcohol, yielded 4.4 g. of the amine; b. p. 172–174° (29 mm.).[13] The amine hydrochloride melted at 279–280°[14] after it had been precipitated from an alcoholic solution by absolute ether.

Anal. Calcd. for $C_{12}H_{14}NCl$: N, 6.75; Cl, 17.08. Found: N, 6.61; Cl, 17.02.

1-(α-Naphthyl)-1-aminopropane (IV).—α-Propionaphthone was produced in 52% yield from propionitrile and α-naphthylmagnesium bromide; b. p. 171–174° (12 mm.).[15]

The oxime was obtained in 88% yield; m. p. 55–57°.[16] Reduction of the oxime with sodium and alcohol yielded the amine in 50% yield; b. p. 148–149° (10 mm.).

The amine hydrochloride melted at 281–282° after precipitation by ether from an alcoholic solution.

Anal. Calcd. for $C_{13}H_{16}NCl$: N, 6.32; Cl, 16.00. Found: N, 6.22; Cl, 15.81.

Diethyl α-Naphthylmethylmalonate.—Two hundred and five grams of this compound was obtained from 288 g. of diethyl malonate, 360 cc. of dry, thiophene-free benzene, 20.7 g. of sodium and 158 g. of α-chloromethylnaphthalene; b. p. 199–201° (3 mm.)[17]; yield 205 g.

Diethyl Methyl-α-naphthylmethylmalonate.—This compound was obtained in 89% yield in the usual manner from 17.5 g. of sodium, 380 cc. of absolute alcohol, 227 g. of diethyl α-naphthylmethylmalonate and 170 g. of methyl iodide; b. p. 207–209° (2 mm.); m. p. 51–52° after recrystallization from alcohol. The compound is soluble in ether, benzene and alcohol.

Anal. Calcd. for $C_{19}H_{22}O_4$: C, 72.59; H, 7.06. Found: C, 72.42; H, 7.12.

Methyl-α-naphthylmethylmalonic Acid.—A mixture of 130 g. of the ester, 1000 cc. of 60% alcohol and 79 g. of potassium hydroxide was refluxed for four hours, the alcohol removed and the residue made acid to congo red; yield 97 g.; m. p. 172–173° (dec.) after recrystallization from dilute alcohol. The acid is soluble in ether and alcohol, slightly soluble in benzene.

(5) Von Braun, Blessing and Zobel [*Ber.*, **56**, 1996 (1923)], who reduced α-naphthonitrile, found 155° (12 mm.).

(6) The melting point[5] is reported as 262–264°.

(7) Stobbe and Lenzner [*Ann.*, **380**, 95 (1911)] found 296–298°.

(8) (a) Rousset [*Bull. soc. chim.*, [3] **15**, 60 (1896)] found 135–136°; (b) St. Pfau and Ofner [*Helv. Chim. Acta*, **9**, 671 (1926)] reported 137–138°.

(9) See "Organic Syntheses," **11**, 58 (1931), for the general procedure.

(10) (a) Samuelsson [Thesis, Univ. Lund, 1923; *C. A.*, **18**, 1833 (1924)] reported 153° (11 mm.); (b) Hayashi, *Sci. Pap. Inst. Physic. Chem. Res.*, **20**, 398; *Chem. Zentr.*, **104**, I, 1728 (1933)] found 183.5° (41 mm.).

(11) The melting point reported[8b] is 220–221° (dec.).

(12) The melting points reported are 142–143°[8a] and 145–146°.[8b]

(13) Samuelsson[10a] found 142–143° (6–7 mm.).

(14) The reported melting point is 199–200°.[10a]

(15) Rousset[8a] found 166–168° (8 mm.).

(16) The melting point reported is 57–58°[8a] (p. 63).

(17) Mayer and Sieglitz [*Ber.*, **55**, 1843 (1922)] found 221° (11 mm.); they used α-bromomethylnaphthalene.

Anal. Calcd. for $C_{15}H_{14}O_4$: C, 69.75; H, 5.47. Found: C, 69.63; H, 5.55.

β-(α-Naphthyl)-isobutyric Acid (IX).—The malonic acid was heated, in 15-g. portions, at 175–180° in an oil-bath for three to four hours. The viscous residue crystallized when rubbed and melted at 91–92° after recrystallization from petroleum ether (90–100°). The acid is soluble in ether, benzene and alcohol.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59. Found: C, 78.60; H, 6.71.

According to a second procedure 11.5 g. of α-naphthaldehyde bisulfite[18] compound was treated with 10% sodium carbonate solution, the aldehyde extracted with ether, the solution dried with fused sodium sulfate and the solvent removed. The aldehyde, mixed with 7.2 g. of methyl ethyl ketone, was kept cool, 0.9 g. of hydrogen chloride passed into it, the mixture shaken for sixteen hours, washed with water and then with sodium carbonate solution. The crude, oily methyl α-methyl-β-(α-naphthyl)-vinyl ketone (VII), which possessed a camphoraceous odor, was dissolved in 100 cc. of alcohol, stirred and cooled and sodium hypobromite, prepared from 24 g. of bromine, 20 g. of sodium hydroxide and 50 cc. of water, was added. During this process the temperature was kept below 20°. The mixture was stirred for one hour at ordinary temperature, filtered and about 7 g. of sodium bisulfite added to destroy any hypobromite. The mixture was evaporated to about one-half of its original volume on a steam-bath, treated with charcoal, filtered and acidified. The precipitated α-methyl-β-(α-naphthyl)-acrylic acid (VIII) weighed 6.4 g.; m. p. 149–150°[19] after recrystallization from benzene.

To 4.2 g. of the acrylic acid, dissolved in 10% sodium carbonate solution, there was added 58 g. of 4% sodium amalgam. After forty-eight hours the alkaline solution was separated, filtered and acidified. The gummy precipitate, which solidified when cooled, weighed 3.6 g. The crude isobutyric acid melted at 91–92°.

β-(α-Naphthyl)-isobutyramide.—A mixture of 77 g. of the isobutyric acid and 50 g. of thionyl chloride was heated in an all-glass apparatus for three hours on a steam-bath, poured into 120 cc. of cold, 28% ammonia water, which was stirred vigorously, and the precipitated amide recrystallized from benzene; yield 73 g.; m. p. 134–135° after recrystallization from benzene.

The amide is soluble in alcohol and benzene and insoluble in ether.

Anal. Calcd. for $C_{14}H_{15}ON$: N, 6.57. Found: N, 6.60.

1-(α-Naphthyl)-2-aminopropane (V).—An alkaline hypobromite solution, prepared from 25.4 g. of bromine, 240 g. of sodium hydroxide and 2400 cc. of water, was cooled to 10–15° and 32 g. of the isobutyramide added. The mixture was heated at 70–80° for one and one-half hours, 24 g. of solid sodium hydroxide added and the mixture heated two hours longer; when cooled, the brown, oily precipitate became crystalline. The latter was extracted with ether; 5 g. of ether-insoluble material proved to be unchanged amide. The ether solution was extracted with 25-cc. portions of 10% hydrochloric acid and the combined extracts made alkaline. The amine was extracted with ether, the solution dried with fused sodium sulfate and treated with hydrogen chloride; 4.8 g. of the amine hydrochloride precipitated. After it had been dissolved in the smallest possible amount of hot absolute alcohol and precipitated by addition of absolute ether the hydrochloride melted at 213–214°.

Anal. Calcd. for $C_{13}H_{16}NCl$: N, 6.32; Cl, 16.00. Found: N, 6.25; Cl, 15.93.

1-(α-Naphthyl)-1-aminobutane (VI).—The required α-butyronaphthone was obtained by addition of 13.8 g. of butyronitrile, dissolved in 50 cc. of ether, to the Grignard reagent prepared from 51.8 g. of α-bromonaphthalene, 6.0 g. of magnesium and 150 cc. of ether. The mixture was refluxed for one hour, the imine decomposed with hydrochloric acid and the ketone purified by distillation; yield 13 g.; b. p. 155–157° (3 mm.).[20]

The oxime, prepared in the manner described, was extracted from the acidified reaction mixture with ether; b. p. 185–187° (8 mm.).[21]

The amine was obtained by reduction of the oxime with sodium and alcohol. The ether extract of the crude amine was shaken with 10% hydrochloric acid whereupon about one-half of the amine separated as hydrochloride after the acidic solution had remained at ordinary temperature for some time. The salt was removed, the filtrate made alkaline and the rest of the amine extracted with ether; b. p. 142–143° (4 mm.).

The amine hydrochloride melted at 281–282° after it had been precipitated from a warm alcoholic solution by the addition of ether.

Anal. Calcd. for $C_{14}H_{18}NCl$: N, 5.92; Cl, 15.05. Found: N, 5.89; Cl, 14.91.

Methyl-α-naphthylmethylbarbituric Acid.—To sodium ethylate, prepared in 30 cc. of toluene, from 0.7 g. of sodium and 1.4 g. of alcohol, there was added 7.7 g. of diethyl methyl-α-naphthylmethylmalonate. The mixture was heated for four hours at 120–125°, shaken with about 100 cc. of water, the aqueous layer separated and acidified. The oily precipitate, which soon solidified, was recrystallized from a mixture of dioxane and petroleum ether (90–100°); m. p. 127–128°.

Anal. Calcd. for $C_{16}H_{14}O_3N_2$: N, 9.92. Found: N, 9.83.

Summary

Several naphthylaminoalkanes—derivatives of methane, ethane, propane and butane—have been prepared and found to exhibit only slight pressor activity. A characteristic pharmacological feature of these compounds is the development of tolerance.

Cinchona Alkaloids in Pneumonia. VII. Amyl and Hydroxyalkyl Apocupreine Ethers

BY MARY HOSTLER GREEN,[1] ALICE G. RENFREW AND C. L. BUTLER[2]

Recent work in the apocupreine ether series[3] has shown that on ascending in the series of alkyl ethers, a high pneumococcicidal activity is maintained through the C_4 derivatives. The situation is somewhat complicated by variations in the structure of the butyl group; however, isobutyl apocupreine dihydrochloride was shown to be as active *in vitro* as the very potent ethyl derivative. This is in marked contrast with the behavior of the corresponding hydrocupreine ethers.[4] It was also shown that hydroxyethylapocupreine,[5] which has found clinical application, has much stronger antipneumococcic activity than the corresponding hydrocupreine derivative. Further, hydroxypropyl ethers of apocupreine have very strong bacteriostatic action and much lower toxicity than the alkyl derivatives.[6] This higher activity in the apocupreine ether series is not surprising in view of the fact that apocupreine itself shows considerable activity, whereas hydrocupreine is quite low in bacteriostatic action.

The present work on β-hydroxypropyl, isomeric hydroxybutyl and isomeric amyl apocupreine ethers was undertaken in order to study further the influence of the size and structure of the ether group on antipneumococcic activity in this series. The amyl ethers were prepared readily by alkylation of apocupreine with the desired amyl *p*-toluenesulfonates. The preparation of the hydroxybutyl derivatives by alkylation with benzyloxybutyl *p*-toluenesulfonates and subsequent hydrolysis of the benzyl group offered no difficulty. Alkylations were also carried out with β-hydroxy-*n*-propyl and β-methyl-β-hydroxy-*n*-propyl *p*-toluenesulfonates. These reagents gave only very low yields of hydroxyalkyl ethers. The results are entirely in agreement with earlier data on the use of glycol monoesters in alkylations of basic phenolic substances.[5,7]

Some biological properties of the apocupreine ethers prepared in the course of the work are shown in Table I. A decided lowering in the toxicity of butyl apocupreine ethers was accomplished by introduction of the hydroxyl group into the butyl radical. This effect was accompanied by a decrease in the *in vitro* bacteriostatic activity, a decrease which was very marked in the β-methyl-β-hydroxy-*n*-propyl and the δ-hydroxy-*n*-butyl ethers. The suitability of the more active α-methylol *n*-propyl and α-methyl β-hydroxy-*n*-propyl ethers for trial in human pneumonia will

depend on the results (not yet available) of tests for visual disturbance.

Experimental[9]

Butylene Glycol Monobenzyl Ethers.—Isomeric monobenzyl ethers were prepared by a method which has already been described.[10]

TABLE II

Substance, ether	B. p. at 6 mm. °C.	Anal. ($H_{16}O_2$: Calcd. for C_{11}- C, 73.3; H, 8.9) C	H
1,2-Butylene glycol 1-monobenzyl	128–132	73.9	9.1
2,3-Butylene glycol monobenzyl	122–125	73.0	9.0
1,4-Butylene glycol monobenzyl	146–149	73.2	9.3

Various *p*-Toluenesulfonyl Esters.—Hydroxypropyl, hydroxybutyl, benzyloxybutyl and amyl *p*-toluenesulfonates were prepared in good yields from propylene glycol, isobutylene glycol, isomeric butylene glycol, monobenzyl ethers and isomeric amyl alcohols by methods described in previous papers in this series. Suitable alkylating reagents were obtained without extensive purification. Three of the esters were crystallized from ether.

Diethylcarbinyl-*p*-toluenesulfonate, m. p. 37°.[11] β-Hydroxy-*n*-propyl-*p*-toluenesulfonate, m. p. 46°. *Anal.* Calcd. for $C_{10}H_{14}O_4S$: S, 13.9. Found: S, 13.7. α-Methyl-β-benzyloxypropyl *p*-toluenesulfonate, m. p. 47°. *Anal.* Calcd. for $C_{18}H_{22}O_4S$: S, 9.7. Found: S, 10.1.

Alkylation of Apocupreine.—Alkylations according to the previously described methods proceeded smoothly and gave good yields of final products except, as noted above, when glycol monoesters were used as reagents. In these experiments, yields of 4–8% were obtained. δ-Benzyloxybutyl apocupreine was obtained in crystalline condition from ether; m. p. 104°; specific rotation −152°.[12] *Anal.* Calcd. for $C_{30}H_{36}O_3N_2$: N, 5.9. Found: N, δ-benzyloxybutylapocupreine, 5.7; α-benzyloxymethyl *n*-propylapocupreine, 5.9; α-methyl-β-benzyloxy-*n*-propylapocupreine, 5.9.

Hydrolysis of the benzyloxybutyl ethers in 1:1 hydrochloric acid proceeded smoothly[6] and good yields of the corresponding hydroxybutyl derivatives were obtained. Some physical properties and analyses of the various ethers which were prepared are shown in Table III.

Steric Hindrance in Ketone–Phenol Condensations. The Synthesis of Cyclo-alkylene Phenols and Cyclo-alkyl Coumaranes[1]

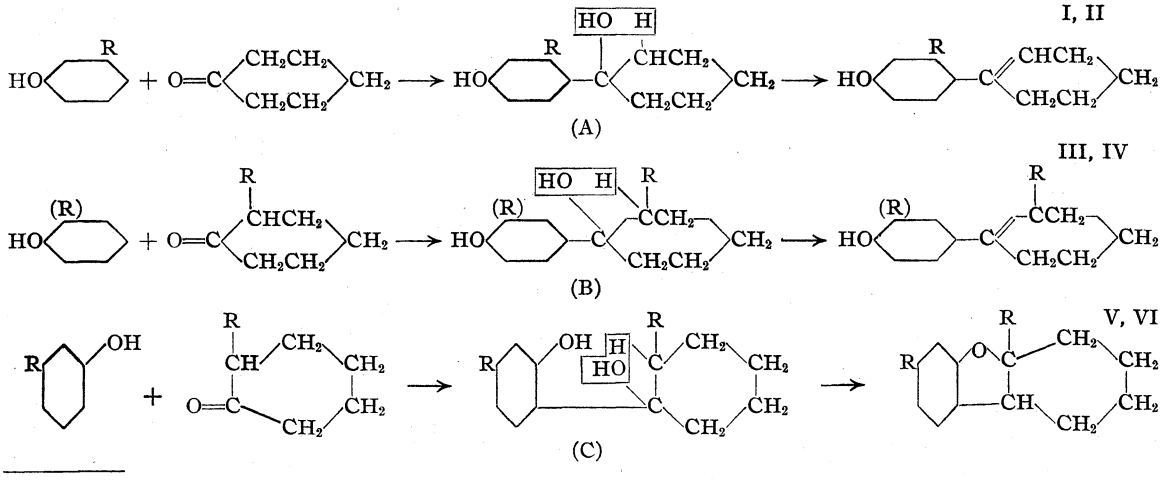
BY JOSEPH B. NIEDERL AND VICTOR NIEDERL

In a previous publication[2] it was asserted that in the condensation of ketones with phenols "the nature of the end-product is influenced not only by the type of carbonyl compound employed, but also by the type of phenol used" and that "this influence exerts itself particularly through the position of the second substituent in the benzene ring, *i. e.*, whether it is ortho, meta or para to the hydroxyl group." As shown in this communication, this hypothesis now has been substantiated fully.

In the following it has been established that meta alkylated phenols react differently than ortho alkylated phenolic compounds; the latter yield alkylidene-diphenols,[3] while the former yield unsaturated compounds in these condensations. The representative types of *m*-alkyl phenols chosen were *m*-cresol and *m*-ethylphenol. These two *m*-alkylated phenols were condensed with cyclohexanone. In each instance the respective cyclohexenyl phenol, the 1-(4′-hydroxy-2′-methyl)-phenylcyclohexene-1 (I) and the 1-(4′-hydroxy-2′-ethyl)-phenylcyclohexene-1 (II) was obtained. In both cases, the alkyl radical in the final condensation product is adjacent to the carbon carrying the cyclohexenyl radical. It appears, then, that such an arrangement in the molecule of the final condensation product inhibits the introduction of a second phenolic radical, which would be the normal course of the reaction (A).

If this hypothesis is correct, then a similar effect should be exerted when a cyclic ketone is chosen for condensation, which would give a condensation product with an alkyl radical adjacent to the carbon carrying the phenolic group. Condensation experiments with *o*-methylcyclohexanone verified this postulation. Thus when *o*-methylcyclohexanone was condensed with phenol itself and with *o*-cresol, compounds which ordinarily yield the respective cyclohexylidene-diphenol, also the unsaturated, monophenolic compound, namely, the 2-methyl-1-(4′-hydroxy)-phenylcyclohexene-1 (III) and the 2-methyl-1-(4′-hydroxy-3′-methyl)-phenylcyclohexene-1 (IV) was obtained, a fact which clearly indicates steric hindrance (B).

Since both the meta-alkylated phenols and the ortho-alkylated cyclohexanones gave rise separately to steric hindrance phenomena, it was then thought to try the extreme case, namely, the condensation of both the above mentioned reactants. The condensation was slow, but positive, but no unsaturated phenolic condensation product was obtained, instead, only coumaranes, the 2,6-dimethyl-2,3-cyclohexyl-coumarane (V), and the 2-methyl-6-ethyl-2,3-cyclohexyl-coumarane



(1) Three of the key substances (I, III, IV) presented in this paper were found by Victor Niederl in pursuance of his thesis researches. The other material presented in this paper is taken from the theses presented by J. Charney, J. Rodgeville and A. Ziering to the Graduate School of New York University in partial fulfilment of the requirements for the degree of Master of Science, June, 1939.

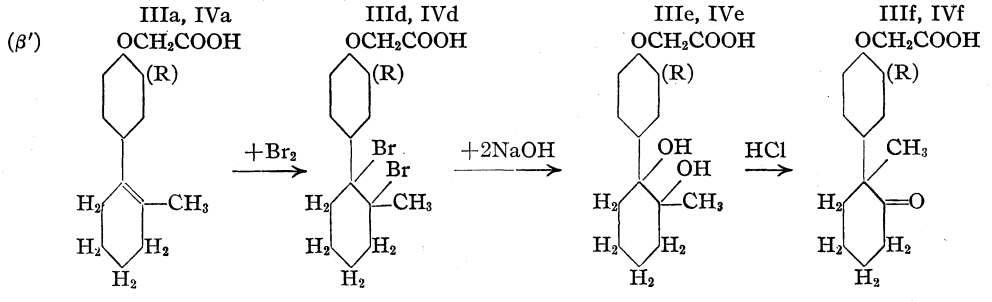
(2) J. B. Niederl and V. Niederl, THIS JOURNAL, **61**, 348 (1939).

(3) M. E. McGreal, V. Niederl and J. B. Niederl, *ibid.*, **61**, 345 (1939).

(VI) resulted. This would indicate that when steric hindrance becomes too great, ortho alkylation takes place (C).

The formation of all three types of condensation products may be formulated as shown.

Of the four crystalline phenolic key substances (I, II, III, IV), all of which exhibit feeble oestrogenic properties (0.2 mg. = 1 rat unit), the following crystalline derivatives were prepared: aryloxyacetic acids (Ia, IIa, IIIa, IVa), phenylurethans (Ib, IIb, IIIb, IVb), acetates (Ic, IIc, IIIc, IVc) and benzoates (IIIh, IVh). For the unsaturation tests the aryloxyacetic acids (Ia, IIa, IIIa, IVa) were chosen. Baeyer's permanganate test[4] was positive in all cases. In addition to this, the aryloxyacetic acids (Ia, IIa, IIIa, IVa) were brominated and the resulting crystalline bromine derivatives isolated (Id, IId, IIId, IVd). Titration of the dibromides (IIId, IVd) with either 0.1 or 0.01 *N* sodium hydroxide solution gave a neutralization equivalent of a tribasic acid, proving that in these titrations both bromine atoms were hydrolyzed, a behavior which is typical of bromine atoms attached to tertiary carbon atoms. Thus it could be shown that the ethylenic linkage is between the carbon atom carrying the phenyl radical and the carbon atom carrying the methyl group. To substantiate this further, dibromides IIId and IVd were hydrolyzed to the respective glycols (IIIe, IVe) and these in turn were subjected to pinacolone rearrangement. The resulting ketones (IIIf, IVf) were identified through their 2,4-dinitrophenylhydrazones (IIIg, IVg).



Experimental

Condensation Method

1-(4′-Hydroxy-2′-methyl)-phenylcyclohexene-1 (I).—Half molar quantities of *m*-cresol and cyclohexanone were dissolved in 100 cc. of glacial acetic acid and the mixture placed in a 1-liter, triple-necked, round-bottomed flask which was provided with a reflux condenser, a thermometer and a gas inlet tube extending to the bottom of the vessel. A vigorous stream of dry hydrogen chloride gas was passed into the system for six hours at room temperature, then the flask stoppered and left standing at room temperature for two to three weeks. After this time the reaction mixture was dissolved in 200 cc. of benzene, this solution washed several times with an equal volume of water and then extracted with 150 cc. of Claisen solution. The Claisen solution extract was acidified with dilute hydrochloric acid; the oil which precipitated out was taken up in 100 cc. of benzene, washed with water and dried with calcium chloride. The benzene was distilled off and the residue distilled under diminished pressure. The fraction boiling between 120 and 140° was collected and redistilled in vacuum; b. p. 130–133° at 4 mm.; $n^{25}D$ 1.5413. After several weeks the substance crystallized; yield 12 to 15%.

1-(4′-Hydroxy-2′-ethyl)-phenylcyclohexene-1 (II).—Half molar mixtures of *m*-ethylphenol and cyclohexanone were condensed exactly as described above and worked up in a similar manner. The pure product boiled at 145–148° and 5 mm.; $n^{25}D$ 1.5421. It also crystallized after several weeks; yield, about 15%.

2-Methyl-1-(4′-hydroxy-phenylcyclohexene-1 (III).—Half molar quantities of phenol and *o*-methylcyclohexanone were condensed as described above, except that no glacial acetic acid was used, and left standing for ten days, by which time the reaction mixture had solidified. The crystalline mass was treated with hot water, filtered off on a sintered glass filter and recrystallized from diisobutylene; yield, 55–60%.

2-Methyl-1-(4′-hydroxy-3′-methyl)-phenylcyclohexene-1 (IV).—Half molar mixtures of *o*-cresol and *o*-methylcyclohexanone were condensed in exactly the same manner as compound III. The reaction mixture, even upon prolonged standing, did not crystallize and after standing for fourteen days it was dissolved in 200 cc. of benzene and worked up as described for compound I. The product was finally distilled in vacuum and the fraction boiling between 155–160° at 12 mm. crystallized in the receiver. It was recrystallized from diisobutylene; yield, 45–50%.

Aryloxyacetic Acid Derivatives (Ia, IIa, IIIa, IVa).—These derivatives were prepared by dissolving the respective compound in 30% sodium hydroxide solution to which sufficient methyl alcohol was added to effect solution. The calculated amount of chloroacetic acid was added, the reaction mixture gently refluxed for two hours, and worked up according to the directions given in Shriner and Fuson.[5]

(4) Mulliken, "A Method for the Identification of Pure Organic Compounds," J. Wiley and Sons, Inc., New York, N. Y., 1904, p. 79.

(5) Shriner and Fuson, "The Systematic Identification of Organic Compounds," J. Wiley and Sons, Inc., New York, N. Y., 1935, pp. 148–149.

Phenylurethans (Ib, IIb, IIIb, IVb).—One gram of substance was dissolved in 1 cc. of phenyl isocyanate in a test-tube which was sealed and placed in a beaker containing boiling water. The test-tube was opened when its content had solidified and the crystalline material placed in a porous tile to dry. It was recrystallized from diisobutylene.

Acetates (Ic, IIc, IIIc, IVc).—Ten grams of the respective phenol was dissolved in 30 cc. of acetic anhydride and the mixture refluxed for four hours in a ground-glass joint apparatus. The acetic anhydride and acetic acid was distilled off and the residual oil distilled in vacuum; b. p.: (Ic) 155–157° (12 mm.), (IIc) 169–174° (12 mm.), (IIIc) 161° (10 mm.), (IVc) 172–174° (12 mm.).

Benzoates (IIIh, IVh).—These two benzoates were prepared by dissolving 0.5 g. of substance in 5 cc. of benzoyl chloride in a test-tube and refluxing the mixture for thirty minutes. Then the solution was poured into 25 cc. of 10% sodium carbonate solution and stirred thoroughly for five minutes. The oil which separated was taken up in 30 cc. of ether and the ethereal solution washed with 1% sodium hydroxide solution and then with water until neutral. The ether solution was dried with calcium chloride and then permitted to evaporate at room temperature. The crystalline residue was twice recrystallized from 80% ethyl alcohol.

Bromine Derivatives of Aryloxyacetic Acids (Id, IId, IIId, IVd).—To a suspension of the respective aryloxyacetic acid derivatives in carbon tetrachloride a solution of bromine in the same solvent (0.3 g. per cc.) was added slowly until the calculated amount of bromine had been introduced. The bromo derivative which precipitated was washed with ether to remove any unreacted acid and the ether insoluble bromine derivative was filtered off and dried on a porous tile. It was recrystallized from ethyl alcohol.

Glycols of Aryloxyacetic Acids (IIIe, IVe).—One gram of the respective aryloxyacetic acid dibromide (IIId, IVd) was dissolved in 30 cc. of 1 *N* aqueous sodium hydroxide solution and the solution was allowed to stand at room temperature for three hours. After this time, the solution was acidified with hydrochloric acid. This caused the separation of a water insoluble oil, which was taken up with ether. The ether extract was washed twice with distilled water and then allowed to evaporate at room temperature. The crystalline residue was twice recrystallized from diisobutylene. One gram of the glycol (IIIe, IVe) was added to 30 cc. of a mixture consisting of two parts of alcohol, one part of cond. hydrochloric acid and eight parts of distilled water. This mixture was refluxed for three hours. It was then diluted with an equal amount of water and twice extracted with 30 cc. of ether. The combined ether extracts were washed once with distilled water and then allowed to evaporate at room temperature. The residue (IIIf, IVf) was dissolved in 30 cc. of alcohol. To this

solution 0.75 g. of 2,4-dinitrophenylhydrazine was added and the mixture refluxed for five minutes. Upon cooling the 2,4-dinitrophenylhydrazone separated out (IIIg, IVg), which was recrystallized from alcohol.

2,6-Dimethyl-2,3-cyclohexylcoumarane (V) and 2-Methyl-6-ethyl-2,3-cyclohexylcoumarane (VI).—Half molar quantities of the respective meta-alkylated phenol and *o*-methylcyclohexanone were dissolved in 100 cc. of glacial acetic acid and condensed as described for compound I, except that the reaction was carried out while the reactants were heated on a water-bath to about 80°. The condensation mixture was left standing for fourteen days, but during this time it was resaturated with hydrogen chloride several times. The reaction product was then dissolved in 200 cc. of benzene, this solution washed several times with water and then extracted with 250 cc. of Claisen solution. Upon acidification of the Claisen solution extract only the unreacted *m*-alkylated phenol (*m*-cresol, or *m*-ethylphenol) was recovered. The benzene solution was then subjected to fractional distillation. Compound V boiled at 139–141° and 12 mm.; $n^{25}D$ 1.5338; sp. gr.^{25}, 1.0252; yield, about 40%. Compound VI boiled at 146–148° and 12 mm.; $n^{25}D$ 1.5302; sp. gr.^{25}, 1.0218; yield, about 30%.

The authors desire to express their appreciation to Reed and Carnrick, Jersey City, N. J., for the physiological tests performed.

Summary

Steric hindrance phenomena encountered in certain types of ketone–phenol condensation systems were studied.

Cycloalkylene phenols and cycloalkyl coumaranes were isolated in such condensation systems. Of the cycloalkylene phenols which represent new types of unsaturated phenols, numerous derivatives were prepared.

The Reaction between Hexabromobenzene and Phenylmagnesium Bromide

BY T. A. GEISSMAN AND R. C. MALLATT

The formation of hexamethyl- and hexaphenylbenzenes in the reaction between hexabromobenzene and methylmagnesium and phenylmagnesium halides was reported by Durand.[1] The identity of the hexamethylbenzene was established by comparison with an authentic sample, but the "hexaphenylbenzene" was later shown to be 1,2,4,5-tetraphenylbenzene by Dilthey,[2] who prepared this compound by an unambiguous method.

A tentative mechanism for the formation of 1,2,4,5-tetraphenylbenzene was suggested by Dilthey,[2] which involved first a replacement of four of the six bromine atoms by phenyl groups, followed by a "reduction," yielding 1,4-dimagnesiumbromide-2,3,5,6-tetraphenylbenzene which on hydrolysis would yield the tetraphenylbenzene actually obtained. No experimental evidence was offered to support this proposal other than the observation that metallic magnesium is without action on hexabromobenzene, showing that a simple removal of two bromine atoms, possibly through a free radical intermediate, did not take place.

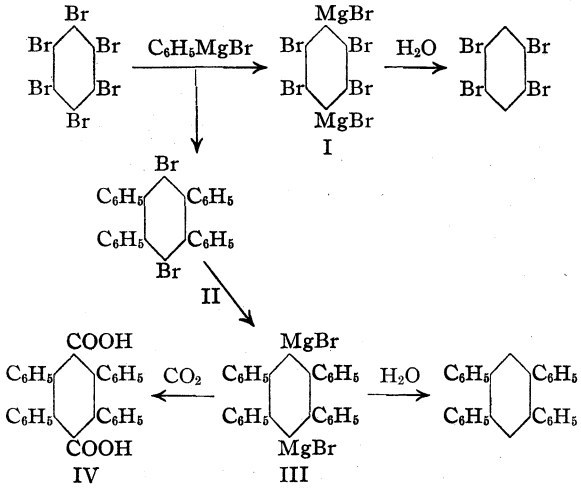
Since other mechanisms for the formation of 1,2,4,5-tetraphenylbenzene are conceivable it was considered of interest to reëxamine the reaction between hexabromobenzene and phenylmagnesium bromide and to isolate (a) intermediates and (b) other products than those mentioned, and to attempt to formulate the reaction upon a factual basis.

The reaction was carried out in ether, as described by Durand, and a few runs were made in benzene. The chief product of the reaction in either solvent was a dark resinous tar from which the products mentioned below were isolated only with difficulty and in small yields. 1,2,4,5-Tetraphenylbenzene and 1,2,4,5-tetrabromobenzene were obtained by hydrolysis of the reaction mixture, while carbonation led to the formation of 1,2,4,5-tetraphenylbenzene-3,6-dicarboxylic acid (IV). Attempts to show the derivation of the tetrabromobenzene from the postulated intermediate (I) failed to yield tetrabromoterephthalic acid. Similar results were obtained when the solutions of the Grignard reagent were filtered before addition of the hexabromobenzene. This observation, coupled with the fact that an ether–benzene solution of the magnesium–magnesium iodide complex was without effect on hexabromobenzene, leads to the conclusion that reaction be-

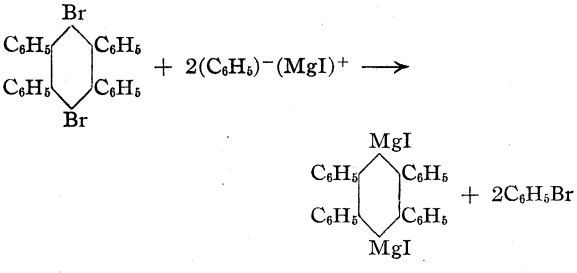
(1) Durand, *Compt. rend.*, **191**, 1460 (1930)
(2) Dilthey, *Ber.*, **67**, 2004 (1934).

tween hexabromobenzene and metallic magnesium or the magnesium–magnesium bromide complex had not occurred.

The results obtained indicate the following course for the reaction



An alternative mechanism in which I is the first intermediate from which III is derived by replacement of the four bromine atoms by phenyl groups cannot explain the formation of hexamethylbenzene when methylmagnesium iodide is used. If this were the mechanism, durene should be formed. In spite of the failure to isolate tetrabromoterephthalic acid by carbonation of the reaction mixture, the above scheme represents the most reasonable picture of the reaction. The reactions leading to I and II are considered to be concurrent and presuppose an amphoteric character in two of the six bromine atoms in hexabromobenzene. The bromine atoms in II, however, as a result of the (−T) effect of the ortho-phenyl groups (in contrast to the effect of ortho-methyl groups) are activated in the same way as the bromine atoms in such compounds as ω-bromoacetomesitylene and diaroylbromomethanes and assume a "positive" character. The reaction of hexabromobenzene with phenylmagnesium iodide then involves, as we now find, the additional step



The formation of large amounts of heavy, resinous material in the reaction can be explained by reactions occurring between the intermediates (I and II) and hexabromobenzene. That the use of a large excess of phenylmagnesium bromide nearly doubled the yield of tetraphenylbenzene substantiates this view since the reaction of II with phenylmagnesium bromide to yield III would be speeded up by a large excess of the Grignard reagent. The reaction of hexabromobenzene with phenyllithium led only to highly polymeric solid substances from which no pure substance could be isolated. This follows on the same basis, the more highly reactive lithium intermediates reacting further to form polymeric substances.

The projected study of the reaction between phenylmagnesium bromide and 1,4-dibromo-2,3,-5,6-tetraalkyl- and arylbenzenes should throw further light on the mechanism of the reaction.

Experimental

Table I presents a number of representative runs. The reactions were carried out by adding the solid hexabromobenzene to the solution of the Grignard reagent and refluxing the solution for eighteen to twenty-four hours. The hexabromobenzene is practically insoluble in ether but dissolves slowly as the reaction proceeds. Carbonation and hydrolysis of the reaction mixtures were carried out in the usual way.

The products of the reaction were worked up by steam distilling to remove diphenyl, followed by crystallization or distillation under reduced pressure.

1,2,4,5-Tetraphenylbenzene.—Distillation of the tarry reaction product under reduced pressure followed by crystallization of the small amount of distillate from acetic acid yielded the hydrocarbon as white needles, m. p. 262–263° (Dilthey[2] reports melting point of 263°).

Anal. Calcd. for $C_{36}H_{22}$: C, 94.24; H, 5.76; mol. wt., 378. Found: C, 94.31; H, 5.62; mol. wt. (Rast), 382.

1,2,4,5-Tetrabromobenzene.—The identity of the product was established by a mixed melting point determination with an authentic sample prepared according to the method of van der Linden.[3]

(3) Van der Linden, *Rec. trav. chim.*, **57**, 781 (1938).

2,3,5,6-Tetraphenylbenzene-1,4-dicarboxylic Acid.—The reaction mixture was carbonated with gaseous carbon dioxide at 0°. After decomposition of the reaction mixture the acidic material was extracted with alkali and precipitated with dilute hydrochloric acid. The resulting solid was boiled with several portions of water to remove benzoic acid and finally crystallized from acetic acid. The acid formed tiny white needles which did not melt up to 320° (bloc Maquenne).

Anal. Calcd. for $C_{32}H_{22}O_4$: C, 81.70; H, 4.70; neut. equiv., 235. Found: C, 81.01; H, 4.71; neut. equiv., 232.

Methyl 2,3,5,6-Tetraphenylbenzene-1,4-dicarboxylate.—The acid was esterified with diazomethane in the usual way. The product crystallized from acetic acid as tiny white prisms, m. p. 280°.

Anal. Calcd. for $C_{34}H_{26}O_4$: C, 81.90; H, 5.40. Found: C, 81.50; H, 5.26.

Phenylmagnesium Iodide and Hexabromobenzene.—To the Grignard reagent prepared from 59.2 g. of iodobenzene and 7.05 g. of magnesium in ether was added 20 g. of hexabromobenzene. After refluxing for twenty-four hours the reaction mixture was hydrolyzed with ice–hydrochloric acid and steam distilled. Extraction of the distillate with ether followed by distillation yielded 3.20 g. of bromobenzene, identified by its boiling point and by the preparation of *p*-nitrobromobenzene, m. p. 127–128°; mixed with an authentic sample, m. p. 126–128°. The residue from the steam distillation yielded 0.90 g. (7.9%) of 1,2,4,5-tetraphenylbenzene, m. p. 260–262°.

Summary

1. The reaction between hexabromobenzene and phenylmagnesium bromide has been reinvestigated, and the intermediate formation of 2,3,5,6-tetraphenylbenzene-1,4-dimagnesium bromide has been established.

2. An explanation of the course of the reaction has been suggested.

Tertiary Alkyl Primary Amines, $RR'R''CNH_2$. I. Ethoxymethyldiallylcarbinamine and Some Analogs[1,2]

BY BRUCE B. ALLEN AND HENRY R. HENZE

There has been in progress in this Laboratory for some years an extensive study of substituted ketones of the alkoxy, aryloxy, and halogenoalkoxy alkyl (and aryl) types. Such ketones have been and are being synthesized from the appropriate substituted nitriles by means of Béhal and Sommelet's[3] modification of the Grignard reaction; with the exception of the tertiary butyl analogs, relatively little difficulty has been experienced in obtaining, for almost every series, both the straight and branched chain alkyl derivatives through the amyls. Since these numerous ketones have been synthesized with the view to their further use in the preparation of compounds having physiological activity, it became desirable to have examples in which the alkoxy alkenyl grouping was represented. Hence, an attempt was made to prepare ethoxymethyl allyl ketone from ethoxyacetonitrile and allylmagnesium bromide.

It was noted with considerable surprise, then, that when equimolecular quantities of allylmagnesium bromide, prepared independently according to Gilman,[4] and ethoxyacetonitrile were brought together, apparently only one-half of the nitrile reacted, and although a constant boiling product was obtained, no ketonic material was formed. Moreover, this product, while possessing physical constants which made impossible its being unreacted nitrile, contained nitrogen, was basic in character, formed solid derivatives with such common amine reagents as picric acid and phenyl isocyanate, but failed to undergo the typical primary amine reaction of isonitrile formation. In a subsequent preparation it was found that by increasing the ratio of Grignard reagent to nitrile from 1:1 to 2:1 no unreacted nitrile was recovered and a correspondingly greater yield of basic product was formed.

Analyses of the purified, basic substance established $C_{10}H_{19}NO$ as its empirical formula. It was possible to conceive of the addition of two molecules of allylmagnesium bromide to one of ethoxyacetonitrile and of subsequent hydrolysis of the addition product to yield a compound of molecular formula $C_{10}H_{19}NO$. Analysis of the picrate of the basic compound obtained verified this formulation.

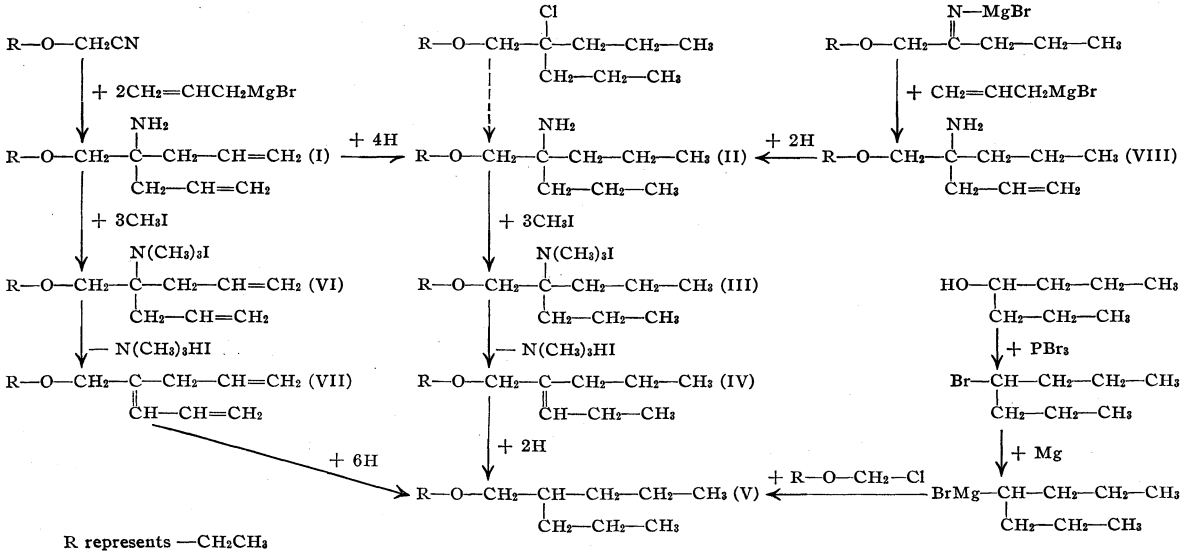
lar refraction values, required that the substance be a primary amine, actual proof that an amine of this class had been formed was not obtained until the methiodide, prepared from (I) with ease and in good yield, was analyzed. The data from these analyses indicated that one molecular weight of the amine had reacted with three of methyl iodide; only primary amines react in this proportion. Final proof of the structure of the primary amino ether (I) was obtained through degradation and through conversion into a substance of established structure. Synthesis of the amino ether by known procedures was made highly improbable, and unsuccessful attempts to do so are recorded in the experimental portion of this report, since reference to the literature indicated that simpler amines of a type in which the primary amino group is attached to a tertiary aliphatic carbon have been prepared in a very limited number of cases and usually in poor yield. Recently Adkins[5] has reported the attempt to synthesize an amine of this type and made the statement that "methods apparently are not available for the preparation in quantity of the aliphatic amines which bear the same relationship to primary amines that tertiary alcohols bear to primary alcohols."

The amino ether (I) was reduced with hydrogen catalytically to produce $C_{10}H_{23}NO$ (II); the introduction of four hydrogen atoms excluded the possibility of (I) having a ring structure. The methiodide of (II) was heated above its melting point to yield an unsaturated ether (IV) of the formula $C_{10}H_{20}O$, which was reduced to form the corresponding saturated ether (V) formulated as being 4-ethoxymethylheptane.



R represents $-CH_2CH_3$

Synthesis of (V) was visualized in the reaction of the Grignard reagent from 4-bromoheptane with chloromethyl ethyl ether. The physical properties and analytical data for the product resulting from such a reaction indicated it to be 4-ethoxymethylheptane and identical with (V). For the sake of completeness, the methiodide of (I) was decomposed in the formation of the corresponding ether containing three double linkages, and then this compound was hydrogenated to form (V). The physical constants for the three samples of 4-ethoxymethylheptane have been collected in Table I.

Additional proof of the structure of the amine (I) was obtained when equivalent amounts of allylmagnesium bromide and the addition product resulting from interaction of ethoxyacetonitrrle and propylmagnesium bromide reacted to form compound (VIII), an amine of structure intermediate between that of (I) and (II) in that of the

groups attached to the tertiary carbon, one was propyl and another allyl. Hydrogenation of (VIII) resulted, as did reduction of (I), in the formation of (II).

Finally, the synthesis of the methoxy and isopropoxy analogs of (I) from allylmagnesium bromide and the appropriate nitriles proves definitely that this reaction is not confined to the formation of only one amine and requires qualification of the statement that there is no method for the preparation of quantities of primary amines in which the amino group is attached to a tertiary aliphatic carbon.

Experimental

Preparation of Alkoxyalkyl-diallylcarbinamines.—In each instance wherein an amine was obtained from a nitrile and allylmagnesium bromide, the Grignard reagent was prepared independently, using essentially those proportions of magnesium, ether, and allyl bromide as suggested by Gilman[4]: to three gram atoms of magnesium turnings, suspended by very rapid stirring in 200 cc. of anhydrous ether, was added the solution of one mole of allyl bromide in approximately 570 cc. of dry ether, the addition being at such a rate that from five to six hours were required. Following the introduction of the last of the bromide, the mixture was stirred for an additional hour while the flask was warmed over a hot-plate. While still slightly warm, the gray-colored ether solution of the Grignard reagent was decanted rapidly from the flask into another of the same size through a 3-inch (8-cm.) Witte plate supported in a large funnel; the funnel, Witte plate, and second flask were at 35–40° so that a fairly rapid evaporation of the solvent would occur during the transfer and thereby tend to minimize contact between moist air and the reagent.

The resulting solution of allylmagnesium bromide was then treated with such an amount of the solution of the appropriate alkoxynitrile[6] as would represent a ratio of two parts of allylmagnesium bromide to one part of nitrile in an equal volume of dry ether; a considerable heat effect was noted during the nitrile addition; hence, the rate of this introduction was moderated until the solvent just refluxed. During the latter half of the reaction period, the addition product generally began to separate as a gummy, grayish-colored solid. Reaction was completed either by allowing the mixture to stand without stirring for from eight to twelve hours or by heating gently over the hot-plate with stirring for from four to six hours.

Hydrolysis of the addition product was accomplished by adding a chilled, saturated aqueous solution of ammonium chloride until all of the solid had dissolved and two clear, liquid layers resulted. These were separated; the lower aqueous layer was extracted twice with ether, and the ether solutions of the amine were combined and

(6) The alkoxynitriles employed in this study were synthesized from the corresponding alpha chloro ethers and cuprous cyanides by following the modification of Gauthier's procedure [Gauthier, *Compt. rend.*, **143**, 831 (1906)] discussed by us previously [Allen with Henze, THIS JOURNAL, **59**, 540 (1937)].

dried over anhydrous sodium sulfate. After the ether had been removed by evaporation under reduced pressure, the amine was purified by distillation, also *in vacuo*. After two such fractionations, the amines could be distilled under atmospheric pressure with no apparent decomposition.

From a typical preparation was obtained 156.6 g. (78.7% yield) of ethoxymethyldiallylcarbinamine when 100 g. (1.18 mole) of ethoxyacetonitrile, 200 g. (8.23 g. atoms) of magnesium, 370 g. (3.06 moles) of allyl bromide, and 2400 cc. of anhydrous ether were combined in the manner described.

The amines, the physical constants, yields, and analytical data for which are summarized in Table II, are colorless oils of not unpleasant, quite characteristic odor which somewhat resembles that of molding wood.

Crystalline picrates could be prepared for all of the amines synthesized by merely dissolving the base in sulfurous acid solution and then adding a saturated aqueous solution of picric acid. The picrates were recrystallized from either water or aqueous alcohol.

Preparation of Ethoxymethylpropylallylcarbinamine.—To the ether solution of propylmagnesium bromide, prepared under the usual anhydrous conditions from 15.6 g. (0.64 atom) of magnesium, 86.3 g. (0.7 mole) of *n*-propyl bromide, and a total of 400 cc. of anhydrous ether, was added 49.5 g. (0.58 mole) of ethoxyacetonitrile dissolved in 100 cc. of ether. After approximately one-third of the nitrile solution had been introduced, separation of a white solid was noted; in order that this solid might not settle to the bottom of the flask and subsequently form the customary gummy mass, the rate of stirring was increased to the maximum possible with the mechanical device employed and kept thus throughout the remainder of the nitrile addition. This vigorous agitation resulted in maintaining the addition product in the form of a finely divided, gray-white, semi-crystalline precipitate.

Approximately thirty minutes after completion of the nitrile–propylmagnesium bromide reaction, the filtered ether solution of allylmagnesium bromide, prepared in the manner previously described from 100 g. (0.83 mole) of allyl bromide, 61 g. (2.5 atoms) of magnesium, and 500 cc. of dry ether, was run into this suspension during thirty minutes. Signs of reaction throughout this addition were feeble refluxing of the ether and, more important, a change in the color and character of the ether-insoluble addition product from the gray-white semi-solid previously described to a heavy, green-brown oil which settled to the bottom of the vessel despite the rapid stirring.

Agitation of the mixture was continued, with the latter at room temperature for one hour after the addition of the allyl compound, and then at such a temperature that the ether refluxed vigorously for two hours; during the last hour of this period the large excess of ether was reduced to a volume which permitted more ease in manipulation. Hydrolysis was accomplished by pouring the ether and viscous material into a mixture of crushed ice and saturated ammonium chloride solution which was stirred rapidly during the reaction.

After separation of the two layers resulting from hydrolysis, the ether solution of the amine was dried over sodium sulfate, the ether removed by the usual evaporation under reduced pressure, and the crude amine purified by two fractionations under the pressure of the water pump. The observed physical constants and analytical data for this compound have been included in Table II.

Preparation of Ethoxymethyldipropylcarbinamine.—This amine was prepared in two separate instances from different starting materials but by the same method, namely, by the catalytic hydrogenation of both ethoxymethyldiallylcarbinamine and ethoxymethylpropylallylcarbinamine. The reduction was accomplished in each case by shaking the solution of 0.1 mole of the unsaturated amine in 40–50 cc. of acetone in the presence of the Adams platinum catalyst and hydrogen under approximately one atmosphere pressure. After hydrogenation was complete, usually in two to six hours, the catalyst was removed by filtration, the solvent by distillation, and the saturated amine purified by fractionation under reduced pressure. The two samples of the amine thus obtained had identical physical constants. These constants, as well as certain analytical data for the amine, have been included in Table II.

Picrates were prepared from both samples of the amine, and the individual melting points and mixed melting point were determined. Both picrates melted at 123.5–124.5° (corr.) and the mixing occasioned no depression of this value.

Exhaustive Methylation of Diallyl- and Dipropylethoxymethylcarbinamines.—Into a 250-cc. Erlenmeyer flask fitted with reflux condenser was introduced in the order named, 0.14 mole of the amine, 75 cc. of 40% aqueous potassium hydroxide solution, and 0.49 mole of methyl iodide. When the flask was rotated gently, vigorous reaction commenced so that cooling with an ice-bath was required to prevent loss of material through the condenser. After reaction had subsided, a change in the density of the organic material was noted; *i. e.*, it constituted the lower layer before, and the upper after, reaction. The mixture was then refluxed gently for one hour, cooled, and transferred to a separatory funnel where it was shaken with 50 cc. of ether to remove any unreacted methyl iodide. The three layers were separated, the uppermost (ether) and the lowest (aqueous) being discarded and the middle layer shaken with an additional 100-cc. portion of ether. After several minutes the viscous quaternary ammonium iodide solidified and could then be filtered from the ether and dried. In both methylations the crude material represented about 94% of that theoretically possible.

The methiodides were recrystallized from anhydrous benzene; after three such treatments the following melting points and analytical data for the solids were obtained:

The product from ethoxymethyldiallylcarbinamine melted at 100.5–101.5° (corr.) and decomposed with effervescence above this temperature. *Anal.* Calcd. for $C_{13}H_{26}INO$: C, 46.02; H, 7.73; N, 4.14. Found: C, 46.32; H, 7.76; N, 4.27.

The product from ethoxymethyldipropylcarbinamine decomposed with effervescence at 132.5–133.5° (corr.). *Anal.* Calcd. for $C_{13}H_{30}INO$: C, 45.48; H, 8.81; N, 4.08. Found: C, 45.55; H, 8.77; N, 3.98.

Pyrolysis of the Quaternary Ammonium Iodides.—When 0.12 mole of either of the two methiodides was

packed into a 50-cc. distilling flask, which was set up as for distillation under diminished pressure, the pressure reduced to that of the water-pump (25–27 mm.), and the flask heated to 150–180° by means of an oil-bath, some effervescence occurred and a colorless liquid began to distill. Heating was continued until no more liquid was produced, at which time 16–21 cc. of crude ether (73–78%) had been collected and a white solid residue remained in the flask. The ethers were purified by distillation under reduced pressure.

In this manner, then, 4-ethoxymethyl-3-heptene was obtained from the methiodide of ethoxymethyldipropylcarbinamine, and 4-ethoxymethyl-1,3,6-heptatriene from that of ethoxymethyldiallylcarbinamine. The following physical constants were determined and analytical results obtained for these two unsaturated ethers:

For 4-ethoxymethyl-3-heptene: yield, 77.8%; b. p. 72.0–73.0° (17 mm.), 173.5–175.0° (corr.) (740 mm.); d^{20}_4 0.8059; $n^{20}D$ 1.4298; *MR* calcd., 49.56; *MR* found, 50.07; γ^{20} 25.08 dynes/cm.; *P* calcd., 433.2; *P* found, 433.9. *Anal.* Calcd. for $C_{10}H_{20}O$: C, 76.86; H, 12.90. Found: C, 77.02; H, 12.91.

For 4-ethoxymethyl-1,3,6-heptatriene: yield, 73.0%; b. p. 71–72° (16–17 mm.); d^{20}_4 0.8484; $n^{20}D$ 1.4701; *MR* calcd., 50.07; *MR* found, 48.62[7]; γ^{20} 25.79 dynes/cm.; *P* calcd., 411.2; *P* found, 404.4. *Anal.* Calcd. for $C_{10}H_{16}O$: C, 78.89; H, 10.59. Found: C, 78.89; H, 10.43.

Preparation of 4-Ethoxymethylheptane.—Three different specimens of this compound were prepared from separate and different starting materials. The physical properties, yields, and analytical data for these three specimens have been referred to previously in Table I.

Two of the three samples were obtained through catalytic hydrogenation of 4-ethoxymethyl-3-heptene and 4-ethoxymethyl-1,3,6-heptatriene using platinum black as a catalyst, acetone as a solvent, and hydrogen under one atmosphere pressure.

The third sample of this ether was obtained as the product of the interaction of chloromethyl ethyl ether and the appropriate heptylmagnesium bromide: to the ether solution of heptylmagnesium bromide, prepared from 8.1 g. (0.33 atom) of magnesium, 67.0 g. (0.38 mole) of 4-bromoheptane,[8] and 260 cc. of anhydrous ether, was added the solution of 31 g. (0.33 mole) of freshly distilled chloromethyl ethyl ether[9] in an equal volume of dry ether.

The pure product from this reaction was obtained after the reaction mixture had been treated with crushed ice and dilute acid (in this case to neutralize the basic salt from any unreacted Grignard reagent) and the ether solution of the product processed in the customary manner.

The analytical data and observed physical properties for this compound likewise appear in Table I.

Attempted Preparation of Ethoxymethyldiallylcarbinamine (4-Amino-4-ethoxymethylheptane).—The methods employed in attempts to synthesize this amine (other than the method described previously) all required the use of the appropriate alkyl halide, namely, 4-chloro-4-ethoxymethylheptane. This halide in turn required the preparation of the tertiary alcohol, 4-hydroxy-4-ethoxymethylheptane. The latter was obtained in 94.6% yield from the interaction of two moles of propylmagnesium bromide and one of *n*-propyl ethoxyacetate[10]; the following constants and analytical data were observed: b. p. 200.0–201.0° (corr.) (752 mm.); d^{20}_4 0.8706; $n^{20}D$ 1.4286; γ^{20} 26.24 dynes/cm.; *MR* calcd., 51.55; *MR* found, 51.57; *P* calcd., 464.2; *P* found, 453.1. *Anal.* Calcd. for $C_{10}H_{22}O_2$: C, 68.91; H, 12.72. Found: C, 69.01; H, 12.67.

This alcohol was converted in 40.7% yield into the desired 4-chloro-4-ethoxymethylheptane merely by shaking it with concentrated hydrochloric acid. The following data were collected concerning this halide: b. p. 94–95° (25 mm.); d^{20}_4 0.9115; $n^{20}D$ 1.4344; γ^{20} 26.33 dynes/cm.; *MR* calcd., 54.89; *MR* found, 55.11; *P* calcd., 481.4; *P* found, 479.0. *Anal.* Calcd. for $C_{10}H_{21}ClO$: Cl, 18.40. Found: Cl, 18.10.

All attempts to convert this chloride into the desired amine were unsuccessful. The methods employed were the Grignard reagent–chloroamine reaction of Coleman, Gabriel's primary amine synthesis, and both liquid ammonia and sodium amide in liquid ammonia treatment. In all instances the chloride was recovered, and no basic material was obtained. The Coleman reaction failed primarily because the halide did not react with magnesium to form the desired Grignard reagent.

Summary

1. An abnormal reaction has been noted between allylmagnesium bromide and ethoxyacetonitrile as a result of which, instead of the anticipated ketone, was produced ethoxymethyldiallylcarbinamine, an amine of unusual type, namely, one in which the primary amino group is attached to a tertiary carbon.

2. The reaction has been shown to be of application more general than to this one isolated case through its utilization in the synthesis of two analogous alkoxyalkyldiallylcarbinamines.

3. Allylmagnesium bromide has been shown to be capable of reaction with a typical Grignard reaction product, namely, that resulting from interaction of *n*-propylmagnesium bromide and ethoxyacetonitrile.

AUSTIN, TEXAS RECEIVED MARCH 30, 1939

(7) The specific exaltation, obtained from the difference between calculated and observed molecular refractivity, is, in this case, 0.96. This value compares favorably with an average value for specific exaltation determined by Auwers and Eisenlohr, *J. prakt. Chem.*, [2] **84**, 1 (1911), as equal to 1.10.

(8) Heptanol-4 was prepared in 53% yield by the action of propylmagnesium bromide upon butyraldehyde: b. p. 71.5–72.5° (25.5–26 mm.); d^{20}_4 0.8183; $n^{20}D$ 1.4205. From this alcohol, a 78.6% yield of 4-bromoheptane was obtained by treatment with phosphorus tribromide: b. p. 64–65° (21–22 mm.); d^{20}_4 1.1373; $n^{20}D$ 1.4498; *MR* calcd., 42.29; *MR* found, 42.31. *Cf.* Sherrill, THIS JOURNAL, **52**, 1982 (1930).

(9) This alpha chloro ether was synthesized after the manner of Henry, *Bull. Acad. Roy. Belg.*, [3] **25**, 439 (1893); and was collected during distillation at 79–80° (748 mm.).

(10) Obtained by passing hydrogen chloride through a solution of ethoxyacetonitrile in *n*-propyl alcohol: yield, 83.4%; b. p. 173.5° (corr.) (748 mm.); d^{20}_4 0.9594; $n^{20}D$ 1.4083; γ^{20} 28.34 dynes/cm.

Hydrogen Fluoride as a Condensing Agent. VII.[1] The Acylation of Aromatic Compounds

BY J. H. SIMONS, D. I. RANDALL AND S. ARCHER

The acylation of aromatic compounds is usually accomplished by the use of metallic halides such as aluminum chloride with acid anhydrides or acid halides as the reagents. The carboxylic acids themselves are not generally useful as the reagents and acidic condensing agents such as sulfuric acid can be used for these reactions only in special cases.[2] In our first experiments using hydrogen fluoride as the condensing agent for acylation reactions we attempted reactions between acetyl chloride and also benzoyl chloride and benzene at both ice temperature and the boiling point of hydrogen fluoride. In these reactions hydrogen chloride is immediately and copiously evolved and the acid fluoride formed, but no detectable amounts of ketones could be isolated.

As our previous work had shown reactions between alcohols and aromatic compounds with the elimination of water, it was believed that the carboxylic acids would react similarly to hydroxyl containing compounds. It has been shown[3] that the carboxylic acids in liquid hydrogen fluoride are analogous to the alcohols in that they both add hydrogen ions, *i. e.*, act as basic substances, to form conducting solutions. This hypothesis is substantiated as it has been found that acetic acid, benzoic acid, and valeric acid produced ketones when mixed with toluene or phenol and hydrogen fluoride, and when the reaction mixture was sealed in a copper bomb and heated at 80 to 100°.

Under similar conditions and at the same temperature it was found that acetyl chloride and benzoyl chloride would react with benzene or toluene to produce the expected ketones. In order to prevent a high pressure from developing in the bomb, at least the major portion of the hydrogen chloride, produced by the reaction between the chlorides and hydrogen fluoride, was allowed to escape before the bomb was sealed and while it was below the boiling point of hydrogen fluoride.

Acetic anhydride has been shown by Fredenhagen[4] to react with hydrogen fluoride to produce a mixture of acetic acid and acetyl fluoride. It would, therefore, be expected to react in a similar manner to acetic acid or acetyl chloride. In a reaction with toluene *p*-methylacetophenone was formed.

It is observed in the two experiments using acetic acid but with different amounts of hydrogen fluoride that larger amounts of the latter result in higher yields of the product. This is to be expected as water is a reaction product which would reduce the activity of the hydrogen fluoride. As hydrogen fluoride forms additional compounds with oxygen containing organic substances, greater amounts are required than in reactions of olefins, or alkyl halides.

The yields reported are calculated on the basis of the amount of acylating reagent added to the original mixture. No attempts were made to recover any unreacted reagents but these were washed out with the hydrogen fluoride. As relatively small amounts of residues were obtained upon distillation of the reaction products, the amounts of side reactions occurring were small. Yields calculated on the difference between the amounts of reagents added and remaining after stopping the reaction would be much higher than those reported.

Experimental

These reactions were all carried out in copper bombs which were made of three-inch (7.6-cm.) copper tubing with one-eighth-inch (3.2-mm.) copper plates silver soldered onto the ends. In one end a three-eighth-inch (9.5-mm.) copper tube was silver soldered. This was capped with a compression fitting which carried a sealed-off piece of tubing. The bombs were about twelve inches (31 cm.) long.

The hydrogen fluoride was run directly into the bomb containing the reaction mixture from the copper condenser which in turn connected to the storage cylinder. The bomb was then sealed, placed in a steam-bath, and heated. Eighteen to twenty-four hours later it was cooled, placed in ice, opened, and the contents poured into iced water. The acid was neutralized with sodium carbonate and the organic materials removed,

separated, and purified. In Table I the results of the experiments are recorded and in Table II are the properties of the derivatives made for identification.

Conclusions

The results of these experiments demonstrate the effectiveness of hydrogen fluoride to promote acylation reactions. The ability to use the carboxylic acids for such reactions should be of considerable value. It has not been found necessary to subject the reagents to extensive purification. Commercial grades of all substances including hydrogen fluoride were entirely satisfactory.

(5) Bachman, THIS JOURNAL, **49**, 236 (1927).

Summary

Hydrogen fluoride has been found effective in the synthesis of ketones from aromatic compounds and carboxylic acids, acid anhydrides, and acyl halides. The reactions proceed at 80 to 100° in copper bombs, and the yields are increased with increasing amounts of hydrogen fluoride. Acetic acid, valeric acid, benzoic acid, acetic anhydride, acetyl chloride, and benzoyl chloride were caused to react with benzene, toluene and phenol to form the expected ketones.

Diphenylmethane as a Thermometric Standard at 25°

BY THOMAS DE VRIES AND HENRY A. STROW[1]

Because a need exists to have a convenient thermometric standard near 25°, it was decided to investigate the melting point of diphenylmethane which has been reported at various times at temperatures ranging from 25 to 27°.[2] The best value seems to be 25.15° which was reported by Smith and Andrews[3] on a sample purified by repeated distillation at reduced pressure. In this investigation we found the value 25.09°.

Experimental.—Two seven-junction copper–constantan thermels were constructed from No. 30 B. and S. gage wire using all the precautions recommended by White.[4] In order to show that the deviations from the thermocouple reference table were nearly linear over the range from 0 to 100°, it was necessary to use a Leeds and Northrup type K potentiometer. Below 10,000 microvolts a White potentiometer was used, namely, for the calibration of the thermels at the transition point of sodium sulfate and for the determination of the melting point of diphenylmethane

The cold junctions of the thermels were maintained at 0° by a "cold cell" of the type first described by White.[5] The thermels were calibrated at the boiling point of water in an hypsometer with copper double walls. The two thermels gave identical electromotive forces. One value of 161 and four values of 162 were obtained as the deviation in microvolts from the reference table,[6] with the boiling point of the water known to 0.01° from the corrected barometric pressure. The barometric readings are known to be accurate to 0.1 mm. by comparison with a Gaertner cathetometer. For the calibration of the thermels at the transition temperature of sodium sulfate decahydrate, the procedure of Dickinson and Mueller[7] was used. The hydrate was prepared from Mallinckrodt Analytical Reagent grade anhydrous sodium sulfate. It was further purified by six recrystallizations. Conductivity water was used throughout. A sharp transition point was obtained. Eight different measurements were made, five giving 60.5 as the deviation from the reference table, and one value each of 60.4, 60.6 and 60.7, the average being 60.5. The two thermels gave identical electromotive forces.

Purification of Diphenylmethane and Results.—The melting point of the diphenylmethane as obtained from the Eastman Kodak Co., was 24.5°. Several methods of purification were tried. Crystallization was decided upon as most likely to give a pure product. First recrystallization from absolute alcohol was attempted, but the alcohol was too difficult to separate from the diphenylmethane. After several other attempts the following method was found to be satisfactory and requiring little attention. The diphenylmethane was frozen slowly over a period of eight to twelve hours until between 5 to 10 cc. was left unfrozen. This was poured off and discarded. For the initial purification about 300 cc. (300 g.) was used. At the end of twenty such recrystallizations about 150 cc. of pure diphenylmethane was obtained. To obtain a uniform cooling rate an apparatus was constructed which gave uniform results regardless of the room temperature. Tap water in the laboratory has a temperature of about 16° and varies only slightly. A metal container was built of two cans so placed as to form a double-walled container. The inside can was of sufficient size to hold a 400-cc. beaker with a clearance of about half an inch (1.25 cm.) on each side. The bottom was covered with an asbestos pad. Tap water was circulated in the space between the two walls and a cover was placed on top. Diphenylmethane was recrystallized daily until a constant melting point was obtained. Seventeen recrystallizations were sufficient, there was less than a 0.001° change for an additional sixteen recrystallizations. Twelve recrystallizations raised the melting point to 25.082°; 5 more to 25.091°; 2 more raised it to 25.092°, and 14 additional recrystallizations produced no further change.

The melting point was determined with the thermel immersed 8 cm. into the diphenylmethane, about one-third of which was liquid. The mixture was stirred in a glass tube, 33 mm. in diameter and 150 mm. deep. Generally the room temperature was such that the diphenylmethane was melting slowly while the measurements were made. The melting point as calculated from the electromotive force was 25.092°. The values relative to each other are not in error exceeding 0.001°, but since the reference tables are consistent to only 0.01°, we report 25.09 ± 0.01° as the melting point of pure diphenylmethane.

Change of Melting Point.—Early in the work it was observed that a sample of diphenylmethane which had been kept in a clear glass bottle in the presence of diffused sunlight showed a marked lowering of the melting point. As a result of long exposure to light a brown color developed in the diphenylmethane and the melting point dropped to 24.1°. The effect of light on the change in the melting point was determined by measuring the melting point of a sample in a clear glass bottle exposed to diffused sunlight and another sample in a brown bottle kept away from light. Melting points were taken over a period of four weeks. The results are given in Table I.

TABLE I

CHANGE OF MELTING POINT UPON STANDING

Time	Melting points, °C. Brown bottle	Clear bottle
0	25.092	25.092
4 days	25.091	25.078
1 week	25.091	25.065
2 weeks	25.091	25.040
3 weeks	25.091	25.013
4 weeks	25.090	24.982

Four recrystallizations were needed to bring the sample in the brown bottle back to its correct melting point.

A more extended test was made by sealing a sample under its own vapor pressure in a tube containing a thermometer well, so that melting points could be taken without admitting air. This tube was kept in the dark over a period of five months except when melting points were determined. A similar sample was kept in an unsealed tube. The readings given in Fig. 1 were taken on these samples. Seven recrystallizations were necessary to bring each sample back to its original melting point.

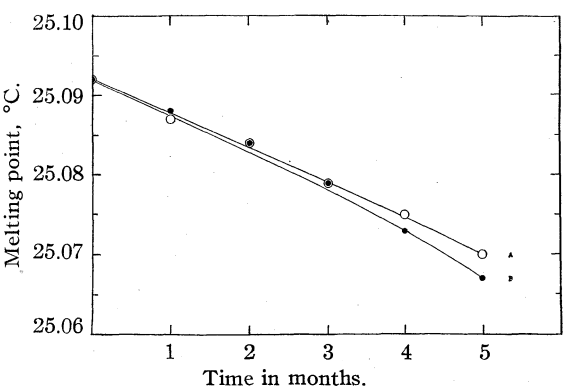

Fig. 1.—Decomposition of diphenylmethane kept in the dark: A, sealed tube, no air present; B, open tube.

Samples of pure diphenylmethane were dried over calcium chloride and over concentrated sulfuric acid in a desiccator without changing the melting point.

Summary

1. The use of diphenylmethane as a thermo-

The Reaction of Zinc with Copper Sulfate in Aqueous Solution

BY F. W. VAN STRATEN[1] AND W. F. EHRET

Although it has long been known[2] that the reaction of zinc with copper sulfate solution is not one of simple displacement, many authors in modern scientific literature still retain the idea that only metallic copper is produced along with zinc sulfate. At the outset of this investigation, sufficient work had been done by others to permit the generalization that in displacement reactions the deposit of the more noble metal is rich in base metal if these metals show a tendency to form compounds when cooled from the melt.[3] That the deposits formed by the action of zinc on copper sulfate were heterogeneous had been noted, particularly by Galecki and Tomaszewski,[4] who studied the variation in their coherence, color, and composition with change in concentration and acidity of the copper ion solution.

In the present work it was hoped that a systematic study of the variation in composition of such deposits with the conditions prevailing during their formation would permit postulating a mechanism for the reactions—particularly since this study involved, in addition to the determination of the over-all chemical composition, an X-ray investigation of the solid phases formed.

Experimental

Materials and Apparatus.—The copper sulfate used was Kahlbaum "pro analyse"; the zinc sulfate, Merck reagent.

The zinc was Baker zinc metal, for standardization. The zinc strips were first washed, rinsed, and then rubbed dry with towels. Next, they were annealed by placing in a glass tube which was evacuated and heated to 200°. The cooling was fairly rapid and vacuum was maintained until the strips reached room temperature. The thickness of each strip was approximately 0.3 mm., which was sufficient to lend rigidity to the metal without introducing end effects by reaction along the sides. In order to prevent reaction on both sides of the strip, one side was covered with spar varnish. Immediately before a run was made, the four strips of zinc necessary to make the run were immersed for thirty seconds in an etching reagent made by mixing 144 ml. of hydrogen peroxide (3%), 24 ml. of concd. ammonium hydroxide, and 144 ml. of distilled water. After rinsing a few times with water, the strips were ready for the run.

A brass stirrer was constructed as shown in Fig. 1a. It was hollow and able to pump liquid from the bottom of the vessel as well as provide efficient turbulent stirring. Cavitation was prevented by insertion of two copper baffles in the solution studied. Both the stirrer and baffles were varnished to prevent reaction with the solution. The latter always had a volume of 1 liter and was contained in a 1-liter beaker immersed in a thermostat. The temperature regulation was to ±0.01° at 25° and to ±0.02° at the higher temperatures. The stirring speed was controlled to ±3 r. p. m.

The zinc strips (four) were attached to a glass cage (Fig. 1b) by cutting them slightly longer than required and folding the extra length, top and bottom, around the horizontal supports of the cage. The effective area of the exposed surface of each zinc strip was 9.6 by 1.25 cm. The long arms of the cage could be inserted in appropriate slots along the bearing of the rotor so that the cage was coaxial with the rotor and could be raised out of the solution being stirred until the latter acquired the proper temperature and until the stirrer was rotating at the required speed. At such time as everything was ready for the run, the cage with the zinc strips could be lowered rapidly into the solution. A stop at the top of one of the long arms of the cage enabled the experimenter, in one operation, to raise, swing, and lower the shaft of the rotor supporting the cage into a beaker of water, permitting the reaction to be stopped almost instantaneously and providing also for the rinsing of the deposit. The strips were placed on the cage with the varnished sides away from the rotor and so that the reacting surfaces were equidistant from the center of the shaft. The duration of all reactions, unless otherwise noted, was one minute at 25°, one-half minute at 50°, and one-fourth minute at 75°.

X-rays were generated by means of a copper target in a Seemann-type tube, using nickel filters. Three Bohlin-type focusing cameras, made according to the specifications of Phragmén and reported by Westgren,[5] were used in connection with the usual powder technique of crystal analysis. The photograms obtained from the deposits were compared with those of known brasses prepared in the manner described elsewhere.[6]

Chemical Analysis.—The chemical analyses of the deposits were made according to a method already outlined.[6] In brief, the method consisted in the removal of the deposit from the zinc strips with a rubber brush, the strips having been rinsed previously with water for one minute, alcohol for ten seconds, and dried for one-half hour. Two samples of about 20–30 mg. were removed and weighed in a goose-neck weighing flask. The deposit was dissolved by the addition of 1.5 ml. of concd. nitric acid and 2 ml. of concd. sulfuric acid. The flasks were then transferred to a crucible furnace, heated to 400°, and kept at that temperature until all traces of sulfuric acid were removed. After cooling, the flasks were again weighed, the contents dissolved in distilled water, and analyzed for copper iodimetrically.

This procedure yields the following information directly: the weight of sample, the weight of combined zinc and copper sulfates, and the weight of copper. The weight of copper sulfate present after evaporation with sulfuric acid is calculated from the weight of copper, and the difference between this value and the weight of mixed sulfates corresponds to the weight of zinc sulfate. From this figure, the weight of zinc may be found.

Every sample of deposit included, in addition to the metals copper and zinc or their alloys, compounds of these with oxygen, hydrogen, and, or, sulfate. The non-metallic portion could not be determined directly by the method of analysis since it was destroyed by the action of the acids used in the solution of the deposits. However, the quantity of these materials could be found indirectly, since the combined weight of copper and zinc was less than that of the deposit by the amount of these radicals originally present. At 25°, this amounted to about 6% of the deposit. At higher temperatures, the value increased to about 9%.

The exact constitution of the compounds of copper and zinc present defied the authors' attempts at complete analysis. This material might consist of one or more or possibly all of the following compounds: cupric and cuprous oxides, zinc oxide, cupric hydroxide, zinc hydroxide, basic salts of copper and zinc, varying degrees of water of hydration, adsorbed water, and adsorbed hydrogen. A serious attempt was made to estimate some of these materials as present in a deposit obtained from a particular run in order to be able to interpret properly subsequent analyses.

The deposit from a representative run containing 6.2% of non-metallic constituents was heated to 230° in a nitrogen atmosphere to determine the amount of adsorbed gas, water and water of hydration (item 2 in Table I). A subsequent heating to the same temperature in a hydrogen atmosphere effected a reduction of the oxides of copper without reducing zinc oxide. The loss in weight due to the removal of oxygen from the oxides of copper is given by item 3. Further, the total amount of $SO_4^=$ was determined using microanalytical technique (item 4). Items 2, 3, and 4 subtracted from item 1 gives the % oxygen combined with zinc. It was also found that the leaching of a fresh sample of deposit with ammonia water under air-free conditions in an apparatus already described[7] resulted in the solution of 3.7% copper and 15.1% zinc. The zinc was present from two sources: the solution of zinc compounds and as a result of the interaction between metallic zinc and copper compounds. In the measure in which the zinc was too high, the percentage of copper found in solution was too low.

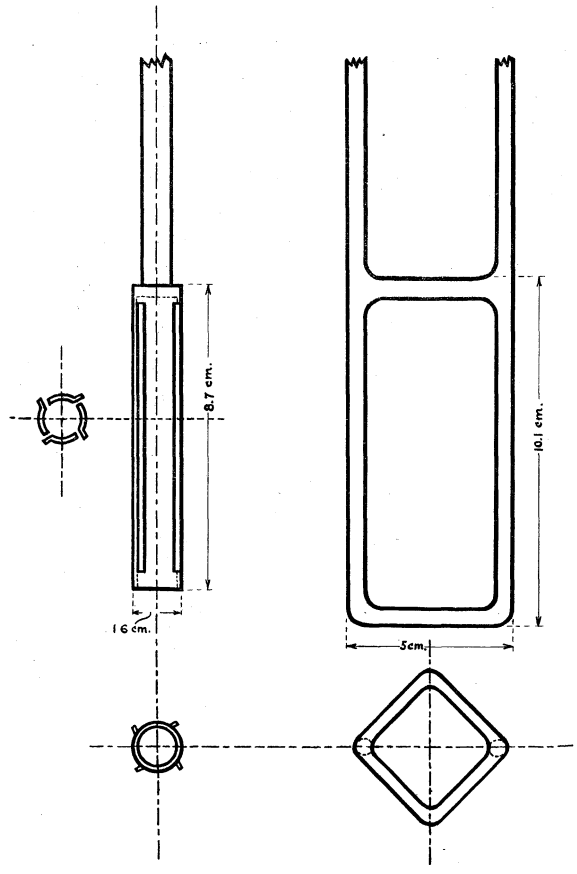

Fig. 1a.—Pump and stirrer.

Fig. 1b.—Glass cage.

These data were coördinated with the previous values in an attempt to ascertain the total composition of the deposits. First, the percentages of copper combining with 2.1% oxygen as cuprous and as cupric oxides were calculated (items 6 and 7). These values for copper lead to the amounts of this metal which were displaced by zinc during the leaching experiments (9 and 10), and also to the amount of zinc so dissolved (11 and 12).

(6) Van Straten, Master's Thesis, New York University, 1937.

(7) Van Straten and Ehret, *Mikrochemie*, **26**, 56 (1939).

Items 13 and 14 then show how much zinc had been present as oxide in the original deposit and 15 and 16 the percentage of oxygen combined with the zinc. In this dual set of data, one item represents the assumption that the cupric was the only oxide of copper present and the other that only cuprous oxide was present. Items 15 and 16 must be compared to item 5. Since there is a closer approximation between item 15 and item 5, it is deduced that cuprous oxide is present predominantly. The presence of cuprous oxide may be accounted for by the interaction of copper with cupric ions or by the incomplete reduction of cupric ions by zinc.

TABLE I

1	% non-metallic constituents (100 minus total % Cu minus total % Zn)	6.2
2	% adsorbed gases, water, etc.	1.6
3	% oxygen combined with Cu as cupric or cuprous oxide	2.1
4	% sulfate combined with Zn[a]	1.1
5	% oxygen combined with Zn as zinc oxide	1.4

[a] Sulfate is considered to be combined only with zinc since copper sulfate if present during washing and drying operations would have been given ample opportunity to react with metallic zinc or alloy.

CALCULATIONS

6	% Cu which was combined with oxygen (item 3) if only cuprous and no cupric oxide were present	16.8
7	% Cu which was combined with oxygen (item 3) if cupric oxide were the only oxide of Cu present	8.4
8	% Zn combined with sulfate (item 4)	0.7
9	Item 6 minus 3.7% (leaching data) equals the % Cu which was displaced by Zn	13.1
10	Item 7 minus 3.7% equals the % of Cu which was displaced by Zn	4.7
11	On basis $[Cu(NH_3)_4]^{++} + Zn \longrightarrow Cu + [Zn(NH_3)_4]^{++}$, % Zn equivalent to item 10	4.7
12	On basis $2[Cu(NH_3)_2]^{+} + Zn \longrightarrow 2Cu + [Zn(NH_3)_4]^{++}$, % Zn equivalent to item 9	6.6
13	15.1 (leaching data) minus item 12 minus item 8 equals the % Zn present which was combined with oxygen as zinc oxide	7.7
14	15.1 minus item 11 minus item 8 equals the % Zn present which was combined with oxygen as zinc oxide	9.7
15	% oxygen which was combined with Zn as per item 13	1.9
16	% oxygen which was combined with Zn as per item 14	2.4

These determinations made it possible to offer a complete analysis for a representative sample of deposit formed at 25° (Table II). The authors believe that this is as close an approximation to the true composition as can be made with present methods.

TABLE II

	%
Water and adsorbed gases	1.6
Cuprous oxide	18.9
Zinc oxide	7.0
Zinc sulfate	1.8
Zinc and copper as metal or alloy	70.7
	100.0

Experimental Results.—In Fig. 2 are given the results of the experiments designed to show the variation in the composition of the deposits with change in stirring speed. The X-ray photogram of all the deposits shown by points on the graph, except for those on curve 5, indicated the presence of copper as principal phase and α-solid solution as secondary. The deposits shown on curve 5 consisted of a mixture of α- and β-brasses.

The variations in composition of the deposits with increase in reaction time and increase in the length of time that the deposits, already formed, were in contact with copper sulfate solution are shown in Figs. 3 and 4. In the former, curve 1 represents runs made at 25° and the additional time is given in fractions of a minute beyond the first minute; curve 2 gives results obtained at 50° and the additional time represents fractions of a half-minute beyond the first half-minute. The deposits used for the runs of Fig. 4 were obtained by one-minute immersion of zinc in 0.0484 *M* copper sulfate solution at 25° and 1000 r. p. m.

X-ray analyses of the deposits from the runs shown in Fig. 5 indicated copper as the principal phase with α-brass of variable concentration secondary at 25°. At the higher temperatures and for low concentrations of copper sulfate there were increasing amounts of α as well as some β-brass.

Figure 6 and Table III show the influence of the addition of zinc sulfate to the bulk solution. The results of the X-ray examination here were particularly interesting and will be referred to later. The symbols used under the column headed *phases* have the usual significance, *i. e.*, Cu > α means there was more of the copper phase than of α; $\alpha \gg \beta$ means there was mostly α and very little β, etc.

The change in *p*H during representative runs is given in Table IV and when these figures are compared with those of Table V in which changes in

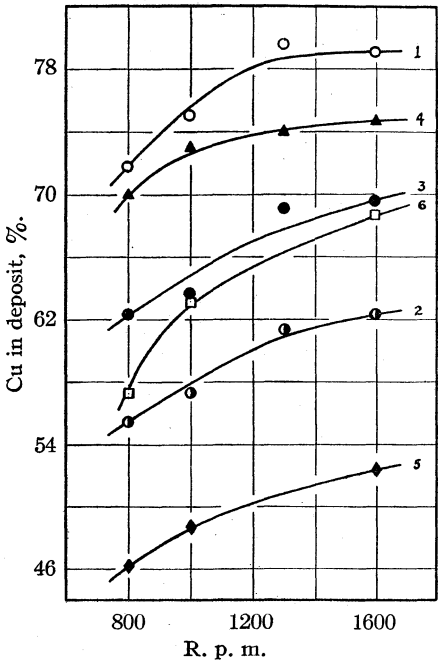

Fig. 2.—Variation in composition of deposit with change in stirring speed in $CuSO_4$: 1, 0.0847 *M*, 25°; 2, 0.0121 *M*, 50°; 3, 0.0484 *M*, 50°; 4, 0.0847 *M*, 50°; 5, 0.0121 *M*, 75°; 6, 0.0484 *M*, 75°.

composition with deliberate changes in acidity are recorded, it is seen that hydrolytic influences play a negligible part in the displacement experiments here reported.

Discussion

Preliminary to the interpretation of the experimental results it will be well to discuss the chemistry of the reaction and the mechanism which will account for the results obtained.

A displacement of this sort is obviously an electrochemical reaction in which the anodic and

cathodic areas are in close contact with each other, forming local elements. The initial reaction is the simple one in which zinc goes into solution and copper plates out at the less active points. According to Erbacher[8] this process is initiated by surface inequalities forming "solubility" local elements whereby one portion of the more active element passes into solution more readily than another, thus resulting in an exchange of surface atoms, less noble for more noble.

This process causes a building up in zinc sulfate concentration due to the solution of metallic zinc. The local elements, Zn/Cu, are bathed, therefore, in a solution of both copper and zinc sulfates. From such a solution brass is deposited rather than pure copper. From this point on, local cells of the type $Zn/ZnSO_4$, $CuSO_4$/brass play an important part in the formation of the deposit. Variation in the composition of the brass makes it possible for one crystal, poor in copper, to act as anode while another, rich in copper, is cathodic. Also both can act as cathode with respect to the

(8) Erbacher, *Z. physik. Chem.*, **A163**, 196 (1933).

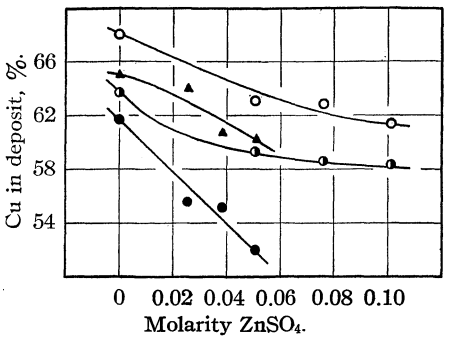

Fig. 6.—Composition of deposits as affected by zinc sulfate addition, in $CuSO_4$ at 1000 r. p. m.: ▲, 0.0242, 25°; ○, 0.0484, 25°; ●, 0.0242, 50°; ◑, 0.0484, 50°.

original zinc. However, as the deposit grows out from the zinc strip, this last reaction becomes less prominent due to the distance between the outermost deposit and the zinc. The main reaction is then the one caused by having brasses of different phase and composition act as cathode and anode. The potential developed by such cells is considerably less than that of the original cell, Zn/Cu, and the proportion of zinc which is plated out on the fringes of the deposit must be reduced greatly since a fairly high potential would be required to deposit zinc-rich alloys. This reduction in zinc is enhanced further by the fact that any zinc and all the copper that plate out, do so at the expense of zinc already laid down in the deposit.

In our work, this effect was somewhat counterbalanced by another. Turbulent stirring and the increased bulk of the loosely adherent deposit caused the ripping off of some of the outer layers. This was only prominent when the run was long or when the reaction was rapid as at the higher temperatures and concentrations of copper sulfate. Since the outer layers were richer in copper than the inner ones and since it was the outer layers which ripped off when droppage occurred, more copper than zinc was lost, and the remaining adherent deposit was thus made relatively zinc rich. Since the deposit lost from the strip was not recovered, the net result was the increase in zinc concentration in the deposit analyzed.

The mechanism postulated above will probably hold for all cases of displacement in which the more noble and the baser metal show a tendency to form compounds or solid solutions. It seems quite capable of explaining the results of Natta[9] who, using the electron diffraction method,

(9) Natta, *Gazz. chim. ital.*, **67**, 10 (1937).

identified the solid solutions formed when palladium, silver or gold was displaced by copper. A similar mechanism with but minor modification was used by Hoar and Price[10] to explain the atmospheric corrosion of base metals.

Although the mechanism given above is capable of explaining the nature of our deposits, it should be noted that the *rates* of displacement were governed by a physical process, diffusion. This was demonstrated both by experiments in which the viscosity of the reacting solution was increased by means of sugar, thus decreasing the diffusion rate and the proportion of copper in the deposit, and by the experiments (Fig. 2) involving the simultaneous increase in stirring speed, diffusion rate, and proportion of copper in the deposit.

The diminishing slope of the curves representing the experiments in Fig. 2 may be accounted for as follows. The higher the stirring speed, the greater was the droppage of deposit, and since, as mentioned earlier, increased droppage corresponds to a decrease in the amount of copper found, the rate of increase in copper due to an increase in stirring speed would be counteracted by the decrease due to droppage.

Statements concerning the effect of droppage on the composition of the deposit are justified by the data shown in Figs. 3 and 4. As the deposit grows out from the zinc strip, beyond a certain point, it becomes progressively richer in copper, due to the decrease in the amount of zinc present in the solution with increasing distance from the zinc strip and also due to the secondary reaction by which zinc is dissolved out of already deposited brass and is replaced by more copper. This process is indicated by the data in Fig. 4, which may be considered a study of secondary reactions. In getting the information for this figure, deposit from a regular run was removed from the zinc strip and then placed in contact with further amounts of solution for varying lengths of time. All the deposit was then analyzed. It was immediately apparent that the rise in copper concentration in the deposit for this material is much greater than that for the deposit formed when the zinc strip with the adherent deposit remains in contact with copper sulfate solution for longer periods of time (Fig. 3). In this latter case, the huge increase noticed in the former is counterbalanced by droppage.

(10) Hoar and Price, *Trans. Faraday Soc.*, **34**, 867 (1938).

Examination of Fig. 5 makes it immediately apparent that although increase in concentration of the copper sulfate increases the concentration of copper in the deposit, the effect is more pronounced when the solution is dilute than when it is concentrated. This phenomenon, the authors believe, can be explained by the fact that in the dilute solutions, little deposit is formed during the specified time of reaction. In this way, even the outermost part of the deposit, at the end of the reaction, is not far removed from the zinc strip, accounting both for the high percentage of zinc in the deposit and the large decrease in this percentage with slight increase in concentration of the copper sulfate. The former is explained by the fact that with such intimate contact between the bulk of the deposit and the zinc strip, this continues to furnish the bulk of the anodic areas for the electrochemical reaction so that there is little solution of the zinc which has already plated out with the copper, and the total zinc concentration in the deposit remains high. The latter effect, the rapid increase with increased concentration, is probably due to the absence of droppage. The outermost layers which are relatively rich in copper are not ripped off so that the full effect of these last layers of copper-rich brass is felt in the analyses. The change in slope as the solution becomes more concentrated, as well as the slight irregularities of the points with respect to the curve, may be explained by the appearance of droppage at these concentrations.

The data of Table III and the corresponding Fig. 6 show the effect produced on the composition of the deposit by the addition of zinc sulfate to the copper sulfate solution. Although the effect is not particularly marked in three of the four cases, it is nevertheless true that increase in the amount of zinc ions in the solution decreases the copper in the deposit. The X-ray data for the lowest of the four curves show that these deposits contain a much greater proportion of β-brass than do the others, which in turn indicates that the conditions in the solution were made progressively more favorable for the deposition of β-brass as the concentration of copper sulfate was lowered and the temperature and zinc sulfate concentration increased. The more rapid descent of the curve in this case is probably due to this preferential β-brass formation. The gradual descent of the other curves may be explained by the nature of the diffusion gradient of the zinc sulfate

solution. In the case of deposition from pure copper sulfate solution, the concentration of zinc sulfate drops from a relatively high value immediately adjacent to the zinc strip to a very low value at the edge of the deposit where this is in contact with the bulk solution. This corresponds to a progressive diminution in zinc ion concentration in contact with the deposit as the deposit is further removed from the zinc strip. When the bulk solution already contains zinc ions, the rate of diminution in zinc ion concentration with distance is not as rapid. However, even fairly large additions of zinc sulfate cause but small alteration in the composition of the deposit, since the over-all increase in zinc ion concentration throughout the deposit is small.

The X-ray part of this investigation was undertaken primarily to prove irrefutably that various kinds of brass are formed by displacement reactions and that change in concentration of the solution from which the deposit is formed may change the phases plated out. However, due to the limitations of the X-ray method of analysis, the data obtained were not very useful in the interpretation of the results. The production of satisfactory X-ray photograms depends to a large extent upon having present a sufficient number of diffracting crystals of dimensions greater than 1×10^{-6} cm. Judging from the line-breadths and general scattering produced, our deposits often contained particles of about this magnitude or smaller. It is not possible to determine the lattice parameters of such crystals and sometimes impossible to detect the phases themselves. The absence of any X-ray indication of the gamma phase (or any other zinc-rich phase) which must be present according to the corresponding chemical analysis, is probably due to this limitation of the X-ray method.

Summary

1. A study was made of the displacement reactions involving the formation of brasses by reaction of zinc with copper sulfate solution at 25, 50, and 75°.

2. The compositions of the deposits obtained by displacement were determined by chemical and X-ray diffraction methods.

3. An increase in concentration of copper sulfate was found to increase the copper content of the deposits, whereas zinc sulfate, added to the copper sulfate solutions, decreased the copper content. These results are in general agreement with work reported by Galecki and Tomaszewski although in their experiments the conditions were less carefully controlled.

4. The amount of copper in the deposit increased with increased stirring of the solution, an indication that the reaction was diffusion controlled.

5. The influence of the changing acidity of the solutions on the nature of the deposits was found to be negligible in the course of the time allotted to a run.

6. An investigation was made of the secondary reactions resulting from prolonged exposure of deposits, in and out of contact with zinc, to copper sulfate solution.

7. An electrochemical mechanism is offered to explain the formation of brasses by displacement.

Photovoltaic Cells: The Spectral Sensitivities of Copper, Silver and Gold Electrodes in Solutions of Electrolytes

BY PAUL E. CLARK AND A. B. GARRETT

The spectral sensitivities of metal and coated-metal electrodes are useful data, in conjunction with other cell characteristics, for the interpretation of the mechanism involved in photovoltaic cells. Spectral sensitivities may also prove to be valuable for the determination of the potential barrier at a metal–solution interface.[1] Moreover, information concerning the effect of light of different wave lengths upon metals commonly used for various types of electromotive force measurements should be made available. This paper reports the determination of spectral sensitivity values of copper, silver, and gold electrodes from λ = 3650 to 6908 Å. These three metals were chosen for this work chiefly because (1) copper and silver are known to have definite photovoltaic action,[2,3] so much so that silver electrodes must be protected from light when used in the potentiometric titration of halides and (2) copper, silver and gold are closely related due to their similar electron configuration.

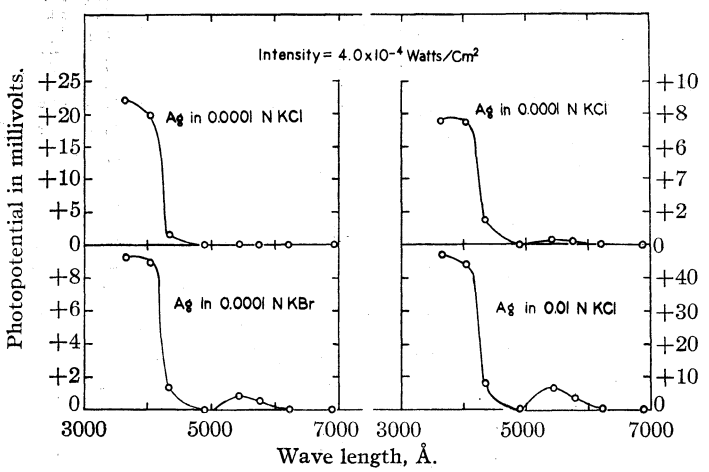

Fig. 1.

Some previous work on observations of photovoltaic cells composed of metal electrodes in solutions of electrolytes has been reported by several workers,[4–7] but no systematic study of the spectral sensitivities is reported for this type of cell. However, Athanasiu[8] has determined the spectral sensitivity of coated metal electrodes of Ag–AgI and Hg–Hg_2I_2 electrodes. Other reported work on spectral sensitivities of coated electrodes is less quantitative and not complete enough for the purpose outlined above.

Experimental

The Solutions.—All solutions used were prepared volumetrically from reagent quality chemicals. Conductivity water was used in all of these preparations.

The Cells.—The cell used was H-type with a chemical Pyrex[9] window through which one electrode could be illuminated and which transmitted radiation from λ = 3300 to 25,000 Å. The electrodes were stamped from sheet metal giving uniform disks approximately 8 mm. in diameter. These were fused to wire of the same metal, polished with 4/0 polishing cloth, annealed in an atmosphere of hydrogen and again cleaned and polished.

Each wire lead was then drawn through a small glass cylinder filled with paraffin, one side of the disk was coated with paraffin and the other side again polished. These were

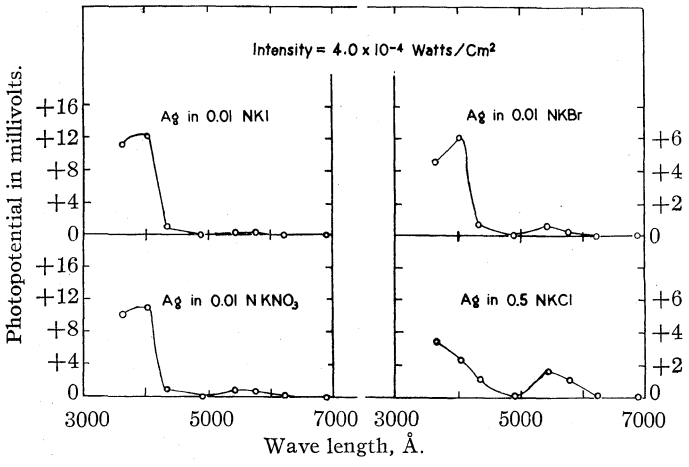

Fig. 3.

washed carefully in conductivity water and placed in the solution in which they were to be used. The silver electrodes were made of Eimer and Amend[10] 999 fine silver, the gold electrodes of Eimer and Amend 24 carat gold and the copper electrodes of pure annealed sheet copper. The copper oxide coating was obtained by heating the copper electrodes in an atmosphere of oxygen. The silver bromide electrodes were obtained by electrolyzing silver electrodes in a solution of silver bromide. The bimetallic electrodes were prepared by electroplating processes recommended by Blum and Hogaboom.[11]

The Thermostat.—The thermostat was a water-bath insulated by means of four concentric tanks of mirror tin, which were separated by wood, air and glass wool, respectively. A top for the bath was of similar construction. This insulation reduced heat transfer to a minimum and eliminated the necessity of an electrical thermostat control which might have been a source of parasitic currents to be picked up by the Pliotron circuit. This type of thermostat gave very steady temperature control; any temperature change in this thermostat was of a unidirectional nature rather than of a fluctuating nature. Such a characteristic is valuable in determining accurately the dark potential drift of the cells studied if any of the potential drift is due to a thermal effect. A chemical Pyrex glass[9] window was mounted in one side of the thermostat. A camera shutter and a glass filter holder were mounted opposite the glass window on the outside of the thermostat. The cell was placed in line with the glass window, in the thermostat, on a mounting on which could also be mounted a thermopile in the place of the cell. The wire leads to the cell were carried through the thermostat wall in glass cylinders filled with sulfur.

The Illumination Source.—A 100-watt mercury vapor lamp, type H-4, manufactured by the General Electric Company, was used as the source of illumination. The characteristics of this lamp are given in Table I.

Monochromatic radiation was obtained by means of a series of glass filters manufactured by the Corning Glass Company.

The Intensity Measurements.—A Moll Microthermopile was used for the measurement of the intensity of the radiation for each filter at various positions of the mercury lamp. This thermopile was calibrated by means of a standard carbon filament lamp which was standardized by the National Bureau of Standards. The calibration was extended to higher intensities than those obtained from the standard lamp at the distance specified by the National Bureau of Standards. This was done with the use of a second standard lamp working at a higher current and by the methods suggested by Leighton and Leighton,[12] as well as by Forbes.[13] A linear relationship of (galvanometer deflection/intensity) for the galvanometer–thermopile system was obtained up to 30 cm. deflection; this

[a] These showed an initial negative surge.

was extrapolated to 50 cm. deflection. Such an extrapolation is justified for this work since the values at these high intensities were of several filters for which the photoresponses were extremely small or nil. In the main, the working intensity was within the limit of the intensity range of calibration of the thermopile.

The Measurement of the Photopotentials.—In some cases the photopotentials were measured with a Leeds and Northrup type-K potentiometer and galvanometer whose sensitivity was 1×10^{-9} amp./mm. All leads were protected with grounded shields.

In most cases, however, the photopotentials were measured with the aid of an F. P. 54 Pliotron tube in a balanced bridge type of circuit designed by Brown and DuBridge.[14] The galvanometer used in this circuit was the same as the one above. The entire circuit was shielded; in addition, the main circuit was protected from humidity effects. In comparison with the potentiometer system this circuit had the advantage of eliminating effects due to polarization since the grid current was of

(14) Brown and DuBridge, *Rev. Sci. Instruments*, **4**, 532 (1933).

the magnitude of 10^{-15} amp.[15] The Pliotron circuit was calibrated with the aid of a voltage divider and the potentiometer circuit described above.

The Data.—The data are shown in Table II and Figs. 1–9, inclusive. These data are all transposed to the same intensity of the 4047 Å. line.

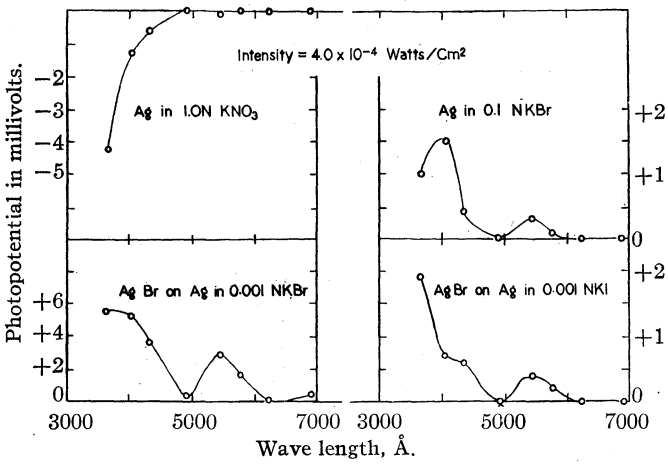

Fig. 5.

This transposition was effected by determining the change in photopotential with the change in intensity for each filter and interpolating or extrapolating the data so obtained.

The accuracy of these data can be determined from the sensitivity of the measuring instruments, the reproducibility of the measurements (relative to each other for a given cell) and the error involved in transposing the data to a standard intensity. The potentiometer circuit had a sensitivity of 1×10^{-5} volt and the vacuum tube circuit 4×10^{-5} volt; the measurements of a cell for each filter were reproducible to $\pm 5\%$ relative to those measurements with other filters of the same cell; the error involved in transposing the data to a standard intensity is not more than 5% of the value of the photopotential of the line chosen as the standard of reference.

The accuracy of the absolute values depends upon their magnitude; thus an expression of the error involved in the absolute values is difficult to formulate. However, since the major merit of the data is their comparative utility, it is safe to conclude that the maximum probable error is not more than $\pm 5\%$ of the value of the photopotential of the 4047 Å. line at the standard intensity of 4.0×10^{-4} watts/sq. cm. and that in most cases it is much lower than this.

The error involved in expressing the threshold value is controlled by the distance between the lines of monochromatic radiation used. Hence it is only possible to suggest that the threshold value lies some place between $\lambda = 4358$ and 4916 Å. and more probably very near $\lambda = 4916$ Å.

In order to detect any possible effect of "activation" by short wave length, a number of cells were studied by consecutive irradiations from the long wave lengths to the short wave lengths then back to the long wave lengths again; these studies showed no "activation."

Drift in the vacuum tube circuit and drift due to slow dark potential changes were determined by a series of potential readings before and after illumination. These drift values, together with the values of the potential on illumination, were plotted as ordinates and times were plotted as abscissas; by this method the value of the photopotential was determined graphically.

The effect of temperature reported by Athanasiu[16] was investigated for a number of the cells.

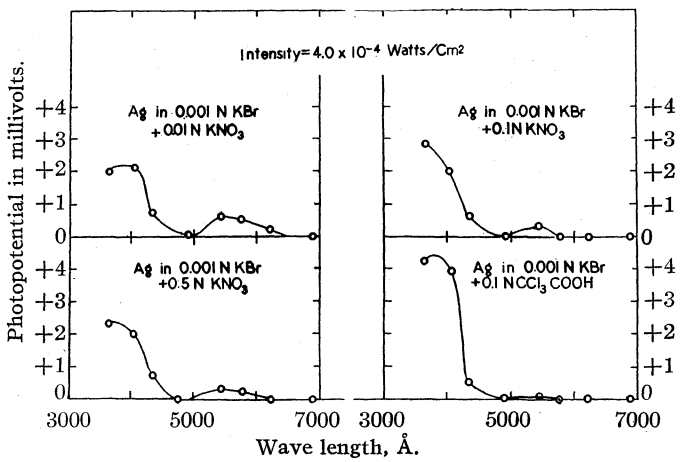

Fig. 6.

Several factors indicate that the potentials developed on illumination were not the direct result of temperature effects. Of those factors can be listed the following: (1) the long wave lengths of light are relatively ineffective in developing photo-

(15) The authors are indebted to Dr. P. M. Harris for suggestions relative to the use of this circuit.

strongly to the fact that the above relationship is apparently more than a fortuitous one.

[a] Column 2, this research; columns 3, 4, and 5, compiled from those given by Hughes and DuBridge, ref. 3, p. 75.

Summary

The spectral sensitivities of copper, silver and gold electrodes have been determined for a number of lines of monochromatic radiation ranging from $\lambda = 3650$ to $\lambda = 6908$ Å. The photovoltaic threshold values for these metal electrodes have been determined.

The sensitivity of coated metal electrodes and some metal electrodes at $\lambda = 5461$ Å. is attributed to the coating on the electrode.

A similarity in the mechanism of the photovoltaic and photoelectric effects is suggested from a comparison of the photoelectric threshold values of metals at various stages of outgassing and the photovoltaic threshold value.

A vacuum tube circuit employing an F.P.-54 Pliotron tube is described as suitable for the measurement of photopotentials.

The Preparation and Identification of Three Alkali Molybdotellurates[1]

BY S. R. WOOD AND ARTHUR CARLSON

The systematic preparation and study of salts of the complex heteropolyacids of molybdenum and tellurium are comparatively recent developments in inorganic chemistry. In 1910 Miolati[2] prepared a compound of apparent formula Te_2O_{11}-K_{10}·$12MoO_3$·$18H_2O$, or possibly TeO_6·K_5H·$6MoO_3$·$8H_2O$. In 1929 Meloche and Woodstock[3] isolated and analyzed two ammonium molybdotellurates, which proved to have the empirical formulas $3(NH_4)_2O$·$2TeO_3$·$6MoO_3$·$10H_2O$ and $3(NH_4)_2O$·TeO_3·$6MoO_3$·$7H_2O$. Since that time Hansen[4] prepared and described a potassium salt, $3K_2O$·TeO_3·$6MoO_3$·$8H_2O$; Thomsen[5] studied a sodium molybdotellurate, $3Na_2O$·TeO_3·$6MoO_3$·$22H_2O$; and Dyess[6] reported the composition of the lithium salt to be $3Li_2O$·TeO_3·$6MoO_3$·$13H_2O$. Specimens of the salts of sodium, lithium, cesium,

potentials; (2) the potential response appears to be inertialess; (3) the temperature effect is negative whereas the photo-response is positive for many of the cells studied. Other unpublished work[17] shows that an important factor for the reversal of the potentials of these cells is the concentration of the electrolyte. This is rather indicative that the photopotential may be the sum of several effects, but the effect due to temperature must certainly be only a minor one.

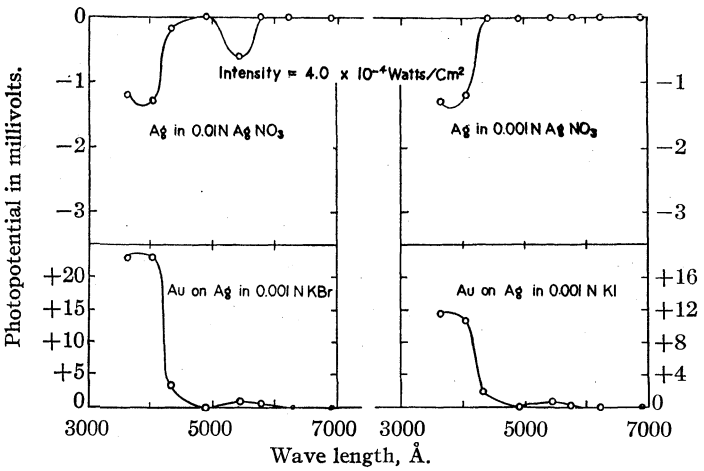

Fig. 7.

The photopotentials cannot be explained in terms of absorption by the solutions, particularly for the halides, since the longest wave lengths absorbed by the potassium halide solutions are given by A. K. Dutta[18] as follows: KCl λ = 2760 Å.; KBr λ = —— Å., and KI λ = 3600 Å. Furthermore he found no appreciable absorption for solutions more dilute than 0.1 normal in case of the chloride and iodide and no appreciable absorption above 2550 Å. for the bromide at any concentration.

The sign of the dark potential had no observable effect on the sign of the photopotential. In general the magnitude of the photopotentials for a given line at a given intensity is characteristic of each cell.

Potential reversals with time[19] were observed for cells marked (*a*). No general statement can be made concerning this phenomenon; the period of the galvanometer limited the observations of this reported negative surge. Further observations should be made concerning the characteristics of this phenomenon.

A number of cells show a hump in the wave length/photopotential graph indicating that the cells are not sensitive to light of λ = 4916 Å. but may be sensitive to λ = 5461 Å. Several cells did not show this effect. It is evident that the hump is much more pronounced in cells having a coated surface such as Cu–CuO, Ag–AgBr, etc. That observation rather suggests that those electrodes showing sensitivity at λ = 5461 probably contained a coating of oxide or halide which was responsible for such an effect.

A comparison of the photovoltaic threshold values with the photoelectric threshold values for the same metals in various stages of outgassing is interesting and is found in Table[20] III. The order of apparent decrease in the value of the work function is in the direction one might expect if the ease of removal of an electron depends upon the material at the interface. Furthermore, this suggests a similarity between the mechanisms involved in both phenomena. Other cell characteristics are necessary before conclusions can be drawn in this regard but thus far it can be said that other unpublished observations point

ammonium (monotellurate) prepared by Wood and the ammonium ditellurate prepared by Meloche were subjected to crystallographic and optical examinations by Donnay and Melon.[7]

Thus most of the alkali metals form corresponding compounds of the type $3M_2O \cdot TeO_3 \cdot 6MoO_3 \cdot nH_2O$. The work here reported was undertaken to learn whether rubidium and cesium yield similar complex salts. By evaporating a solution containing alkali metal hydroxides, telluric acid, and molybdenum trioxide in the proper proportions, we have indeed obtained a rubidium salt, $3Rb_2O \cdot TeO_3 \cdot 6MoO_3 \cdot 6H_2O$ and a cesium salt, $3Cs_2O \cdot TeO_3 \cdot 6MoO_3 \cdot 7H_2O$. We also have duplicated the preparation of the sodium salt already mentioned and verified its composition. All of these salts are beautifully crystalline, but effloresce rapidly when exposed to the open air.

It is worthy of note that all the alkali metal molybdotellurates can be formulated satisfactorily according to the Miolati–Rosenheim theory[8] as $M_6[Te(MoO_4)_6] \cdot nH_2O$. The original salt of this type prepared by Miolati was apparently an acid salt, $K_5H[Te(MoO_4)_6] \cdot 8H_2O$, having the same degree of hydration as the normal salt.

Materials Used: Telluric Acid.—Pure telluric acid was prepared by a modification of the Staudenmeyer[9] method. This procedure depends on the chromic acid oxidation of pure tellurium dioxide in dilute nitric acid solution. Six recrystallizations were carried out to ensure a very pure product. Analyses of the telluric acid for tellurium showed that it was 99.86% pure.

Molybdic Oxide.—Analyzed molybdic anhydride of 99.9% purity was used.

Cesium Nitrate.—Pure cesium nitrate was used.

Rubidium Hydroxide.—The rubidium hydroxide was prepared by treating pure rubidium chloride with the stoichiometrically calculated amount of pure silver oxide. The precipitated silver chloride was filtered off, leaving rubidium hydroxide in solution. This base was recovered by evaporation.

Sodium Hydroxide.—C. P. sodium hydroxide was used.

Preparation.—In the preparation of these salts, the reagents were dissolved in water, in the ratios of 0.06 mole of the respective alkali metal compounds, sodium hydroxide, rubidium hydroxide, or cesium nitrate, to 0.01 mole of pure telluric acid to 0.06 mole of molybdenum trioxide. The clear solution was then evaporated to a small volume on a water-bath. On cooling, colorless crystals appeared. Each of the three compounds was recrystallized from water six times. In order to prepare samples for analysis, the crystals were dried by successive washings with alcohol and ether.

Methods of Analysis: Tellurium.—The tellurium content of the compounds was determined by the Lenher–Homberger[10] method in which elementary tellurium was precipitated by the combined action of water saturated with sulfur dioxide and a solution of hydrazine hydrate upon a dilute acid solution of the sample.

Molybdenum Trioxide.—The filtrate from the tellurium analysis was evaporated to dryness on a hot-plate and fumed with 10 ml. of concentrated sulfuric acid. After the resulting solution had been diluted until the acid concentration was about 6%, the molybdenum was determined by reduction in a Jones reductor and titration with potassium permanganate. The titration was corrected by a blank. Standardization of the permanganate was made upon both sodium oxalate and pure molybdenum trioxide.

Alkali Metals.—Original samples were taken for the determination of rubidium, cesium, and sodium in the respective salts. The sample was placed in a previously weighed porcelain boat, and the boat placed inside a combustion tube. It was then heated to 500° for several hours in a stream of dry hydrogen chloride gas, the temperature being observed by the use of a thermoelectric pyrometer. Tellurium and molybdenum were thus converted to volatile oxychlorides, which sublimed away to the cooler portions of the tube. This left as residue the respective alkali chlorides which were weighed.

Water.—According to the usual practice, the hydrated salt was weighed, then dried at 110° to constant weight.

Thomsen in his analysis found the sodium molybdotellurate to contain 22 moles of water to each mole of salt. His method of determining water lay in heating a 0.5-g. sample in a combustion tube for several hours at 200°, the evolved water being swept into a tared phosphorus pentoxide tube with dried air. One of us determined the water by drying to constant weight, thus verifying the formula previously found by Thomsen.

Properties.—In appearance, all of the salts are composed of crystals of very definite and characteristic qualities. The crystals in the pure state are colorless, hexagonal rhombohedra. The cesium salts tend to crystallize out as somewhat larger crystals. When the sodium salt was allowed to crystallize slowly, crystals of enormous size were obtained, some being 2–3 cm. in length. All three of the salts are of a highly efflorescent character. When newly crystallized, they are transparent to translucent and possess a decided luster. When removed from the mother liquor and left exposed to the air, the surface turns white and opaque in a few hours time, and in a few days they crumble away to an opaque white powder.

Anal. Calcd. for $3Cs_2O \cdot TeO_3 \cdot 6MoO_3 \cdot 7H_2O$: Cs_2O, 42.02; TeO_3, 8.73; MoO_3, 42.98; H_2O, 6.27. Found: Cs_2O, 42.06; TeO_3, 8.62; MoO_3, 42.92; H_2O, 6.25.

Anal. Calcd. for $3Rb_2O \cdot TeO_3 \cdot 6MoO_3 \cdot 6H_2O$: Rb_2O, 32.82; TeO_3, 10.27; MoO_3, 50.58; H_2O, 6.33. Found: Rb_2O, 32.77; TeO_3, 10.15; MoO_3, 50.53; H_2O, 6.26.

Summary

A rubidium molybdotellurate, $3Rb_2O \cdot TeO_3 \cdot 6MoO_3 \cdot 6H_2O$, and a cesium molybdotellurate, $3Cs_2O \cdot TeO_3 \cdot 6MoO_3 \cdot 7H_2O$, have been isolated and analyzed for the first time. The sodium molybdotellurate described by Thomsen has again been prepared and its composition verified. The alkali metal molybdotellurates form a corresponding series with the general formula $3M_2O \cdot TeO_3 \cdot 6MoO_3 \cdot nH_2O$, perhaps to be written as $M_6[Te(MoO_4)_6] \cdot nH_2O$.

Molecular and Cybotactic Weight Measurements of Resinous and Crystalline Materials[1]

BY HOWARD L. BENDER

Introduction

In the analytical determination of molecular weight numbers for phenol-formaldehyde resins, for crystalline abietic acid, and for some crystalline materials used as standards, irregularities were noted in the boiling points of their solutions. These changes are considered as a function of the time and of the initial temperature used in making the solutions. The molecular weights calculated from the boiling points of the solutions thus showed wide fluctuations. It is not considered that actual molecular structures are varying to the extent shown by these measured changes.

Irregular variations occur in resin solutions as shown[2] by increasing and decreasing viscosity measurements on the same solution held under constant conditions. Also thixotropic and similar structural changes occur under experimental variations.

These changing viscosity data imply a very puzzling shift in the determined molecular weight where the Staudinger viscosity rule is used to calculate the magnitude of the chemical molecules.

For solutions of resins, these calculated "molecular weights" shift with change of time conditions, even though boiling point temperature measurements were made with the same solvent, same resin sample and same temperature conditions. Thus for such solutions, analytical molecular weight values are an uncertain foundation upon which to build structural molecular formulas.

Stewart[3] has coined an apt term for application to changing liquid particles to meet such a difficulty of stability phenomena in the field of pure liquids. According to this concept, the term "cybotaxis" is applied to describe the state wherein easily changed cybotactic groups of molecules are changing in particle size from dimolecules to a factor of approximately one thousand molecules. By Stewart's theory, when liquid molecules collide they temporarily adhere into groups but move from group to group so rapidly that actual particle detection is very difficult in low viscosity liquids.

It is now suggested that this term cybotaxis gives an apt and convenient term to describe the unstability state manifested by the unstability of supercooled liquid particles. Measurements are here given for this type material suspended in solvent solutions. The term cybotactic weight is thus proposed to replace the molecular weight number calculated from the effect of such resinous particles in solution. The proposed cybotactic analytical weight is thus a determined but transitory average value obtained by the use of ordinary molecular weight constants. Hence choice of terms between molecular weight and cybotactic weight depends upon a factor of constancy over an extended time period. This cybotactic weight value thus is a convenient analytical method for expressing the momentarily average particle size of an easily changed particle which will vary directly with the average disintegration of the mass in the solvent medium used. The values found for resins will vary with the conditions used for the determination so the conditions, including time, should always be carefully stated. The term cybotactic weight thus emphasizes the supercooled liquid state of resins. The high viscosity of undercooled liquids at the temperature of solidi-

fication implies slow change and one expects to find such supercooled liquid groups to be slow in measured changes when compared to low viscosity liquids. Thus solid cybotactic groups of resins should be, even in solvent suspension, capable of measurement both as to average size and as to comparative change in size with time. This paper deals with measurements of change in comparative sizes rather than with their absolute size values.

A very great variety of data are available to show a type of slow change which such undercooled particles undergo. The data include variations from Staudinger's reported "Molecular Weights" of styrene polymers[4] which are reduced in value by simple passage through an orifice, from consideration of the time change of viscosity[5] in resin solution on standing, to the purposeful reduction of particle size[6] in the cellulose derivative field and in the synthetic resin masses.[7]

Speaking of ordinary pure liquids and crystalline solids, Stewart draws a clear working picture in the statement: "The melting point and likewise the boiling point depend directly and indirectly upon the forces which are responsible for the crystalline and liquid states. . . that these characteristics are carried over from the solid to the liquid up to the boiling point. This makes reasonable also characteristic structural differences in the liquid state." This theory of liquid structure gives a concept for ordinary liquids which clears up many of the past difficulties and conveniently may be carried over into the field of undercooled liquids with modification for an expected equilibrium rate change.

Puzzling data as to shifting molecular weight values have been reported previously. The clearest case so far noted has been the data by McMaster,[8] who has kindly furnished us some data in addition to those published. With a freezing point method for determination of molecular weight of a crystalline material in camphor, he obtained two values depending on rapidity of cooling. The values also varied with different solvents.

Other reports show that various rubbers differ as to the effect of heating on the viscosity. Some increase and others decrease in polymer number.[9] Also *p*H has been reported to affect the polymer number of cellulose derivatives much the same as the well-known effect of *p*H on proteins.[10] The time cycle disintegration and aggregation of cellulose derivatives as measured by solubilities and viscosities have been reported.[11]

The polymerization of acetic acid is said to be affected by heat, by some solvents and by traces of water.[12]

Additional quantitative numerical data applying directly to such a concept of cybotactic, that is, to easily changed oriented groups of molecules for supercooled liquids, are now reported.

Under some conditions, the fluctuation in boiling point of a dilute solution of resin in solvent seems to be due to fluctuations in size (and hence in numbers) of the resin masses present in the solution. Thus, under certain conditions, no means were found for obtaining continued constant boiling points even though all the known mechanical aids to reduce superheating were used. These aids included the vapor pumps, roughened glass surfaces, added particles and the very rapid vibration obtained on a 60-cycle per second shaking machine. These data seem to give emphasis to the "micro-crystalline hypothesis" (that is, the actual existence of oriented small groups of molecules) as distinguished from the "quasi-crystalline hypothesis" which is a mere statistical characterization favored by Prins.[13] These data show that the cybotactic weight of a resin changes with time at any one temperature and changes with temperature on any one time cycle. We have previously reported boiling point determinations of molecular weight on a phenol-formaldehyde Novolak resin and have obtained values of 200 to 300.[14] Other reports in the literature show generally higher values so that one wonders at the variation of data. Lignin[15] has lately been reported as having two sets of molecular weights by use of two different methods. In fact, agreement as to resin molecular weights by two different methods is the exception rather than the rule. This condition has caused us to reexamine the analytical determination of the mo-

lecular weight number for phenol-formaldehyde resins.

The data indicate that many of the past determined molecular weight numbers for resins are simply arbitrary numbers dependent upon the method of measurement and no present scheme of selection is capable of evaluating the true molecular weight, unless one relies upon the minimum weight as determined by all known methods for indicating the true molecule. The data indicate that present methods are measuring changing particles which vary in size with at least three factors and perhaps more. The factors which always vary the determined numbers are temperature, time and the previous treatment of the sample.

Bernal[16] notes the changing configuration of a liquid as a function of temperature and pressure. To this he adds that changes which require increased energy, such as high viscosity, favor the formation of glasses. "A glass being defined as a supercooled liquid in which the viscosity has become so high that the configuration remains fixed at a state not corresponding to the equilibrium configuration but one determined by the heat treatment and the time elapsed." From the present data, the conclusion is drawn that the undercooled liquid average particle is not constant in size but that such size is a function of present temperature and previous treatment. McBain[17] reports that tested high viscosity solvent solutions of cellulose derivatives are disintegrating to end at low viscosity solutions as a function of time and of solvent power. This seems to make the supposed molecular size and shape of cellulose directly dependent upon a factor of time.

In classifying the various solvents as to their various viscosity effects, those which cause swelling cause higher viscosity.[18]

This known difference of solvent effect makes necessary a choice of solvents in the Staudinger viscosity method for determining weight numbers. No good way is known to bridge the gap between solvent choice and solvent effect except the arbitrary statement that this class of solvent may be used and that one may not be used unless one uses a compensating factor. Such methods of choice simply predetermine the molecular weight numbers to agree with wished-for results. For instance, using the case of styrene polymers in solvents, the reason given by Staudinger for the preferred use of non-polar solvents is that the values obtained from the group of non-polar solvents agree well among themselves yet different values are obtained from the group of polar solvents. We now find that in use of a single solvent those conditions which favor swelling favor high number values for the so-called molecular weights.

Experimental

In the following data, wherever molecular weight methods give variations of over ±5% we shall call the values obtained cybotactic weights. Yet even cybotactic weights may be closely checked at a desired number by proper control of experimental conditions. The ability to check arbitrary number values is the first requisite to their use for analytical control, but the fact that arbitrary values may be checked under arbitrary conditions does not impart an absolute significance to such obtained values. As shown by Table I, some but not all crystalline materials will give constant values.

TABLE I

STANDARDIZATION DATA. MENZIES–WRIGHT METHOD[19]
Concentration limits 0.5 to 1.0%

Substance	Theory	Found High	Found Low	Found Av.	Remarks Solvent acetone
p-Dihydroxydiphenyldimethylmethane	228	231	229	229	Vibrated 60 cycles per sec. $K = 17.2$
p-Hydroxy diphenylmethane	170	172	168	171	$K = 17.2$ Vibrated
Benzidine	184.1	187	177	184	$K = 17.2$ Vibrated
The above results indicate molecular weights.					
Abietic acid (crystalline)	302	400	359	378	$K = 17.2$ Vibrated
% variation		+32	+19	+25	Above theory
From av.		+5.8	−5.0		Range 10.8% for abietic acid indicates cybotaxis

These abietic acid values are thus uncertain and are called cybotactic weights. They may be varied at will as shown later.

A sample, No. 1, of well-washed phenol-formaldehyde fusible resin was held for one hour under 1 mm. vacuum at 240° to free from low boiling solvents, and this was tested for molecular weight effects under the same conditions. The values obtained as shown in Table II are more variable than those for the crystalline abietic acid.

The problem, then, was to find a reason for and control of these fluctuations. There was a suspicion in these data that the way in which the sample was first mixed with the solvent might in-

Sample No. 1	..	1276	1241	1253	Cold

These variations seemed significant, so were applied to other resin determinations and results are illustrated by the data in Table IV.

TABLE IV

CYBOTACTIC WEIGHT VARIATIONS

Sample 4 phenol-formaldehyde fusible resin

	Solvent	High	Low	Av.	Remarks
A	Hot acetone	790	674	743	$K = 17.2$
B	Hot ethyl acetate	820	755	766	$K = 27.9$
C	Hot methyl alcohol	840	810	820	$K = 8.8$
D	Cold acetone, detd. b. p.	1190	1080	1135	$K = 17.2$
E	Cold ethyl ether, detn. hot	..	..	1082	$K = 21.6$
F	Hot ethyl ether	..	..	720	

On Curve 1, the effect of the original solution temperature is seen to persist in determinations of weight numbers made by the Menzies–Wright method at the boiling point of acetone. These determinations were all made after boiling for five minutes in acetone.

In attempting to use quinine sulfate as a standard to determine K for ethyl alcohol, we were able to get checking curves using $K = 11.7$, where the cybotactic values start at 470 and fall when read over five-minute time intervals until 370 is reached, when the values again rise steadily until

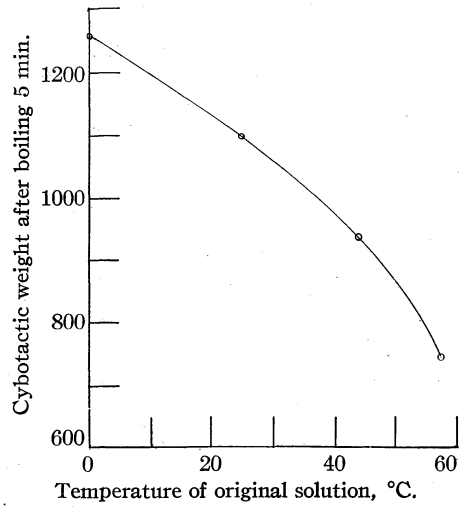

Fig. 1.—Effect of original solution temperature on cybotactic weight determinations by boiling point method. Sample, phenol–formaldehyde fusible resin and solvent acetone; $K = 17.2$.

about four constant readings may be obtained at around 600. The drop and rise cycle is completed in about one hour. Thus even crystalline standards may vary with the time factor of determination.

Curve 2 is a curve of change with time of continued reflux. At first the values drop rapidly, then after a fairly level period begin to rise. At present both the drop and rise in boiling phenomena are considered the result of change in size of the dissolved particles of a supercooled liquid. We have no present reason for attributing the changes to the acetone itself.

This Curve 2 is considered as a composite of three parts. Portion A is a curve of disintegration with time. Portion B is a curve of aggregation or growth with time. Portion C is the numerical resultant of these two factors. The intercept with the weight axis of an extension of B considered as a straight line is about 210 value. This intercept is considered as the more probable molecular weight value from these data. All values above 210 are considered as changing cybotactic weights. On this basis, solution is found as complete after two hundred and fifty minutes of reflux at 56°. In this connection, the data of McBain[17] on the viscosity drop of cellulose nitrate solutions with time of exposure at 55° are of interest.

A Cottrell[20] apparatus was assembled and mo-

(20) Cottrell, THIS JOURNAL, 41, 729 (1919).

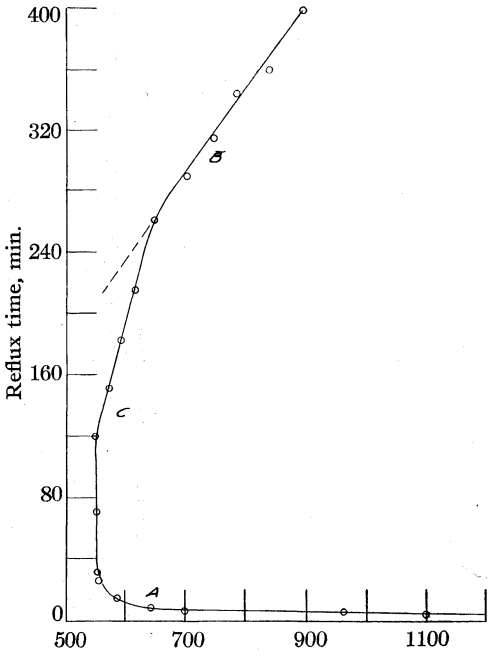

Fig. 2.—Change of weight values with continued reflux time: phenol–formaldehyde fusible resin in acetone, determination made by five-minute boiling periods.

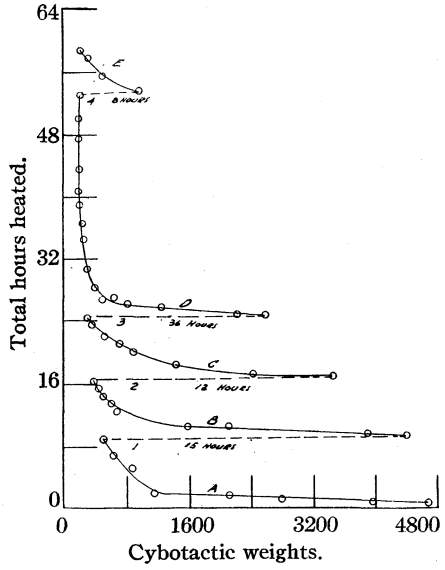

Fig. 3.—Changes in cybotactic weights on heating and on standing cold: Solvent, acetic acid; sample, phenol–formaldehyde fusible resin; K = 30.7. Sections A, B, C, D and E heated at 116° as indicated on scale. Sections 1, 2, 3 and 4 standing cold as marked.

lecular weight determinations made to establish a constant K = 30.7 for acetic acid. The apparatus was then refilled and sample of Novolak resin no. 1 placed therein. It was then closed with drying tubes and all other known precautions to avoid outside influences. Over a hundred readings of the variations of the cybotactic weights under various conditions were taken and are given on the curve. All points off the average curve are indicated.

Curve 3 shows the changes in determined values of one sample in a protected solvent system as a function of both time and temperature with actual reversal in curve direction at some undetermined temperature between the tested points of 25 and 116°. However, the decay rate at the boiling point of acetic acid was sufficiently slow to enable boiling point measurements to be made and rechecked.

Summary

The structural group in resin solutions may be varied so easily that it seems undesirable to designate such shifting particles as chemical molecules. Nor, in fact, should their weight expressions be confused with true chemical molecular weights.

The determined molecular weight numbers of a resin in solvent are shown to be changing quantities with the temporary equilibrium numerical values shifting many fold as conditions change. Any molecular weight number determined for resins is defined as an arbitrary number and considered as a cybotactic particle value, the magnitude of which value is dependent upon the conditions under which the analytical determinations are made. These measurements of what seem to be actual cybotactic particles in the resinous state change slowly in this supercooled liquid condition.

The data obtained are interpreted as in line with the expectations of the cybotactic theory as applied to glassy polymers and are contrary to the expectations of the chain molecular theory of polymeric materials.

Reactions of Beryllium Chloride. Normal and Basic Organic Salts of Beryllium[1]

BY GEO. B. FEILD[2]

Recent work in this Laboratory has led to an improved method for preparing anhydrous beryllium chloride and a study of the reactions of this compound has been undertaken. In the course of an investigation of the catalytic action of anhydrous beryllium chloride[3] in certain types of Friedel–Crafts reactions it was found that organic acid anhydrides react vigorously with this salt to produce beryllium salts of the acid and the corresponding acyl halide.

Anhydrous beryllium chloride also reacts smoothly with various organic acids to yield hydrogen chloride and the normal beryllium salt. Funk and Römer[4] recently have reported the reaction of formic and acetic acids with anhydrous beryllium chloride.

Although there is a fairly extensive literature on the organic salts of beryllium it cannot be reviewed in detail here, but it may be pointed out that previously the various salts have nearly always been prepared by the action of aqueous acid solutions upon beryllium carbonate or hydroxide.[5–9]

The proposed formulas for these salts usually have been calculated from the beryllium content alone. Some investigators have preferred to regard these substances as mixtures or solid solutions of the products of hydrolysis[10] rather than as definite compounds. On the other hand, there are a number of definite organo-beryllium compounds[11–13] to which rational constitutional and even configurational formulas have been assigned. In terms of the newer ideas of valence these compounds, and probably also the so-called basic beryllium salts, are covalent compounds in which beryllium is quadricovalent.[14] For example, the X-ray examination of basic beryllium acetate, presumably $Be_4O(CH_3CO_2)_6$, suggests a tetrahedral distribution of the valence bonds of beryllium.[15]

In view of the situation it was felt that the above methods for preparing the beryllium salts from beryllium chloride should be especially interesting and valuable. The point of greatest importance, aside from the convenience of the procedure, appeared to be the possibility of working in the complete absence of water. This suggested that it might be possible to obtain exclusively the normal salts, since hydrolysis could presumably be avoided. Subsequent experiments confirmed this expectation.

For the preparation of normal salts from organic acids careful preliminary drying is necessary, since only one-fourth mole equivalent of water is sufficient for the complete hydrolysis of the normal to the basic salt.

$$4Be(RCOO)_2 + H_2O = Be_4O(RCOO)_6 + 2RCOOH$$

In a special experiment 5.0 g. of normal beryllium acetate, prepared in the presence of dry benzene, remained as a stable, insoluble solid during prolonged refluxing. When the calculated amount of water (0.035 g.) was added the normal salt rapidly dissolved and the basic acetate crystallized from the mixture on cooling. For this reason it was found necessary to use an all-glass apparatus in which the initial reaction and subsequent purification of the product could be carried out without contamination from cork or rubber connections or from atmospheric moisture. It was also necessary to avoid excessive heating, inasmuch as in earlier experiments attempts to free the normal salt from excess reagents or solvent by heating *in vacuo*, either with a small flame or on an oil-bath, resulted in partial decomposition. The remainder of the product (75–80%) was always the basic salt. It is probable that the decomposition produced enough water to hydrolyze the remaining normal salt.

Using the indicated precautions it was possible to prepare the normal salts from formic, acetic, propionic, benzoic, and *o*-chlorobenzoic acids as well as from acetic, propionic and benzoic anhydrides. The normal salts were all microcrystalline solids, insoluble in benzene and similar solvents, but soluble with decomposition in water, dilute acids and alkalies, and in most polar solvents. The composition was determined by analysis for beryllium, or in some cases by combustion, and agreed closely with the formula $Be(RCOO)_2$.

The pure normal *n*-butyrate was not obtained from either the acid or the anhydride in spite of rigorous drying or various modifications of the procedure. With the latter reagent *n*-butyryl chloride was formed in high yields, as usual, but the crude salt was always waxy or semi-liquid. Unlike the other salts it formed an emulsion with benzene or ligroin, and could neither be crystallized nor completely freed of solvent. Distillation produced partial decomposition and the liquid distillate was identified as the basic salt by its properties and by analysis.

Most of the basic salts were first obtained as by-products during the earlier attempts to prepare the normal salts. When desired they were later prepared by carrying out the reaction with reagents of ordinary grade or by the deliberate introduction of moisture. All of the basic salts were obtained pure except the formate. Addition of the calculated amount of water to the pure normal formate did not cause the usual smooth conversion to the basic salt. However, the normal formate dissolved readily in excess water and the solution then gave a glass on evaporation. The other basic salts, except the butyrate, crystallized from benzene. They are readily soluble in most organic solvents but insoluble in water or dilute acids or alkalies. The solids melted sharply and could be sublimed without serious decomposition. The analyses agreed closely with the formula $Be_4O(RCOO)_6$.

From these results it is believed that previous attempts to prepare normal beryllium salts usually have failed because of the presence of water and that the new methods afford a convenient and reliable process for obtaining either the normal or basic salts, as desired, at least from simple monobasic acids. The results herein reported have been supplemented by small scale reactions of beryllium chloride with numerous other representative monobasic acids of various types. It was noted that all of the reactions followed the usual pattern and the products formed possessed the general properties of the basic beryllium salts. This reaction is therefore probably quite general.

In the latter connection it should be mentioned that beryllium chloride has been observed to react, usually vigorously, with practically every class of organic compounds in which active hydrogen atoms are present. Hydrogen chloride is evolved and the other product as a rule has the general properties of covalent compounds. With the exception of the reactions with acids this behavior of beryllium chloride is not reported in the literature. Although the "solubility" of beryllium chloride in ethyl alcohol and acetone has been reported, no mention is made of the fact that a chemical reaction occurs,[16,17] and no description of the products of these reactions has been given. Apparently the difficulty of obtaining anhydrous beryllium chloride has been partially responsible for the neglect of this promising field. With this reagent now more available a more detailed study of some of these reactions has been undertaken with the hope that they may yield a variety of organo-beryllium compounds not readily accessible by other methods. It is hoped that results of this work will be reported at a later date.

The author wishes to express his indebtedness to Prof. J. M. Breckenridge for direction and to Prof. A. W. Ingersoll for advice.

Experimental

Preparation of Beryllium Chloride.—Beryllium chloride is perhaps most easily prepared by heating the beryllium oxide in a stream of phosgene,[18] but the handling of this latter reagent involves numerous difficulties and hazards. An improvement of the method of Rose[19] was therefore used. This involves heating beryllium oxide with carbon in a stream of chlorine. Since adequate directions for this method of preparing beryllium chloride could not be found in the literature, the improved method may be described in some detail.

Beryllium oxide was prepared from the nitrate (Pfaltz and Bauer, Inc.) by precipitation of the hydroxide with ammonium hydroxide and ignition. This was then mixed with carbon as follows. Five hundred grams of sucrose and 50 g. of the oxide, previously ground to 200-mesh, were heated with stirring in a large evaporating dish until a viscous sirup was obtained. This was then ignited

and allowed to burn without further application of heat. By this means practically all volatile matter was burned off, leaving a very intimate but porous mixture of the oxide and carbon. This was crushed with care to avoid forming much fine powder.

One-third of the oxide–carbon mixture (about 16.7 g. of BeO) was then poured, without packing, into the 500-cc. Pyrex glass reaction chamber (B) of the apparatus shown in Fig. 1. The lower arm of the reaction chamber was previously closed by a loose plug of glass wool near the bulb. The train was then disconnected at the ground-glass joint (K) and the opening into the 1-liter flask (C) temporarily closed with a stopper to prevent the entrance of moisture. To facilitate connection or disconnection at K without disturbance of other connections, the entire train to the right of K was mounted on rollers. Parts of the apparatus rested upon rubber mats (G) to minimize strains. The electric furnace (J) was then slowly heated and the burners under the preheater (A) were lighted. A slow stream of nitrogen was passed through the reaction chamber and continued until the apparatus and charge were thoroughly dried. Toward the end of this process the burner at K was lighted to expel moisture at that point. The heating was so adjusted that when the apparatus was free from moisture the temperature in the preheater and furnace was about 550° or just below the softening point of Pyrex glass. This temperature was then maintained.

The movable part of the train was connected at K and the passage of chlorine, mixed with about an equal volume of nitrogen, was begun. The nitrogen was necessary to offset the decrease in volume that accompanies the reaction and to assist in removing the beryllium chloride from the reaction zone. The use of additional chlorine for this purpose is wasteful and the exit gas is objectionable from the standpoint of disposal. It also should be explained that preheating the gases permitted running the reaction at about 550°. Without preheating, a furnace temperature of about 650–700° was necessary. Use of the preheater therefore made it possible to construct the entire apparatus from Pyrex glass and thus minimize breakage due to uneven expansion of joints. The preheater was loosely filled with broken plate or Pyrex chips and was shielded by a gauze or iron pipe.

At the indicated temperature the reaction occurred readily and the beryllium chloride passed from the reactor as a smoke. The greater part settled in the exit tube and flask C. The tube was heated intermittently at K and sometimes at C and D to prevent clogging. When the stream of nitrogen was properly adjusted, about 95% of the product collected in C, about 4% in D and the greater portion of the remainder in E. Some smoke passed into the trap but the loss was found to be negligible. A charge of the size indicated could be run in about eighteen hours (two nine-hour periods) without significant loss, or in a much shorter time if some loss were permitted or more collection chambers were used. The product collecting in C could be transferred to F and removed occasionally. For this purpose C was heated gently with a large soft flame while being shielded from drafts. The product collecting in D and beyond was usually allowed to accumulate during several runs. The product was transferred and stored with minimum exposure to air.

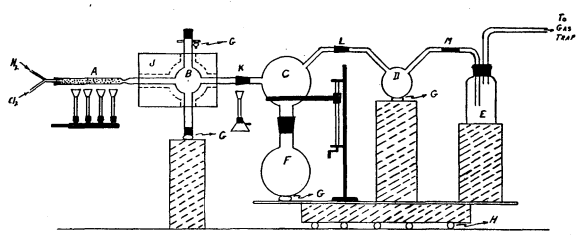

Fig. 1.

The yield of beryllium chloride was 32–37 g. in various runs. Based on the oxide taken, this is 60–70% conversion. The remaining oxide probably escaped conversion because of the removal of all carbon in direct contact with it. The spent charge was removed by withdrawing the glass wool plug from the lower limb of the reaction chamber and was then ignited to recover the oxide. This appeared to contain some non-volatile oxychlorides but was quite suitable for use in preparing another charge. In a series of runs the conversion of the oxide to the chloride was therefore practically quantitative.

In a series of preliminary experiments attempts were made to prepare beryllium chloride from the mixture of iron, aluminum and beryllium oxides obtained from beryl. Although the sublimation points of the corresponding chlorides are reported as 177.8, 315 and 475°, respectively, no appreciable separation could be effected by fractional sublimation. For this reason, commercial beryllium salts as well as the oxide, were unsuitable for the present work.

Preparation of Organic Salts. (a) **Materials.**—The anhydrides were purified by distilling C. P. reagents and collecting the appropriate fraction. Formic acid was prepared by treating the 99% material with phosphorus pentoxide and distillation, with rejection of the forerun. The liquid acids were refluxed with a small amount of the corresponding anhydrides and distilled. The solid acids were recrystallized and dried in a desiccator. Benzene, toluene and ligroin were dried with magnesium perchlorate and distilled.

(b) **Procedure.**—This already has been outlined briefly. In the preparation of normal salts by the use of organic acids, an all-glass apparatus constructed as follows was used. A 250-cc. round-bottomed flask was fitted with a separatory funnel and a side-arm distilling column. A water jacket was fitted into the distilling column, thus enabling refluxing or distillation at will without dismantling. All connections were made by means of ground glass joints. A weighed quantity of the powdered chloride was placed in the flask. The equivalent amount or a slight excess of the acid dissolved in about 5 parts of dry benzene or toluene was then admitted through the separatory funnel. When the initial reaction subsided the mixture was refluxed gently for about one hour, and was then distilled on a water-bath. A little fresh diluent was admitted and the distillation repeated. Analysis of the distillate accounted for approximately the theoretical amount of hydrogen chloride. The residual salt was washed repeatedly with dry benzene and ligroin (b. p. 30–60°), filtered by suction and dried *in vacuo* at room temperature or on a steam-bath. This procedure removed any excess acid and any

basic salt. The normal salts were stable during brief exposure to moist air, but on prolonged exposure gave the odor of the corresponding acid and changed to the basic salt.

A similar procedure was used with acid anhydrides, except that the volatile acyl chlorides distilled with the benzene or toluene while benzoyl chloride was recovered from the filtered washings. In semi-quantitative experiments the acyl halides were isolated in 60–80% yields by fractional distillation and were identified by their boiling points or by conversion to anilides.

Reactions were also carried out with a large excess of the liquid acids or anhydrides in the absence of benzene but the procedure was less satisfactory because of the difficulty of removing the excess reagent.

Most of the basic salts were first prepared as by-products in preliminary experiments in which anhydrous conditions were not maintained. Alternatively, the procedure for forming the normal salts was followed and then moist benzene was added. The mixture was refluxed until the product dissolved. The hot filtered solution deposited the basic salt on cooling. Basic beryllium acetate could also be crystallized from acetic acid.

(c) **Analyses.**—The salts were dissolved in hot, concentrated nitric acid. For the basic salts it usually was necessary to reflux for a few minutes to complete the decomposition and in this case care was taken that none of the material was lost by volatilization. The solution was then diluted and the beryllium was precipitated as hydroxide with excess ammonium hydroxide and ignited to the oxide. In the case of the benzoates and *o*-chlorobenzoates the partially nitrated acid appeared on dilution but dissolved in an excess of ammonia. Although calculated values of BeO were obtained in this way, these analyses were also confirmed in some cases by combustion, using the method of Fieser.[20] The properties and analyses are recorded in the table.

Summary

1. A convenient procedure for the preparation of anhydrous beryllium chloride is described.

2. A new method is described for the preparation of beryllium salts by means of the reactions of anhydrous beryllium chloride with organic acids or acid anhydrides.

3. Normal beryllium formate, acetate, propionate, benzoate, and *o*-chlorobenzoate and also basic beryllium acetate, propionate, *n*-butyrate, benzoate and *o*-chlorobenzoate were prepared and analyzed.

Hydrogen Fluoride as a Condensing Agent. VIII.[1] The Alkylation of Benzene by Esters

BY J. H. SIMONS, S. ARCHER AND D. I. RANDALL

The alkylation of aromatic compounds by esters recently has been reported by Kane and Lowy,[2] by Bowden,[3] who used aluminum chloride, and by McKenna and Sowa,[4] who employed boron trifluoride as the condensing agent.

In this communication it is shown that in the presence of hydrogen fluoride esters react with benzene to produce mainly alkylbenzenes. The reaction may be represented by the equation

$$RCOOR' + C_6H_6 = RCOOH + C_6H_5R''$$

where R'' may be the same as R' or a rearranged form thereof. As it has been found[1] that acids can acylate aromatic compounds in the presence of hydrogen fluoride, the presence of ketones in the reaction products would be expected from a reaction of the liberated acid with either benzene or the alkylbenzene present. This actually proved to be the case, as in a number of experiments ketones were isolated in sufficient quantities to permit characterization. Bowden[3] in his study of this type of reaction using aluminum chloride, did not isolate any carbonyl compounds although he made a special effort to do so.

McKenna and Sowa[4] postulated that this type of alkylation proceeded through two stages, first, the formation of an olefin and an acid from the ester and second, the reaction of the olefin with benzene to give the alkylated benzene. An alternative mechanism, which they rejected, involved a metathesis between the ester and the aromatic compound. Rejection was based on the fact that esters of straight chain alcohols do not give normal alkylbenzenes. There is, however, another mechanism by which this reaction can occur. Hydrogen fluoride is an extremely powerful ionizing solvent. The ester may ionize to produce a positive alkyl ion and a negative acyl ion. This reaction would be assisted by the strong acid properties of the solvent, which would neutralize the acyl ion to form the carboxylic acid which in turn would further react with the solvent.[5] As the charge on the alkyl ion probably would not be localized, reaction would occur with the carbon atom which would result in the greatest reduction of free energy. A rearranged product could be formed.

$$RCO_2R' + HF = RCO_2H_2^+ + R'^+ + 2F^-$$

The fact that benzyl acetate will react with benzene to give, in the presence of hydrogen fluoride, diphenylmethane in yields of 75% of the theoretical seems to be strong evidence supporting the ionic rather than the olefin mechanism.

In accordance with the observations of previous investigators it was found that *n*-butyl acetate and *s*-butyl isobutyrate gave *s*-butylbenzene, isopropyl acetate gave isopropylbenzene, and *t*-butyl and benzyl acetates gave the corresponding alkylbenzenes.

Experimental

TABLE I

In every case one-third mole of ester and 400 cc. benzene were used. All boiling points are at 742 mm. unless otherwise noted.

Ester	G. HF	Time, hrs.	Product[6] % yield	Name	B. p., °C.	n^{20}
t-Butyl acetate	89	16	71	*t*-Butylbenzene	170–171	1.4921
t-Butyl acetate	169	16	73	*t*-Butylbenzene	72 at 32 mm.	1.4923
Isopropyl acetate	165	17	53	Isopropylbenzene	149–150	1.4911
n-Butyl acetate	180	17	60	*s*-Butylbenzene	170.5–171	1.4902
s-Butyl isobutyrate	90	17	56	*s*-Butylbenzene	170–171	1.4901
Benzyl acetate	70	15	75	Diphenylmethane	259–261	

The reactions were carried out in a copper bomb at steam-bath temperature in a manner reported previously.[1] All the acetates except *t*-butyl were made from the alcohol, acetic anhydride, and sodium acetate. *t*-Butyl acetate

(5) Simons, *Chem. Rev.*, **8**, 213 (1931).

(6) The physical constants checked closely those reported in the summary by Ward and Kurtz, *Ind. Eng. Chem., Anal. Ed.*, **10**, 559 (1938).

was prepared according to the method of Norris and Rigby.[7] *s*-Butyl isobutyrate was made from the proper alcohol and acid using sulfuric acid as catalyst. The boiling points of the esters were *t*-butyl acetate 109–110°, isopropyl acetate 86–87°, *n*-butyl acetate 123.5–124°, *s*-butyl isobutyrate 141–142°, all at 734 mm., and benzyl acetate 105–105.5° (18 mm.).

The reaction of *t*-butyl acetate in which 169 g. of HF was used gave 3 g. of acetophenone, identified by means of its semicarbazone. The melting point was 198–199°, and when mixed with a known sample gave a melting point of 197–199°. Isopropyl acetate gave 4 g. of acetophenone, m. p. and mixed m. p. of the semicarbazone was 197–199°. A higher boiling ketonic fraction weighing 5 g. was also obtained. Its oxime melted at 68–69.5°. Widman[8] reports the melting point of *p*-isopropyl acetophenone oxime as 70–71°. When treated with semicarbazide in the usual manner a crystalline solid, m. p. 197°, was obtained. When mixed with acetophenone semicarbazone the m. p. was 169–175°.

Some higher boiling fractions were obtained in other experiments, but in quantities too small to permit positive identification.

To prove that the alkylbenzene obtained from *n*-butyl acetate and *s*-butyl isobutyrate was in both cases *s*-butylbenzene a diacetamino derivative was prepared. That of the *n*-butyl acetate melted at 188–189° and when mixed with the same derivative of the latter compound did not depress in melting point.

(8) Widman, *Ber.*, **21**, 2226 (1888).

Summary

Hydrogen fluoride has been found to be an effective agent to alkylate benzene by means of esters. Reactions were carried out in a copper bomb at 80 to 100°. *t*-Butylbenzene, isopropylbenzene, and diphenylmethane were made from benzene and the acetates. *n*-Butyl acetate and *s*-butyl isobutyrate both gave secondary butylbenzene. Ketones also were formed in the reactions. Acetophenone was identified from those reactions in which acetates were used.

The Isolation of Keturonic Acids as Crystalline Alkaloidal Salts[1]

BY J. P. HART AND M. R. EVERETT

In studies of the bromine oxidation of dilute solutions of more than 50 carbohydrates, Everett and Sheppard[2] have demonstrated the accumulation of keturonic acids. They found the yields of these substances to be related to the *cis–trans* structures of the original carbohydrates. Structural studies of the keturonic acids required their isolation in pure form. We are now reporting the isolation of alkaloidal salts of several keturonic acids, and the structures indicated by the properties of these salts. In order to avoid confusion the authors have named the keturonic acids as ketose derivatives.[3] Individual acids are differentiated by numbering the carboxyl carbon, the terminal carbon nearest the potential carbonyl being called one.[4]

Calcium *l*-sorbo-6-uronate has been isolated previously from *d*-glucose and *d*-gluconic lactone solutions oxidized by bromine,[5,6] and has been shown to be identical in properties with the calcium salts of Boutroux[7] and Kiliani.[8]

[a] All melting points uncorrected with short stem thermometers. [b] M. p. two samples mixed 174–175° (dec.). [c] A dihydrate, m. p. 182° (dec.), obtained by recrystallization from 80% alcohol. [d] M. p. of two samples mixed 165–166°.

The authors have prepared the crystalline brucine salt of *l*-sorbo-6-uronic acid by decomposition of the pure calcium salt. They have found it to be identical in all of its properties with the brucine salt prepared from *d*-glucose solutions oxidized by bromine for forty-two days. Ultimate analyses of the reducing brucine salts isolated from similarly oxidized solutions of *d*-mannose, *d*-gulonic lactone, and *d*-galactose show that these compounds were all salts of hexuronic acids (Table I). The stability of these acids in bromine water, compared with the rapid oxidation of alduronic acids by bromine,[9] indicates that they have ketose structures. The naphthoresorcinol, orcinol, and Molisch tests for the principal reducing brucine salts isolated from oxidized solutions of the four aldohexoses (Table II) are characteristic and identical. This implies by analogy structures stereoisomeric with *l*-sorbo-6-uronic acid, but proof of structure is to be the subject of further investigations. Melting points, optical rotations, and Sumner reducing equivalents show each compound to be pure and unique (see Tables I and III). These findings verify the conclusions of Everett and Sheppard[2,10] based on quantitative studies of oxidized hexose solutions. The position of the carbonyl in the keturonic acid isolated from the oxidized solutions of *d*-xylose is undetermined. Ultimate analysis and the stability of this acid in the presence of bromine establish it as a ketopenturonic acid.

1-Desoxy-*l*-fructo-6-uronate	−32°	.37	1.21

[a] For 1% aqueous solution. [b] For 2 mg. per ml. concentrations of the salts.

Oxidation of *l*-rhamnose for twenty-one days produces two keturonic acids, 1-desoxy-*l*-fructo-6-uronic acid and *l*-fructo-6-uronic acid, which have been isolated and separated by fractional crystallization of their brucine salts. The lactone of the desoxyketuronic acid has been isolated by Votoček and Malachta.[11] An identical brucine salt of *l*-fructo-6-uronic acid has been isolated from oxidized solutions of *d*-gulonic lactone. This acid evidently arises from oxidation of the methyl group of *l*-rhamnose, *l*-rhamnonic acid or 1-desoxy-*l*-fructo-6-uronic acid to a primary alcoholic group, an unusual reaction, previously unrecognized.

Experimental

Oxidation of Carbohydrate Solutions.—One per cent. carbohydrate solutions were oxidized with bromine for forty-two days, using the procedure of Everett and Sheppard.[2,9] Four hundred ml. of a 1% aqueous solution of each carbohydrate was placed in a glass-stoppered bottle. Fifteen ml. of bromine was then added and the mixture kept in the dark at approximately 25°. The solution was shaken at two to three day intervals, and more bromine was added whenever the liquid phase disappeared during the oxidation. After forty-two days the solution was aerated with washed air.

General Method for Isolation of Mixed Barium Salts.—The aerated oxidized carbohydrate solution was shaken with an excess of lead carbonate, filtered, allowed to remain in the refrigerator at 10° for twenty-four hours, and filtered again. The remaining bromide ion was removed by shaking with moist freshly prepared silver carbonate, centrifuging, decanting and immediately saturating the solution with hydrogen sulfide. The precipitated lead and silver sulfides were filtered off, and the filtrate aerated to remove excess hydrogen sulfide. This treatment removed most of the dibasic sugar acids present in the oxidized solutions.[2,6] Analysis by the Sumner method showed little loss of reducing material. The solution was then treated with an excess of barium carbonate at 40 to 45° for two hours. The filtrate was concentrated *in vacuo* to one-twelfth volume, and the barium salts were precipitated by addition of 8 volumes of alcohol. The salts were allowed to settle, filtered with suction, and washed twice with alcohol and twice with ether. They were dried in a desiccator and the barium content determined gravimetrically. Yields of barium salts obtained from 4 g. of original carbohydrates were as follows: *d*-glucose, 3.9 g.; *d*-mannose, 3.0 g.; *d*-gulonic lactone, 3.1 g.; *d*-galactose, 2.0 g.; and *d*-xylose, 4.1 g.

General Method of Preparing Solutions of Brucine Salts.—Weighed portions of the mixed barium salts were dissolved in two to three times their weight of water, and the barium was removed quantitatively by addition of the calculated quantities of *N* sulfuric acid. Enough alcohol was then added to produce a 70% solution. The mixture was placed in the refrigerator for fifteen minutes, then centrifuged free of barium sulfate and the calculated quantity of 10% alcoholic brucine solution was added.

Brucine *l*-Sorbo-6-uronate.—A solution of brucine salts was prepared from 2.5 g. of the mixed barium salts obtained from oxidized *d*-glucose. Crystallization began in fifteen minutes and apparently was complete after eighteen hours in the refrigerator. The brucine salt was filtered off, washed three times with alcohol and once with ether, and dried in a desiccator. The 2.2 g. yield was recrystallized from a small quantity of hot water, from which it separated as the monohydrate on cooling. It also was obtained as the dihydrate by dissolving in the least amount of hot water, adding 5 volumes of alcohol and allowing to crystallize in the refrigerator.

The same salt was prepared by decomposing a suspension of calcium *l*-sorbo-6-uronate in dioxane with the calculated quantity of sulfuric acid. After removal of calcium sulfate the dioxane was removed *in vacuo*, and the sirupy acid dissolved in a little water. After addition of an equivalent quantity of alcoholic brucine solution, the salt was crystallized as above.

Brucine *d*-Fructo-6-uronate.—A solution of this salt was prepared from 1 g. of the mixed barium salts from oxidized *d*-mannose. Crystallization started during slow concentration of the solution *in vacuo*. The mixture was then placed in a desiccator in the refrigerator, and the small fraction of crystalline material that separated in two hours was discarded. The mother liquors gave a second crop (0.3 g.) of crystals of the desired salt within twenty-four hours. This material was recrystallized by dissolving in a little hot water and adding 5 volumes of methyl alcohol.

Brucine *l*-Fructo-6-uronate.—A solution of this salt was prepared from 2 g. of the mixed barium salts from oxidized *d*-gulonic lactone. The solution was concentrated *in vacuo* until crystals began to form, and was then placed in a desiccator in the refrigerator. After twelve hours 0.58 g. of the salt was obtained. It was recrystallized by dissolving in hot water and adding 4 volumes of alcohol.

Brucine *l*-Tagato-6-uronate.—A solution of the salt was prepared from 4 g. of the mixed barium salts from oxidized *d*-galactose. In this preparation methyl alcohol was substituted for ethyl alcohol. The solution was concentrated to 30 ml. *in vacuo* and placed in a desiccator in the refrigerator. After twelve hours a small fraction of non-reducing salt was filtered off. A large fraction of a second non-reducing salt was separated in three days. After one week a third fraction of crystals appeared. It contained the reducing salt, which was purified by dissolving in a small quantity of hot water, adding 8 volumes of alcohol and allowing to crystallize in the refrigerator. The yield of recrystallized salt was 0.52 g.

Brucine *d*-Xyloketuronate.—A solution of brucine salts was prepared from 1 g. of the mixed barium salts from oxidized *d*-xylose. The solution was concentrated to one-half volume *in vacuo* and then placed in a desiccator in the refrigerator. With occasional scratching, 0.2 g. of crystalline material separated in twelve hours. The salt was recrystallized by dissolving in a small quantity of hot water and adding 5 volumes of alcohol.

Brucine 1-Desoxy-*l*-fructo-6-uronate.—The mixed barium salts from *l*-rhamnose solution, that had been oxidized twenty-one days, were obtained as a viscous gum. The product from 4 g. of *l*-rhamnose was dissolved in 50 ml. of water, and an aliquot was analyzed for barium. The barium was removed with an equivalent amount of sulfuric acid, and the solution was concentrated to 20 ml. The calculated quantity of brucine was dissolved in 30 ml. of alcohol and added to the solution. The latter slowly was concentrated *in vacuo* until crystals appeared. The solution was then placed in a desiccator in the refrigerator for twenty-four hours. The yield was 1.1 g. of the brucine salt of *l*-fructo-6-uronic acid. After another twenty-four hours the mother liquor deposited 4.1 g. of brucine 1-desoxy-*l*-fructo-6-uronate. This salt was recrystallized by dissolving in a small volume of hot water, adding 6 volumes of alcohol, and placing in the refrigerator for three days.

Summary

1. Six keturonic acids have been isolated as crystalline brucine salts.

2. Brucine *d*-fructo-6-uronate, *l*-fructo-6-uronate, *l*-tagato-6-uronate, and *d*-xyloketuronate are the first pure preparations of these acids described.

3. Isolation of *l*-fructo-6-uronic acid from oxidized *l*-rhamnose solution demonstrates that the methyl group is susceptible to controlled oxidation.

Reaction of Propene with Isoolefins in the Presence of Sulfuric Acid

BY V. N. IPATIEFF, HERMAN PINES AND B. S. FRIEDMAN

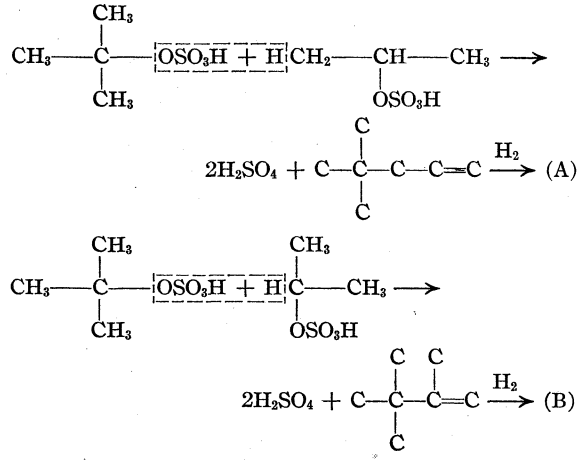
It was previously[1] shown that under the influence of sulfuric acid aliphatic olefins containing four or more carbon atoms undergo conjunct polymerization yielding, in addition to polymeric olefins, paraffinic and cyclic hydrocarbons. The predominance of the one or other type of hydrocarbon depends greatly upon the concentration and amount of sulfuric acid used.

Propene was found to be more resistant to polymerization for when contacted under atmospheric pressure with 96% sulfuric acid at 0 and 25°, it yielded chiefly isopropyl sulfates and only negligible amounts of hydrocarbons. The addition of cupric sulfate or mercuric sulfate to the sulfuric acid did not promote the polymerization of propene.[2]

However, when mixed with more reactive olefins such as isobutene or isopentenes and then contacted with sulfuric acid, the propene reacted with the other olefins to yield among other products heptenes and octenes, respectively. No hydrocarbons corresponding to the dimer or trimer of propene were found in the reaction product. With straight chain olefins such as *n*-butene scarcely any of the propene reacted to form liquid hydrocarbons when contacted with concentrated sulfuric acid.

The amount of heptenes formed from the reaction of isobutene with propene varied from 8 to 35% (based on the liquid hydrocarbons produced) and was dependent on the concentration of the acid, temperature, and mode of addition of the olefins. The reaction of isopentenes with propene yielded hydrocarbons of which 16% were octenes and 17% tridecenes.

The combined lower boiling fractions of a number of isobutene–propene experiments were hydrogenated and then distilled through a 100-plate bubble cap still.[3] Fractions amounting to 45% of the heptanes present were identified by physical properties and Raman spectra analysis as 2,2-dimethylpentane (A) and 5% as 2,2,3-trimethylbutane (B); another fraction (15% of the heptanes) consisted of 2,3-dimethylpentane (C). (A) and (B) possess the carbon skeletons expected of primary polymers



but (C) probably results from a rearrangement of the 2,2-dimethylpentenes and/or 2,2,3-trimethylbutene under the influence of the sulfuric acid. Similar carbon skeleton isomerizations in the presence of acid catalysts have been observed by others.[4]

Several experiments were made in which the propene–isoolefin mixture was treated with isopropyl esters prepared by combining one mole of propene with one mole of 96% sulfuric acid. The proportion of propene which reacted with isoolefins was greater than in the case when sulfuric acid alone was used as a catalyst.

Experimental

Apparatus and Procedure.—The apparatus used for reactions at ordinary pressure was essentially the same as that described for previous experiments.[1] When higher temperatures and pressures were employed, a stainless steel stirring autoclave equipped with a copper liner was used. The sulfuric acid or its esters was placed in the reaction flask or in the autoclave and the olefin mixture passed into the rapidly stirred catalysts through an inlet tube. During the addition of the olefins the temperature was controlled by surrounding the reaction flask or chamber by an ice-bath or water-bath. The time required for the addition of the hydrocarbons varied from two to seven hours.

After being allowed to stand overnight at room temperature the two layers of the reaction product were separated.

5[a]	0–17	273[b]	375	573[h]	396	711	64	53	16% C_8 range
									17% C_{13} range

[a] Total of three experiments. [b] 96% sulfuric acid. [c] Total of two experiments. [d] Monoisopropyl sulfate used; it was prepared by the addition of 2.74 moles of propene to 2.67 moles of 96% sulfuric acid. [e] 64% sulfuric acid. [f] Maximum pressure 191 lb./sq. in. [g] Maximum pressure 180 lb./sq. in. [h] Isopentenes used.

The hydrocarbon layer was steam-distilled from over alkali, dried, and distilled from over sodium. The sulfuric acid layer was decomposed with water, rendered alkaline with sodium hydroxide, and subjected to steam distillation. The distillate so obtained was saturated with potassium carbonate to complete the separation of the alcohols. The latter were dried and distilled.

Material non-volatile with steam was not analyzed; the nature and constitution of these high boiling fractions have been discussed in an earlier work.[1] The experimental conditions are given in Table I.

Isobutene–Propene Mixed Polymerization

Hydrocarbon Layer.—From the hydrocarbon product of the mixed polymerization of isobutene and propene there was obtained material boiling 75.2 to 78.6°; d^{20}_4 0.689. *Anal.* Calcd. for C_7H_{14}: C, 85.62; H, 14.38; mol. wt., 98. Found: C, 85.60; H, 14.45; mol. wt., 97.

The presence of a *t*-butyl group in the heptene was shown by the method of depolyalkylation.[5a] Fifteen cc. of the heptenes was dissolved in 19 g. of *t*-butylbenzene and the mixture was shaken with 10 cc. of 96% sulfuric acid at 0°. The hydrocarbon was then separated from the sulfuric acid, washed with alkali and water, and distilled. The fraction boiling 238–250° contained crystals of *p*-di-*t*-butylbenzene.

The combined lower boiling fractions of runs 1 and 2 were hydrogenated at 60° in the presence of nickel catalyst[5b] and hydrogen, 100 kg./cm.² initial pressure. From the resulting paraffins the following fractions were separated by distillation through a 100-plate[3] column.

Fraction	Cc.	B. p., °C. 750 mm.	$n^{20}D$	d^{20}_4
1–3	29	69–77		
4	63	77–78	1.3838	0.6764
5	61	78–78.8	1.3830	.6738
6–10	59	78.8–88		
11	41	88–90.4	1.3928	.6960
		Literature Data		
2,2-Dimethylpentane[6]		78.9 (760)	1.38233	0.6737
2,2,3-Trimethylbutane[6]		80.9 (760)	1.38940	.6900[7]
2,3-Dimethylpentane[6]		89.7 (760)	1.39201	.6952

(5) (a) Ipatieff and Pines, THIS JOURNAL, **58**, 1056 (1936); (b) Ipatieff and Corson, *Ind. Eng. Chem.*, **30**, 1039 (1938).

(6) Edgar and Calingaert, THIS JOURNAL, **51**, 1540 (1929); Edgar, Calingaert and Marker, *ibid.*, **51**, 1483 (1929).

(7) Levene and Marker, *J. Biol. Chem.*, **91**, 77 (1931).

Raman Spectrum Analysis.[8]—Fractions 4 and 5 consisted of 90–95% 2,2-dimethylpentane, and 5–10% of 2,2,3-trimethylbutane. Fraction 11 consisted solely of 2,3-dimethylpentane.

Sulfuric Acid Layer.—The alcohols obtained from the sulfuric acid layer by the method described above were fractionated in a precision still. The following fractions were separated: (1) 79.4–80.0°, 78%, $n^{20}D$ 1.3782; (2) 80–84°, 17.5%, $n^{20}D$ 1.3785.

In order to determine whether *t*-butyl or isopropyl alcohol was produced, the entire product was dehydrated over alumina at 300°.[9] By distillation on a low temperature Podbielniak distilling apparatus and by sulfuric acid absorption it was determined that the olefins formed consisted of pure propene.

Isopentene–Propene Mixed Polymerization

Hydrocarbon Layer.—Sixteen per cent. of the hydrocarbons consisted of octenes, b. p. 96–125°. The fraction boiling 100–116°, $n^{20}D$ 1.4174–1.4203, was hydrogenated at 100° (initial hydrogen pressure of 100 kg./sq. cm.) in the presence of a nickel catalyst. The hydrogenated product distilled between 112 and 116°; $n^{20}D$ 1.4033–1.4042; d^{20}_4 0.7168. *Anal.* Calcd. for C_8H_{18}: C, 84.10; H, 15.90; mol. wt., 114. Found: C, 83.95; H, 16.00; mol. wt., 113.

Sulfuric Acid Layer.—From the acid layer there was isolated an alcohol identified as isopropyl alcohol, b. p. 79–82°, $n^{20}D$ 1.3779–1.3782; 3,5-dinitrobenzoate, m. p. 121.5–122.[10]

Summary

Sulfuric acid catalyzed the reaction between propene–isobutene and propene–isopentenes to yield among other products heptenes and octenes, respectively. The hydrogenated heptenes contained 2,2-dimethylpentane, 2,3-dimethylpentane and some 2,2,3-trimethylbutane. These heptanes were identified by physical constants and Raman spectra analysis.

Propene alone under similar conditions does not undergo polymerization.

Tritylation Experiments in the Sugar Alcohol Series

BY M. L. WOLFROM, W. J. BURKE AND S. W. WAISBROT

For the purposes of another problem under investigation in this Laboratory, we were interested in the tritylation,[1] by the Helferich procedure,[2] of sugar alcohols of the five and six carbon atom series. By this general reaction of tritylation, followed by acetylation and detritylation, the 2,3,4,-5-tetraacetate[3] and 2,3,4,5-tetrabenzoate[4] of *d*-mannitol have been prepared previously. We were able to obtain a monotrityl ether of mannitol as its crystalline pentaacetate by treating an excess of mannitol with trityl chloride. This derivative is of interest because the two terminal positions of mannitol are chemically equivalent.

The methylpentitols offer the interesting case of presenting only one primary hydroxyl group to react with the tritylation reagent and accordingly the 2,3,4,5-tetraacetate of *l*-fucitol was synthesized. The detritylation of trityl-*l*-fucitol tetraacetate presented some difficulty as the Helferich detritylation procedure using hydrogen bromide in glacial acetic acid resulted in the formation of the bromide rather than the free hydroxyl group. This type of behavior was reported previously from this Laboratory[5] with acyclic derivatives of glucose and galactose. To avoid this bromine replacement, detritylation of this substance was effected with hot dilute acetic acid according to the procedure of Kuhn and co-workers.[6] Retritylation of the fucitol tetraacetate produced the original trityl-*l*-fucitol tetraacetate and treatment of the tetraacetate with hydrogen bromide yielded the same bromide tetraacetate that was obtained on detritylation by the Helferich procedure. The pentaacetate of *l*-fucitol was also synthesized in crystalline form. In the pentitol series, we have also obtained ditrityl-xylitol triacetate.

The tritylation of dulcitol presents an interesting case. Valentin[7] reports that dulcitol does not form a trityl compound when treated with a pyridine solution of trityl chloride. We found that a ditrityl compound was formed but that it separated from the reaction mixture as a dipyridinium hydrochloride addition compound. The acidity of this addition compound was sufficient to detritylate the dulcitol when the compound was recrystallized from hot ethanol. The dipyridinium compound was decomposed readily by bases without detritylation and in this manner ditrityl dulcitol was obtained. Ditrityl dulcitol crystallizes from ethanol with one mole of alcohol of crystallization. This behavior of ditrityl dulcitol with pyridine hydrochloride is reminiscent of the behavior of *d*-sorbitol with pyridine, wherein a readily crystallizable pyridine compound is formed.[8]

Acetylation of ditrityl dulcitol yielded the ditrityl dulcitol tetraacetate, from which 1,6-dibromodulcitol tetraacetate was obtained on detritylation with hydrogen bromide in glacial acetic acid. Ditrityl dulcitol formed a dibenzylidene compound without detritylation. In preparing this substance we removed the excess of benzaldehyde by allowing it to oxidize in the air to benzoic acid and removing the latter with a mild alkali.

Experimental

1-Trityl *l*-Fucitol Tetraacetate.—*l*-Fucitol (1.5 g., 1 mol) and 2.6 g. (1 mol) of trityl chloride were dissolved in 20 cc. of warm, dry pyridine and kept at 60° for two days. To the cooled solution was added 18 cc. of acetic anhydride and the solution kept at 45° for twenty-four hours. The product crystallized from the reaction mixture and was recrystallized from ethanol: yield 2.4 g., m. p. 152°, spec. rot. −18° (30°, *c* 1.9, $CHCl_3$).[9] A further quantity of the substance (0.6 g.) was obtained by pouring the pyridine mother liquor into ice and water.

Anal. Calcd. for $C_6H_9O_5(COCH_3)_4C(C_6H_5)_3$: $C(C_6H_5)_3$, 42.2; CH_3CO, 6.94 cc. 0.1 *N* NaOH per 100 mg. Found: $C(C_6H_5)_3$ (7), 41.9; CH_3CO, 6.89 cc.

The same product was obtained on acetylation of the trityl-*l*-fucitol of Valentin.[7]

1-Bromo-*l*-fucitol Tetraacetate.—To a solution of 2.5 g. (1 mol) of 1-trityl-*l*-fucitol tetraacetate in 10 cc. of glacial acetic acid was added 2 cc. of a glacial acetic acid solution of hydrogen bromide (4 mols). The precipitated

(1) Trityl = triphenylmethyl.

(9) All specific rotations are recorded to the D-line of sodium light; 30° is the temperature; *c* is the concentration in g. per 100 cc. of soln., the chloroform used was U. S. P. (United States Pharmacopoeia). All substances were recrystallized to constant rotation and melting point.

trityl bromide was removed by filtration and the filtrate was poured into ice and water. The crystalline precipitate was removed by filtration and recrystallized from ethanol; yield 0.9 g., m. p. 142–143°; spec. rot. −9.8° (22°, *c* 1.76, $CHCl_3$).

The compound was readily soluble in glacial acetic acid, chloroform, acetone and hot ethanol. It was practically insoluble in water and petroleum ether.

Anal. Calcd. for $C_6H_9O_4(COCH_3)_4Br$: CH_3CO, 10.1 cc. 0.1 *N* NaOH per 100 mg.; Br, 20.1. Found: CH_3CO (Freudenberg method[10]), 10.1 cc.; Br, 20.4.

l-Fucitol 2,3,4,5-Tetraacetate.—1-Trityl *l*-fucitol tetraacetate (10 g.) was dissolved in 40 cc. of warm glacial acetic acid and the mixture heated under a reflux condenser. Water (10 cc.) was added in 2-cc. portions and the mixture was refluxed for one hour. Water (50 cc.) was then added, the mixture cooled to room temperature and the separated trityl carbinol (4.3 g., 95%) separated by filtration. The sirup obtained on solvent removal under reduced pressure was taken up in ether and the ether solution was shaken first with a suspension of calcium carbonate in water and finally with water. The dried ether extract (carboraffin) was treated with petroleum ether to incipient opalescence and allowed to stand overnight at icebox temperature; yield 1.2 g., m. p. 92–94°. A second crop (0.7 g., m. p. 92–94°) was obtained from the mother liquor on the addition of more petroleum ether. The substance is readily recrystallized from xylene; m. p. 92–94°, spec. rot. −15° (25°, *c* 3.0, $CHCl_3$). The above procedure is essentially the detritylation procedure of Kuhn, Rudy and Weygand.[6]

The compound crystallizes in elongated prisms from water. It is readily soluble in chloroform, acetone, ethanol, acetic acid, warm ether and warm xylene and is practically insoluble in petroleum ether. It is slightly soluble in cold and fairly soluble in hot water.

Anal. Calcd. for $C_6H_{10}O_5(COCH_3)_4$: C, 50.3; H, 6.64; CH_3CO, 12.0 cc. 0.1 *N* NaOH per 100 mg. Found: C, 50.5; H, 6.59; CH_3CO, 11.9 cc.

The original 1-bromo-*l*-fucitol tetraacetate was regenerated on treatment of *l*-fucitol tetraacetate (0.25 g.) in glacial acetic acid (8 cc.) with 4 cc. of acetic acid saturated with hydrogen bromide and allowing the mixture to stand for three hours. The crystalline product obtained on pouring the reaction mixture into ice and water was removed by filtration, washed with water and recrystallized from 60% ethanol; yield 0.13 g., m. p. 143° (mixed m. p. unchanged).

l-Fucitol Pentaacetate.—*l*-Fucitol (0.95 g.) was acetylated with pyridine (5 cc.) and acetic anhydride (10 cc.) for sixteen hours at room temperature and the reaction product obtained crystalline on pouring the acetylation mixture into ice and water; yield 2.0 g. (93%), m. p. 126°. The product was recrystallized from ethanol; m. p. 127°, spec. rot. +20.5° (25°, *c* 3.0, $CHCl_3$).

The substance crystallizes from ethanol in prisms and is insoluble in petroleum ether, soluble in hot ethanol and is readily soluble in chloroform, acetone and acetic acid.

Anal. Calcd. for $C_6H_9O_5(COCH_3)_5$: C, 51.0; H, 6.43; CH_3CO, 13.3 cc. 0.1 *N* NaOH per 100 mg. Found: C, 51.1; H, 6.33; CH_3CO, 13.3 cc.

(10) K. Freudenberg and M. Harder, *Ann.*, **433**, 230 (1923).

1,6-Ditrityl Dulcitol Dipyridinium Hydrochloride.—Five grams (1 mol) of dulcitol and 16 g. (2 mols) of trityl chloride were added to 30 cc. of dry pyridine. The mixture was shaken intermittently for five days. The dulcitol gradually went into solution and a product precipitated. The product was removed by filtration and washed with pyridine and then with water; m. p. 182–184°, mixed m. p. 172–178° with ditrityl dulcitol (see below) of m. p. 184°. Upon acetylation with pyridine and acetic anhydride the product was converted into ditrityl dulcitol tetraacetate (see below); m. p. 233°, mixed m. p. unchanged. When the product was dissolved in hot ethanol, dulcitol, identified by melting point and mixed melting point, separated on cooling. From the mother liquor trityl ethyl ether (m. p. 83°, mixed m. p. unchanged) was recovered. When the product (odorless) was heated a distinct odor of pyridine was observed.

Anal. Calcd. for $C_6H_{12}O_6[C(C_6H_5)_3]_2 \cdot [C_5H_5N \cdot HCl]_2$: Cl, 7.90; HCl, 2.23 cc. 0.1 *N* NaOH per 100 mg. Found: Cl, 8.2; HCl, 2.16 cc.

1,6-Ditrityl Dulcitol Ethyl Alcoholate.—The 1,6-ditrityl dulcitol dipyridinium hydrochloride obtained from 5 g. of dulcitol was suspended in 250 cc. of water, 0.1 *N* sodium hydroxide was added until the solution was basic, mechanical stirring was then maintained for two hours and the product removed by filtration and washed with water, yield 18 g.; after two recrystallizations from ethanol, yield 14 g., m. p. 183–184° (slight sintering at 80°).

The compound crystallizes in rectangular prisms from ethanol. It is readily soluble in benzene, moderately so in pyridine, chloroform and hot ethanol and insoluble in water and petroleum ether.

Anal. Calcd. for $C_6H_{12}O_6[C(C_6H_5)_3]_2C_2H_5OH$: $C(C_6H_5)_3$, 68.3; C_2H_5OH, 6.46. Found: $C(C_6H_5)_3$, 68.4; C_2H_5OH (loss in weight at 110° under reduced pressure), 6.38; OC_2H_5, present.

1,6-Ditrityl Dulcitol.—This substance was obtained as a crystalline residue on heating its ethyl alcoholate for sixteen hours at 110° under reduced pressure and over phosphorus pentoxide; yield quantitative, m. p. 183–184°.

Anal. Calcd. for $C_6H_{12}O_6[C(C_6H_5)_3]_2$: $C(C_6H_5)_3$, 73.0; C, 79.2; H, 6.33. Found: $C(C_6H_5)_3$, 72.7; C, 78.9; H, 6.31.

1,6-Ditrityl Dulcitol Tetraacetate.—1,6-Ditrityl dulcitol ethyl alcoholate (2.5 g.) was dissolved in 23 cc. of pyridine, cooled to 0°, 15 cc. of acetic anhydride added slowly and the mixture kept at icebox temperature. In about three hours crystals began to form and crystallization was completed on standing overnight; yield 2.5 g., m. p. 232–234°. Pure material was obtained on recrystallization from trichloroethylene; m. p. 237–238°.

Anal. Calcd. for $C_{14}H_{20}O_{10}[C(C_6H_5)_3]_2$: C, 74.8; H, 6.04; $C(C_6H_5)_3$, 58.3; mol. wt., 838.4. Found: C, 74.3; H, 6.03; $C(C_6H_5)_3$, 58.7; mol. wt. (Rast), 870, 824.

1,6-Dibromodulcitol Tetraacetate.—1,6-Ditrityl dulcitol tetraacetate (4.5 g.) was detritylated with hydrogen bromide in glacial acetic acid as described previously for the synthesis of 1-bromo-*l*-fucitol tetraacetate, except that the filtrate from the trityl bromide was poured into chloroform (100 cc.) and the chloroform was washed with cold water until free of halogen. The residue obtained on solvent

removal was triturated with ether and recrystallized several times from ethyl acetate; yield 1.1 g., m. p. 197–198°. The substance was practically insoluble in ether and alcohol but was soluble in chloroform, hot ethyl acetate and hot benzene.

Anal. Calcd. for $C_6H_8O_4(COCH_3)_4Br_2$: CH_3CO, 8.40 cc. 0.1 *N* NaOH per 100 mg.; Br, 33.57. Found: CH_3CO, 8.38 cc. (Freudenberg method[10]); Br, 33.45.

1,6-Dityityl Dibenzylidene Dulcitol.—1,6-Dityityl dulcitol (3 g.) was dissolved in 10 cc. of benzaldehyde and 3 to 4 g. of freshly fused zinc chloride was added. The mixture was shaken until the zinc chloride dissolved and kept overnight at room temperature. Chloroform (50 cc.) was then added and the solution washed with water to remove the zinc chloride, dried and placed in a 12-inch (30-cm.) evaporating dish. The solution was heated over a light bulb and dry, warm air was blown over its surface. After about a day there was only a very faint odor of benzaldehyde. The resulting crystalline mass was dissolved in chloroform, washed repeatedly with an aqueous solution of sodium bicarbonate to remove the benzoic acid and finally with water. The crystalline residue obtained on solvent removal from the dried (carboraffin) chloroform solution was recrystallized from trichloroethylene; yield 2.9 g., m. p. 233–234°, optically inactive in chloroform solution for the D-line of sodium light. When the substance was dissolved in concentrated sulfuric acid and diluted with water, a distinct odor of benzaldehyde could be noted.

Anal. Calcd. for $C_{20}H_{20}O_6[C(C_6H_5)_3]_2$: C, 82.6; H, 5.98; $C(C_6H_5)_3$, 57.7. Found: C, 82.4; H, 5.78; $C(C_6H_5)_3$, 57.3.

1,5-Dityityl Xylitol Triacetate.—Nineteen grams (2 mols) of trityl chloride was added to 5 g. (1 mol) of xylitol sirup in 25 cc. of dry pyridine and the solution was kept at room temperature for four days, whereupon 15 cc. of acetic anhydride was added. In a few hours a crystalline product separated from the reaction mixture. Recrystallization was effected by solution in hot xylene (carboraffin) followed by the addition of ethanol; yield 17 g., m. p. 206°.

Anal. Calcd. for $C_5H_7O_5(COCH_3)_3[C(C_6H_5)_3]_2$: $C(C_6H_5)_3$, 63.8; CH_3CO, 3.94 cc. 0.1 *N* NaOH per 100 mg. Found: $C(C_6H_5)_3$, 63.7; CH_3CO, 3.81 cc.

1-Trityl[11]-*d*-mannitol Pentaacetate.—Ten grams (2 mols) of dry mannitol, 7.8 g. (1 mol) of trityl chloride and 60 cc. of dry pyridine were heated at 90° for twelve hours, whereupon the solution was cooled and poured in a thin stream into ice and water (2 liters). The precipitated mass hardened on standing at ice box temperature for several hours and was identified as ditrityl mannitol tetraacetate[3] on acetylation; yield of ditrityl mannitol tetraacetate 10 g., m. p. 183–184° (mixed m. p. with an authentic specimen unchanged).

(11) Positions 1 and 6 are equivalent.

The aqueous filtrate above was concentrated until a sticky mass separated. This was removed by chloroform extraction and the sirup obtained on solvent removal from the dried extract was acetylated overnight with pyridine (20 cc.) and acetic anhydride (15 cc.). The crystalline product obtained on pouring the acetylation mixture into ice and water was removed by filtration, washed with water, dried and recrystallized from xylene (carboraffin); yield 4 g., m. p. 163–164°, spec. rot. +35.5° (25°, *c* 4, $CHCl_3$).

Anal. Calcd. for $C_6H_8O_6(COCH_3)_5C(C_6H_5)_3$: $C(C_6H_5)_3$, 38.3; CH_3CO, 7.88 cc. 0.1 *N* NaOH per 100 mg. Found: $C(C_6H_5)_3$, 37.9; CH_3CO, 7.92 cc.

We wish to express our indebtedness to the Atlas Powder Co. for furnishing the mannitol used in this investigation and also for preparing the other sugar alcohols from the corresponding aldoses by high pressure, catalytic reduction. We also wish to express our indebtedness to Mr. H. S. Clark for the microcombustion analyses.

Summary

1. The acetates of monotrityl-*d*-mannitol, dityityl-xylitol, trityl-*l*-fucitol and dityityl-dulcitol have been synthesized.

2. *l*-Fucitol 2,3,4,5-tetraacetate has been synthesized.

3. Detritylation of trityl-*l*-fucitol tetraacetate and of dityityl dulcitol tetraacetate with hydrogen bromide in acetic acid resulted in bromine replacement of the trityl groups.

4. *l*-Fucitol 2,3,4,5-tetraacetate on retritylation produces the original trityl-*l*-fucitol tetraacetate and on treatment with hydrogen bromide the same acetylated bromide is obtained as on detritylation with hydrogen bromide in acetic acid.

5. *l*-Fucitol pentaacetate has been synthesized.

6. On tritylation of dulcitol with pyridine and trityl chloride, a dipyridinium hydrochloride compound of the reaction product is formed, from which the dityityl dulcitol may be obtained, as a monoethyl alcoholate or in the non-solvated form.

7. Dibenzylidene dityityl dulcitol has been synthesized.

8. All compounds reported were obtained in crystalline form and were purified to constant rotation and melting point.

The Syntheses of 2-Thio-4-arylthiazolines

BY F. B. DAINS AND ORLAND A. KROBER

Previous investigations[1] have shown that the alkyl and aryl thiocyanates in general add thio acids yielding esters of an acyldithiocarbamic acid. Thus benzyl thiocyanate and thiobenzoic acid gave the benzyl ester of benzoyl-dithiocarbamic acid, $C_6H_5CONHCSSCH_2C_6H_5$, and ethyl thiocyanate and thioacetic acid, the corresponding acetyl-ethyldithiocarbamate. In some cases the reaction is not so smooth and decomposition products are formed.

In view of this interesting addition to the SCN grouping, a study has been made of the action of the thio acids on the phenacyl thiocyanates which contained a labile keto grouping, and hence are capable of secondary reactions. Our results show that phenacyl thiocyanate readily adds thiobenzoic acid, yielding the phenacyl ester of benzoyl-dithiocarbamic acid, $C_6H_5CONHCSSCHCOC_6H_5$, which on heating with dilute hydrochloric acid reacts in the enol form, losing benzoic acid and closing the ring with the formation of 2-thio-4-phenylthiazoline.

$$\underset{\text{S—CS—NHC}(C_6H_5)=\text{CH}}{\text{S—CS—NHC}(C_6H_5)=\text{CH}}$$

In the case of thioacetic acid, only the end-product, the thiazoline, could be isolated.

Experimental

The phenacyl thiocyanates are prepared readily by this general procedure.

A mixture of *p*-bromophenacyl chloride (50 g.), potassium thiocyanate (20 g.) and ethanol (100 cc.) was refluxed for two hours or until the sharp odor of the chloride had disappeared completely. Water was then added and the solid product washed free from mineral salts; the *p*-bromophenacyl thiocyanate (I) (m. p. 147°) was purified by crystallization from alcohol.

The following thiocyanates were synthesized for later use: (II) *p*-chloro, (III) *p*-iodo, (IV) *p*-methoxy and (V) *m*-nitrophenacyl thiocyanate.

TABLE I

			M. p., °C.	N, % Calcd.	N, % Found	S, % Calcd.	S, % Found

Synthesis of the Thiazolines

2-Thio-4-phenylthiazoline (VI).[2]—Phenacyl thiocyanate (14 g.), thioacetic acid (12 g.) and benzene (60 cc.) were heated for three hours on a steam-bath. After concentrating the solution and cooling, the thiazoline was filtered off and purified from alcohol. The light yellow crystals which were soluble in alkali melted at 168°.

The intermediate acetyl-phenacyldithiocarbamate was not isolated in this or any other case where thioacetic acid was used, but with thiobenzoic acid such intermediate

(1) Chanlaroff, *Ber.*, **15**, 1887 (1882); Wheeler and Merriam, THIS JOURNAL, **23**, 283 (1901); Wheeler, *Am. Chem. J.*, **26**, 345 (1901); Wheeler and Johnson, *ibid.*, **26**, 185 (1901).

(2) The compound had been made previously by Miolati by the action of phenacyl bromide on ammonium dithiocarbamate [*Gazz. chim. ital.*, **23**, I, 580 (1893)].

dithiocarbamates were more stable and were obtained in a pure condition.

Action of Thiobenzoic Acid.—Molar quantities of phenacyl thiocyanate and thiobenzoic acid were heated in benzene solution for four hours. The product isolated melted at 95° and corresponded to benzoyl-phenacyl-dithiocarbamate (VII), $C_6H_5CONHCSSCH_2COC_6H_5$, since on heating with dilute hydrochloric acid it gave benzoic acid and the thiazoline (VI), m. p. 168°.

As shown in the table, thiazolines were obtained from thiocyanates I–V, using thioacetic and thiobenzoic acids, but the intermediate dithiocarbamates were isolated only in some cases with thiobenzoic acid.

2-Thio-4,5-diphenylthiazoline (XVI).—Desyl thiocyanate and thioacetic acid gave in good yield this thiazoline (m. p. 214°).

Wheeler and Johnson[3] on treating the desyl thiocyanate with thiobenzoic acid, had isolated an unidentified compound melting at 137°, which was doubtless the benzoyl addition product. Using the same reagents, evidence was obtained of an immediate product melting about 132–133° which went over readily into the diphenylthiazoline (m. p. 214°).

The enol nature of the thiazoline was shown by the formation of a 2-benzyl ether (XVII) when the diphenylthiazoline was treated with benzyl chloride.

Rhodanine. 2-Thio-4-thiazolidone, XVIII.—Diethyl thiocyanomalonate was heated in benzene solution with thiobenzoic acid.[4] On distilling off the benzene, an oil was left which failed to crystallize and had the odor of ethyl benzoate. When this oil was evaporated to dryness with dilute hydrochloric acid, rhodanine was obtained (m. p. 166°). Its identity was proved by analysis and comparison with a synthetic specimen.

(3) Wheeler and Johnson, *Am. Chem. J.*, **26**, 202 (1901).

Summary

This paper describes the syntheses of several substituted aryl thiocyanates and their behavior with thioacetic and thiobenzoic acids. The final products in all cases were 2-thio-4-arylthiazolines, but with thiobenzoic acid the more stable intermediates, benzoyl-phenacyl-dithiocarbamates, were isolated.

(4) Wheeler, *Am. Chem. J.*, **26**, 351 (1911), described the intermediate, the benzoyl-dithiourethan; but did not hydrolyze it. Rhodanine was also obtained by Miolati [*Ann.*, **262**, 62–85 (1891)] from chloroethyl acetate and ammonium dithiocarbamate.

2,4,6-Trimethyl-β-phenyl- and Benzyl-D-glucosides[1]

BY NELSON K. RICHTMYER

In a previous study on the cleavage of glycosides by catalytic hydrogenation,[2] mention was made of a trimethyl-β-phenylglucoside and a trimethyl-β-benzylglucoside in which the methyl groups were located presumably in the 2,4,6-positions of the glucose chain. The appearance of four recent papers dealing with 2,4,6-trimethylglucose and its derivatives makes a description of the two named glucosides seem desirable at this time.

2,4,6-Trimethyl-D-glucose was obtained first by Haworth and Sedgwick[3] through the hydrolysis of partially methylated glucose and sucrose. The allocation of methoxyl groups was confirmed later by Oldham[4] through a synthesis, the details of which have just been published. Recently, Lake and Peat[5] isolated 2,4,6-trimethylglucose by acid hydrolysis of the corresponding β-methylglucoside which is one of the products resulting from the action of boiling sodium methylate on 4,6-dimethyl-2,3-anhydro-β-methyl-D-mannoside. Barker, Hirst and Jones[6] have separated it from the products arising from incomplete methylation of α-methylglucoside with methyl iodide and thallous hydroxide. Freudenberg and Plankenhorn[7] synthesized it by methylation of 3-benzylglucose, followed by reductive cleavage of the benzyl group and acid hydrolysis of the glycosidic methoxyl group. It is of interest to note also that, from the cell wall of yeast, Zechmeister and Tóth[8] have isolated a glucose polysaccharide, which, after methylation and hydrolysis, furnished this same 2,4,6-trimethylglucose.

Tetraacetyl-β-phenylglucoside is readily accessible through the condensation of phenol with glucose pentaacetate, in the presence of *p*-toluenesulfonic acid as catalyst according to Helferich and Schmitz-Hillebrecht.[9] The incomplete

methylation of β-phenylglucoside or its tetraacetate with methyl sulfate and alkali, as described below, yields crystalline 2,4,6-trimethyl-β-phenyl-D-glucoside as the product most readily separated from the mixture[10]; this series of reactions, followed by acid hydrolysis of the glucoside, offers a suitable method for the preparation of crystalline 2,4,6-trimethyl-D-glucose.

Crystalline 2,4,6-trimethyl-β-benzyl-D-glucoside has been obtained similarly from the incomplete methylation of β-benzylglucoside.

Experimental

2,4,6-Trimethyl-β-phenyl-D-glucoside.—To a solution of 100 g. of β-phenyl-D-glucoside dihydrate in 200 cc. of water (or an equivalent amount of tetraacetyl-β-phenyl-D-glucoside suspended in sufficient 50% aqueous sodium hydroxide to deacetylate it) was added 180 cc. of 50% aqueous sodium hydroxide and 100 cc. of methyl sulfate. The mixture was stirred mechanically, heated to 95° in a water-bath, cooled, and the process repeated until a total of 2160 cc. of alkali and 1200 cc. of methyl sulfate had been added. The methylated phenylglucoside, which crystallized in needles or small pellets when the reaction mixture was cooled, was extracted completely with ether, and the ethereal solution washed with water, dried with granular calcium chloride and concentrated. From the sirup, by fractional crystallization with ether and petroleum ether (b. p. 26–30°), was isolated 14.5 g. of 2,4,6-trimethyl-β-phenyl-D-glucoside in glistening, prismatic needles, melting at 108–109°, and with $[\alpha]_D$ −57.5° in chloroform (*c*, 2).

Anal. Calcd. for $C_{15}H_{22}O_6$: C, 60.37; H, 7.44; OCH_3, 31.21. Found: C, 60.38; H, 7.58; OCH_3, 30.95.

A second product having the composition also of a trimethyl-β-phenyl-D-glucoside was isolated in small amounts. It melted at 105–106°; a mixture with the 2,4,6-isomer melted at 80–95°.

Anal. Calcd. for $C_{15}H_{22}O_6$: C, 60.37; H, 7.44; OCH_3, 31.21. Found: C, 60.31; H, 7.33; OCH_3, 31.21.

Hydrolysis to 2,4,6-Trimethyl-D-glucose.—A solution of 3 g. of the 108–109° trimethylphenylglucoside in 200 cc. of 5% aqueous hydrochloric acid was boiled four hours under a reflux condenser. The solution was neutralized with solid barium carbonate, concentrated *in vacuo* to a small volume, and extracted with ether in a Soxhlet apparatus arranged for the continuous extraction of liquids. The ethereal solution deposited prismatic needles of 2,4,6-trimethyl-D-glucose which was identified by direct comparison with a specimen supplied through the courtesy of Dr. J. W. H. Oldham.[4] The two specimens, alone or mixed, melted at 122–123° when heated rapidly, and at 113–122° when heated slowly in soft glass melting point tubes. A mixture of the new 2,4,6-isomer with an authentic sample of 2,3,6-trimethylglucose melted at 87–105°. The rotation, $[\alpha]_D^{20}$ +111° in methyl alcohol (*c*, 1), changed in six days at 20° to $[\alpha]_D^{20}$ +71° (constant) upon the addition of a drop of concentrated hydrochloric acid; these values are in agreement with the earlier data, and distinguish clearly between the 2,4,6- and the 2,3,6-trimethylglucoses.[7]

Anal. Calcd. for $C_9H_{18}O_6$: C, 48.62; H, 8.17; OCH_3, 41.90. Found: C, 48.58; H, 7.96; OCH_3, 41.93.

2,4,6-Trimethyl-β-benzyl-D-glucoside.—To a solution of 32 g. of β-benzyl-D-glucoside in 100 cc. of water was added 44 cc. of methyl sulfate and 80 cc. of 50% aqueous sodium hydroxide; the mixture was stirred mechanically, heated to 70° with a water-bath, cooled, and the process repeated with nine more portions of methyl sulfate and alkali. After the final addition, the water was kept at 100° for one hour to decompose any excess methyl sulfate. The product was extracted with chloroform, concentrated, and methylated again with the same quantities of reagents. The methylated benzylglucoside was extracted with chloroform, and the chloroform solution washed with water, dried over calcium chloride, and concentrated *in vacuo*. With the aid of ether and petroleum ether (b. p. 26–30°) there was obtained 4.6 g. of 2,4,6-trimethyl-β-benzyl-D-glucoside; a thrice recrystallized sample melted at 94–95°, and showed $[\alpha]_D^{20}$ −49.1° in chloroform (*c*, 2).

Anal. Calcd. for $C_{16}H_{24}O_6$: C, 61.50; H, 7.75; OCH_3, 29.81. Found: C, 61.54; H, 8.15; OCH_3, 29.50.

Hydrolysis to 2,4,6-Trimethyl-D-glucose.—A 1.5-g. sample of the trimethylbenzylglucoside was heated with 5% aqueous hydrochloric acid, and the product isolated and identified as described above.

This work has been aided by a grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences. The author desires to thank the Chemical Foundation of New York for a Research Associateship which he held while completing a portion of the research.

Summary

2,4,6-Trimethyl-β-phenyl-D-glucoside has been obtained through incomplete methylation of β-phenyl-D-glucoside. The method is recommended for the preparation of 2,4,6-trimethyl-D-glucose.

2,4,6-Trimethyl-β-benzyl-D-glucoside has been described.

WASHINGTON, D. C. RECEIVED MAY 8, 1939

(10) Work on the separation of the other components has been discontinued; tetramethyl-β-phenyl-D-glucoside is described by Voss and Wachs, *Ann.*, **522**, 252 (1936).

The Behavior of Glucose Dimethylacetal toward Carbohydrases[1]

BY NELSON K. RICHTMYER, MILDRED ADAMS AND C. S. HUDSON

Under the title "The Enzymotic Cleavage of Acetals," Neuberg and Ziffer[2] have reported that acetal itself (acetaldehyde diethylacetal) is subject to enzymotic hydrolysis by top yeast, by taka-diastase, and by commercial emulsin, in aqueous solution at 37° in the presence of calcium carbonate and toluene. Upon the appearance of that paper, our own experiments, which were then in progress, on the behavior of glucose dimethylacetal[3] toward various carbohydrases were extended to include the conditions used by Neuberg and Ziffer. In no case, however, have we been able to detect any cleavage of glucose dimethylacetal by top yeast, taka-diastase, emulsin, maltase, invertase, pancreatic amylase, or malt amylase. The conditions of temperature, time, *p*H, and the final rotation of the solutions are recorded in Table I; the details of the enzyme preparations, amounts, and activities are reported in the Experimental section.

TABLE I

GLUCOSE DIMETHYLACETAL AND CARBOHYDRASES

Enzyme	*p*H	Buffer	Time, hrs.	Temp., °C.	$[\alpha]^{20}D$[a]
Invertase	7.1	Phosphate[b]	20	20	+14.2°
Invertase	5.1	Phosphate	20	20	15.3
Maltase	6.9	Phosphate	21	20	14.0
Emulsin	5.4	Acetate[c]	68	20	14.7
Malt amylase	4.6	Acetate	65	20	14.3
Pancreatic amylase	7.1	Phosphate[d]	22	20	14.2
Taka-diastase	5.2	Phosphate	20	20	14.4
Taka-diastase	7.1	Phosphate	20	20	14.1
"Clarase"	5.3	Phosphate	23	20	14.0
Taka-diastase (concd.)	5.5	Acetate	24	20	13.7
Taka-diastase (concd.)	[e]	[e]	24	38	14.6
Emulsin	[e]	[e]	24	38	15.6
Top yeast	[e]	[e]	45	38	14.2

[a] The specific rotation of the glucose dimethylacetal was +14.3 ± 0.3° in water (*c*, 5); if completely hydrolyzed to glucose its apparent specific rotation would be +41.8°. All other specific rotations are correct to ±0.9°. [b] The phosphate buffers are about 1% in sodium phosphates. [c] The acetate buffers are about 0.1 or 0.2 *N* in acetic acid–sodium acetate mixtures. [d] The solution was also 0.04 *M* in sodium chloride. [e] The aqueous solution contained no buffer except solid calcium carbonate; two drops of toluene were added.

Our results are in accord with the statement by Pacsu[4] that fructose dimethylacetal is not affected by yeast at *p*H 7, or by invertase at *p*H 4 or 7. The failure of these glucose and fructose acetals to be cleaved by enzymes, however, must not be construed as evidence that other acetals may not be susceptible to enzymotic hydrolysis.

Experimental

Cleavage Experiments.—A weighed amount of glucose dimethylacetal[3] in a volumetric flask, such that the final concentration would be 2 g. per 100 cc., was dissolved in the desired buffer solution, a definite weight or volume of the enzyme added, and the flask filled to the mark with additional buffer solution. After standing for the length of time and at the temperature noted in Table I, the solution was adjusted to volume and filtered if necessary, and the rotation observed in a 1-dm. tube at 20°.

Invertase.—An autolysate of bakers' yeast was dialyzed, and treated with bentonite as described previously.[5] The eluate was concentrated and purified further by precipitation with ammonium sulfate; the aqueous extract, after dialysis, contained 32.6 invertase units[6] in 100 cc., with a time value[6] of 0.20 minute. For the cleavage experiments, 0.5 g. of the acetal, in the desired buffer solution, was treated with 1 cc. of the invertase solution in a total volume of 25 cc.

Maltase.—The fractional autolysis of brewers' yeast according to Weidenhagen[7] produced a maltase solution of concentration such that 1.25 g. of maltose in a total volume of 25 cc., containing 1% phosphate buffer of *p*H 6.9, was 50% hydrolyzed by 5 cc. of the enzyme solution in one hundred and eighty-seven minutes at 20°. The enzyme solution was capable also of hydrolyzing α-methylglucoside. For the cleavage experiment, 5 cc. of the maltase solution was used with 0.5 g. of the acetal.

Emulsin.—Sweet almond emulsin was obtained by the zinc sulfate and tannic acid procedure of Helferich and his collaborators.[8] The activity of the enzyme was such that 25 cc. of a 2% solution of salicin in about 0.2 *N* sodium acetate buffer of *p*H 5.0 was 50% hydrolyzed by 1 cc. of emulsin solution in ten and two-tenths minutes at 20°. For the cleavage experiments 1 cc. of emulsin was added to 0.5 g. of the acetal.

Malt Amylase.—The aqueous extract from distillers' barley malt was purified by the method of Sherman, Caldwell and Doebbeling.[9] The enzyme preparation had an activity of 1240 on the scale of Sherman, Kendall and Clark[10]; this is a measure of the saccharogenic rather than

of the amyloclastic power. No cleavage was observed when 10 mg. of enzyme was added to 0.2 g. of the acetal.

Pancreatic Amylase.—The method of purification of Sherman and Schlesinger[11] yielded a product with a saccharogenic activity[10] of 3300. Of this amylase, 6 mg. was without effect on 0.5 g. of the acetal.

Taka-diastase.—This was a commercial preparation with a saccharogenic activity of 10.

"Clarase."—This was a more concentrated commercial preparation of the amylase from *Aspergillus oryzae*, and had a saccharogenic activity of 28. With each of these last two preparations 15 mg. was added to 0.5 g. of the acetal.

Taka-diastase, Concentrated.—Commercial taka-diastase was purified to a saccharogenic activity of 390 by the method of Sherman and Tanberg[12]; it had no action when 10 mg. was added to 0.2 g. of the acetal.

Top Yeast.—To 0.5 g. of the acetal was added 100 mg. of washed top yeast, from the Gunther Brewing Co. of Baltimore, Maryland.

Summary

Glucose dimethylacetal was not hydrolyzed, under a variety of conditions, by invertase, maltase, emulsin, malt amylase, pancreatic amylase, taka-diastase, or top yeast.

The Cleavage of Cellobiose and Celtrobiose by Emulsin[1]

BY NELSON K. RICHTMYER AND C. S. HUDSON

In a recent paper by Helferich and Pigman[2] it was reported that the β-galactosido linkage of neolactose (4-β-D-galactosido-D-altrose)[3] was cleaved by sweet almond emulsin only one-seventh as rapidly as the similar linkage of lactose (4-β-D-galactosido-D-glucose). The difference in the ease of hydrolysis of the two β-galactosides was attributed to the change in configuration of the third carbon atom of the glucose molecule which occurs (together with an inversion about the second carbon atom) during the transformation of lactose into neolactose; the effect was likened to that of ortho-substitution, contrasted to that of meta- or para-substitution, in the hydrolysis of phenylglucosides by sweet almond emulsin.[4]

With the corresponding β-glucosides, cellobiose (4-β-D-glucosido-D-glucose) and celtrobiose (4-β-D-glucosido-D-altrose),[5] available in this Laboratory, we decided to make a similar comparison of their behavior toward sweet almond emulsin. The cleavage of cellobiose by emulsin was observed first by Fischer and Zemplén,[6] and has been studied more recently by Weidenhagen[7] and by Helferich, Gootz and Sparmberg.[8]

In Tables I and II are recorded the data obtained in our comparisons of the action of emulsin upon the two disaccharides. The hydrolysis constants are based on the assumption that the reactions are unimolecular. The ratio of the average value of the constants, 10.8:1.59, indicates that cellobiose is hydrolyzed 6.8 times more rapidly than celtrobiose under the same conditions. The lengths of time required for 50% hydrolysis of the disaccharides, as obtained by interpolation, are 281 and 2105 minutes for cellobiose and celtrobiose, respectively; their ratio indicates that cellobiose is hydrolyzed 7.5 times more rapidly than celtrobiose. For 25% hydrolysis, a quotient of 6.7 is obtained. Thus it appears that the inversion of H and OH which is brought about on the second and especially on the third carbon atoms of the reducing glucose molecule in the transformation of cellobiose to celtrobiose has the same effect upon the rates of hydrolysis of these disaccharides as does the similar change of configuration in the corresponding β-galactosides lactose and neolactose. The

change from D-glucose to D-altrose in the "aglycone" portion of the glycosides, which has resulted in the hydroxyl on carbon atom 3 being nearer spatially to the glycosidic union at carbon atom 4, as interpreted by the customary models, has produced such a steric hindrance to cleavage of the disaccharide linkage at carbon atom 4 that the velocity of hydrolysis has been reduced to one-seventh of its original rate.

The fact that celtrobiose is hydrolyzed by the β-glucosidase of sweet almond emulsin, and is not cleaved by maltase (an α-glucosidase), confirms the assignment of the β-glucosidic linkage in celtrobiose; this linkage had been assumed previously because the sugar was prepared from cellobiose.

Experimental

Emulsin (β-D-Glucosidase) was prepared[9] by extraction of defatted sweet almond meal with zinc sulfate solution, fractional precipitation of the enzyme with tannic acid, removal of the tannic acid with acetone and extraction of the emulsin from the residue with water. The product had a small negative rotation, necessitating a slight correction in later observations. Although the actual β-glucosidase value was not determined, the activity of the enzyme was such that 25 cc. of a 2% solution of salicin in about 0.2 *N* acetic acid–sodium acetate buffer of *p*H 5.0 was 50% hydrolyzed by 1 cc. of emulsin solution in 10.2 minutes at 20°.

The enzymotic hydrolyses were carried out by dissolving 4.000 g. of cellobiose or 4.211 g. of celtrobiose monohydrate, respectively, in about 0.2 *N* acetic acid–sodium acetate buffer of *p*H 5.0, adding 4 cc. of the emulsin solution at zero time, and diluting with a small additional amount of buffer exactly to 100 cc. at 20°. The cellobiose solution was kept in a water-bath at 20 ± 0.1°, and the celtrobiose solution in a room at 20 ± 1°. At appropriate times, a 15-cc. portion of the desired solution was removed, and 10 cc. of *N* aqueous sodium carbonate added to stop the enzyme action and to complete the mutarotation of the sugars. The optical rotation was observed after five minutes, in a 2-dm. tube at 20°. The data are recorded in Tables I and II, with the percentage cleavage, and the hydrolysis constants calculated in minutes and decimal logarithms.

Maltase (α-D-Glucosidase) was prepared by the fractional autolysis of brewers' yeast with ethyl acetate according to Weidenhagen[10]; although the solution was decidedly active toward maltose and α-methyl-D-glucoside, no evidence of cleavage of celtrobiose could be detected at *p*H 7.0 in forty-eight hours at 20°.

One of the authors (N. K. R.) desires to thank the Chemical Foundation of New York for a Research Associateship.

Summary

Celtrobiose is hydrolyzed by sweet almond emulsin only one-seventh as rapidly as cellobiose. This relationship is in agreement with the experience of Helferich and Pigman with the corresponding galactosides, neolactose and lactose.

The cleavage of celtrobiose by emulsin, but not by maltase, is presented as confirmatory evidence for a β-glucosidic linkage in celtrobiose (4-β-D-glucosido-D-altrose).

[CONTRIBUTION FROM THE BUREAU OF ENTOMOLOGY AND PLANT QUARANTINE, UNITED STATES DEPARTMENT OF AGRICULTURE]

The Constituents of Certain Species of Helenium. II. Tenulin

BY E. P. CLARK

In the first paper of this series[1] attention was directed to a statement by Reeb[2] that helenalin from *Helenium autumnale* is a vermifuge. The writer has found it to be a fairly effective fish poison, and in unpublished experiments entomologists of this Bureau have shown that it has possibilities as an insecticide. These facts stimulated investigation of other species of the genus for possible sources of helenalin or other materials likely to be related to it. The results of this work have shown that *Helenium macrocephalum* also contains helenalin, while three other species—*H. tenuifolium*, *H. elegans*, and *H. badium*—contain a crystalline substance hitherto unreported. This material has been named "tenulin" from *H. tenuifolium*, the plant from which it was first obtained.

Tenulin was prepared from the species of *Helenium* mentioned above by extraction and crystallization from organic solvents. Because of the retention of solvent of crystallization, it separates from a number of such solvents with different melting points, but after undergoing some purification it may be recrystallized from water or aqueous organic solvents and then has a constant composition represented by $C_{17}H_{22}O_5$ and a melting point of 193–195°.

It is bitter and mildly sternutative and has a pronounced toxic effect upon fish in a concentration of 1–5000.

Tenulin is optically active; $[\alpha]^{20}D$ is $-21.7°$ in ethanol. Reactions for hydroxyl, carboxyl, and carbonyl groups have so far given negative results. Alkoxyl groups are absent, but it does give a small quantity of alkyl iodide, which when calculated to methoxyl corresponds to approximately 0.5%. Hydrogenation of tenulin yields a dihydro compound which readily gives a phenylhydrazone, whereas the unreduced material does not. Upon bromination, two atoms of bromine are added, indicating a double bond or its equivalent. One of the bromine atoms, however, is readily lost, and a monobromo compound is formed. When a small tube containing tenulin is plunged into a bath at 300°, the material melts with the rapid evolution of gas. As the bath cools to 275°, the reaction is complete and a golden-colored melt results, which yields a crystalline substance, m. p. 172°. This has been shown by analysis to be anhydrotenulin, $C_{17}H_{20}O_4$. The action of acetic anhydride and sodium acetate upon tenulin is anomalous. A product is obtained which analyzes for $C_{22}H_{26}O_5$ but does not contain acetyl.

Mild treatment of tenulin with alkali converts it to an isomer which melts, according to the method of making it, at 158–162°. The following procedures were used to obtain this isomer, which has been designated isotenulin: (1) triturating finely powdered tenulin with 0.1 *N* sodium hydroxide for three minutes; (2) triturating finely powdered tenulin with 5% sodium carbonate solution and allowing the mixture to stand for periods of fifteen minutes to twenty-four hours; (3) boiling an aqueous solution of tenulin with norit, which because of the alkaline reaction imparted to the solution by the carbon caused isomerization; and finally (4) treating an aqueous methanolic solution with a small quantity of 1% sodium hydroxide.

According to the procedure used, practically pure isotenulin or a mixture of isotenulin and a new substance, $C_{15}H_{20}O_4$, m. p. 255°, may be obtained.

Isotenulin is of interest because it is the compound described in 1937 by Buehler, Whitehead, and Goodge,[3] which they obtained from *Helenium tenuifolium*. These investigators reported upon an indefinite material which melted over a range of 152–170°. It was not purified or analyzed, but upon treatment with dilute sodium carbonate solution gave a well-defined compound, $C_{17}H_{22}O_5$, which melted at 158°. This is the material designated above as isotenulin. They record three derivatives of it: a monobromo compound, m. p. 200°; a dihydro compound, m. p. 150.8°; and a phenylhydrazone of the latter, m. p. 209–210°.

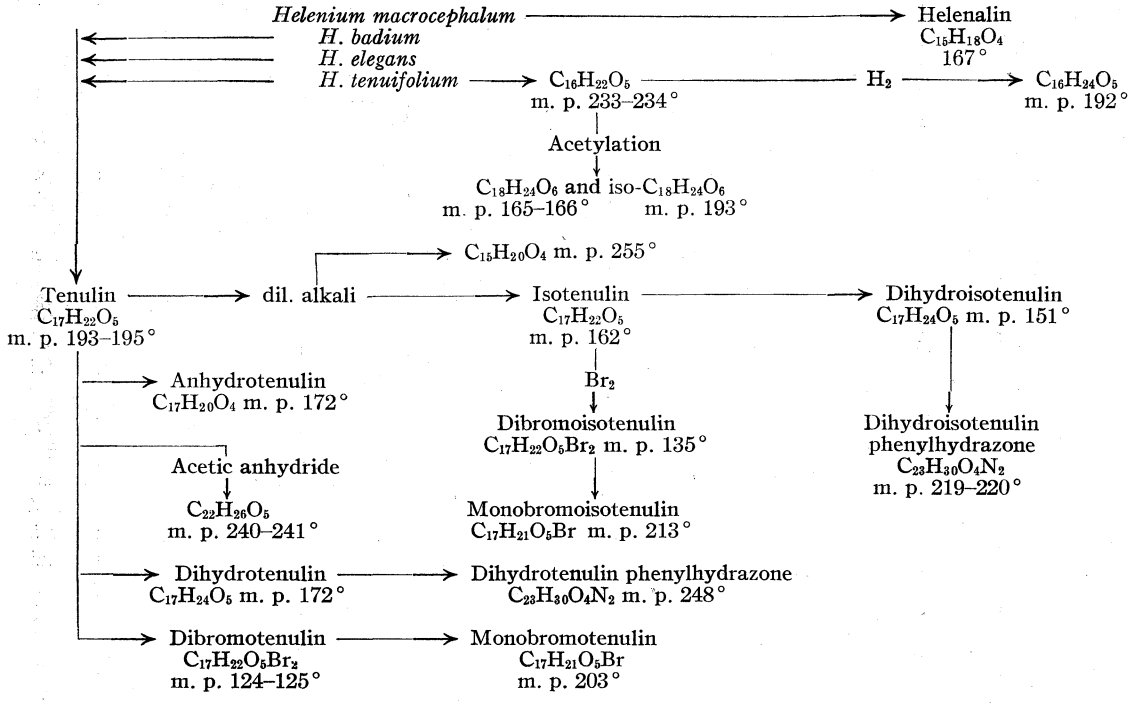
A comparison of the melting points recorded by Buehler and co-workers for these substances with isotenulin and the corresponding derivatives which were made for the purpose agree only in two

(1) Clark, THIS JOURNAL, **58**, 1982 (1936).

(2) Reeb, *J. Pharm. Elsas Lothringen*, **37**, 149 (1910).

(3) Buehler, Whitehead and Goodge, THIS JOURNAL, **59**, 2299 (1937).

DIAGRAM SHOWING THE INTERRELATIONS OF THE VARIOUS SUBSTANCES UNDER CONSIDERATION



instances, namely, isotenulin and its dihydro derivative. The phenylhydrazone of dihydroisotenulin melts at 219–220°, and bromination of isotenulin according to Buehler's method yields a dibromo compound, m. p. 135°. This, however, can be converted readily to a monobromo derivative, m. p. 213°. In spite of these differences, it is quite safe to say that the material obtained by Buehler and co-workers is isotenulin, for in working up plant extracts according to their directions the writer obtained isotenulin.

The preparation of tenulin from different lots of *Helenium tenuifolium* was accompanied by considerable variation in yields and in the ease with which the material was obtained. Some samples contained relatively large quantities of non-crystallizable material, which greatly inhibited the crystallization of tenulin. One shipment of *H. tenuifolium*, obtained in 1936, gave with difficulty poor yields of crystalline material, while the same drug, obtained in 1934 from essentially the same location, gave a clean extractive from which tenulin was obtained with ease.

Upon treatment for purification the material used in 1936 was found to consist of about 60% of tenulin and 40% of another compound, $C_{16}H_{22}O_5$. This C_{16} material gave a dihydro derivative, $C_{16}H_{24}O_5$, and two isomeric monoacetyl derivatives. One of these, obtained by the action of boiling acetic anhydride and sodium acetate, melted at 165–166°; the other, made by allowing the material to react with acetic anhydride and cold pyridine, melted at 193°. The new compound contains no alkoxyl groups, but under the conditions employed to determine these groups an alkyl iodide was obtained, which when calculated to methoxyl corresponded to 3.8%. This reaction strongly indicates a diortho-substituted isopropyl group.[4]

No attempt is made here to interpret the reactions under consideration, but they serve to characterize tenulin, show its relation to Buehler, Whitehead, and Goodge's compound, and indicate the occurrence of several apparently closely related compounds in certain species of *Helenium*. A summary of the sources of the various products under consideration and their relation to each other is given in the accompanying diagram.

Experimental

Helenalin from Helenium macrocephalum.—This plant, which yields helenalin, was treated in the manner described for obtaining helenalin from *H. autumnale*.[1]

Preparation of Tenulin from Different Plant Sources.—The following procedure for preparing tenulin is the most satisfactory of several employed. This method was used in processing all three species of *Helenium* containing tenulin mentioned before.

(4) Clark, THIS JOURNAL, **51**, 1479 (1929); Adams and Butterbaugh, *ibid.*, **60**, 2174 (1938).

Twenty-five hundred grams of ground whole plant was moistened with 2 liters of chloroform and allowed to stand in a tight container overnight. The drug was then packed in a percolator and extracted with 10 liters of chloroform. The extract was concentrated under diminished pressure to a thick sirup and then dissolved in 1.5 liters of hot ethanol. The alcoholic liquid was diluted with 6 liters of boiling water and acidified (litmus) with acetic acid, and a solution of 20 g. of normal lead acetate was added. After standing overnight the solution cleared and was filtered through a folded filter paper. The filtrate was evaporated under reduced pressure to 1 liter and then extracted with chloroform. The chloroform extract was dried with sodium sulfate and evaporated under reduced pressure to a thick sirup, which was dissolved in boiling benzene and allowed to crystallize.

This procedure gave satisfactory results with all species of *Helenium* except occasionally *tenuifolium*. In these cases the thick chloroform extract was dissolved in 250 cc. of methanol, 75 cc. of ethylene glycol was added, and most of the methanol removed by distillation under reduced pressure. The resulting glycol solution was removed from the flask with the aid of 20 cc. of hot methanol and treated with water until turbidity occurred. It was then placed in a cool box and allowed to crystallize. The yield was usually 1.5% of the weight of the drug.

The purification of the material obtained by either of the foregoing procedures was accomplished in several ways:

(1) Five grams of crude tenulin was dissolved in 20 cc. of hot ethylene glycol. To this solution was added 60 cc. of water. Crystallization soon began and yielded 3.6 g., m. p. 183°.

(2) Tenulin was dissolved in the necessary quantity of *n*-butanol, and 4 volumes of *n*-butyl ether was added. The material melted at 191° and cleared at 196°. The melting point frequently varied, however, as illustrated in the following experiment. Tenulin with a melting point of 191° was recrystallized several times from butanol and butyl ether as above. The first recrystallization gave a product which melted at 178°, the second at 183°, the third at 186°, and the fourth at 175°. In all cases the product separated as dense prisms. Apparently all the different specimens were pure but contained solvent.

(3) The best method thus far found was to dissolve the crude substance in acetone and add to this a relatively large quantity of hot water (250 cc. of water to 5 g. of tenulin), then evaporate the resulting liquid under reduced pressure, and remove the crystals from time to time. When pure material thus prepared was allowed to dry in the air, it melted at 193–195° and analyzed for a compound with the composition $C_{17}H_{22}O_5$.

(4) Highly colored material was purified as follows. A solution of 10 g. of substance in 10 cc. of boiling *n*-butanol was diluted with 80 cc. of benzene and allowed to crystallize. This removed much of the color, and it could then be recrystallized from water.

When pure and recrystallized from water, tenulin consists of six-sided plates, frequently forming clusters which break into angular fragments. It melts at 193–195°. Its indices of refraction, determined by the immersion method, are: η_α, 1.525; η_β, 1.565; η_γ, 1.585; all ± 0.003. All the indices are readily found. The birefringence is extremely strong, and the polarization colors are brilliant. In convergent polarized light (crossed nicols) partial biaxial figures are seen on many of the plates. The optic axis is perpendicular to many of them. The acute bisectrix was difficult to obtain; therefore, a determination of the axial angle could not be made.[5]

Tenulin is optically active; 115.46 mg. dissolved in 2.28 cc. of ethanol ($C = 5.2$) at 20° rotated the plane of polarized light in a 96-mm. tube 1.1° to the left; $[\alpha]^{20}D$ is −21.6°. 4.74 mg. of tenulin dissolved in 49.95 mg. of camphor; Δ, 11.75°. This corresponds to a molecular weight of 323.

Anal. Calcd. for $C_{17}H_{22}O_5$: C, 66.65; H, 7.27; mol. wt., 306.4. Found: C, 66.52; H, 7.51; mol. wt., 323. Recrystallized from *n*-butanol and *n*-butyl ether, m. p. 191. Found: C, 66.61; H, 7.47.

Dihydrotenulin.—One gram of tenulin dissolved in 50 cc. of ethyl acetate was reduced at atmospheric pressure with hydrogen and the platinum catalyst of Voorhees and Adams.[6] One mole of hydrogen was absorbed. The catalyst was removed and the solution evaporated to 5 cc. To this 10 cc. of benzene was added. There was obtained 0.9 g. of colorless crystals, which sintered at about 160°, with the evolution of benzene (benzene of crystallization). The material finally melted at 180°.

This was recrystallized from its solution in 10 cc. of methanol upon the addition of three volumes of hot water. Thus obtained, it consisted of short, thick rods, which melted at 182°. The rods appeared to contain solvent of crystallization, for upon exposure to the air for some time the crystals became broken and had an effloresced appearance. It then melted at 172°. The material in this condition was analyzed.

Anal. Calcd. for $C_{17}H_{24}O_5$: C, 66.21; H, 7.84. Found: C, 66.05; H, 7.83.

Dihydrotenulin Phenylhydrazone.—An ethanolic solution of 0.1 g. of dihydrotenulin, 0.1 g. of phenylhydrazine, and 2 drops of acetic acid was diluted with sufficient water to produce cloudiness. A drop of ethanol was then added to clarify the liquid. Upon standing for a few minutes colorless rods, m. p. 238–240°, separated. These were recrystallized from their methanolic solution upon the addition of water. The purified material consisted of long, thin, square-ended rods, which melted and flowed with decomposition at 248°.

Anal. Calcd. for $C_{23}H_{30}O_4N_2$: N, 7.03. Found: N, 6.96.

Dibromotenulin.—An ethyl acetate solution of 0.5 g. of tenulin was treated portionwise with 0.26 g. of bromine (2 atoms) dissolved in ethyl acetate. The reaction was rapid, and when it was complete the ethyl acetate was removed by distillation under reduced pressure. The residue was dissolved from the flask with 10 cc. of methanol and poured into 200 cc. of water. The white amorphous precipitate was removed and air-dried. The yield was 0.75 g. The reaction was entirely addition, as no hydrobromic acid was formed.

(5) The optical data recorded in this communication were determined by George L. Keenan, of the Food and Drug Administration of the U. S. Department of Agriculture.

(6) Voorhees and Adams, THIS JOURNAL, **44**, 1397 (1922).

The material was crystallized from its solution in the necessary quantity of boiling methanol by adding 0.5 volume of hot water. It separated as rosets of fine colorless needles and melted with decomposition at 124–125°. Further recrystallization did not change its melting point.

Anal. Calcd. for $C_{17}H_{22}O_5Br_2$: Br, 34.3. Found: Br, 34.1.

Monobromotenulin.—After standing for two to three days, the mother liquors from recrystallizing dibromotenulin became acid to congo red and deposited a white material. This was separated and dissolved in hot methanol. The solution was filtered and then crystallized by adding an equal volume of hot water. Thin, colorless, rectangular plates, melting at 198–199°, were obtained. When recrystallized from dilute methanol, it melted with decomposition at 202–203°.

Anal. Calcd. for $C_{17}H_{21}O_5Br$: Br, 20.7. Found: Br, 20.3.

Anhydrotenulin.—A test-tube containing 0.5 g. of tenulin was placed in a small bath of fused sodium and potassium nitrates at 300°. The tenulin melted with the evolution of gas. By the time the bath had cooled to 275° the reaction was complete, and a golden-colored melt resulted. This was dissolved in 2 cc. of boiling methanol, and an equal volume of water was added. Crystallization began at once and yielded 0.35 g. of crystals which melted at 163°. These were dissolved in methanol, and the filtered solution was crystallized by adding an equal volume of water. The product consisted of colorless crystals which melted at 172°.

Anal. Calcd. for $C_{17}H_{20}O_4$: C, 70.81; H, 6.99; mol. wt., 288.3. Found: C, 71.03; H, 7.09; mol. wt., 294.

Action of Acetic Anhydride and Sodium Acetate upon Tenulin.—A mixture of 2 g. of tenulin, 15 cc. of acetic anhydride, and 0.5 g. of dry sodium acetate was boiled for one hour. Most of the excess anhydride was removed by distillation, and the residue was treated with water. After standing for some time, with occasional stirring, the resulting oil was dissolved in methanol. Crystallization began at once. There was obtained 0.6 g. of material which melted at 230°. It was recrystallized from boiling butanol and when pure melted at 240°.

Anal. Calcd. for $C_{22}H_{26}O_5$: C, 71.33; H, 7.08; mol. wt. 370.4; $C_{22}H_{28}O_5$: C, 70.94; H, 7.58; mol. wt. 372.4. Found: C, 71.21, 71.18; H, 7.27, 7.18; mol. wt. (Rast), 355; acetyl was negative.

Isotenulin.—One gram of finely powdered tenulin in a mortar was triturated for three minutes with 50 cc. of 0.1 *N* sodium hydroxide. The mixture was then acidified with sulfuric acid, and a crystalline material with a melting point of 158° was obtained. The yield was 0.75 g.

It was recrystallized from its solution in the necessary quantity of *n*-butanol by adding four volumes of *n*-butyl ether. The product consisted of long colorless rods, which melted at 162°. Its indices of refraction are: η_α 1.519; η_β not determined, only faint interference figures were observed: η_γ 1.555, both ± 0.003. η_α is shown lengthwise, and η_γ is shown crosswise on the rods. In parallel polarized light (crossed nicols) the polarization colors are brilliant, the extinction is parallel, and the elongation is negative. In convergent polarized light (crossed nicols) only faint biaxial figures showing the acute bisectrix are observed. Apparently 2E is large.

Anal. Calcd. for $C_{17}H_{22}O_5$: C, 66.65; H, 7.24. Found: C, 66.81; H, 7.37.

When finely powdered tenulin was triturated for fifteen minutes with 5% sodium carbonate solution and then filtered, almost pure isotenulin, m. p. 162°, was obtained.

A solution of 0.5 g. of tenulin dissolved in 80 cc. of water was boiled for two minutes with 0.5 g. of norit. Upon cooling, isotenulin separated as colorless needles, m. p. 160–161°. The identity of the material was established by comparing it with an authentic sample made by the action of sodium carbonate upon tenulin. There was no depression of the melting point. Since norit suspended in water imparts to the latter an alkaline reaction, *p*H 7.5, it was assumed that the alkali was the cause of the transformation. This was proved to be the case, since an aqueous solution of tenulin acidified with acetic acid and then treated with norit failed to isomerize.

Still another procedure which yielded isotenulin is the following. To a solution of 0.5 g. of tenulin dissolved in 2 cc. of boiling methanol was added 10 cc. of hot water. Immediately 1 cc. of 1% sodium hydroxide solution was added. The turbid liquid was stirred for three minutes, during which time crystallization occurred. It was then acidified and allowed to stand for a few minutes, and the crystals, m. p. 157°, were removed. The yield was 0.37 g.

The Substance, m. p. 255°, Obtained by the Action of Alkali upon Tenulin.—When finely powdered tenulin is triturated occasionally during twenty-four hours with a 5% sodium carbonate solution, isotenulin is the main product of the reaction, but another substance also is formed. One gram of tenulin thus treated yielded 0.7 g. of yellow crystals, which melted unsharply at 155°. These were suspended in 5 cc. of hot methanol, and the mixture was then cooled and filtered. There was obtained 0.1 g. of a substance which melted at 241° and cleared at 246°. This was recrystallized to constant melting point from *n*-butanol. It consisted of short, thick, colorless rhombs, which melted at 255°. Analysis showed that the material had the composition $C_{15}H_{20}O_4$.

Anal. Calcd. for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63. Found: C, 68.08; H, 7.69.

Upon dilution with three volumes of water, the methanolic mother liquors from which the foregoing substance was obtained gave light yellow isotenulin, m. p. 160°.

The material that melted at 255° is also formed when finely powdered tenulin is triturated occasionally with 0.1 *N* sodium hydroxide for one and one-half hours. The yield is essentially the same as that obtained with sodium carbonate, but no isotenulin could be obtained by this procedure.

Dihydroisotenulin.—This compound was prepared in the same manner as dihydrotenulin. The ethyl acetate solution was evaporated to dryness, dissolved in methanol, and crystallized by adding water. The crude material had a melting point of 150°. It was recrystallized from its methanolic solution by adding two volumes of boiling water. It separated as thick, colorless prisms, many of which were rhombs. Its melting point was 151°.

Anal. Calcd. for $C_{17}H_{24}O_5$: C, 66.21; H, 7.84. Found: C, 66.30; H, 8.07.

Dihydroisotenulin Phenylhydrazone.—This material was prepared by the same procedure as dihydrotenulin phenylhydrazone. When recrystallized by adding water to its methanolic solution, it melted at 219–220°.

Anal. Calcd. for $C_{23}H_{30}O_4N_2$: N, 7.03. Found: N, 7.00.

Dibromoisotenulin.—This compound was made in the same manner as dibromotenulin, and also by the procedure given by Buehler and co-workers.[3] In each case the material was purified by dissolving it in the necessary quantity of boiling methanol and adding 0.5 volume of hot water. It separated as dense, irregular-shaped prisms tending to be octahedra. It melted at 135° with decomposition.

Anal. Calcd. for $C_{17}H_{22}O_5Br_2$: Br, 34.3. Found: Br, 34.2.

Monobromoisotenulin.—Dibromoisotenulin was boiled for three minutes in a 5% methanolic solution of potassium acetate. The liquid was then diluted with three volumes of water and allowed to crystallize. The yield was quantitative, and the product was quite pure. By dissolving it in the necessary quantity of boiling methanol and adding three volumes of hot water, it was brought to a constant melting point of 213° with decomposition.

Anal. Calcd. for $C_{17}H_{21}O_5Br$: Br, 20.7. Found: Br, 21.3.

The Substance $C_{16}H_{22}O_5$ Found in One Shipment of Helenium tenuifolium.—In one shipment of *H. tenuifolium* obtained in 1936 it was difficult to obtain tenulin. The material obtained after the extract had stood for a long time gave roughly 60% of tenulin and 40% of another compound relatively insoluble in ethanol. Because of this property the unknown compound was readily separated from tenulin and purified by recrystallization from boiling ethanol. It consisted of long, thin, fluffy colorless rods, which melted at 233–234°. An alkoxyl determination gave a value corresponding to 3.85% of methoxyl.

Anal. Calcd. for $C_{16}H_{22}O_5$: C, 65.29; H, 7.55. Found: C, 65.22, 65.36; H, 7.58, 7.55.

Dihydro Derivative of $C_{16}H_{22}O_5$.—One gram of the C_{16} compound was suspended in ethyl acetate and hydrogenated as was tenulin. The suspension gradually disappeared, and when the reaction was completed one mole of hydrogen was consumed. The filtered solution was concentrated and crystallized. The material separated as colorless rods with a melting point of 192°. Recrystallization from boiling ethyl acetate did not change the melting point.

Anal. Calcd. for $C_{16}H_{24}O_5$: C, 64.84; H, 8.16. Found: C, 64.78; H, 8.11.

Acetyl Derivatives of the Substance $C_{16}H_{22}O_5$.—(1) A mixture of 1 g. of the C_{16} compound, 0.25 g. of dry sodium acetate, and 4 cc. of acetic anhydride was boiled for one hour. Most of the excess anhydride was then removed by distillation, and the residue was treated with water. After being stirred for some time, a semicrystalline material separated. This was dissolved in methanol and crystallized by adding water. The yield was 0.7 g. of a substance which melted at about 150°. Upon repeated recrystallization from 50% methanol the substance melted at 163°.

Anal. Calcd. for $C_{18}H_{24}O_6$: C, 64.27; H, 7.19; acetyl, 12.8. Found: C, 64.17; H, 7.30; acetyl, 10.9.

(2) When a solution of 0.5 g. of the new material in 3 cc. of pyridine and 2 cc. of acetic anhydride was allowed to stand overnight and then treated with water, crystallization occurred at once. Six-tenths gram of thick prisms, m. p. 193°, was obtained. Recrystallization of this material from its methanolic solution by adding 4 volumes of water did not change the melting point. The product consisted of thick colorless prisms many of which were hexagonal.

Anal. Found: C, 64.28; H, 7.32; acetyl, 10.8.

Summary

Helenium macrocephalum has been found to contain helenalin. *Helenium tenuifolium*, *H. elegans* and *H. badium* contain a hitherto unrecorded compound, $C_{17}H_{22}O_5$, which has been designated tenulin. Some derivatives of tenulin have been prepared which suffice to establish definitely the molecular formula given for tenulin and at the same time show that the compound obtained from *H. tenuifolium* and reported by Buehler, Whitehead, and Goodge is isotenulin. In one lot of *H. tenuifolium*, another new substance, $C_{16}H_{22}O_5$, was isolated. Several derivatives of this material have been prepared.

A diagram showing the relation between the various compounds and their origin is presented.

The Apparent Shape of Protein Molecules[1]

BY HANS NEURATH

It has been recognized for some time that the term *globular proteins* does not necessarily imply spherical shape. Measurements of the double refraction of flow,[2-5] dielectric dispersion,[6,7] and viscosity[8-11] of protein solutions have in many instances proved that protein molecules may be unsymmetric. Whether a protein molecule is spherical may also be determined from combined sedimentation and diffusion measurements, as Svedberg[12] showed many years ago. The application of Svedberg's theory to the calculation of the relative dimensions of a number of representative protein molecules was described by us on a previous occasion, incidental to a discussion of the diffusion of proteins.[10]

In the present paper, further studies are reported on the *relative* and *absolute* dimensions of protein molecules and their respective dissociation and aggregation products. After a brief outline of the theory and its implications and limitations, the results are presented, and discussed from the general viewpoint of protein structure.

Theoretical

Svedberg[12,13] has introduced the term *dissymmetry constant* as an indirect measure for the deviations of molecules from spherical shape. The ratio f/f_0, where f is the measured molar frictional coefficient, and f_0 the theoretical molar frictional coefficient for a spherical molecule of the same molecular weight, ought to be unity for spherical molecules, and greater than unity for elongated molecules. The dissymmetry constant is related to the sedimentation constant, s, the molecular weight, M, the diffusion constant, D, the partial specific volume of the solute, V, and the density of the solution, ρ, according to equation (1).

$$f/f_0 = \frac{M(1 - V\rho)/s}{6\pi\eta N(3MV/4\pi N)^{1/3}} \qquad (1)$$

From the way in which this equation was derived it follows that, in the ideal case, f/f_0 must be identical with the ratio D_0/D, where D is the observed diffusion constant, and D_0 the diffusion constant of a spherical molecule of the same molecular weight. Hence, f/f_0 may be calculated merely from the molecular weight, the partial specific volume, and the observed diffusion constant, according to equation (2)

$$f/f_0 = \frac{kT}{6\pi\eta N(3MV/4\pi N)^{1/3}}\frac{1}{D} \qquad (2)$$

where k is the Boltzmann constant, η, the viscosity of the solvent, and N, the Avogadro number.

The strict validity of equations (1) and (2) requires the use of such dilute solutions that interactions between solute molecules become negligible. While this requirement may be fulfilled by sedimentation measurements, diffusion measurements necessarily have to be confined to more concentrated solutions. It is only when the experimentally determined value for f, calculated from either sedimentation equilibrium or diffusion measurements, is found to be independent of the protein concentration, that an unambiguous value may be ascribed to f/f_0.[14]

Difficulties also arise in assigning a true value to f_0. It is known that molecular weight data may be in error by as much as 10%. Although the molecular weight enters into the calculation of f_0 only as the cube root, yet small variations in f/f_0 may result in significant variations in shape factors calculated therefrom.

Another source of uncertainty in the calculation of shape factors relates to the influence of hydration.[16,17] While the theoretical molar frictional coefficient, f_0, is calculated from the molecular weight and partial specific volume of the unhy-

(14) Lamm and Polson,[15] for instance, reported an increase of the diffusion constants of egg albumin, hemoglobin and serum albumin in dilute protein solutions. In the case of egg albumin, serum albumin, insulin and pepsin, for instance, the molar frictional coefficient calculated from diffusion, f_d, differs from that calculated from sedimentation, f_s, by about 10 p. c., whereas equation (1) assumes equality of f_d and f_s.

drated molecule, the measured molar frictional coefficient, f, is determined by the hydrated molecule of higher partial specific volume, and molecular weight. If deviations of the dissymmetry constant from unity were to be ascribed exclusively to effects of hydration, a value of $f/f_0 = 1.1$ would correspond to $V = 0.82$ (assuming 20% hydration), whereas higher values of f/f_0 would result in V greater than unity. While it cannot be denied that the influence of hydration would tend to decrease the apparent dissymmetry constant to some extent, it is evident that hydration cannot account for values of f/f_0 greater than 1.1, even if the high values for the partial specific volume and hydration, suggested by Adair and Adair,[16] are used. As an approximation, we have assumed in this paper that the influence of hydration on dissymmetry constants is of second order. Specifically, the dissymmetry constants have been related to the apparent shape of the *unhydrated* protein molecules.

A quantitative relation between the relative dimensions of proteins and the dissymmetry constant may be obtained by combination of equation (2) with Perrin's[18] equation for the linear diffusion of ellipsoidal molecules. This equation, derived from hydrodynamic considerations, relates the ratio of the short to long axis of a prolate ellipsoid of revolution, a/b, to the ratio of the diffusion constants, D/D_0.[19]

$$\frac{D}{D_0} = \frac{(a/b)^{2/3}}{\sqrt{1-(a/b)^2}} \ln \frac{1+\sqrt{1-(a/b)^2}}{a/b} \quad (3)$$

The absolute values of the length of the short and long axis, a and b, may be estimated by combining equation (3) with the equation for the volume of a prolate ellipsoid of revolution. If M is the molecular weight, V the partial specific volume of the protein, and N the Avogadro number, then

$$MV = a^2 b \pi N/6 \quad (4)$$

It has to be emphasized that the results of such calculations may be subject to considerable error. The true values of b/a depend on the effective shape of the molecules, on the nature of their surface, and on the extent of interaction between solute and solvent. If the surface of the solute molecules is irregular and if there is marked interaction between solute and solvent (hydration), there will be, in addition to the frictional resistance due to the molecular shape, a frictional resistance produced by the surface of the molecules. Perrin's equation is for the specific case of a molecule having the shape of a prolate ellipsoid of revolution and devoid of any interaction with the solvent.

Further uncertainties are due to the fact that the dissymmetry constants recorded in the literature are exact only to one significant place, whereas variations in the second significant place may produce marked changes in the absolute dimensions, b and a. The true values of these constants are, in addition, largely dependent on the exact molecular shape. Thus, if one assumes as effective shape a cylinder, for instance, the short axis of the molecule would be one-third shorter than that of an ellipsoid of revolution of equal length. As, however, the shape of an ellipsoid of revolution is used for the calculation of the *relative* dimensions, the use of the same model for calculating the *absolute* dimensions will most likely give the best results.

Calculations

In spite of these theoretical uncertainties, we have calculated the relative and absolute dimensions of a large number of proteins, with equations (2), (3), and (4). It was felt that sufficient evidence has accumulated by other experimental methods for the belief that a physical meaning may be ascribed to the great variations in the observed dissymmetry constants. The limits of the error involved in these calculations may be appreciated by considering the assumptions discussed in the preceding paragraphs. Most of the calculations have been based on the values for the dissymmetry constants tabulated by Svedberg.[20] In some instances these have been recalculated from values for the molecular weight and diffusion constant. Where marked discrepancies between our and Svedberg's values have been found, both values have been listed (see Table II). For convenience, $V = 0.75$ has been assumed throughout the calculations.

In Table I, values for f/f_0, b/a, b, and a, are given. Unless stated otherwise, they have been calculated from f_d, and from the molecular weight as determined by diffusion and sedimentation velocity measurements. For reasons to be mentioned in the discussion, the proteins have been arranged according to increasing values of the short diameter of the molecule, a. In Table II the corre-

(18) Perrin, *J. phys. Radium*, **7**, 1 (1936).

(19) A similar relation exists for flat ellipsoids of revolution, but in all probability such a model has no significance for considerations of protein molecules.

[a] Unless otherwise stated, the values on which these calculations are based have been taken from Svedberg's tables.[17]

[b] Calculated from sedimentation equilibrium values.

Discussion

It is striking that, with a few exceptions, protein molecules are not spherical, and most exhibit high molecular dissymmetry.

Also it is well known that the apparent shape of macromolecules frequently reflects in some manner their stereo-chemical structure. If proteins are considered to consist of polypeptide chains, folded or fully extended, the long diameter of the molecule may be thought of as being determined by the length of the chains, whereas the short diameter would reflect the number of chains within the molecule. Led by such considerations, we have arranged, in Table I, the proteins according to their absolute dimensions. The length of the short diameter has been chosen as the criterion for our classification. It is interesting to note that proteins which belong to different groups as regards their molecular weight become members of the same group if arranged in this manner. Thus, cytochrome C, gliadin, and erythrocruorin (*Chironimus*), with the molecular weights of 15,600, 26,000 and 31,400, respectively, are found to have a common short diameter of about 18 Å. Likewise proteins of molecular weight 35,000, 96,000, 248,000 and 920,000, respectively, fall into one group. Although the calculated absolute dimensions may be subject to considerable error, we feel that their value for comparative purposes is unquestionable.

TABLE II

APPROXIMATE RELATIVE AND ABSOLUTE DIMENSIONS OF PROTEINS AND THEIR RESPECTIVE DISSOCIATION AND AGGREGATION COMPONENTS

M = molecular weight. f/f_0 = dissymmetry constant. a = short diameter of molecule. b = long diameter of molecule. The arrows indicate the direction of cleavage: → parallel to long axis; ↓ parallel to short axis.

The importance of such considerations becomes even more apparent if the dimensions of protein are compared with those of their respective dissociation and aggregation components.[26] From Table II it may be seen that dissociation of phycocyan (*Ceramium*) for instance, affects only the length of the short axis, when the molecular weight is halved. Similarly, dissociation of hemocyanin (*Eledone*) only decreases the short axis when the molecular weight drops from 2,790,000 to 457,000. Such data immediately suggest that these molecules split in the direction parallel to the major molecular axis. In other cases, only the major axis is shortened during dissociation indicating that splitting takes place at right angles to the major axis. In Table II, the apparent direction of splitting is indicated by arrows, a horizontal arrow indicating cleavage along the major axis, and a vertical arrow cleavage along the minor axis.[27]

Comparison of the absolute dimensions of the anti-pneumococcus serum globulins indicates a similar relationship. These proteins seem to differ chiefly in respect to the length of the molecule, if the species from rabbit, man, and horse are compared with each other (Table I). An exact interpretation of the molecular dimensions in terms of chemical configuration would be premature at present. Only in a few isolated cases, such as zein,[7] or hemoglobin,[29] has yet a satisfactory agreement between the shape factors determined by different independent methods been established. Further experimental work is needed before the values recorded in Tables I and II can be accepted as exact values.

The work of Astbury[30] and of Bergmann and Niemann[31] has furnished much evidence for the hypothesis that the difference between fibrous and globular proteins is merely a quantitative one. The data presented in this paper likewise illustrate the fibrous character of the globular proteins, thus lending support to the theory that both types of proteins are structurally closely related.

(26) Here the influence of hydration is most likely the same for the undissociated protein and its respective dissociation products.

(27) In the case of the dissociation of hemoglobin by urea, this regularity does not seem to hold exactly. It appears from such considerations, as well as from others,[28] that the value for the dissymmetry constant of this protein is somewhat too low.

(28) Neurath, *Symposia Quant. Biol.*, **6**, 23 (1938).

Summary

A method for the estimation of the relative and absolute dimensions of protein molecules from the dissymmetry constant and Perrin's diffusion equation is outlined and its limitations discussed. The data indicate that most proteins are unsymmetric in shape. A certain regularity exists, independent of the molecular weight, when proteins are grouped on the basis of their molecular dimensions. Comparison of the dimensions of proteins with those of their respective dissociation and aggregation products indicates that cleavage occurs only in directions parallel to either the major or minor molecular axis.

The Hydroxylation of Unsaturated Substances. V. The Catalytic Hydroxylation of Certain Unsaturated Substances with Functional Groups

BY NICHOLAS A. MILAS, SIDNEY SUSSMAN AND HOWARD S. MASON

Further application of the recent hydroxylation method developed in this Laboratory[1] has led to the production of a number of useful products which hitherto have been rather difficult to procure in satisfactory yields. Of particular interest along this line is the production of glycolaldehyde from divinyl ether in yields as high as 96%. Furthermore, it has been found possible to add hydroxyl groups to substances containing double bonds adjacent to carbonyl groups. Böeseken,[2] for example, has found that ethyl fumarate and ethyl maleate were not appreciably oxidized with perbenzoic acid, and in the case of unsaturated ketones having the same arrangement of groups he reports[3] oxidation of the ketones without the formation of epoxy derivatives but with cleavage

(1) Milas and Sussman, THIS JOURNAL, **58**, 1302 (1936); **59**, 2345 (1937).

(2) Böeseken, *Rec. trav. chim.*, **45**, 838 (1926).

(3) Böeseken and co-workers, *ibid.*, **50**, 827 (1931); **52**, 874 (1933); **55**, 786 (1936).

of the carbon–carbon bond next to the double bond or the carbonyl group. Table I summarizes some of the results obtained in the present investigation.

TABLE I

SUMMARY OF HYDROXYLATION EXPERIMENTS

Olefinic substance	Main product	% yield
Ethyl crotonate	Ethyl dihydroxybutyrate	56
Diethyl maleate	Diethyl mesotartrate	41
Diethyl fumarate	Diethyl racemate	58
Mesityl oxide	2-Methylpentanediol-2,3-one-4	23
Vinyl acetate	Glycolaldehyde	60
Divinyl ether	Glycolaldehyde	96.0
Vinyl bromide	Glycolaldehyde	12.5(?)
Oleic acid	9,10-Dihydroxystearic acid	60
Cinnamyl alcohol	β-Phenylglycerol	12.2
	Di-[β-phenylglycerol] ether	4.5

In the case of the vinyl compounds it was not found possible to isolate the corresponding glycols since these rearranged spontaneously to yield glycolaldehyde. With cinnamyl alcohol the greater portion of the β-phenylglycerol formed was further oxidized to benzaldehyde and glycolaldehyde, both of which were isolated.

Experimental

Ethyl Dihydroxybutyrate from Ethyl Crotonate.—Ethyl crotonate was prepared in accordance with the method of Michael[4] and was purified by fractionation under reduced pressure; b. p. 43–45° (17 mm.). To 8.55 g. (0.075 mole) of this ester was added 42.9 cc. (0.075 mole) of 5.95% hydrogen peroxide reagent[1] in *t*-butyl alcohol, the solution cooled to 0° and to it added 1 cc. of osmium tetroxide solution likewise in *t*-butyl alcohol. The reaction was complete in three days at 0° when the solvent was removed by distillation at the temperature of the water-bath and the residue fractionated under reduced pressure. The fraction boiling at 123–125° (18 mm.) was collected and found to have the following properties. Unlike the ethyl crotonate, it was completely soluble in water and had a neutralization equivalent of 146 as compared with 148 for ethyl dihydroxybutyrate. A yield of 56% was obtained based on the amount of ethyl crotonate used.

Diethyl Mesotartrate from Diethyl Maleate.—Eight and six-tenths grams (0.05 mole) of diethyl maleate (Eastman Kodak Company) was dissolved in 28.6 cc. (0.05 mole) of a 5.95% solution of the hydrogen peroxide reagent, the solution cooled to 0° and to it added 1.5 cc. of the osmium tetroxide catalyst, but since no noticeable reaction occurred after four days at this temperature, the mixture was allowed to come to room temperature, at which the reaction was completed at the end of two days. The solvent was then removed by distillation and the residue fractionated under reduced pressure and the fraction boiling at 162–166° (18 mm.) collected. Kuhn and Wagner-Jauregg[5] reported a b. p. for diethyl mesotartrate of 157.5° (14 mm.) and a m. p. of 55°. Our compound was a highly viscous liquid which when crystallized from ether had a m. p. of 53.5–55°. A neutralization equivalent gave a value of 107 as against 103 calculated for diethyl mesotartrate. A yield of 41% was obtained based on the amount of diethyl maleate consumed.

Diethyl Racemate from Diethyl Fumarate.—Eight and six-tenths grams of diethyl fumarate (Eastman Kodak Company) was dissolved in 28.6 cc. of a 5.95% solution of hydrogen peroxide reagent, the solution cooled to 0° and to it added 1.5 cc. of the osmium tetroxide reagent. As in the case of diethyl maleate the reaction mixture was brought, after four days at 0°, to room temperature, at which it was found to be complete at the end of one day. The solvent was then removed by distillation, the residue fractionated under reduced pressure and the fraction boiling at 163–167° (21 mm.) was collected. Anschuetz and Pictet[6] reported a b. p. of 162° (19 mm.) for diethyl *d*-tartrate and Perkin[7] has shown that the b. p. of this ester is identical with that of diethyl racemate. Attempts to crystallize this ester were unsuccessful. The saponification equivalent was found to be 106 as against 103 calculated for diethyl racemate. The yield of diethyl racemate was 58% based on the amount of diethyl fumarate used.

2-Methylpentanediol-2,3-one-4 from Mesityl Oxide.—To 9.8 g. (0.1 mole) of mesityl oxide (Eastman Kodak Company) was added 57.2 cc. (0.1 mole) of a 5.95% solution of hydrogen peroxide reagent, the solution cooled to 0° and to it added 0.5 cc. of the osmium tetroxide catalyst. After two days at 0° the reaction was complete, the solvent distilled, the residue fractionated under reduced pressure and the fraction boiling at 104–110° (16 mm.) collected. Harries and Pappos[8] reported a b. p. of 109° (19 mm.) for 2-methylpentanediol-2,3-one-4. Our product was found to reduce Fehling's solution instantly in the cold.

This glycol has not been characterized fully and in order to characterize it, the *p*-nitrophenylosazone was prepared by allowing it to react, at the temperature of the water-bath, with *p*-nitrophenylhydrazine in dilute acetic acid. The dark red precipitate obtained from this reaction was recrystallized several times from pyridine; m. p. 251–253°, with decomposition. This substance was analyzed for nitrogen.

Anal. Calcd. for $C_{18}H_{20}O_5N_6$: N, 21.00. Found: N, 20.87.

A yield of 23% was obtained based on the amount of mesityl oxide consumed.

Glycolaldehyde from Vinyl Acetate.—The vinyl acetate (Eastman Kodak Company) used was fractionated just before the experiments through a Vigreux column and the fraction boiling at 72.5–73° collected. To 17.7 g. of this substance was added 110 cc. of 6.23% hydrogen peroxide reagent, the mixture cooled to 0° and to it added 1 cc. of the osmium tetroxide catalyst. After five days at 0° the reaction mixture turned brown and the peroxide had disappeared completely. The mixture was then distilled to remove the solvent and the unconverted vinyl acetate and the residue fractionated under reduced pressure and the fraction boiling at 90–98° (4.5 mm.) collected and examined for glycolaldehyde. Fischer and Feldmann[9]

(4) Michael, *Ber.*, **33**, 3766 (1900).
(5) Kuhn and Wagner-Jauregg, *ibid.*, **61**, 485 (1928).
(6) Anschuetz and Pictet, *ibid.*, **13**, 1177 (1880).
(7) Perkin, *J. Chem. Soc.*, **51**, 364 (1887).
(8) Harries and Pappos, *Ber.*, **34**, 2979 (1901).
(9) Fischer and Feldmann, *Ber.*, **62**, 854 (1929).

reported a b. p. of 110–120° (12 mm.) for glycolaldehyde. Our product reduced Fehling's solution in the cold and with *p*-nitrophenylhydrazine formed an osazone which on recrystallization from pyridine had a m. p. of 306–307°. A m. p. of 308.5° is recorded in the literature[10] for this substance. Mixed m. p. with an authentic sample gave a m. p. of 306.5°. A yield of 60% of glycolaldehyde was obtained based on the amount of vinyl acetate consumed. Identical yields were obtained when the reaction was run with larger quantities: 86 g. of vinyl acetate and 630 cc. of the peroxide reagent.

In this reaction, the glycolaldehyde is formed as the result of a rearrangement of the initial glycol in accordance with the equation

$$CH_2{=}CHOAc + HOOH \xrightarrow{OsO_4} CH_2(OH){-}CH(OH){-}OAc \longrightarrow CH_2(OH){-}C(=O){-}H + AcOH$$

and may serve as a general reaction for the preparation of α-hydroxy aldehydes

$$RCH{=}CHOAc \xrightarrow{HOOH} RCH(OH){-}C(=O){-}H + AcOH$$

Glycolaldehyde from Divinyl Ether.—The divinyl ether used in this work was kindly supplied by Merck and Co. through the courtesy of Dr. R. T. Major. It was fractionated through a Davis column and the fraction boiling at 28.3° collected and used in our experiments.

To 3.5 g. of divinyl ether was added 60 cc. of 6.23% hydrogen peroxide reagent, the mixture cooled to 0° and to it added 0.5 cc. of the osmium tetroxide catalyst. The mixture warmed up considerably so that the flask had to be connected to a reflux condenser and thence to a trap immersed in solid carbon dioxide so that any volatile products could be condensed and isolated. At the end of three days the reaction was over and the mixture fractionated to remove the unconverted ether as well as the acetaldehyde which was formed almost in equal quantities with glycolaldehyde showing that only one of the double bonds hydroxylated and the product thus formed rearranged spontaneously. In the low boiling fractions the acetaldehyde was estimated by preparing its *p*-nitrophenylhydrazone, whereas in the residue the glycolaldehyde was estimated by precipitating its *p*-nitrophenylosazone. On recrystallization from pyridine, the latter had a m. p. of 306.5–307°. A yield of 96% of glycolaldehyde was obtained based on the amount of divinyl ether reacted.

Glycolaldehyde from Vinyl Bromide.—Vinyl bromide was prepared from ethylene dibromide and alcoholic potash,[11] b. p. 16°.

To 10.7 g. of freshly prepared vinyl bromide was added 64 cc. of 5.27% hydrogen peroxide reagent, the mixture cooled to 0° and to it added 2 cc. of the osmium tetroxide catalyst and 10 g. of finely powdered calcium carbonate to take up the hydrogen bromide evolved during the reaction. The mixture was allowed to stand in an ice-box at 5–10° for twenty-four days, then worked up for the presence of glycolaldehyde; a yield of 12.5% of this aldehyde was obtained.

9,10-Dihydroxystearic Acid from Oleic Acid.—Seven grams of oleic acid, b. p. 230–235 (21 mm.), was mixed with 14.3 cc. of 5.95% solution of the hydrogen peroxide reagent, the mixture cooled to 0° and to it added 0.5 cc. of the osmium tetroxide catalyst; the solution became orange and after standing overnight at this temperature turned colorless and the reaction was complete. A considerable amount of the 9,10-dihydroxystearic acid had precipitated out. The solvent was removed under reduced pressure and the residue washed thoroughly with ether to remove the unconverted oleic acid and the crude solid recrystallized from absolute alcohol; m. p. 129–131° (corr.). Le Sueur[12] has reported a m. p. of 131–132° (corr.) for the high melting 9,10-dihydroxystearic acid. A neutralization equivalent was taken and found to be 319 as against 316 calculated for 9,10-dihydroxystearic acid. The yield obtained amounted to 60%.

Phenylglycerol from Cinnamyl Alcohol.—To 24.5 g. of cinnamyl alcohol (Eastman Kodak Company) was added 171 cc. of 5.43% hydrogen peroxide, the mixture stirred at 0° and to it added 2 cc. of the osmium tetroxide catalyst. If stirring were omitted in this experiment, it was not found possible to isolate phenylglycerol which, due to local heating, was rapidly oxidized to benzaldehyde and glycolaldehyde. The reaction was complete in four days, the solvent removed under reduced pressure, the highly viscous residue (26 g.) fractionated and the fraction coming over at 171° (1 mm.) failed to crystallize, but when treated with benzoyl chloride in pyridine it yielded chiefly a tribenzoate, m. p. 115.5–116°. The tribenzoate of β-phenylglycerol has been found by Prévost and Losson[13] to melt at 116.5°.

In the purification of the crude tribenzoate, a small amount of a product was found to be sparingly soluble in methanol. This was successively recrystallized from benzene, a 50–50 mixture of ethanol and methanol, and a 50–50 mixture of petroleum ether and benzene into fine white needles; m. p. 217°.

Anal. Calcd. for $C_{46}H_{38}O_9$: C, 75.20; H, 5.18. Found: C, 75.11; H, 5.24.

This analysis seems to agree very well with that calculated for the tetrabenzoate of a mono-ether of β-phenylglycerol. In view of the small quantities available no further work was done on this product.

The viscous residue from the original fractionation, after the volatile products and the β-phenylglycerol had been removed, was extracted several times with hot water and the hot aqueous extract decolorized with charcoal whereby a white crystalline product soluble in hot but sparingly soluble in cold water separated out. It was recrystallized several times from water; m. p. 155.5–156°. It is soluble in ethanol and glacial acetic acid but sparingly soluble in ether and chloroform.

Anal. Calcd. for $C_{18}H_{22}O_5$: C, 67.92; H, 6.91. Found: C, 67.36, 67.68; H, 6.86, 6.92.

A micromolecular weight determination in camphor gave a value of 345 as against 318 calculated for $C_{18}H_{22}O_5$, another mono-ether of β-phenylglycerol.

This product was then benzoylated in pyridine and the

(10) Milas, THIS JOURNAL, **53**, 231 (1931).
(11) Marderosian, B.S. Thesis, M. I. T., 1935.
(12) Le Sueur, *J. Chem. Soc.*, **79**, 1315 (1901).
(13) Prévost and Losson, *Compt. rend.*, **198**, 659 (1934).

benzoate recrystallized from a 50–50 mixture of petroleum ether and benzene; m. p. 118–119°. A mixed m. p. with the tribenzoate of β-phenylglycerol gave a m. p. of 104–106°, showing that the two are different.

Anal. Calcd. for $C_{46}H_{38}O_9$: C, 75.20; H, 5.18. Found: C, 75.52, 75.12; H, 4.99, 5.19.

Hydrolysis of this product gave back the mono-ether of β-phenylglycerol, m. p. 155.5–156°. It is therefore the tetrabenzoate of another mono-ether of β-phenylglycerol and is certainly different from the one obtained in small quantities from the distillate of the main reaction product.

The yield of the β-phenylglycerol amounted to about 12.2% while that of its mono-ethers amounted to about 4.5%. A considerable amount of the cinnamyl alcohol went over to a resin as well as benzaldehyde and glyceraldehyde, both of which were isolated.

Summary

1. The hydroxylation of certain unsaturated substances with functional groups using hydrogen peroxide in *t*-butyl alcohol and osmium tetroxide as the catalyst has led to the production of a number of useful glycols.

2. From ethyl crotonate, diethyl maleate, and diethyl fumarate, the corresponding hydroxylated esters were obtained in fairly good yields.

3. From mesityl oxide, 2-methylpentanediol-2,3-one-4 was obtained in about 23% yield.

4. From vinyl acetate, divinyl ether, and vinyl bromide, glycolaldehyde was obtained in yields of 60, 96, and 12.5%, respectively.

5. From oleic acid a yield of 60% of the high melting dihydroxy stearic acid was obtained.

6. From cinnamyl alcohol was obtained β-phenylglycerol and two different new mono ethers of this glycerol. The tetrabenzoates of the ethers were prepared and analyzed.

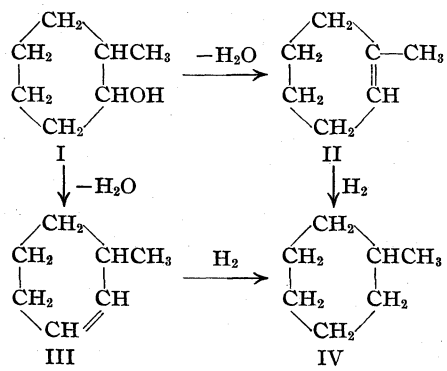
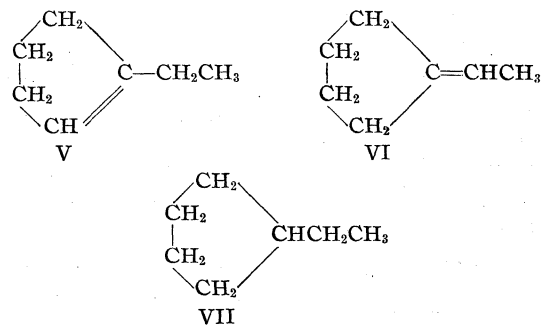
The Dehydration of *trans*-2-Methylcyclohexanol

BY CHARLES C. PRICE

It recently has been reported[1] that the dehydration of 2-methylcyclohexanol with phosphoric anhydride, followed by hydrogenation of the olefin thus obtained, yielded a methylcyclohexane differing in its physical properties from any previously reported. It was suggested that this material was a new isomer, arising from the non-planar nature of the cyclohexane ring. Since the properties reported for the cyclo-olefin and cycloparaffin closely resembled those of 1-ethyl-1-cyclopentene and ethylcyclopentane, respectively, and since ring contraction could conceivably occur during the dehydration, the olefin intermediate in the transformation of the alcohol to the cycloparaffin has been examined carefully.



(1) Vogel, *J. Chem. Soc.*, 1323 (1938).



An examination of Table I reveals the similarity in physical properties of the cycloölefin obtained by Vogel with the cycloölefins III and V, as well as the similarity between his cycloparaffin and VII.

The dehydrations of *trans*-2-methylcyclohexanol carried out in this Laboratory, however, using phosphoric anhydride at temperatures varying from 140 to 230°, always resulted in the formation of a mixture containing only compounds II and III. The mixtures contained 35 to 50% of II; the components could be separated by fractional distillation.

The structures of the cycloölefins were determined by oxidation of the crude mixture with aqueous potassium permanganate. The products isolated were ε-ketoheptanoic acid (as its semi-

TABLE I

PHYSICAL PROPERTIES OF THE VARIOUS HYDROCARBONS

	B. p., °C.	$n^{20}D$	d^{20}_4	$M^{20}D$ (found)	$M^{20}D$ (calcd.)

carbazone) from II and succinic acid[2] from III. In spite of careful examination, no oxidation products corresponding to V or VI could be detected. Ring contraction on dehydration must therefore be negligible, if it occurs at all.

It was found that 1-methyl-1-cyclohexene (II) was quite sensitive to exposure to air and moisture, its physical properties changing appreciably in a day or so even when the material was loosely stoppered. Over 10% of high boiling material was isolated from a sample of the pure olefin which had been standing in a glass-stoppered bottle for several months. The boiling point and index of refraction indicated that this material consisted chiefly of methylcyclohexanol and cyclohexylcyclohexene.

Considerable difficulty was encountered in attempting to hydrogenate the olefin mixture using Raney nickel or Adams platinum catalyst, even after repeated distillation.[3] Conversion to the saturated compound was readily accomplished, however, after the crude olefin had been distilled with alcohol, with which it forms an azeotropic mixture boiling at 70–72°. Removal of the catalyst poison in this manner yielded material which absorbed hydrogen readily to form methylcyclohexane identical in every respect with an authentic sample prepared from cyclohexanone by treatment with methylmagnesium chloride followed by dehydration and hydrogenation. The pure methylcyclohexane, moreover, showed no change in physical properties, even after standing a month.

Experimental

***trans*-2-Methylcyclohexanol (I).**—The material employed was a commercial grade. It was redistilled and the portion boiling from 164–166°, $n^{20}D$ 1.5625, was used. The unrecrystallized phenylurethan, prepared by treating the alcohol with phenyl isocyanate, had a melting point of 102–103°, indicating that the starting material must have consisted of more than 95% of the *trans*-isomer.[4]

Dehydration of I.—To 115 g. of the alcohol in a 500-cc. modified Claisen flask was added 60–80 g. of phosphoric anhydride rapidly and the flask immediately stoppered. The mixture boiled vigorously and considerable olefin distilled. After the initial vigorous reaction the mixture was heated gradually to 210–220°; 65–75 g. (68–78%) of olefin was obtained. In other experiments, the reaction mixture was kept cool during the addition of the phosphoric anhydride and then gradually heated. Olefin was evolved continuously at reaction mixture temperatures from 130–250°. The composition of olefin from different experiments and at different temperatures did not vary greatly, consisting of 35 to 50% II, the remainder being III. The percentage of the two constituents was determined by refractive index and density measurements as well as separation of the components by repeated fractional distillation. The purest sample of 3-methyl-1-cyclohexene (III) separated from this mixture by repeated fractional distillation had the following properties: b. p. 106–106.5°; $n^{20}D$ 1.4426; d^{20}_4 0.7986; $M^{20}D$ (found) 31.85; $M^{20}D$ (calcd.) 31.87.

A typical distillation of the crude olefin mixture gave fractions as follows.

B. p., °C.	Cc.	$n^{20}D$	d^{20}_4	$M^{20}D$
105–108	3.5	1.4448	0.8009	31.87
108–109	2.0	1.4458	.8033	31.85
109–110	3.5	1.4469	.8058	31.84
110–111	2.5	1.4480	.8063	31.86

Oxidation.—Ten grams of olefin mixture (40% II as determined by the index of refraction) was oxidized with 40 g. of potassium permanganate in 250 cc. of water at 0° for twenty-four hours with vigorous mechanical stirring. After filtration and ether extraction, 50 cc. of concentrated hydrochloric acid and 200–300 g. of ammonium sulfate were added. Ten extractions with 10–15 cc. portions of ether followed by evaporation of the ether left 8 g. of water-soluble acids as a yellow oil. On treatment with saturated semicarbazide solution this formed a precipitate of 2.5 g. (60%) of ε-ketoheptanoic acid semicarbazone, m.

(2) The primary oxidation product, α-methyladipic acid, has a tertiary hydrogen atom α to a carboxyl group. Such a structure is not stable toward alkaline potassium permanganate.

(3) Vogel also noted this difficulty in attempting to hydrogenate his cycloölefin.

(4) Vavon, Perlin and Horeau, *Bull. soc. chim.*, [4] **51**, 648 (1932).

p. 142–143°.[5] Extraction of this mother liquor with ether recovered 6 g. of the straw-yellow oil, the major portion of which crystallized. Dried on a clay plate, the crystalline material had the correct melting point (m. p. 183–185°) and neutral equivalent (neut. equiv. 62) for succinic acid.

Hydrogenation.—Five grams of olefin mixture (distilled with alcohol, washed with water to remove the alcohol and then fractionated, 30% II) was dissolved in 25 cc. of alcohol and 2–3 g. of Raney nickel added. Hydrogenation at three atmospheres pressure was complete in three or four hours. The product had the following properties: b. p. 101–101.5°; $n^{20}D$ 1.4230; d^{20}_4 0.7712; $M^{20}D$ (found) 32.36; $M^{20}D$ (calcd.) 32.34.

1-Methyl-1-cyclohexene (II).—This compound was obtained by dehydration of 1-methyl-1-cyclohexanol prepared from cyclohexanone and methylmagnesium chloride. Its properties agreed with those reported in the literature: b. p. 110–110.5°; $n^{20}D$ 1.4500; d^{20}_4 0.8103; $M^{20}D$ (found) 31.84; $M^{20}D$ (calcd.) 31.87.

(5) Wallach, *Ann.*, **329**, 371 (1903).

Oxidation.—Oxidation of 0.7 g. of this olefin (II) with permanganate as above yielded 0.6–0.7 g. (50%) of the semicarbazone of ε-ketoheptanoic acid, m. p. 142–143°.

Hydrogenation.—Hydrogen added readily to this olefin (II) using Adams catalyst in alcohol at three atmospheres pressure. The product had the same properties as the methylcyclohexane prepared from III: b. p. 101.5–102°; $n^{20}D$ 1.4234; d^{20}_4 0.7711; $M^{20}D$ (found) 32.35; $M^{20}D$ (calcd.) 32.34.

Summary

The dehydration of *trans*-2-methylcyclohexanol with phosphoric anhydride yielded a mixture of 1-methyl-1-cyclohexene and 3-methyl-1-cyclohexene. The methylcyclohexane obtained by hydrogenation of this olefin mixture was found to be identical in every respect with other authentic samples of this hydrocarbon.

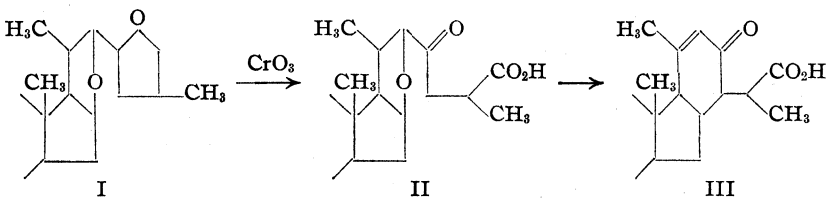
Sarsasapogenin. IV. Further Observations Concerning Sarsasapogenoic Acid and Related Compounds

BY LOUIS F. FIESER, EDWARD M. FRY[1] AND R. NORMAN JONES[2]

From the work of Jacobsen in this Laboratory[3] it was concluded that anhydrosarsasapogenoic acid has the partial structure III and that its formation from sarsasapogenin by oxidation to sarsasapogenoic acid and treatment of the latter with alcoholic alkali is most plausibly interpreted by regarding these substances as having the structures I and II, first tentatively suggested by Tschesche and Hagedorn.[4] The structure III for the anhydro compound was based upon the results of oxidation and reduction experiments and upon spectrographic evidence[5] of the presence of an α,β-unsaturated carbonyl system. The spectrographic evidence has now been extended by a determination of the ultraviolet absorption spectrum of the methyl ester acetate of anhydrosarsasapogenoic acid in absolute alcohol[5] (curve 1, Fig. 1). This and the other determinations reported were made by one of us (R. N. J.) by a technique which will be described in a future paper (measurements at room temperature, slit width 0.12 mm.). Both the principal and the secondary absorption bands at 243 mμ (log ε = 4.13) and 303 mμ (log ε = 1.86) correspond in position and intensity with those characteristic of α,β-unsaturated ketones,[6] in conformity with formula III. The dibasic acid $C_{27}H_{40}O_7$[3b] resulting from the permanganate oxidation of anhydrosarsasapogenoic acid was regarded as having two carbonyl groups. The absorption spectrum of the dimethyl ester of this acid (curve 2, Fig. 1) definitely has carbonyl characteristics and lacks the original feature of conjugation, but it is hardly possible from the spectrographic evidence to distinguish between a monoketo and diketo carboxylic acid.



I II III

The spectrum of the acetate of sarsasapogenoic acid (curve 2, Fig. 2) is characterized by the ap-

pearance of a low intensity band at 281 mμ (log ε = 1.92), which is indicative of the presence of a non-conjugated carbonyl group, as in formula II. A determination made with a sample of chlorogenoic acid diacetate monohydrate[7] kindly supplied by Professor C. R. Noller gave a practically identical result (maximum at 286 mμ, log ε = 1.91; solvent, 95% alcohol). A similar absorption curve (curve 1, Fig. 2) was found for the acidic oxidation product obtained[3c] from desoxysarsasapogenin and previously regarded as an unsaturated, conjugated diketo acid in the form of a hydrate, $C_{27}H_{40}O_4 \cdot H_2O$. Reëxamination of the acid has provided indications that it is indeed a hydrate, but the spectrum shows that it lacks conjugation. The similarity to the above sapogenoic acid suggests that the substance in question may be a mono-carbonyl compound of the same type, namely, desoxysarsasapogenoic acid. The analyses reported[3c] for the acid agree satisfactorily with the revised formula $C_{27}H_{42}O_4 \cdot H_2O$, and the results for the unhydrated methyl ester and monoxime accord better with the new formulation than with that originally proposed. The apparent presence of an active hydrogen atom in the ester[3c] may be due to enolization or other change. Another acid which appears to be of the same type has been obtained by the oxidation of sarsasapogenone with chromic acid. Analyses of the acid and its methyl ester point to the formula $C_{27}H_{40}O_5$ of dehydrosarsasapogenoic acid, and this designation is supported by the sensitivity of the compound to alkali.

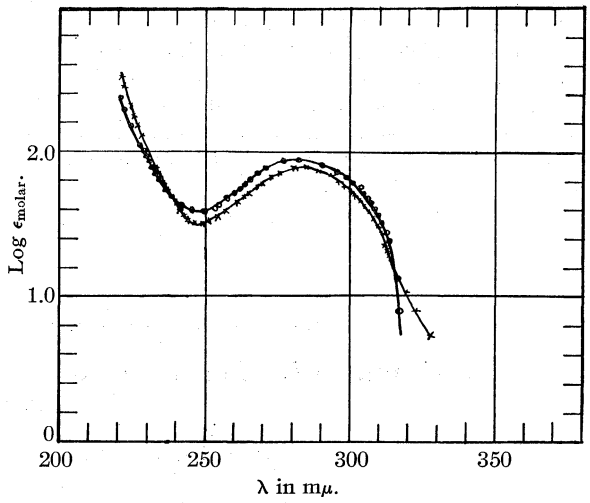

Fig. 2.—Curve 1 (crosses), desoxysarsasapogenoic acid ($C_{27}H_{42}O_4 \cdot H_2O$) in absolute alcohol; curve 2 (circles), sarsasapogenoic acid acetate in absolute alcohol.

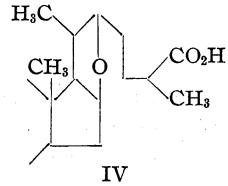
Spectrographic examination was also made of the "anhydrotetrahydrosarsasapogenoic acid"[3b] resulting from the slow and irregular catalytic hydrogenation of the sapogenoic acid. The formula of a γ-keto acid, previously considered as a possibility, is definitely eliminated by the present observation that the substance shows no selective absorption in the ultraviolet region. Since this is true also of sarsasapogenin, the reduction product probably contains one of the original oxidic linkages and has the structure IV. On this interpretation the reaction consists in the reduction of the carbonyl group of II to a methylene group, which would account for the slow and irregular absorption of hydrogen. The same formula has been ascribed by Marker and Rohrmann[8] to an



IV

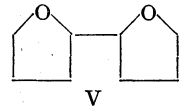
(8) Marker and Rohrmann, *ibid.*, **61**, 846 (1939).

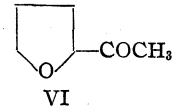
acid (sarsasapogentic acid) obtained by hydrogenating sarsasapogenin in an acidic medium and oxidizing the resulting crude 3-acetate dihydride. Their acid is stated to melt at "187°" ("189°" is given in the theoretical discussion) and to form a crystalline methyl ester. Our acid, like certain other compounds of the series, melts over a characteristically long range (174–184°, corr.) and gives a liquid methyl ester, isolated as the crystalline acetate and benzoate.

Marker and Rohrmann[8] found that sarsasapogenin not only can be hydrogenated in acid solution, but also can be reduced by the Clemmensen method, and brominated in the presence of hydrogen bromide. These workers also noted that the sapogenin acetate is attacked by selenium dioxide in acetic acid–benzene, but no reaction product was isolated.[9] They considered these observations to indicate the presence of a spiro ketone acetal grouping in the side chain and suggested that formula I should be modified by transposing the terminal oxidic linkage from C_{23} to C_{22}. This formulation seems contrary to the evidence from our oxidation experiments, particularly since it provides no rational interpretation of the formation and properties of anhydrosarsasapogenoic acid (III). On the other hand, the newly observed transformations at least can be formulated on the basis of the side chain structure I postulated by Tschesche and Hagedorn. It is a more subtle problem to decide whether such a formulation is justifiable. The most distinctive feature of the hydrogenation, reduction, and halogenation reactions is that they proceed only in acidic media, and their occurrence, therefore, may well be dependent upon the same structural features which are responsible for the well-known sensitivity of the sapogenin side chain to cleavage[10,3a] and isomerization[3a,8] by mineral acids. The susceptibility to attack by acids is, to be sure, a matter of degree, for while the side chain is subject both to fission by hydrochloric–acetic acid[10,3a] and to reductive cleavage in the Clemmensen reaction,[8] conditions have been found under which the carbonyl group of sarsasapogenone can be reduced by the Clemmensen method without disturbance of the oxidic side chain.[3c,11] Furthermore, no alteration of the genin occurs during its liberation from the glycoside by acid hydrolysis.[10] There is little basis for deciding from known analogy if a substance having the oxidic structure I should show acid sensitivity of just the degree found in the natural product; on the keto acetal formulation the persistence of the oxide ring structure in the Clemmensen reduction of sarsasapogenone would seem to require explanation. Marker and Rohrmann[8] observed that under the conditions employed for the acid-specific reactions of the sapogenin, tetrahydrofurfuryl acetate is resistant to hydrogenation, bromination, and oxidation with selenium dioxide, and they considered this an argument against formula I. The monocyclic acetate did not seem to us an adequate model, and we consequently investigated octahydro-α,α'-difuryl (V). This compound is attacked readily by acids.



V

Acetolysis of sarsasapogenin can be accomplished by short heating at 90° with equal volumes of acetic acid and concentrated hydrochloric acid, and under the same conditions V is converted largely into a higher boiling liquid which appears to be a chlorohydrin formed by cleavage of one of the oxide rings. Octahydro-α,α'-difuryl also slowly absorbs a full mole of bromine in acetic–hydrobromic acid solution and is attacked by chromic acid at 60°. The freshly purified material did not undergo hydrogenation under conditions similar to those employed by Marker and Rohrmann[8] and was inert to selenium dioxide, although on standing in the air the material rapidly became contaminated with an impurity which is oxidized by this reagent. Since the nature of the selenium dioxide reaction on the sapogenin is unknown and occurrence or absence of hydrogenation dependent upon the nature of the catalyst as well as the presence of acids, the similarities between octahydro-α,α'-difuryl and sarsasapogenin seem more striking than the differences. We also examined α-acetotetrahydrofuran (VI) as a possible model



VI

for sarsasapogenoic acid, formulated as in II, and found that, like this acid, the simpler compound

(9) We have observed that sarsasapogenin, or its acetate, is oxidized rapidly by lead tetraacetate in acetic acid or acetic anhydride solution at temperatures from 60 to 100°. With either one or two moles of oxidizing agent considerable starting material was recovered and the remainder was non-crystalline.

(11) Marker and Rohrmann, THIS JOURNAL, **61**, 1284 (1939).

is sensitive to alcoholic alkali and rapidly undergoes alteration.

From these observations we conclude that on present evidence the Tschesche–Hagedorn formulation provides the most satisfactory expression of the known properties of the sapogenins.

Experimental Part[12]

Preparation of Desoxysarsasapogenin.—Results obtained by the procedure[3c] previously given for the Clemmensen reduction of sarsasapogenone were somewhat irregular. After several trials it was found that the reduction proceeds better when the proportion of benzene (to methanol) is decreased, and that with very brisk refluxing the time can be greatly decreased. The identification of the product is somewhat uncertain because the melting point is close to that of the starting material and because mixtures of the two substances show no depression. There is little difference in the optical rotations of the compounds, the value found for desoxysarsasapogenin being $\alpha^{24}D$ −59.6° (1.5% in benzene), while that for sarsasapogenone was $\alpha^{27}D$ −45° (1.2% in benzene). A convenient method of separation and identification was found in the removal of the ketone as the oxime. The following procedure is believed to provide a reliable method of obtaining the pure desoxy compound, and the yield is considerably better than by the previously reported process[3c] or by reduction with unamalgamated zinc in alcohol according to Marker and Rohrmann.[11]

A mixture of 2 g. of sarsasapogenone, 20 g. of zinc (treated with 2 g. of mercuric chloride), 75 cc. of methanol, 75 cc. of benzene, and 20 cc. of 6 *N* hydrochloric acid was refluxed very vigorously on the steam-bath for six and one-half hours, adding 5-cc. portions of concentrated hydrochloric acid after the second and fourth hours. After dilution with water and separation, the aqueous layer was extracted with ether and the extracts combined with the benzene layer and concentrated to the point of crystallization. The crystalline material obtained in successive crops was freed of adhering oil by washing with cold alcohol, giving 1.51 g. of crude desoxysarsasapogenin. This was suspended with 1.5 g. of hydroxylamine hydrochloride in 5 cc. of pyridine and 10 cc. of alcohol and the mixture was refluxed for two hours. The desoxy compound did not dissolve to any noticeable extent, and after cooling the suspension the solid was collected and washed with water and alcohol, giving 1.3 g. (68%) of satisfactory desoxysarsasapogenin, m. p. 213–217°. The mother liquor afforded 0.13 g. of crude material, m. p. about 130°, which probably is sarsasapogenone oxime.

Desoxysarsasapogenoic Acid.—The oxidation of desoxysarsasapogenin (5 g.) was conducted essentially as before[3c] (in 450 cc. of solvent, adding 4.6 g. of chromic anhydride in 15 cc. of water) but at a lower temperature (45–50°) and for a longer time (eight hours). After filtering from 0.15 g. of starting material the acidic fraction was worked up as described, giving after crystallization from dilute acetone 1.41 g. (26%) of product. This melted at 109–114° to a jelly-like mass which became clear at 121°; $\alpha^{24}D$ −112° (0.65% in alcohol). None of the high melting acid[3c] was observed.

The reported analyses[3c] are to be compared with the percentages calculated for the revised formula $C_{27}H_{42}O_4 \cdot H_2O$: C, 72.28; H, 9.89; ester ($C_{28}H_{44}O_4$): C, 75.63; H, 9.97; oxime ($C_{27}H_{43}O_4N$): C, 72.77; H, 9.73; N, 3.14.

When the acid was heated in a bath at 200° a gas was evolved and a condensate formed on the cool portion of the tube and then evaporated. After adding ether (moist) to the oil remaining on cooling, the material crystallized and was identified as the starting material (hydrate). Contrary to the previous observations,[3c] the acid slowly decolorizes permanganate even in the cold, giving largely non-crystalline material. The compound undergoes alteration in alkaline solution even in the cold and the change could be followed by observing the optical rotation, but no crystalline product was isolated. The alkali-modified material absorbed hydrogen in an acidic medium in the presence of Adams catalyst. No hydrogenation was observed with desoxysarsasapogenoic acid itself, although the methyl ester absorbed somewhat less than one mole of gas, giving unchanged ester and an oil.

Dehydrosarsasapogenoic Acid.—A solution of 5 g. of sarsasapogenone in 390 cc. of glacial acetic acid was stirred at room temperature (30°) and treated with a solution of 4.2 g. of chromic anhydride in 75 cc. of 80% acetic acid. At the beginning this was added at the slow rate at which the reagent was consumed, but after half of the oxidant had been added (eight hours) the remainder was introduced rapidly and stirring was continued for fourteen hours longer at 33°. After dilution with water the cloudy reaction mixture was extracted with ether and the washed solution was extracted with 1 *N* alkali. Fine needles of a sodium salt separated at this point, but as the material was not easily filtered the alkaline suspension was acidified and the product taken into ether. After evaporation of the solvent the oily residue gave a crystalline salt when treated with 1 *N* sodium hydroxide solution. This was collected and washed with 1 *N* alkali, and when a solution of the salt in water was acidified there was obtained 1.28 g. of fairly pure, crystalline dehydrosarsasapogenoic acid. The alkaline mother liquor remaining after removal of the crystalline sodium salt gave on acidification 2 g. of a crusty, non-crystalline acid mixture. No satisfactory acid, ester, or semicarbazone was isolated. The neutral fraction (1 g.) from the oxidation yielded unidentified material crystallizing in plates, m. p. 202–209°. Oxidations at temperatures up to 75° gave lower yields of the crystalline sodium salt.

Dehydrosarsasapogenoic acid crystallized from dilute alcohol in needle clusters. Water of crystallization was held tenaciously but was removed on drying for three hours at 130° and 10 mm. The substance melts at 164–165°; $\alpha^{25}D$ (air dried) −105° (1.1% in alcohol).

Anal. Calcd. for $C_{27}H_{40}O_5$: C, 72.94; H, 9.07; neut. equiv., 445. Found: C, 72.82; H, 9.12; neut. equiv., 445, 442.

The acid absorbed about 2 moles of hydrogen in acetic acid solution using Adams catalyst, giving a small amount of product, m. p. about 200°. The sapogenoic acid is attacked rapidly by alkaline permanganate and is converted into an oily reaction product on refluxing for ten

(12) Experiments by E. M. Fry. All melting points are corrected. Microanalyses by Lyon Southworth.

minutes with 1 *N* alkali. After being heated at 85° with a 1:1 mixture of acetic acid and concentrated hydrochloric acid for two hours, only about one-third of the acid could be recovered as the sodium salt, and the remainder was an oil. Sarsasapogenoic acid is also altered on similar treatment.

The **methyl ester** was obtained by esterification both with diazomethane and with methanol and hydrogen chloride. The substance crystallizes from dilute acetone in the form of rectangular plates, m. p. 125–126°; $\alpha^{27}D$ −101° (1.5% in alcohol). The analytical sample was dried at 66° and 10 mm.

Anal. Calcd. for $C_{28}H_{42}O_5$: C, 73.32; H, 9.23. Found: C, 73.16, 73.35; H, 9.61, 9.30.

Octahydro-α,α′-difuryl (V).—α,α′-Difuryl was obtained by the method of Reichstein and co-workers[13] as a colorless oil, b. p. 67° at 12 mm. Hydrogenation was tried without success in alcoholic solution in the presence of Adams catalyst or palladium charcoal, but in the same solvent with Raney nickel the reaction proceeded satisfactorily at 150° in the pressure apparatus. The octahydride distilled as a colorless liquid, b. p. 73–76° at 12.5 mm., completely soluble in water and giving a negative test for the furan nucleus. Kondo and co-workers[14] effected the hydrogenation with palladium charcoal in acetone and found the b. p. 77–80° at 13 mm.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.92. Found: C, 67.37; H, 9.66.

Bromination of V.—A solution of 1.03 g. of octahydro-α,α′-difuryl in 35 cc. of glacial acetic acid was treated with 2 drops of 48% hydrobromic acid and a solution of 1.15 g. of bromine in 3 cc. of glacial acetic acid was run in slowly to the solution held at 55°. The reagent was absorbed slowly and the molecular amount was consumed in the course of a day.

Oxidation and Hydrogenation Tests.—A solution of 0.05 g. of V in 90% acetic acid consumed 0.035 g. of chromic anhydride in about two hours at 60°.

On heating 2.05 g. of octahydro-α,α′-difuryl on the steam-bath with a solution of 2.7 g. of selenium dioxide in 11 cc. of acetic acid and 1 cc. of water, a red precipitate of selenium formed almost at once and did not increase in amount in the course of one hour. The excess dioxide was then neutralized with potassium acetate and the solvent removed by distillation at reduced pressure. The recovered oil distilling at 50–70° at 13 mm. was redistilled twice over sodium carbonate, giving 1.3 g. of purified octahydro-α,α′-difuryl, b. p. 75.5–76.5° at 12.5 mm.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.92. Found: C, 67.34; H, 10.28.

This purified and freshly distilled material was not attacked by selenium dioxide under the above conditions, but after standing for two days the same sample again gave a positive test for oxidation by this reagent. The freshly purified substance (0.6 g.) likewise absorbed no hydrogen in a mixture of alcohol (9 cc.) and concentrated hydrochloric acid (1 cc.) in the presence of Adams catalyst (50 mg.). A sample (1 g.) which had not been purified with selenium dioxide under similar conditions absorbed about 17% of the theoretical amount of hydrogen; the reaction then stopped and did not proceed further on adding fresh catalyst. The recovered material boiled at 78° (13 mm.).

Acid Cleavage of V.—A mixture of 2.21 g. of octahydro-α,α′-difuryl, 2 cc. of glacial acetic acid, and 2 cc. of concentrated hydrochloric acid was heated on the steam-bath (88°) for two hours, the solution acquiring a brown color. After evaporation at reduced pressure the remaining oil was neutralized with solid sodium carbonate and distilled, giving a fore-run of 0.98 g. of starting material, b. p. 75° (12 mm.), and a fraction (0.93 g.) boiling at 140–143° (12 mm.). This material, only grossly purified, was found to have approximately the composition of a chlorohydrin $C_8H_{15}O_2Cl$ (Calcd.: C, 53.9; H, 8.5; Cl, 19.8. Found: C, 54.9; H, 8.3; Cl, 18.6). A diester was obtained by heating 0.08 g. of the substance with 0.2 g. of 3,5-dinitrobenzoyl chloride on the steam-bath for six hours. The mixture was treated with 1 *N* sodium hydroxide at room temperature, and after the excess reagent had been destroyed the extracted oil was caused to crystallize from alcohol–ether (0.1 g.). The substance has no m. p. but decrepitates with explosive violence. It is sparingly soluble in the usual solvents and decomposes easily. For purification it was dissolved in alcohol (15 cc.) and the solution allowed to evaporate, giving hexagonal crystals. The analysis corresponds approximately to the formula of a dinitrobenzoate of the glycol corresponding to the chlorohydrin.

Anal. Calcd. for $C_{22}H_{20}O_{13}N_4$: N, 10.22. Found: N, 10.71.

The crystalline derivative (32 mg.) on hydrolysis with 0.5 *N* alkali gave 20 mg. of 3,5-dinitrobenzoic acid.

α-Acetotetrahydrofuran (VI).—The starting material, **tetrahydrofuroamide** was prepared by the hydrogenation of recrystallized commercial furoamide in alcohol at atmospheric pressure and room temperature using 10% palladium charcoal catalyst. Purified by crystallization from benzene and distillation, the substance boiled at 135–138° (10 mm.) and showed a wide range of m. p. (65–76°). The composition (C, 52.3; H, 7.2) is close to that calculated for $C_5H_9O_2N$ (C, 52.1; H, 7.8). Wienhaus and Sorge[15] give about the same b. p. but state that this was at 20 mm.; they make no mention of the range in m. p.

This amide (9.8 g.) was suspended in a Soxhlet thimble in the drip from a condenser in a flask containing the Grignard reagent prepared from 8.5 g. of magnesium, 250 cc. of ether, and excess methyl chloride. As the amide was carried into the solution on refluxing a vigorous reaction ensued with separation of a white complex. After refluxing and stirring for forty-five hours, the mixture was treated with water and 20 cc. of glacial acetic acid and extracted thoroughly with ether. The oil from the ether on first distillation afforded 5.9 g. of colorless ketone, b. p. 53–58° (10 mm.). After three further distillations the substance boiled at 52.3–54.8° (10 mm.); the analysis indicates that it probably contained some water (Calcd.: C, 63.1; H, 8.8. Found: C, 62.4; H, 8.9).

(13) Reichstein, Grüssner and Zschokke, *Helv. Chim. Acta*, **15**, 1068 (1932).

(15) Wienhaus and Sorge, *Ber.*, **46**, 1930 (1913).

For characterization the aceto compound (0.15 g.) was refluxed in alcohol (10 cc.) and acetic acid (5 drops) with 2,4-dinitrophenylhydrazine (0.2 g.). The product separating in bright yellow crystals (0.24 g.) proved to be a mixture of stereoisomers present in about equal amounts. Fractional crystallization from alcohol gave orange plates, m. p. 122–124°, and yellow needles, m. p. 135–136°, of the isomeric **2,4-dinitrophenylhydrazones.**

Anal. Calcd. for $C_{12}H_{14}O_5N_4$: C, 48.98; H, 4.79; N, 19.04. Found, plates: C, 48.92; H, 4.73; N, 18.89. Found, needles: C, 48.92; H, 4.59; N, 18.75.

Action of Alkali on α-Acetotetrahydrofuran.—The ketone (2 g.) was refluxed for two hours with 16 cc. of alcohol and 4 cc. of 10 *N* sodium hydroxide, 10 cc. of alcohol was added to the two-phase, dark red mixture and refluxing was continued for two hours. After removing the alcohol at reduced pressure the alkaline liquor was extracted with ether. Distillation gave a small fraction (0.35 g.) of colorless liquid of b. p. close to that of the starting material (61–63° at 10 mm.). The remainder was a dark red oil which did not distil to an appreciable extent up to 190° (8 mm.). In another experiment the proportion of red oil was about the same after refluxing for only one hour. This oil seemed to contain an alcoholic reaction product for there were indications of interaction with dinitrobenzoyl chloride in pyridine and with both phenyl isocyanate and α-naphthyl isocyanate; the products were obtained only as oils. There was no reaction with dinitrophenylhydrazine and the reagent was recovered unchanged.

Summary

Spectrographic evidence confirms the previous indications that anhydrosarsasapogenoic acid contains an α,β-unsaturated carbonyl group and that sarsasapogenoic is a non-conjugated carbonyl compound. Another compound of the sapogenoic acid type has been obtained by the oxidation of sarsasapogenone, and a previously described oxidation product has been recognized as desoxysarsasapogenoic acid. Anhydrotetrahydrosarsasapogenoic acid shows no selective absorption in the ultraviolet and hence does not contain a carbonyl group as previously supposed; a new formula is suggested.

Octahydro-α,α′-difuryl, examined as a possible model for the Tschesche-Hagedorn formulation of the side chain, exhibits sensitivity to acids comparable with that characteristic of the sapogenins. It is considered that this formulation accounts satisfactorily for the acid-specific reactions as well as for the oxidation results.

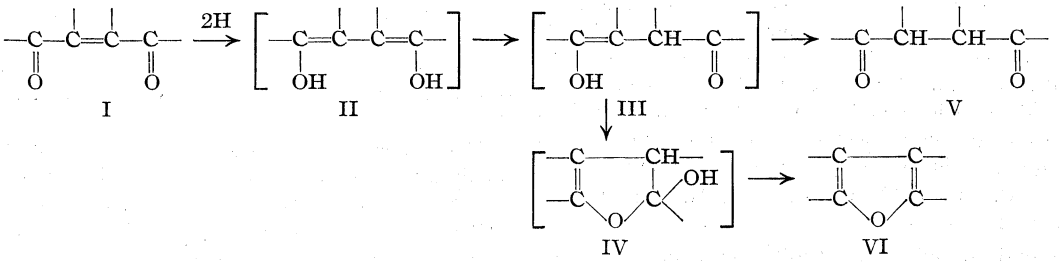
The Mechanism of Reduction of Conjugated Systems with Terminal Carbonyl Groups. Dienols Obtained from Unsaturated 1,4-Diketones[1]

BY ROBERT E. LUTZ AND WILLIAM G. REVELEY

There is definite evidence that reductions of unsaturated 1,4-diketones by means of soluble reducing agents, by metal combinations, and even by catalytic hydrogen under certain conditions, proceed largely if not exclusively through 1,6-addition of hydrogen or its equivalent at the oxygen atoms with the formation of intermediate dienols (II) which correspond to hydroquinones formed in the reduction of quinones, but which are unstable and ketonize quickly to the saturated 1,4-diketones (V) or undergo dehydration to the corresponding furans (VI).[2]



The furans probably are not formed directly from the dienol but rather through rearrangement to the monoenol III, cyclization to IV, and finally loss of water. In support of this sequence of changes mention should be made of the formation of the furan from the monoenol produced by 1,4-

(1) This paper was presented at the Baltimore meeting of the American Chemical Society, April 4, 1939.

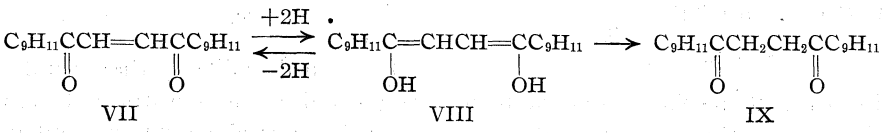
(2) *Cf.* (a) Conant and Lutz, THIS JOURNAL, **45**, 1047 (1923) (b) Lutz, *ibid.*, **51**, 3008 (1929); (c) Lutz and Palmer, *ibid.*, **57**, 1947 1953, 1957 (1935).

addition of hydrogen chloride to the α,β-unsaturated ketone system of $C_6H_5COCH{=}C(Cl)CO-C_6H_5$,[3] and the close analogy for cyclization of the type suggested in the ready formation of hydroxyfuranones from 1,2,4-triketone enols.

It has been shown that reduction of the analogous conjugated system of the α-diketones with zinc or catalytic hydrogen proceeds 1,4 to give mobile intermediate ene-diols of the type RC(OH)=C(OH)R which could be fixed and isolated as diacetates.[4] Recently the important discovery that enols of mesityl ketones are extraordinarily persistent and slow to ketonize[5a] has been utilized to demonstrate this mechanism: catalytic reduction of three monomesityl α-diketones[5b,c] of the type $C_9H_{11}COCOR$ produces fairly persistent ene-diols which undergo rearrangement to the α-hydroxy ketones or ready oxidation back to the α-diketones; and dimesityl diketone is reducible to stereoisomeric metastable crystalline ene-diols.[4b,6] The extraordinary persistence of these ene-diols appears to be at a maximum in compounds such as the dimesityl derivative where the migrating hydrogen must go to a carbon directly linked to a mesityl nucleus.

Further experiments on 1,4-dimesityl unsaturated 1,4-diketones were suggested by the above facts and have been carried out in order to obtain more information concerning reduction of conjugated systems of the type involved and the chemistry of the dienols which are produced.

Hydrogenation of di-(trimethylbenzoyl)-ethylene (VII) in ethanol at 0° with platinum as catalyst takes place rapidly with absorption of one molecule of hydrogen. Di-(trimethylbenzoyl)-ethane (IX) is obtained practically quantitatively when the reaction mixture is allowed to stand for a period of time under hydrogen, preferably with a small amount of added piperidine to catalyze ketonization.



The dienol VIII was shown to be the chief primary product under these conditions by filtering the solution rapidly under an atmosphere of nitrogen and running it directly into a solution of a known amount of iodine, the unused excess then being determined by titration with standard sodium thiosulfate. Assuming the amount of iodine used up to be a measure of the amount of the dienol present, yields of over 90% were demonstrated in several experiments. The oxidation of the dienol is presumably a 1,6-process and analogous to the oxidation of *p*-hydroquinones.

Reduction of di-(trimethylbenzoyl)-ethylene (VII) by means of zinc and acetic acid, a representative metal combination, ordinarily produces di-(trimethylbenzoyl)-ethane (IX) in good yield. It has been possible to show that here also the chief primary product is the dienol VIII. The reaction was carried out under modified conditions at 0°, and the resulting solution filtered from the zinc directly into iodine solution under an atmosphere of nitrogen; 61% of one mole of iodine was reduced. The dienol is decidedly mobile in the type of solvent used, however, as was shown in catalytic hydrogenations carried out in a somewhat similar solvent combination. Assuming a comparable rate of ketonization during manipulation in the zinc–acetic acid reduction and making due allowance, the result indicates that addition was practically exclusively 1,6, as would be expected.[2a]

In many of the experiments using the iodine oxidation method of analysis of the products of reduction, the results were checked by actual isolation and separation of the mixture of saturated and unsaturated 1,4-diketones. Fractional crystallization, while effective and successful in several instances, was laborious and inaccurate. A rapid and convenient method of separating was developed utilizing the conversion of the unsaturated diketone into the water soluble addition product X by the action of a boiling solution of sodium bisulfite in 60% ethanol; the water soluble sulfonate could be separated easily from the saturated diketone which was recovered and

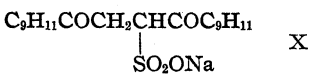
(6) Fuson and Corse, *ibid.*, **61**, 975 (1939). Incidentally, in connection with the above facts, attention may be called to the significant parallelisms between 1,4-reductions of α-diketones, pinacol reduction and dimolecular reduction of acid chlorides [*cf.* Werner, *Chem. Ztg.*, **1**, 4; Erlenmeyer, *J. prakt. Chem.*, **65**, 351 (1902); Klinger, *Ber.*, **24**, 1268, 1271 (1891); **31**, 1217 (1898)], and between the 1,4-oxidation of ene-diols and 1,2-glycols.

weighed, the amount of the unsaturated diketone being determined by difference.



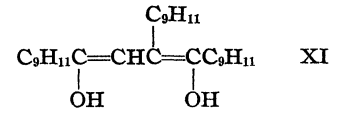
X

In connection with the mechanism of the main course of reduction in these experiments, 1,2-addition directly at the ethylene linkage, or 1,4-reduction of the α,β-unsaturated ketone grouping with the formation of an intermediate monoenol of the type III, giving intermediate products oxidizable directly or through subsequent enolizations to the unsaturated 1,4-diketone, could not account for the formation of the easily oxidizable dienol and are therefore excluded. Enols and dienols in this series would be unstable and enolization of a carbonyl group during or after reduction would be most unlikely under the conditions of these experiments. Furthermore, there is now evidence in another series for the existence of four substituted monoenols of the type III, one of which has been isolated crystalline; and none of these are oxidizable by air or iodine nor enolized further under ordinary conditions.[7]

Experiments were made to determine the persistence of the dienol (VIII). The best yields were obtained by reduction in ethanol at 0°. Ketonization under these conditions is evidently very slow in spite of the manipulations covering nearly three hours between initiation of hydrogenation and the reaction with iodine. Solutions of the dienol, filtered from catalyst under an atmosphere of nitrogen and allowed to stand quietly at 26–29°, were found to possess a half life period of about twelve hours; however, when shaken at room temperature either in the hydrogenation flask and in the presence of the catalyst, or in another vessel, filtered from catalyst and under an atmosphere of nitrogen, the half life period was considerably less (approximately two hours). The dienol, then, is moderately persistent even though there is no hindering group directly attached to either of the carbons to which the enol hydrogens migrate.

Preliminary attempts to isolate the dienol have not been successful. Attempted reaction with diazomethane brought about ketonization instead. However, a crystalline dienol of this type, namely, XI, melting at 70–71°, has been obtained in the 1,2,4-trimesityl series and will be described in a later report.[7]

(7) Lutz and Kibler, results to be published shortly.



XI

It seemed unlikely that catalytic hydrogen would add 1,6 to unsaturated 1,4-diketones exclusively under all conditions, and an attempt was made to find conditions favoring normal hydrogenation at the ethylene linkage. Of course the conditions tested were necessarily limited to those under which the dienol would likely be persistent. In ethanol solution, temperature has a very marked effect as shown by a typical experiment carried out at room temperature instead of 0°, the time elapsing between initiation of reduction and analysis of the resulting mixture being held to a minimum (seven minutes). The amount of dienol formed, allowing for the small amount of ketonization which would occur during the manipulation, was approximately 30%, in contrast with 90–94% obtained in the experiments carried out at 0°. It is therefore evident that the reduction is more ordered and consistently 1,6 at lowered temperatures.

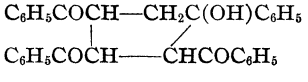
A series of reductions using platinum as catalyst was carried out at 0° in different solvents, the products being analyzed by the iodine oxidation method. The following percentages of dienol were found: in 95% ethanol, 91–94%; in a 4–1 dioxane–ethanol mixture, 90%; in ethyl acetate, 78%; in isopropyl ether, 60%; in benzene (at 5°), 54%; in *n*-hexane, 60%; and in decalin, 17%. These reductions must have proceeded 1,6 at least to the extent of the figures given, and possibly a little more since a small amount of ketonization may have occurred before completion of hydrogenation and analysis of the solution. The amount of ketonization in these solvents at 0° is probably very small and there is no reason to suspect that there would be an abnormally high rate in decalin, the one solvent in which the yield of dienol is very low.

The catalytic reduction of VII in an acetic–propionic acid mixture at 0° gave a yield of dienol on the order of 40–50%. This value is a rough approximation only, because of the mobility of the dienol under these conditions, and was estimated by extrapolation from values determined in several runs in which the time of shaking the reaction mixture was varied.

From the foregoing results it is obvious that conditions have a marked and varied influence on

the mode of catalytic hydrogenation of di-(trimethylbenzoyl)-ethylene, and that there is no consistent solvent effect. The contrasting yields of dienol obtained in *n*-hexane and in decalin are surprising. In the latter solvent when 1,6-addition is at a minimum, 1,2-addition directly at the ethylene linkage is probably the dominant reaction, although of course 1,4-addition is also possible.

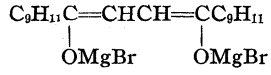
In this connection attention should be called to the effect of solvent and conditions on the yield of cyclic dimolecular products in the catalytic reduction of dibenzoylethylene.[2c] In alcohol as one extreme a mechanism involving at least one carbonyl must be involved in view of the large yield of cyclic dimolecular product (XII). On the other hand, when hydrogenation is carried out in decalin as the solvent, complications involving enolic intermediates are at a minimum with normal net hydrogenation at the ethylene linkage predominant. In the case of reduction of the allyl ether system of pseudocodeine types, conditions also have a marked effect on the course of addition, some consistently favoring one mode over another.[8]



XII

This work is being extended to other and longer conjugated systems, including types in which an aromatic nucleus furnishes one or more of the double bonds involved in the system connecting the two carbonyl groups.

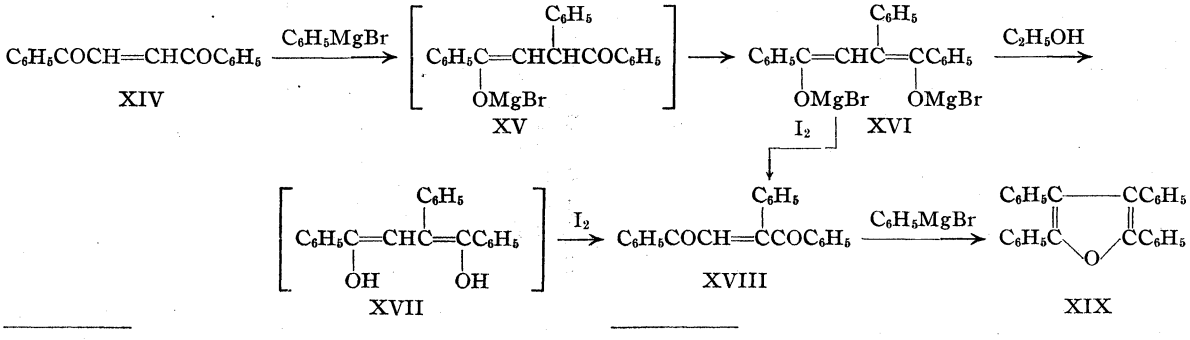
The fact that the dienol produced in reduction of di-(trimethylbenzoyl)-ethylene is sufficiently persistent to permit oxidation back suggested a simple method of converting the 1,4-dimesityl saturated 1,4-diketones into the corresponding unsaturated diketones through hydrolysis of the dimagnesium dienolate under oxidizing conditions. This method is of value because it makes possible the synthesis of a type of unsaturated diketone which cannot be prepared by the usually convenient nitric acid oxidation of the corresponding furan. In the case of di-(trimethylbenzoyl)-ethane, the dimagnesium dienolate (XIII) is easily made by heating the saturated diketone (IX) with an excess of phenylmagnesium bromide at 110° in isoamyl ether. The mixture, when poured into a precooled solution of iodine in 95% ethanol, gave *trans*-di-(trimethylbenzoyl)-ethylene (VII).



XIII

The above procedure has proved useful in the preparation of dimesityl unsaturated diketones with substituents on the ethylene linkage, utilizing the dimagnesium dienolates produced by the action of the Grignard reagent on di-(trimethylbenzoyl)-ethylene.[7,9]

It would be expected that the dienols of ordinary saturated 1,4-diketones such as dibenzoylethane would be extremely unstable and would undergo rapid ketonization if formed in any reaction. Nevertheless, it seemed possible that some dienols of this type might exist long enough to be caught by the oxidation reaction. No simple method is available to study the dienol of dibenzoylethane and the dimagnesium dienolate has not been made. However, ether solutions of a phenylated analog, namely, the dimagnesium dienolate XVI formed by the addition of phenylmagnesium bromide to dibenzoylethylene (XIV), is readily available;[9] when decomposed in cold alcoholic iodine solution *cis*-dibenzoylphenylethylene (XVIII) is obtained and none of the saturated diketone. This result is of particular significance in that it demonstrates in another way the correctness of the mechanism proposed for the action of the aryl Grignard reagents on unsaturated 1,4-diketones.[9]



(8) Lutz and Small, THIS JOURNAL, **54**, 4715 (1932).

(9) Lutz and Tyson, *ibid.*, **56**, 1341 (1934).

An interesting result was observed when the ether solution of the dimagnesium dienolate XVI, containing a large excess of phenylmagnesium bromide, was poured into a cooled ether solution of an excess of iodine. Tetraphenylfuran (XIX) was produced. Evidently the dienolate XVI was first oxidized directly to dibenzoylphenylethylene (XVIII), and was then converted into tetraphenylfuran by 1,4-addition of phenylmagnesium bromide followed by the equivalent of dehydration, the latter reactions (known[10]) competing favorably with cleavage of phenylmagnesium bromide by iodine.

Experimental Part

The Catalytic Reduction of Di-(trimethylbenzoyl)-ethylene.—In a number of preliminary experiments an apparatus was devised to carry out hydrogenations at −5 to 0° with an arrangement for manipulating the solution afterward under an inert atmosphere. The hydrogenation flask was immersed in a cooling bath. The main side neck of the flask was fitted with a glass tube slip joint holding a siphon tube with a stopcock; this siphon tube could be pushed down into a small depression blown in the bottom of the flask whereby the solution could be drawn out by suction. A separatory funnel was sealed to the neck of the flask for introduction of solvent. The siphon was connected to a sintered glass funnel and this in turn to a receiving flask arranged for sweeping with nitrogen and for application of suction. The material being reduced was first dissolved in the hot solvent and the solution quickly chilled to produce fine crystals (since the reactions were run at 0° the solid unsaturated diketone was usually present but passed into solution as the hydrogenation proceeded). Completion of the reduction was indicated by the marked slowing down or stopping of hydrogen absorption after approximately one molecule had been used up, and by solution of the unsaturated diketone and discharge of its yellow color. Upon completion of reduction, the siphon was lowered and the solution drawn over by suction, through the sintered glass funnel to remove the catalyst, protected by an atmosphere of hydrogen or nitrogen, into the receiving flask. The hydrogenation flask was then rinsed with several portions of pure solvent. In most of the experiments the receiving flask contained an excess of aqueous or alcoholic iodine (a known amount); the dienol present was oxidized immediately by the iodine, and the unreacted iodine was then determined at leisure by titration with standardized sodium thiosulfate. In some experiments the receiving flask was used as a means of storage for testing the stability of the dienol under certain conditions, and for experiments on the dienol itself, suitable arrangements being made for the introduction of reagents or for the removal of aliquot parts, all under a protective atmosphere of purified nitrogen.

In a number of experiments carried out at room temperature an attempt was made to minimize the time elapsing between initiation of reduction and analysis of the product. A device was used to introduce the catalyst after arranging and sweeping the apparatus because it was found that hydrogenation started to some extent before shaking was begun. The catalyst was placed in a thin glass bulb blown on the end of a glass tube passing through a rubber stopper into the main side neck of the flask; this was filled with alcohol; the siphon tube, also filled with alcohol, was inserted into the glass bulb through a rubber tube slip joint and served as a plunger; when ready the siphon tube was pressed down breaking the glass bulb and allowing the catalyst to drop into the mixture, shaking being started immediately thereafter.

In several runs with certain batches of catalyst, only small amounts of dienol were obtained and in these instances it was demonstrated that there was present in the catalyst a trace of alkali sufficient to be detectable by indicators in the washings. This trace of alkali was not easily removed. In a typical case a sample of catalyst containing alkali was treated as follows: it was washed, repeatedly with water, then with dilute nitric acid, and again with water; it was dried *in vacuo* at 200°; it was then washed with dilute ammonium hydroxide and successive portions of water and dried at 200° *in vacuo*, the process being repeated a second time. Only at the end of this treatment was the sample of catalyst free from alkali or acid, giving, when reduced with hydrogen in pure water, an aqueous suspension which was neutral to indicators. This batch of catalyst, though less active than other preparations, brought about reduction of di-(trimethylbenzoyl)-ethylene to the dienol in 90% yield through the usual manipulation. The production of traces of alkali in the catalyst apparently was minimized by lowering the sodium nitrate fusion temperature during the preparation.

The results of a series of experiments under different conditions of temperature, solvent and time, are listed in the table.

SOME TYPICAL CATALYTIC HYDROGENATIONS OF DI-(TRIMETHYLBENZOYL)-ETHYLENE

Solvent	Vol. of solvent per g.,[a] cc.	Time, min.	at °C. (Temp.)	Dienol,[b] % obtained
95% Ethanol	120	7	−5 to 0	31.5

Benzene[i]	135	85	+5	53.5[c]
n-Hexane[ij]	148	120	−5 to 0	59.5
Decalin[i]	167	135	−5 to 0	16.7[c]

[a] The amount of VII used in each run was 0.5 to 0.6 g. The amount of catalyst (PtO_2) per gram was 0.15 to 0.30

(10) Hahn and Murray, THIS JOURNAL, **36**, 1484 (1914).

g. [b] Determined by iodine oxidation and titration for unused iodine. [c] These results were checked by separation of the products after iodine oxidation, using the sodium bisulfite method, and isolating and weighing the saturated 1,4-diketone (IX). [d] The solution containing the reduction products (largely dienol) was filtered from the catalyst and allowed to stand quietly under an atmosphere of purified nitrogen for the lengths of time and at the temperatures given, aliquot parts then being drawn off and analyzed by the iodine oxidation method. A larger amount of VII was used in this experiment (1.2 g). [e] The solution of reduction products was allowed to come to room temperature; then, without removing the catalyst, the shaking was continued 90 min. [f] 63% by volume of acetic acid. The purpose of adding propionic acid was to lower the freezing point so that the reaction could be run at 0°. [g] 80% by volume dioxane; the ethanol was added to lower the freezing point. [h] Dried over anhydrous sodium sulfate and distilled once. [i] Dried over sodium and distilled twice. [j] A larger amount of catalyst was used here in order to speed up the reaction.

Semi-quantitative checks on many of the determinations of the dienol yields were made as follows: the product, consisting of a mixture of the saturated and the unsaturated diketones (VII and IX), was isolated, dried and weighed. This mixture was then subjected to the action of a boiling 60% ethanol solution containing a large excess of sodium bisulfite until the yellow color of the unsaturated diketone was thoroughly bleached. The mixture was then diluted with water and the precipitate of unreacted di-(trimethylbenzoyl)-ethane was filtered off and weighed. The amount of unsaturated 1,4-diketone was determined by difference and corresponded to the amount of dienol which had been oxidized. In every case indicated in the table the results of the iodine oxidation and titration for unused iodine were checked by this method within a few per cent.

In some cases the absorption of hydrogen was apparently low due to temperature fluctuation in the cooling system or to reduction getting under way before shaking was begun. In several such instances the check analysis by the bisulfite method showed that reduction had actually been complete; if reduction had not been complete the yield of the saturated diketone would have been lower and the yield of unsaturated diketone higher than the values indicated by the iodine oxidation analysis.

1,4-Dimesitylbutane-1,4-dione-2-sulfonic Acid (see X).—Two grams of di-(trimethylbenzoyl)-ethylene (VII) and 2 g. of sodium bisulfite were added to 25 cc. of 60% ethyl alcohol and the mixture refluxed on a steam-bath for fifteen minutes. The free sulfonic acid, liberated by pouring the reaction mixture into dilute hydrochloric acid, crystallized out as white plates; it was moderately soluble in water and in ether; the yield was 2.2 g. (88%). It was purified by conversion into the *lead salt* in aqueous medium, using lead acetate, and by repeated crystallization of this from methanol–water mixtures.

Anal. Calcd. for $C_{16}H_{18}O_5SPb$: Pb, 20.5. Found: Pb, 20.1.

Zinc and Acetic Acid Reduction.—A hot solution of 3 g. of VII in 40 cc. of concd. acetic acid, 40 cc. of diethyl ether and 1 cc. of water was cooled to −5 to 0°, fine crystals being produced, and 1.5 g. of zinc dust was then added over a period of three minutes. The mixture was shaken for twenty minutes and was filtered and washed directly into cooled alcoholic iodine. The whole operation was carried out under a protective atmosphere of purified nitrogen. Previous experiments had shown that reduction was complete within this time. Analysis for the unused iodine showed 60.9% dienol to have been present at the moment of filtration.

Preparation of *trans*-Di-(trimethylbenzoyl)-ethylene (VII) from Di-(trimethylbenzoyl)-ethane (IX).—A sample of IX (0.79 g.) was treated with an excess of methylmagnesium iodide in isoamyl ether and the mixture heated for seventy-five minutes at 110°; at the end of this time the evolution of methane had ceased, approximately two moles being liberated (collected). The mixture was then poured into a cooled solution (0°) of 1.6 g. of iodine in 60 cc. of 95% ethanol. The solvent was removed by distillation and 0.33 g. of VII was recovered (42%).

Preparation of *cis*-1,2,4-Triphenylbutenedione-1,4 (Dibenzoylphenylethylene) (XVIII) and Tetraphenylfuran (XIX) from Dibenzoylethylene (XIV).—Four grams of dibenzoylethylene was added to a solution of phenylmagnesium bromide made from 2.5 g. of magnesium and 10 cc. of bromobenzene in 100 cc. of absolute ether. The mixture was refluxed for twenty minutes, cooled to 0°, and poured into 200 cc. of 95% ethanol containing 9 g. of iodine (cooled to the same temperature). After removal of the solvents, a brown oil was obtained from which 0.65 g. of *cis*-dibenzoylphenylethylene was isolated (12.3%) and identified by mixture melting point with an authentic sample.

A solution of phenylmagnesium bromide, made from 3 g. of magnesium, was treated with 4.75 g. of dibenzoylethylene (added slowly), and the mixture poured into a cooled absolute ether solution of iodine; as the iodine color faded, more was added so that an excess was maintained (except momentarily during the addition). On hydrolysis, washing out the iodine, and working up the product, 2.1 g. (38%) of nearly pure tetraphenylfuran was isolated and identified (m. p. 174°).

Summary

Reduction of di-(trimethylbenzoyl)-ethylene by zinc and acetic acid or by catalytic hydrogen in certain solvents at 0° has been shown to be largely 1,6 by the formation of the moderately persistent dienol which is readily oxidizable back to the unsaturated 1,4-diketone.

Unsaturated dimesityl 1,4-diketones are prepared in a new way by hydrolysis under oxidizing conditions of the dimagnesium dienolates made from the saturated 1,4-diketone directly or from the unsaturated 1,4-diketone by reaction with an arylmagnesium halide.

The Structure of Proteins

BY LINUS PAULING AND CARL NIEMANN

1. Introduction

It is our opinion that the polypeptide chain structure of proteins,[1] with hydrogen bonds and other interatomic forces (weaker than those corresponding to covalent bond formation) acting between polypeptide chains, parts of chains, and side-chains, is compatible not only with the chemical and physical properties of proteins but also with the detailed information about molecular structure in general which has been provided by the experimental and theoretical researches of the last decade. Some of the evidence substantiating this opinion is mentioned in Section 6 of this paper.

Some time ago the alternative suggestion was made by Frank[2] that hexagonal rings occur in proteins, resulting from the transfer of hydrogen atoms from secondary amino to carbonyl groups with the formation of carbon–nitrogen single bonds. This *cyclol hypothesis* has been developed extensively by Wrinch,[3] who has considered the geometry of cyclol molecules and has given discussions of the qualitative correlations of the hypothesis and the known properties of proteins.

It has been recognized by workers in the field of modern structural chemistry that the lack of conformity of the cyclol structures with the rules found to hold for simple molecules makes it very improbable that any protein molecules contain structural elements of the cyclol type. Until recently no evidence worthy of consideration had been adduced in favor of the cyclol hypothesis. Now, however, there has been published[4] an interpretation of Crowfoot's valuable X-ray data on crystalline insulin[5] which is considered by the authors to provide proof[6] that the insulin molecule actually has the structure of the space-enclosing cyclol C_2. Because of the great and widespread interest in the question of the structure of proteins, it is important that this claim that insulin has been proved to have the cyclol structure be investigated thoroughly. We have carefully examined the X-ray arguments and other arguments which have been advanced in support of the cyclol hypothesis, and have reached the conclusions that there exists no evidence whatever in support of this hypothesis and that instead strong evidence can be advanced in support of the contention that bonds of the cyclol type do not occur at all in any protein. A detailed discussion of the more important pro-cyclol and anti-cyclol arguments is given in the following paragraphs.

2. X-Ray Evidence Regarding Protein Structure

It has not yet been possible to make a complete determination with X-rays of the positions of the atoms in any protein crystal; and the great complexity of proteins makes it unlikely that a complete structure determination for a protein will ever be made by X-ray methods alone.[7] Nevertheless the X-ray studies of silk fibroin by Herzog and Jancke,[8] Brill,[9] and Meyer and Mark[10] and of β-keratin and certain other proteins by Astbury and his collaborators[11] have provided strong (but

(6) In ref. 4d, for example, the authors write "The superposability of these two sets of points represented the first stage in the proof of the correctness of the C_2 structure proposed for insulin. ... These investigations, showing that it is possible to deduce that the insulin molecule is a polyhedral cage structure of the shape and size predicted, give some indication of the powerful weapon which the geometrical method puts at our disposal."

(7) A protein molecule, containing hundreds of amino acid residues, is immensely more complicated than a molecule of an amino acid or of diketopiperazine. Yet despite attacks by numerous investigators no complete structure determination for any amino acid had been made until within the last year, when Albrecht and Corey succeeded, by use of the Patterson method, in accurately locating the atoms in crystalline glycine [G. A. Albrecht and R. B. Corey, THIS JOURNAL, **61**, 1087 (1939)]. The only other crystal with a close structural relation to proteins for which a complete structure determination has been made is diketopiperazine [R. B. Corey, *ibid.*, **60**, 1598 (1938)]. The investigation of the structure of crystals of relatively simple substances related to proteins is being continued in these Laboratories.

not rigorous) evidence that these fibrous proteins contain polypeptide chains in the extended configuration. This evidence has been strengthened by the fact that the observed identity distances correspond closely to those calculated with the covalent bond lengths, bond angles, and N-H $\cdots$ O hydrogen bond lengths found by Corey in diketopiperazine.

The X-ray work of Astbury also provides evidence that α-keratin and certain other fibrous proteins contain polypeptide chains with a folded rather than an extended configuration. The X-ray data have not led to the determination of the atomic arrangement, however, and there exists no reliable evidence regarding the detailed nature of the folding.

X-Ray studies of crystalline globular proteins have provided values of the dimensions of the units of structure, from which some qualitative conclusions might be drawn regarding the shapes of the protein molecules. An interesting attempt to go farther was made by Crowfoot,[5] who used her X-ray data for crystalline insulin to calculate Patterson and Patterson–Harker diagrams.[12] Crowfoot discussed these diagrams in a sensible way, and pointed out that since the X-ray data correspond to effective interplanar distances not less than 7 Å. they do not permit the determination of the positions of individual atoms;[13] the diagrams instead give some information about large-scale fluctuations in scattering power within the crystal. Crowfoot also stated that the diagrams provide no reliable evidence regarding either a polypeptide chain or a cyclol structure for insulin.

Wrinch and Langmuir[4] have, however, contended that Crowfoot's X-ray data correspond in great detail to the structure predicted for the insulin molecule on the basis of the cyclol theory, and thus provide the experimental proof of the theory. We wish to point out that the evidence adduced by Wrinch and Langmuir has very little value, because their comparison of the X-ray data and the cyclol structure involves so many arbitrary assumptions as to remove all significance from the agreement obtained. In order to attempt to account for the maxima and minima appearing on Crowfoot's diagrams, Wrinch and Langmuir made the assumption that certain regions of the crystal (center of molecule, center of lacunae) have an electron density less than the average, and others (slits, zinc atoms) have an electron density greater than the average. The positions of these regions are predicted by the cyclol theory, but the magnitudes of the electron density are not predicted quantitatively by the theory. Accordingly the authors had at their disposal seven parameters, to which arbitrary values could be assigned in order to give agreement with the data. Despite the numbers of these parameters, however, it was necessary to introduce additional arbitrary parameters, bearing no predicted relation whatever to the cyclol structure, before rough agreement with the Crowfoot diagrams could be obtained. Thus the peak B″, which is the most pronounced peak in the $P(xy0)$ section (Fig. 2 of Wrinch and Langmuir's paper) and is one of the four well-defined isolated maxima reported, is accounted for by use of a region (V) of very large negative deviation located at a completely arbitrary position in the crystal; and this region is not used by the authors in interpreting any other features of the diagrams. This introduction of four arbitrary parameters (the three coördinates and the intensity of the region V) to account for one feature of the experimental diagrams would in itself make the argument advanced by Wrinch and Langmuir unconvincing; the fact that many other parameters were also assigned arbitrary values removes all significance from their argument.

It has been pointed out by Bernal,[14] moreover, that the authors did not make the comparison of their suggested structure and the experimental diagrams correctly. They compared only a fraction of the vectors defined by their regions with the Crowfoot diagrams, and neglected the rest of the vectors. Bernal reports that he has made the complete calculation on the basis of their structure, and has found that the resultant diagrams show no relation whatever to the experimental diagrams. He states also that with seven density values at closest-packed positions as arbitrary parameters he has found that a large number of structures which give rough agreement with the experimental diagrams can be formulated.

We accordingly conclude that there exists no satisfactory X-ray evidence for the cyclol structure for insulin.

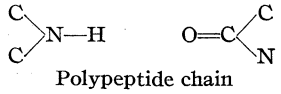
3. Thermochemical Evidence Regarding Protein Structure

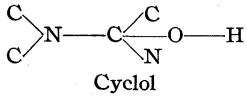
It is, moreover, possible to advance a strong argument in support of the contention that the cyclol structure does not occur to any extent in any protein.

X-Ray photographs of denatured globular proteins are similar to those of β-keratin, and thus indicate strongly that these denatured proteins contain extended polypeptide chains.[15] Astbury[16] has also obtained evidence that in protein films on surfaces the protein molecules have the extended-chain configuration, and this view is shared by Langmuir, who has obtained independent evidence in support of it.[17] Now the heat of denaturation of a protein is small—less than one hundred kilogram calories per mole of protein molecules for denaturation in solution,[18] that is, only a fraction of a kilogram calorie per mole of amino acid residues. Consequently the structure of native proteins must be such that only a very small energy change is involved in conversion to the polypeptide chain configuration.

It is unfortunate that there exist no substances known to have the cyclol structure; otherwise their heats of formation could be found experimentally for comparison with those of substances such as diketopiperazine which are known to contain polypeptide chains or rings. It is possible, however, to make this comparison indirectly in various ways. A system of values of bond energies and resonance energies has been formulated[19] which permits the total energy of a molecule of known structure to be predicted with an average uncertainty of only about 1 kcal./mole for a molecule the size of the average amino acid residue. The polypeptide chain (amide form) and cyclol can be represented by the following diagrams

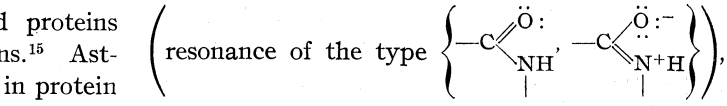


Polypeptide chain



Cyclol

The change in bonds from polypeptide chain to cyclol is N–H + C=O ⟶ N–C + C–O + O–H. With N–H = 83.3, C=O = 152.0, N–C = 48.6, C–O = 70.0, and O–H = 110.2 kcal./mole, the bonds of an amino acid residue are found to be 6.5 kcal./mole less stable for the cyclol configuration than for the chain configuration. This must further be corrected for resonance of the double bond



which amounts for an amide to about 21 kcal./mole[19]; there is no corresponding resonance for the cyclol, which involves only single bonds. We conclude that the cyclol structure is less stable than the polypeptide chain structure by 27.5 kcal./mole per amino acid residue.

This value relates to gaseous molecules, containing no hydrogen bonds, and with the ordinary van der Waals forces also neglected. It is probable that the ordinary van der Waals forces would have nearly the same value for a cyclol as for a polypeptide chain; and the available evidence[19,20] indicates that the polypeptide hydrogen bonds would be slightly stronger than the hydrogen bonds for the cyclol structure. Moreover, the observed small values (about 2 kcal./mole) for the heat of solution of amides and alcohols show that the stability relations in solution are little different from those of the crystalline substances. We accordingly conclude that the polypeptide chain structure for a protein is more stable than the cyclol structure by about 28 kcal./mole per amino acid residue, either for a solid protein or a protein in solution (with the active groups hydrated[21]).

The comparison of the polypeptide chain and cyclol can also be made without the use of bond energy values. The heat of combustion of crystalline diketopiperazine, which contains two glycine residues forming a polypeptide chain,[22] is known;[23] from its value, 474.6 kcal./mole, the heat of formation of crystalline diketopiperazine (from elements in their standard states) is calculated to be 128.4 kcal./mole, or 64.2 kcal./mole per glycine residue. A similar calculation cannot be made directly for the cyclol structure, because no sub-

(20) M. L. Huggins, *J. Org. Chem.*, **1**, 407 (1936).

(21) The suggestion has been made [F. C. Frank, *Nature*, **138**, 242 (1936)] that the energy of hydration of hydroxyl groups might be very much greater than that of the carbonyl and secondary amino groups of a polypeptide chain; there exists, however, no evidence indicating that this is so.

(22) R. B. Corey, ref. 7.

(23) M. S. Kharasch, *Bur. Standards J. Research*, **2**, 359 (1929).

stance is known to have the cyclol structure; but an indirect calculation can be made in many ways, such as the following. One hexamethylenetetramine molecule and one pentaerythritol molecule contain the same bonds as four cyclized glycine residues and three methane molecules; hence the heat of formation of a glycine cyclol per residue is predicted to have the value 32.2 kcal./mole found experimentally[24] for $\frac{1}{4}C_6H_{12}N_4(c) + \frac{1}{4}C(CH_2OH)_4(c) - \frac{3}{4}CH_4(c)$. Similarly the value for $N(C_2H_5)_3(c) + C_2H_5OH(c) - 3C_2H_6(c)$ is 40.2 kcal./mole. The average of several calculations of this type, 36 kcal./mole, differs from the experimental value of the heat of formation of diketopiperazine per residue, 64 kcal./mole, by 28 kcal./mole. This agrees closely with the value 27.5 kcal./mole found by the use of bond energies, and we can be sure that the suggested cyclol structure for proteins is less stable than the polypeptide chain structure by about this amount per amino acid residue. Since denatured proteins are known to consist of polypeptide chains, and native proteins differ in energy from denatured proteins by only a very small amount (less than 1 kcal./mole per residue), we draw the rigorous conclusion that *the cyclol structure cannot be of primary importance for proteins; if it occurs at all (which is unlikely because of its great energetic disadvantage relative to polypeptide chains) not more than about three per cent. of the amino acid residues could possess this configuration.*

The above conclusion is not changed if the assumption be made that polypeptide chains are in the imide rather than the amide form,[3b] since this would occur only if the imide form were the more stable. In this case the experimental values of heats of formation (such as that of diketopiperazine) would still be used as the basis for comparison with the predicted value for the cyclol structure, and the same energy difference would result from the calculation.

It has been recognized[25-27] that energy relations present some difficulty for the cyclol theory (although the seriousness of the difficulty seems not to have been appreciated), and various suggestions have been made in the attempt to avoid the difficulty. In her latest communication[3h] Wrinch writes, "The stability of the globular proteins, under special conditions, in solution and in the crystal, we attribute to definite stabilizing factors;[26,27] namely, (1) hydrogen bonds between the oxygens of certain of the triazine rings, (2) the multiple paths of linkage between atoms in the fabric, (3) the closing of the fabric into a polyhedral surface which eliminates boundaries of the fabric and greatly increases the symmetry, and (4) the coalescence of the hydrophobic groups in the interior of the cage." These factors are, however, far from sufficient to stabilize the cyclol structure relative to the polypeptide chain structure. (1) The hydrogen bonds between hydroxyl groups in the cyclol structure would have nearly the same energy (about 5 kcal./mole) as those involving the secondary amino and carbonyl groups of the polypeptide chain. The suggestion[26] that resonance of the protons between oxygen atoms would provide further stabilization is not acceptable, since the frequencies of nuclear motion are so small compared with electronic frequencies that no appreciable resonance energy can be obtained by resonance involving the motion of nuclei. (2) We are unable to find any aspects of the bond distribution in cyclols which are not taken into consideration in our energy calculation given above. (3) There is no type of interatomic interaction known to us which would lead to additional stability of a cage cyclol as the result of eliminating boundaries and increasing the symmetry. (4) The stabilizing effect of the coalescence of the hydrophobic groups has been estimated[26] to be about 2 kcal./mole per CH_2 group, and to amount to a total for the insulin molecule of about 600 kcal./mole. It seems improbable to us that the van der Waals interactions of these groups are much less than this for polypeptides. The maximum of 600 kcal./mole from this source is still negligibly small compared with the total energy difference to be overcome, amounting to about 8000 kcal./mole for a protein containing about 288 residues.[28]

We accordingly conclude that the cyclol structure is so unstable relative to the polypeptide structure that it cannot be of significance for proteins.

It may be pointed out that a number of experiments[29-31] have added the weight of their evi-

(24) The values of heats of combustion used are $C_6H_{12}N_4(c)$, 1006.7; $C(CH_2OH)_4(c)$, 661.2; $CH_4(c)$, 210.6; $N(C_2H_5)_3(c)$, 1035.5; $C_2H_5OH(c)$, 325.7; $C_2H_6(c)$, 370.0 kcal./mole.

dence to the general conclusion reached in this communication that the cyclol bond and the cyclol fabric are energetically impossible.

4. Further Arguments Indicating the Non-existence of the Cyclol Structure

There are many additional arguments which indicate more or less strongly that the cyclol structure does not exist. Of these we shall mention only a few.

It has been found experimentally that two atoms in adjacent molecules or in the same molecule but not bonded directly to one another reach equilibrium at a distance which can be represented approximately as the sum of certain van der Waals radii for the atoms.[19,32] Two carbon atoms of methyl or methylene groups not bonded to the same atom never approach one another more closely than about 4.0 Å., and two hydrogen atoms not bonded to the same atom are always at least 2.0 Å. apart. It has been pointed out by Huggins[33] that the cyclol structure places the carbon atoms of side chains only 2.45 Å. apart, and that in the C_2 structure for insulin there are hydrogen atoms only 0.67 Å. apart. We agree with Huggins that this difficulty alone makes the cyclol hypothesis unacceptable.

A closely related argument, dealing with the small area available for the side chains of a cyclol fabric, has been advanced by Neurath and Bull.[34] The area provided per side chain by the cyclol fabric, about 10 sq. Å., is far smaller than that required; and, as Neurath and Bull point out, the suggestion[3e,26] that some of the side chains pass through the lacunae of the fabric to the other side cannot be accepted, because this would require non-bonded interatomic distances much less than the minimum values found in crystals.

One of the most striking features of the cyclol fabric is the presence of great numbers of hydroxyl groups: in the case of cyclol C_2 there are 288 hydroxyl groups exclusive of those present in the side chains. Recently Haurowitz[35,36] has subjected the cyclol hypothesis to experimental tests on the basis of the existence or non-existence of cage hydroxyl groups. In the first communication[35] Haurowitz concludes on the basis of his and previous experiments[37-39] on the acylation and alkylation of proteins that the experimental evidence is in decided opposition to the conception that proteins possess great numbers of hydroxyl groups and therefore to the cyclol hypothesis. It seems to us that the objection raised by Haurowitz[36] is worthy of consideration and it certainly cannot be disposed of on the grounds that the original structure has been destroyed unless some concrete evidence can be submitted to indicate that this is the case. In a second communication Haurowitz and Astrup[36] write that "According to the classical theory of protein structure the carboxyl and amino groups found after hydrolytic splitting of a protein come from —CO—NH— bonds. According to the cyclol hypothesis, however, the free carboxyl and amino groups must be formed, during the splitting, from bonds of the structure =C(OH)—N=. The classical theory would predict on hydrolysis no great change in the absorption spectrum below 2400 Å. because the CO groups of the amino acids and of the peptide bonds both are strongly absorbing in this region.[40] On the other hand, the cyclol hypothesis would predict a greatly increased absorption because of the formation of new CO groups. . . . The absorption for genuine and for hydrolyzed protein is about equal. This seems to be in greater accordance with the classical theory of the structure of proteins than with the cyclol theory."

Mention may also be made of the facts that no simple substances with the cyclol structure have ever been synthesized[29] and that in general chemical reactions involving the breaking of covalent bonds are slow, whereas rapid interconversion of polypeptide and cyclol structure must be assumed to occur in, for example, surface denaturation. These chemical arguments indicate strongly that the cyclol theory is not acceptable.[41]

5. A Discussion of Arguments Advanced in Support of the Cyclol Theory

Although a great number of papers dealing with the cyclol theory have been published, we have

(40) M. A. Magill, R. E. Steiger and A. J. Allen, *Biochem. J.*, **31**, 188 (1937).

(41) Another argument against cyclols of the C_2 type can be based on the results reported by J. L. Oncley, J. D. Ferry and J. Shack, *Symposia on Quant. Biol.*, **6**, 21 (1938), H. Neurath, *ibid.*, **6**, 196 (1938), and J. W. Williams and C. C. Watson, *ibid.*, **6**, 208 (1938), who have shown that dielectric constant measurements and diffusion measurements indicate that the molecules of many proteins are far from spherical in shape.

had difficulty in finding in them many points of comparison with experiment (aside from the X-ray work mentioned above) which were put forth as definite arguments in support of the structure.

One argument which has been advanced is that the cyclol theory "readily interprets the total number of amino acid residues per molecule, without the introduction of any *ad hoc* hypothesis"[3e] and that "The group of proteins with molecular weights ranging rom 33,600 to 40,500 are closed cyclols of the type C_2 containing 288 amino acid residues."[3e] Now the presence of imino acids (proline, oxyproline) in a protein prevents its formation of a complete cyclol such as C_2, and many proteins in this molecular weight range are known to contain significant amounts of proline: for insulin 10% is reported,[3f] for egg albumin 4%,[42] for zein 9%,[43] for Bence–Jones protein 3%,[44] and for pepsin 5%.[45] Wrinch has stated that "a future modification" (in regard to the number of residues) "is also introduced if imino acids are present"[3c]; "these numbers perhaps being modified if imino acids are present",[3e] and "if certain numbers of imino acid residues are present, these numbers" (of residues) "may be correspondingly modified."[3g] This uncertainty regarding the effect of the presence of imino acids in cyclols on the expected number of residues leaves the argument little force. In fact, even the qualitative claim that the cyclol hypothesis implies the existence of polyhedral structures containing certain numbers of amino acid residues and so predicts that globular proteins have molecular weights which fall into a sequence of separated classes can be doubted for the same reason.

It has been claimed[36] that the cyclol hypothesis explains the facts that proteins contain certain numbers of various particular amino acid residues and that these numbers are frequently powers of 2 and 3,[46] and it is proper that we inquire into the nature of the argument. Wrinch states[27] "An individual R group" (side chain) "is presumably attached, not to just any α-carbon atom, but only to those whose environment makes them appropriate in view of its specific nature. As an example of different environments, we may refer to the cyclol cages; here the pairs of residues at a slit have 'different environments' and the residues not at a slit fall into sets which again have 'different environments.' We therefore expect characteristic proportions to be associated with aromatic, basic, acidic, and hydrocarbon R groups, respectively, even perhaps with individual R groups. In any case a non-random distribution of the proportions of each residue in proteins in general is to be expected on any fabric hypothesis. On the cyclol hypothesis, for example, α-carbons having equivalent environments occur in powers of 2 and 3. . . . It is difficult to avoid interpreting the many cases which have recently been summarized in which the proportions of many types of residue are powers of 2 and 3 as further direct evidence in favor of the cyclol fabric. This fabric consists of an alternation of diazine and triazine hexagons, with symmetries respectively 2 and 3." Also it has been said by Langmuir[47] that "The occurrence of these factors, 2 and 3, furnishes a powerful argument for a geometrical interpretation such as that given by the cyclol theory. In fact, the hexagonal arrangement of atoms in the cyclol fabric gives directly and automatically a reason for the existence of the factors 2 and 3 and the non-occurrence of such factors as 5 and 7."

On examining the cyclol C_2, however, we find that these statements are not justified. The only factors of 288 are of the form $2^n\ 3^m$; moreover, the framework of the cyclol C_2 has the tetrahedral symmetry T, so that if the distribution of side chains conforms to the symmetry of the framework the amino acid residues would occur in equivalent groups of twelve. But in view of the rapid decrease in magnitude of interatomic forces with distance there would seem to be little reason for the distribution of side chains over a large protein molecule to conform to the symmetry T; it is accordingly evident that any residue numbers might occur for the cyclol C_2. We conclude that the cyclol hypothesis does not provide an explanation of the occurrence of amino acid residues in numbers equal to products of powers of 2 and 3.

Although there is little reason to expect that the distribution of side chains would correspond to the symmetry of the framework, it is interesting to note that the logical application of the methods of argument used by Wrinch suggests strongly that sixty residues of each of two amino acids should be present in a C_2 cyclol. This cyclol contains twenty lacunae of a particular type—each surrounded by a nearly coplanar border of twelve diazine and triazine

(47) I. Langmuir, *Symposia on Quant. Biol.*, **6**, 135 (1938).

rings. Each of these has trigonal symmetry so far as this near environment is concerned. Hence it might well be expected that a particular amino acid would be represented by three residues about each of these twenty lacunae, giving a total of sixty residues. But the number 60 cannot be expressed in the form $2^n 3^m$, it is not a factor of 288, and the integer nearest the quotient 288/60, 5, also cannot be expressed in the form $2^n 3^m$.

One of the most straightforward arguments advanced by Wrinch[3c,d] is that a protein surface film must have all its side chains on the same side, which would be the case for a cyclol fabric but not for an extended polypeptide chain. This argument now has lost its significance through the recently obtained strong evidence that proteins in films have the polypeptide structure,[16,17] and not the cyclol structure.

There can be found in the papers by Wrinch many additional statements which might be construed as arguments in support of the cyclol structure. None of these seems to us to have enough significance to justify discussion.

6. The Present State of the Protein Problem

The amount of experimental information about proteins is very great, but in general the processes of deducing conclusions regarding the structure of proteins from the experimental results are so involved, the arguments are so lacking in rigor, and the conclusions are so indefinite that it would not be possible to present the experimental evidence at the basis of our ideas of protein structure[48] in a brief discussion. In the following paragraphs we outline our present opinions regarding the structure of protein molecules, without attempting to do more than indicate the general nature of the evidence supporting them. These opinions were formed by the consideration not only of the experimental evidence obtained from proteins themselves but also of the information regarding interatomic interactions and molecular structure in general which has been gathered by the study of simpler molecules.

We are interested here only in the role of amino acids in proteins—that is, in the simple proteins (consisting only of α-amino and α-imino acids) and the corresponding parts of conjugated proteins; the structure and linkages of prosthetic groups will be ignored.

The great body of evidence indicating strongly that the amino acids in proteins are linked together by peptide bonds need not be reviewed here.

The question now arises as to whether the polypeptide chains or rings contain many or few amino acid residues. We believe that the chains or rings contain many residues—usually several hundred. The fact that in general proteins in solution retain molecular weights of the order of 17,000 or more until they are subjected to conditions under which peptide hydrolysis occurs gives strong support to this view. It seems to us highly unlikely that any protein consist of peptide rings containing a small number of residues (two to six) held together by hydrogen bonds or similar relatively weak forces, since, contrary to fact, in acid or basic solution a protein molecule of this type would be decomposed at once into its constituent small molecules.

There exists little evidence as to whether a long peptide chain in a protein has free ends or forms one more peptide bond to become a ring. This is, in fact, a relatively unimportant question with respect to the structure, as it involves only one peptide bond in hundreds, but it may be of considerable importance with respect to enzymatic attack and biological behavior in general.

A native protein molecule with specific properties must possess a definite configuration, involving the coiling of the polypeptide chain or chains in a rather well-defined way.[49] The forces holding the molecule in this configuration may arise in part from peptide bonds between side-chain amino and carboxyl groups or from side-chain ester bonds or S–S bonds; in the main, however, they are probably due to hydrogen bonds and similar interatomic interactions. Interactions of this type, while individually weak, can by combining their forces stabilize a particular structure for a molecule as large as that of a protein. In some cases (trypsin, hemoglobin) the structure of the native protein is the most stable of those accessible to the polypeptide chain; the structure can then be reassumed by the molecule after denaturation. In other cases (antibodies) the native configuration is not the most stable of those accessible, but is an unstable configuration impressed on the molecule by its environment (the influence of the antigen) during its synthesis; denaturation is not reversible for such a protein.

Crystal structure investigations have shown

(48) We believe that our views regarding the structure of protein molecules are essentially the same as those of many other investigators interested in this problem.

(49) H. Wu, *Chinese J. Physiol.*, **5**, 321 (1931); A. E. Mirsky and L. Pauling, *Proc. Nat. Acad. Sci.*, **22**, 439 (1936).

that in general the distribution of matter in a molecule is rather uniform. A protein layer in which the peptide backbones are essentially coplanar (as in the β-keratin structure) has a thickness of about 10 Å. If these layers were arranged as surfaces of a polyhedron, forming a cage molecule, there would occur great steric interactions of the side chains at the edges and corners. (This has been used above as one of the arguments against the C_2 cyclol structure.) We accordingly believe that *proteins do not have such cage structures*.[50] A compact structure for a globular protein might involve the superposition of several parallel layers, as suggested by Astbury, or the folding of the polypeptide chain in a more complex way.

One feature of the cyclol hypothesis—the restriction of the molecule to one of a few configurations, such as C_2—seems to us unsatisfactory rather than desirable. The great versatility of antibodies in complementing antigens of the most varied nature must be the reflection of a correspondingly wide choice of configuration by the antibody precursor. We feel that the biological significance of proteins is the result in large part of their versatility, of the ability of the polypeptide chain to accept and retain that configuration which is suited to a special purpose from among the very great number of possible configurations accessible to it.

Proteins are known to contain the residues of some twenty-five amino acids and it is not unlikely that this number will be increased in the future. A great problem in protein chemistry is that of the order of the constituent amino acid residues in the peptide chains. Considerable evidence has been accumulated[46] suggesting strongly that the stoichiometry of the polypeptide framework of protein molecules can be interpreted in terms of a simple basic principle. This principle states that the number of each individual amino acid residue and the total number of all amino acid residues contained in a protein molecule can be expressed as the product of powers of the integers two and three. Although there is no direct and unambiguous experimental evidence confirming the idea that the constituent amino acid residues are arranged in a periodic manner along the peptide chain, there is also no experimental evidence which would deny such a possibility, and it seems probable that steric factors might well cause every second or third residue in a chain to be a glycine residue, for example.

The evidence regarding frequencies of residues involving powers of two and three leads to the conclusion that there are 288 residues in the molecules of some simple proteins. It is not to be expected that this number will be adhered to rigorously. Some variation in structure at the ends of a peptide chain might be anticipated; moreover, amino acids might enter into the structure of proteins in some other way than the cyclic sequence along the main chain.[51] The structural significance of the number 288 is not clear at present. It seems to us, however, very unlikely that the existence of favored molecular weights (or residue numbers) of proteins is the result of greater thermodynamic stability of these molecules than of similar molecules which are somewhat smaller or larger, since there are no interatomic forces known which could effect this additional stabilization of molecules of certain sizes. It seems probable that the phenomenon is to be given a biological rather than a chemical explanation—we believe that the existence of molecular-weight classes of proteins is due to the retention of this protein property through the long process of the evolution of species.

We wish to express our thanks to Dr. R. B. Corey for his continued assistance and advice in the preparation of this paper, and also to other colleagues who have discussed these questions with us.

Summary

It is concluded from a critical examination of the X-ray evidence and other arguments which have been proposed in support of the cyclol hypothesis of the structure of proteins that these arguments have little force. Bond energy values and heats of combustion of substances are shown to lead to the prediction that a protein with the cyclol structure would be less stable than with the polypeptide chain structure by a very large amount, about 28 kcal./mole of amino acid residues; and the conclusion is drawn that proteins do not have the cyclol structure. Other arguments leading to the same conclusion are also presented. A brief discussion is given summarizing the present state of the protein problem, with especial reference to polypeptide chain structures.

PASADENA, CALIF. RECEIVED APRIL 22, 1939

(50) Wrinch recently has suggested[9h] that even if proteins are not cyclols the cage structure might be significant.

(51) H. Jensen and E. A. Evans, Jr., *J. Biol. Chem.*, **108**, 1 (1935), have shown that insulin probably contains several phenylalanine groups attached only by side-chain bonds to the main peptide chain.

Heats of Organic Reactions. VIII. Some Further Hydrogenations, Including Those of Some Acetylenes

BY JOHN B. CONN, G. B. KISTIAKOWSKY AND ELGENE A. SMITH

In the previous publications of this series[1] have been reported the heats of addition of hydrogen to a wide variety of unsaturated organic molecules as well as the heats of addition of chlorine and bromine to some of the simpler ethylenic hydrocarbons. The data previously presented have shown correlation between molecular constitution and the thermal effects accompanying these addition reactions. The generalizations drawn and semi-empirical rules formulated have been amplified and modified as the progress of the investigation justified. In the present paper we shall present some additional data, and, it being essentially the final report on this work, we shall give a discussion of the entire set of data from a concordant point of view. The information of general significance which emerges from it concerns the rather strong interactions between non-bonded atoms or atomic groups within a molecule.

Preparation of Materials

We are indebted to the late Professor E. P. Kohler and his co-workers for the cyclic compounds used in this work; their preparation is reported elsewhere.[2]

Acetylene.—Tank acetylene (Prest-O-Lite) was purified by passage through a series of 10 spiral wash bottles, which contained in order: (1) saturated sodium bisulfite solution, (2) water, (3) and (4) 0.2 *N* iodine in aqueous potassium iodide solution, (5) and (6) sodium thiosulfate solution, (7) and (8) alkaline sodium hydrosulfite with sodium anthraquinone β-sulfonate as indicator and oxygen carrier, (9) and (10) 10% aqueous potassium hydroxide solution. The gas then traversed a trap in Dry-Ice and two large drying tubes, the first of which contained calcium chloride and the second, Dehydrite. A 38-cm. mercury escape valve served to ensure a constant back pressure. The solutions described above were renewed just prior to each run and never became exhausted during their period of use.[3]

Methylacetylene.—Sodium acetylide was prepared by passing acetylene, purified as above, into a Dry-Ice cooled solution of 72 g. of sodium in 1 l. of liquid ammonia until the blue color disappeared.

Methyl sulfate (400 g.) which had been washed previously with sodium bicarbonate solution and dried with anhydrous magnesium sulfate was next introduced by means of a special dropping funnel, so designed as to deliver small droplets, and containing a side-arm on both the stem and the pressure equalizer tube through which a slow stream of nitrogen passed. This device protected the tip and the liquid in the funnel from contact with ammonia. It had been found previously that an ordinary funnel not only delivered drops of such size as to cause an almost explosive reaction, but also soon became plugged with a white solid (presumably $CH_3NH_3SO_4CH_3$).

When introduction of methyl sulfate was started the bath was allowed to warm up to the boiling point of the ammonia. The exit gases were freed from ammonia by passage through 2.5 liters of water and 1.5 liters of 12 *N* sulfuric acid. The latter solution never became alkaline. The hydrocarbon was dried with a large calcium chloride tower and then condensed in a trap immersed in Dry-Ice–methanol mixture. The yield of crude methylacetylene was 83%, in agreement with the observation of Vaughn, Hennion, Vogt and Nieuwland.[4]

The product was given a double bulb-to-bulb distillation to free it as well as possible from acetylene, and then fractionated in a six-foot (1.8-meter) vacuum-jacketed Podbielniak type column. The middle fraction, which boiled at $-23.23 \pm 0.05°$[5] (760 mm.) was transferred *in vacuo* to a small monel metal tank just before use. The freezing point was $-102.74°$.[6]

Dimethylacetylene.—Initial attempts to prepare this hydrocarbon from sodium methylacetylide and methyl sulfate gave unsatisfactory yields: however, the dialkyl acetylene synthesis described by Bried and Hennion[7] was found to work very well. Sodium acetylide was prepared in the usual manner from 25 g. of sodium in 500 cc. of liquid ammonia, and to this a suspension of sodamide from 30 g. of sodium in 500 cc. of liquid ammonia[8] was added, followed by 266 g. of methyl sulfate with stirring. After standing overnight at −80°, the contents of the flask were boiled off; the ammonia was removed as before, and the hydrocarbon was condensed in a series of two traps, the first of which was kept at −20°, and the second at −80°. Nearly all of the dimethylacetylene was caught in the first trap. The yield of crude product was 80%. The hydrocarbon was fractionated in the six-foot Podbielniak column; the portion reserved for calorimetric study boiled at $26.69 \pm 0.03°$ (760 mm.).[9]

Dimethyldiacetylene.—Methylacetylene was generated from purified propylene bromide and potassium hydroxide in boiling butyl alcohol according to Heisig and Davis.[9] The yield was 81%.

(730 mm.) 145° and $n^{20}D$ 1.474 for cyclooctene and $n^{20}D$ 1.4586 for cycloöctane. [d] Reference *b* reports $n^{20}D$ 1.4440 for cycloheptane.

The methylacetylene was now converted to the cuprous salt by passing it slowly into a vigorously stirred solution of 1.5 times the theoretical amount of ammoniacal cuprous chloride. Absorption was complete. The cuprous methylacetylide was filtered off and preserved in a desiccator containing concentrated ammonia water.

When an attempt was made to oxidize all of the cuprous salt at once with potassium ferricyanide as described by Griner,[10] much methylacetylene was regenerated and very little of the desired product was obtained. However, when the salt was added in small portions to the hot, rapidly stirred ferricyanide solution, the yield was 42%. The hydrocarbon sublimed cleanly with steam from the reaction flask and was washed with distilled water and dried over Dehydrite. It developed a slight yellow tinge on long standing, but could be freed from this impurity by subliming with steam.

Results

Cyclic Hydrocarbons.—Incompleteness of reaction was tested for by the usual bromine (II) titration. In no case was unsaturation found in the product. There was no irreversible adsorption on the cobalt–nickel catalyst and a large variation of relative rates of flow of hydrogen and hydrocarbon had no effect on the heat evolved. As Kohler, Tishler, Thompson and Potter[2] have indicated, it is very difficult to obtain these hydrocarbons in a pure state as judged by the freezing point method. The difficulty of their preparation in general precludes the use of Column A for their distillation, and repeated fractionations through Column B failed to give a product with a flat freezing curve. Two reasons lead us to believe that this failure is not serious. The first is the extremely large freezing point depression constants which uniformly characterize these hydrocarbons. Thus even a minute amount of impurity would give the material a poor freezing point. The second is a result of repeated hydrogenations of cycloheptene using samples of different purities as judged by the freezing points. Three different samples were used which gave samples of cycloheptane freezing at −12.2°, −8.4° and −8.4°.[11] However, the heat of hydrogenation of the entire set can be expressed as 26,419 ± 56 cal. per mole. The average of the two runs with cycloheptene which had been distilled through column A is about 100 cal. higher than this average and represents what we consider the correct value. The earlier results are quoted only to show how much more sensitive the freezing point test is than the heat of the reaction. The cycloheptene itself tended to form a glass and it was difficult to get good freezing curves. The best sample froze at about −56°.

The cycloheptadiene gave a good freezing flat at −110.4°. The product of hydrogenation gave an excellent flat at −7.98°. This we take to be the true freezing point of cycloheptane.

Cycloheptatriene gave only a fair "flat" at −79.5°, and its hydrogenation product froze at −8.3°.

The cycloöctene froze at −22.1° and the hydrogenation product froze at 7.95°. Both of these determinations left much to be desired as freezing points but do not indicate any large amounts of impurities. Table I shows the pertinent data on these compounds.

Cyclic Ketones.—The hydrogenation of the cyclic ketones proceeded smoothly on the cobalt–nickel catalyst. There was no irreversible adsorption, and variations in the rates of flow produced no effect. As was the case with acetone and methyl ethyl ketone, the hydrogenation was not complete. This incompleteness was measured in the following manner: 0.5 cc. of the product was mixed with an equal volume of sodium methoxide and 1 cc. of a standard solution of *p*-nitrobenzaldehyde in methyl alcohol. After heating gently for two minutes the color was matched with that produced by a 0.5% solution of the ke-

tone in methyl alcohol, by diluting the unknown with methyl alcohol until a match was obtained. This test consistently showed a concentration of 0.9% of ketone in the case of the cyclopentanone and 0.7% in the case of the cyclohexanone. No trace of dimolecular reduction could be detected by carefully fractionating samples of the product in a small Podbielniak still.

A calculation of the incompleteness of the hydrogenation from the freezing point of the product in the case of the cyclohexanone yields a figure in substantial agreement with that found by means of the above test. The true freezing point of cyclohexanol was used as 25.47° and the freezing point depression constant was taken from "I. C. T." Table II lists the pertinent data on these compounds.

Acetylenic Compounds.—Acetylene and methylacetylene were hydrogenated over a 10% platinum on asbestos catalyst. In neither case could any irreversible adsorption be detected. Wide variations in the rate of gas flows failed to show any effect on the heat produced. Ammoniacal silver nitrate solution was used to test for 1-acetylenes in the product; the exit gases were passed through the reagent for five minutes. In every case this test was negative. Samples of the ethane and propane from the hydrogenations were collected and subjected to vapor pressure measurements in a differential manometer. No significant differences in vapor pressure between the first and last fractions to vaporize could be detected. Thus polymers were shown to be absent. Dimethylacetylene would not hydrogenate completely over the 10% platinum catalyst, and therefore the reaction was carried out on cobalt–nickel, at 82°. A bromine titration test showed only 0.01% unsaturation in the hydrogenation product, but the irreversible adsorption test was somewhat inconclusive. There may have been a small amount of condensation on the catalyst, which also was manifested by a slight progressive change in the heat liberated with the repetition of the measurements. We believe that the true heat of reaction is slightly higher than reported and are increasing the estimate of the over-all error to care for this possibility. An attempt was made to hydrogenate dimethyldiacetylene but due to an incomplete reaction on the platinum catalyst and considerable irreversible adsorption on cobalt–nickel the effort was unsuccessful. Table III gives the data on these compounds.

Discussion

1. The New Experimental Data.—Rather large variations of the heats of hydrogenation in the cycloölefin series are reported here and in the preceding papers (III and V). The numerical values, which range from 28.59 kcal. for cyclohexene to 23.52 kcal. for cycloöctene, are spread over almost as wide a range as those observed in the ethylene (32.82 kcal.) to tetramethylethylene (26.63 kcal.) series, although in the present case a constant number of alkyl groups *are* adjacent to the double bond. The following discussion will make plausible the contention that the same fundamental cause is responsible for the variations of the reaction heats in both series of compounds, namely, the interactions of the newly formed bonds with near-by, non-bonded atoms and atomic groups.

Hydrogenation of rings with increased unsaturation has provided information on the resonance energy in these conjugated systems. If, in ac-

TABLE IV

EFFECT OF SUBSTITUENTS ON THE HEATS OF HYDROGENATION

$CH_3C{\equiv}CCH_3 + H_2$	−37.63[a]		$CH_3CH{=}CHCH_3 + H_2$	−27.95[a]	

[a] To and from an equilibrium mixture of *cis*- and *trans*-butenes-2.

cordance with the procedure used in earlier papers of this series, the resonance energy in a diene is taken as the difference in the heats of hydrogenation of the diene to an olefin and of this olefin to the paraffin, then cycloheptadiene has 2.77 kcal. resonance energy. Comparison with cyclohexadiene (1.81 kcal.) and cyclopentadiene (2.96 kcal.) shows that it is substantially the same in all ring compounds, but is somewhat smaller than in the open chain dienes (3 to 4 kcal., *cf.* V). It should be noted, however, that the steric effects discussed later make the calculation of the resonance energy in all these instances somewhat doubtful.

A subtraction of the heat of hydrogenation of cycloheptatriene from that of cycloheptene, taken three times, leaves 6.7 kcal. as the resonance energy in the former. Steric effects again make the absolute magnitude of this value somewhat uncertain, but they should be substantially eliminated by taking the ratio of the resonance energies of cycloheptatriene and diene. This is found equal to 2.4, while Pauling and Sherman and later Lennard-Jones[12] calculated for open chain trienes and dienes the ratio 2.1.

The heats of hydrogenation of cyclic ketones are of some interest because they reproduce the trend established for cycloölefins, the six-membered ring compound having again the higher heat of reaction. In the present case, however, it is cyclopentanone which has a reaction heat (12.50 kcal.) close to that of its open chain homologs (13.34 and 13.17 kcal. for acetone and methyl ethyl ketone, respectively, *cf.* VI), while the heat evolution with cyclohexanone is almost as large as with acetaldehyde (15.42 and 16.75 kcal., respectively).

The heats of hydrogenation of acetylene and its homologs vary with substitution of alkyl groups in much the same manner as do those of ethylene and its homologs. The analogy between the two series of compounds is even quantitative, as the following Table IV shows. This constitutes additional evidence for the conclusion reached (VII) on the basis of the heats of bromination of olefins, that the variations in the heats of addition reactions are caused mainly by the steric effect of substituents on the addenda used in the reactions. Were the effects of substituents on the several carbon–carbon bonds involved in hydrogenations considerable, the result of Table IV would be a rather improbable accident.

The following discussion is an effort to evaluate the character and magnitude of these effects.

2. The General Nature of Steric Effects.—Of all the available data the heats of hydrogenation of unsaturated ring compounds supply perhaps the most direct, although qualitative, information on the character of interactions of nonbonded atoms within a molecule. In a paper of this series (V) comments were made on the heats of hydrogenation of five-membered rings which, being some 2 kcal. lower than those of corresponding six-membered systems and of open chain disubstituted ethylenes, seemed to disprove the existence of strain energy in cyclopentene and cyclopentadiene although the bond angles in these compounds deviate from tetrahedral values. In the meantime Professor Pauling has told one of the present authors that in the opinion of Dr. V. Schomaker this conclusion is subject to revision because five-carbon systems are planar, while six-carbon rings are puckered. In the planar rings the C–H bonds must be in the eclipsed configuration, while in puckered rings they may take up staggered positions; hence the relative heats of hydrogenation may be employed to evaluate the strain energy in cyclopentene only after correction has been made for these steric effects. Studies of the internal rotation of methyl groups in ethane[13] have indeed shown that approximately 2.75 kcal. energy difference exists between the staggered and the eclipsed (in-line) configuration of the C–H bonds in the two methyl groups.

Two alternatives must now be considered, both of which are consistent with the observations on ethane: the configuration of lowest energy may be that in which C–H bonds are farthest apart

(12) Pauling and Sherman, *J. Chem. Phys.*, **1**, 679 (1933); Lennard-Jones, *Proc. Roy. Soc.* (London), **A158**, 280 (1937).

(13) See Kistiakowsky, Lacher and Stitt, *J. Chem. Phys.*, **7**, 289 (1939), for other references.

(staggered) or that in which they are closest together. If the former is true, then the low heats of hydrogenation of cyclopentene and pentadiene are due to the placement of hydrogen atoms into positions of higher energy as compared with the reaction of cyclohexene and a correction for this effect will result in values at least qualitatively consistent with the expected strain energies of the unsaturated C_5 rings. But if this explanation is the correct one, then the heat of combustion of cyclopentane, per CH_2 group, should be larger than that in open chain paraffins by about 3 kcal. because in the former the carbon bonds are not free to take up the (staggered) positions of lowest energy. Experimental data[14] give 157.9 kcal. (Swietoslawski) heat of combustion per CH_2 group in cyclopentane and 157.5 kcal. (Swietoslawski) in methylcyclopentane as against 157.9 kcal. (Richards) or 157.2 kcal. (Swietoslawski) in cyclohexane and 157.1 (Rossini) in normal open chain hydrocarbons, all referred to the vapor phase. These data suggest about 0.5 kcal. excess energy content per CH_2 group in cyclopentane and are in poor agreement with the discussed interpretation (the uncertainties are, however, large). Nevertheless, the other alternative leads to much greater inconsistencies. Cyclohexane, in which, due to puckering, the C–H bonds cannot all have in-line configuration, has nearly the same heat of combustion per CH_2 group as the open chain hydrocarbons, instead of being considerably higher. Furthermore, the lower heats of hydrogenation of the C_5 rings now must mean that the strain energy decreases with increasing unsaturation (*i. e.*, with increasing deviation from tetrahedral angles!), becoming negative unless the experimental heat of combustion of cyclopentane is in error by being too low. In this case, however, large strain energy would have to be assigned to cyclopentane, even though the C–C–C angles in this compound (108°) barely deviate from tetrahedral values. All this is so improbable that we select the first alternative unreservedly and assume that the positions of minimum energy are those in which the C–H bonds are farthest apart, *i. e.*, the staggered configuration of ethane.

The greater stability of the staggered configuration of C–H bonds may be formally ascribed to the existence of repulsive interactions ("steric hindrance") between non-bonded atoms in polyatomic molecules. The observed lower heats of hydrogenation of rings larger than cyclohexene are consistent with this idea since hydrogen atoms on non-adjacent carbons are forced close together in such rings because of their extensive puckering. Further supporting evidence is offered by the observations that the energy content difference of *cis*- and *trans*-butenes-2 is 0.95 kcal.[15] at 355°K. The planar zig-zag hydrocarbon chains in crystals also speak for the staggered configuration being the stable one. It appears[16] that the heats of fusion of the normal hydrocarbons are substantially higher than those of corresponding cyclo-paraffins. Supposing that the staggered configuration of the crystalline straight chain compounds were the strained one, the opposite relation could be expected. Still other favorable facts will be cited in the following.

3. The Relative Energies of Steric Hindrance.—The repulsive interactions in polyatomic molecules result in inconstancy of bond energies. However, whichever one speaks of, one is beset by a rather fundamental difficulty in stating a precise experimental definition of the magnitude of the interaction energy or of the variable bond strength. Consider, for instance, the two hypothetical reactions: $CH_4 \rightarrow CH_3 + H + E_1$ and $C_2H_6 \rightarrow C_2H_5 + H + E_2$. The difference $E_2 - E_1$ may be taken as the direct measure of the difference in bond energies, that is, of the difference in steric hindrances on a hydrogen atom in ethane and methane. Strictly speaking, however, this is incorrect as the removal of a hydrogen atom from the two molecules has probably altered to a different extent the bonding energies of the remaining atoms. Nevertheless only the first procedure can be followed through consistently with the available data and it will be used therefore in the following.

From Rossini's[17] combustion data the following thermochemical equations can be set up

$$2CH_4 \longrightarrow C_2H_6 + H_2 + 15.54 \text{ kcal.} \quad (1)$$

$$CH_4 + C_2H_6 \longrightarrow C_3H_8 + H_2 + 13.28 \quad (2)$$

(14) Kharasch, *Bur. Standards J. Research*, **2**, 359 (1929); Rossini, see references below.

(15) The as yet unpublished measurements on the gaseous heat capacities of these compounds indicate that at absolute zero their energy difference is even larger.

(16) Parks, Huffman and Thomas, THIS JOURNAL, **52**, 1032, 4381 (1930).

(17) Rossini, *Bur. Standards J. Research*, **6**, 37 (1931); **12**, 735 (1934); **13**, 201 (1934); *J. Chem. Phys.*, **6**, 168 (1938). Room temperature data referring to the gaseous state have been used here and in the following. A conversion to absolute zero is so uncertain for most of the compounds considered that the accruing theoretical improvement would be wholly fictitious. We do not believe that such a conversion will change the results significantly.

$$2C_2H_6 \longrightarrow n\text{-}C_4H_{10} + H_2 + 10.63 \quad (3)$$
$$2C_3H_8 \longrightarrow n\text{-}C_6H_{14} + H_2 + 9.57 \quad (4)$$
$$CH_4 + C_3H_8 \longrightarrow (CH_3)_3CH + H_2 + 11.26 \quad (5)$$
$$CH_4 + (CH_3)_3CH \longrightarrow C(CH_3)_4 + H_2 + 9.80 \quad (6)$$

The reactions involved all consist in the severance of two C–H bonds and a formation of an H–H and a C–C bond, the changes in the heats therefore being due exclusively to the variable steric hindrance. To what extent this latter may rise under exceptional circumstances is brought out by the calorimetric measurement of Bent and Cuthbertson:[18] $2(C_6H_5)_3CH \rightarrow (C_6H_5)_3C\text{–}C(C_6H_5)_3 + H_2 + 40$ kcal.

The heats of reactions (3) and (4) are sufficiently near together to justify an assumption that only substitutions on the same atoms to which the bonds considered belong have substantial effects on the *relative* magnitude of steric hindrance. This assumption is in accord with conclusions drawn by Rossini.[17]

Using the following notation

A : energy of severance of a C–H bond in methane
A-X: energy of severance of a C–H bond in ethane (or primary C–H bonds in higher homologs)
A-Y: energy of severance of a secondary C–H bond in propane
A-Z: energy of severance of a tertiary C–H bond in isobutane
B : energy of severance of a C–C bond in ethane
B-x: energy of severance of a C–C bond in propane
B-y: energy of severance of an internal C–C bond in butane
B-y': energy of severance of a C–C bond in isobutane
B-z : energy of severance of a C–C bond in neopentane

one obtains from equations (1) to (6)

$$\text{from (1) – (2)} : X - x = 2.26 \text{ kcal.} \quad (7)$$
$$\text{from (1) – (3)} : 2X - y = 4.91 \quad (8)$$
$$\text{from (1) – (5)} : Y - y' = 4.28 \quad (9)$$
$$\text{from (1) – (6)} : Z - z = 5.74 \quad (10)$$

The simplest assumption concerning steric hindrance is to treat the effects of substituent alkyl groups as additive, so that $Y = 2X$; $Z = 3X$; $y = 2x$; $y' = 2x$; $z = 3x$. The following are the results

$$\text{from (1) – (2)} : X - x = 2.26 \quad (11)$$
$$\text{from (1) – (3)} : X - x = 2.45 \quad (12)$$
$$\text{from (1) – (5)} : X - x = 2.14 \quad (13)$$
$$\text{from (1) – (6)} : X - x = 1.91 \quad (14)$$

The assumption of additivity of the steric effects evidently is fairly but not completely successful. Better agreement can be obtained, of course, by using more parameters but their introduction would be difficult to justify.

(18) Bent and Cuthbertson, THIS JOURNAL, **58**, 170 (1936).

As seen above, thermal data on saturated hydrocarbons alone cannot disentangle the steric effects upon the C–H and the C–C bonds, only a difference appearing in the final equations. This is true of all thermochemical data, barring direct measurements of the heats of formation of free radicals; therefore an assumption is required to obtain individual values. One which we shall make is that the entire observed effect of alkyl substituents upon the heats of addition reactions to unsaturated hydrocarbons is due to their steric hindrance on the newly formed bonds (*cf.* p. 9). This means that their effect upon a $=CR_1R_2$ group is equal to their effect upon the group $-CHR_1R_2$ resulting from hydrogenation.

From the heats of hydrogenation of various olefins the mean effect of substitution of one alkyl group into ethylene is found equal to 2.6 kcal. (± 0.1). Substitution of the second alkyl group in symmetric position lowers the heat of hydrogenation by another 2.3 kcal. (± 0.1) if the heat of hydrogenation of the equilibrium mixture of the isomeric pentenes-2 or butenes-2 is taken for this calculation. This choice is justified by the consideration that the resultant normal pentane or *n*-butane has presumably approximately the same proportions of the *cis*- and the *trans*-configurations as the olefins.

The introduction of the third methyl group lowers the heat evolution by 1.0 kcal. and the fourth decreases it another 0.3 kcal. The trend of these figures is qualitatively the same as that observed in equations (11) to (14) but the quantitative agreement is imperfect, showing the crudeness of the underlying assumptions. Taking for the differential effect of a methyl group upon a C–H bond (X) the mean of 2.6 and 2.3 kcal., 2.45 kcal., and substituting into equation (11) or (12) one finds that x is very nearly zero, hence that the energy of the C–C bonds is constant in saturated hydrocarbons. The energy of the multiple carbon–carbon bonds is similarly independent of substitution since an identical differential effect of methyl groups has been assumed for all carbon–carbon bonds and has now been found equal to zero.

Heats of bromination (VII) reveal with the aid of the same assumption as above that for the C–Br bond the order of the hydrogen and the methyl group hindrances is reversed, the former hindering more, the quantity corresponding to X in equation (11) being *ca.* – 0.5 kcal. In the same

manner Rossini's combustion data on primary alcohols[19] show that the methyl groups have lesser steric hindrance on the C–O bond. It seems that the relative steric effectiveness of hydrogen atoms and of methyl groups is correlated with the polarity of the bond on which the hindrance is exercised.

Some years ago Eyring[20] made an approximate wave-mechanical calculation of the interactions between non-bonded atoms in methane and in ethane, concluding that in the latter, because of greater steric hindrance of a CH_3 group, the C–H bond is effectively weaker by 3 kcal. On the preceding pages 2.5 kcal. was estimated for the same effect in excellent agreement with Eyring's calculation. To reduce the mathematical complexity of the problem, Eyring had to make several drastic simplifications, in view of which and of the frequent failure of approximate quantum mechanical calculations to obtain accurate interaction energies at close distances of approach, the agreement of his and of the present values is surprising; we are inclined to regard it as somewhat accidental because in other details Eyring's calculation does not agree so well with experimental data.

4. Hindrance of Internal Rotation.—According to Eyring the energy difference between the staggered and the eclipsed configurations of ethane is only 0.35 kcal., while observations give 2.75 kcal.[13] This large discrepancy has now led him to suggest[21] that some other effects are responsible for the hindrance of internal rotation. However, the general steric hindrance and the hindrance of internal rotation change in such analogous manner from case to case that the introduction of new effects seems rather unnecessary. Methyl groups were shown above to exert greater steric hindrance upon C–H bonds and parallel to this it is found that the hindrance of internal rotation changes from 2.75 kcal. in ethane to approximately 3.2 kcal. in propane,[22,23] 3.8 in isobutane[22] and 4.2 in neopentane.[22] In propylene[22,23] the hindrance of internal rotation was found equal to only 0.8 kcal., indications being that only three angular positions of minimum potential energy exist for the methyl group. This suggests, in accord with the facts to be considered later, that the steric effect of a $=CH_2$ group is not much larger than that of a hydrogen atom or a methyl group, although the existence of only three equilibrium positions, if confirmed, must be in addition explained by some special properties of a double bond (*cf.* ref. 23). The consideration of the case of cyclopentane has shown that the staggered position of C–H bonds is that of lower energy, which again agrees with steric hindrance as the cause of the hindrance of internal rotation.

Between the two alternatives: postulating different mechanisms for the steric hindrances and for the hindrances of internal rotation or considering Eyring's calculations as only qualitatively correct, we prefer the second. To reconcile various facts cited above with calculations of the type made by Eyring, the energy of repulsive interactions should be made a steeper function of distance and be made larger at short distances.

5. Energies of Steric Hindrance.—Some facts which we shall consider now suggest indeed that steric hindrance by atoms bonded to the same carbon upon another of its bonds is considerably larger than the 2.5 kcal. calculated by Eyring for a hydrogen–hydrogen interaction in methane.

The hydrogenation of the first double bond in allene evolves 11 kcal. more heat than the hydrogenation of propylene. To correlate this observation with other discussed facts we suppose again that the steric hindrance of a methylene group is not much larger than that of a methyl group or even of a hydrogen atom. Then the large heat evolution in the reaction of allene is obtained because the secondary hydrogen in the resultant propylene has no other hydrogen neighbors on the same carbon, while the primary hydrogen of the methyl group has steric hindrance from only one hydrogen atom on the adjacent carbon. It is, of course, impossible to separate all these effects, but an estimate of something of the order of 9 kcal. for the hydrogen–hydrogen interaction on the same carbon seems not unlikely, considering that this interaction occurs over the shortest distance.

The preservation of tetrahedral angles in halogenated methanes occasionally has been cited as evidence of rather weak interactions between non-bonded atoms, but actually this evidence merely shows that the difference between interactions of a halogen with another halogen and with hydrogen is rather small. This conclusion is confirmed by many other facts, only the obser-

vations of Beach and Palmer[24] on the strong hindrance of internal rotation in *sym.* dihalogenethanes being possibly in disagreement with it.

The manner in which the absolute magnitude of the steric hindrances could be found would be by removing some of the atoms present. Fortunately this is at least approximately realized in molecules in which the carbon atom forms a double bond and indeed spectroscopic evidence[25] points strongly to the H–C–H angle being greater than the tetrahedral value in formaldehyde and in ethylene. It may be argued, of course, that this is the "natural" configuration of carbon bonds, when one of them is double, but until this is conclusively proved we choose to think that the increase of the angle is due to repulsions between hydrogen atoms.

Considerable interest has been aroused by the finding of Herzberg that in methylacetylene the single carbon–carbon bond is appreciably shortened in comparison with those in saturated compounds.[26] Similar observations have been since made on the C–Cl and C–Br bonds in halogenated acetylenes[27] and the effect has been ascribed to resonance. Pauling[28] has pointed out that resonance cannot account for a decrease of the C–H distance in acetylene as compared with that in methane and yet, as Table V shows, the fractional change of the bond distances is nearly the same in all observed cases. The slight increase of the effect from the C–H to the C–Br bond is quite likely due to additional contribution of resonance, manifested by the changed dipole moments of the carbon–halogen bonds in acetylenes. For the C–H bond, however, wholly and for the C–C bond predominantly, we consider the reduced steric hindrance by adjacent atoms to be the cause of bond shortening in acetylenic compounds.

TABLE V

EFFECT OF ADJACENT CARBON–CARBON BONDS UPON INTERATOMIC DISTANCES

	Single, Å.	Triple, Å.	S:T ratio
C–H	1.093[a]	1.058[b]	1.034 (±0.005)
C–C	1.54 ±0.03[c]	1.463[d]	1.051 (± .025)
C–Cl	1.77 ± .02[c]	1.68 ±0.04[e]	1.052 (± .035)
C–Br	1.91 ± .02[c]	1.80 ± .03[e]	1.060 (± .028)

This requires that a ≡CH group exercise much smaller steric hindrance than do three hydrogen atoms in methane, a conclusion which is a natural extension of the earlier remarks on the effect of a methylene group. If the steric effects of a —CH_3, =CH_2 and a ≡CH group upon a C–H or a C–C bond do not differ greatly, then one may perhaps conclude also that the difference in the steric effects of a hydrogen atom and a methyl group upon all these groups is approximately the same. Such a conclusion is supported by data of Table IV and already has been made use of in section 3.

A numerical relation between bond length and bond energy, similar to those between bond length and the force constant, is not known, but one can surmise that a reduction of the bond length by some 3 to 4% causes much more than a proportionate increase in the bond energy. Hence repulsive interactions between atoms in methane must reduce the energy of the "isolated" C–H bond by a considerable amount.

In ethylenic compounds the C–H and the C–C bond length should be the mean of those in acetylene and in ethane, that is, 1.075 and 1.50 to 1.51 Å., respectively. The former would require the H–C–H angle in formaldehyde and in ethylene to be about 120°. It is claimed that in ethylenic compounds the C–C distance is the same as in paraffins but a difference of 0.04 Å. is so close to the admitted experimental error (0.03) that the evidence of electron diffraction is not yet conclusive.

In the partial hydrogenation of butadiene and other dienes, the added secondary hydrogen atom is subjected to steric hindrance by the group —CH=CH_2 rather than by —CH_2—CH_3 as in the hydrogenation of olefins. According to what has been said before, this means lower steric hindrance and hence higher heat of hydrogenation. Therefore resonance energies calculated in the beginning of this discussion by a simple procedure should be increased by 1 or even as much as 2 kcal. (*cf.* discussion of allene) which would bring their absolute magnitude into better agreement with theoretical values calculated by Lennard-Jones[12] and Coulson.[29]

We have restricted our discussion to the simplest organic compounds because only for them reliable thermochemical and structural data exist, but one could readily extend it *ad infinitum* by borrowing from the more qualitative organic evidence. Concluding, we wish to stress that steric hindrance in the sense discussed above is generally responsible for the effects of substituents upon the "standard" properties of functional groups in polyatomic molecules and that therefore it is rightly placed next to resonance in importance as the source of variety among organic compounds.

Acknowledgment.—We are indebted to the late Professor E. P. Kohler and Dr. J. B. Conant for much helpful advice. Professor E. B. Wilson has been kind enough to criticize the general part of this paper. Some of the ideas contained in it found their inception while one of the present authors (G. B. K.) was a Baker Non-Resident Lecturer at Cornell University and he wishes to express his gratitude to the staff of the Cornell Department of Chemistry for many valuable discussions. Drs. Ralph B. Thompson and W. E. Vaughan and Mr. M. A. Dolliver have taken part in the earlier experiments here described. A grant from the Rockefeller Foundation made this work possible.

Summary

The following heats of hydrogenation have been determined. All data refer to 355°K. in the gaseous phase.

$C_7H_{12} + H_2 \longrightarrow C_7H_{14} - 26{,}515 \pm 20\ (150)$ cal./mole
$C_7H_{10} + 2H_2 \longrightarrow C_7H_{14} - 51{,}260 \pm 49\ (150)$
$C_7H_8 + 3H_2 \longrightarrow C_7H_{14} - 72{,}846 \pm 10\ (300)$
$C_8H_{14} + H_2 \longrightarrow C_8H_{16} - 23{,}525 \pm 35\ (150)$
$C_6H_8O + H_2 \longrightarrow C_6H_9OH - 12{,}498 \pm 61\ (150)$
$C_6H_{10}O + H_2 \longrightarrow C_6H_{11}OH - 15{,}424 \pm 81\ (150)$
$C_2H_2 + 2H_2 \longrightarrow C_2H_6 - 75{,}062 \pm 66\ (150)$
$C_3H_4 + 2H_2 \longrightarrow C_3H_8 - 69{,}703 \pm 14\ (150)$
$C_4H_6 + 2H_2 \longrightarrow C_4H_{10} - 65{,}581 \pm 130\ (300)$

A consideration of the entire work on the heats of addition reactions and of other experimental data found in the literature reveals the large magnitude of steric hindrances exercised by nonbonded atoms in simple organic molecules. These repulsive interactions are stronger than supposed hitherto and contribute largely to the variation in the properties of the functional groups.

Internal Rotation and Resonance in Hydrocarbons

BY EVERETT GORIN, JOHN WALTER AND HENRY EYRING

Introduction

Recent experimental evidence indicates the existence of a potential barrier of the order of 3000 cal. restricting the rotation of the methyl groups about the C–C bond in ethane. The data on the specific heat of ethane gas at low temperatures[1] and the entropy of ethane as determined both from the third law and from the hydrogenation of ethylene are in accord with this assumption.[2] The structure of the rotation bands in the ethane spectrum has also been interpreted as indicating a barrier of at least 2000 cal.[3]

On the other hand the repulsion due to the hydrogen atoms calculated according to standard quantum mechanical procedure for the usual valence bond structure yields a potential barrier of 300 cal. with a minimum corresponding to the staggered position of symmetry D_{3d}. In this calculation the van der Waals attractive potential between hydrogens was taken as $101/R^6$.[4]

It was pointed out by Penney[5] that with the Slater–Pauling model for the carbon bond in ethane the repulsions taken account of in the above calculation are the only ones present if we use the single valence structure.

Barrier Height if Protons Replace Hydrogen Atoms.—If we suppose the hydrogen atoms be replaced by protons, the structure otherwise remaining unchanged, the potential barrier from the coulomb repulsions is 5200 cal. with a minimum in the staggered position. This is of course an upper limit and a more exact calculation than

the one which yielded 300 cal. could not give a much larger value since it can only be a small fraction of the 5200 cal.

Lack of Cylindricity of the C–C Bond.—The carbon–carbon bonding orbitals are distorted by the presence of the three hydrogen atoms on each methyl radical so that they are no longer cylindrically symmetric about the C–C bond. If this distortion were large, conceivably a large barrier might arise simply from the lack of cylindrical symmetry of the interaction between the carbon–carbon bonding orbitals. The orbital of lowest energy which can be added is limited by symmetry considerations to the $4f$ orbital, $\psi_{4f} = f(r) \sin^3\theta \cos 3\varphi$, that is, the C–C bonding eigenfunction can be written as

$$\psi = c_1\psi_{2t\sigma} + c_2\psi_{4f}$$

where $\psi_{2t\sigma}$ is the tetrahedral function whose axis lies along the bond direction.

This $4f$ orbital overlaps the hydrogen nuclei only very slightly so that the perturbations of the hydrogen atoms can at most give rise to a very small value for c_2. If we consider that the interaction of the hydrogen atoms can be represented by their coulombic attraction for the C–C bonding orbitals, we can estimate roughly an upper limit for the barrier resulting from this cause. That this neglect of the exchange integrals will not change the order of magnitude of the coefficient c_2^2 is indicated by the calculations of Wood on methane,[6] where he finds the exchange and coulombic interactions are approximately equal in magnitude. The position of maximum binding is given by the position of maximum overlap of the two bond distributions if the exchange term in the (ff) interaction predominates, or by the position of minimum overlap if the coulombic term predominates. The potential barrier is of the form $V_0/2 \cos 3\chi$ where χ is the angle of rotation with respect to the opposed position as zero. V_0 is given by $c_2^2\,(ff)$, where (ff) is the interaction between the f orbitals on the two carbon atoms. A variational calculation indicates that c_2 is of the order of magnitude of 0.015. Since the energy of an f orbital is near the ionization limit, we expect the (ff) binding to be considerably less than the binding due to the tetrahedral carbon orbitals. As the barrier is proportional to c_2^2, which as we see is small, we conclude that the contribution to the barrier from the distortion in the cylindrical symmetry of the carbon–carbon bonding orbitals is negligibly small.

Barrier Due to Hybridization between Tetrahedral and 3d Orbitals.—It is also possible to modify the C–H bonding functions in such a way that the sum of their charge distributions is not cylindrically symmetric about the C–C bond. To do this it is necessary to take such a linear combination of the $2s$, $2p$, and $3d$ orbitals as to give three equivalent bonds. For simplicity, we have taken the combination which gives four equivalent tetrahedral bonds.[7]

$$\begin{aligned}
\psi_{111} &= c_1 s + \frac{c_2}{(3)^{1/2}}(p_x + p_y + p_z) + \\
&\qquad \frac{c_3}{(3)^{1/2}}(d_{x+y} + d_{x+z} + d_{y+z}) \\
\psi_{1\bar{1}\bar{1}} &= c_1 s + \frac{c_2}{(3)^{1/2}}(p_x - p_y - p_z) + \\
&\qquad \frac{c_3}{(3)^{1/2}}(-d_{x+y} - d_{x-z} + d_{y+z}) \\
\psi_{\bar{1}1\bar{1}} &= c_1 s + \frac{c_2}{(3)^{1/2}}(-p_x + p_y - p_z) + \\
&\qquad \frac{c_3}{(3)^{1/2}}(-d_{x+y} + d_{x+z} - d_{y+z}) \\
\psi_{\bar{1}\bar{1}1} &= c_1 s + \frac{c_2}{(3)^{1/2}}(-p_x - p_y + p_z) + \\
&\qquad \frac{c_3}{(3)^{1/2}}(+d_{x+y} - d_{x+z} - d_{y+z})
\end{aligned} \qquad (2)$$

The coördinate system used here is so defined that the carbon atom is located at the origin. The x, y and z axes are perpendicular to the faces of the cube about the carbon atom as center. The four orbitals point out toward the 111, $1\bar{1}\bar{1}$, $\bar{1}1\bar{1}$ and $\bar{1}\bar{1}1$ corners of the cube.

Slater's wave functions were used for the s and p orbitals with effective nuclear charge equal to 3.25. This same effective nuclear charge was also used in the d orbitals. No doubt a better value for the energy could have been obtained by introducing the effective nuclear charge as a variable parameter in the d functions. This, however, has not been done as we were only interested in a rough estimate of the energy. The coefficients are chosen so that the functions are normalized and orthogonal. We have considered that as a good approximation the amount of d-ness in the C–H bonds of ethane is the same as in methane. The third relationship necessary to fix the values of the coefficients is given by the condition that the total energy of methane must be a minimum. The energy of the methane molecule upon the assumption of electron pairing can be expressed approximately as

$$E = Q_1 + 4\alpha - 3(\beta + \gamma + 2\delta). \qquad (3)$$

(6) Wood, *Trans. Faraday Soc.*, **28**, 877 (1932).

(7) L. Pauling, THIS JOURNAL, **53**, 1367 (1931).

Q_1 = orbital energy + coulombic interaction between all orbitals.
α = exchange energy of C–H bond.
δ = exchange energy of C with H orbitals not bound together.
β = exchange energy between two H atoms.
γ = exchange energy of carbon orbitals.

The coefficient c_3 in equation (2) can be determined by minimizing the energy as expressed in (3). The exchange integral α gives a contribution of the same sign and the same order of magnitude as the coulombic integrals, while the integrals β and δ are small. Neglecting the integrals α, β, δ, since the effect of including α, β, δ would be to increase c_3, we calculate a minimum value for $c_3 = 0.086$. If we assume, as is reasonable from Wood's calculation on methane, that the exchange and coulombic integrals are equal, we get a value twice as large. The sums of the squares of the eigenfunctions give for the non-cylindrically symmetric part of the charge distribution the expression

$$\frac{2}{3\pi}\left(\frac{15}{2}\right)^{1/2} c_2 c_3 \, f(r) \sin^3\theta \cos 3\varphi \qquad (4)$$

where $f(r)$ is the product of the normalized radial part of the $2p$ and $3d$ eigenfunctions. The electrostatic interaction of the two charge distributions also gives a barrier of the form

$$(V_0/2) \cos 3\chi$$

Rigorously, we would have to subtract from V_0 an amount corresponding to one-half the exchange interactions between those parts of the orbitals not bound together which depend upon the angle χ. This can at most be equal to $^1/_2 V_0$, and probably would be considerably less. Since for the electrostatic repulsion between the electrons the coulombic integral is always greater than the neglected exchange integral, V_0 is equal to the coulombic interaction between the two charge distributions, one on each carbon atom, given by (4).

In kcal., the calculated value of V_0 is $23.2c_3^2$. Including the exchange integrals would approximately double the calculated value $c_3 = 0.086$ so that we take as a reasonable value $c_3 = 0.15$; we have a maximum for the barrier due to this interaction between the hybridized C orbitals of 500 cal. favoring the staggered configuration.

There is still one other contribution to the barrier arising from this hybridization, *i. e.*, that due to interaction between the H atoms on one carbon with the carbon orbital on the other. Again we will consider only the coulombic interaction since including the exchange integrals would at most reduce the barrier arising in this way by a factor of two. The coulombic potential of an electron in the field of a hydrogen atom is given by $-\frac{e^2}{a_0}\left(1 - \frac{a_0}{r}\right)e^{-2r/a_0}$. The coulombic integral between the non-symmetrical part of the charge distribution about the carbon atom is therefore given by

$$-\frac{e^2}{a_0}\left(\frac{3.25}{a_0}\right)^6 \frac{6^{1/2} c_2 c_3}{729\pi} \int r_a^3 \exp.(-5/6 \cdot 3.25 r_a/a_0)(x_a^3 - 3x_a y_a^2)\left(1 + \frac{a_0}{r_b}\right)\exp.(-2r_b/a_0)\,d\tau \qquad (5)$$

Here r_a, x_a, y_a, z_a refer to a coördinate system about the carbon atom as center and the z-axis lies along the C–C bond direction. r_b refers to the hydrogen atom as center of coördinates. Upon evaluating this integral and introducing the value 0.15 for c_3 we obtain for a hydrogen atom in the opposed position 120 cal. Due to the three-fold symmetry of the charge distribution all hydrogen atoms are equivalent. In the staggered position the integral is just the negative of this, *i. e.*, −120 cal. The barrier is thus equal to 12 × 120 cal. or 1440 cal. This is larger than the effect calculated previously and of opposite direction. If we included exchange interactions this would be reduced at most to 700 cal. Summarizing the results, then, we get the following contributions to the barrier, 300 cal. staggered from the hydrogen repulsions, 250 minimum to 500 cal. maximum from the interaction between the hybridized carbon orbitals with the staggered configuration favored and 700 minimum to 1400 maximum cal. from the interactions between the hydrogen atoms and the hybridized carbon orbitals with the opposed configuration stable. We thus see that the sum of these effects gives a small barrier of up to 600 cal. with the opposed configuration the stable one. It is a rather surprising result that there should be enough resonance between the tetrahedral sp^3 configuration of carbon and the higher configurations containing $3d$ orbitals to actually change the stable form from the staggered to the opposed configuration. However, there are still other resonance effects to consider which we will now discuss.

Resonance Involving Double Bond Structures.—In discussing the resonance between the single and double bond structures it is convenient to adopt the nomenclature for the electronic orbitals indicated by the letters in Fig. 1. Reso-

nance between the following bond structures was considered in the usual quantum mechanical scheme to find the lowest energy. The eigenfunctions are indicated by writing together the

$$\begin{vmatrix} 3\alpha - \frac{W}{3} & \frac{3}{4}(\xi + \mu - 2\zeta) \\ \frac{3}{4}(\xi + \mu - 2\zeta) & \frac{15}{4}\alpha + \frac{3}{4}(\xi + \mu + 2\zeta) - \frac{3}{4}W \\ \frac{3}{2}(\epsilon + \varphi - 2\eta) & -\frac{3}{2}(\gamma + \beta) \end{vmatrix}$$

two letters which form a bond.

$$\begin{aligned} \psi_1 &= ae\ cg\ bf\ dh\ kn\ il\ jm \\ \psi_2 &= ae\ fl\ bi\ dh\ cg\ kn\ jm \\ \psi_3 &= em\ aj\ dh\ bf\ cg\ il\ kn \\ \psi_4 &= gn\ ck\ dh\ ae\ bf\ il\ jm \\ \psi_5 &= bk\ fn\ dh\ ae\ cg\ jm\ il \\ \psi_6 &= fm\ bj\ ae\ cg\ dh\ kn\ il \\ \psi_7 &= el\ ai\ dh\ bf\ cg\ kn\ jm \\ \psi_8 &= en\ ak\ dh\ cg\ bf\ jm\ il \\ \psi_9 &= ci\ gl\ ae\ bf\ jm\ kn\ dh \\ \psi_{10} &= cj\ gm\ ae\ bf\ dh\ kn\ il \end{aligned} \quad (6)$$

From symmetry considerations we know that the proper linear combination of eigenfunctions must have the form

$$\varphi = a\psi_1 + b\sum_{i=2}^{4}\psi_i + c\sum_{j=5}^{10}\psi_j \quad (7)$$

This leads to the following secular equation

$$\begin{aligned} &a(H_{11} - S_{11}E) + 3b(H_{12} - S_{12}E) + 6c(H_{1,10} - S_{1,10}E) = 0 \\ &3a(H_{12} - S_{12}E) + b[3H_{22} + 6H_{23} - (3S_{22} + 6S_{23})E] \\ &+ 6c[H_{10,2} + H_{10,3} + H_{10,4} - (S_{10,2} + S_{10,3} + S_{10,4})E] = 0 \\ &(6a[H_{1,10} - S_{1,10}E) + 6b[H_{10,2} + H_{10,3} + H_{10,4} \\ &- (S_{10,2} + S_{10,3} + S_{10,4})E] + 6c[H_{55} + 2H_{56} + 3H_{57} \\ &-(S_{55} + 2S_{56} + 3S_{57})E] = 0 \end{aligned} \quad (8)$$

The exchange integrals between the following pairs of orbitals are indicated by the Greek letters.

$$\begin{aligned} \alpha &= ae = bf = cg = kn = jm = il \\ \theta &= dh \\ \xi &= bi = aj = ck \\ \mu &= fl = em = gn \\ \zeta &= am = cn = bl = if = je = kg \\ \epsilon &= cj = ci = ak = ai = bk = bj \\ \varphi &= gm = gl = em = el = fn = fm \\ \eta &= cm = cl = al = an = bn = bm = ie \\ &= ig = jf = jg = kf = ke \\ \delta &= ec = eb = fa = fc = ga = gb = il \\ &= in = jl = jn = km = kl = df = de \\ &= dg = lh = hm = hn \\ \beta &= eg = ef = fg = lm = mn = nl \\ \gamma &= ac = ab = bc = ij = jk = ik = db \\ &= ad = cd = jh = ih = kh \\ \sigma &= dm = dl = dn = hf = he = hg \\ \lambda &= di = dj = dk = ah = eh = ch \end{aligned} \quad (9)$$

The matrix components were calculated in the way described by Eyring and Kimball.[8] Determinant (8) after the slight rearrangement corresponding to orthogonalizing the three eigenfunctions which are the coefficients of a, b and c in equation (7) takes the simplified form

$$\begin{vmatrix} \frac{3}{2}(\epsilon + \varphi - 2\eta) & & \\ -\frac{3}{2}(\gamma + \beta) & & = 0 \\ \frac{15}{2}\alpha + \frac{3}{2}(\epsilon + \varphi + 2\eta) + 3\delta - \frac{3}{2}(\gamma + \beta) - \frac{3}{2}W & & \end{vmatrix} \quad (10)$$

W of equation 10 is related to E by

$$W = E - Q + 1/2\Sigma - 3/2\,\theta,$$

where E is the actual total bonding energy for ethane formed from two quadrivalent carbon atoms. Q is the coulombic energy and Σ is the sum of the 91 exchange integrals listed in (9).

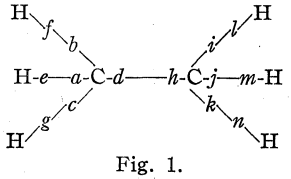

Fig. 1.

In the following numerical calculations for the difference in energy between staggered and opposed forms due to the double bonds we assume the usual tetrahedral carbon bonds. In Table I we list the values for the exchange integrals occurring in (10) for the various calculations of interest. All values in Table I are in kcal.

In all the calculations of Table I where the value of an integral for a staggered configuration is not explicitly given it was taken equal to the corresponding value in calculation 1. The same is true for opposed configurations. In calculating the integrals α and δ the values given by Van Vleck[9] for the elementary $N_{\sigma\sigma} = 2.3$, $N_{ss} = +2.0$, $N_{\pi\pi} = -0.6$ and $N_{\sigma s} = +1.0$ in volts were used in his formulas

$$\begin{aligned} -4\alpha &= N_{ss} + 3N_{\sigma\sigma} + 2(3)^{1/2}N_{\sigma s} \\ -12\delta &= 3N_{ss} + N_{\sigma\sigma} + 8N_{\pi\pi} - 2(3)^{1/2}N_{\sigma s} \end{aligned}$$

to give his values $\alpha = 72$ cal., $\delta \approx 0$. Van Vleck's formula

$$16\gamma = F_0(2s;\ 2s) - 2F_0(2s;\ 2p) + F_0(2p;\ 2p) + 28\,F_2 + 4\,G_1$$

with the value given by Voge[10] for the F's and G's was used to calculate γ. β was taken from the H–H Morse curve with the constants $D = 102.4$, $r_0 = 0.74$, $\omega_0 = 4375$ which gives a value for Morse's a of 1.94. The exchange binding was

opposed					22.3	2.4		8.6	18.7		661.3		

taken as 0.8 of the total. ζ and η are special cases of the more general integral

$$I = 3/4 \left\{ C_1^2 N_{\sigma\sigma} + \frac{2}{\sqrt{3}} C_1 N_{\sigma s} + 1/3 N_{ss} + (C_2^2 + C_3^2) N_{\pi\pi} \right\}$$

where

$$C_1 = 2/3 \sqrt{2}\, a \cos\varphi + b/3$$
$$C_2 = (1 - a^2 \sin^2\varphi)^{-1/2}(-2/3\, 2^{1/2}\, b - 1/3\, a \cos\varphi)$$
$$C_3 = (1 - a^2 \sin^2\varphi)^{-1/2}(2/3\, 2^{1/2}\, a^2 \sin\varphi \cos\varphi - 1/3\, ab \sin\varphi).$$

in which $a = 0.486$, $b = -0.874$. φ is the angle of rotation of the hydrogen atom about the C–C axis. $\varphi = 0$ where the hydrogen atom and the interacting carbon orbital lie in a plane which includes the C–C bond direction. ζ is obtained from these formulas by inserting $\varphi = 0$ for the opposed form and $\varphi = 180°$ for the staggered configuration. For η, one should use $\varphi = 120°$ for the opposed form and $\varphi = 60°$ for the staggered. The integrals $N_{\sigma\sigma}$, $N_{\sigma s}$, etc., were assumed to vary with the distance in the way given by a C–H Morse curve.

The exchange interaction between carbon orbitals other than those forming the carbon–carbon bond and on opposite carbons can be expressed in terms of the more fundamental integrals by the formula

$$I_{\text{carbon–carbon}} = C_2^4 (N_{yy,yy} - N_{xy,xy}) \cos^2\omega + \{C_1^2 C_2^2 (2N_{ssyy} + 2N_{syys}) + C_1 C_2^2 C_3 (4N_{syyz} + 2N_{yysz}) + C_2^2 C_3^2 (2N_{yyzz} + 2N_{yzzy})\} \cos\omega + C_1^4 N_{ssss} + C_2^4 N_{xyxy} + C_3^4 N_{zzzz} + 2C_1^2 C_2^2 N_{ysys} + C_1^2 C_3^2 \{2N_{sszz} + 4N_{szsz}\} + 2C_2^2 C_3^2 N_{yzyz} + 4C_1 C_3^3 N_{zzzs} + 4C_1^3 C_3 + C_1 C_2^2 C_3 \{4N_{ysyz} + 2N_{yysz}\}$$ where $c_1 = 1/2$ $c_2 = (2/3)^{1/2}$ $c_3 = (2(3)^{1/2})^{-1}$

where the integrals $N_{mn,op}$ are defined by the expression

$$N_{mn,op} = \int\int \psi_{am}(1)\, \psi_{bn}(1)\, H'\, \psi_{ao}(2)\, \psi_{bp}(2)\, d\nu_1\, d\nu_2$$

where a refers to the function ψ_a about carbon atom a as center and b to function ψ_b about the carbon atom b.

$$H' = e^2 \left(1/r_{12} + \frac{z^2}{R} - \frac{z}{r_{a1}} - \frac{z}{r_{b2}} \right)$$

z is the effective nuclear charge of the carbon atom. The coefficient $(N_{yy,yy} - N_{xy,xy})$ of $\cos^2\omega$ is $(C_{\pi\pi\pi\pi} - C_{\pi\pi'\pi'\pi})$ in Penney's notation.[11] We have used the value of 1.5 e. v. given for this quantity by Pauling and Wheland.[12] The estimates given by Penney[13] were used as a basis for evaluating the part of the integral that is independent of ω. The estimates are listed below:

$N_{ssss} = C_{ssss}$	$= 1.0$	$N_{szsz} = C_{s\sigma\sigma s}$	$\cong 1.75$
$N_{xyxy} = C_{\pi\pi'\pi'\pi}$	$\cong 0$	$N_{zzss} = C_{\sigma s\sigma\sigma}$	$\cong 2.29$
$N_{zzzz} = C_{\sigma\sigma\sigma\sigma}$	$= 3.0$	$N_{sssz} =$	$\cong 1.32$
$N_{szsz} = C_{s\sigma\sigma s}$	$\cong 1.75$	$N_{yzyz} =$	-0.5
		$N_{ysys} =$	-0.4

No integrals similar to $N_{yz,yz}$ were estimated by Penney. They must be negative, however, since due to orthogonality only the electrostatic repulsion term e^2/r_{12} need be considered. From similar integrals evaluated by Bartlett[14] we can expect them to be relatively small. We arbitrarily take for the integrals $N_{yz,yz}$ and $N_{ys,ys}$ the values -0.5 and -0.4 volt, respectively. None of the integrals involved in the coefficient of $\cos\omega$ have been evaluated. However, we would expect this coefficient to be small since the integrals involved are alternately + and −, *i. e.*, the integrals $N_{ss,yy}$, $N_{yy,sz}$ and $N_{yy,zz}$ are positive in the sense here used, *i. e.*, positive energy corresponds to attraction, while $N_{sy,ys}$, $N_{sy,yz}$ and $N_{yz,zy}$ are negative. The coefficient should be positive since the maximum binding should be obtained when the orbitals are *cis* where their overlap is greatest. Also similar integrals evaluated by Bartlett indicate that the positive integrals are considerably greater in

magnitude than the negative ones. In calculations 1 and 2 the coefficient of cos ω was chosen to be zero while in 3 and 4 it was taken to be 2 kcal. The value of I_{C-C} in kcal. is then

$$I_{C-C} = 15.3 \cos^2 \omega + 13.4 \text{ in calculations 1 and 2} \quad (11)$$

$$I_{C-C} = 15.3 \cos^2 \omega + 2.0 \cos \omega + 13.4 \text{ in calculations 3 and 4}$$

ξ in the opposed form is obtained by inserting $\omega = 0$ in (11), while in the staggered configuration $\omega = 180°$. η is obtained from (11) by using the values $\omega = 60$ and 180° for the staggered and opposed configurations, respectively. In calculations 1 and 3 the Heitler–London values were used for the hydrogen–hydrogen interactions, μ and φ, while in calculations 2 and 4 80% of the Morse curve values were taken.

Calculation 5 was undertaken to show that by a proper choice of the unknown coefficient of cos ω in the exchange integral I_{C-C} the staggered form could be made stable with respect to the opposed. The coefficient was taken to be −10 kcal. This seems to us to be unreasonable since it makes this interaction stronger in the *trans* position than in the *cis* position while one would expect that since the overlap is strongest in the *cis* position that it would be more stable. The last column gives the difference ΔE in the energies of the staggered and opposed configuration when the van der Waals forces are neglected. If the van der Waals forces are included about 400 cal. should be added to this figure. The effect of the *d*-ness would also be approximately additive since the presence of a small amount of *d*-ness in our wave functions should not appreciably affect the resonance energy. If this effect is included, then an additional 300 to 900 cal. should be added to ΔE.

Possible Effect of Resonance on Melting Points.—There is a well-known rule that the more symmetrical a molecule, other things being equal, the higher its melting point. In certain cases at least this is associated with the fact that the more symmetrical compounds are able to make their rotational transitions at low temperatures, *i. e.*, in the solid state and therefore there is not the incentive to melt that there otherwise would be. We see this most readily from the equation connecting the heat and entropy of melting $\Delta F = 0 = \Delta H - T\Delta S$ or $T = \Delta H/\Delta S$. Thus effects which increase ΔS or decrease ΔH lower the melting point. In Fig. 2 are plotted the heats, temperatures and entropies of melting for the paraffins. The values for methane are taken from Bichowsky and Rossini.[15] Those for ethane are from Witt and Kemp,[16] while those for propane are from Kemp and Egan.[17] Parks, Shomate, Kennedy and Crawford[18] provide the values for butane while the other values are from the treatise, "The Science of Petroleum."[19]

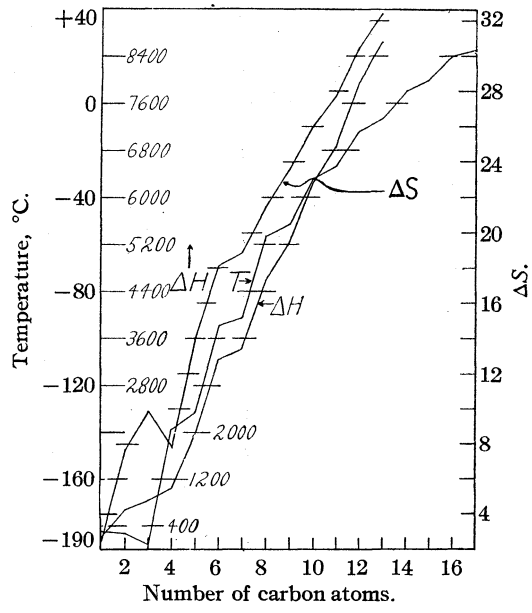

Fig. 2.—Heat, entropy and temperature of melting of paraffins.

The initial drop in the melting points from methane to propane is associated with an increase in the entropy of fusion which more than offsets the increase in the heat of fusion. This may be understood in the following way. In the liquid state these molecules presumably rotate very nearly freely about all axes as is shown by their normal entropy of vaporization at their boiling points. The entropies of vaporization from methane to butane are 19.37, 19.09, 19.42, 19.50. The value for methane is from the "International Critical Tables." The other values come from the sources quoted above. The almost spherical structure of methane permits it to rotate in the solid so that we expect a value only slightly larger than the two units of communal entropy.[20] The

observed value is 2.48 e. u. On the other hand ethane being able to rotate only about the C–C axis in the solid would be expected to get an increase in entropy due to changing from oscillation to free rotation about the other two axes. The observed value is 7.60 e. u. If the end of the vector which coincides with the C–C axis is free to describe ten times as large a solid angle in the liquid as in the solid it would explain the increase of entropy from 2.48 to 7.60. The greater value of 9.86 e. u. for propane arises in all probability from restricted rotation about all three axes in the solid state. Butane has a lower entropy change of 7.79 e. u. For longer hydrocarbons than butane there is little even–odd alternation except near hexane. The older entropy quoted by Landolt–Börnstein for hexane would fall more nearly on the straight line through the higher values. We must conclude that the considerable alternation above butane in the melting points arises principally from ΔH rather than ΔS. Going with large ΔH values of fusion we will necessarily have large changes in the density. The problem is thus reduced to a determination of the cause of the relatively better packing in the solid for the even members of the series. Müller,[21] for example, concludes, from his X-ray studies, that the relatively higher melting points of the even dicarboxylic acids is associated with closer packing and with different symmetry properties associated with a modified crystal form. Malkin[22] has criticized the theories advanced by Nekrassow,[23] Müller,[21] and Pauly[24] to explain alternating properties which are based on the fact that in the even series the terminal groups are *trans* while in the odd compounds they are *cis* with respect to one another. He shows that in the case of vertical chains there is no difference in the spacing of the planes containing the terminal groups and therefore there should be no difference in melting point for even and odd compounds. Malkin then divides long chain compounds into two series: those that show alternation and those that do not. The monobasic acids, dibasic acids, and their methyl esters, for example, belong to the alternating series. In all these substances there is a transition in the solid just below the melting point from the vertical chain structure to one where they are tilted with respect to the long axis of the crystal. Malkin finds that for the tilted chains there is a large difference in the spacing of the terminal planes for the even and odd compounds, *i. e.*, the density is greater for the even compounds than for the odd ones. He gives a geometrical explanation for the observed difference in spacing. By this he explains the fact that the even compounds melt higher and also why the transition to the tilted structure takes place with greater ease in the even series.

Those compounds which, according to Malkin, do not show alternation such as the paraffins, ethyl esters, and alcohols possess vertical chains and do not show a transition to the tilted form.

Beach[25] has explained alternating properties on the basis of alternating strong and weak bonds while Cuy[26] and Pauly[24] attribute the phenomena to alternately positive and negative carbon atoms. Malkin criticizes these theories since one would expect alternation in other physical properties as well as melting points which are not in general observed.[27]

The paraffins and ethyl esters which are cited by Malkin as examples of non-alternating series of compounds really do show alternation as is illustrated for the paraffins in the figure. Since these cases are not explained on a purely geometrical basis, some other explanation must be sought. We propose a theory which has some points of similarity to Beach's theory of alternating strong and weak bonds. Our calculations on ethane have shown that resonance with double bond structures lowered the total energy by about 12 kcal. in the opposed form and 10 kcal. in the staggered form. Now if we consider propane we see that it is possible to have a double bond between any two of the neighboring carbon atoms but not between both simultaneously as the structure corresponding to drawing two double bonds on the same carbon lies so high in energy above the normal state as not to contribute appreciably to the stability of the molecule. In the case of butane, however, it is possible to have structures containing two double bonds simultaneously which contribute to the total energy in the same way as in ethane. Thus we see in general that in the odd series both end carbons cannot be simultaneously double bonded while in the even compounds the end carbons can both be double bonded simul-

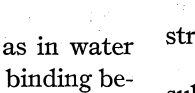
taneously. The hydrogen atoms attached to the end carbons in the even series will thus be more free on the average to form bonds of a coördination type with other molecules than in the odd series. This is because there is a somewhat unoccupied 1s level on a hydrogen attached to a carbon that has become double bonded, which is available for coördination bonding with similar atoms on neighboring molecules. We call such binding intermolecular coördination to distinguish it from the intramolecular coördination binding between the hydrogen atoms in a single ethane molecule. Thus the intermolecular forces will be stronger in the even than in the odd compounds and they will consequently melt higher. Most of these coördination bonds would be broken in the liquid state due to the expansion which usually takes place upon melting. One would expect as is observed, therefore, that alternation in physical properties should be much less marked in the liquid state. This relative lack of alternating properties in the liquids is due to the lack of alternation in the molar refraction of even and odd compounds, and indicates that the binding forces in the liquid are largely of the polarization type. The importance of coördination type of binding in determining the stability of crystals and its relative unimportance for the stability of normal liquids is illustrated in the case of ethylene. Thus ethylene melts 13° higher than ethane but boils 17° lower. This can be explained by the tendency of the electrons forming the double bond to couple on to the double bond of another ethylene molecule. The coördination binding between the double bonds would not be nearly as strong in the liquid because of rotation and therefore liquid ethylene would be expected to boil lower than ethane due to its fewer number of hydrogen atoms. Because ethylene rotates in the liquid it is less dense than liquid ethane.

In the ordinary hydrogen bonding as in water there is in addition to the electrostatic binding between the hydrogen and oxygen atoms of neighboring molecules a large amount of this coördination type of binding. Due to the large electrostatic contribution we would expect the hydrogen bonding in water to be much stronger than the intermolecular binding discussed above. This coordination binding may also explain why one gets tilting of the chains in the cases discussed by Malkin and thus enhancement of the alternating phenomena. For example, according to Malkin, the methyl esters form double molecules in the crystal and tilted chains while the ethyl esters form only single molecules in the crystals and vertical chains. This property of forming tilted chains is evidently connected with how well the ends of the molecules form bonds with their neighbors. Thus, in the methyl esters, part of the double bond in the carbonyl group will tend to go over toward the methyl group, thus releasing the methyl hydrogens to form coördination bonds with the atoms at the end of the chain of the neighboring molecules. When the methyl group is replaced by an ethyl group, the same tendency to loosen the hydrogen atoms at the end of the molecule will no longer be present since the end methyl group is now farther removed from the carbonyl group and also because of the alternation in double bond effect. The methyl esters would thus be expected to form double molecules and tilted chains much more readily than the ethyl esters.

This phenomenon of the tendency of a double bond to be partially shared by its neighboring single bonds is illustrated by the general reactivity of the α-carbon atom in the carboxylic acids and especially by the marked reactivity of the hydrogens attached to the α-carbon in malonic acid. This type of effect is also illustrated by the definite shortening of the C–C single bond in methylacetylene as compared with its value in saturated hydrocarbons.[28a] The shortening of a single bond which is next to a double or triple bond has been discussed by Pauling, Brockway and Beach.[28b]

An interesting example of what we have called intermolecular coördination is exhibited by the solid hydroboranes. Bauer and Pauling[29] have pointed out that the twenty-one structures for diborane each having two one-electron bonds resonate to form the stable molecule. One of the structures is the following



As a result all the hydrogens will on the average be sharing less than the usual two electrons and so will tend to form coördination compounds with neighboring molecules. Since such bonds are short range they will decrease rapidly with the expansion accompanying either a rise of temperature or the melting process. This will give

(28) (a) G. Herzberg, F. Patat and H. Verleger, *J. Phys. Chem.*, **41**, 121 (1937); (b) Pauling, Brockway and Beach, THIS JOURNAL, **57**, 2705 (1935).

(29) Bauer and Pauling, *ibid.*, **58**, 2403 (1936); Bauer, *ibid.*, **59**, 1096 (1937).

a relatively higher ΔH for melting without a corresponding increase in ΔS so that from the formula $\Delta H/\Delta S = T$ we expect higher melting points for the boranes than for the corresponding hydrocarbons in spite of the fact that the former contain two less electrons. That this is true is shown by the following comparisons

	B_2H_6	C_2H_6	B_4H_{10}	C_4H_{10}	BCl_3	$CHCl_3$
M. p., °C.	−165.5	−183.2	−120	−139	−107	−70
B. p., °C.	− 92.5	− 89	18	−0.6	18.2	61.2

When this coördination cannot take place as in BCl_3, we have a melting point considerably lower, rather than higher, than $CHCl_3$ the most nearly analogous carbon compound containing two more electrons.

X-Ray and Other Evidence Concerning Relative Stabilities of Staggered and Opposed Configurations.—The X-ray evidence on solid hydrocarbons[30] indicates that they are in the form of a zigzag chain with all the carbon atoms in a plane. This structure corresponds to the staggered configuration about all of the carbon–carbon linkages. This seems to us to be a serious objection against any theory which postulates the opposed as the stable structure as does the theory of intramolecular coördination proposed above. This objection possibly can be met in the following way. The same carbon atom cannot support two double bonds simultaneously, so that we would expect that the carbon–carbon bonds would be alternately double and single. Thus in butane we would have two double bonds at the end carbons with a single bond in the middle. If we assume that the single bond can assume the staggered configuration this would lead to a plane structure for butane. However, when a fifth carbon atom is added it would no longer tend to be in the plane of the other four. Thus, in order to get a plane zigzag structure it is necessary to assume that every fifth carlon atom is forced into the plane by the crystal forces, which expenditure of energy is compensated for by the resultant better packing. Since the crystal energy that is available is of the order 4000 kcal. per C–C bond, as is shown by the heat of sublimation of the hydrocarbons, this is by no means impossible. Electron diffraction and Raman investigations on dichloroethane[31] indicate that the chlorine atoms are in the *trans* position, *i. e.*, that the configuration is the staggered one about the C–C axis. The electronegativity of the chlorines, however, withdraws electrons away from the carbons so that a double bond cannot be formed easily between the carbon atoms. We would thus expect that the C–C bond would remain single and that the repulsions of the chlorines would determine the stability of the *trans* position. The importance of the electron affinity of the halogen in chemical reactions is shown by the results of Conn, Kistiakowsky and Smith[32] on the heats of halogenation of substituted ethylenes. The greater the number of substituted alkyl radicals the higher is the heat of halogenation. This is explained easily by the fact that in the substituted compounds there is a greater reservoir of electrons for the chlorines to draw upon. This effect more than compensates for the increased steric repulsions in the substituted compounds.

Attempts have been made to interpret the infrared and Raman spectra of liquid ethane as indicating the stability of either the opposed or the staggered structure. Thus Bartholemé, Karweil and Schafer[33,34] conclude on the basis of Raman spectra that the molecular symmetry is D_{3h}, *i. e.*, opposed since the observed frequency at 2260 cm.$^{-1}$ cannot be fitted to D_{3d}, the staggered form. Crawford, Avery and Linnett[35] have attempted to effect a complete analysis of the vibrational spectrum of ethane and conclude that at the present time the evidence is insufficient to exclude the D_{3d} configuration. Prof. E. B. Wilson[36] informs us that the most recent considerations do not allow them to reach any conclusion concerning the relative stabilities of the staggered and opposed forms.

It is interesting to compare the relative stabilities of cyclopentane and cyclohexane. In cyclopentane the configuration about all the carbon–carbon bonds is the opposed form. In cyclohexane, however, in the chair form all the bonds are staggered, we might expect, therefore, that if the staggered structure is the stable one, then cyclohexane would be more stable by 3 kcal. per methylene group. Heat of combustion data[37] show, however, that cyclohexane is only slightly more stable than cyclopentane, the heat of com-

bustion per methylene group being 157.5 kcal. as compared with 157.9 kcal. for cyclopentane. In the boat form of cyclohexane, however, two of the bonds can be opposed, while the greater possibility of resonance with double bonded structures in cyclohexane would tend to stabilize it with respect to cyclopentane. Cyclopentane would also be expected to have some strain, so that the above evidence can be reconciled with the opposed structure. If cyclohexane were flat, for example, all the bonds would be opposed. The fact that among the cyclic hydrocarbons the even members melt higher is exactly as would be expected on the coördination theory but cannot be understood on the theory of Malkin for straight chain compounds. This alternation is illustrated in Fig. 3. With the information available we are unable to rule out the possibility that alternations in entropy are more important in the cyclic than in the straight chain paraffins. We see no reason for expecting this, however.

Eyring[38] has derived a formula for the mean length of a hydrocarbon chain which as was stated is valid under conditions of free rotation. This formula in simplified form is

$$C_a = C_1\left\{\frac{n - x(2 + nx - 2x^n)}{(1 - x)^2}\right\}^{1/2}$$

where C_a is the length of the molecule, C_1 is the distance between neighboring carbon atoms, x is the cosine of the valence angle. Several investigators have concluded that the agreement between experimentally determined lengths and the result given by this formula is evidence of free rotation in these long chain compounds. We would like to point out, however, that even with high barriers one obtains the same result if the molecule vibrates about two equivalent minima 180° apart, three equivalent minima 120° apart, or any higher number of symmetrically placed equivalent minima.

The fact that agreement of observed lengths with this formula implies a random distribution of the orientations about the single bonds would seem at first sight inconsistent with the long zigzag chain observed in the solid compounds. However, the measurements of lengths which fit this formula were made in solvents consisting of small molecules. When the long chain compounds are dissolved in a solvent of this kind there is no longer the advantages in lying flat that they would have if they were present in an environment of their own molecules and consequently they can curl up with little or no extra energy.

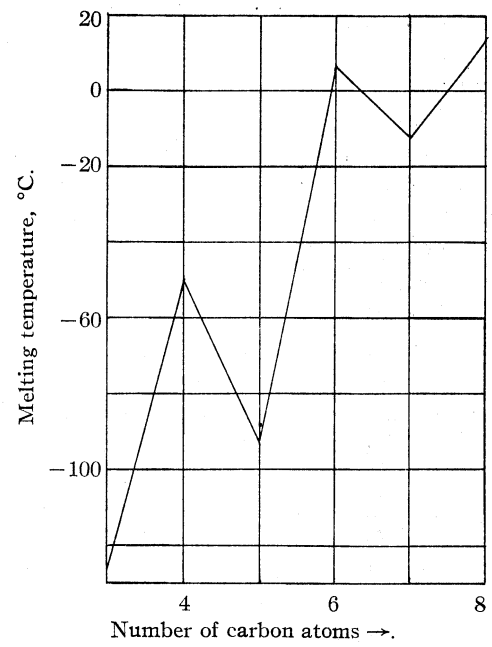

Fig. 3.—Melting temperatures of cycloparaffins.

Addendum.—Since this paper was completed, an article by Eucken and Schäffer[39] has appeared in which the view is put forward that the potential barrier in ethane arises from the induction by the C–H dipoles on each methyl group of a lack of cylindrical symmetry in the carbon–carbon bonding orbitals. They write the perturbed orbital in the form $\psi_{2t\sigma}(1 + 0.1 \cos 3\varphi)$ where $\psi_{2t\sigma}$ is the unperturbed bonding orbital and the factor $(0.1 \cos 3\varphi)$ arises from perturbation of the carbon–hydrogen orbitals. Since the orbitals in this form show 4% greater overlap in the opposed as compared with the staggered configuration, the opposed configuration should be more stable by about 4% of the binding energy, giving a potential barrier of the order of 3000 kcal.

We have discussed this effect in the first section of this paper using a somewhat different potential and have concluded that this effect gives a negligibly small contribution to the barrier. In view of the results of Eucken and Schäffer we have repeated this calculation using as they did a potential due to a charge of one-tenth the electronic charge at each of the hydrogen nuclei. The perturbed eigenfunction can be written as

$$\psi'_{2t} = \psi_{2t\sigma} + \frac{0.3\int \psi_{2t\sigma}\frac{e^2}{r_b}\psi_{4f}\,d\tau}{E_0 - E_{4f}}\psi_{4f}$$

(39) Eucken and Schäffer, *Naturwissenschaften*, **8**, 122 (1939).

where the factor 0.3 arises from the fact that there are three equivalent charges of 0.1 each on each methyl group. $E_0 - E_{4f}$ is the difference in energy of the $4f$ and normal states and is about equal to the ionization potential or 10–12 electron volts. The functions $\psi_{2l\sigma}$ and ψ_{4f} were chosen to be hydrogen-like and are given below. The effective nuclear charge equal to three

$$\psi_{2l\sigma} = Are^{-3/2\,r/a_0}\,(1 + \sqrt{3}\cos\Theta)$$
$$\psi_{4f} = Br^3e^{-3/4\,r/a_0}\,\Theta_{33}\,\Phi_{3\cos\varphi}$$

is approximately that obtained by application of Slater's[40] rules for the screening constants of atomic orbitals. A and B are normalizing factors, and $AB = (2.45 \times 10^{-2})/\sqrt{\pi}$. The phase of $\Phi_{3\cos\varphi} = (1/\sqrt{\pi})\cos 3\varphi$ was so chosen that the hydrogen atoms lie in the planes $\varphi = 0$, $\pi/3$ and $2\pi/3$ corresponding to the maximum values of $\Phi_{3\cos\varphi}$. The term $1/r_b$ was expanded in terms of spherical harmonics about the center of the carbon atom. Due to orthogonality, all terms integrate out except those involving the harmonics $\Theta_{33}\phi_3\cos\varphi$ and $\Theta_{43}\phi_3\cos\varphi$. The result is that $0.3\int\psi_{2l\sigma}e^2/r_b\psi_{4f}d\tau = 1.56 \times 10^{-2}$ e. v. and the coefficient of the $4f$ function is correspondingly about 1.5×10^{-3}. This coefficient is, as we see, so small that no appreciable contribution to the barrier can come from this cause, in agreement with our earlier result and in disagreement with Eucken and Schäffer. The barrier therefore arises from other causes such as are considered in this paper.

(40) Slater, *Phys. Rev.*, **36**, 57 (1930).

We wish to express our appreciation to Drs. William Baker and John Beach for helpful discussions.

Summary

1. The problem of restricted rotation about the C–C bond in ethane is discussed. It is shown that the repulsions between the hydrogen atoms cannot account for a barrier of 3000 cal. The effect of the distortion of the spherical symmetry around the carbon atoms by the perturbations of the hydrogen atoms is considered. It is shown that this effect tends to make the opposed form more stable but also cannot account for a barrier of the required height. The effect of resonance with double bonded structures is then considered and it is shown that with reasonable assumptions concerning the angular dependence of the exchange integrals between carbon orbitals, the opposed structure is the stable one with a barrier height of 0.7 to 1.9 kcal. If we add to this the effect of the dissymmetry of the carbons a barrier of the right order of magnitude is obtained.

2. It is shown that this effect of resonance with double bonded structures can be used to explain the alternation in physical properties such as melting points of long chain compounds.

3. The experimental evidence in favor of the staggered or opposed structures for long chain and cyclic compounds is discussed.

Primary and Secondary Acids and Bases

BY GILBERT N. LEWIS AND GLENN T. SEABORG

The most general classification[1] of bases and acids does not extend the class of bases much beyond the group of substances now recognized under that name. On the other hand, if we define an acid as any substance one of whose atoms is capable of receiving into its valence or coördination or resonance shell the basic electron-pair of another atom, then we have a great group of generalized acids in which the hydrogen acids are not the strongest and not always the most typical members.

The self-consistency of this group of generalized acids has been brought out in a recent paper[2] which emphasizes the extraordinary similarity in every type of behavior, extending even to the colors of their compounds with indicators, between hydrogen acids and all the other acids of the class. All the acids can be ranked roughly by their strengths. Thus, for example, sulfur dioxide is ordinarily weaker than hydrochloric acid, which in turn is much weaker than boron trifluoride or stannic chloride. Aside, however, from these considerations of relative strength, there was proposed in that paper an entirely independent classification into *primary* and *secondary*

acids and bases which, as far as we can now see, probably represents a difference, not of degree, but of kind. It was assumed that there is a large group of acids and bases, called primary, which require no energy of activation in their mutual neutralization, but that apparently there is another group, called secondary, such that a secondary acid does not combine, even with a primary base, nor a secondary base with a primary acid, except when energy, and frequently a large energy of activation, is provided.

It is to be presumed that an acid which conforms to the defintion of our first paragraph is primary and that when a heat of activation is found to be necessary, it means that some change in the condition or structure of the molecule is needed to make it conform to that definition. Frequently we can see in advance that such a change is necessary. For example, an isolated molecule of an acid might be primary, but when dissolved in a basic solvent may be completely neutralized by forming a complex with the solvent, which would have to be dissociated before the acid could combine with some stronger base. We should then expect a heat of activation which may be smaller, but cannot be larger, than the heat of dissociation of the complex. In other cases a known structural change must occur, as, for example, in the change from a keto to an enol form, before a substance shows marked acid properties. Such a substance has been called by Hantzsch[3] a pseudo acid.

The Possibility of Electromerism

Such cases of secondary acids and bases as we have just mentioned, in which the acid or basic properties appear only after the breaking of some bond or the rearrangement of the atoms within a molecule, are familiar. We are going to see, however, that there are numerous secondary acids and bases which do not appear to conform to these specifications of what we may call the classical type. The explanation of the behavior of these substances is a perplexing and at present an unsolved problem. There is one possible explanation which must be considered.

A quarter of a century ago many chemists hoped to find isomers of the type called *electromers*, that is, two forms of a molecule with the atoms in the same, or nearly the same, relative position, but with a difference in electronic distribution. The advent of the electron-pair bond and the associated idea of the mobility of this bond under inductive influence seemed to make assumption of such electromers superfluous in the case of simple molecules.[4] Moreover, the development of the concept of resonance has appeared to exclude electromerism in all cases except the trivial one in which two parts of a molecule are so far insulated from one another that they behave like separate molecules.

When in a given substance there is said to be resonance between two or more limiting structures, the phenomenon is most marked when there is little difference of energy or of spacial position in the resonating structures, but we assume that even when these conditions are not fulfilled there will be some resonance effect, although perhaps minute. On the other hand, there are structures which we must believe are prohibited from any mutual resonance whatsoever. Such a prohibition occurs when one of the structures is paramagnetic and the other diamagnetic. In other cases, even when spins are not considered, the quantum mechanical equation sometimes has two sets of solutions which are not mutually "combining." A structure representing one set and a structure representing the other should be incapable of mutual resonance, and therefore should behave as true electromers. We are going to consider the electromeric hypothesis as a possible method of accounting for the sharp distinction between primary and secondary acids and bases, although we are by no means convinced that this is the only possible way of accounting for the phenomena that we shall describe.

Some Secondary Acids and Bases

In our still mysterious group of secondary acids the most familiar one is carbon dioxide. It has long been known that a cold aqueous solution of carbon dioxide cannot be titrated instantly with alkali. By using another solvent and lower temperature this phenomenon can be rendered more striking, as shown in the experimental section. Among organic substances with the carbon–oxygen double bond it seems likely that the acid chlorides and the acid anhydrides will in general prove to be secondary acids. By analogy it was thought that compounds containing the carbon–carbon double bond might show secondary characteristics, and several compounds of this type

(3) Hantzsch, *Ber.*, **32**, 575 (1899).

(4) Lewis, "The Atom and the Molecule," THIS JOURNAL, **38**, 762 (1916).

will be discussed in the experimental section. None of the latter proved to be secondary acids or bases.

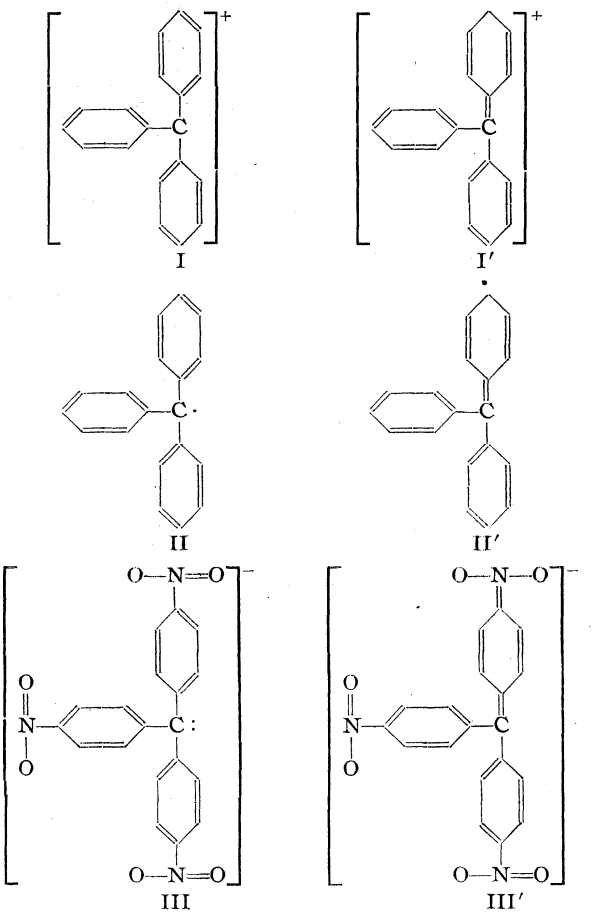
Another large group of secondary acids is found in the triphenylmethyl cation and its many derivatives. Such ions as those of crystal violet and malachite green combine slowly with hydroxide ion to form the carbinol, and the heat of activation is large. Even triphenylmethyl chloride in chlorobenzene is partly ionized and when circumstances produce a recombination of the ions this process is a slow one, especially at 0°, as shown in the preceding paper.[2]

Before considering the problem of secondary bases let us consider for a moment the class of substances which in a sense is intermediate between acids and bases, namely, the odd molecules. It has been supposed that the union of two odd molecules should not require activation energy. This supposition, moreover, was supported by experimental observations. Thus nitric oxide and oxygen, in both of which there are odd electrons, combine instantly at the temperature of liquid air. However, it has been discovered by Ziegler[5] that two molecules of triphenylmethyl require an activation energy of 6–8 kcal. when combining to form one molecule of hexaphenylethane. We shall try to explain this interesting fact by assumptions entirely similar to those which we are going to make in interpreting the behavior of the triphenylmethyl cation.

The question now arises as to whether we can find any secondary bases. By analogy to the compounds we have just been discussing it seemed likely that the negative triphenylmethide ion might prove to be such a substance. This ion itself is not very convenient to study, but it has long been known that 4,4′,4″-trinitrotriphenylmethane behaves as a weak acid. It dissolves in alkaline alcohol to give an intense blue color which is due to the substituted triphenylmethide ion, the investigation of which we describe in the paper immediately following. There we show that this ion is truly a secondary base since at low temperatures it is neutralized slowly by a wide variety of acids, the heat of activation in each case being approximately 9 kcal.

The only other group of secondary bases which is now known to us was called to our attention by Professor Branch. Nitromethane and many of its derivatives form salts in alkaline solution and the anions thus produced are only slowly neutralized by weak acids to give back the nitromethane. The general course of this process of neutralization, even to the inhibiting effect of strong acids, is so similar to the behavior of the trinitrotriphenylmethide ion that a common explanation is strongly suggested.

Let us now consider how we should regard triphenylmethyl and its ions if we are to adopt the electromeric hypothesis. In the accompanying graphical scheme formulas I, II and III show what may be called the old-fashioned representations of the triphenylmethyl cation, the triphenylmethyl free radical and the trinitrotriphenylmethide anion. In each of these the central carbon has only three bonds and the formulation indicates that the central carbon is the seat of the respective behaviors as acid, odd molecule and base.



The formulas I′, II′ and III′ represent, somewhat inadequately, the resonance structures which we now believe to characterize these molecules in their normal state. Formula I′, for example, exhibits but one of the nine structures which almost

(5) Ziegler, Orth and Weber, *Ann.*, **504**, 131 (1933).

equally contribute to the resultant resonance state. Thus the central carbon may be doubly bonded to any one of the three phenyl groups and any one of the ortho or para carbons may be regarded as possessing the acid character and the positive charge. Similarly in II′ the odd electron may be placed upon any one of nine carbon atoms. In formula III′ the basic property is to be equally distributed among the three nitro groups.

The structures on the left in our scheme have heretofore been assumed to contribute to a greater or less degree to the general resonating molecule. We are now suggesting the possibility that they do not contribute to any degree whatsoever to the molecule in its normal state. According to this hypothesis we may have in solution two distinct substances, each with its own properties, and, if the two are in equilibrium with each other, their relative concentrations will depend chiefly upon the temperature and upon the difference in their energies. Each member of an electromeric pair must be assumed to have not only its own physical properties, such as color, but also its specific chemical properties. It is by the latter that we may ordinarily expect to detect the existence of the two forms. Thus, for example, each of the two forms II and II′ is an odd molecule, but the first will combine instantly with another odd molecule at the central carbon atom. So two molecules of II will combine instantly to form hexaphenylethane, while two molecules of II′ can combine without activation only to form another dimer in which two phenyl groups are directly attached. It seems probable that such a dimer exists in small amount, in rapid equilibrium with the monomers, in any system containing such free radicals.

Similar conditions are to be assumed in the case of the trinitrotriphenylmethide ion. In form III the central carbon should behave as a typical primary base. When we go over to the more stable ion III′ the basic character has not been lost, but the pair of electrons, which was on the central carbon, is now resonating chiefly between the three nitro groups. If, therefore, a strong enough acid is added to the blue ion, we should expect hydrogen ion to add, and add instantly, at one of these positions. This is one of the phenomena which will be described in the paper immediately following. The fact that a substance may act as a secondary acid or base with respect to neutralization at one point in the molecule and at the same time behave as a primary acid or base with respect to some other point of neutralization must be constantly borne in mind.

Unless the distinction between primary and secondary acids and bases is a fundamental one, it would be expected that the number of slow neutralizations, which have been observed in the neighborhood of room temperature, would rapidly increase as we study reactions at successively lower temperatures. We shall see, however, in our experiments which were carried out progressively at lower and lower temperatures, until finally numerous experiments were made at $-160°$, that not a single case was found of a secondary acid or base, except those already listed.

Other Possible Explanations

At present we have no definite clue as to the origin of the distinction between secondary and primary acids and bases. Neither are we able to predict, except by analogy to other substances of a similar sort, when we may expect to find substances of the secondary type. One suggestion is worth serious consideration. In the case of each secondary acid or base that we have found, the process of neutralization causes a notable change in the geometry of the molecule. Thus CO_2, which is linear, becomes a planar structure when it adds to OH^-. In triphenylmethyl ion, the central carbon, and the three phenyl carbons to which it is attached, are presumably coplanar, but when the ion adds OH^- or Cl^- a tetrahedral molecule results. If our trinitrotriphenylmethide ion is completely representable by formula III′, once more the central atom and the three attached carbons should be coplanar. On the other hand, if it were all in the form III, it should be tetrahedral like ammonia. If both forms were in resonance together, then we should expect a slightly pyramidal form, the departure from coplanarity being dependent upon the contribution that formula III makes to the resonance state.

Is the activation energy which is required in the neutralization of secondary acids and bases to be regarded as a consequence of these important changes in the geometry of the system? Our present answer is in the negative, chiefly because of two experiements which will be described and which were designed expressly to test this point. The strong acids boron trichloride and trifluoride are in all probability completely planar, like triphenylmethyl ion, and go over into tetrahedra

when a base is added. It therefore seemed important to ascertain whether these acids show any signs of secondary behavior. We shall see that they both behave as primary acids and are neutralized instantly (within a fraction of a second) even at the extremely low temperature $-160°$. As an even closer analog to triphenylmethyl ion it would be interesting to study the rate of neutralization of the acid triphenylboron.

The only remaining alternative to the electromeric hypothesis that has occurred to us is that when a substance acts as a secondary acid or base with respect to neutralization at a certain point in the molecule, this point is covered and protected, either by some chelation in the molecule itself, or by some hitherto unsuspected type of combination with the solvent or other solute molecules. We have pointed out the great similarity between our new secondary base and the anion of the derivatives of nitromethane. In the new edition of Sidgwick's "*Organic Chemistry of Nitrogen*"[6] there is a very full discussion of the various structures of such an ion which have been suggested to account for the observed properties, especially the retention of optical activity. It is there pointed out that no one of these structures appears to be satisfactory. It is our opinion that the observed properties of nitromethide ions are not those of any substance which can be expressed by a formula which ignores a complex with the solvent, and indeed if a solvent could be found which does not form such complexes, the properties of the ion would be entirely different. Assuming now one or more molecules of the solvent, usually alcohol, attached to the simple ion, such molecules might conceivably form such a chelated system as to protect the methide carbon from immediate attack. The process of activation would then consist in breaking the attachment. Moreover, as our studies have progressed, we have found numerous examples of the formation of peculiar complexes with solvent molecules of the type which might conceivably lead to such protection of an atom as to prevent its action as a primary acid or base. Nevertheless, after considering all the cases now available, and especially the simplest and most typical case of carbon dioxide in water or alcohol, we regard the electromeric hypothesis as the most probable explanation of our phenomena.

Whatever the explanation may be, our immediate purpose must be to substantiate the idea that a secondary acid or base exists in two different forms, in only one of which neutralization at a given point proceeds rapidly and without activation.

(6) Sidgwick, Clarendon Press, Oxford, England, 1937.

Kinetics

Recognition of the distinction between primary and secondary acids and bases leads to certain kinetic considerations which were implied in the preceding paper[2] and which we must now subject to careful analysis. We are going to discuss two theses, neither of which can be regarded as proved, but both of which have become increasingly plausible as our experiments have proceeded.

Thesis I.—The first thesis, which is a direct consequence of our assumptions, is that in the neutralization of a secondary acid or base the rate of the reaction will frequently be determined, either by the rate of formation of the primary form from the secondary form, or by the concentration of the primary which is in equilibrium with the secondary form.

Let A be any primary acid and let B_S be the ordinary state of a secondary base, whose primary form, of higher energy, may be called B_P, and let us consider the following sequence of reactions

$$B_S \longrightarrow B_P \qquad B_P + A \longrightarrow BA \qquad (1)$$

We may first consider the case in which the first step is slow compared with the second; in other words, the first is the rate determining process. This rate of forming B_P from B_S will be given by an expression of the Arrhenius form in which the coefficient involves probabilities, and the exponent contains the heat of activation q, which is the difference in energy between B_P and B_S. As long, therefore, as the first step is rate determining, the rate of the reaction, at each temperature, will be independent of the concentration and of the nature of A. If this case can be realized experimentally, under conditions which permit no misinterpretation of the experiments, we shall have the most direct proof of our assumptions. We have not yet found a case of this sort.

Let us next consider the case in which the second step of reaction (1) is much slower than the first. Then B_S and B_P are in equilibrium, so that (ignoring differences in entropy) c_P/c_S, the ratio of the two concentrations, is proportional to exp. $(-q/RT)$. If then the reaction is bimolecular with respect to acid and B_P, it is also bimolecular with respect to acid and B_S. Once more q will be

the heat of activation. Therefore according to our assumptions we may expect to find in reactions of this type a heat of activation which is often independent of the nature of the acid.

Ordinarily it would be assumed that the process that we are considering would occur, not as represented in mechanism 1, but by the mechanism of the activated complex. According to the latter view a molecule of B_S and a molecule of A occasionally would collide with sufficient energy so that in a single step the combined system could pass over some potential barrier to produce the stable molecule BA. With a given base the height of the barrier and therefore the heat of activation would vary with the nature of the acid. According to our view also this would be the mechanism if an acid were found for which the barrier that we have just mentioned is lower than the difference in energy between B_S and B_P. Supposing, for example, that this barrier were proportional to some inverse function of the strength of the acid, then according to the theory of the activated complex, the heat of activation found for different acids would be expected to fall upon line I of the schematic diagram, Fig. 1. On the other hand, according to our view, the experimentally found heat of activation might follow the same line up to a point, but from that point on the values would be constant (line II). This would be approximately the point at which the height of the barrier of the activated complex would begin to exceed the heat of activation of mechanism 1, namely, $E_P - E_S$.

In the following paper we show that in the neutralization of trinitrotriphenylmethide ion the heat of activation is essentially constant with acids covering the great range from chloroacetic acid to ethyl alcohol. In other words all these cases seem to fall on the horizontal line (line II) of Fig. 1. It would seem almost impossible to interpret these results by the theory of the activated complex.

Thesis II.—The second of our main theses is much wider in its scope, since it concerns, not the rarer cases of the secondary kind, but rather all molecules of the resonance type. When a substance is said to resonate between several structures, then, if the energy calculated for one of the structures is very much larger than that for the actual substance, that structure is said to contribute very little to the actual state of the substance. The question however is one of degree

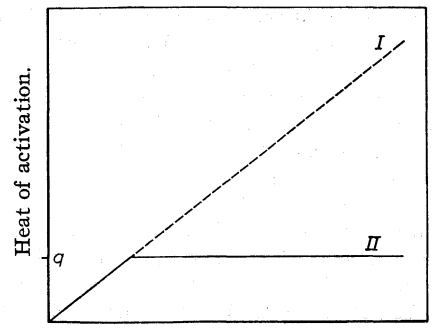


Fig. 1.

and we may assume, except when there is an absolute prohibition of resonance such as we have been discussing, that all possible electronic structures, no matter how small their contribution, must be regarded as members of the resonance family.

It has been assumed that if a resonating molecule reacts in a way which could only be interpreted as a behavior peculiar to one of the contributing structures, and if this structure is one of high energy, then such a reaction must require a heat of activation corresponding roughly to the difference between the normal energy of the molecule and the energy calculated for that particular structure.[7] Just the *opposite* of this assumption is the one we are now going to propose as our second thesis.

Let S be any resonating molecule in its state of lowest energy, and let S_1, S_2, . . . be individual structures which may be said to contribute to the actual molecule S. Let E be the actual energy and E_1, E_2, . . . the higher energies calculated for the hypothetical individual structures. Now we are going to assume that, to permit a reaction characteristic of the form S_1, we do not require an activation energy of the order of $E_1 - E$ but that the process *may* occur without any activation no matter how large this energy difference is. With respect to heat of activation, the difference between a set of tautomers and a set of resonating forms may be expressed as follows. A tautomer can be converted into another tautomer of higher energy only when the requisite energy is obtained from an external source; on the other hand, a resonating molecule, even when isolated, may be said to pass through its various phases, some of low energy and some of high, by processes which were forbidden in the old mechanics but permitted in the new.

(7) See for example Anderson, *J. Chem. Soc.*, 1042 (1936).

What we have said pertains to the exponential part of the Arrhenius expression for reaction velocity. Does the coefficient of this expression, which depends, in the case of a bimolecular reaction, upon the probability that each collision is effective, vary greatly with the extent to which the structure S_1 contributes to the general resonance state S? We have at present no answer to give to this question except for the following remark.

It is occasionally convenient to consider that in a resonating molecule there is a rapid oscillation in the electron cloud so that the system approaches now one, now another, of the particular structures such as S_1, S_2, ... If we take this view we have to consider, not only what fraction of the time the molecule can react as though it were in the form S_1, but also how frequently this state or phase recurs, or, in other words, the resonance frequency. In the case of a gaseous collision the duration of the collision is presumably of the same order of magnitude as the resonance time. In such a case the chance of an effective collision might depend very greatly upon whether the reacting form is a major or minor constituent of the resonating molecule. On the other hand, in a liquid, if two molecules come together, they probably remain together for a considerable time, during which a resonating molecule may pass many times through its various phases. In such case it would appear that the probability of effective collision would not depend very greatly upon the extent to which the reacting form contributes to the resonance state. As a matter of fact the experiments we are to describe are consistent with the latter supposition.

When we apply our second thesis specifically to acids and bases we find the following consequences. When one of the contributing structures of a resonating substance, no matter how small the contribution may be, has the form of an acid or a base, the substance will behave as a primary acid or base, and when it combines with any primary base or acid it will do so without activation. There is no connection whatsoever between the ability to act as a primary acid or base and the acid or basic strength. All of the substances of secondary type that we have found have been moderately strong acids and bases. On the other hand, we are going to describe experiments with extraordinarily weak bases which do not combine to any appreciable extent except with the very strongest acids; but insofar as the process of neutralization occurs, it occurs instantly, even at very low temperatures.

Some of the bases that we have used in our experiments have ionization constants which we estimate to be as low as 10^{-22} and a very rough calculation of $E_1 - E$ in such a case would give something like 20–30 kcal. Nevertheless our experiments show that such bases are neutralized within a fraction of a second at $-160°$. Considering the dilution of our solutions, we may state that the heat of activation, if it exists at all, cannot be greater than 4 kcal.

Experiments

Carbon Dioxide as a Secondary Acid.—If at $-60°$ we dissolve carbon dioxide in alcohol and divide the solution equally between two tubes, A and A′, and if at the same temperature we have an alcohol solution containing dilute sodium ethylate and a little indicator, such as brom cresol purple, divided equally between the two tubes, B and B′, then if A is added to B at once there is no immediate change of color. However, on standing for some fifteen minutes the carbon dioxide neutralizes the ethylate ion and the indicator passes slowly through its color changes. If now, having stood for half an hour or so, the contents of A′ are added to B′, the indicator goes at once to the acid color. We have not yet ascertained whether the time required to produce the acid color is the same in the two cases.

The latter of these experiments, which shows that the solution of carbon dioxide in alcohol only slowly becomes an acid, might conceivably, although improbably, be explained on the assumption that the oxygen of C_2H_5OH adds immediately to the carbon of CO_2 but that it takes time for the hydrogen to pass over to one of the oxygens of the CO_2, producing the ordinary ethyl ester of carbonic acid. However, the former experiment shows the falsity of this explanation. In that case the basic ion $C_2H_5O^-$ can add directly to the carbon of CO_2 to give the final stable product. The fact that it does not do so immediately at low temperatures shows that a heat of activation is necessary, or in other words, that carbon dioxide is a secondary acid.

Methods of Studying Reactions with Indicators at Very Low Temperatures.—Numerous experiments were made with reactions at a variety of low temperatures, but since these were all repeated at our lowest temperature, with identical results, we shall proceed immediately to describe a series of experiments made at $-160°$ (113°K.). As far as we are aware, this is the lowest temperature at which chemical reactions have been observed except in the case already cited of the instantaneous union of the two odd molecules NO and O_2 at 90°K. At the temperature of $-160°$ we may be sure that if any instantaneous reaction has any heat of activation at all it cannot be greater than about 4 kcal. To obtain any evidence for a smaller heat of activation than this it will be necessary to use indirect methods, of which several are available, but which we have not yet tried.

The experimental method first used was extremely simple. The acid or base to be tested was dissolved in petroleum ether of freezing point $-160°$. This was placed in a flask which could be attached to the vacuum line by a ground-glass joint. The solution was then frozen and the flask exhausted. The contents were then melted and in order to get rid of the small amount of air remaining, the process of freezing and exhausting was repeated. The connection between the flask and line now being closed by a stopcock, the line, comprising about 50 cc., was filled with the vapor of the base or acid to be used for the neutralization, at a pressure of about 10 cm. The liquid air, which had been used for freezing, was now

removed and the solution in the flask was agitated by a small piece of iron enclosed in glass which had been placed at the bottom of the flask and was now moved by means of a small permanent magnet held outside the flask. When the contents of the flask were about half melted the experiment was performed by opening the stopcock. When the vapor is such as produces a color change, then at the instant at which the vapor impinges upon the surface of the solution the color appears. This color then spreads through the solution, soon after which sometimes a colored precipitate forms. The time from opening the stopcock to appearance of bright color is not more than a few tenths of a second.

Although the amount of vapor entering the flask is very small, it seemed possible that the surface temperature might be raised appreciably by it. Therefore the more crucial experiments were repeated in a new apparatus in which constancy of temperature was assured. This apparatus was attached to the vacuum line by a horizontal ground glass joint. In a plane perpendicular to the axis of the joint an inverted Y-tube could be rotated so as to mix and stir the contents of the tube. With acid in one limb and base in the other, each dissolved in petroleum ether, the whole was immersed in a large bath of half-frozen petroleum ether. When completely cooled the apparatus was then rocked and as the liquids mixed an instantaneous color change was observed. Observations with the two types of apparatus were in every case identical. All the following experiments were made at −160° and in petroleum ether as solvent.

Boron Trichloride as an Extremely Strong Primary Acid.—When boron trichloride was added to a solution of butter-yellow there formed instantly the pure red which is characteristic of the compounds of this indicator with all acids, whether of the hydrogenic or the non-hydrogenic type. Within a few seconds a red precipitate was formed. This experiment proves that boron trichloride, in spite of its geometrical resemblance to triphenylmethyl ion, is a primary acid, at least if we decide for the present to call all acids and bases primary which are neutralized instantly at −160°. Incidentally this experiment shows also that butter-yellow is a primary base.

Boron Trifluoride as an Extremely Strong Primary Acid.—The previous experiment was repeated with boron trifluoride instead of boron trichloride. The result was the same, showing that boron trifluoride is a primary acid. It is generally assumed that boron trifluoride is on the average a stronger acid than boron trichloride, but as far as our experiments have gone this idea is not confirmed. Since, moreover, boron trifluoride is in general more destructive to organic substances than boron trichloride, the latter has been used in the majority of our further experiments.

Trinitrobenzene and Trinitrotoluene as Weak Primary Acids.—These two substances stand alone among common indicators in that their acid behavior is not due to giving up hydrogen ion, or forming a hydrogen bond, but is due to the direct addition of a base. When solutions of these two substances are treated with ammonia gas at our lowest temperature they at once change from colorless to bright red. The reason that ammonia was used in this experiment, rather than a stronger base such as diethylamine, we shall discuss in another paper. Incidentally this experiment shows that ammonia is a primary base.

Dibenzalacetone and its Analogs as Very Weak Primary Bases.—Dibenzalacetone, dipiperonalacetone and dianisalacetone give in concentrated sulfuric acid strongly colored solutions, orange, purple and red, respectively. Their relative basic strengths in this solvent were estimated through the method of Baeyer and Villiger by Stobbe and Haertel,[8] who found that the basicity increased in the order listed. We find that they are all stronger bases than acetone, although the difference is not great in the case of the first substance; for in this case the gradual addition of acetone to the colored solution in 95% sulfuric acid destroys the greater part of the color. When these three substances are dissolved in concentrated aqueous hydrochloric acid the first shows only the yellow color characteristic of the uncombined substance, the second gives a pale purple and the last a stronger red. If these substances are dissolved in petroleum ether and gaseous boron trichloride added, the initial colors produced are, as far as can be noted visually, identical with those in sulfuric acid. When boron trichloride was introduced at −160° all three color changes were instantaneous, showing that all three substances are primary bases.

Unsymmetrical Diphenylethylene as a Very Weak Primary Base.—This substance treated with boron trichloride in the usual way at the lowest temperature gave an instantaneous red color. It is therefore, by our present criterion, a primary base. It is a stronger base than the symmetrical compound, stilbene, which is not appreciably neutralized by boron trichloride in petroleum ether. Another base which also proved too weak is diphenyloctatetraene. This last substance, and the other polyene which we are about to discuss, were kindly furnished to us by Dr. M. Calvin. Also the tetracyclic hydrocarbon, perylene which was kindly furnished to us by Professor L. F. Fieser, proved to be too weak a base for our purpose, although in 95% sulfuric acid it is colored.

Symmetrical Diphenyldodecahexaene and β-Carotene as Extremely Weak Primary Bases.—These substances represent the very weakest bases that are appreciably neutralized by boron trichloride in petroleum ether. They both give a blue color in 95% sulfuric acid and an intense blue in fuming acid. They both prove to be primary bases. Carotene at our low temperature gave with boron trichloride an instantaneous blue color, followed in a few seconds by a green precipitate. The diphenyldodecahexaene also gave an instantaneous brilliant color, but instead of the expected blue a brilliant orange appeared. However, upon warming to about −80°, the color changed to blue, while the orange color reappeared when the solution was once more cooled. Apparently the compound adds more than one molecule of boron trichloride at very low temperatures.

Summary

Most acids and bases neutralize one another rapidly at all temperatures. These are called primary. Some other acids and bases, called secondary, require heat of activation for the neu-

(8) Stobbe and Haertel, *Ann.*, **370**, 99 (1909).

tralization process. Sometimes this secondary behavior is predictable from familiar considerations based on solvation or tautomerism. However, there are other cases where such considerations do not at present suffice for an adequate explanation.

In an attempt to find new secondary acids and bases, involving in their neutralization small heats of activation, the neutralization process has been studied in numerous cases at temperatures as low as −160°C. (113°K.). No new cases of secondary behavior were found. These results indicate a striking distinction between primary and secondary. It is suggested that every secondary acid or base also exists in an independent primary form and that the relative amounts and the difference in energy of the two forms can be ascertained by kinetic studies.

In order to interpret the distinction between the two forms various hypotheses are considered. The hypothesis that at present seems most probable is that two electromeric forms may exist, incapable of resonance with one another, and differing in the laws which govern electronic distribution. Such a hypothetical electromerism is illustrated not only for acids and bases but also for a certain class of odd molecules.

Our second kinetic thesis concerns systems in which there is resonance between a number of contributing structures. It asserts that a resonating molecule may without activation take part in a reaction characteristic of one of its contributing structures, even though the contribution of that structure may be extremely small and the calculated energy of that structure extremely high. This thesis is demonstrated by experiments upon numerous acids and bases at a very low temperature.

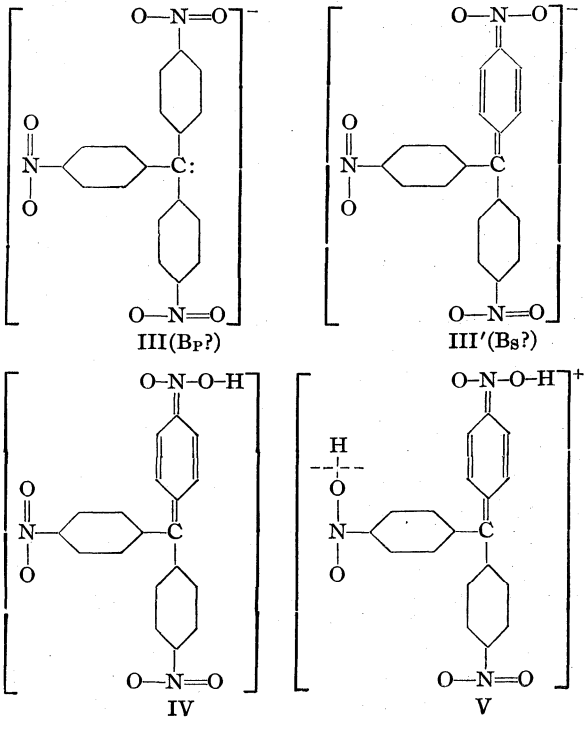
Trinitrotriphenylmethide Ion as a Secondary and Primary Base

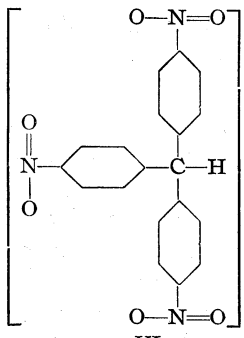
BY GILBERT N. LEWIS AND GLENN T. SEABORG

When we started this investigation we were unacquainted with any typical secondary base. It seemed not unlikely, however, by analogy to the variously substituted positive triphenylmethyl ions, all of which behave as secondary acids, that the negative triphenylmethide ions would prove to be secondary bases.

The substance chosen for investigation was 4,4′,4″-trinitrotriphenylmethane, which is represented by formula VI in the accompanying graphical scheme. This substance in alkaline alcoholic solution loses hydrogen ion, giving the intensely blue trinitrotriphenylmethide ion which may be represented by formula III′. According to our expectation this solution, when acidified with acetic acid at temperatures ranging from −30 to −80°, fades slowly, and fades more slowly the lower the temperature, thus showing that the blue ion is not behaving as a primary base with respect to the addition of an acid at the central carbon atom.

According to the views expressed in the paper just preceding, a secondary base of this sort should exist in two forms. One form is to be identified with the substance as it ordinarily is, in the state of a secondary base. The other form, of higher energy, is one in which the substance be-





VI

haves as a primary base. If there are these two forms we must see whether the difference in energy between them can be ascertained from a study of the kinetics of the neutralization process.

We have also discussed certain hypotheses to account for the behavior of secondary acids and bases. It is unnecessary in the present paper to commit ourselves to any hypothesis, but for the sake of clarity we show in formulas III and III′ the two states of the trinitrotriphenylmethide ion in terms of the electromeric hypothesis. The former is capable of adding acid directly to the central carbon atom, the latter is not. Since, however, we are now concerned only with our more fundamental assumptions, we shall represent the primary substance as B_P^- and the secondary as B_S^-.

At first we had intended to study the trinitrotriphenylmethide ion only far enough to demonstrate its behavior as a secondary base, but some intricacies of behavior, which were puzzling at first, led us to make an extensive, although not very exact, experimental survey of the kinetics of this system.

When the blue ion has been formed and the central carbon has lost its power of acting immediately as a base, the basic character has, in a certain sense, been transferred to the three nitro groups. Therefore a sufficiently strong acid should attach itself at one of the nitro groups and in this process the blue ion should act as a primary base. This expectation was verified. If to the blue alcoholic solution at low temperature we add hydrochloric acid instead of acetic, a brilliant orange appears. An excess of sodium ethylate restores the blue color and we may titrate back and forth between blue and orange with sodium ethylate and hydrochloric acid. These changes even at $-85°$ are instantaneous. At first it was thought that the orange compound might correspond to formula IV, although it is hard to see why a compound of that formula should show any color, except perhaps a pale yellow. In fact we shall see that more than one equivalent of H^+ is used in the formation of the orange compound from the blue ion.

The Kinetics of the Neutralization of the Blue Ion.—Trinitrotriphenylmethane, which was kindly prepared for us by Mr. R. L. Caswell, under the direction of Professor T. D. Stewart, may be purified rapidly by successive recrystallizations from toluene and may be kept for weeks unchanged, either as solid or in the toluene solution. In alcohol, especially in the presence of alkali, the substance is sensitive to oxygen and to small amounts of substances of the type of the organic peroxides. A stock solution in toluene was kept and added to alcohol just before each experiment. Our solvent, therefore, in all the experiments to be described, contained by volume 85% absolute ethyl alcohol and 15% toluene, except when otherwise stated. That very nearly the same results would have been obtained in pure alcohol was shown by experiments in which the percentage of toluene was varied.

The reaction vessel in the form of an inverted Y was exhausted to the point where the small amount of residual oxygen no longer had any deleterious effects. This vessel, with the alkaline solution in one limb and the acid in the other, was placed in the low temperature bath (of acetone and carbon dioxide). When the temperature equilibrium was attained the vessel was tipped rapidly back and forth until the contents were thoroughly mixed. The reaction was then followed by comparing the color with a set of standard color tubes. After the experiments had indicated that the reaction was always of first order with respect to the colored ion, the procedure was simplified further. The time was taken merely between the mixing and the matching of a single color standard.

In each experiment one limb of the reaction vessel contained 5.5 cc. of the blue alkaline solution and the other limb contained 1.0 cc. of the acid solution. The concentrations given refer to the total volume of 6.5 cc. after mixing. The initial alkaline solution was always the same and contained 0.0015 *M* sodium ethylate and 0.001 *M* trinitrotriphenylmethane. Later experiments showed that in this solution only one-eighth of the methane is in the form of the blue methide ion. After mixing the reaction was allowed to continue until this ion fell to one-sixteenth of its initial concentration, or a little less than 0.00001 *M*, when the elapsed time was read. The acids varied in concentration from 0.003 to 1.0 *M*, from which we obtain the actual concentration by subtracting the concentration of the ethylate, ignoring the very small concentration of the blue ion.

An accuracy of 10% in the measurement of the time was all that was sought. In a work of this sort, which is prospecting in a large field, it seems undesirable to spend much time upon the refinement of the technique of measurement, or even upon the purification of the reagents. Of the sixteen acids used in the following experiments several were far from pure, and our conclusions

must be drawn from the results as a whole, and not from those obtained with a single acid. There is, moreover, a more fundamental reason for distrusting the generality of results obtained from a given acid. When we are comparing reactions of a given substance with various other substances and under various conditions, it is important that that given substance should be the same in the several experiments. In our case, however, we are going to conclude that this is not in general true. There is every reason to believe that the blue ion in alcohol is a complex between trinitrotriphenylmethide ion and the solvent. Now when a new solute is added, such as one of the acids used for the titration, it may replace some of the solvent molecules in the complex, thus changing the nature of the reacting substance and its heat of activation. We are going to show that at least three substances, phenol, boric acid, and water appear to form such new complexes.

The first experiments were carried out with acetic acid. Here, as with many other acids, the rate of the reaction was found, within our limits of accuracy, to be proportional to the concentration, when the acid concentration is small. At higher concentrations the rate increased less rapidly than the concentration, the discrepancy amounting to 20% at 0.015 *M*. It seems probable that this effect is due to departures from the ideal solution. In the more dilute solutions the reaction may be regarded as strictly bimolecular.

Added salts were found to have no appreciable influence upon the rate, except in the case of silver salts, which produce insoluble compounds with the blue substance. The rate with acetic acid was also found to be unaffected by sodium acetate, showing that the rate is determined solely by the undissociated acid and not by the small concentration of hydrogen ion which is present. It was fortunate that while doubtless many of our solutions were supersaturated at the temperature of the measurements, there was no precipitation during the course of the measurements except in one or two cases, notably in the case where sodium chloroacetate was formed.

Since the reaction was found to be bimolecular and free from catalysis or neutral salt effect, we may calculate the heat of activation without ambiguity. If $-dc_B/dt$ represents the diminution per second of the concentration of the ion B_S^-, the rate constant k is determined by the equation $-dc_B/dt = kc_Ac_B$ where c_A is the molal concentration of the acid. Values of k for acetic acid (0.0046 *M*) were obtained at the four temperatures −53, −63, −76 and −82°. Plotting log k against $1/T$ gave a good straight line, the individual departures corresponding to differences in k of only a few per cent. Here, however, we are only testing the experimental method. No such accuracy is claimed for the results as a whole, nor was it desired, as we have already explained.

We shall attempt to interpret our results in terms of the following mechanism.

$$B_S^- \xrightarrow{(a)} B_P^-$$

$$B_P^- + HY \xrightarrow{(b)} BHY^- \xrightarrow{(c)} HB + Y^- \qquad (1)$$

We assume that (b) is the rate-determining step. Then the concentration of B_P^- depends upon the concentration of B_S^-, the temperature, and the difference in energy between B_P^- and B_S^-. If the reaction proceeds through this mechanism and not through that of the activated complex, the measured heat of activation should be the same for the several acids and equal to the difference in energy between the primary and secondary forms of the base.

We have collected in Table I the results obtained with various acids. The question marks indicate that only one or two observations were made. The acids are arranged according to the ionization constant, K_{H_2O}, in water at room temperature. The ionization constants in alcohol at low temperature are certainly of a quite different order of magnitude but probably are roughly in the same order. The rate constant k at −60° is given in the third column, concentrations being in moles per liter and time in seconds. With the six strongest acids in this list the reaction proved to be bimolecular and from the temperature co-

TABLE I

Acid	$-\log K_{H_2O}$	k	Heat of activation, kcal.
Chloroacetic (+ $CH_2ClCOOLi$)	2.80	30	10.2
Furoic	3.15	10	8.8
α-Naphthoic	3.70	5.3	8.5
Lactic	3.85	3.2	8.9
Benzoic	4.15	5.1	10.0
Acetic	4.75	3.0	8.6
p-Nitrophenol	7.10	1.0 (?)	
2,4-Dichlorophenol	7.55	0.87 (?)	
Hydrocyanic	9.15	.13	
Boric	9.20	.090	
Catechol	9.50	.27 (?) (0.15 *M*)	
β-Naphthol	9.60	.12	
Phenol	9.85	.090	

efficient of k we have calculated the heats of activation given in column 4.

We regard the several values of the heat of activation as equal within the limits of experimental error and of uncertainties concerning the constancy of composition of the blue ion, of which more will be said later. The average value is 9.1 kcal. which we may take as the difference in energy between the primary and secondary forms of the base. A still more striking verification of the constancy of the heat of activation will be furnished presently. The study of stronger acids than chloroacetic would have been extremely interesting but was prevented by the formation of the orange compound.

It will be noticed that k increases regularly with acid strength. It appears as though increasing electrical polarization of the acid, by its orienting effect, increases the probability that a given collision between the acid and the primary base will be effective. Taking the highest rate constant, $k = 30$, obtained for chloroacetic acid, we may obtain an idea of the rate constant for the primary base itself. It has become common in a case of this kind to calculate the ratio of the concentrations of two forms from the difference in their energies by means of the Boltzmann equation. Such a calculation shows B_S^- to be 2×10^9 times as concentrated as B_P^-, whence the rate constant for B_P^- would be $30 \times 2 \times 10^9 = 6 \times 10^{10}$. Comparing this with other bimolecular rate constants we would conclude that B_P^- and $CH_2ClCOOH$ have a very large chance of reacting at each collision. We believe, however, that this calculation is erroneous. The ratio of the concentrations depends not only upon the change of energy but also upon the change of entropy. There are no data from which the latter can be calculated but we may make a guess. In going from B_S^- to B_P^- there is likely to be a loss of attached alcohol molecules, together with a loosening of constraints such as those operating upon the nitro groups. Both of these changes would produce an increase in entropy. It is therefore probable that the concentration of B_P^- is considerably larger than that which we have just calculated, and the rate constant correspondingly smaller.

When we come to the weaker acids of Table I the values of k are those calculated formally from the velocity at 0.015 M, but k is no longer a true constant, for the rate is no longer proportional to the acid concentration. The most extreme cases are that of phenol, in which changing from 0.015 to 0.15 M only doubles the rate, and that of boric acid in which, through the same range of concentration, the rate increases by only 10%. This result was at first perplexing. The evidence is entirely against the supposition that either of these two acids is much polymerized in alcohol. Another possible explanation was suggested by the fact that there are slight but perceptible differences in color when different acids are used. We already have alluded to the possibility that the blue ion in alcohol, which presumably holds alcohol molecules through hydrogen bonds at the three nitro groups, may have some of these alcohol molecules replaced by solute molecules when certain substances are dissolved. The fact that phenol and boric acid give lower rates than hydrocyanic acid and β-naphthol, and also show the least effect of concentration upon reaction rate, suggested that phenol and boric acid displace the alcohol from the nitro groups to an extent depending upon their concentration, and that the ion with phenol attached is less reactive than the corresponding alcohol compound. These assumptions would explain qualitatively both the reduced reaction rate and the small effect of concentration.

In order to test these assumptions quantitatively the rate of fading of the blue color was studied with a mixture containing large amounts of phenol or boric acid and small amounts of acetic or benzoic acid. Although the effects were small, of the order of 10–30%, they were always in the same direction, namely, the rate in the mixture was smaller than that calculated from the behavior of the pure acids. We have, therefore, evidence that boric acid and phenol do form complexes with the reacting substance, which diminish its reactivity, and we shall later obtain more conclusive evidence on this point. On the other hand, the magnitude of the effect is by no means sufficient to account for the fact that the rate with boric acid and phenol is nearly independent of the concentration.

The true explanation of this effect proved to be a very simple one. Alcohol is itself an acid, and although its acid strength is not high enough to cause the fading of the blue color to occur to any great extent before equilibrium is established, it does, in the presence of a stronger acid, play an important and sometimes preponderating part in the mechanism of the fading process. This is due to the relatively large number of alcohol molecules present. Side by side, therefore, with the reaction we have considered so far, is this reaction with the solvent, which may be written as

$$B_P^- \xrightarrow{(a)} B_P^-$$

$$B_P + HOR \xrightarrow{(b)} (BHOR)^- \xrightarrow{(c)} HB + OR^- \quad (2)$$

to which must be added $OR^- + HY \longrightarrow HOR + Y^-$ in the presence of another acid such as phenol.

In order to determine the rate of the pure reaction (2) in the absence of any other acid than alcohol we have proceeded indirectly. In some experiments with *m*-cresol, and also in experiments with phenol to which sodium phenolate was added, the fading of the blue color did not run to an end but came to an equilibrium color. Evidently as concerns its dissociation to form the blue ion, the trinitrotriphenylmethane is an acid of about the same strength as phenol. So also in alcohol containing varying amounts of sodium ethylate we were able to measure the equilibrium ratio of B_S^- to HB. This ratio at a given temperature is proportional to the concentration of ethylate ion and at a given concentration of the latter increases with increasing temperature. From measurements at a series of temperatures, which we shall not give in detail, we were able to obtain the increase in energy in going from HB + OR^- to HOR + B_S^-. This amounts to 2.2 kcal. The equilibrium constant $(B_S^-)/(HB)(OR^-)$ at $-60°$ is 15.8.

In certain experiments the color of the equilibrium solution was studied when small amounts of water were added successively to the alcohol. If the ethylate ion is largely hydrolyzed in the presence of small quantities of water, we should expect the essential equilibrium now to be that between HB + OH^- and H_2O + B_S^- and therefore we should expect the amount of color to diminish rapidly as the water is added. In fact no change in color was found until the water had reached nearly 10 mole per cent. At first sight this seemed to indicate that the ethylate ion is not largely hydrolyzed. This, however, is not the probable explanation. We are presently going to produce evidence that water replaces alcohol in the blue ion forming a more stable substance. Apparently this effect is just counteracting the expected effect, when water is added to the solution.

Starting with a solution of trinitrotriphenylmethane in alcohol and adding a solution of sodium ethylate, we were able to study the rate of formation of the blue ion in a range sufficiently remote from equilibrium. The rate of this reaction, which is the reverse of reaction (2), is strictly proportional to the concentration of ethylate ion and of HB. From such measurements at different temperatures we obtained the value of the rate constant at $-60°$, and the heat of activation, which amounts to 11.1 kcal.

Subtracting from this heat of activation the heat of reaction obtained from the equilibrium measurements, we obtain 8.9 kcal. as the heat of activation of reaction (2). No great accuracy can be claimed for this determination, but the agreement of this value with the value 9.1 kcal. obtained as a mean for the much stronger acids, ranging from chloroacetic to acetic, very strongly substantiates our assumption that the heat of activation in all these cases is the heat required to form B_P^- from B_S . If the activation occurred only at the moment of collision between the reacting molecules, it would be hard to explain why the heat of activation or, in other words, the potential barrier in the activated complex should be the same for such very different substances as alcohol and our other acids.

When we came to determine the rate constant of reaction (2) by finding the ratio between the equilibrium constant and the rate constant in the reverse direction, we expected to find the rate due to the alcohol alone a little smaller than the rate which had been observed with dilute solutions of phenol and boric acid. In fact, however, the rate which we calculated was nearly twice the one observed in the presence of those two substances. This result was at the time so surprising that the whole determination was repeated with greater care, but the result was the same. We see no explanation except in the assumption for which we have already shown other evidence, namely, that the blue ion is a different substance when small amounts of phenol or boric acid are present.

If the blue ion in alcohol itself is not as simple as indicated in structure III′, but rather has alcohol molecules attached by hydrogen bonds to the several nitro groups, and if when certain substances such as phenol are added (and this may be true to some extent for any of the other acids we have employed), the solute molecules replace the alcohol molecules in the complex, then these new and more stable molecules may be expected to react more slowly either by reaction (1) or (2). In the course of another investigation we have found that crystal violet in toluene forms complexes with alcohols and acids, and the stability of these compounds reaches a maximum in the case of phenol.

In this connection we may mention the effect of water upon the reaction rates that we have been discussing. If, for example, to a 0.01 molal solution of acetic acid in alcohol we add water to the extent of 2 *M*, the rate of the reaction is reduced by one-half. This effect we attribute mainly to the formation of a stabler complex in which water replaces alcohol in the blue ion.

Colors and Reactions with the Chloroacetic Acids

When to the alkaline solution containing the blue ion B_S^- at low temperatures we add trichloroacetic acid, the same orange color is obtained as with hydrogen chloride and, as in that case, this color fades very slowly compared with the rate of fading of the blue color in the presence of acids like acetic. In other words, trichloroacetic acid, although even at room temperature in alcohol[1] its ionization constant is smaller than that in water by a factor lying between 10^4 and 10^5, still behaves as a strong acid toward our indicator.

If now we use dichloroacetic acid we obtain the same pure orange color but the fading of this color is much faster. This was interpreted to mean that the solution contains an amount of the blue ion too small to be observed visually, but large enough, because of its much higher specific reaction rate, to permit the rapid disappearance of the orange color. In other words, on account of the rapid equilibrium between orange and blue, the color disappears chiefly through the reaction of the latter. This view was supported by further experiments and it was found possible to make a rough estimate of the fraction of the substance in the blue form.

We wished to ascertain whether the orange substance is produced from the blue by the addition of undissociated acid or by the addition of free hydrogen ion, and by "free" we do not mean uncombined with the solvent but only uncombined with the dichloroacetate ion. Therefore we added various amounts of sodium dichloroacetate in addition to that which was regularly produced in the reaction vessel. The effect was large. With increasing concentration of salt the color changed regularly from orange to blue and the rate of reaction increased correspondingly. Now this addition of dichloroacetate does not appreciably affect the activity of the undissociated acid, but it diminishes greatly the activity of hydrogen ion, and it is therefore evident that the orange compound is formed from the blue by the addition of free hydrogen ions.

The question as to whether the orange is produced from the blue substance by the addition of one hydrogen ion or more seems to be decided by our experiments on the rate of fading at different concentrations of dichloroacetic acid. If we assume here, as in our other cases, that the rate of fading is proportional to the product of the concentrations of blue ion and of the acid, then it is evident that if only one H^+ is required to change the blue substance to the orange, the rate of the reaction could not be diminished by increasing the acid concentration. In fact, however, the rate is diminished. In going from 0.003 *M* $CHCl_2COOH$ (where the color is not quite pure orange) to 0.03 *M*, the rate decreases about threefold. We conclude therefore that our orange substance does not correspond to formula IV, but rather to a formula such as V with either two or three hydrogen ions attached to the nitro groups. Attempts to find direct proof of the existence of the intermediate pale or colorless substance failed, and this may indicate that it exists over a very narrow range of H^+ concentration. This would not be surprising, for IV is a less resonating form lying between the strongly resonating forms III′ and V, as in the numerous similar cases discovered by Schwarzenbach.[2]

Turning now to monochloroacetic acid we find at corresponding concentrations very much less of the orange compound and much faster fading. When the acid is at 0.0015 *M* the solution appears to be pure blue. Making allowance for the smaller specific absorption of the orange substance, it would be hard to believe that this solution contains more than 10–20% of the orange. Therefore its rate of fading should be nearly as high as if the substance were all blue. This proves to be very far from the case. If to this solution, which already contains a small amount of chloroacetate ion, we add lithium chloroacetate (the sodium salt being peculiarly insoluble) we find a great increase in the reaction rate. When the salt is at 0.015 *M* the rate has increased threefold and is then unaffected by further addition of the salt. The values so obtained are used in Table I. Although these measurements should be extended and quantitative studies of the absorption spectrum made, at present the simplest explanation of these facts is that in addition to the blue and orange the colorless form is present which, compared to the blue, is relatively unreactive.

The Fading of the Orange Compound

The behavior of the orange compound, which we have identified tentatively with formula V, is not our immediate concern. However, some

(1) Kraus, "The Properties of Electrically Conducting Systems," The Chemical Catalog Co., New York, 1922, p. 185.

(2) Schwarzenbach, Ott and Hagger, *Helv. Chim. Acta*, **20**, 498 (1937).

study was made of the rate of its conversion into trinitrotriphenylmethane. This rate proves to be strictly unimolecular with respect to the orange substance and entirely independent of the acid concentration. It is, moreover, the same for hydrochloric and trichloroacetic acids.

The rate is, however, extremely sensitive to water content and this effect is in the opposite direction to the one found with the blue ion. The rate increases with water concentration more rapidly than that concentration itself. Thus at $-34°$ with 2, 3 and 6% water (by volume) the times required to reach the same color standard were, respectively, 360, 135, and 41 seconds.

Since this phenomenon was not investigated further, any explanation must be provisional, but we suggest the following. Since the transfer of an electron pair to the central carbon, forming a primary base at that point (as in formula III), becomes less and less probable as hydrogen atoms are added at the nitro groups, such a configuration occurs too rarely to permit the direct addition of hydrogen ion at that point to contribute appreciably to the reaction rate. On the other hand, the hydrogens on the nitro groups are too far removed from the central carbon to permit a direct rearrangement. If, however, we imagine a chain of water molecules attached at one end to one of the hydrogens of formula V while the other end may come in contact with the central carbon, such a chain might act as a resonating system which could remove hydrogen from the nitro group and add it to the central carbon *as a single act.* This is entirely analogous to the explanation of the very high mobility of hydrogen ion in water, namely, that hydrogen ion is added at one end of a water chain while another hydrogen ion can be removed at the other end. This peculiar mobility of hydrogen ion, although very much smaller, is still present in alcohol solutions, and we may therefore, by analogy, suppose that our rearrangement, although slow, would still exist, even in completely dry alcohol.

Summary

Trinitrotriphenylmethide ion was expected and has proved to be a secondary base. In alcohol when this blue ion is added to any weak acid at temperatures between -30 and $-80°$ the formation of the corresponding methane is slow and can be followed colorimetrically. The rate of neutralization was studied with numerous acids and under like conditions the rates diminish with diminishing acid strength. With the weakest acids the rates are not proportional to the concentration of acid, and this fact is explained. With the six acids of intermediate strength the rates were found proportional to the concentrations of blue ion and of un-ionized acid, and unaffected by neutral salts. In these cases the heat of activation was calculated from the temperature coefficient of the rates and was found approximately constant with a mean value of 9.1 kcal. By indirect methods the rate of neutralization by alcohol itself was determined. Here the heat of activation is found to be 8.9 kcal. The constancy of the heat of activation over the great range from chloroacetic acid to alcohol can hardly be explained by the theory of an activated complex. The value obtained is taken as a measure of the difference in energy between the primary and secondary forms of the base. The small departures from this constant value are attributed in part to experimental error, but especially to differences in the actual composition of the reacting ion. Several kinds of evidence are adduced to show that the actual composition of the blue ion depends not only upon the solvent but in several cases upon the presence of other solutes.

While the trinitrotriphenylmethide ion is a secondary base with respect to addition of acid to the central carbon, it is a primary base with respect to addition of acid to the nitro groups. In the presence of strong acids an orange substance is thus formed which contains more than one free hydrogen ion per molecule. The very slow rate of fading of the orange compound is studied, and an explanation is suggested for the large catalytic effect of water. Mono- and dichloroacetic acids give mixtures of the orange and blue substances and the rate of fading in these solutions leads to some of the conclusions already mentioned.

The Sterols of Rye Germ Oil

BY STEWART W. GLOYER[1] AND H. A. SCHUETTE

Early investigators found indications of a marked similarity in the sterols which they isolated from wheat and rye germ oils. Interest in the unsaponifiable matter of the latter, however, has not kept pace with that aroused by the former for the sterols of wheat germ oil have been extensively investigated since the turn of the century. For this reason it was deemed desirable to re-investigate the nature of the sterols of rye germ oil; particularly in the light of the newer knowledge[2] that the principal phytosterol, sitosterol, is indeed a mixture of several sterols. These are now designated, in the order of the insolubility in the common non-aqueous solvents, as γ-, β-, and α-sitosterol.

γ-Sitosterol, which is the least soluble of this group, was isolated by Anderson and co-workers[2] from corn and wheat germ oils. Wallis and Chakravorty[3] found that the β-form is the major component of the sterol fraction of cottonseed oil and Ichiba[4] isolated it from wheat germ oil. Wallis and Fernholz[5] succeeded in separating from the most soluble sterol fraction of wheat germ oil two components which they designated as α_1- and α_2-sitosterol, respectively. We have succeeded in isolating from rye germ oil not only those sterols which are known to be characteristic of wheat germ oil, or α_1-, β-, and γ-sitosterol, but also a hitherto unreported compound which we tentatively designated as α_3-sitosterol.

α_1-Sitosterol was isolated from the most soluble sterol fraction by taking advantage of the fact, as did Wallis and Fernholz,[5] that the corresponding *m*-dinitrobenzoates differ greatly in solubility, the α_1-sitosterol derivative having the lesser solubility. They isolated α_2-sitosteryl *m*-dinitrobenzoate from the mother liquor. We found no evidence for the presence of this sterol in rye germ oil. In its place there was isolated a sterol-like compound which we have named α_3-sitosterol. Combustion data on the dinitrobenzoate indicate the empirical formula $C_{36}H_{50}N_2O_6$ which corresponds to $C_{29}H_{48}O$ for the free sterol. Perbenzoic acid titrations indicate the presence of two double bonds, thereby making α_3-sitosterol an isomer of stigmasterol and also of α_1-sitosterol.

α_1- and α_3-sitosterol give the Liebermann–Burchard color reaction, the final color being a dark purple. The Salkowski reaction for both is similar to that of ergosterol in that the sulfuric acid layer becomes colored while the chloroform layer remains colorless. The Rosenheim color reaction with chloroacetic acid is negative for both. α_1- and α_3-sitosterol are precipitated by digitonin.

Dihydrositosterol, which has been reported in as much as from 1–1.5% yields in wheat germ oil, has not been isolated from rye germ oil in this study. Although the specific rotation could be reduced from −31.53 to −8.41 by recrystallization, nevertheless the amounts present were too small to isolate by either the Schöenheimer[6] or the Anderson–Nabenhauer[7] methods.

Experimental

Approximately 12 kg. of rye oil was obtained by extracting thoroughly sifted, cleaned rye germ stock[8] with ethyl ether, first in the cold and then in a continuous extractor. An ether extraction of the saponified oil yielded some 800 g. of orange-colored unsaponifiable matter.

The sterol fraction was separated from the non-crystalline fraction with ice-cold petroleum ether yielding 474 g. of crude sterol, which is equivalent to 58% of the unsaponifiable matter. The crude sterol was submitted to a systematic triangle scheme of crystallization from alcohol and benzene in which, during the course of 115 recrystallizations, 12 fractions were obtained.

Isolation of γ-Sitosteryl Acetate.—The third and fourth top fractions (m. p. 141–142°, $[\alpha]^{27}D$ −31.26; m. p. 140–141°, $[\alpha]^{27}D$ −30.68) were acetylated and then brominated.[9] A small amount of material precipitated. It was debrominated by refluxing its alcohol solution with zinc and acetic acid, after which it was recrystallized from alcohol. The melting point, 138–139°, $[\alpha]^{24}D$ −41.51, showed that it was not stigmasteryl acetate.

The dibromide from the filtrate of the original brominated solution was precipitated, by the addition of water,

debrominated, and recrystallized sixteen times from alcohol. The remaining material, which melted at 143–143.5°, $[\alpha]^{23}D$ −45.02, corresponded to pure γ-sitosteryl acetate (26.24 mg. in 2 cc. of chloroform in a 2-dm. tube gave $\alpha^{23}D$ −1.094).

Anal. Calcd. for $C_{31}H_{52}O_2$: C, 81.51; H, 11.48. Found: C, 81.62; H, 11.45.

γ-Sitosterol.—The acetate was hydrolyzed with a 2% alcoholic solution of potassium hydroxide, precipitated with water and recrystallized twice from alcohol, yielding the free sterol. It melted at 146°, $[\alpha]^{24}D$ −42.02 (21.29 mg. in 2 cc. of chloroform).

Anal. Calcd. for $C_{29}H_{50}O$: C, 83.98; H, 12.16. Found: C, 83.96, 84.03; H, 12.33, 12.47.

Isolation of β-Sitosteryl Benzoate.—The three bottom or most soluble fractions, weighing 63 g. (m. p. 139.5–140°, $[\alpha]^{27}D$ −17.90; m. p. 139.5–140°, $[\alpha]^{27}D$ −17.00; m. p. 139.5–140°, $[\alpha]^{24}D$ −17.66), were dissolved in 260 cc. of pyridine. To this solution there was added benzoyl chloride (55 cc.), after which the mixture was heated on a boiling water-bath for one hour. After working up the product in the usual manner, the benzoate was four times recrystallized. It melted at 146–147°; $[\alpha]^{24}D$ −13.75 (30.54 mg. in 2 cc. chloroform in a 2-dm. tube gave $\alpha^{24}D$ −0.389).

Anal. Calcd. for $C_{36}H_{56}O_2$: C, 83.33; H, 10.50. Found: C, 83.28; H, 10.61.

β-Sitosterol.—The benzoate was hydrolyzed and the liberated sterol precipitated as before. On recrystallization from alcohol it melted at 137–137.5°; $[\alpha]^{24}D$ −36.66 (23.82 mg. in 2 cc. of chloroform).

Anal. Calcd. for $C_{29}H_{50}O$: C, 83.98; H, 12.16. Found: C, 84.03; H, 12.26.

Isolation of α_1-Sitosteryl *m*-Dinitrobenzoate.—In the mother liquor from the first crystalliation of β-sitosteryl benzoate there remained the most soluble corresponding α-derivative. These benzoates were saponified with alcoholic potassium hydroxide solution. Conversion to the *m*-dinitrobenzoates was effected by dissolving the free sterol in 110 cc. of pyridine and adding 15 g. of *m*-dinitrobenzoyl chloride. This mixture was kept on a boiling water-bath for two hours, after which it was worked up in the usual manner. The crude dinitrobenzoate was recrystallized four times from ethyl acetate, yielding 0.8 g. of very insoluble, tiny needles of m. p. 225°; $[\alpha]^{25}D$ +37.05 (19.16 mg. in 2 cc. of chloroform).

Anal. Calcd. for $C_{36}H_{50}N_2O_6$: C, 71.24; H, 8.31; N, 4.62. Found: C, 71.12; H, 8.32; N, 4.67.

α_1-Sitosterol.—The dinitrobenzoate was hydrolyzed and the liberated sterol precipitated as before. On recrystallization from alcohol it melted at 163°; $[\alpha]^{25}D$ −1.84 (26.42 mg. in 2 cc. of chloroform).

Anal. Calcd. for $C_{29}H_{48}O$: C, 84.38; H, 11.73. Found: C, 83.93[10]; H, 11.68.

α_1-Sitosteryl Benzoate.—The free sterol was converted to the benzoate in pyridine solution in the usual manner. On recrystallization from alcohol it had a melting point of 167–168°; $[\alpha]^{26}D$ +40.77 (22.69 mg. in 2 cc. of chloroform).

Anal. Calcd. for $C_{36}H_{52}O_2$: C, 83.68; H, 10.15. Found: C, 83.62; H, 10.42.

Titration with Perbenzoic Acid.—To 19.56 and 26.14 mg. of α_1-sitosteryl *m*-dinitrobenzoate there was added an excess of a chloroform solution of perbenzoic acid. After standing in the refrigerator at −7° for fifty-six hours there was added 5 cc. of a 10% potassium iodide solution, and the liberated iodine titrated with 0.02007 *N* sodium thiosulfate solution. The compound consumed 0.98 and 1.32 mg. of oxygen, respectively. The theoretical amount for 2 atoms of oxygen is 1.03 and 1.37 mg., respectively. These results correspond to 1.91 atoms of oxygen consumed, thus indicating the presence of two double bonds.

Isolation of α_3-Sitosteryl *m*-Dinitrobenzoate.—To the concentrated mother liquor from the first crystallization of α_1-sitosteryl *m*-dinitrobenzoate alcohol was added, while the solution was being boiled, until needles began to crystallize out. The material thus obtained (m. p. 183–184°) was recrystallized five times from ethyl acetate and alcohol, and twice from acetone, after which the melting point and the specific rotation remained unchanged. The yield of pure α_3-sitosteryl *m*-dinitrobenzoate was increased by concentrating and recrystallizing the material in the mother liquors from α_1-sitosteryl *m*-dinitrobenzoate, and by giving similar treatment to the material from the mother liquors obtained in recrystallizing the crude α_3-dinitrobenzoate. The total yield was 3 g. The product had a melting point of 202.5–203°; $[\alpha]^{27}D$ +15.35 (31.69 mg. in 2 cc. of chloroform).

Anal. Calcd. for $C_{36}H_{50}N_2O_6$: C, 71.24; H, 8.31; N, 4.62. Found: C, 71.23, 71.04; H, 8.32, 8.55; N, 4.72.

α_3-Sitosterol.—The dinitrobenzoate was hydrolyzed and the liberated sterol precipitated as before. On recrystallization from alcohol it melted at 142°, $[\alpha]^{25}D$ +1.65 (25.72 mg. in 2 cc. of chloroform).

Anal. Calcd. for $C_{29}H_{48}O$: C, 84.38; H, 11.73. Found: C, 83.65, 83.81[10]; H, 11.55, 11.64.

α_3-Sitosteryl Benzoate.—The free sterol was converted to the benzoate in pyridine solution in the usual manner. On recrystallization from alcohol it melted at 167.5–168°; $[\alpha]^{28}D$ +14.85 (22.20 mg. in 2 cc. of chloroform).

Anal. Calcd. for $C_{36}H_{52}O_2$: C, 83.68; H, 10.15. Found: C, 83.65; H, 9.89.

Titration with Perbenzoic Acid.—To 17.42 and 28.16 mg. of α_3-sitosteryl *m*-dinitrobenzoate was added an excess of a chloroform solution of perbenzoic acid. After standing in the refrigerator at −7° for a week there was added 5 cc. of a 10% potassium iodide solution, and the liberated iodine titrated with 0.02007 *N* sodium thiosulfate solution. The compound consumed 0.96 and 1.24 mg. of oxygen, respectively. The theoretical amount for two atoms of oxygen is 0.92 and 1.47 mg., respectively. These results correspond to 2.10 and 1.70 atoms of oxygen consumed, giving an average of 1.90 atoms of oxygen. These results, although not as good as those obtained with α_1-sitosteryl *m*-dinitrobenzoate, indicate the presence of two double bonds in this sterol.

Attempted Isolation of Dihydrositosterol.—The two top fractions were investigated for the presence of dihydrositosterol and stigmasterol. These fractions, $[\alpha]^{27}D$

(10) These sterols apparently retain a small amount of solvent of crystallization, thereby lowering the value for the percentage of carbon.

-28.62, and $[\alpha]^{27}D$ -28.06, respectively, were brominated by the Schöenheimer[6] method. To the reaction mixture was added a one per cent. solution of digitonin. A small amount of digitonide precipitated, which upon decomposition with pyridine[11] yielded a sterol of somewhat lower rotation, $[\alpha]^{24}D$ -21.30. This value seemed to indicate that dihydrositosterol, if present, would be found only in very small amount.

The dibromide still in solution was precipitated with water, debrominated, and then acetylated. The acetyl derivative was recrystallized ten times in the hope of concentrating the dihydrositosterol, if present, in the top fraction. It was then brominated,[9] but since no precipitate of insoluble stigmasterol tetrabromide was formed, the presence of this sterol was eliminated. The dibromide was precipitated with water and debrominated according to the method of Anderson and Nabenhauer.[7] The regenerated acetyl derivative was dissolved in carbon tetrachloride and treated twenty times with portions of acetic anhydride and sulfuric acid. There was only a slight color reaction after these treatments. The carbon tetrachloride was evaporated but only a small amount of brown resinous mass remained from which no crystals of dihydrositosterol could be obtained.

A separate sample of 33 g. of crude sterol (m. p. 138–139°; $[\alpha]^{25}D$ -31.53) was recrystallized twenty-three times, after which it had a melting point of 137°; $[\alpha]^{24}D$ -8.41. This sample was now dissolved in alcohol, brominated by the Schöenheimer method[6] and an excess of digitonin solution added. However, no insoluble digitonide was formed.

The fact that the specific rotation could be lowered to -8.41 and that the rotation of the two top fractions was lowered by treatment with digitonin would indicate the possibility that small amounts of dihydrositosterol were present. However, these amounts were too small for isolation.

(11) R. Schöenheimer and H. Dam, *Z. physiol. Chem.*, **215**, 59 (1933).

Summary

A new doubly unsaturated sterol which is an isomer of stigmasterol has been isolated in a pure state from the most soluble sterol fraction of rye germ oil.

The presence of α_1-, β-, and γ-sitosterol has been demonstrated.

The absence of α_2-sitosterol and stigmasterol has been shown.

An analysis for dihydrositosterol failed to yield the pure compound by either the Schöenheimer[6] or Anderson–Nabenhauer[7] method.

MADISON, WISCONSIN RECEIVED JUNE 12, 1939

Studies in the Sitosterol Complex. The Isolation of α_3-Sitosterol

BY SEYMOUR BERNSTEIN[1] AND EVERETT S. WALLIS

That sitosterol is in reality a mixture of several sterols was first shown by Anderson and his co-workers.[2] These investigators showed that sitosterol obtained from various sources contains dihydrositosterol and at least three other sterols which they named α-, β- and γ-sitosterol.

In 1936 Wallis and Fernholz[3] showed that the most soluble fraction of the sitosterol complex from wheat germ oil named by Anderson and his co-workers α-sitosterol was in reality a mixture of at least two new sterols α_1- and α_2-sitosterol. A detailed method of their separation and isolation was given, and certain properties of these sterols and their derivatives were listed.

In this paper we wish to report the results of certain experiments which show that a third sterol, α_3-sitosterol, is also present in the sterol complex from wheat germ oil. Our work in this connection was prompted by the fact that for continuance of our studies on the structure of α_1-sitosterol, the results of which will be reported shortly in another paper, it was necessary to obtain further quantities of this interesting material. Following the procedure described by Wallis and Fernholz,[3] we obtained from recrystallization of 1627 g. of a sitosterol from wheat germ oil, 6.5 g. of α_1-sitosteryl *m*-dinitrobenzoate and 6.0 g. of the more soluble fraction which in melting point corresponded to α_2-sitosteryl *m*-dinitrobenzoate. Hydrolysis of this latter fraction and conversion into its acetate gave a product from which not only α_2-sitosteryl acetate (m. p. 126°, $[\alpha]D$ $+17$) was isolated but also there was obtained in a pure condition 1.0 g. of a new acetate, α_3-sitosteryl acetate (m. p. 152–153° $[\alpha]^{20}D$ $+6.1$).

Several derivatives of this new sterol were prepared and their properties together with those of α_1- and α_2-sitosterol are given in Table I.

(1) Research Assistant on Special Funds from the Rockefeller Foundation.

(2) Anderson, Shriner and Burr, THIS JOURNAL, **48**, 2987 (1926). See also Anderson, *ibid.*, **46**, 1450 (1924).

(3) Wallis and Fernholz, *ibid.*, **58**, 2446 (1936).

TABLE I

Derivative	α_1-Sitosterol M. p., °C.	α_1-Sitosterol $[\alpha]_D$	α_2-Sitosterol M. p., °C.	α_2-Sitosterol $[\alpha]_D$	α_3-Sitosterol M. p., °C.	α_3-Sitosterol $[\alpha]_D$
Sterol	164–166	− 1.7	156	+ 3.5	142–143	+ 5.2
Acetate	137	+29	124–126	+17	152–153	+ 6.1
Benzoate	168–172	+42	164–166	+27	173–175	+12.0
m-Dinitrobenzoate	222	+37	206	+26	210–211.5	+12.2

We also wish to report certain other important observations. α_3-Sitosterol in all probability is an isomer of stigmasterol, $C_{29}H_{48}O$, and α_1-sitosterol, $C_{29}H_{48}O$. Titration with perbenzoic acid shows that two double bonds are present. That the two double bonds are not conjugated is indicated by an absorption spectrum study. No maxima were found in the ultraviolet region of the spectrum. α_3-Sitosterol gives a positive Liebermann color reaction. The final color is a dark blue with a reddish tint. The Salkowski reaction for α_3-sitosterol is similar to that of ergosterol, α_1- and α_2-sitosterol; the sulfuric acid layer becomes colored, while the chloroform stays colorless. The opposite is true for cholesterol, γ-sitosterol, and stigmasterol. α_3-Sitosterol is precipitated by digitonin.

Experimental Part

Sixteen hundred and twenty-seven grams of a crude sitosterol (source, wheat germ oil) was worked up according to the method of Wallis and Fernholz,[3] and yielded 6.5 g. of α_1-sitosteryl *m*-dinitrobenzoate and 6.0 g. of a material which in melting point (206°) corresponded with that of α_2-sitosteryl *m*-dinitrobenzoate previously described by Wallis and Fernholz.[3]

Isolation of α_3-Sitosteryl Acetate.—The above described material (m. p. 206°) was hydrolyzed by refluxing it with a 5% alcoholic potash solution. The free sterol, so obtained, was then converted into the acetate by refluxing with acetic anhydride. Crystallization of the crude acetate from ethyl alcohol, gave two distinct fractions. The more insoluble fraction, α_3-sitosteryl acetate (plates, wt. 1.0 g.), melted at 152–153°, $[\alpha]^{20}D$ +6.1 (0.0264 g. in 2 cc. of chloroform solution gave $\alpha^{20}D$ +0.08). The more soluble portion was found to be the α_2-sitosteryl acetate (m. p. 124–126°, $[\alpha]^{25}D$ +17) already described by Wallis and Fernholz. The melting point of the sterol acetate (152–153°) is depressed by α_2-sitosteryl acetate.

Anal. Calcd. for $C_{31}H_{50}O_2$: C, 81.88; H, 11.08. Found: C, 81.8; H, 11.3.

α_3-Sitosterol.—A portion of the above described α_3-sitosteryl acetate was hydrolyzed with a 5% alcoholic potash solution by heating on the water-bath for one hour. The free sterol was worked up in ether. Crystallization from alcohol gave platelets which melted at 142–143°, $[\alpha]^{20}D$ +5.2° (0.0482 g. in 5 cc. of chloroform solution). α_3-Sitosterol is precipitated by digitonin.

Anal. Calcd. for $C_{29}H_{48}O$: C, 84.40; H, 11.73. Found: C, 84.44; H, 11.83.

An absorption spectrum study of α_2-sitosterol was carried out by Dr. T. J. Webb of the Research Laboratories of Merck and Company, Inc. No maxima were found in the ultraviolet region of the spectrum.

α_3-Sitosteryl Benzoate.—One-tenth of a gram of α_3-sitosterol dissolved in pyridine was heated for one hour on the water-bath with benzoyl chloride. The benzoate was worked up in ether. Crystallization from benzene and alcohol gave plates of m. p. 173–175°, $[\alpha]^{20}D$ +12.0° (0.0266 g. in 2 cc. of chloroform).

Anal. Calcd. for $C_{36}H_{52}O_2$: C, 83.66; H, 10.14. Found: C, 83.4, 83.5; H, 10.18, 10.00.

α_3-Sitosteryl *m*-Dinitrobenzoate.—A sample of α_3-sitosterol, dissolved in pyridine, was heated for one hour on the water-bath with *m*-dinitrobenzoyl chloride. The product was extracted with ether and the ether solution was decolorized with animal charcoal and worked up in the usual manner. Recrystallization from ethyl acetate and alcohol gave needles which were white with a very slight yellow luster; m. p. 210–211.5°; $[\alpha]^{20}D$ +12.2° (0.0312 g. in 2 cc. of chloroform solution).

Anal. Calcd. for $C_{36}H_{50}N_2O_6$: C, 71.25; H, 8.31; N, 4.62. Found: C, 71.40, 71.13; H, 8.36, 8.37; N, 4.80.

Titration with Perbenzoic Acid.—Thirty-three and three-tenths milligrams of α_3-sitosteryl acetate took up 2.12 mg. of oxygen on standing for three days at −2°, with an excess of a chloroform solution of perbenzoic acid. The theoretical amount for two atoms of oxygen is 2.34 mg.

We wish to take this opportunity to express our thanks to the Rockefeller Foundation for a grant-in-aid for this work, to Merck and Company, Inc., of Rahway, New Jersey, for the analyses and absorption data published in this paper, and to Dr. O. H. Emerson of the University of California for kindly furnishing part of the crude sterol from wheat germ oil used in this work.

Summary

1. A new doubly unsaturated sterol, α_3-sitosterol, has been isolated from the most soluble fraction of the sitosterol complex obtained from wheat germ oil.

2. The acetate, benzoate and *m*-dinitrobenzoate of the new sterol have been prepared and characterized.

3. An absorption spectrum study indicates that the two double bonds in the new sterol are not conjugated.

4. The new sterol is precipitated by digitonin.

5. α_3-Sitosterol is probably an isomer of stigmasterol, and α_1-sitosterol.

PRINCETON, N. J. RECEIVED JUNE 15, 1939

[CONTRIBUTION FROM THE DIVISION OF INDUSTRIAL AND CELLULOSE CHEMISTRY, MCGILL UNIVERSITY]

Studies on Reactions Relating to Carbohydrates and Polysaccharides. LVI. The Synthesis of the Higher Polyoxyethylene Glycols[1]

BY REID FORDYCE,[2] EDWIN L. LOVELL[3] AND HAROLD HIBBERT

During the past ten years interest in the preparation and properties of long-chain polymers, of their derivatives and of co-polymers has been intensified because of their importance in the manufacture of plastics and synthetic fibers. One of the most important considerations has been the question of whether very high polymeric substances of the polyethylene oxide and cellulose types exist in solution as long macro-molecules, completely dispersed, or as aggregations of much shorter molecules associated in the micellar state.

One of the chief proponents of the former view, Staudinger[4] has carried out an immense amount of invaluable work on the viscosity of solutions of such linear polymers. His conclusions regarding chain length have been based almost entirely on such measurements interpreted on the basis of the Staudinger viscosity relation, $\eta_{sp}/c = K_m M$.

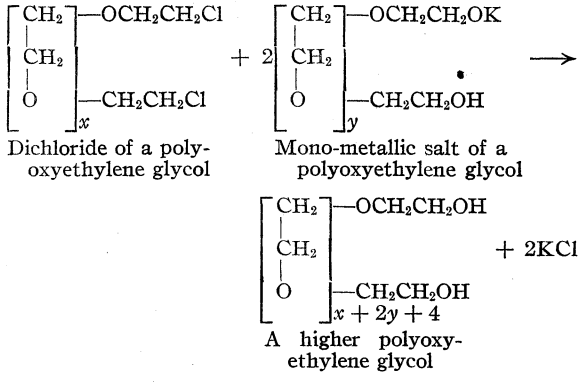
Staudinger's researches in the high molecular weight range were admittedly carried out on polymeric mixtures obtained by fractional precipitation, because apart from the synthetic long chain polypeptides of Emil Fischer[5] and Abderhalden and Fodor,[6] no other chemically pure, homogeneous long-chain polymers were available.

In view of this, an investigation was commenced ten years ago in this Division on the synthesis of pure homogeneous long-chain polyoxyethylene glycols, since it has been definitely established that these are identical in structure with Staudinger's polyethylene oxides.[7]

Considerable experimental difficulties have been encountered with increase in chain length and the present communication deals with the synthesis, purification and characterization of the lower polymers, *viz.*, hexaoxyethylene glycol $HO(CH_2CH_2O)_6H$, octadekaoxyethylene glycol $HO(CH_2CH_2O)_{18}H$ and dotetracontaoxyethylene glycol $HO(CH_2CH_2O)_{42}H$.

Polyethylene glycols were first prepared by Lourenco[8] and later by Wurtz[9] who heated ethylene glycol with water.

However, the first direct method of synthesizing a given polyoxyethylene glycol was that of Perry and Hibbert.[7] Their reaction may be written generally as



Dichloride of a polyoxyethylene glycol

Mono-metallic salt of a polyoxyethylene glycol

A higher polyoxyethylene glycol

This method, with certain modifications, was used in the present work to synthesize the 6-, 18- and 42-membered polyoxyethylene glycols.

From the nature of the reaction it is essential that the mono rather than the dimetallic salt of the glycol be used since, if the latter were present in appreciable quantities, a chain condensation reaction could take place yielding polyoxyethylene glycols of indefinite length. For this reason, the sodium salt of diethylene glycol formed during the synthesis of hexaoxyethylene glycol was isolated in the crystalline state and, by conversion to its trityl derivative, was shown to be the monosodium salt.

The potassium salts of the 6- and the 18-membered polyoxyethylene glycols were not isolated. No formation of hydrogen chloride was detectable during the condensation reaction and in each case the potassium chloride formed was isolated in the theoretical amounts.

For the synthesis of the hexaoxyethylene glycol

2 moles of the monosodium salt of diethylene glycol was condensed with 1 mole of β,β'-dichloroethyl ether. In the preparation of the 18- and 42-membered glycols, 2 moles of the monopotassium salt of hexaoxyethylene glycol and 2 moles of the potassium salt of 18-membered oxyethylene glycol, respectively, was condensed with one mole of hexaoxyethylene glycol dichloride.

In addition to the evidence for structure provided in the actual synthesis various other supporting data were obtained. Hydrogen was evolved in every case by interaction with metallic potassium and the presence of hydroxyl confirmed by the Grignard reagent. The molecular weights of the individual glycols were proved by chlorine analysis of their dichlorides and by cryoscopic molecular weights. The polyoxyethylene glycols synthesized were found free from halogen.

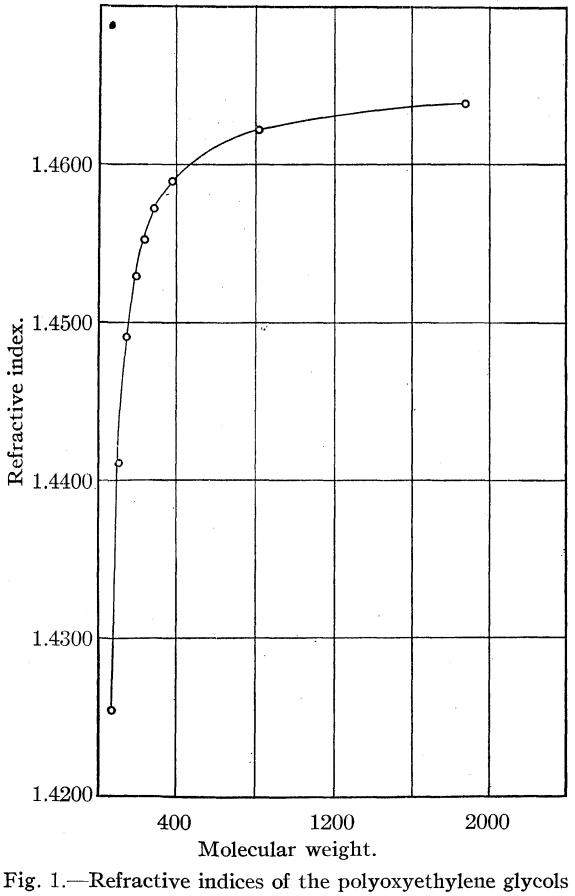

Fig. 1.—Refractive indices of the polyoxyethylene glycols at 40°.

As Fig. 1 shows, refractive index measurements of the synthetic polyoxyethylene glycols were found in agreement with their respective positions in the polyoxyethylene glycol series, although it is evident that this property does not differentiate sharply between the higher glycols.

The agreement of the calculated molecular refractive indices with the observed values is interesting but it is not significant in establishing the identity of each glycol since the controlling factor in determining both values is the molecular weight itself.

The polyoxyethylene glycols show a uniform solubility behavior. They are readily soluble in water and the usual organic solvents, with the exception of ether and petroleum ether. Hexaoxyethylene glycol dichloride is soluble in ether and insoluble in water; while the 18-membered and the 42-membered polyoxyethylene glycol dichlorides are completely soluble in water and rather less soluble in ether, although to a greater extent than the corresponding glycol. Otherwise the solubilities of the dichlorides are quite similar to those of the glycols.

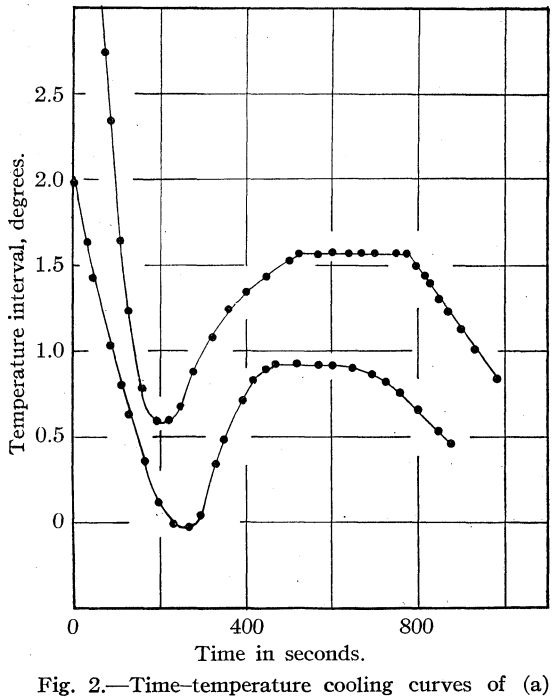

Fig. 2.—Time–temperature cooling curves of (a) hexaoxyethylene glycol (upper); and (b) hexaoxyethylene glycol containing 2.5 mole per cent. 42-membered oxyethylene glycol (lower).

The glycols crystallize in the form of characteristic, radiating clusters of thread-like crystals, which, under the polarizing microscope, show complete extinction of plane-polarized light.

It is obviously of great importance to establish, with certainty, the purity of these polyoxyethylene glycols. The shape of the time–temperature cool-

ing curve is perhaps the most significant, non-comparative, criterion of purity of a chemical compound[10] and was therefore applied in the present research. A sharp break in the cooling curve when freezing is complete is perhaps one of the most sensitive effects observable with a very pure substance, as well as the actual length of the flat portion. From Figs. 2, 3, 4 and 5 it is evident that the polyoxyethylene glycols show both these effects and also that the addition of a small amount of a second component gives rise to a definite "rounding-out" of the break at the end of the flat portion. The cooling curve obtained from a polymeric mixture of glycols prepared and fractionated according to Staudinger[4] shows no flat portion (compare Fig. 3), as is to be expected from such polymeric mixtures in contrast to chemically pure, homogeneous substances.

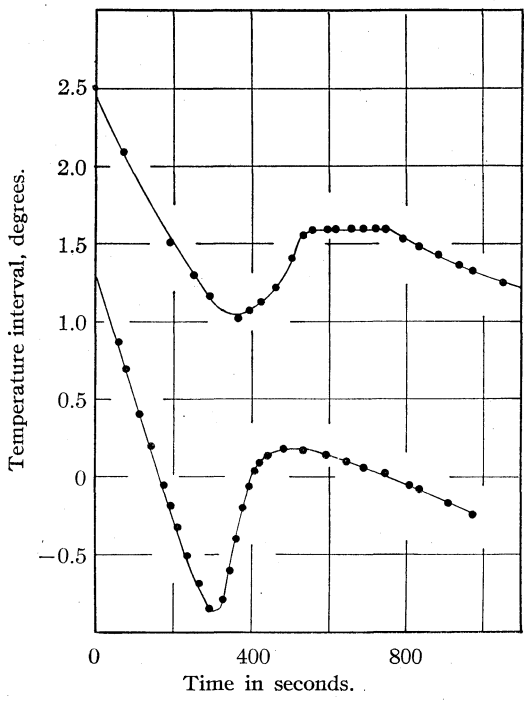

Fig. 3.—Time–temperature cooling curves of (a) 18-membered oxyethylene glycol (upper); and (b) the polymeric mixture of glycols (lower).

Experimental Part

Materials.—Commercial diethylene glycol and β,β'-dichloroethyl ether were prepared by careful fractionation. Since the glycols are hygroscopic, all reagents, solvents and apparatus were thoroughly dried prior to use and an atmosphere of dry, oxygen-free nitrogen maintained in the reaction flask during the formation of the monometallic salts of the glycols and their condensation with the dihalides.

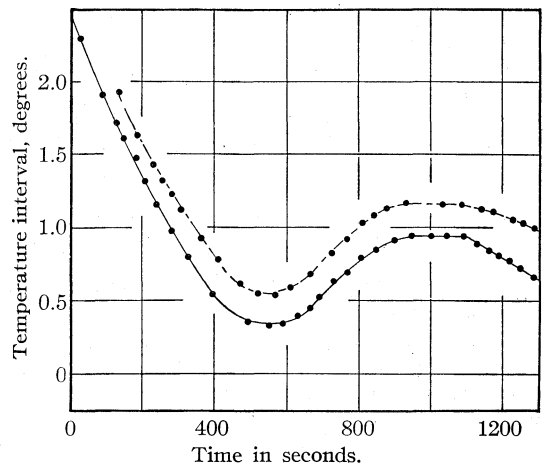

Fig. 4.—Time–temperature cooling curves of (a) 42-membered oxyethylene glycol (lower); and (b) 42-membered oxyethylene glycol containing 6.12 mole per cent. 18-membered oxyethylene glycol (upper).

Synthesis of Hexaoxyethylene Glycol, $HO(CH_2CH_2O)_6H$.—Ninety-two grams (4.0 moles) of sodium was dissolved in 700 cc. of methanol in a 2-liter Claisen flask, 900 g. (8.5 moles) of diethylene glycol added and the solution stirred at 40° for fifteen minutes. The methanol was then removed from the reaction mixture at 100° (20 mm.). Pure β,β'-dichloroethyl ether (314.6 g., 2.2 moles, 10% excess) was then added slowly and continuously through a dropping funnel during a three-hour period, the mixture being maintained at 95° and stirred vigorously throughout the addition, and then for a further three days at the same temperature. The neutral reaction mixture (phenolphthalein) was filtered from sodium

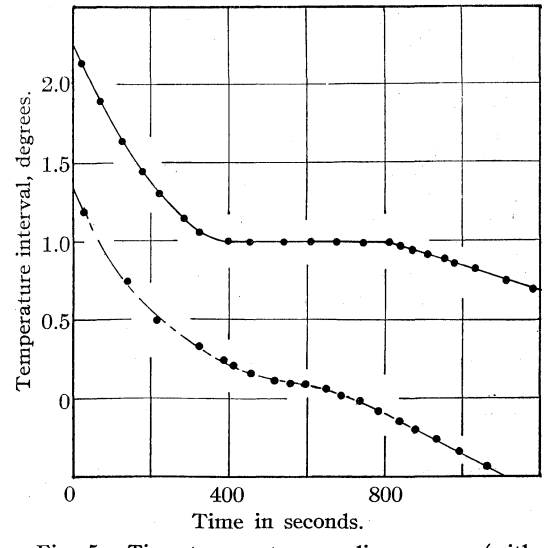

Fig. 5.—Time–temperature cooling curves (without supercooling) of (a) 42-membered oxyethylene glycol (upper); and (b) 42-membered oxyethylene glycol containing 24 mole per cent. 18-membered oxyethylene glycol (lower).

chloride and the filtrate distilled at 2 mm. pressure until everything boiling up to 200° had been removed. Repeated high vacuum distillation of the residual liquid yielded 260 g. (48% of theoretical) of hexaoxyethylene glycol as a colorless oil; b. p. 185–185.7° (0.015 mm.). The refractive index remained constant throughout the distillation.

Isolation of the Sodium Salt of Diethylene Glycol and Conversion into Trityl Derivative

If, during the previous synthesis of hexaoxyethylene glycol, the solution containing the sodium salt of diethylene glycol left after removal of the methanol is allowed to cool, large, hygroscopic, transparent crystals of the monosodium salt containing 1 mole of diethylene glycol of crystallization separate out. These crystals were separated by filtration, washed repeatedly with dioxane, then ether and dried.

Anal. Calcd. for $C_8H_{19}O_6Na$: Na, 9.83. Found: Na, 9.65, 9.44.

Trityl Derivative.—To a solution of 8.0 g. (0.0287 mole) of trityl chloride in 80 cc. of dioxane heated to 70° was added with stirring 6.7 g. (0.0287 mole) of the sodium salt and the reaction product kept at this temperature for two hours. It was then poured into twenty volumes of ice water. The resulting trityl derivative was recrystallized from a mixture of benzene–petroleum ether (30–50°): yield 9.0 g. (90%); m. p. 116–116.5°.

Anal. Calcd. for $C_{23}H_{24}O_3$ (monotrityl derivative): C, 79.3; H, 6.9. Found: C, 79.1, 79.2; H, 6.87, 6.97.

Preparation of Hexaoxyethylene Glycol Dichloride.—To 350 g. (1.24 moles) of hexaoxyethylene glycol dissolved in 205.8 g. of anhydrous pyridine was added slowly and with vigorous stirring at 45°, over a period of twenty minutes, 310.8 g. (2.67 moles, 10% excess) of thionyl chloride. The temperature of the reaction mixture rose to 80° during the addition and stirring was continued at this temperature for a further ten minutes. After cooling to room temperature the reaction mixture was extracted three times using 500, 400 and 300 cc. of ether, respectively. The extract was neutralized with sodium carbonate, and filtered, and the pyridine, ether and excess thionyl chloride removed at 100° (10 mm.). The residual oil on vacuum distillation yielded 245 g. (77%) of hexaoxyethylene glycol dichloride as a colorless liquid: b. p. 168–169° (0.100 mm.); f. p. −12.4°.

Anal. Calcd. for $Cl(CH_2CH_2O)_5CH_2CH_2Cl$: Cl, 22.26; mol. wt., 319. Found: Cl, 22.20, 22.34; mol. wt. (cryoscopic), 310.

Synthesis of Octadecaoxyethylene Glycol, $HO(CH_2CH_2O)_{18}H$.—Hexaoxyethylene glycol (230 g., 0.817 mole) was placed in a flask and covered with a layer of petroleum ether (b. p. 100–110°) and then, at room temperature, potassium metal (21.8 g., 0.56 mole) added in the form of small pieces. After stirring for fifteen hours at room temperature, this gradually was raised to 65° to complete the potassium salt formation. Hexaoxyethylene glycol dichloride (97.6 g., 0.306 mole, 10% excess) was then added, with stirring, at 135° over a two-hour period. After stirring at 175° for a further five hours, the reaction mixture was neutral to phenolphthalein. The precipitated potassium chloride was removed by filtration and the filtrate distilled at a bath temperature of 265° (0.010 mm.) using a Claisen flask immersed to the side-arm.

The residual oil was then continuously extracted with ether (500 cc.) for three to four days. Methanol was added at room temperature to the ether extract until the glycol which had separated during extraction just dissolved. This solution was now decolorized by stirring for two hours with charcoal, filtered, the clear solution cooled to −11° and allowed to stand overnight at this temperature. The crude crystalline product was filtered, washed with anhydrous ether, then transferred to a flask and warmed gently with about 750 cc. of anhydrous ether. Most of the glycol remained undissolved and just sufficient anhydrous methanol was added (approx. 165 cc.) to effect its complete solution. Crystallization again was brought about by cooling at −11°. This recrystallization process was repeated six or seven times under the same conditions and with the same volumes of solvents until the freezing point of the final product remained constant: yield 113 g. (50.3%); f. p. 23.8°.

Preparation of Octadecaoxyethylene Glycol Dichloride.—Octadecaoxyethylene glycol (5.04 g., 0.00623 mole) was dissolved in pyridine (3.96 g.); to this was added, dropwise, thionyl chloride (1.92 g., 0.0161 mole, 30% excess) and the mixture stirred at 65° for three hours. The reaction mixture was then extracted with four 25-cc. portions of ether, solid sodium bicarbonate added to the combined extracts and the mixture allowed to stand until neutral. After filtration, the filtrate was distilled at 0.0025 mm. to a temperature of 175° to remove lower boiling constituents. The residual oil was dissolved in ether, decolorized with charcoal and then recrystallized three times at −80° from pure ether: yield 2.02 g. (38.5%), white crystalline solid; f. p. 22.9°.

Anal. Calcd. for $Cl(CH_2CH_2O)_{17}CH_2CH_2Cl$: Cl, 8.38. Found: Cl, 8.51, 8.50.

Synthesis of the Dotetracontaoxyethylene Glycol, $HO(CH_2CH_2)_{42}H$.—Octadecaoxyethylene glycol (141.2 g., 0.1745 mole) was placed in a three-necked flask, fitted with mercury seal stirrer and nitrogen inlet tube and covered with a layer of petroleum ether (b. p. 100–110°). Potassium metal (6.83 g., 0.1745 mole) previously weighed and cut into small pieces under anhydrous petroleum ether (b. p. 50°) was introduced in one addition to the stirred mixture at room temperature and the stirring maintained for about seventeen hours. The temperature was now gradually raised, over the following three-hour period to 135°, and the mixture stirred at this temperature for a further two hours to complete the potassium salt formation. Hexaoxyethylene glycol dichloride (30.6 g., 0.0958 mole, 10% excess) was now added at 135° with stirring during some fifteen minutes and after a further period of stirring for seventeen hours at the same temperature the reaction mixture reacted neutral to phenolphthalein. Filtration while still warm removed the precipitated potassium chloride and the filtrate was then continuously extracted with ether (250 cc.) for three days. Anhydrous methanol, about 40 cc., was then added at room temperature to the ether extract until the oily glycol, which had separated out during the extraction process, just dissolved. The mixture was cooled in a

[a] Calculations are based on the atomic values suggested by Auwers and Eisenlohr, *Ber.*, **43**, 806 (1910).

brine-bath (−11°) and the crude glycol crystallized out. It was filtered, washed with anhydrous ether, then recrystallized from a mixture of 600 cc. of ether and just enough anhydrous methanol (*ca.* 155 cc.) to effect a solution of the glycol, and again recrystallized by cooling. After six or seven such crystallizations to constant freezing point, the pure 42-membered oxyethylene glycol was obtained: yield 113 g. (47% of theoretical); mol. wt. calcd. 1866, found (cryoscopic) 1748; f. p. 33.8°.

Preparation of the Dotetracontaoxyethylene Glycol Dichloride, $Cl(CH_2CH_2O)_{41}CH_2CH_2Cl$.—The 42-membered oxyethylene glycol (4.35 g., 0.00233 mole) was dissolved in 5 cc. of pyridine and to this was added, dropwise, thionyl chloride (0.722 g., 0.00607 mole, 30% excess). The mixture was stirred for two and one-half hours at 65° and the reaction mixture then extracted with six 400-cc. portions of ether. Any acid present was removed by adding solid sodium bicarbonate to the combined ether extracts and allowing to stand for one and one-half hours. After filtration, the ether, thionyl chloride and pyridine were removed at 100° (10 mm.). The residual oil was recrystallized three times from about 50 cc. of ether and gave 1.25 g. (28.1% of theoretical) of a white crystalline solid; f. p. 33.4°.

Anal. Calcd. for $Cl(CH_2CH_2)_{41}CH_2CH_2Cl$: Cl, 3.72. Found: Cl, 3.69, 3.71.

Physical Properties and Constants of the Polyoxyethylene Glycols and their Dihalides.—Refractive indices were measured by means of an Abbe refractometer fitted with compensating prisms. Birefringence was observed with this instrument with the 18- and 42-membered oxyethylene glycols at a temperature 1° below their freezing points.

The freezing points ("setting" points) have been reported for these compounds rather than melting points because the former are known in general to be much more reproducible than the latter.[11] With the glycols investigated they were found to be reproducible to ±0.1°.

The molecular weight values were determined cryoscopically in a standard Beckmann freezing-point apparatus, access of moisture to the solutions being prevented by a slow stream of dry air directed into the side-arm of the cryoscopic tube. For the 6-membered glycol and its dichloride, as well as for the 18-membered glycol, carbon tetrachloride (cryoscopic constant, 29) was used as solvent; for the 42-membered glycol, pure, dry dioxane[12] (K = 4.8) in which the polyglycols are not associated,[4] was employed. The results given are the average in each case of several determinations at concentrations in the range 0.07 to 1 mole per cent.

Density measurements were carried out by using a small specific gravity bottle (volume 1.8 cc.), having a removable ground-in capillary and cap. The temperature of the bath used in these measurements was maintained constant to within ±0.02°.

The reproducible time–temperature cooling curves were obtained by using an alcohol thermometer of low heat capacity and reading to ±0.01°. This was immersed in 5 cc. of the sample contained in a suitably lagged test-tube surrounded by a cooling bath maintained about 8° below the freezing point of the sample. In Fig. 2 cooling curves for both pure hexaoxyethylene glycol and for a mixture of this with 2.5 moles of diethylene glycol are shown. Figure 3 shows the cooling curve for the 18-membered oxyethylene glycol and also that of a polymeric mixture of glycols, freezing point 26.0°, which had been obtained by the fractionation procedure outlined by Staudinger. The effect of a 6.12 mole per cent. addition of the 18-membered ethylene glycol to the 42-membered glycol upon the cooling curve is shown in Fig. 4, while Fig. 5 shows the complete distortion produced when 24 mole per cent. impurity is added.

In conclusion, the authors wish to express their indebtedness to Dr. J. C. Pullman for preliminary experimental work in connection with this method of synthesis.

Summary

1. The syntheses and properties of pure straight chain polyoxyethylene glycols of the general formula $HO(CH_2CH_2O)_nH$, where n = 6, 18 and 42, are described.

2. The purity of these compounds was established by the time–temperature cooling

Studies on Reactions Relating to Carbohydrates and Polysaccharides. LVII. The Synthesis of 90-Membered Oxyethylene and 186-Membered Oxyethylene Glycols[1]

BY REID FORDYCE[2] AND HAROLD HIBBERT

The Williamson ether synthesis described previously[3] has been used to synthesize further higher members of the polyoxyethylene glycol series, namely, the 90-membered and the 186-membered polyoxyethylene glycols $HO(CH_2CH_2O)_{90}H$ and $HO(CH_2CH_2O)_{186}H$, respectively.

These were synthesized by reaction of 2 moles of the respective monosodium salts of 42- and 90-membered oxyethylene glycols with one mole each of the 6-membered oxyethylene glycol dichloride.

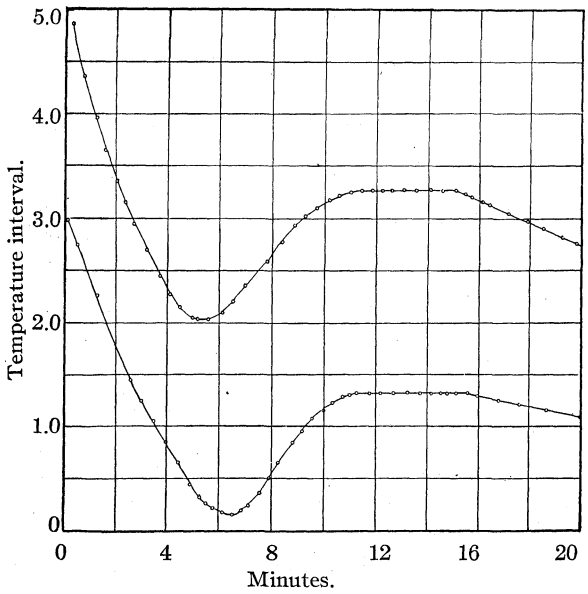

Fig. 1.—Time–temperature cooling curves of (a) 186-membered oxyethylene glycol (upper); (b) 90-membered oxyethylene glycol (lower).

Chlorine could not be detected in either of the isolated reaction products and their refractive indices gave the values to be expected for such higher members of this series.

Their purity was shown by the constancy of the freezing point following several recrystallizations. A further series of recrystallizations was carried out on the pure glycols and, while the final product represented only about 60% of the starting material, it was found that the freezing point of initial and final products was the same. Additional evidence of the purity of the 90- and 186-membered oxyethylene glycols was found in their time–temperature cooling curves (Fig. 1).

The preparation of derivatives of the two glycols suitable for end-group molecular weight determinations proved impracticable because the solubility and other physical characteristics of such derivatives were found to parallel those of the corresponding glycols so closely, even when large groups were attached, that their isolation in the pure state was rendered almost impossible.

Cryoscopic molecular weights, also, could not be employed as they had no significance due to the difficulty in measuring accurately the small freezing-point depression in question.[4]

The method of synthesis of the glycols together with the evidence of their purity, as shown by their physical properties, is strong evidence for the establishment of their molecular weights. Furthermore, the freezing points are shown to vary in a regular manner with the molecular weight and in ascendancy with a relationship developed by Lovell and Hibbert.[5]

The solubility characteristics of 90- and 186-membered glycols are the same as those of the lower members of the series. One of the most outstanding properties of these long chain compounds is their ready solubility in common solvents.

The birefringence observed[3] with the lower members of this series is shown in the photomicrograph

(4) An investigation of the determination of the molecular weights of the polyoxyethylene glycols by the "spinning top" method is being carried out by Professor McBain, Stanford University, and it is our intention to obtain supporting evidence from osmotic pressure measurements.

(5) Lovell and Hibbert, THIS JOURNAL, **61**, 1916 (1939).

of the extinction cross produced through crossed nicols by a thin film of 90-membered oxyethylene glycol when allowed to cool slowly. A similar effect has also been observed by Staudinger, Staudinger and Sauter[6] for higher molecular weight polyethylene oxides.

Experimental Part

The operations were carried out by the method described previously[3] and the same precautions taken to ensure purity and freedom from moisture of the necessary reagents. Because of the very small amounts of sodium required to form the sodium salts of the 42- and 90-membered polyoxyethylene glycols, respectively, it was necessary to carefully free these glycols from all trace of water prior to use. This was accomplished by passing a very fine stream of dry air through the glycol at 100° at a pressure of 0.010 mm. After four hours of this treatment the glycol was moisture free. The vacuum was then broken by admitting, very carefully, dried oxygen-free nitrogen and an atmosphere of the gas maintained in the flask throughout the sodium salt formation and the ensuing reaction with the dichloride.

Synthesis of the 90-Membered Oxyethylene Glycol, $HO(CH_2CH_2O)_{90}H$.—42-Membered oxyethylene glycol (20.0 g., 0.0108 mole) was placed in a 50-cc. side-arm distilling flask and dried as described above. Metallic sodium (0.25 g., 0.0108 mole), which had been cut and weighed under petroleum ether (b. p. 30–50°), was added in one addition at 80° to the glycol, kept under a nitrogen atmosphere. The reaction mixture was stirred by a mercury seal type of stirrer and a slow stream of nitrogen was kept flowing constantly through the side arm. After stirring for eleven hours at 80° the temperature was raised during two hours to 135° and then stirred at this temperature for a further three hours to complete the sodium salt formation. Hexaoxyethylene glycol dichloride (1.91 g., 0.006 mole, 10% excess) was then added at 135°, dropwise, to the glycol solution of the sodium during a twenty-five minute period and stirring continued for a further nineteen hours until the solution reacted neutral to phenolphthalein.

The reaction mixture was cooled, mixed with four volumes of dioxane, centrifuged and, after decanting from the precipitated potassium chloride, the dioxane removed at 100° (0.15 mm.).

The residual oil was dissolved in 100 cc. of methanol, 350 cc. of ether added and then decolorized by stirring for four hours with charcoal (3 g.). After filtration, the crude crystalline glycol was obtained by cooling to −11° in a brine-bath. The product was filtered, washed with anhydrous ether, redissolved in a mixture of methanol (100 cc.) and ether (350 cc.) and recrystallized at −11°.

Repeated recrystallizations under the same conditions to constant freezing point gave the pure 90-membered oxyethylene glycol (8.0 g., 36.7%); f. p., 40.6°; $n^{60°}D$ 1.4570.

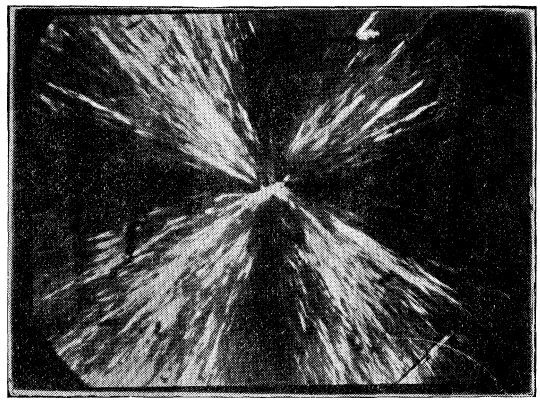

Fig. 2.

Synthesis of 186-Membered Oxyethylene Glycol, $HO(CH_2CH_2O)_{186}H$.—The 90-membered oxyethylene glycol (14.3 g., 0.0036 mole), contained in a 50-cc. side-arm distilling flask, was dried as above under vacuum in a nitrogen atmosphere. Metallic sodium (0.08 g., 0.0035 mole) which had been cut and weighed under petroleum ether (30–50°) was added in one addition at 80°. The reaction mixture was stirred with a mercury seal type of stirrer and a dry nitrogen atmosphere maintained throughout the reaction. After stirring for seventeen and one-half hours at 80° the temperature was raised during one hour to 135° and stirring continued at that temperature for an additional five and one-half hours to complete the sodium salt formation. Hexaoxyethylene glycol dichloride (0.60 g., 0.00188 mole, 4% excess) was then added dropwise during a period of five minutes and stirring continued at the same temperature for six and one-half hours until neutral (phenolphthalein). The reaction mixture was cooled, dissolved in four volumes of anhydrous dioxane, centrifuged and after decanting from the precipitated potassium chloride the dioxane then removed at 100° (15 mm.).

The residual oil was dissolved in 135 cc. of methanol and 35 cc. of ether added, the solution decolorized by stirring for three hours with charcoal and the crystalline glycol isolated by cooling to −11°. It was filtered, washed with anhydrous ether, then dissolved in methanol (135 cc.), ether (35 cc.) added, and recrystallized again by cooling. After ten or eleven such crystallizations to constant freezing point, pure 186-membered oxyethylene glycol was obtained: yield, 4.72 g. (47% of theoretical); f. p., 44.1°; $n^{60°}D$ 1.4572.

Summary

1. The syntheses of 90-membered oxyethylene glycol, $HO(CH_2CH_2O)_{90}H$, and 186-membered oxyethylene glycol, $HO(CH_2CH_2O)_{186}H$, are described.

2. The time–temperature cooling curves of the recrystallized products serve to indicate their purity.

Studies on Reactions Relating to Carbohydrates and Polysaccharides. LVIII. The Relation between Chain Length and Viscosity of the Polyoxyethylene Glycols[1]

BY REID FORDYCE[2] AND HAROLD HIBBERT

Introduction

In applying the Staudinger equation, $\eta_{sp.}/c = K_m M$, to the determination of the chain length of polymeric substances or, conversely, as a method of determining its validity, Staudinger[3] has found it necessary to restrict the experimental conditions surrounding its application within certain definite limits based both on theoretical and practical considerations, a fact which many investigators have unfortunately ignored.

In the first instance, the products under investigation must be the members of a polymer homologous series having a straight chain structure and a relatively high molecular weight. That both these requirements are satisfied in the case of the synthetic polyoxyethylene glycol polymers has been shown in previous communications.[4]

In addition, Staudinger considers it advisable, if not actually necessary, to carry out the viscosity measurements in homopolar solvents since only under these conditions are the long chain molecules surrounded by a monomolecular layer of solvent molecules.[5] The applicability of the equation has been further extended recently by Staudinger and Daumiller[6] to include certain heteropolar solvents, as, for example, cellulose in phosphoric acid. In the present investigation only solvents of homopolar character, namely, 1,4-dioxane and carbon tetrachloride, have been employed.

A further and very important factor emphasized by Staudinger is that all viscosity measurements must be made in very dilute solutions. This restriction is based upon his concept of the "sol" and "gel" states of macromolecules in solution and is a point of view emphasized by him repeatedly in numerous publications.[7] The viscosities reported in the present communication are those for "ground molar" solutions (4.4% by weight) of the polyoxyethylene glycols. The viscosities have been determined at three different temperatures, 20, 40 and 60°, in order to show the effect of temperature variation on the validity of the Staudinger relationship connecting specific viscosity and chain length.

Materials and Methods

The synthesis and purification of the polyoxyethylene glycols already have been reported.[4] The triethylene glycol was a commercial product purified by careful fractionation. 1,4-Dioxane was purified according to the method of Eigenberger[8] (f. p. 11.7°). The carbon tetrachloride was allowed to stand over solid potassium hydroxide for three days and then distilled from it, a middle fraction being employed (b. p. 76.5° at 750 mm.).

The viscometer was an Ostwald type instrument constructed according to the specifications given in British Engineering Standards[9] with dimensions corresponding to those for a uniform capillary of diameter 0.493 mm. and having a range of 0.9 to 7.2 cp.

Kinetic energy corrections were not necessary with this instrument since, using water as standard, a value was found for the absolute viscosity of aniline at 20°, agreeing within 0.35% with that obtained by Appleby.[10] Density corrections were not applied to the viscosity measurements of the polyoxyethylene glycol solutions since Staudinger[3] has shown, and confirmation is provided by the authors, that the change in density of such dilute solutions can be neglected. Since the volume of fluid is adjusted within the viscometer itself, no error is introduced by thermal expansion of the fluid or the viscometer.

The temperature of the bath used was kept constant within ±0.02°. Loss of solvent due to volatilization at high temperatures, as well as contamination of the solutions in the viscometer with moisture, was prevented by means of the customary connection joining the upper parts of the two limbs of the instrument.

Discussion of Results

The tabulated specific viscosities of the polyoxyethylene glycols in carbon tetrachloride and dioxane at 20, 40 and 60° are shown in Tables I and II. It can be seen that the curves (Fig. 1) obtained by plotting specific viscosity against molecular weight (or chain length), both in dioxane and carbon tetrachloride and at different tempera-

tures, all have the same general shape, namely, a linear form within the molecular weight range 810–8200, and characterized in the lower members of the series by a sharp departure from the linear form.

A curve of the same general type is obtained by plotting the values found by Staudinger for the viscosities of his fractionated polyethylene oxide polymers in dioxane at 20°. The deviations found in the case of the lower members, namely, diethylene-, triethylene- and hexaoxyethylene glycols, from the linear relationship is to be expected, since Staudinger[3] has emphasized repeatedly that the lower members of any polymer homologous series do not obey his viscosity law, which is strictly applicable only to the longer chain molecules of a series. In other words, it is confined to the class of long, linear, thread-like molecules and does not include polymers of low molecular weight whose configuration is not far removed from a spherical shape.

The effect of increase in temperature upon the shape of the $\eta_{sp.}/c$–mol. wt. curve was found to vary in the two solvents. From Table II it can be seen that in dioxane there is only a slight lowering of the specific viscosity value, in other words, K_m changes only slightly with increasing temperature in this solvent. Similar results were also found by Staudinger[3] for dioxane solutions of his polyethylene oxide polymers. In carbon tetrachloride (Table I), on the other hand, there is a considerable decrease in specific viscosity as the temperature is increased. The general shape of

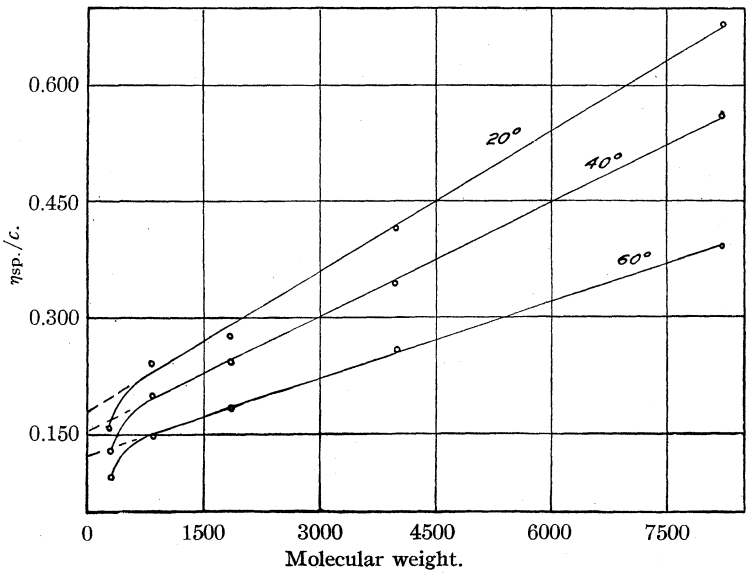

Fig. 1.—The mol. wt.–$\eta_{sp.}/c$ curves for carbon tetrachloride solutions of polyoxyethylene glycols at 20, 40 and 60°.

the specific viscosity–molecular weight curve for polyoxyethylene glycols in carbon tetrachloride is indicated in Fig. 1, as well as the influence of an increase in temperature. This latter effect can be regarded as a desolvation of the solute molecules brought about by an increase in temperature.

Of far greater significance than temperature variation of specific viscosity is the fact that a *linear relationship between specific viscosity and chain length is clearly shown to exist, both in different solvents and at different temperatures.* The validity of the Staudinger viscosity equation has been disputed by Hess and Rabinovitch,[11] Sakurada,[12] Karrer and Ferri,[13] Meyer and Van der Wijk,[14] and many others, but there are presented here, for the first time, viscosity data based on pure, long chain, chemical individuals, and which definitely point to a straight line relationship between specific viscosity and molecular weight in the case of solutions having the same "ground molar" concentration.

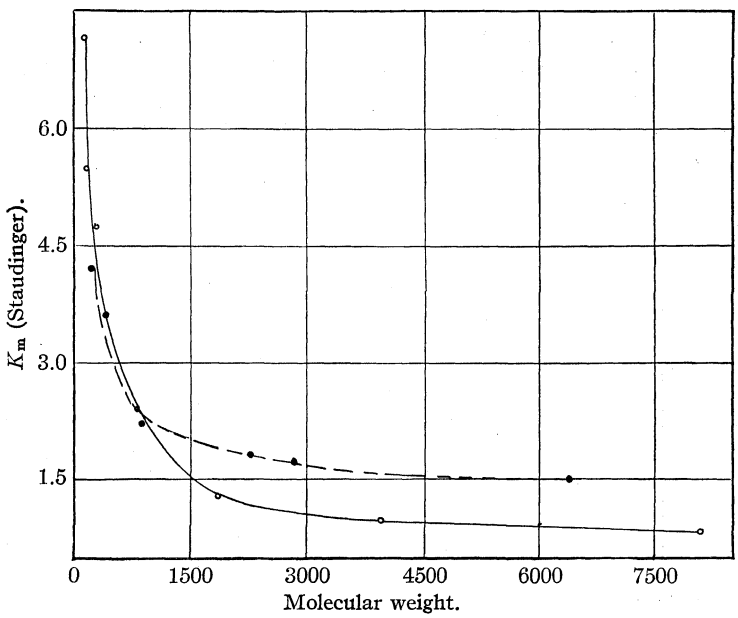

Fig. 2.—Variation of K_m with mol. wt.: (a) pure polyoxyethylene glycols, solid curve ○; (b) Staudinger's polyethylene oxides, broken curve ●.

The Staudinger equation, $\eta_{sp.}/c = K_m M$, which expresses a linear relationship between $\eta_{sp.}/c$ and M, implies a straight line passing through the origin. However, extrapolation of the linear section of the specific viscosity–molecular weight curves obtained from the data presented here, as well as those based on Staudinger's own data for other polymer homologous series, in general, shows an intercept on the specific viscosity axis. In other words, neglecting the lower members of a given series, the new data submitted indicate that the Staudinger equation should be modified as follows

$$\eta_{sp.}/c = K'_m M + \beta \qquad (1)$$

where β is the $\eta_{sp.}/c$ intercept.

The values of K'_m and β, as well as the values of K_m calculated according to the Staudinger equation, are tabulated in Tables I and II. It can be seen that K'_m has a constant value, especially for carbon tetrachloride solutions at 40 and at 60° whereas the Staudinger constant K_m is still only *approaching* a constant value. For higher molecular weights the effect of the $\eta_{sp.}/c$ intercept upon the value of K_m in Staudinger's equation becomes negligible and K_m then has a constant value.

More recently Staudinger and Daumiller[15] have published data concerning the variation of K_m of cellulose triacetates with degrees of polymerization varying from those of the oligosaccharide acetates to the very high molecular weight cellulose acetates. The general trend of the K_m variation in that series is quite similar to that observed in the present investigation of the polyoxyethylene glycols (Fig. 2). It would seem from this that more accurate values for the molecular weight of the lower members of a series, and still within the range of validity of the Staudinger viscosity law, can be obtained by the application of the authors' modified viscosity equation, (1). While it is true that Staudinger[3] also has postulated a similar equation $\eta_{sp.}/c = ny + x$, this is derived from an entirely different concept than the one on which that of the authors is based. Moreover, the application of the above modified Staudinger equation has been confined almost entirely to polymeric homologous forms of hydrocarbon series.

In any interpretation and comparison of the viscosity results obtained with pure polyoxyethylene glycols, it must be remembered that the present results are based on an examination, for

the first time, of the behavior of pure, homogeneous, individual, long chain polymers, whereas all similar investigations in this field have been carried out on polymers obtained by fractionation of synthetic and natural polymers, and therefore necessarily mixtures. From the form of the Staudinger viscosity equation as well as from consideration of the assumptions involved in its evolution, it readily can be shown that the viscosity-producing influence of extremely long molecules is very great as compared with that exerted by those of shorter chain length. In brief, the solution viscosity of a polymeric mixture is influenced profoundly by the distribution of molecular weights about the mean value. Schulz[16] has derived an equation connecting the value of K_m for a polymer of uniform chain length with that of a polymeric mixture of the same substance, in terms of a defined distribution function. He shows, experimentally, as well as theoretically, that in the case of the polyisobutylene polymers it is possible for the value of K_m of such a polymeric mixture to be double that of a pure polymer of the same series.

In Fig. 2 the variation of K_m with increasing degree of polymerization in the case of the pure polyoxyethylene glycols is compared with that found by Staudinger and Lohmann[3] (p. 287) for polymeric ethylene oxide mixtures. It is readily seen from this that the K_m value for the pure glycol is lower than that of the polymeric mixture of the same average molecular weight. The observed lower K_m values for the uniform polymers are in agreement with the views of Schulz.

Work is in progress in these Laboratories with the object of obtaining a quantitative relationship between these two constants in terms of the distribution function.

Regarding the question of Staudinger's much-discussed "Fadenmolekül" very little can be said concerning the configuration of the polyoxyethylene glycols. Sakurada,[17] Mark[18] and Huggins[19] have demonstrated quite conclusively that there is no *a priori* reason for assuming a rigid stretched-out form of the molecule in order to explain a linear relationship between molecular weight and specific viscosity. The presence of numerous ether linkages in the polyoxyethylene glycols, considering the well-known difference in, and variability of, the oxygen valence angle as compared with carbon,[20] indicates that these compounds probably exist in solution in a convoluted form rather than as rigid rod-like structures.

Summary

1. The solution viscosities of long chain polyoxyethylene glycols have been measured in carbon tetrachloride and dioxane at 20, 40 and 60° and agreement with the Staudinger linear relationship between chain length and $\eta_{sp.}/c$ has been obtained in each case.

2. A slightly modified form of the Staudinger equation, *viz.*, $\eta_{sp.}/c = K'_m M + \beta$, is suggested as a more accurate mathematical expression, especially in the case of the lower members of a given homologous series.

Studies on Reactions Relating to Carbohydrates and Polysaccharides. LIX. The Precipitability of Pure Hemicolloidal Polyoxyethylene Glycols

BY EDWIN L. LOVELL[1] AND HAROLD HIBBERT

Introduction

In a recent communication describing the quantitative precipitation behavior of a polymer homologous series of polystyrenes, G. V. Schulz[2] has investigated a new property of these high molecular products which it is suggested may lead to a new method for the determination of molecular weights of moderately high polymeric substances. This property is the "precipitability (γ)," or relative proportion of a non-solvent which must be added to the solution of a polymer in order to initiate precipitation. Schulz has endeavored to correlate the precipitability of such high polymers with their solubility and degree of polymerization, respectively, and, proceeding on the basis of certain assumptions, has arrived at two equations expressing these relationships

$$\ln c = a - b\gamma \quad (1)$$

$$\gamma^* = \alpha + (\beta/P) \quad (2)$$

where c is the solubility of the polymer in grams per liter, in a mixture of solvents having the composition represented by γ, γ^* is the precipitability expressed as percentage of non-solvent added to bring about precipitation at any particular solubility value, and P the degree of polymerization. The other symbols refer to constants. In the first equation P is regarded as constant, while in the second the solubility c is constant.

Such a mathematical derivation is of great interest to all workers in the field of macro-molecular chemistry, not only from the purely practical point of view, since it would seem to offer a simple and accurate means of molecular weight determination, but also from the theoretical standpoint in that it concerns the solution states of long molecules. However, the only experimental data so far available have been those obtained by Staudinger and Heuer[3] on a single type of polymer, namely, the polystyrenes. Nevertheless Schulz's conclusions, as he has shown, appear to find support in the molecular weight data of these authors, as obtained from viscosity measurements on these same products. In the present case, the solubility and precipitability of four pure, long chain polyoxyethylene glycols, with molecular weights ranging from 1000 to 9000, have been studied in methanol–ether and dioxane–ether mixtures at 0° with a view to determining the general validity of the relations between the variables, postulated by Schulz.

It appears from this work that the relationship between the precipitability and degree of polymerization is not in conformity with the Schulz generalization, but instead follows a simple empirical law which also seems to fit the polystyrene data of Staudinger and Heuer. The relation between precipitability and solubility for these crystalline polyoxyethylene glycol polymers follows the law to be expected in the case of *pure crystalline* substances.

Experimental

The measurements were carried out in a very simple apparatus (Fig. 5), consisting of a removable glass cylinder open at one end and attached, by means of a large ground-glass joint, to a second glass cylinder provided with a pair of side arms into which the delivery ends of two microburets were closely fitted. The first cylinder had a capacity of about 20 ml. of solution. Precautions were taken to avoid entrance of moisture into either the solution undergoing precipitation or the anhydrous solvents contained in the burets. The latter were used without lubricating grease. The apparatus was provided with a suitable stirring arrangement.

The preparation, purification and identification of the pure polyoxyethylene glycols used in this work have been described in previous papers.[4] The solvents used were carefully purified, anhydrous products.

In determining the precipitation point at various concentrations, usually about 0.1–0.4 g. of glycol was weighed into the precipitation cylinder, together with 1–8 g. of solvent. The resulting solution was cooled to 0°, by surrounding it with a large beaker of ice, and then titrated slowly with the non-solvent—observing the solution meanwhile under strong illumination, and with the use of a black background, until minute crystals first became visible. The amount of precipitate at the end-point was always negligible as compared with the amount remaining in solution. This precipitation point could be reproduced to within $\pm 1\%$ or better, the quantity of ether added being obtained by direct weighing, rather than by volume measurement.

The method of determining solubility in mixed solvents by measuring the precipitation concentration has been used both by Brönsted[5] and by Staudinger and Heuer,[3] for high molecular polystyrenes.

The measurements in dioxane solution were carried out in a slightly different manner. Ground-molar solutions (44 mg./cc.) of the glycols in dioxane were made up and in each case a volume of just 2 cc. was placed in a 15-cc. precipitation tube by means of a pipet. Titration with ether was then carried out as described above, but the volume of non-solvent required was read directly from the microburet. Suitable precautions were taken to avoid evaporation of the ether during an experiment.

Treatment and Discussion of Results

In Table I are given the solubility (mg. of glycol per gram of mixed solvent added) and precipitability values for each of the five polyoxyethylene glycols $HO(CH_2CH_2O)_PH$ investigated, using methanol as the solvent and ether as the precipitant. The data are expressed graphically in Figs. 1 and 2. It is seen that in all cases the solubility varies in logarithmic fashion with the precipitability, in agreement with the behavior of the polystyrene polymers.

TABLE I

SOLUBILITY IN METHANOL–ETHER AT 0°

Glycol (P)	γ* %	c (mg./g.)	Log$_{10}$ c
6	90.2	360.0

	23.8	14.63	1.1652
	23.1	11.20	1.0492

It may be remarked that Brönsted[5] found that the solubility of a very high-molecular polystyrene (mol. wt. 600,000) had no effect on the precipitability at very high dilutions.

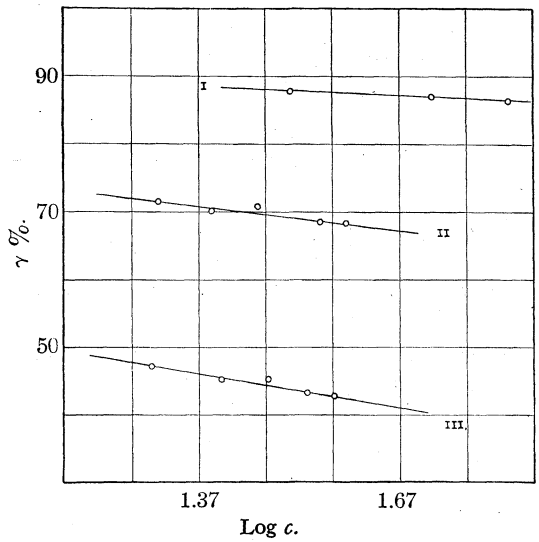

Fig. 1.—The relation between solubility c (mg./gr.) and precipitability in methanol–ether: I, 18-membered; II, 42-membered; III, 90-membered.

Methanol Solutions.—Before considering the effect of degree of polymerization on the precipitability of these glycols at constant solubility, it is necessary to examine the underlying basis of the Schulz equations, (1) and (2). The assumptions made by him in deriving these equations are really adapted to a specific case, namely, that of the high-polymeric polystyrenes or related polymers; they are based on the theory that these products are not precipitable in a purely crystalline form, and on the fact that their melting points are in general high or indeterminable. Neither of these conditions apply to the polyoxyethylene glycols used in the present experiments. There is no doubt as to the crystallinity of the latter when precipitated in the manner described, as has been shown in a previous communication.[4] Furthermore the relatively low setting points (25–45°) of each of these pure glycols have been determined very accurately. It is found that they are in very close agreement with the values derived from the equation

$$t_s = P/(a + bP) \qquad (3)$$

(Fig. 4) where t_s is the setting point in degrees centigrade, P the degree of polymerization and a and b constants having the values of 0.391 and 0.02036, respectively. The equation of Austin[6] connecting the melting points and molecular

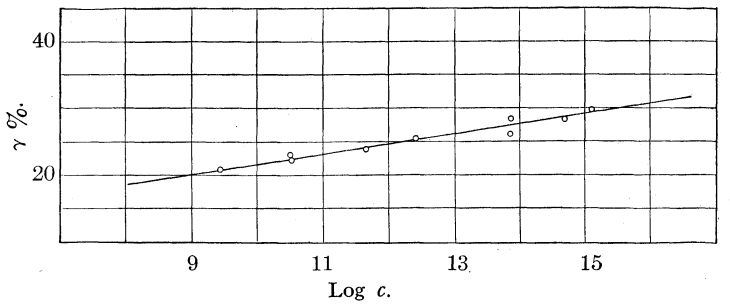

Fig. 2.—Effect of increasing concentration of ether upon the solubility of 186-membered glycol in methanol.

weights of the series of paraffin hydrocarbons, alcohols, etc., is quite inapplicable in the case of these polymer homologous glycols.

It follows that with the pure crystalline products used by the authors it is not necessary to resort to the assumptions and approximations applied by Schulz; instead it is possible to find very simply a theoretical equation connecting the variables—degree of polymerization, precipitability and solubility, of this type of polymer—by applying the thermodynamic solubility equation[7]

$$\ln N_2 = \frac{Q}{RT}\frac{T_s - T}{T_s} \qquad (4)$$

where N_2 is the mole fraction of solute, T_s the absolute melting point and Q the molecular heat of solution. According to Schulz, on the basis of experiments with the polystyrenes

$$Q = P(A' + B'\gamma) \qquad (5)$$

where A' and B' are constants. This may be expected to be a general relation for the heats of solution of polymer homologous substances. For high-molecular substances dissolved in common solvents, it may further be written approximately that

$$N_2 \doteq c/M \qquad (6)$$

where M is the molecular weight of the polymer, nearly a simple multiple of P. Combining equations (3), (4), (5) and (6) gives

$$RT \ln c = RT \ln P + \frac{A'P^2}{a' + b'P} + \frac{B'P^2}{a' + b'P}\gamma \qquad (7)$$

where $a' = 273a$, $b' = 1 + 273b$ and the other symbols and constants have the same values as previously mentioned. For a given polymer (P constant) this last equation becomes identical in form with (1) which is in good agreement with the present experimental data. If c is regarded as constant, the result obviously is not in accord with Schulz's generalization (equation 2), and indeed Table II shows that γ is not a linear function of $1/P$.

The validity of this treatment may be confirmed semiquantitatively by measuring the ratio of the log c–γ slopes for two glycols. The calculated ratio from the coefficient of γ in equation (7) for the 18- and 42-membered glycols is 2.26 (using the empirical constants of equation (3)); the observed ratio is 2.3, in excellent agreement. The slope of this curve for the 90-membered glycol, however, is somewhat less (ratio 1.4) than that calculated in this manner (ratio 1.55), while that of the 186-member is actually negative, over the concentration range 0.9–3.2% (Fig. 2).

A very careful study of the system methanol–ether which has been made by Sapgir[8] shows that

(7) Hildebrand, "Solubility of Non-electrolytes," Reinhold Pub. Co., New York, N. Y., 1936.

(8) Sapgir, *Bull. soc. chim. Belg.*, **38**, 392 (1929).

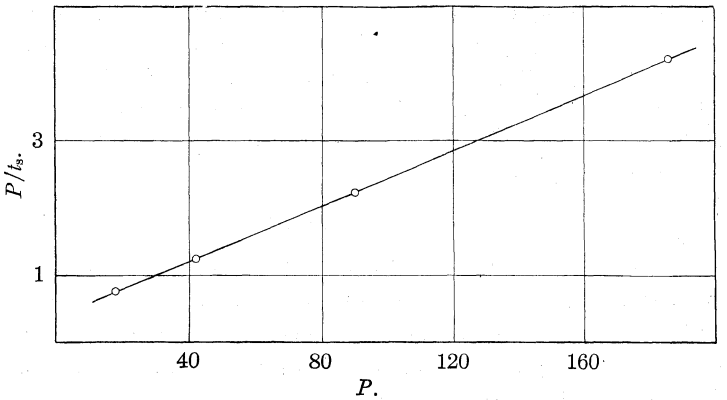

Fig. 4.—Setting points of the polyoxyethylene glycols.

these two solvents do not form mutual complexes, such as might have a complicating effect on the solubility relations of any substance in the mixture. The effect, however, appears to be peculiar to the methanol solutions, for in dioxane solution the 186-membered glycol shows the normal decrease in solubility with increasing proportion of precipitant (Table III). It is not entirely clear, however, why the 186-membered glycol, alone of all the glycols studied, should show this abnormal behavior in methanol.

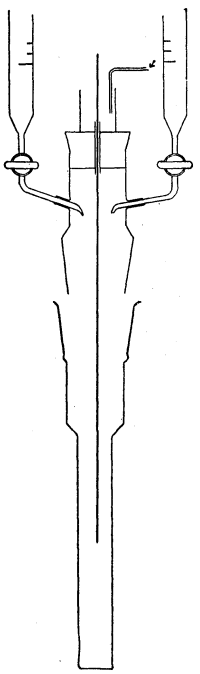

Fig. 5.—Apparatus.

Dioxane Experiments.—These results are given in Table III; here γ_0 is the volume percentage of non-solvent at the end-point when a 4.4% solution of the glycol is titrated. This quantity is shown in Curve I of Fig. 6 to be a direct linear function of the degree of polymerization.

[a] Experiment at 8.6°.
[b] c init. = 33.02 mg./cc.

The characteristic precipitability γ_0 for any polymer differs from the γ^* used above in that the latter quantity is expressed always at the same solubility for the polymeric series, while the solubility value corresponding to γ_0 is necessarily different for each polymer, as of course the volume of the solution being titrated changes with the amount of precipitant which it is necessary to add. To bring the results of the methanol experiments into line with those in dioxane, the data of Table II are recalculated in Table IV in terms of volume percentages; these in turn are readily converted into γ_0 values, also given in the Table. Figure 6 demonstrates that these values also show

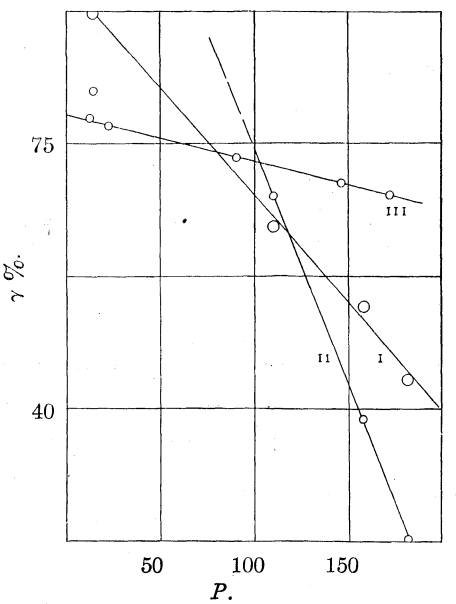

Fig. 6.—Relation between degree of polymerization (P) and precipitability of ground-molar solutions (γ_0): polyoxyethylene glycols, (I) in dioxane–ether; (II) in methanol–ether; polystyrenes[3] (III) in benzene–ethanol (scale m. wt./50).

a linear variation of γ_0 with P although, as might be expected from the result discussed previously, the 186-membered glycol does not fit the curve.

To further establish the validity of this wider generalization, the precipitability results of Staudinger and Heuer[3] for the hemicolloidal polystyrenes are included in Fig. 6. It is obvious from these curves that both types of polymers conform to this simple relationship.

Conclusion.—A point of interest in connection with the above experiments is the significance of the log c–γ slope changes as the higher degrees of polymerization are reached. It is customary to fractionate mixtures of polymer homologous compounds by successive additions of some precipitant to a solution of the mixture, the higher members being first precipitated and followed in order by the lower members as the precipitant concentration is increased.[9]

However, if the concentrations and nature of solvents used are such that the situation expressed in Fig. 3 exists, the results of such a fractionation would be unlikely to lead to the simple separation of high and low members expected. Indeed, the literature contains not a few examples of fractional precipitations which have apparently resulted in the low molecular weight members being precipitated first,[10] but little attention seems to have been paid to this fact. The importance of obtaining as nearly uniform polymers (in chain length) as possible in studies of the macromolecular state points to the advantage and desirability of *quantitative* studies of precipitation and fractionation phenomena.

(10) See, for example, Okamura, *Cellulosechemie*, **14**, 135 (1933); Glückmann, *Kolloid-Z.*, **76**, 84 (1936).

Summary

1. The relationships between the precipitability, solubility and degree of polymerization of a number of pure long-chain polyoxyethylene glycols have been determined in methanol–ether and dioxane–ether mixtures.

2. For each glycol, the logarithm of the solubility (in per cent.) was found to be a linear function of the percentage of precipitant (ether) in the mixed solvent methanol–ether.

3. An anomalous behavior of the 186-membered glycol, in this respect, is recorded, and its possible significance for the customary methods of fractionation of higher polymers, especially those of a micro-crystalline character, is pointed out.

4. The experimental results have been compared with those of other authors on polystyrene polymers, and certain theoretical and actual differences indicated. A new generalization relating the precipitability factor to the degree of polymerization is suggested, which brings both these sets of results into general agreement.

MONTREAL, CANADA RECEIVED MAY 3, 1939

NOTES

The Crystal Structure of Synthetic Antimony Trisulfide

BY HAROLD P. KLUG AND G. B. HEISIG

Red (orange) and black varieties of antimony trisulfide have been prepared in various ways from very early times, and likewise occur in nature.[1] The red variety has been regarded as amorphous, while the black variety is crystalline and reported to be identical with the mineral stibnite, Sb_2S_3, except in sp. gr.[1] Stibnite has been investigated by several workers,[2] but no one seems to have reported X-ray observations on the artificial sulfides. Recently we have been interested in the two varieties of antimony trisulfide as prepared in the laboratory, and have examined them with X-rays. The results are in accord with earlier observations by other methods, and we report them primarily as a matter of record.

Red antimony trisulfide was prepared by passing a current of hydrogen sulfide through a hydrochloric acid solution of antimony trichloride

(1) Mellor, "Comprehensive Treatise on Inorganic and Physical Chemistry," Vol. IX, Longmans, Green and Co., New York, 1929, p. 512.

(2) See for example: Gottfried, *Z. Krist.*, **65**, 428 (1927); Gottfried and Lubberger, *ibid.*, **71**, 257 (1929); Hoffmann, *ibid.*, **86**, 225 (1933).

containing tartaric acid. The red variety was converted into the black variety by heating at 115°.

X-Ray powder photographs were taken at room temperature using CuK and FeK radiation. The above red product, and a sample of the red sulfide from Kahlbaum, both gave photographs showing absolutely no evidence of a crystalline nature. The black variety prepared above gave a pattern identical with that of stibnite, both as to position and intensity of the lines, indicating that there could be little if any amorphous material in the product.

Sulfonic Acid Esters of 4,4′-Dihydroxydiphenyl

BY STEWART E. HAZLET

In connection with some other work in progress in this Laboratory a number of aryl sulfonic acid esters of 4,4′-dihydroxydiphenyl have been prepared. The method of preparation used was the same as that previously reported[1] except that the phenol (5 g.) was treated with 2.1 molecular proportions of the necessary acid chloride. The crystalline products were colorless except in the case of the *m*-nitrobenzenesulfonate, which was obtained as tan flakes. Of the esters, the benzene- and the *o*-nitrobenzenesulfonyl derivatives are best suited for use as derivatives for the identification of the phenol, for they are the ones most readily purified. The experimental results are summarized in Table I.

TABLE I

SULFONIC ACID ESTERS OF 4,4′-DIHYDROXYDIPHENYL

Sulfonyl chloride used	Solvent	Yield,[a] %	M. p., °C.	Formula	Analyses, % Calcd.	Found
Benzene	*n*-PrOH	89	148	$C_{24}H_{18}O_6S_2$	S, 13.73	13.97

[a] Crude product. [b] This compound was prepared by Gilman, Beaber and Myers [THIS JOURNAL, **47**, 2047 (1925)] by treating the phenol with the acid chloride in the presence of potassium hydroxide. Benzene was used for crystallization and a product melting at 189–190° was obtained in 21.2% yield. [c] The compound was first dissolved in acetone and then precipitated by the addition of water; it was purified by crystallization from cyclohexanol and finally by washing with ethanol.

Sterols. LXVII. Sarsasapogenin Derivatives. Bromo Compounds

BY RUSSELL E. MARKER AND EWALD ROHRMANN

In a preceding paper[1] of this series the reaction of sarsasapogenin acetate with bromine to yield a monobromo derivative of the composition $C_{29}H_{45}O_4Br$ was described. We have made several additional observations which are of interest concerning the nature of the bromo compounds.

The great ease of bromination of sarsasapogenin and its derivatives is exemplified by the fact that sarsasapogenone reacts with one mole of bromine to give a compound which is identical with the compound formed when bromosarsasapogenin is oxidized at 25° with chromic anhydride.

The bromo compounds are peculiar in that they appear to be unaffected by boiling with pyridine or by treatment with pyridine and silver nitrate in the cold. The bromine is, however, easily eliminated by other reactions. Catalytic hydrogenation of bromosarsasapogenin acetate in hot acetic acid followed by hydrolysis gave a rather poor yield of dihydrosarsasapogenin.[1] Treatment of bromosarsasapogenin acetate with sodium and amyl alcohol gave a good yield of sarsasapogenin. Similar results were obtained with sodium and ethanol. Treatment of bromosarsasapogenin acetate with zinc dust and acetic acid gave sarsasapogenin acetate. Attempts to hydrolyze the bromo compounds with potassium acetate were unsuccessful, non-crystalline mixtures being obtained. Bromosarsasapogenin, upon Clemmensen reduction in alcohol solution with amalgamated zinc, gave a good yield of tetrahydrosarsasapogenin.

We wish to thank Parke, Davis and Company for their generous support and assistance in the various phases of this work.

(1) Marker and Rohrmann, *ibid.*, **61**, 846 (1939).

Experimental Part

Bromosarsasapogenin.—A solution of 820 mg. of sarsasapogenin in 50 cc. of glacial acetic acid was cooled to 20°. Two drops of 48% hydrobromic acid was added and 2.1 cc. of 1.05 *M* bromine in acetic acid solution run in dropwise. The bromine was taken up readily with the liberation of hydrogen bromide. The mixture was poured into water and the precipitated solid collected and washed with water. The residue was crystallized from aqueous acetone to give white needles which began to decompose at about 125°.

Anal. Calcd. for $C_{27}H_{43}O_3Br$: C, 65.4; H, 8.8. Found: C, 65.1; H, 8.8.

In carrying out the bromination of sarsasapogenin derivative on a somewhat larger scale (5–10 g.) the reaction mixture often became deep blue in color.

Bromosarsasapogenone from Bromosarsasapogenin.—To a solution of 100 mg. of bromosarsasapogenin in 50 cc. of glacial acetic acid was added 300 mg. of chromic anhydride in 10 cc. of 80% acetic acid. After standing at room temperature for forty minutes the mixture was poured into water, the precipitated material was extracted with ether and the ethereal extract washed with sodium carbonate solution and water. The ether was evaporated on the steam-bath and the residue crystallized from acetone to give pale tan crystals, m. p. 191° dec. This gave no depression with a sample of bromosarsasapogenone prepared by the direct bromination of sarsasapogenone.

Anal. Calcd. for $C_{27}H_{41}O_3Br$: C, 65.7; H, 8.4. Found: C, 65.3; H, 8.3.

Bromination of Sarsasapogenone.—Sarsasapogenone was treated with bromine as described in the preceding experiments. The material was crystallized from acetone to give white crystals, m. p. 190° dec. The material evidently was contaminated with some of the dibromo compound as is shown by the analysis. The material gave no depression with the product obtained in the preceding experiment.

Anal. Calcd. for $C_{27}H_{41}O_3Br$: C, 65.7; H, 8.4. Found: C, 65.1; H, 8.0.

Reduction of Bromosarsasapogenin Acetate. (a) **With Zinc and Acetic Acid.**—To a solution of 500 mg. of bromosarsasapogenin acetate in 50 cc. of glacial acetic acid heated on the steam-bath was added with shaking 3 g. of zinc dust in small portions over a period of twenty minutes. White crystals had separated out at the end of this time. The mixture was poured into water and extracted with ether. The ethereal extract was washed first with sodium carbonate solution and then with water. Evaporation of the ethereal solution gave a crystalline residue which was crystallized from acetone to give white needles, m. p. 142°; yield 250 mg. This gave no depression with an authentic sample of sarsasapogenin acetate. The mother liquors yielded some unchanged bromosarsasapogenin acetate.

(b) **With Sodium and Amyl Alcohol.**—To a boiling solution of 700 mg. of bromosarsasapogenin acetate in 50 cc. of *n*-amyl alcohol was added 2.5 g. of sodium in small pieces over a period of two hours. The mixture was cooled and shaken first with an excess of dilute hydrochloric acid and then with water. The amyl alcohol was evaporated on the steam-bath and the residue, after treatment with Norite, was crystallized from acetone to give white needles of sarsasapogenin, m. p. 197°, which gave no depression with an authentic sample.

Similar results were obtained with sodium and absolute ethanol.

(c) **By Catalytic Hydrogenation.**—A mixture of 1 g. of bromosarsasapogenin acetate, 0.5 g. of Adams catalyst, and 80 cc. of glacial acetic acid was shaken with hydrogen at 3 atmospheres and 70° for eight hours. The mixture was filtered and the filtrate evaporated *in vacuo*. The oily residue was diluted with water and the mixture extracted with ether. The ethereal solution was washed with water and the ether evaporated. The residue would not crystallize; it was refluxed for fifteen minutes with an excess of alcoholic potassium hydroxide, poured into water and extracted with ether. The ethereal extract was washed with water and the ether evaporated on the steam-bath. The residue was crystallized from ether–pentane to give white needles, m. p. 163°. This gave no depression with a sample of dihydrosarsasapogenin. The yield was rather poor and the mother liquors contained brominated products.

Anal. Calcd. for $C_{27}H_{46}O_3$: C, 77.4; H, 11.1. Found: C, 77.3; H, 11.2.

(d) **By Clemmensen Reduction.**—Reduction of 500 mg. of the bromoacetate by the Clemmensen method, as described in a previous paper for sarsasapogenin acetate gave a product which crystallized from acetone as compact white crystals, m. p. 191°; yield 375 mg. This gave no depression with an authentic sample of tetrahydrosarsasapogenin, m. p. 193°.

(e) **Treatment with Pyridine.**—Treatment of bromosarsasapogenin acetate with boiling pyridine for twelve hours did not remove the bromine. Treatment with pyridine and silver nitrate at 25° for twenty-four hours was likewise without effect on the substance.

Dibromosarsasapogenone.—To a solution of 7 g. of sarsasapogenone in 350 cc. of glacial acetic acid was added 5 drops of 48% hydrobromic acid and 33.8 cc. of 1.05 *M* bromine in glacial acetic acid was slowly run in over a period of forty minutes at room temperature. The solution became intensely blue and much hydrogen bromide was liberated. The solution was poured into 2 liters of water and the precipitate collected and washed with water. The dried material was crystallized from acetone–ethyl acetate to give small compact white crystals, m. p. 190° dec.

Anal. Calcd. for $C_{27}H_{40}O_3Br_2$: C, 56.7; H, 7.1. Found: C, 57.2; H, 7.3.

Sterols. LXVIII. Highly Branched Aliphatic Esters of Estrone and α-Estrodiol

BY RUSSELL E. MARKER AND EWALD ROHRMANN

The trimethylacetates and the *t*-butylacetates of estrone and α-estrodiol were prepared by the

reaction of these compounds with the corresponding acid chlorides in pyridine. Catalytic hydrogenation of the estrone derivatives in neutral medium yielded the mono esters of α-estrodiol. Estrone *t*-butylacetate was also prepared by the Schotten–Baumann procedure. The esters prepared appear to be somewhat more soluble than are many of the other well known esters of these substances.

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part

Estrone Trimethylacetate.—To a solution of 300 mg. of estrone in 12 cc. of dry pyridine was added 1 cc. of trimethylacetyl chloride. The resulting mixture, after standing at room temperature for thirty-six hours, was diluted with water and the precipitated solid taken up in ether. The ethereal extract was washed with dilute hydrochloric acid and dilute sodium carbonate solution. Evaporation of the ether gave white needles which was recrystallized from acetone–methanol as thick white needles, m. p. 164–166°.

Anal. Calcd. for $C_{23}H_{30}O_3$: C, 77.9; H, 8.5. Found: C, 77.6; H, 8.3.

α-Estrodiol-3-trimethylacetate.—A mixture of 200 mg. of estrone trimethylacetate, 300 mg. of Adams catalyst, 50 cc. of ether and 50 cc. of ethanol was shaken with hydrogen at 1 atmosphere pressure at room temperature for eighteen hours. The mixture was filtered and the filtrate evaporated *in vacuo*. The residual sirup was treated with Norite and crystallized from aqueous methanol as white needles, m. p. 178–180°.

Anal. Calcd. for $C_{23}H_{32}O_3$: C, 77.5; H, 9.0. Found: C, 77.7; H, 9.0.

α-Estrodiol-3,17-*bis*-trimethylacetate.—A mixture of 100 mg. of α-estrodiol, 10 cc. of pyridine and 0.5 cc. of trimethylacetyl chloride was treated as described for the preparation of estrone trimethylacetate. The product was crystallized from acetone–methanol as white needles, m. p. 174–176°.

Anal. Calcd. for $C_{28}H_{40}O_4$: C, 76.3; H, 9.15. Found: C, 76.0; H, 9.2.

Estrone *t*-Butylacetate.—Estrone *t*-butylacetate was prepared by the pyridine method as described for estrone trimethylacetate. The product was crystallized from methanol as white plates, m. p. 148–150°.

Anal. Calcd. for $C_{24}H_{32}O_3$: C, 78.2; H, 8.7. Found: C, 78.1; H, 8.6.

To a solution of 50 mg. of estrone in 150 cc. of 10% aqueous potassium hydroxide was added 1 cc. of *t*-butylacetyl chloride. The mixture was shaken vigorously for five minutes, and the solid collected, washed and dried. The product crystallized from methanol as white plates, m. p. 147.5–149.5°. This gave no depression with that prepared above.

α-Estrodiol-3-*t*-butylacetate.—This was prepared as described for α-estrodiol-3-trimethylacetate. The product was crystallized from aqueous methanol as white needles, m. p. 127–129°.

Anal. Calcd. for $C_{24}H_{34}O_3$: C, 77.8; H, 9.2. Found: C, 78.1; H, 9.4.

α-Estrodiol-3,17-di-*t*-butylacetate.—This was prepared from α-estrodiol as described for α-estrodiol-3,17-*bis*-trimethylacetate. The product was crystallized from methanol as white plates, m. p. 98–100°.

Anal. Calcd. for $C_{30}H_{44}O_4$: C, 76.9; H, 9.5. Found: C, 76.9; H, 9.5.

COMMUNICATIONS TO THE EDITOR

THE ANTIHEMORRHAGIC ACTIVITY OF CERTAIN NAPHTHOQUINONES

Sir:

We have briefly reported on the antihemorrhagic activity of phthiocol, 2-methyl-3-hydroxy-1,4-naphthoquinone, the first completely identified form of vitamin K [THIS JOURNAL, **61** 1611 (1939)]. Phthiocol has been isolated as the pigment of *Mycobacterium tuberculosis* (human) and synthesized by Anderson and co-workers [*J. Biol. Chem.*, **101,** 773 (1933); **103,** 197 (1933); **105,** 279 (1934)]. This organism is known to contain vitamin K [*Proc. Soc. Exp. Biol. Med.*, **38,** 336 (1938)].

Treatment of vitamin K concentrates with sodium methylate produces a reddish pigment the quantity of which is proportional to the activity of the concentrate [THIS JOURNAL, **61,** 1610 (1939)]. The pigment has a strong red color in alkaline media, from which it can be extracted by adding hexane or ethyl ether and acidifying. It then assumes a yellow color. These color changes of the derived pigment are very similar to those exhibited by phthiocol and similarly

substituted naphthoquinones. A positive color reaction for 2-hydroxy-1,4-naphthoquinones [*ibid.*, **58,** 1174 (1936)] was obtained with highly purified concentrates of vitamin K from alfalfa.

The positions of ultraviolet absorption maxima reported in vitamin K concentrates, especially at 328 and 248 mμ [*Helv. Chim. Acta*, **22,** 310 (1939)], are close to the 334 and 250 maxima of phthiocol [*J. Biol. Chem.*, **115,** 479 (1936)], and the general shapes of the absorption curves are similar.

We have made quantitative assays by our improved method [*Biochem. J.*, in press] of phthiocol and several related compounds. In addition to the substances listed in Table I, we have tested lapachol and lomatiol. Both of these proved inactive, first at a 20-mg. level and later at a 100-mg. level. A preliminary test of a preparation of phthiocol monoacetate indicated a greater degree of activity than that of phthiocol.

An aqueous solution of phthiocol was made by dissolving 2 mg. in each cc. of a 0.05 molal phosphate buffer, *p*H 7.4. The *p*H of the final solution was 7.0. Sufficient of this solution was injected daily into the breast muscle of chicks to equal the amount consumed by chicks on the 20-mg. level. A control group received the same amount of solution orally. The average prothrombin time for 6 injected chicks was 31.9 seconds, while that for 6 orally fed chicks was 32.4 seconds. An 0.05 molal phosphate buffer, *p*H 7.8, dissolved 4 mg. of phthiocol per cc. to a final *p*H of 7.1. Chicks receiving no vitamin K in the diet were given intravenously 2 mg. each of phthiocol in aqueous solution. A comparable group of chicks was given the same dosage orally. After an interval of two days, the prothrombin time of 5 injected chicks was 29.6 seconds, and that of 5 orally fed chicks 30.3 seconds. Phthiocol appeared to exhibit approximately the same activity whether given in the diet or as a solution orally, intramuscularly or intravenously.

The antihemorrhagic activity of phthiocol lies between that of the methyl naphthoquinone and the hydroxy naphthoquinone (Table I). Consideration of the activities of various compounds indicates that the methyl group is functionally important, while the hydroxyl group seems to reduce activity. The latter effect may be largely physical. Phthiocol is obviously lower in activity than the more complex form of vitamin K existing in alfalfa. This lower activity is more than compensated for by the low cost of preparation and great convenience of administration of the compound.

SIMPLE COMPOUNDS WITH VITAMIN K ACTIVITY

Sir:

The announcement of Almquist and Klose [THIS JOURNAL, **61,** 1611 (1939)] that pure synthetic phthiocol has anti-hemorrhagic activity prompts us to publish certain observations on related compounds. We have found that 2-methyl-1,4-naphthoquinone is practically as active as vitamin K, and that the diacetate of the corresponding hydroquinone appears to be somewhat inferior in potency. The chicks survived doses of several thousand units of these compounds, the cure was as dramatically rapid as with natural vitamin K and the animals developed normally thereafter. The activity of phthiocol reported by Almquist and Klose was confirmed with a preparation made from the above compounds, but the potency of the phthiocol thus prepared was several hundred times less than that of vitamin K. Duroquinone was found to be inactive in doses of as high as 1 mg.

QUINONES HAVING VITAMIN K ACTIVITY

Sir:

Certain indications from recent publications of others and from preliminary oxido-reduction potential measurements conducted at Northwestern University have led us to postulate that the antihemorrhagic vitamin K_1 of alfalfa is a 2,3-dialkyl-1,4-naphthoquinone. From the similarity of vitamin K_2 [Doisy, *et al.*, THIS JOURNAL, **61**, 1295, 1612 (1939)] in absorption spectrum, ease of oxidation of the hydroquinone and other properties, it is probable that this substance is of the same type. As a specific hypothesis it is suggested (L. F. F.) that vitamin K_1 may be 2,6(?)-dimethyl-3-phytyl-1,4-naphthoquinone (or the 2-monomethyl compound) and vitamin K_2 2,3-difarnesyl-1,4-naphthoquinone. These structures seem consistent with the spectra [Doisy, *et al.*; Dam, Karrer, *et al.*, *Helv. Chim. Acta.* **22**, 310 (1939)], the analyses and hydrogen absorption [Doisy, *et al.* (assuming the saturation of one ring of the naphthalene nucleus)], the sensitivity to heat and light, and the hindered character of the functional groups of the quinone (K_1) [Almquist, *et al.*, *J. Biol. Chem.*, **125**, 681 (1938); Riegel, Schweitzer and Smith, in press] and hydroquinone diacetates (K_1 and K_2) [Doisy, *et al.*]. They also accord with recognized processes of biogenesis: K_1 (alfalfa) from dimethylnaphthoquinone (or toluquinone plus isoprene) and phytol [occurrence in green leaves: Dam, *Z. Vitaminforsch.*, **8**, 248 (1938–39); relationship between vitamins E and K_1]; K_2 (putrefied sardine meal) from naphthoquinone and farnesol (relationship of the alcohol to squalene).

These considerations suggested (B. R. and L. F. F.) the testing of various quinones available from previous researches or from the collection of the late Samuel C. Hooker. The synthesis of compounds of the type indicated has been undertaken at Harvard. Exploratory assays of ten compounds were kindly carried out by Dr. W. L. Sampson of the Merck Institute by a procedure based on that of Ansbacher [*J. Nutrition*, **17**, 303 (1939)]. Day old chicks were placed on the Almquist vitamin K deficient diet for twelve days and given a dose of 250 γ of substance in 1 cc. of peanut oil, administered by a tube into the crop, and the blood clotting time determined (Almquist method) the following morning.

The preliminary results suggest that some of the 2-hydroxy-3-alkyl-1,4-naphthoquinones possess positive vitamin K activity at the dose level fed [compare phthiocol, Almquist and Klose, THIS JOURNAL, **61**, 1611 (1939)] and that the 2,3-dimethyl derivative is at least 1/250 as active as Doisy's vitamin K_1.

2-Allyl-1,4-naphthoquinone (m. p. 36–36.5°, found: C, 78.82; H, 5.14) was prepared from 2-allyl-1-naphthol through the azo compound and amine (W. P. C.). 2,3-Diallyl-1,4-naphthohydroquinone diacetate (m. p. 92.5–93°, found: C, 74.18; H, 6.33) was obtained by heating 1,4-naphthohydroquinone diallyl ether (m. p. 49.5–50°, found: C, 80.09; H, 6.74) with diethylaniline and acetic anhydride (M. F.). The diacetate is

[4] M. p. 51.5–52°, found: C, 74.76; H, 6.34 (W. P. C.).

[5] M. p. 16°, found: C, 76.71; H, 6.75; by oxidation of the 130–131° isomer with silver oxide (E. M. F.).

resistant to alkaline hydrolysis (compare Doisy's dihydro vitamin diacetates); on cleavage with a Grignard reagent and air oxidation in ether it gave a quinone, m. p. 129–130° (absorption maxima at 245, 267, and 330 mμ in ethanol). 2,3-Dimethyl-1,4-naphthoquinone shows maxima at 246 and 265 mμ (log ε between 4.2 and 4.3) and 330 mμ (log ε = 3.4). The spectra (R. N. J. and D. M. B.) resemble those reported for vitamins K_1 and K_2 (Doisy, *et al.*, Dam, Karrer, *et al.*) except for the absence of fine structure in the two intense bands.

SYNTHESIS OF ANTIHEMORRHAGIC COMPOUNDS

Sir:

The further bio-assays by Dr. W. L. Sampson given in Table I lend added support to our conception of the nature of vitamin K_1 and K_2. Of special significance is the contrast between the highly active 2,3-dimethyl-1,4-naphthoquinone and the much less potent 2,6- and 2,7-isomers, the contrast between quinones of the benzene and naphthalene series, and the high potency encountered in a 1,4-naphthoquinone having a β-unsaturated side-chain (allyl) in the quinonoid ring, as postulated for both vitamins. The spectrographic data of Table II also indicate a close correspondence between the natural vitamins and model substances of the postulated structure of 2,3-dialkyl-1,4-naphthoquinones. Dr. T. J. Webb of the Merck Research Laboratories independently examined 2,3-dimethyl-1,4-naphthoquinone and pointed out to us definite indications of fine structure in the two intense bands; this was subsequently discerned in a new reading of our plates. The resolution of the most intense band of the 6,7-dimethyl-2,3-diallyl compound is still more distinct, particularly in hexane. We are indebted to Dr. Webb for the other determinations indicated.

The following examples illustrate methods developed for the synthesis of quinones of the type considered favorable for vitamin K activity. (1) 2,6-Dimethyl-8-naphthol was allylated, the ether rearranged, and the once distilled allyldimethylnaphthol (b. p. 152–157° at 2 mm. Found: C, 84.20; H, 7.74) converted to the 5-amine and this oxidized in acetone suspension with ferric chloride to give 2,6-dimethyl-3-allyl-1,4-naphthoquinone, m. p. 42–42.5° (Found: C, 79.82; H, 6.36). (2) The lower melting diallylhydroquinone (87–90°) was oxidized with silver oxide to the quinone (oil); 2,3-dimethylbutadiene was added to this, the product was isomerized to a hydroquinone, and on oxidation with chromic acid this afforded 6,7-dimethyl-2,3-diallyl-1,4-naphthoquinone, m. p. 69.5–70.7° (Found: C, 81.46; H, 6.96). 6,7-Dimethyl-1,4-naphthoqui-

(Dam, Karrer, *et al.*)	248	261, 270	328
Vitamin K_2 (Doisy, *et al.*)	249	261, 269	320
2,3-Dimethyl-1,4-naphthoquinone (T. J. Webb)	244, 249 (4.29)	264, 270 (4.27)	332 (3.39)
(D. M. B., new reading)	243, 249 (4.26)	262, 267 (4.24)	330 (3.38)
6,7-Dimethyl-2,3-diallyl-1,4-naphthoquinone	253, 260 (4.40)	273, 278 (4.12)	343 (3.45
(In hexane)	253, 260 (4.41)	271, 276 (4.14)	338 (3.46)
2-Allyl-1,4-naphthoquinone	246, 251 (4.31)	Shoulder	332 (3.43)
(In hexane)	243, 251 (4.1)	260 (3.9)	Not measured
2-Methyl-1,4-naphthoquinone (T. J. Webb)	250 (4.29)	263 (4.24)	334 (3.38)
2,6-Dimethyl-1,4-naphthoquinone (T. J. Webb)	256 (4.33)		340 (3.47)
2,6-Dimethyl-3-allyl-1,4-naphthoquinone[a]	249 (4.30) 256 (4.35)	266, 272 (4.17)	335 (3.39)

none, m. p. 118–119° (Found: C, 77.43; H, 5.61), was similarly prepared from the known diene addition product. (3) Monobutadiene-1,4-benzoquinone with allyl bromide and potassium carbonate in acetone gave 5,8-dihydro-1,4-naphthohydroquinone diallyl ether, m. p. 64–65° (Found: C, 79.51; H, 7.55), and when heated in kerosene this rearranged smoothly to 5,8-dihydro-2,3-diallyl-1,4-naphthohydroquinone, m. p. 108–109° (Found: C, 79.36; H, 7.78). Chromic acid oxidation in acetic acid gave 2,3-diallyl-1,4-naphthoquinone, m. p. 29–30° (Found: C, 80.53; H, 6.02). The substance (m. p. 130°) obtained previously by the action of ethyl or *n*-butylmagnesium bromide on 2,3-diallyl-1,4-naphthohydroquinone diacetate is a naphthoquinone (spectrum) having two hydrogen atoms more than the expected diallyl compound (Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71. Found: C, 80.06, 79.93; H, 6.78, 6.76). More gentle cleavage with methylmagnesium bromide and silver oxide oxidation gave 2,3-diallyl-1,4-naphthoquinone, m. p. 28.5–29.5°, identical with the above sample.

In the Dam–Karrer color test with sodium ethylate in ethanol, regarded by some as characteristic of vitamin K_1 (Almquist and Klose, THIS JOURNAL, **61**, 1610 (1939); see, however, Fernholz, *et al.*, *ibid.*, **61**, 1613 (1939)), our synthetic naphthoquinones having at least one allyl group in the quinonoid ring all give intense and transient blue or purple colors and contrast sharply with the 2,3-dimethyl compound (weak, purplish color).[a]

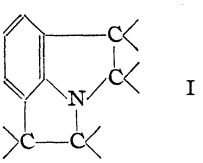
THE STEREOCHEMISTRY OF TERVALENT NITROGEN

Sir:

Jackson and Kenner [*J. Chem. Soc.*, 573 (1928)] briefly reviewed the existing evidence bearing

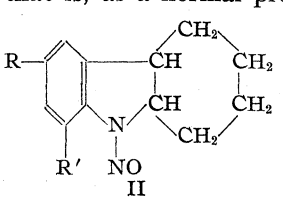
on the spatial configuration of tervalent nitrogen compounds in which three separate groups are attached to the nitrogen atom. They pointed out that "the search for isomerides demanded by a non-planar configuration has been (almost completely) unsuccessful, and it would therefore appear that, in general, the non-planar readily passes into a planar form, from which the original or its enantiomorph may be regenerated; or else the normal configuration is plane [compare Meisenheimer, *Ber.*, **57**, 1747 (1924)].

"Before, however, such conclusions can be accepted, it is desirable that the negative results on which they rest should be supplemented by positive evidence. This would be supplied by the preparation of a compound in the molecule of which a nitrogen atom is common to two ring structures which are at the same time plane and co-planar. Since . . . there is no evidence available which renders doubtful the plane configuration of five-membered ring structures, it would appear that these conditions would be fulfilled by a structure of type I, if Kekulé's formula for benzene and its derivatives be accepted."

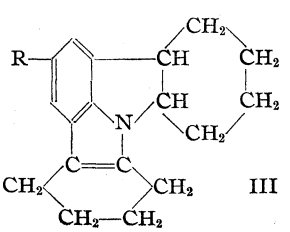


I

Jackson and Kenner were unable to report the preparation of a compound of this type. However, there had been recorded just previously some experiments by Manjunath [*J. Indian Chem. Soc.*, **4**, 271 (1927)] in which it was shown that treatment of a glacial acetic acid solution of 9-nitroso-hexahydro-carbazole (II, R,R = H) containing cyclohexanone with zinc dust, and then warming, led to formation of a crystalline substance $C_{18}H_{21}N$, which he described as "8,9-(1,2-cyclohexyl)-tetrahydro-carbazole." His structural formula for this substance is obviously incorrect as it represents a substance of formula $C_{19}H_{23}N$. Every analogy suggests that Manjunath's compound should be formulated as III (R = H), that is, as a normal product of a Fischer indole ring closure, and as a substance fulfilling the requirements of Jackson and Kenner's test.



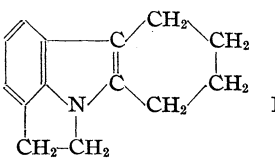
II



III

We have now confirmed Manjunath's result, and his further observation that a similar substance (III, R = CH_3) can be obtained in a similar manner from 9-nitroso-6-methyl-hexahydro-carbazole (II, R = CH_3, R′ = H). On the other hand, we have been unable to prepare a substance of similar structure from 9-nitroso-8-methyl-hexahydro-carbazole (II, R = H, R′ = CH_3) because the ortho position essential for indole ring closure has been "blocked" by the methyl group.

That the substances III have the structures assigned to them is strongly supported by the fact that addition of zinc dust to an acetic acid solution of 1-nitroso-indoline containing cyclohexanone, followed by warming, leads to formation of a colorless crystalline neutral substance, $C_{14}H_{15}N$, melting at 154°. There can be no doubt that this must be formulated as IV, so that it, also, must be regarded as fulfilling the requirements of Jackson and Kenner's test.



IV

There is thus no doubt that substances can be prepared containing a tervalent nitrogen atom with three separate atoms attached to the nitrogen, in which the three nitrogen valences must be regarded as definitely co-planar.

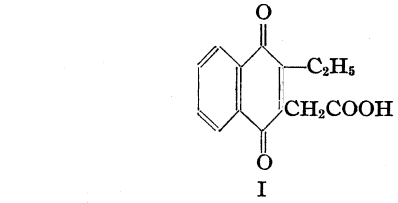
ON THE CONSTITUTION OF VITAMIN K_1

Sir:

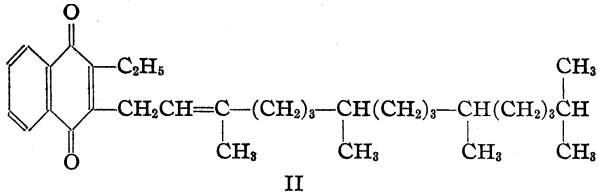
In a previous communication [THIS JOURNAL, **61**, 1295 (1939)] we suggested that vitamins K_1 and K_2 contain the quinone structure, and subsequently [*ibid.*, **61**, 1612 (1939)] we confirmed this by preparation of the diacetates by reductive acetylation. The pure yellow color of the vitamins suggests that they belong to the 1,4 series of quinones and this conclusion is supported by the discovery that 1,4-naphthoquinone has vitamin K activity whereas 1,2-naphthoquinone does not. Investigation of a considerable number of quinones has revealed only the derivatives of 1,4-naphthoquinone as having vitamin K activity.

On catalytic hydrogenation vitamin K_1 absorbs four moles of hydrogen with the formation of a hydroquinone. A naphthoquinone nucleus would account for three moles of hydrogen, the fourth mole being used in the saturation of an ethylenic linkage.

Ozonolysis of the diacetate of vitamin K_1 hydroquinone resulted in the formation of a ketone which gave a semicarbazone melting at 66–67°. *Anal.* Found: C, 70.04; H, 12.13; N, 12.83, 12.88. Calcd. for $C_{19}H_{39}ON_3$: C, 70.10, H, 12.08; N, 12.91. The semicarbazone of 2,6,10-trimethylpentadecanone-14 melts at 66–67° [G. F. Fischer and K. Lowenberg, *Ann.*, **464**, 69 (1928)]. The identity of our semicarbazone with that of Fischer and Lowenberg will be tested as soon as a specimen becomes available for determination of the mixed melting point. The formation of this ketone probably indicates the presence of a phytyl side chain in the vitamin molecule.



I



II

Vitamin K_1 was oxidized with chromic acid and the oxidation products separated into neutral and acidic fractions. Two crystalline acids were obtained from the latter fractions. One of these acids crystallized from water and had a melting point of 191° in a sealed tube. It was identified as phthalic acid by conversion to the anhydride. This melted at 127–128°. When mixed with authentic phthalic anhydride (m. p. 128–129°) the melting point was 128–129°. *Anal.* Calcd. for $C_8H_4O_3$: C, 64.87; H, 2.72. Found: C, 64.78; H, 3.05.

The second solid acid which was obtained in small amounts crystallized in well-formed yellow needles and melted with decomposition at 210°. If the phytyl radical is directly united to a 1,4-quinone ring, this would presumably be a substituted naphthoquinone acetic acid. This acid, like vitamin K_1, gives no color reaction with ethyl cyanoacetate [R. Craven, *J. Chem. Soc.*, 1605 (1931)] and so is presumably substituted in both the 3 and 4 positions. *Anal.* Calcd. for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95. Found: C, 68.69; H, 4.85. The acid is probably 2-ethyl-1,4-naphthoquinone-3-acetic acid (I). The synthesis of this acid is at present in progress for purposes of comparison. On the basis of these degradation products we believe that the structure of the vitamin K_1 molecule is 2-ethyl-3-phytyl-1,4-naphthoquinone (II).

EVIDENCE FOR THE PRESENCE OF VITAMIN A AND CAROTENOIDS IN THE OLFACTORY AREA OF THE STEER

Sir:

In connection with our general project on the chemistry and sources of the fat-soluble vitamins, we became interested in examining the olfactory area of various animals for the presence of these vitamins, especially so for the presence of vitamin A's and their precursors. Since the absence of vitamin A from the diet causes the drying up of the mucous membranes of the body, it was suspected that the epithelia of the olfactory area together with the mucous membranes of the nasal passages in animals having normal diets might be rich in this vitamin. No work has been reported along these lines, and we decided to make a preliminary study of the olfactory area of the steer, but especially that area located at the upper end of the nasal cavity and known as the "yellow patch." This is composed of nerve filaments passing from the brain through the sieve-like cribriform plate into the nasal cavity and terminating at the upper third of this cavity. In the steer the epithelium of the olfactory area is dirty yellowish-brown in color while in the human being it is said to be yellow.

Forty heads of freshly killed steers were split open along the length of the nasal passages and by means of bone-cutters the olfactory area together with the bone and cartilage to which the epithelia were attached were removed. Most of the bone and cartilage were then removed from the yellowish-brown tissue, leaving a sample of about 470 g. This tissue was well ground and autolyzed with ethyl alcohol. Both the alcohol

extract and the autolyzed tissue were subjected to several extractions with pure ether in an atmosphere of nitrogen. The ether extracts were combined, washed with water and dried over anhydrous sodium sulfate.

An absorption spectrum of the deep yellow ethereal solution in the visible spectrum showed bands at 420, 442, 478 and 655 mμ, respectively. In petroleum ether the same extract showed bands at 420, 444, 472 and 656 mμ, respectively, while the antimony trichloride color in chloroform showed prominent bands with maxima at 420, 495 and 610 mμ, respectively.

The sample was then saponified in an atmosphere of nitrogen, the non-saponifiable fraction taken up in ether, the ethereal solution filtered at 0° and an absorption spectrum taken of the filtrate in the visible region of the spectrum. It showed bands at 446 and 474 mμ, respectively. The spectrum of the antimony trichloride color showed bands at 410, 440, 495, 620 and in one case at 690 mμ, respectively. An ultraviolet absorption spectrum of this sample in ethyl alcohol is shown plotted in Fig. 1. A maximum is readily

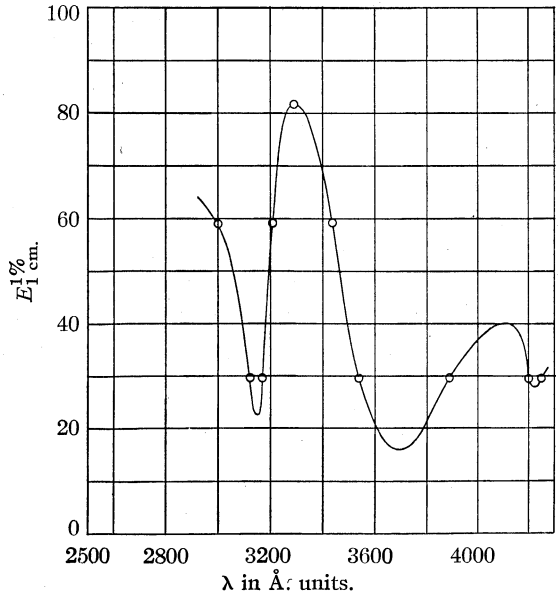

Fig. 1.

seen at 328 mμ which together with that of the antimony trichloride at 620 mμ is characteristic of vitamin A_1. The band of the antimony trichloride color at 690 mμ may be due to the presence of vitamin A_2, although the appearance of this band was not consistent. From the intensity of the maximum at 328 mμ and the concentration of the solution, we calculated $E_{1\text{ cm.}}^{1\%}$ to be 82 for our sample which, on the basis of the purest vitamin A having a potency of 3,250,000 U. S. P. vitamin A units per gram [Milas and Heggie, unpublished results] would have a potency of 116,000 U. S. P. vitamin A units per gram. In another sample taken from a single steer head we found a potency of about 76,000 U. S. P. vitamin A units per gram.

The bands of the visible spectrum at 420, 442–446, 472–478 mμ, respectively, are due to carotenoids. We have not as yet identified the other bands reported in this paper and inasmuch as we are continuing with our work, we are hoping to report a more complete account of it later.

THE FORMATION OF α-ETHYLTHIOGLUCOPYRANOSIDE FROM GLUCOSE ETHYLMERCAPTAL

Sir:

It has been found two years ago [Green and Pacsu, THIS JOURNAL, **59,** 1205 (1937)] that α-ethyl- and α-benzylthioglucosides [Schneider, *et al.*, *Ber.*, **49,** 2054 (1916); **51,** 220 (1918); **61,** 1244 (1928)] are furanosides and not of "normal" (pyranoid) structure as their discoverers believed. This was shown by acid hydrolysis constants, conversion into ethylglucofuranoside, and calculations from Hudson's rules of isorotation. On account of certain irregularities observed by Green and Pacsu during the process of hydrolysis, the behavior of α-ethylthioglucofuranoside in 0.01 *N* hydrochloric acid at 100° was subsequently studied [Pacsu and Wilson, THIS JOURNAL, **61,** 1450 (1939)]. It was found that in this unprecedented hydrolysis about one-half of the α-ethylthioglucofuranoside changed into glucose and mercaptan whereas the other half escaped the hydrolyzing effect of the acid by shifting the furanoid ring into the acid resistant pyranoid ring. The ring shift resulted in the formation of α-ethylthioglucopyranoside, a new thioglucoside, which was isolated and characterized by its tetraacetate. In a recent paper [Brigl, Gronemeier and Schulz, *Ber.*, **72,** 1052 (1939)] which was submitted for publication one month later but appeared one month earlier than the article of Pacsu and Wilson, Brigl and co-workers re-

ported the preparation of the same α-ethylthioglucopyranoside and its tetraacetate. These authors proposed to use glucose ethylmercaptal for disaccharide synthesis and mixed the mercaptal in 22% hydrochloric acid with glucose. Instead of the desired disaccharide Brigl and co-workers obtained this α-ethylthioglucopyranoside in an apparently undetermined yield. As to the mechanism of the reaction the authors stated that the mercaptal lost one mercaptan residue which was partly transferred to the admixed glucose, the whole process being represented by the following two-stage reaction:

(a) $C_6H_{12}O_5(SC_2H_5)_2 = C_6H_{11}O_5(SC_2H_5) + C_2H_5SH$
(b) $C_2H_5SH + C_6H_{12}O_6 = C_6H_{11}O_5(SC_2H_5) + H_2O$

Since we had reasons to believe that this mechanism might not be the correct one, we repeated Brigl's experiment with the modification that we *omitted* glucose. From the reaction mixture we obtained α-ethylthioglucopyranoside in about 20% minimum yield. Also, we obtained the same compound but in somewhat smaller yield (15%) from the reaction of equimolecular quantities of glucose and ethylmercaptan in 22% hydrochloric acid. In our first experiment there was but a mere trace of glucose present in the acetone insoluble residue consisting mainly of barium chloride, whereas in the second experiment, when glucose was used as starting material, the acetone insoluble salt contained a fairly large quantity of unchanged glucose. In both instances the lower rotating component of the reaction mixture represented probably the acid resistant β-ethylthioglucopyranoside, since in neither case could we find glucose ethylmercaptal. These results seem to indicate that the formation in 22% hydrochloric acid of α-ethylthioglucopyranoside from the mercaptal on one hand, and from glucose and mercaptan on the other, are two distinct and independent reactions.

RECEIVED JUNE 20, 1939

VITAMIN B_6, A GROWTH PROMOTING FACTOR FOR YEAST

Sir:

The rate of proliferation of *S. cerevisiae* in purified solutions is known to be profoundly affected by a group of substances known as bioses. The multiple nature of bios is firmly established and further evidence of the multiplicity of bios was found in the discovery of the bios action of thiamine [Schultz, Atkin and Frey, THIS JOURNAL, **60,** 490 (1938)].

We have now found that crystalline vitamin B_6 has the properties of a bios factor. This substance acts on the yeast types A and B in an advantageous manner. The work with crystalline B_6 was made possible by the gift of a few milligrams by Merck and Company.

TABLE I

TWENTY-FOUR HOUR GROWTH OF YEASTS A AND B AS INFLUENCED BY VITAMIN B_6, ETC.

Total volume in each case: 30 ml. (seeded with 1 mg. of moist yeast and rocked at 30° for 24 hours). Crop × 4.54 gives mg. of moist yeast. Supplements: inositol (1) 1 mg.; β-alanine (IIA) 0.005 mg.; bios IIB 0.13 mg.; thiamine 0.01 mg.; vitamin B_6 (VI) 0.05 mg.

Ingredients of bios tests: all C. P. sugar, salts, buffer, I and IIA, plus	24-Hour crop Type A	Type B
Nil	Trace	40
II B	15	210
II B plus thiamine	100	120
Vitamin B_6 (VI)	Trace	40
II B plus Vitamin B_6	150	200
II B plus B_6, plus thiamine	170	200

The properties of crystalline B_6 are: (1) stimulation of Type A yeast to produce a 24-hour crop of 100–120; (2) removal of the inhibition imposed on Type B yeast by thiamine; (3) stimulation of Type A yeast to give a high 24-hour crop in the absence of thiamine.

Crystalline vitamin B_6 was found to have a certain activity as a fermentation accelerator under the conditions of our fermentation test [Schultz, Atkin and Frey, THIS JOURNAL, **59,** 2457 (1937)]. The stimulation is of about the same type as the nicotinic acid effect [Schultz, Atkin and Frey, *ibid.*, **60,** 1514 (1938)] and may be overcome in the same way, *i. e.*, by adding about 0.05 mg. of B_6 to each test.

There are indications that the growth method may be useful as a method for the determination of vitamin B_6. A growth test in which all factors except B_6 are present in excess will respond to solutions or concentrates in proportion to their B_6 content as indicated by rat curative tests which were made by R. F. Light and L. J. Cracas of our Laboratory.

VITAMIN B_6 AS A YEAST NUTRILITE

Sir:

In corroboration of the findings of Schultz, Atkin and Frey [THIS JOURNAL **61**, 1931 (1939)], we wish to indicate that we have independently found that vitamin B_6 is effective in yeast growth stimulation. A typical experiment is outlined below.

The basal medium was similar to that used in previous work [Williams and Saunders, *Biochem. J.*, **28**, 1887 (1934)], but contained 0.1 g. of aspartic acid per liter instead of asparagin. It also contained 0.03 mg. of thiamine, 0.3 mg. of β-alanine, and 30 mg. of autolyzed liver extract per liter. The liver extract had been treated with charcoal and with fuller's earth. The yeast seeding was 0.03 mg. of a pure culture isolated from a Fleischmann cake per 12 ml. culture and the growth period was fourteen hours at 30°. The vitamin B_6 used had been generously furnished by Dr. Samuel Lepkovsky.

TABLE I

EFFECT OF VITAMIN B_6 ON YEAST GROWTH

Vitamin B_6 added (γ per culture)	Yeast crop (mg. per 12 ml. culture)
0	4.47
0	4.53
0.0005	4.44
.001	4.95
.005	6.29
.01	6.82
.05	8.01
.1	8.58
.5	7.94
1	8.27

This finding makes more emphatic the close relationship between "B" vitamins and substances effective for the stimulation of the growth of yeasts (as well as other microörganisms).

VITAMIN K ACTIVITY OF SOME QUINONES

Sir:

In view of the recent note of Almquist and Klose [THIS JOURNAL, **61**, 1611 (1939)] and their conclusion "that phthiocol is the simplest member of an homologous series of anti-hemorrhagic substances," we are submitting a report on the potencies of a rather extensive series of quinones.

As soon as our investigations on vitamin K indicated a quinone structure [THIS JOURNAL, **61**, 1295 (1939)], we began a survey of the potencies of quinones.

Using the assay procedure previously described [*J. Soc. Exp. Biol. Med.*, **40**, 478 (1939); **41**, 199 (1939)] the following quinones were found to be inactive at a level of 5 mg.: anthraquinone β-sulfonic acid, thymoquinone, tolu-*p*-quinone, dihydro-anthraquinone diacetate, 1,2-naphthoquinone, phenanthraquinone, diamylhydroquinone, *p*-xyloquinone, 2-allyl-1,4-naphthoquinone (tested only at 2.0 mg.) and 1,4-benzoquinone.

With the exception of 2-allyl-1,4-naphthoquinone all of the derivatives of 1,4-naphthoquinone show vitamin K activity. Moreover, the diacetates of two of the dihydro-1,4-naphthoquinones show activity, perhaps due to hydrolysis in the gastro-intestinal tract. 2-Allyl-4-amino-1-naphthol hydrochloride in aqueous solution gives a positive reaction.

Our data are summarized in Table I. They show that the 2-methyl-1,4-naphthoquinone is the most active compound in this group; however, when compared with the natural vitamin K_1 (1000 units per mg.) or K_2 (660 units per mg.), the activity is relatively insignificant. Other more complex derivatives of 1,4-naphthoquinone are being prepared for a study of their physiological activity.

TABLE I

Active compounds	Our standard units per milligram
1,4-Naphthoquinone	1.0
2-Methyl-1,4-naphthoquinone	10.0
2-Ethyl-1,4-naphthoquinone	8.0
Phthiocol, 2-methyl-3-hydroxynaphthoquinone	2.0
2-Bromo-3-methyl-1,4-naphthoquinone	> 0.10
2,3 - Dibromo - 2 - methyl - 1,4 - dioxotetrahydronaphthalene	> 0.10
1,4-Naphthalenediol diacetate	0.50
2-Methyl-1,4-naphthalenediol diacetate	5.00

Our discovery of the activity of 1,4-naphthoquinones and the inactivity of other quinones has been of considerable assistance in developing the structure of vitamin K_1 [THIS JOURNAL, **61**, 1928 (1939)].

NEW BOOKS

Volumetric Analysis Including the Analysis of Gases, with a Chapter on Simple Gravimetric Determinations. By Dr. A. J. Berry, M.A., Fellow of Downing College and University Lecturer in Chemistry, Cambridge. Fifth edition. The University Press, Cambridge: The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1939. 196 pp. 9 figs. 14 × 22 cm. Price, $2.50.

The author states in the preface that this book was written in the interests of his own pupils and that his object was to provide a practical book for students having a sufficient background of theoretical principles. He adds that it "would occupy a position intermediate between that of the elementary works of necessarily limited scope and that of standard treatises on volumetric analysis."

A chapter is included on the theory of indicators and a separate chapter has also been added to the present edition devoted to modern developments. Such items as oxidation–reduction indicators, adsorption indicators, the use of ceric sulfate, constant boiling hydrochloric acid, and the use of ammonium persulfate are included in this chapter. It appears unfortunate, however, that these newer developments have not been incorporated at their appropriate point in the body of the book.

Little use is, however, made of the modern theories of ionic reactions, and the inquiring student would find difficulty with the treatment of *p*H, since the author merely states that a convenient way of expressing hydrogen-ion concentration is to take the logarithm of the concentration, omitting the negative sign, and write this as *p*H.

The printing and binding of the book are good.

CHESTER M. ALTER

Physik für Studierende an Technischen Hochschulen und Universitäten. (Physics for Students in Technical Institutes and Universities.) By Ing. Dr. PAUL WESSEL, Lecturer, Wigan and District Mining and Technical College, Wigan. Edited by Dr. V. RIEDERER VON PAAR. Verlag von Ernst Reinhardt, Munich, Germany, 1938. xii + 548 pp. 227 figs. 13 × 21 cm. Price, Mk. 4.90.

This book is intended for university students in their first year and is supposed to be accompanied by a course of lectures and demonstrations in general physics. These students have usually had in school a fairly comprehensive course in physics. The aim of the book is to assist them to a rapid review of all the phenomena in the general field of physics, even including some of the latest discoveries and theories, with applications to modern engineering, chemistry, and medicine.

The arrangement of material follows the conventional order: mechanics, acoustics, heat, optics, magnetism, electricity, electronics, and atomic physics. It is intended to relieve the student of the necessity of taking notes on the lectures so that he can give his undivided attention to the experimental demonstrations. Following the 354 pages of very condensed text, there are 60 pages entitled "A Short Repetitorium" and including a collection of formulas. Then follow 63 pages of questions based on the text, each with a reference to a particular page where the answer may be found. Finally, there are 38 pages of tables and physical constants. The text has many diagrams which are small but very clearly drawn. The style is straightforward.

The American teacher feels the lack of experimental detail in the book and also the absence of historical and biographical references. For example, nowhere does one find a description of Michelson's classical experiment in measuring the speed of light. Anyone who is familiar with American textbooks in college physics will be astonished at the vast amount of material which can be obtained in such an inexpensive volume.

N. HENRY BLACK

Dictionary of Scientific Terms as Used in the Various Sciences. By C. M. BEADNELL, C.B., F.Z.S. Chemical Publishing Company of New York, Inc., 148 Lafayette Street, New York, N. Y., 1939. x + 235 pp. 12.5 × 19 cm. Price, $3.00.

The author in his introduction calls this a book of reference rather than a dictionary. It does indeed give a considerable amount of exact and pertinent information in its definitions and is therefore of corresponding value to the reader who is in doubt as to the meaning of an unfamiliar scientific word. Only some three thousand terms are listed, which seems to be a narrow choice from among the hundreds of thousands in use in the sciences represented. The selection, however, is good, although undoubtedly favoring the biological sciences. Newer words are not neglected.

The volume is all it claims to be, namely, a good book for the desk of the general reader, especially one with scientific training whose reading ventures into other fields than his own.

WILLIS A. BOUGHTON

Proceedings of the Sixth Summer Conference on Spectroscopy and its Application. Held at the Massachusetts Institute of Technology, Cambridge, Massachusetts, July 18–20, 1938. Edited by George R. Harrison. The Technology Press: John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1939. vii + 172 pp. Illustrated. 19 × 25.5 cm. Price, $3.00.

Again, a list of topics of current interest, and of contributors outstanding in their respective fields. Spectroscopic equipment and method, to be sure, are not discussed at such great length as in 1937. Impressive, in this section, is the high-speed absorption spectrophotometer at Massachusetts Institute of Technology which measures and plots within a hundred seconds one thousand transmissions covering the range 10,000 to 2000 Å. Also the

account of the apparatus and methods for obtaining the new tables of 100,000 principal spectrum lines, measured in the same laboratories with accuracy of 0.01 Å. or better. Intensities are given on a scale of one hundred.

Applied photochemistry is well covered, as follows from a partial list of topics: criminal investigation, rare earths in plants, identification of minerals, vitamin determination, enzymes, medical problems, dispersion filters, dyestuffs, analysis of gas mixtures, photochemistry of vision, chemical energy from light, and the problem of the photographic latent image.

These annual demonstrations of the versatility, speed and dependability of optical and photochemical methods cannot fail to exert a beneficial influence upon scientific practice in American and foreign laboratories.

GEORGE S. FORBES

Les origines françaises de la chimie analytique. (The French Origins of Analytical Chemistry.) By A. JOUNIAUX. Hermann et Cie., Éditeurs, 6 Rue de la Sorbonne, Paris, France, 1938. 59 pp. 16.5 × 25 cm. Price, fr. 11.

It is always of academic interest to determine the actual sources of our present information. Jouniaux, in this little book, has shown the important part that French chemists have played in the development of analytical chemistry, largely by direct quotations from the original papers. Such information cannot be obtained from the textbooks of analytical chemistry. Even though an analytical procedure may be correctly credited to Gay-Lussac, for example, the original reference will not usually be given if the work dates back about one hundred years. This is partly because it is better to give an approved procedure which takes into consideration all improvements that have been made and partly because most library files are more or less deficient in journals printed at about the beginning of the nineteenth century.

The author's contention is that the French created chemical analysis and originated most of its methods. Since, however, no reference whatever is made to work done outside of France, except for publishing an illustration of an old English buret, the reviewer is left quite unconvinced.

The author's claim that gravimetric analysis began with Lavoisier is surely not correct. This claim is here based upon Lavoisier's inaccurate analyses of carbon dioxide and of water and the fact that he appears to have been the first to determine carbon and hydrogen in organic compounds by combustion in oxygen with measurement of the water and carbon dioxide formed. The Swedish chemist, Torbern Olaf Bergman (1735–1784), made many quantitative analyses of minerals before the work of Lavoisier was published. He used our present methods of fusion with sodium carbonate for decomposing silicates, and he separated calcium and magnesium ions by precipitation with ammonium oxalate. The use of the balance in the assay of ores was common several centuries previous to the work of Lavoisier, who did, to be sure, emphasize the importance of the balance in chemistry and with it he helped overthrow the phlogiston theory.

WILLIAM T. HALL

Die chromatographische Adsorptionsmethoden. Grundlagen, Methodik, Anwendungen. (Chromatographic Adsorption Methods: Principles, Methods, Applications.) By DR. L. ZECHMEISTER, Professor, and DR. L. v. CHOLNOKY, Lecturer, Chemical Institute of the University of Pécs (Ungarn). Second, revised edition. Verlag von Julius Springer, Linkstrasse 22–24, Berlin W 9, Germany, 1938. xiii + 354 pp. 74 figs. 14.5 × 21.5 cm. Price, RM. 19.80.

The second edition of this excellent book, somewhat larger than the first, is an invaluable survey of the literature of chromatographic adsorption methods. The authors have themselves contributed a great deal of research work in this field, so that their advice as to the technique and their predictions as to the possibilities in detection and purification of substances by the Tswett column analysis must be given great weight.

Their historical review of the development of the subject since Tswett's original contribution in 1906 is presented in good teaching style. The discussion of the various powders used in columns and the variations in activity due to different methods of preparing the dry powders is most helpful. The solvents and mixtures of solvents, both for adsorption media and for washing purposes, are given full attention. The various aluminas seem to be highly favored by these authors, with reason, but there are two minor points about these aluminas which might be clarified. The authors refer to "Alumina III of Brockmann." As a matter of fact the reviewer first used this phrase to describe a product sold by the Aluminum Company of America and the phrase was copied by other authors. In the same connection it might be noted that the word "Hydralo," once used by this industrial organization to describe its commercial alumina, has been discarded in favor of the phrase "activated alumina."

Biochemists, organic chemists, and analysts may well be interested in this book for it presents to them very useful tools in identification and in separation of substances. Micro chromatographic separations are included, as is a system of qualitative analysis for cations and anions. Although originally Tswett, Willstätter, and others were primarily interested in separating plant pigments by column analysis, Zechmeister and Cholnoky now present extended discussions of separation, even of purification, of dyes, hormones, enzymes, and seven vitamins. Obviously there are many of us who must own this book.

HARRY N. HOLMES

Systematic Qualitative Organic Analysis. By H. MIDDLETON, M.Sc. (Manchester), A.I.C. Lecturer in Organic Chemistry, Bradford Technical College. Longmans, Green and Company, 114 Fifth Avenue, New York, N. Y., 1939. 279 pp. Illustrated. 14.5 × 22.5 cm. Price, $2.50.

This book on qualitative organic analysis appears to have been designed for pharmaceutical students with a quite elementary knowledge of organic chemistry. The general scheme follows Mulliken closely, the first classification being made on the basis of elementary analysis and physical state. But little emphasis is placed on solubility for further subdivision. About 600 pure organic compounds,

including most of those given in the British Pharmacopoeia, are considered. These have been carefully examined by the author, and a systematic procedure which gives decisive results is described. While this should assist the beginning student to gain confidence in his work, the loss in flexibility is serious, and the book fails to provide to the full extent for that exercise in logical deduction from experiment which is the particular beauty of the best courses in qualitative organic analysis. Directions are concise and abbreviated; no descriptive or explanatory matter is included and a rather extended series of lectures on the laboratory work would be necessary to make the book effective. The procedures while generally standard depart in several instances from common practice and the extensive use of color reactions is more in keeping with pharmaceutical work. The newer derivatives for many classes of compounds have been omitted. The manual therefore does not seem well suited for the general course in qualitative organic analysis, but it may well be recommended for those students for whom it primarily was written.

THOMAS L. JACOBS

Colloidal Phenomena. An Introduction to the Science of Colloids. By ERNST A. HAUSER, Ph.D., Associate Professor of Chemical Engineering, Massachusetts Institute of Technology. McGraw-Hill Book Co., Inc., 330 West 42d St., New York, N. Y., 1939. xx + 294 pp. 123 figs. 16 × 23.5 cm. Price, $3.00.

This work by a recognized authority and successful practitioner of the art should find a place in almost every chemical and industrial library. It is a guide to the chief textbooks and monographs and to the more important recent papers and concepts in this field. It is intentionally and unfortunately not "another textbook on colloidal chemistry." It reveals the theoretical apparatus with which an important group of colloid workers operate, largely under the influence of Wo. Ostwald, there being forty-six page citations to him, thirty-nine to von Buzagh, thirty-eight to Freundlich and twenty-eight to the author. The text itself is completely non-mathematical.

The book begins with a preface emphasizing the breaking of some of the barriers of "physicochemistry," and an interesting historical introduction, followed by chapters commenting on the dispersed state, terminology, difform systems, form and shape, production, kinetics, electrical properties, surface phenomena, protection and sensitization, dispersion, coagulation, mechanical and optical properties as influenced by particle shape, aggregates bonded by primary and by secondary forces, and colloidal aggregates. Then comes one of the most valuable features, an Appendix of forty-six pages giving the formulas and equations commonly referred to, with notes on some of the experimental methods.

As presented in this monograph, the subject is clearly not an exact science, but it is one of compelling practical importance where any hint is valuable as a guide to comprehension or to remarkable industrial applications. The text is facile and readable, but if one stops to analyze the meaning, it is not clear. Much that is usually discriminated is taken as synonymous as, for example, charge and potential, dispersion and peptization; and much of the description is as vague as the undefined expression (page 171) "liquid gel," or (page 169) the statement that "a colloidal sol can be considered a statistical mixed crystal." Many statements are not intended to be taken literally. The expressions evidently serve to recall examples of materials or behavior showing parallelisms which are useful in investigating further systems because they may recur, perhaps in modified or even contrasting form.

The numerous diagrams are beautifully clear, but they are largely schematic and are not referred to actual examples or measurements.

J. W. MCBAIN

The Plant Alkaloids. By THOMAS ANDERSON HENRY, D.Sc., Director, Wellcome Chemical Research Laboratories. Third edition. P. Blakiston's Son and Company, Inc., 1012 Walnut Street, Philadelphia, Pa., 1939. viii + 689 pp. 15 × 23 cm. Price, $12.00.

The reviewer has little but praise for this excellent and scholarly treatise on the alkaloids, which represents an expansion of the second edition by 233 pages. Together with Winterstein–Trier (1931) it is indispensable in any well-equipped scientific library, or to anyone interested in natural products. The literature references are abundant, comprising approximately 6060, and extending through most of 1938. The author and publishers are to be congratulated on this feat, as well as on the comparative freedom from errors. The references have been collected at the end of each section in such compact form as to make it a little difficult to find a desired citation. The frequent designation of bibliographies is a welcome feature.

Criticisms that can be offered are very minor in nature. The structural formulas are reproduced from drawings, but are clear and accurate. An error in the sinomenine formula on page 7 has been carried over from the original publication. The term "deracemization" is somewhat unusual, and "habitués" in the sense used on p. 623 is inacceptable. It is a question, to what extent the physical properties of somewhat remote derivatives should be described in a text of this sort, since it may generally be assumed that one interested in such derivatives will have access to the literature. The occasional citation of specific rotations to the second decimal place without specification of temperature, solvent, or concentration, certainly seems inconsistent.

As in the previous edition, the listing of plant sources is unusually complete, but the illustrations of important alkaloid-bearing plants have been sacrificed. Discussion of physiological action is necessarily limited, but numerous pertinent references are supplied. Much space has been saved by omission of the details of methods of estimation of the alkaloids, which may be found easily in pharmacopoeias and special reports.

Classification of the alkaloids according to nuclear type has been followed much as in the older edition. As would be expected, the sections on the isoquinoline and indole groups have been greatly enlarged. The up-to-date discussion of the Strychnos alkaloids is most welcome

even though it is necessarily condensed. The lupinanes, phenanthridine, pyrrolidine, and quinazoline are new groups; the section on the purine bases has been omitted, as the material is easily accessible elsewhere. The book is durably and attractively bound, and well printed.

LYNDON SMALL

The Electrochemistry of Gases and Other Dielectrics. By G. GLOCKLER, Professor of Physical Chemistry, and S. C. LIND, Professor of Physical Chemistry and Dean of the Institute of Technology, University of Minnesota. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1939. xiii + 469 pp. 82 figs. 15.5 × 23.5 cm. Price, $6.00.

In contrast to the texts on photochemistry, which continue to multiply, there has hitherto been no monograph on research in the field of chemical reactions produced by the various types of ionizing agencies. In this present volume the need for such has been handsomely met and the authors are to be thanked sincerely for an onerous task well accomplished.

The book is divided into three sections. The first deals with typical reactions in various forms of electrical discharge, the glow discharge, silent electrical, corona, electrodeless and arc discharge, cathode rays and electrons of controlled speeds. The second part attempts to summarize the studies of reactions in the various forms of discharge the data for all forms of activation being collected together for a given substance and its reactions. The final section of the book treats of the theoretical and physical aspects of discharge reactions. As an illustration of the depth of the treatment we may cite the 47 pages on hydrogen and the hydrocarbons or the 40 pages on active nitrogen. The former summarizes the influence of spark, silent discharge and luminous discharge on the properties of hydrogen and gives *inter alia* an extended discussion of the reactions of various hydrocarbons under ozoning conditions. There is a bibliography of 123 titles to this chapter while that on active nitrogen cites 152 titles. This latter chapter illustrates, too, the breadth of the problems covered; spectroscopy, luminescence and phosphorescence, molecular structure and chemical kinetics are all involved.

The final section of the book dealing with the theoretical aspects of the subject is exceedingly interesting. After sections on electron affinities and ion mobilities a chapter is devoted to the results of mass spectroscopy with a convenient summary of the experimental results. The two following chapters on ionization produced by chemical reaction and on cathodic sputtering of metals seem to the reviewer less pertinent to the theme of this section. The final chapter of 13 pages on mechanism is all too brief for the physical chemist since here, if anywhere, is the heart of the subject from his point of view. That the chapter could not have included a discussion of the several interesting papers which have only appeared quite recently notably by Gunther, Mund, Essex and their co-workers, all dealing with reaction mechanism in this field, is to be regretted, but the student can start his inquiries in this field with the Glockler–Lind chapter and turn then to the literature of 1938–1939 for a very interesting field of fundamental research.

JOURNAL OF THE
AMERICAN CHEMICAL SOCIETY

VOLUME 61 AUGUST 5, 1939 NUMBER 8

[CONTRIBUTION FROM THE NOYES CHEMICAL LABORATORY, THE UNIVERSITY OF ILLINOIS]

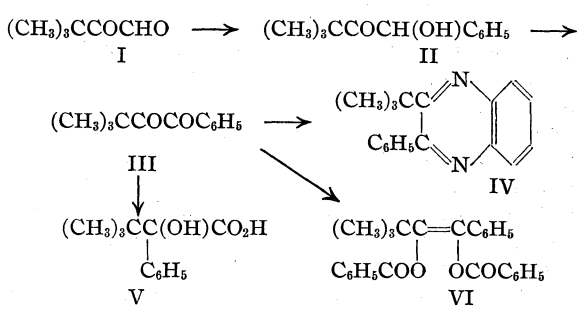
Acyloins from *t*-Butylglyoxal[1]

BY REYNOLD C. FUSON, HUGH GRAY[2] AND J. J. GOUZA

The condensation of arylglyoxals with aromatic compounds[1] provides a convenient method for making mixed benzoins. It seemed probable that the method could be used also for acyloins of the type RCOCH(OH)Ar. To test this suggestion we have prepared *t*-butylglyoxal[3] and treated it with aromatic compounds in the presence of aluminum chloride. The expected acyloins were formed in good yields.

t-Butylglyoxal (I) was synthesized from pinacolone by oxidation with selenium dioxide according to the general procedure of Riley, Morley and Friend.[4] The glyoxal was a yellow liquid boiling at 114–115°. It formed a hemihydrate, a phenylhydrazone, a 2,4-dinitrophenylhydrazone, an osazone, a semicarbazone, a dioxime and a quinoxaline derivative. Treatment with aqueous alkali transformed the glyoxal into β,β,β-trimethyllactic acid. When allowed to stand the glyoxal polymerized to a viscous liquid from which it could be regained by heating.

Condensation with benzene in the presence of aluminum chloride gave a solid product, melting at 46–47°, which proved to be the expected phenylpivalylcarbinol (II).



The latter was identified by formation of the 2,4-dinitrophenylhydrazone, the benzoate and *t*-butyl phenyl diketone (III), which was treated with *o*-phenylenediamine to give 2-*t*-butyl-3-phenylquinoxaline (IV).

Condensation of *t*-butylglyoxal with toluene, *m*-xylene and mesitylene in the presence of aluminum chloride gave the corresponding acyloins, from which the diketones were prepared by oxidation with concentrated nitric acid. The mesityl diketone was isolated as the solid mononitro derivative.

The *p*-tolyl diketone gave a quinoxaline derivative, but the *m*-xylyl and 3-nitromesityl analogs did not react with *o*-phenylenediamine under these conditions.

A rearrangement of the benzilic acid type was effected by treatment of *t*-butyl phenyl diketone with alkali, giving β,β,β-trimethylatrolactic acid (V). This is the first recorded example of such a reaction with a mixed aromatic–aliphatic 1,2-diketone.

(1) This is the fourth paper in this series. For the preceding communication see Fuson, Emerson and Weinstock, THIS JOURNAL, **61**, 412 (1939).

(2) Röhm and Haas Research Assistant, 1938–1939.

(3) Since this work was completed the synthesis of the glyoxal and its hemihydrate was reported by Taylor, Callow and Francis [*J. Chem. Soc.*, 257 (1939)].

(4) Riley, Morley and Friend, *ibid.*, 1875 (1932).

t-Butyl phenyl diketone resembled benzil[5] in its behavior with metallic sodium; benzoyl chloride converted the sodium derivative to the dibenzoate of *t*-butylphenylacetylene glycol (VI).

Experimental

***t*-Butylglyoxal.**—A mixture of 100 cc. of methyl alcohol,[6] 5 cc. of water and 111.2 g. of selenium dioxide was refluxed, with stirring, until the selenium dioxide dissolved, and then 122 cc. of pinacolone was added rapidly. The clear solution became red and then black after a few minutes. Refluxing and vigorous stirring were continued for six hours,[7] after which the reaction mixture was cooled and the precipitated selenium was removed by filtration. The yellow filtrate was distilled at atmospheric pressure from a modified Claisen flask having a 7-in. (18-cm.) column. After rejection of a fraction distilling from 65 to 110°, a yellow distillate was collected from 110 to 120°. A high-boiling residue which contained selenium was always present. Fractionation of the yellow oil gave 60 cc. of the yellow *t*-butylglyoxal, boiling at 114–115°.[8] The yield was 52% of the theoretical amount. Analyses for carbon and hydrogen showed that the product was not entirely pure. It became viscous on standing, even in a sealed container. The refractive index of the freshly distilled glyoxal increased rapidly, a typical determination showing a rise from 1.4287 to 1.4454 during the first hour. The resulting polymer was unreactive, hence it was necessary to distill the material before use. It was also found convenient to keep the glyoxal as the hydrate. The anhydrous monomer was prepared from its hydrate by dissolving the latter in methyl alcohol and subjecting the solution to fractional distillation.

Hemihydrate.—To 5 cc. of the glyoxal was added 1 cc. of water; appreciable evolution of heat was observed. The solution was allowed to stand overnight to allow the product to crystallize. It was recrystallized from 10 cc. of benzene, m. p. 91–92°,[9] with softening at 85°.

Anal. Calcd. for $C_{12}H_{22}O_5$: C, 58.51; H, 9.01. Found: C, 58.55; H, 9.10.

The 2,4-dinitrophenylhydrazone separated from alcohol as yellow crystals, m. p. 171–172°.

Anal. Calcd. for $C_{12}H_{14}O_5N_4$: C, 48.98; H, 4.80; N, 19.04. Found: C, 49.01; H, 4.87; N, 19.19.

Treatment with phenylhydrazine gave a **phenylhydrazone** or an **osazone,** depending upon the conditions employed. An excellent yield of the phenylhydrazone was obtained by allowing an alcohol solution of equimolecular amounts of the reactants to stand at room temperature for one hour. The pale yellow phenylhydrazone was precipitated by the addition of water and crystallized from ethyl acohol, m. p. 119–120°.

Anal. Calcd. for $C_{12}H_{16}ON_2$; C, 70.55; H, 7.90; N, 13.72. Found: C, 70.11; H, 7.83; N, 13.72.

The **osazone** was prepared by dissolving the theoretical amounts of the reactants in alcohol, adding a few drops of concentrated hydrochloric acid and heating the resulting solution for six hours under reflux. The warm (50°) solution was diluted with water until turbid and allowed to cool. The bright yellow osazone was recrystallized from ethyl alcohol, m. p. 119.5–120°.[10] A mixture of the osazone and the phenylhydrazone melted at about 100°.

Anal. Calcd. for $C_{18}H_{22}N_4$: C, 73.43; H, 7.54; N, 19.03. Found: C, 73.69; H, 7.60; N, 18.97.

Treatment with semicarbazide gave a **monosemicarbazone** which, after recrystallization from aqueous ethyl alcohol, melted at 134–135°.

Anal. Calcd. for $C_7H_{13}O_2N_3$: C, 49.11; H, 7.65; N, 24.55. Found: C, 49.23; H, 7.51; N, 24.35.

The dioxime was crystallized from aqueous ethyl alcohol, m. p. 100.5–101.5°.

Anal. Calcd. for $C_6H_{12}O_2N_2$: C, 49.98; H, 8.39; N, 19.43. Found: C, 50.10; H, 8.50; N, 19.11.

Wittorf,[11] who obtained this compound by the action of hydroxylamine on dibromopinacolone, reported a melting point of 101–102°.

Nitroquinoxaline.—To a refluxing solution of 1.5 g. of *p*-nitro-*o*-phenylenediamine in 25 cc. of glacial acetic acid was added 1.25 g. of *t*-butylglyoxal hydrate. The solution was refluxed for one hour, diluted with water until the appearance of turbidity, and cooled to room temperature. The nitroquinoxaline was treated with Norite and recrystallized from ethyl alcohol, m. p. 134.5–135°.

Anal. Calcd. for $C_{12}H_{13}O_2N_3$: C, 62.32; H, 5.67; N, 18.18. Found: C, 62.27; H, 5.53; N, 18.14.

β,β,β-Trimethyllactic Acid.—One gram of *t*-butylglyoxal hydrate was added to a solution of 8 g. of sodium hydroxide in 24 cc. of water. The mixture was shaken for a few minutes, and the resulting clear solution was allowed to stand at room temperature. After about one hour the sodium salt of β,β,β-trimethyllactic acid precipitated. This material was separated by filtration, dissolved in water, and the solution acidified with hydrochloric acid. The solution was extracted with three 25-cc. portions of ether, and the ether solution was dried over anhydrous magnesium sulfate. The white crystalline β,β,β-trimethyllactic acid, obtained by evaporation of the solvent, was purified by recrystallization from high-boiling petroleum ether. The yield was 93% of the theoretical amount, m. p. 86.5–87.5°. This melting point is in agreement with the findings of Favorskiĭ,[10] Wittorf[11] and Glücksmann.[12]

Phenylpivalylcarbinol.—A mixture of 54 g. (0.4 mole) of aluminum chloride and 80 cc. of dry benzene was cooled in an ice-bath and a solution of 23 g. (0.2 mole) of freshly distilled *t*-butylglyoxal in 20 cc. of dry benzene was added, with stirring, over a period of one-half hour. The reaction

(5) Nef, *Ann.*, **308**, 264 (1899).

(6) Various other solvents (dioxane, acetic anhydride and benzene) proved to be unsatisfactory due to difficulties in fractionation of the product.

(7) In several cases formation of a solid cake of precipitated selenium during the first hour made further stirring impracticable.

(8) This boiling point is in agreement with that reported by Taylor, Callow and Francis.[3]

(9) Taylor, Callow and Francis[3] give a melting point of 85°.

(10) This compound was obtained by Favorskiĭ [*J. Russ. Phys.-Chem. Soc.*, **44**, 1339 (1912); *J. prakt. Chem.*, [2] **88**, 641 (1913)] by the action of phenylhydrazine on pivalylcarbinol.

(11) Wittorf, *ibid.*, **32**, 88 (1900); *Chem. Zentr.*, **71**, II, 29 (1900).

(12) Glücksmann, *Monatsh.*, **10**, 770 (1889).

mixture became black during the addition. Stirring was continued for six hours (one hour in ice-bath, five hours at room temperature) and the mixture was allowed to stand overnight at room temperature. It was added, with vigorous stirring, to a mixture of 100 cc. of concentrated hydrochloric acid and 300 g. of ice. The yellow benzene layer was washed with dilute sodium bicarbonate solution and with water, and dried over anhydrous sodium sulfate. The residue, after evaporation of the solvent, distilled at 90–102° (2 mm.). The acyloin so obtained soon solidified, and was recrystallized from aqueous alcohol, m. p. 46–47°. The yield was 49% of the theoretical amount.

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39. Found: C, 75.19; H, 8.49.

The 2,4-dinitrophenylhydrazone was recrystallized from ethyl alcohol, m. p. 174–175°.

Anal. Calcd. for $C_{18}H_{20}O_5N_4$: C, 58.05; H, 5.41; N, 15.04. Found: C, 58.12; H, 5.48; N, 14.74.

Benzoate.—One-half gram of phenylpivalylcarbinol was dissolved in 1 cc. of benzoyl chloride and warmed for a few minutes. The solution was cooled and poured into 20 cc. of water, with vigorous stirring. The water was removed by decantation and the oily residue was warmed with 5 cc. of 10% sodium hydroxide solution. The mixture was cooled overnight, and the solid material was removed by filtration and washed with water. Recrystallization from ethyl alcohol gave lustrous white crystals, m. p. 96–97°.

Anal. Calcd. for $C_{19}H_{20}O_3$: C, 77.00; H, 6.80. Found: C, 76.94; H, 6.81.

***t*-Butyl Phenyl Diketone.**—This diketone and the others described below were made by the following method. The acyloin (0.05 mole) was added to 15 cc. of concentrated nitric acid and the mixture was warmed on the steam-cone for two hours. When cool the reaction mixture was poured into 50 cc. of water and the yellow oily layer separated. It was dissolved in ether, and the ether solution washed with aqueous sodium bicarbonate solution and with water. After the ether solution was dried over sodium sulfate, the solvent was evaporated and the residue distilled under diminished pressure, b. p. 75–76° (1 mm.); d^{20}_{20} 1.016; $n^{20}D$ 1.5086.

Anal. Calcd. for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42; M_D, 55.1.[13] Found: C, 75.71; H, 7.47; M_D, 55.8.

2-*t*-Butyl-3-phenylquinoxaline.—*t*-Butyl phenyl diketone was converted to the corresponding quinoxaline by the following procedure. The yield was nearly quantitative. To a refluxing solution of 0.6 g. of *o*-phenylenediamine and 25 cc. of glacial acetic acid was added 1 cc. of the diketone. After the refluxing had continued for two hours the solution was diluted with water to the appearance of turbidity and allowed to cool. The 2-*t*-butyl-3-phenylquinoxaline was recrystallized from aqueous ethyl alcohol, m. p. 108–109°.

Anal. Calcd. for $C_{18}H_{18}N_2$: C, 82.41; H, 6.91; N, 10.68. Found: C, 82.19; H, 6.97; N, 10.59.

(13) In this calculation as well as in those made for the molecular refractivity of other 1,2-diketones mentioned in this paper, an exaltation of 1.05 is ascribed to the conjugation of the two carbonyl groups and three olefinic linkages are assigned to the aromatic nucleus. See Auwers, *Ber.*, **51**, 1116 (1918).

***p*-Tolylpivalylcarbinol.**—The use of toluene in the Friedel–Crafts reaction gave 21.5 g., a yield of 52% of the theoretical amount, of the acyloin, m. p. 48–49°. (The crude material boiled at 115–125° at 2 mm.)

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.79. Found: C, 75.69; H, 8.67.

The diketone boiled at 97–97.5° (1 mm.); d^{20}_{20} 1.016; $n^{20}D$ 1.5125.

2-*t*-Butyl-3-*p*-tolylquinoxaline.—By use of the procedure outlined for the phenyl analog this quinoxaline was obtained in almost the theoretical yields, m. p. 109–110°.

Anal. Calcd. for $C_{19}H_{20}N_2$: C, 82.57; H, 7.30; N, 10.14. Found: C, 82.41; H, 7.51; N, 10.18.

***m*-Xylylpivalylcarbinol.**—When *m*-xylene was used there was obtained 18.5 g. of the liquid acyloin, b. p. 133–135° (4 mm.). The yield was 42% of the theoretical amount; d^{20}_{20} 1.100; $n^{20}D$ 1.5134.

Anal. Calcd. for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15; M_D, 59.6. Found: C, 76.44; H, 9.03; M_D, 60.1.

A solid material which precipitated from the crude acyloin before distillation was recrystallized from alcohol, giving 6 g. of **di-(*m*-xylyl)-pivalylmethane,** m. p. 111.5–112°.

Anal. Calcd. for $C_{22}H_{28}O$: C, 85.66; H, 9.15. Found: C, 85.84; H, 9.03.

The diketone boiled at 103–104° (1 mm.); d^{20}_{20} 1.017; $n^{20}D$ 1.5177.

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31; M_D, 64.3. Found: C, 76.72; H, 8.34; M_D, 65.0.

Treatment for eleven hours with a boiling solution of *o*-phenylenediamine in acetic acid failed to yield any quinoxaline. The original diketone was recovered. It was identified by conversion to 2,4-dimethyl-3,5-dinitrobenzoic acid described below.

2,4-Dimethyl-3,5-dinitrobenzoic Acid.—A mixture of 5 cc. of concentrated nitric acid and 5 cc. of concentrated sulfuric acid was cooled in an ice-bath and 0.25 cc. of *t*-butyl *m*-xylyl diketone was added dropwise, with stirring. The solution was poured on ice, with stirring, and the precipitated acid separated by filtration. It was recrystallized from glacial acetic acid, m. p. 202–203°.

Anal. Calcd. for $C_9H_8O_6N_2$: C, 45.00; H, 3.38; N, 11.66. Found: C, 45.54; H, 3.41; N, 11.35.

Claus[14] reported a melting point of 199–200° (uncorr.) for this compound.

Mesitylpivalylcarbinol.—Distillation of the excess mesitylene from the reaction product left a solid residue which was recrystallized from alcohol. There was obtained 14 g., a yield of 30% of the theoretical amount, of the acyloin, m. p. 118–118.5°.

Anal. Calcd. for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46. Found: C, 76.91; H, 9.45.

***t*-Butyl 3-Nitromesityl Diketone.**—The mesitylpivalylcarbinol was heated for three hours with 15 cc. of concentrated nitric acid. The oil which was isolated by dilution of the mixture with water was dissolved in ether.

(14) Claus, *J. prakt. Chem.*, [2] **41**, 483 (1890).

washed and dried; it distilled at 110 to 170° (*ca.* 0.5 mm.). The distillate was heated for three hours with a fresh 15-cc. portion of nitric acid. The product was isolated, dissolved in ether, washed and dried. Evaporation of the ether gave the bright yellow diketone, which was recrystallized from aqueous methyl alcohol, m. p. 58–59°.

Anal. Calcd. for $C_{15}H_{19}O_4N$: C, 64.96; H, 6.91; N, 5.05. Found: C, 64.87; H, 7.03; N, 5.15.

Like the xylyl analog this diketone failed to give a quinoxaline. Even after fifteen hours' treatment the diketone was almost entirely recovered.

β,β,β-Trimethylatrolactic Acid.—One cubic centimeter of *t*-butyl phenyl diketone was added to a solution of 2 g. of potassium hydroxide and 1 cc. of ethyl alcohol in 10 cc. of water. This mixture was refluxed until a clear solution was obtained (about six hours). Acidification with hydrochloric acid precipitated an oily material which was separated and treated with low-boiling petroleum ether. The white solid acid which separated was removed by filtration and recrystallized from high-boiling petroleum ether, m. p. 105–106°.

Anal. Calcd. for $C_{12}H_{16}O_3$: C, 69.21; H, 7.75; neut. equiv., 208. Found: C, 69.33; H, 7.95; neut. equiv., 208.

Dibenzoate of *t*-Butylphenylacetylene Glycol.—A mixture of 0.26 g. of sodium, 20 cc. of dry toluene and 1 cc. of *t*-butyl phenyl diketone was refluxed in an atmosphere of nitrogen for two hours, with vigorous stirring. After addition of 1.25 cc. of benzoyl chloride, the dark brown reaction mixture was heated and stirred for a few minutes and then cooled to room temperature. The excess sodium and the precipitated sodium chloride were removed by filtration and the filtrate was concentrated to a viscous brown oil. The dibenzoate was recrystallized from high-boiling petroleum ether, m. p. 138–139°.

Anal. Calcd. for $C_{26}H_{25}O_4$: C, 77.98; H, 6.04. Found: C, 77.96; H, 6.12.

Summary

t-Butylglyoxal condenses with benzene, toluene, *m*-xylene and mesitylene to give acyloins of the type $(CH_3)_3CCOCH(OH)Ar$. Oxidation with nitric acid converts the acyloins to the corresponding diketones. In the case of the mesityl compound the diketone is isolated in the form of its mononitro derivative.

The diketones derived from benzene and toluene react normally with *o*-phenylenediamine to give quinoxalines. This reaction could not be effected with the *m*-xylyl or mesityl diketones.

t-Butyl phenyl diketone undergoes the benzilic acid rearrangement to give β,β,β-trimethylatrolactic acid. The sodium derivative of this diketone reacts with benzoyl chloride to give the dibenzoate of *t*-butylphenylacetylene glycol. The two foregoing types of reaction hitherto had been restricted to benzils and aliphatic 1,2-diketones.

The Methylation of β-Ketonitriles

BY REYNOLD C. FUSON AND DONALD E. WOLF

The discovery that α-cyanoacetomesitylene (IV) and α-cyanopropiomesitylene gave only O-methylation products[1] suggested that the steric hindrance present in these β-ketonitriles favored O-methylation.[2] As a test of this suggestion an unhindered β-ketonitrile, *p*-bromophenacyl cyanide (I), has been methylated under similar conditions. It reacted with methyl sulfate in the presence of aqueous potassium hydroxide to give the O-methyl ether (II). When the alkylating agent was methyl iodide in the presence of sodium ethoxide, a different compound, the C-methylated product (III), was formed.

The structure of the enol methyl ether (II) was established by analysis for methoxyl and by its insolubility in alkali. Both the parent compound (I) and the C-methylated derivative (III) are soluble in 10% sodium hydroxide solution and in 10% sodium carbonate solution. Compound III was hydrolyzed easily to give *p*-bromobenzoic acid. When allowed to stand for some time it decomposed spontaneously, probably by autoxidation of its enol—a phenomenon previously noted for compounds of this type.[3]

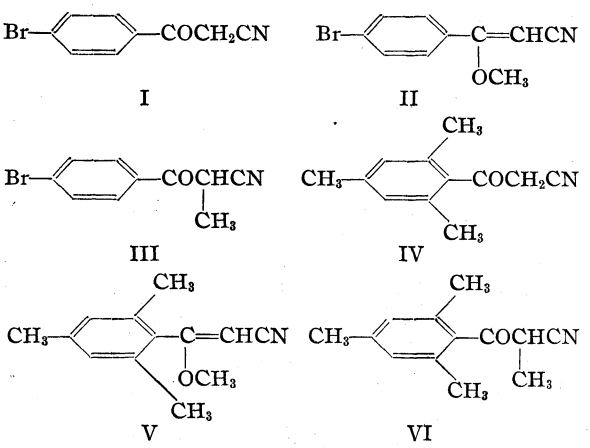
The structure of the C-methylated product, α-(*p*-bromobenzoyl)-propionitrile (III), was established by synthesis, employing the method used by Dorsch and McElvain[4] for similar compounds. Ethyl *p*-bromobenzoate was condensed with propionitrile in the presence of sodium ethoxide. The product proved to be α-(*p*-bromobenzoyl)-propionitrile (III).

(1) Fuson, Ullyot and Gehrt, THIS JOURNAL, **60**, 1199 (1938).

(2) This idea was developed by Kohler and his co-workers in connection with mesityl ketones. For a leading reference see Kohler and Thompson, *ibid.*, **59**, 887 (1937).

(3) Jenkins, *ibid.*, **57**, 2733 (1935).

(4) Dorsch and McElvain, *ibid.*, **54**, 2960 (1932).



The formation of the O-methylated derivative (II) of an unhindered phenacyl cyanide is not without precedent since Arndt and his co-workers[5] have reported recently that phenacyl cyanide reacts with diazomethane to give *trans*-β-methoxycinnamonitrile. The formation of the C-methylated derivative (III) by the method employed here seems to be a new reaction.

Inasmuch as the experimental conditions used in methylating *p*-bromophenacyl cyanide were not entirely parallel with those used by Fuson, Ullyot and Gehrt[1] in working with α-cyanoacetomesitylene, a further study was made of the latter (IV). It was found that when the methylating agent was methyl iodide in the presence of sodium ethoxide both O-methylated (V) and C-methylated (VI) derivatives were obtained in nearly equivalent amounts.

Two crystalline forms of the β-methoxy-β-mesitylacrylonitrile (V) were isolated. The identity of each was established by mixed melting points with authentic samples prepared by Fuson, Ullyot and Gehrt.[1] The structure of α-cyanopropiomesitylene (VI) was established by the synthesis of this compound, using the method described by Fuson, Ullyot and Gehrt.[1]

It therefore appears that the steric hindrance present in α-cyanoacetomesitylene favors O-methylation but not to the complete exclusion of C-methylation.

Experimental

p-Bromophenacyl Cyanide (I).—The method used by Grothaus and Dains[6] for the preparation of this compound from *p*-bromophenacyl chloride and sodium cyanide was not found satisfactory when *p*-bromophenacyl bromide was the starting material. The method accordingly was modified as follows. Ten grams of *p*-bromophenacyl bromide was dissolved in about 400 cc. of 95% ethanol. To this solution was added, dropwise and with stirring, a solution of 4.7 g. of potassium cyanide in the minimum amount of water. The reaction mixture was stirred for five hours at room temperature during which time a white crystalline precipitate formed, and then for one hour in an ice–salt bath. The precipitate was collected on a filter and dissolved in water. The cloudy aqueous solution was clarified with Darco. Treatment with hydrochloric acid gave 6 g. of a fine white precipitate of *p*-bromophenacyl cyanide (m. p. 162–163°) sufficiently pure for use.

Methylation of *p*-Bromophenacyl Cyanide with Methyl Sulfate.—A mixture of 2 g. of dry *p*-bromophenacyl cyanide and 4.6 g. of methyl sulfate was heated under reflux to 70° and 3 g. of potassium hydroxide in 40 cc. of water was added slowly, with stirring, over a fifteen-minute period while the bath temperature was raised from 70 to 130°. A yellow oil separated during the addition of potassium hydroxide solution. One and thirty-five hundredths grams of methyl sulfate was added and the heating continued for five minutes. The container was surrounded by an ice-bath and 1 g. of potassium hydroxide in 150 cc. of water was added. The yellow oil solidified leaving a clear solution. The oily solid was dried and treated with petroleum ether. The insoluble portion was starting material melting at 162–163°. The petroleum ether solution was washed with potassium carbonate solution and the solvent evaporated. The crude methoxy nitrile (II) weighed about 0.7 g. and melted at 56–58°. It was recrystallized twice from high boiling petroleum ether and melted at 58.5–59.5°.[7]

Anal. Calcd. for $C_{10}H_8BrNO$: C, 50.46; H, 3.39; OCH_3, 13.03. Found: C, 50.49; H, 3.33; OCH_3, 12.94, 12.92.

No other product could be detected.

Methylation of *p*-Bromophenacyl Cyanide with Methyl Iodide and Sodium Ethoxide.—To a solution of 0.35 g. of clean sodium in 100 cc. of absolute ethanol was added 3.45 g. of dry *p*-bromophenacyl cyanide. The reaction mixture was heated, with stirring, until it refluxed gently. Not all the solid was in solution. A solution of 3.5 cc. of methyl iodide in 40 cc. of absolute ethanol was added slowly, with stirring. The remaining solid dissolved. Refluxing was continued until samples of the reaction mixture gave a neutral test with moist litmus paper (one to one and a half hours).

The solution was concentrated to 25 cc. and the concentrate cooled to 0°. Forty cubic centimeters of ice water was added followed by 40 cc. of ether, and the solution was shaken to dissolve the solid. A few drops of 10% sodium hydroxide solution were necessary to bring about complete solution. The aqueous layer was separated and acidified with dilute sulfuric acid, giving a solid and an oil. Treatment with ether dissolved the precipitate. The ether extract was washed with saturated sodium bicarbonate solution to remove any *p*-bromobenzoic acid, then with water and finally was dried over anhydrous sodium sulfate. The solvent was evaporated yielding an oil which crystallized

(5) Arndt, Loewe, Günter and Sepahi, *Ber.*, **71B**, 1627 (1938); Arndt, Loewe, Özsöy, Ogüt, Arslan and Bagevi, *ibid.*, **71B**, 1631 (1938).

(6) Grothaus and Dains, THIS JOURNAL, **58**, 1334 (1936).

(7) The melting points reported in this paper have all been corrected.

when cooled. The product was difficult to purify because when it was heated with methyl alcohol or aqueous sodium carbonate it decomposed to give *p*-bromobenzoic acid. Purification was accomplished by dissolving the solid in cold sodium carbonate solution (10%), decolorizing with Darco and very carefully precipitating the product by addition of dilute sulfuric acid to the solution at 0° until the first appearance of turbidity. A pure product was also obtained from aqueous methanol when heating was avoided. The pure ketonitrile (III) melted at 74.5–75.5°.

Anal. Calcd. for $C_{10}H_8BrNO$: C, 50.46; H, 3.39. Found: C, 51.06; H, 3.49.

A Zeisel determination showed the absence of a methoxyl group.

The identity of the *p*-bromobenzoic acid resulting from the decomposition of the C-methyl derivative (III) was verified by a neutral equivalent determination and a mixed melting point with an authentic sample.

Synthesis of α-(*p*-Bromobenzoyl)-propionitrile (III).—A mixture of 23 g. of ethyl *p*-bromobenzoate and 6.8 g. of sodium ethoxide was warmed under reflux to 80° and stirred until it became homogeneous. Seven grams of propionitrile was added slowly, with stirring, to this mixture over a period of half an hour. Following the addition of propionitrile the temperature of the mixture was raised to 110–120° and maintained at this point for ten hours, with continuous stirring.

The reaction mixture was cooled to 0°, treated with 40 cc. of ice water and 100 cc. of ether, and shaken until the solid was dissolved. The aqueous layer was separated and acidified with dilute sulfuric acid, giving an oil and a white solid. The insoluble material was extracted with ether and washed three times with saturated sodium bicarbonate solution, then once with water, and the ether solution dried over anhydrous sodium sulfate.

When the ether was evaporated a tan oil was left which yielded crystals when cooled. The crude product was dissolved in 10% sodium carbonate solution, decolorized with Darco and precipitated by careful addition of dilute sulfuric acid to the ice cold solution until the appearance of turbidity. The melting point of the pure α-(*p*-bromobenzoyl)-propionitrile was 74.5–75.5°.

A mixed melting point with the ketonitrile (III) prepared by methylation of *p*-bromophenacyl cyanide was 74.5–75.5°.

Anal. Calcd. for $C_{10}H_8BrNO$: N, 5.89. Found: N, 5.83.

Methylation of α-Cyanoacetomesitylene with Methyl Iodide.—To a solution of 0.615 g. of clean sodium in 200 cc. of absolute ethanol was added 5 g. of α-cyanoacetomesitylene. The reaction mixture was stirred and heated until it refluxed gently, precautions being taken to preserve anhydrous conditions. To the refluxing solution was added slowly 6.7 cc. of methyl iodide dissolved in 25 cc. of absolute ethanol. Refluxing was continued for two hours following addition of the methyl iodide; at the end of this time the reaction mixture gave no basic test with moist red litmus paper.

The solution was concentrated to 50 cc., cooled in an ice-bath and poured into 100 cc. of ice water to which 5 cc. of a 10% sodium hydroxide solution had been added. The mixture was shaken with 100 cc. of ether.

The ether layer was separated and shaken with a 10% sodium carbonate solution to take out any alkali-soluble material which might be present. The ether was then dried over sodium sulfate and evaporated, giving an oil. Crystallization was brought about when methanol was added and the solution was immersed in a dry-ice–acetone bath. The crude O-methylated product (V) thus obtained melted at 64–65.5° and weighed about 0.85 g. A small amount of oil remained from which no solid product could be obtained even on long standing dissolved in ligroin. Compound V was dissolved in ligroin and allowed to crystallize slowly. The first crop consisted of small rhombic crystals which melted at 65.5–66°. This was evidently the *cis* form identical with the low melting form obtained by Fuson, Ullyot and Gehrt.[1] A mixed melting point with a sample of their compound confirmed the identity. On longer standing a second crop of crystals appeared, this time in rosets of needles melting at 68–69°. These were the mixed-crystal form consisting of both *cis* and *trans* isomers. A mixture with an authentic sample of the same form showed no lowering of the melting point.

The aqueous layer and the sodium carbonate solution employed to wash the ether layer above were treated as follows. The solution was acidified with dilute sulfuric acid and the precipitate extracted with ether. The ether was dried over sodium sulfate and evaporated, leaving an oil which crystallized to colorless plates on standing in an ice box. The crude material melted at about 126°. It was dissolved in cold 10% sodium carbonate solution, cooled in an ice-bath and acidified to the first permanent turbidity with dilute sulfuric acid. Approximately 0.9 g. of white crystals (VI) was thus obtained melting at 127–128.5°. Addition of more sulfuric acid caused the precipitation of about 0.5 g. more of solid material which proved to be mainly starting material. Compound VI was further purified by recrystallization from aqueous methanol giving small white crystals melting at 130–131°. A mixed melting point with a sample synthesized by the method of Fuson, Ullyot and Gehrt[1] showed no lowering.

Summary

1. It has been shown that *p*-bromophenacyl cyanide reacts with methyl sulfate in the presence of potassium hydroxide to yield the O-methyl ether (II). When the alkylating agent was methyl iodide in the presence of sodium ethoxide the C-methyl derivative (III) was obtained.

2. α-Cyanoacetomesitylene when treated with methyl iodide in the presence of sodium ethoxide has been found to yield roughly equal quantities of the O-methylated derivative (V) and the C-methylated derivative (VI).

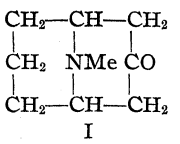
The Validity of the Structure Assigned to Cycloöctatetrene: Pyrolysis of *bis*-Quaternary Ammonium Hydroxides Related to 1,2- and 2,3-Butenes

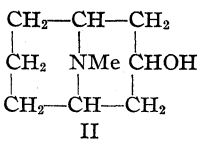
BY CHARLES D. HURD AND LEWIS R. DRAKE

The evidence for the structure of 1,3,5,7-cycloöctatetrene, discovered by Willstätter and Waser[1] and used so widely in theoretical discussions concerning the structure of the aromatic nucleus, rests chiefly on its mode of synthesis from pseudopelletierine and on its hydrogenation to cycloöctane. The hydrogenation evidence does not establish the position of the double bonds at 1,3,5,7 for any cycloöctatetrene should hydrogenate to cycloöctane. In the evidence of synthesis there was the tacit assumption that exhaustive methylation would give rise to conjugate unsaturation; but this was the very feature they were trying to establish. Of course, if other types of unsaturation were present, the structural similarity to benzene would disappear. As is well known, cycloöctatetrene is reactive and displays no such inertness as is found in benzene or diphenylhexatriene,[2] C_6H_5—$(CH=CH)_3$—C_6H_5.

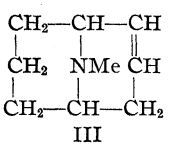
These steps were involved in Willstätter and Waser's synthesis. Pseudo-pelletierine (I) was reduced to II, which was dehydrated to N-methylgranatenine (III). Next, III was converted to a quaternary ammonium salt with methyl iodide, then subjected to a Hofmann degradation. The reaction product was assigned structure IVa,



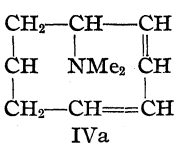
I



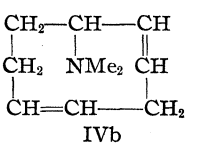
II



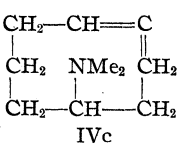
III



IVa



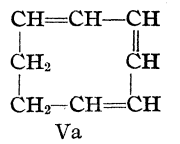
IVb



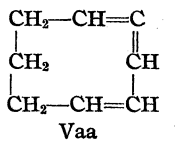
IVc

without submitting evidence, however, to show that this cycloöctadiene skeleton must possess 1,3-unsaturation as in (a) to the exclusion of 1,4- or 1,2-unsaturation as in (b) or (c).

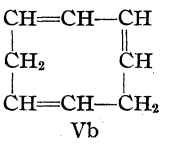
From IVa, a cycloöctatriene was prepared by another process of exhaustive methylation. Its structure was listed as Va, but Vaa may have been produced concurrently. Furthermore, if IVb and IVc were involved in the exhaustive methylation, two other isomers would appear, namely, Vb and Vbb.



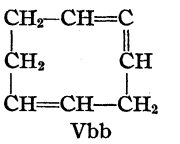
Va



Vaa

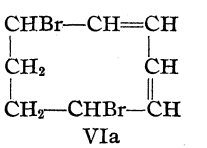


Vb

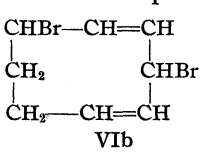


Vbb

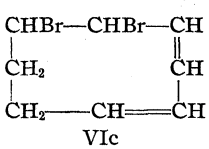
The next step was one of bromine addition to convert C_8H_{10} into $C_8H_{10}Br_2$. If all four cycloöctatrienes participated in this reaction, fourteen such dibromides would be anticipated by normal addition at 1,2- or 1,4- or 1,6-positions (four isomers each from Va and Vaa, and three each from Vb and Vbb). Even if Va were the only isomer, as Willstätter and Waser assumed, these four isomers would be reasonable reaction products



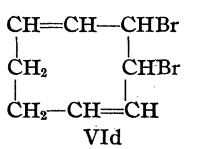
VIa



VIb



VIc



VId

but only from VIa would it be possible to synthesize the conjugated cycloöctatetrene, unless molecular rearrangements were assumed. No evidence eliminated VIb, VIc or VId as reaction products and no evidence was submitted to uphold VIa.

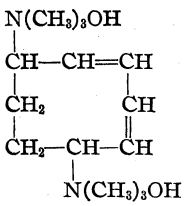
Next, the dibromide (or the dibromide mixture) was heated in benzene with dimethylamine to obtain the *bis-t*-amine, $C_8H_{10}(NMe_2)_2$. Willstätter mentions that this material was not homogeneous but consisted chiefly of an amine which was stable toward acids together with a lesser quantity of an amine which could be hydrolyzed readily. Structures such as C—C—C—NMe_2 or C=C—C—NMe_2 are stable toward hy-

(1) Willstätter and Waser, *Ber.*, **44**, 3433 (1911); Willstätter and Heidelberger, *ibid.*, **46**, 517 (1913)

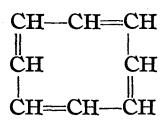
(2) Kuhn and Winterstein, *Helv. Chim. Acta*, **11**, 87 (1928).

drolytic scission, but C—C=C—NMe_2 is a structure which hydrolyzes with acids. It is an ammono analog of the enol ethers and as such it should hydrolyze readily with acids. Structures Vaa and Vbb would yield dibromides which, in turn, would generate the *bis-t*-amines containing the hydrolyzable group C—C=C—NMe_2. It is evident that if Vaa and Vbb are present, this makes a strong case for the presence of all the other isomers.

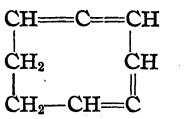
The final step of the synthesis was conversion of the *bis-t*-amine to the *bis*-quaternary ammonium hydroxide, $C_8H_{10}(NMe_3OH)_2$, and pyrolysis of the latter in a Hofmann degradation. The above argument points to the presence of between one and fourteen isomeric quaternary hydroxides. Let us, however, assume the presence of only one of these isomers, namely, the isomer (VII) required by Willstätter and Waser.



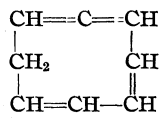
VII



VIIIa



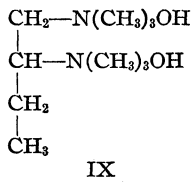
VIIIb



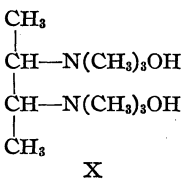
VIIIc

Its breakdown should not necessarily follow an exclusive course leading to 1,3,5,7-cycloöctatetrene (VIIIa). There should be concurrent production of the 1,2,4,5- and 1,2,4,6-isomers (VIIIb and VIIIc, respectively). Of course, other isomers would appear if any of the other fourteen hydroxides entered the reaction.

The question involved may be restated as follows. Must a *bis*-quaternary ammonium hydroxide give rise to conjugate double bonds wherever possible and avoid the production of cumulative double bonds? To obtain evidence on this point it was decided to study the decomposition of some simple *bis*-quaternary bases so that the results would be determined unambiguously. The bases selected for study were the 1,2- and the 2,3-disubstituted butanes, IX and X. The products anticipated from IX by pyrolysis would be methylallene and ethylacetylene, but not 1,3-butadiene. From X one would expect 1,3-butadiene, methylallene and dimethylacetylene.



IX



X

It is possible to analyze either type of gas mixture volumetrically by absorbing ethylacetylene in alkaline potassium iodomercurate solution, 1,3-butadiene in molten maleic anhydride,[3] and methylallene or dimethylacetylene in 82% sulfuric acid. By so doing it was established that IX yielded a mixture containing 44% of ethylacetylene and 56% of methylallene. There was no 1,3-butadiene. The hydrocarbons from X did contain 1,3-butadiene as expected, but it was only to the extent of 42–47% instead of being quantitative. The other 58–53% was a mixture of methylallene and dimethylacetylene. The fact that none of the conjugated hydrocarbon came from IX, and that 1,3-butadiene was not the exclusive product from X casts serious doubt on the structure of Willstätter's cycloöctatetrene.

Experimental Part

Reagents.—Trimethylamine was prepared by the method given in "Organic Syntheses."[4] It was distilled from a Davis column, b. p. 3–4.5°. The synthesis of pure 1-butene and pure 2-butene was described by Hurd and Goldsby.[5] Both of these hydrocarbons were available from this source and were used in the present work. The purity of both was reëstablished, however, by analytical distillation through the Frey–Hepp column. Pure 1-butene also was prepared in the present investigation by pyrolysis of *n*-butyltrimethylammonium hydroxide.

The pure 1-butene was converted into 1,2-dibromobutane by gradual addition of it into a solution of bromine in carbon tetrachloride at −10°. Purification was by distillation through an efficient vacuum-jacketed column. The fraction collected distilled at 165–166°. Similarly, pure 2,3-dibromobutane, b. p. 158–159°, was prepared from pure 2-butene.

***n*-Butyltrimethylammonium Bromide.**—This salt was prepared by mixing 30 g. of *n*-butyl bromide (b. p. 100°) with 12 g. of trimethylamine in a stoppered flask at 0°. After twelve hours, crystals were noticeable. The mixture was then left at room temperature for a week. The nearly solid mass was crystallized several times from butanol, washed a few times with ether, and centrifuged. The salt was deliquescent. In a sealed tube it melted at 197–198°. The yield was 39.7 g. or 92.5%.

Anal. Calcd. for $C_7H_{18}NBr$: Br, 40.8. Found: Br, 40.8, 40.6.

(5) Hurd and Goldsby, THIS JOURNAL, **56**, 1813 (1934).

1-Butene.—To 6.65 g. of the bromide dissolved in 30 cc. of water, 3.94 g. of silver oxide was added. The mixture was shaken intermittently for one hour and the silver bromide filtered off. The filtrate was placed in a modified 50-cc. Claisen flask attached in series to a 50-cc. receiver, a small bubbler containing concd. hydrochloric acid, and a 2.5-liter bottle filled with salt solution. The bottle was disconnected at the outset.

The air in the system was displaced by nitrogen, and the contents of the flask heated to incipient boiling. Then the bottle was connected. When all the water was distilled off, the oil-bath temperature was raised slowly to 250°. Vigorous bubbling took place and about 750 cc. of gas was collected in the bottle.

The gas was dried through a soda-lime tube and was liquefied at −80° in the bulb of the Frey–Hepp column.[5] On distillation, 630 cc. of pure 1-butene was collected between −6.0° and −5.6°. There was no 2-butene.

1,2-Butane-bis-(trimethylammonium) Bromide.—A mixture of 22 g. of 1,2-dibromobutane and 10 g. of trimethylamine was left for two weeks at room temperature in a tightly-stoppered flask. The amount of crystals did not increase much after the first week. The excess of trimethylamine was boiled off and absorbed in hydrochloric acid. Then the excess of dibromobutane was decanted and the solid recrystallized from 20 cc. of butyl alcohol, rinsed repeatedly with dry ether, centrifuged, and stored in a vacuum desiccator over sulfuric acid; yield, 4.86 g. or 21%.

Anal. Calcd. for $C_{10}H_{26}N_2Br_2$: Br, 47.87. Found: Br, 47.77, 48.08.

Pyrolysis

Run 1.—A mixture of 4.26 g. (0.0128 mole) of this bromide, 30 cc. of water, and 3 g. (0.0128 mole) of silver oxide was shaken for one hour and the solution was filtered. The filtrate was heated first at 100°, then at 200–250° as described above for the decomposition of butyltrimethylammonium bromide. At the end of the reaction, the apparatus was filled with water to drive over the last portion of gas. In all, 300–310 cc. of gas was obtained.

Run 2.—The same quantities and apparatus were used as before, but this time the solution was allowed to drip into the hot flask (oil-bath at 250°) instead of warming the solution gradually. As before, the apparatus was filled with water at the end of the run. Three hundred thirty cc. of gas was secured.

Analysis.—No 1,3-butadiene was found. It was sought for by passing a sample of the gas through molten maleic anhydride[3] at 100°. Ethylacetylene was determined by absorption[6] in alkaline potassium iodomercurate solution. Methylallene, or a mixture of methylallene and dimethylacetylene, was determined by absorption in 83% sulfuric acid. Air made up 23.0–23.5% of the gas in both runs.

On an air-free basis, run 1 contained 44.5% ethylacetylene and 55.5% methylallene. Run 2 contained 45.5% ethylacetylene and 54.5% methylallene.

2,3-Butane-bis-(trimethylammonium) Bromide.—The same general procedure was used as that for the 1,2-analog. The quantities taken were 32 g. of trimethylamine and 52 g. of 2,3-dibromobutane. As before, a small quantity of oil separated in the first twelve hours only to be replaced by small cubical crystals in another twelve hours. The reaction was left for two weeks. After thorough purification, 4.9 g. (or 6.1%) of the salt was obtained.

Anal. Calcd. for $C_{10}H_{26}N_2Br_2$: Br, 47.87. Found: Br, 46.73, 48.90.

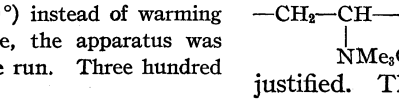
Pyrolysis.—Two runs were performed. Run 1 followed the conditions of run 1 of the 1,2-analog, with 3.72 g. of the salt in 30 cc. of water being treated with 2.6 g. of silver oxide. The volume of gaseous decomposition products was 250 cc. Run 2, with 4.00 g. of the salt, 30 cc. of water and 2.8 g. of silver oxide, corresponded in manipulative detail to run 2 of the 1,2-analog. About 240 cc. of gas was collected.

Gas Analysis.—On an air-free basis runs 1 and 2, respectively, analyzed as follows: 1,3-butadiene 42.5, 47.5; methylallene (or methylallene + dimethylacetylene) 57.5, 52.5. In both runs, there was 45–46% of air present.

Summary

Both 1,2- and 2,3-butane-*bis*-(trimethylammonium) bromides have been prepared from pure specimens of 1,2-dibromobutane and 2,3-dibromobutane. Pyrolysis of the *bis*-quaternary hydroxide from the 1,2-salt gave rise to ethylacetylene and methylallene, but no 1,3-butadiene. Pyrolysis of the bis-quaternary hydroxide from the 2,3-salt yielded 1,3-butadiene and methylallene (or methylallene + dimethylacetylene), the latter being slightly in excess of the 1,3-butadiene.

The assumption that conjugated unsaturation results exclusively during pyrolysis of the



functional group is unjustified. This assumption was made by Willstätter and Waser in their alleged synthesis of 1,3,5,7-cycloöctatetrene. The fact that 1,3-butadiene was not the exclusive product from 2,3-butane-*bis*-(trimethylammonium) hydroxide casts serious doubt on the structure of Willstätter's cycloöctatetrene.

Carbonium Ions and the Hydrolysis of Alkyl Halides

BY R. A. OGG, JR.

A considerable controversy has developed concerning interpretation of the rates of alkyl halide hydrolysis by neutral water (as distinguished from substitution reaction with hydroxyl ion).[1] Hughes and Ingold assume that the mechanism embodies a slow unimolecular dissociation of the alkyl halide into halide ion and organic cation with an incomplete valence shell (an "open sextet"), followed by the rapid reaction of this cation with water to yield alcohol and hydrogen ion. Olson and Halford, as well as Taylor, conclude that the rate determining step is a bimolecular reaction of a water molecule with alkyl halide to yield halide ion and a cation whose valence shell is completed by coordination of a previously unshared electron pair of a water molecule. The further complications suggested by Hammett do not affect the important distinction between these mechanisms. The author wishes to show that consideration of the energetics of the various reactions allows an unequivocal decision as to the mechanism of methyl halide hydrolysis.

The energy of dissociation of a gaseous methyl halide into gaseous ions has been made accessible to calculation by the determination of the ionization potential of methyl radical.[2] The application of Hess' law in the case of methyl chloride is given below. The energies of reaction are given in kilocalories per mole, roughed off to the nearest whole number (because of experimental uncertainties).

$$\begin{aligned} CH_3Cl(g) &\longrightarrow CH_3(g) + Cl(g) && -75\ ^{3} \\ CH_3(g) &\longrightarrow CH_3^+(g) + e(g) && -258^{2} \\ Cl(g) + e(g) &\longrightarrow Cl^-(g) && +86\ ^{4} \\ \hline CH_3Cl(g) &\longrightarrow CH_3^+(g) + Cl^-(g) && -247 \end{aligned}$$

Similarly, one finds

$$\begin{aligned} CH_3Br(g) &\longrightarrow CH_3^+(g) + Br^-(g) && -238 \\ CH_3I(g) &\longrightarrow CH_3^+(g) + I^-(g) && -229 \end{aligned}$$

The energies of dissociation[3] of CH_3Br and CH_3I are taken, respectively, as 62 and 45 kcal., and the electron affinities[4] of Br and I as 82 and 74 kcal. While the estimated energy effects apply to reactions at absolute zero, for purposes of this discussion they are not significantly different from the reaction energies at moderate temperatures (a few hundred degrees absolute).

To estimate the energy effects for the corresponding processes in aqueous solution, it is necessary to know the energies of solution of the various substances in water. Energies of solution of gaseous methyl halides in water have not been determined. However, the energies of solution of the liquid halides are certainly small, and will be taken as zero. The energy of vaporization of the liquid halide then gives the desired quantity.

If the methyl ion in solution retains its open sextet of valence electrons, as assumed by Hughes and Ingold, then its solvation energy must arise from essentially the same factors contributing to the solvation energy of positive ions of noble gas type—*i. e.*, alkali metal ions. The hydration energy[4] of alkali metal ions is an inverse function of the ionic "size"—*i. e.*, of the effective extension of electron charge density. Since the methyl ion has eight electrons and a nuclear charge distributed over four centers, its spatial extension of electron charge density is certainly greater than that of lithium ion (with only two electrons), and in fact is probably similar to that of sodium ion (ten electrons). Hence the hydration energy of lithium ion safely may be taken as an upper limit for the hydration energy of methyl ion with an open sextet of electrons.

The following hydration energies[4] are used

$$\begin{aligned} Li^+(g) + Cl^-(g) &\longrightarrow Li^+(aq) + Cl^-(aq) + 206 \\ Li^+(g) + Br^-(g) &\longrightarrow Li^+(aq) + Br^-(aq) + 197 \\ Li^+(g) + I^-(g) &\longrightarrow Li^+(aq) + I^-(aq) + 186 \end{aligned}$$

Therefore it is to be assumed

$$\begin{aligned} CH_3^+(g) + Cl^-(g) &\longrightarrow CH_3^+(aq) + Cl^-(aq) + (<206) \\ CH_3^+(g) + Br^-(g) &\longrightarrow CH_3^+(aq) + Br^-(aq) + (<197) \\ CH_3^+(g) + I^-(g) &\longrightarrow CH_3^+(aq) + I^-(aq) + (<186) \end{aligned}$$

(As before, reaction energies are in kilocalories per mole.)

From the above, one may estimate a lower limit for the energy of dissociation of aqueous methyl chloride into aqueous chloride ion and aqueous methyl ion (with an open sextet).

(4) J. E. Mayer and L. Helmholz, *Z. Physik*, **75**, 19 (1932).

$$CH_3Cl(g) \longrightarrow CH_3^+(g) + Cl^-(g) \quad -247$$
$$CH_3^+(g) + Cl^-(g) \longrightarrow CH_3^+(aq) + Cl^-(aq) \quad +(<206)$$
$$CH_3Cl(aq) \longrightarrow CH_3Cl(l) \quad 0$$
$$CH_3Cl(l) \longrightarrow CH_3Cl(g) \quad -5^5$$
$$CH_3Cl(aq) \longrightarrow CH_3^+(aq) + Cl^-(aq) \quad -(>46)$$

Similarly

$$CH_3Br(aq) \longrightarrow CH_3^+(aq) + Br^-(aq) \quad -(>47)$$
$$CH_3I(aq) \longrightarrow CH_3^+(aq) + I^-(aq) \quad -(>50)$$

(The energies of vaporization[5] of CH_3Br and CH_3I are taken, respectively, as 6 and 7 kcal.)

These figures must be regarded not only as lower limits for the dissociation energies, but as very much below the probable values. It was pointed out above that the "size" of a methyl ion with an open sextet is probably similar to that of a sodium ion. If the hydration energies[4] of the two are assumed to be the same, then the corresponding dissociations of aqueous methyl chloride, bromide and iodide into ions are endothermic by 72, 72 and 74 kcal., respectively.

The unimolecular dissociations postulated by Hughes and Ingold would thus be endothermic by at least some 50 kcal. (and more probably by some seventy) in the case of methyl halides. The activation energies would in consequence be greater than 50 kcal. A unimolecular reaction with a normal temperature independent factor[6] of some 10^{13} sec.$^{-1}$ and an activation energy of 50 kcal. would have a rate constant of only some 10^{-16} sec.$^{-1}$ at 100°. This must be regarded as an absolute upper limit for the rate constant of methyl halide hydrolysis at 100° by the Hughes–Ingold mechanism. Actually, the respective rate constants for the hydrolysis of methyl chloride, bromide and iodide in aqueous solution[7] at 100° are 1.08×10^{-4}, 1.31×10^{-3} and 4.47×10^{-4} sec.$^{-1}$. Thus the actual reactions are more rapid by many powers of ten than is possible by the Hughes–Ingold mechanism. The observed respective activation energies are some 22.7, 21.4 and 23.1 kcal. at 100°, and some 27.7, 26.5 and 28.1 kcal. at 25°—values far lower than the lowest possible limits for the Hughes–Ingold mechanism.

On the other hand, it can be shown that the energetics of the Olson–Halford mechanism are entirely compatible with the experimental data for methyl halide hydrolysis. It is to be noted that a methyl ion coördinated to a water molecule is identical with a proton coördinated to a methyl alcohol molecule—only one electronic structure being possible for $CH_3OH_2^+$. Hence the basic strength of methyl alcohol gives a clue to the energy relations of $CH_3OH_2^+$. For the distribution of protons between methyl alcohol and water molecules the equilibrium constant[8] at 25° is some 0.235—water being the stronger base. It appears unlikely that the transfer of a proton from methyl alcohol to water will involve a large entropy change. If it is assumed that the free energy change is given entirely by the energy of reaction, this latter is equal to $RT \ln (1/0.235)$, which at 298° absolute is only about 1 kcal. Hence it is assumed

$$H_3O^+ + CH_3OH \longrightarrow H_2O + CH_3OH_2^+ \quad -1$$

To estimate the energy of dissociation of aqueous methyl chloride into chloride ion and $CH_3OH_2^+$ the following summation is used.

$$CH_3Cl(aq) + OH^-(aq) \longrightarrow CH_3OH(aq) + Cl^-(aq) \quad +18^9$$
$$2H_2O(l) \longrightarrow H_3O^+(aq) + OH^-(aq) \quad -14^5$$
$$H_3O^+(aq) + CH_3OH(aq) \longrightarrow H_2O(l) + CH_3OH_2^+(aq) \quad -1$$
$$CH_3Cl(aq) + H_2O(l) \longrightarrow CH_3OH_2^+(aq) + Cl^-(aq) \quad +3$$

Similarly it is found

$$CH_3Br(aq) + H_2O(l) \longrightarrow CH_3OH_2^+(aq) + Br^-(aq) + 0$$
$$CH_3I(aq) + H_2O(l) \longrightarrow CH_3OH_2^+(aq) + I^-(aq) + 3$$

Thus dissociation of aqueous methyl halide into halide ion and $CH_3OH_2^+$ is a practically thermoneutral (or slightly exothermic) reaction. This is entirely compatible with the activation energy of the hydrolytic reaction by the Olson–Halford scheme. It is apparent that the reverse reaction (synthesis of methyl halide) must have a considerable activation energy. That is, the slowness of the reactions is due to a "true" activation energy.

It therefore appears that the experimental results of methyl halide hydrolysis are explicable in terms of the Olson–Halford mechanism, but not by that of Hughes and Ingold. The course of the reaction is to be pictured (using say CH_3Cl)

$$H_2O + CH_3Cl \longrightarrow H_2OCH_3^+ + Cl^- \quad \text{(slow)} \quad (1)$$
$$H_2O + H_2OCH_3^+ \longrightarrow H_3O^+ + HOCH_3 \quad \text{(rapid)} \quad (2)$$

Reaction (1) is formally similar to a substitution reaction of alkyl halide with a negative ion[10] in that one electron pair bond is broken and one is formed. Like the negative ion substitution reac-

tion, it is undoubtedly attended by Walden inversion.[10]

The dissociation energy of ethyl radical[2] into gaseous ethyl ion and electron is 245 kcal. per mole. If the bond energies are the same as for methyl halides, then the dissociation energies of gaseous ethyl halides into gaseous ethyl radical and halide ions are each some 13 kcal. less than the corresponding values for methyl halides. On the other hand, the "size" of the ethyl ion is undoubtedly greater than that of methyl ion, and in consequence its hydration energy (retaining the "open sextet" structure) must be less than that of methyl ion. Hence the calculated dissociation energies of aqueous ethyl halides into aqueous ethyl ion (with an "open sextet") and aqueous halide ions must be similar in magnitude to the corresponding values for methyl halides.

Only qualitative information is available concerning the rate of hydrolysis of ethyl halides by neutral water. At 100° the hydrolysis of ethyl iodide[11] is definitely slower than that of methyl iodide, but the two rates are of comparable magnitudes. A similar relation may be inferred for the hydrolysis of ethyl bromide and chloride. It thus seems probable that the activation energies for ethyl halide hydrolysis are similar to those for methyl halides, *i. e.*, some 25–30 kcal. From the preceding paragraph it is apparent that this is far less than the value demanded by the Hughes-Ingold mechanism. On the other hand, since the basic strengths of methyl and ethyl alcohols are similar, the dissociation of aqueous ethyl halide into $C_2H_5OH_2^+$ and halide ion is essentially thermoneutral. Thus the observed activation energy for ethyl halide hydrolysis is entirely compatible with the Olson–Halford mechanism.

For various other processes occurring in aqueous solution, in which CH_3^+ and $C_2H_5^+$ may be postulated as intermediates, energy calculations similar to the above indicate that the required activation energies are so large as to rule out the participation of these ions in reactions observable at ordinary temperatures. It is interesting to note the parallelism with the state of protons in aqueous solution. It is now generally recognized that the extremely large hydration energy of a proton is explicable only in terms of coördination with an unshared electron pair of a water molecule, forming H_3O^+. Similarly, methyl and ethyl "ions" in aqueous solution must be regarded as $CH_3OH_2^+$ and $C_2H_5OH_2^+$. Just as the concept of transient existence of "naked" protons has been discredited, so it appears that the concept of transient existence of CH_3^+ or $C_2H_5^+$ with an "open sextet" must be abandoned.

Considerations similar to the above apply to solvents other than water, whose molecules still possess one or more unshared electron pairs. Such solvents are ammonia, amines, sulfur dioxide, ethers, alcohols, carboxylic acids, etc. Since solvation energies of ions in such solvents do not differ radically from those in water, the production of methyl or ethyl ions with an open sextet demands activation energies comparable to those calculated for aqueous solutions, and hence is too slow to contribute to observable reactions. The real ionic intermediates are to be regarded as the coördination complexes of CH_3^+ or $C_2H_5^+$, such as $CH_3NH_3^+$, $CH_3OHCH_3^+$, etc.

Extension of such numerical calculations to higher alkyl halides cannot be made reliably. Bond energies are more uncertain, and appropriate data regarding ionization potentials of higher alkyl radicals are completely lacking. However, it must be borne in mind that solvation energies of larger alkyl radicals (with an "open sextet") are necessarily considerably less than that of CH_3^+. While it is probably true that the ionization potentials of large radicals are also less than that of methyl radical, it seems highly improbable that the difference of ionization potential and solvation energy can decrease sufficiently to make the Hughes–Ingold mechanism energetically feasible in any case. It appears that all "carbonium ions" are to be regarded as coordination complexes with a solvent molecule, and that any reaction calling for participation of ions with an "open sextet" will probably be too slow to be observable under ordinary conditions. The kinetic studies of the hydrolysis of higher alkyl halides are all to be interpreted in terms of the mechanism discussed above for methyl halides —*i. e.*, as a reaction with the solvent molecule, yielding halide ion and $R_3COH_2^+$.

Carbonium ions with an "open sextet" have been postulated freely in mechanisms for various molecular rearrangements. As a typical example, the formation of a mixture of crotyl bromide and methylvinylcarbinyl bromide from either of the pure carbinols and hydrogen bromide[12]

(11) J. Greenspan, S. Liotta and V. K. La Mer, *Trans. Faraday Soc.*, **31**, 824 (1935).

(12) W. G. Young and J. F. Lane, THIS JOURNAL, **60**, 847 (1938).

has been interpreted in terms of resonance between the structures $CH_3—CH=CH—CH_2^+$ and $CH_3—CH^+—CH=CH_2$. If such ions are coordinated with solvent molecules, obviously the possibility of resonance disappears. The following alternative mechanism is entirely in accord with the considerations advanced above

$$CH_3—CH=CH—CH_2OH + HBr \longrightarrow CH_3CH=CH—CH_2OH_2^+ + Br^- \quad (1)$$

$$CH_3—CH=CH—CH_2OH_2^+ + Br^- \longrightarrow CH_3—CH=CH—CH_2Br + H_2O \quad (2)$$

$$CH_3—CH=CH—CH_2OH_2^+ + Br^- \longrightarrow CH_3—CHBr—CH^-—CH_2OH_2^+ \quad (3)$$

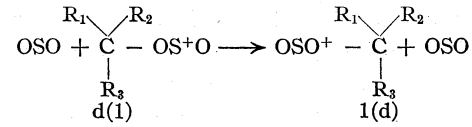
$$CH_3—CHBr—CH^-—CH_2OH_2^+ \longrightarrow CH_3—CHBr—CH=CH_2 + H_2O \quad (4)$$

and similarly for methylvinylcarbinol. It should be noted that reaction (2) (of the usual type accompanied by Walden inversion) gives the normal product, while reactions (3) and (4) yield the rearranged product. Reactions (3) and (4) are similar to those previously postulated to explain the addition of halogens to ethylene linkages.[13]

The various cases in which rapid racemization of optically active carbonium ions has been noted[14] are explicable in terms of an identical exchange reaction of the coördinated ion with the solvent molecules, as, say, in liquid sulfur dioxide.

(13) R. A. Ogg, Jr., THIS JOURNAL, **57**, 2727 (1935).

(14) E. S. Wallis and F. H. Adams, *ibid.*, **55**, 3838 (1933); E. Bergmann and M. Polanyi, *Naturwissenschaften*, **21**, 378 (1933).



The above two examples are typical. It seems legitimate to state that it is never necessary to assume the existence of carbonium ions with an open sextet as intermediates in organic reactions, and that in view of the considerations of reaction energetics advanced above, preference is to be given to mechanisms not involving such ions.

Summary

It is shown that dissociation of a methyl halide (in aqueous solution) into a methyl ion with an "open sextet" and a halide ion is endothermic by at least some 50 kcal. per mole, and more probably by some 70 kcal. On the other hand, reaction with water to yield halide ion and the coordinated methyl ion $CH_3OH_2^+$ is practically thermoneutral. Comparison with the experimental data for methyl halide hydrolysis leads to rejection of the Hughes–Ingold mechanism (involving CH_3^+) in favor of the Olson–Halford mechanism (involving $CH_3OH_2^+$).

It is suggested that carbonium ions with an open sextet never play an appreciable role in observable organic reactions, and that mechanisms employing such ions must be abandoned.

Physical Studies of Non-aqueous Solvates. III. The Vapor Pressure of Zinc Bromide–Diethyl Ether Solutions

BY H. H. ROWLEY AND FLORENCE V. OLSON[1]

Considerable work has been reported on the preparation and properties of magnesium bromide–diethyl ether systems.[2–4] Extension of the investigation of non-aqueous solvates would naturally include systems resembling the one already mentioned. The zinc bromide–diethyl ether system was chosen for this investigation since zinc belongs to the same periodic group as magnesium and the formulas of the compounds of the two metals are similar. Further, zinc, like magnesium, adds to alkyl halides in an ether medium to form organo-metallic compounds.

One of the first to report in the literature on zinc bromide diethyl etherates was Nickles,[5] who found them to be quite unstable. Raynaud[6] later prepared zinc bromide, using Nickles' method. The two layer system first formed, the lower layer of which was reddish in color, disappeared on further addition of bromine to give a homogeneous, brownish-violet liquid. Removal of excess ether left a

black liquid stable at 110°, which on analysis corresponded to $ZnBr_2 \cdot (C_2H_5)_2O$. Raynaud claimed verification of this monoetherate by preparing it in a different manner. Sublimed zinc bromide was dissolved in ether and the excess ether removed by heating on a water-bath. The resulting viscous solution was allowed to crystallize in a desiccator containing tallow and concentrated sulfuric acid. Analysis of the solid gave percentages that corresponded to those calculated for the monoetherate.

To check these results and establish other possible diethyl etherates of zinc bromide as well as to learn something of their stability, the vapor pressures of saturated solutions of zinc bromide–diethyl ether solutions were measured over the temperature range −10 to +35°. The wet solids in contact with the saturated solutions were also analyzed at certain temperatures.

Experimental

Apparatus and Materials.—The vapor pressures were measured by the static method using the same apparatus and technique described in a previous paper.[4c] The diethyl ether was of reagent grade, dried, distilled and kept over freshly cut sodium, only the middle third fraction of the distillate being used.

At first, an attempt was made to prepare the solution of zinc bromide in ether by Nickles' method,[5] which was to treat pure zinc turnings in ethyl ether with liquid bromine, cooling when necessary to avoid too violent a reaction. But instead of a colorless two-layer system, like that of magnesium bromide in ether,[2] a yellowish colored two-layer system was first formed, which upon further addition of bromine became a homogeneous purplish-black liquid, as was described by Raynaud.[6]

Another method tried was that of treating a solution of dry hydrogen bromide in ether with zinc turnings. Hydrogen was evolved, and after a short interval a colorless, partially immiscible liquid phase appeared which lasted only as long as the solution was saturated with hydrogen bromide. No solid was precipitated at room temperature from solutions thus prepared.

The method finally used in preparing the solutions was that of adding pure anhydrous zinc bromide to dry ether until a fairly concentrated solution was obtained. The solid zinc bromide was obtained by subliming the C. P. anhydrous product (Baker Analyzed) in a specially constructed Pyrex vessel. During the sublimation and in all subsequent handling of the solutions, the work was carried out in an atmosphere of dry carbon dioxide.

Procedure.—The unsaturated solution, at room temperature, was transferred to the vapor pressure flask, cooled to −78° in carbon dioxide–acetone bath, quickly sealed to the apparatus and evacuated at that temperature with a good oil pump for about thirty minutes. The mercury was then raised in the differential manometer, cutting off the sample flask from the vacuum system, and the sample raised to a sufficiently high temperature to dissolve the solid which was precipitated at the low temperature. The sample was again cooled to −78° and the space above evacuated. In this way, occluded gases could be removed from the sample.

Before readings on the differential manometer were taken, the flask was kept at the desired temperature for several hours, if a solid phase were present at that temperature. If the solution were unsaturated at the desired temperature, known amounts of ether were distilled from the sample until it did contain a solid phase under the conditions desired. Since the solid phases seldom formed of themselves, because of suspended transformation, in order to obtain the stable solid phases it was necessary to cool the samples to fairly low temperatures and then bring them to the desired temperature range and allow them to come to equilibrium.

It was found that a sample which contained considerable solid at 0° might be unsaturated at higher temperatures. Thus as the temperature was raised it was necessary to reduce the amount of ether in the sample. The excess ether was condensed in a calibrated reservoir and the volume recorded. At the end of the measurements all the ether was distilled from the sample into the reservoir, the sample flask was filled with dry air, cut off, and weighed. It was then cleaned, dried and weighed again, and the weight of the pure zinc bromide determined. From the volume and the density of ether at 25°, the moles of ether could be calculated and the mole ratio of diethyl ether to zinc bromide determined for any series of measurements.

The approximate composition of the stable solid phase in equilibrium with the saturated solution at a definite temperature, was determined in the following manner. Saturated solutions were prepared in small flasks, allowed to come to equilibrium and the supernatant solution was poured off quickly. Keeping the temperature as nearly constant as possible, the wet solid was drained for a few minutes, then a sample was weighed, dissolved in water and the total bromide concentration determined gravimetrically as silver bromide.

To check the results of Raynaud,[6] solutions saturated at room temperature were decanted into small evaporating dishes, which were placed in a desiccator containing lard and concentrated sulfuric acid for the adsorption of ether vapor. After a few days, a solid was precipitated, samples of which were taken and analyzed in the manner just described.

Discussion of Results

The vapor pressure study of this system presented difficulties due to the high solubility of zinc bromide in diethyl ether giving rise to viscous, sluggish solutions. Unsaturated solutions at +25°, which would normally contain solid at +15°, could be cooled to 0° and left there for an indefinite time without crystallization occurring. An example of this suspended transformation is shown in Fig. 1, where the logarithm of the vapor pressure is plotted against the corresponding reciprocal absolute temperature. The continuous line at the left in the graph is for the system liquid–

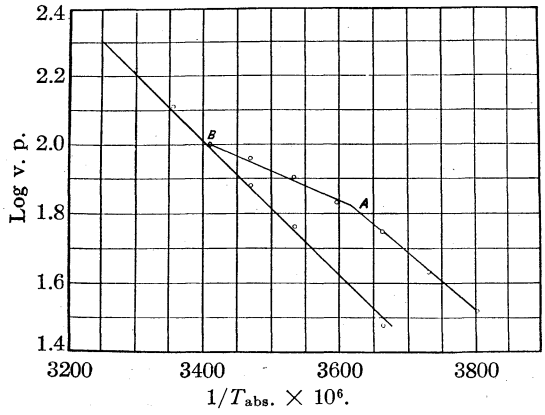

Fig. 1.

vapor, containing no solid. Above point B it represents an unsaturated solution, below B, a supersaturated solution. The other two lines represent the same system when stable solid phases were present with the liquid and vapor phases.

TABLE I

CHANGE OF VAPOR PRESSURE WITH TEMPERATURE FOR THE SYSTEM ZINC BROMIDE–DIETHYL ETHER

Temp. of bath, °C.	$1/T_{abs.} \times 10^6$	Vapor press., mm.	No. of samples	Log v. p.
−10	3802	34 ± 1	4	1.5315
− 5	3731	41 ± 2	4	1.6128
0	3663	57 ± 2	7	1.7559
+ 5	3597	70 ± 4	4	1.8451
10	3534	79 ± 4	4	1.8976
15	3472	89 ± 4	4	1.9494
20	3413	101 ± 2	4	2.0043
25	3356	118 ± 3	5	2.0719
30	3300	156 ± 1	2	2.1931
35	3247	192 ± 1	2	2.2833

Table I lists the data graphed in Fig. 2 for systems of zinc bromide–diethyl ether in which there was a solid, liquid and vapor phase present for the temperature range −10 to +35°. The extreme slowness with which the system attained equilibrium and the persistence of the metastable phases made it difficult to obtain precise vapor pressure measurements. It is to be noted in both Fig. 1 and Fig. 2 that there is a definite change of slope at points A and B. The first break, at point A in both graphs, occurs between 0 and 5°, and the second, at point B, in the neighborhood of 20°. These changes in slope would indicate a change in the nature of the solid phase in equilibrium with the solution. Since there are three sections to the curve, it might be assumed that three distinct solid phases are present in the temperature interval −10 to +35°, the first stable up to about 5°, the second between 5 and 20° and the third stable above 20°.

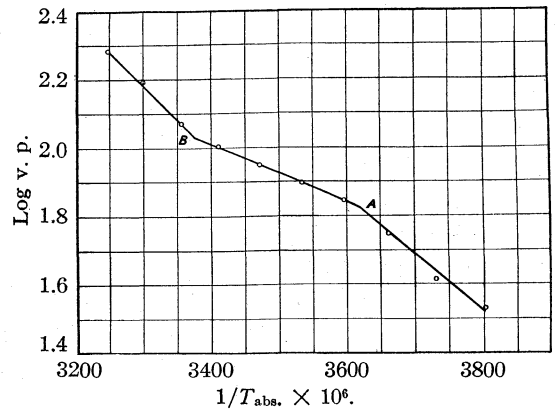

Fig. 2.

These changes in the solid phases could be seen directly. The solid in equilibrium with the saturated solution at 0° crystallized in transparent plates. Between 0 and 5° these disappeared and the solid in equilibrium at 15° was composed of transparent needles. At 25° and above the equilibrium solid was opaque and finely divided so that no crystalline shape was evident.

In order to establish the composition of the solid phase in equilibrium with the solution, samples were analyzed as described. Due to the unstability of the solids and viscosity of the solutions, it was not possible to remove all of the occluded liquid. Hence the "wet solids" were analyzed in an effort to obtain an approximate composition. The results of these analyses at 0, 15 and 25° are summarized in Table II.

TABLE II

ANALYSIS OF "WET SOLIDS" IN EQUILIBRIUM WITH SOLUTIONS

Temp., °C.	No. of samples analyzed	Wt. % $ZnBr_2$
0	5	58.7 ± 0.6
15	3	70.7 ± 0.5
25	6	85.6 ± 1.4

Determinations of zinc bromide in the wet solid at 0° always gave values around 59 wt. %. The theoretical value of zinc bromide in the dietherate, $ZnBr_2 \cdot 2(C_2H_5)_2O$, is 60.3% and that in the trietherate, $ZnBr_2 \cdot 3(C_2H_5)_2O$, is 50.3 wt. %. The value for the zinc bromide in the solid will be lower than that in the pure etherate because the solid was always wet with solution, which contains only 55–57 wt. % of zinc bromide at 0°. Therefore, it can be concluded that the solvate in equilibrium with the solution at 0° is the dietherate.

Likewise, the average value of 70.7 wt. % for the determination of zinc bromide in the solid, stable in contact with the saturated solution at 15°, agrees favorably with the theoretical value, 75.3, of the weight per cent. of zinc bromide in the monoetherate, $ZnBr_2 \cdot (C_2H_5)_2O$. The solubility of zinc bromide at 15° is approximately 68–69 wt. %.

Analyses of the wet solid, stable in contact with the saturated solution at 25°, would vary somewhat according to the extent to which the viscous solution was drained from the solid. The average value of 85.6% indicates that the monoetherate is not stable at this temperature. The solubility of zinc bromide at 25° is approximately 69–70 wt. %.

From these results, it would appear that the transition in the solid phase in the range 0 to 5° is that of the dietherate of zinc bromide to the monoetherate, and the transition of the solid phase in the neighborhood of 20° is that of the monoetherate to the unsolvated zinc bromide.

The results of this investigation do not agree with those of Raynaud.[6] He stated that the solubility of zinc bromide in diethyl ether at 25° was about 45 wt. %; the value found in this work is 69–70 wt. %. He stated further that the monoetherate is stable at room temperature. Part of his work was repeated in this Laboratory and the wet solid formed by allowing a solution to evaporate in a desiccator gave an average value of 86.7 wt. % zinc bromide. With a specially well drained sample this value rose to 90%. The indications in the present work are that the monoetherate, in contact with solution, decomposes in the neighborhood of 20°.

Several possible sources of error may be pointed out in Raynaud's work. As was found in the present study, bromination of zinc in diethyl ether led to the formation of a dark homogeneous liquid. To conclude that this was a pure solution of zinc bromide in ether or to draw any conclusions on the existence of the monoetherate from analysis of this dark liquid certainly was not justifiable. In the present study, a dark liquid was not obtained at any time when pure zinc bromide was dissolved in ether. A further criticism of Raynaud's work is that he mentioned taking no special precautions to exclude moisture in the dissolving of solid zinc bromide in ether. Since zinc bromide hydrolyzes in water, the presence of moisture may have caused the variations in the analyses of the solutions and in the analyses of the solid obtained by allowing the solution to evaporate in a desiccator.

Summary

1. A study of the vapor pressures of the system zinc bromide–diethyl ether over the temperature range −10 to +35° has been made.

2. The existence of the two etherates, the dietherate of zinc bromide, $ZnBr_2 \cdot 2(C_2H_5)_2O$, and the monoetherate, $ZnBr_2 \cdot (C_2H_5)_2O$, has been indicated by (a) breaks occurring between 0 and 5° and in the neighborhood of 20° in the curve obtained by plotting the logarithms of the vapor pressures of the system against the reciprocal of the absolute temperature; (b) analyses of the wet solids in contact with the saturated solutions at 0, 15 and 25°; (c) changes in the appearance of the solids in the ranges 0 to 5° and in the neighborhood of 20°.

3. Disagreements with Raynaud on the system zinc bromide–diethyl ether have been mentioned, and possible sources of error in his work indicated.

Changes in pH of Irradiated Egg Albumin Solutions[1]

BY F. W. BERNHART

A change can be observed in the pH of a protein solution after denaturation. The changes in pH produced by the denaturation process vary qualitatively and quantitatively, depending upon the type of denaturation employed. Previous reports in regard to the changes of pH resulting from ultraviolet denaturation of proteins in solutions are at variance. Mond[2] observed decreases of pH after ultraviolet irradiation of egg albumin and serum albumin solutions when the initial pH of the solution was above the protein isoelectric point, and a rise in pH when the initial pH was below the isoelectric point. Clark[3] found that the pH of egg albumin solutions decreased after irradiation when the initial pH was either acid or alkaline with respect to the isoelectric point. Stedman and Mendel[4] found that irradiation caused a drop in the pH, but the initial pH of the solutions was not given. Decreases in the pH of unbuffered distilled water after ultraviolet irradiation led these workers to interpret the drop in pH during irradiation of protein solutions as due to a change in the water. The present investigation was undertaken to examine the validity of these conflicting results.

Methods.—A Burdick air-cooled quartz mercury arc was used as a source of ultraviolet radiant energy. Two quartz mercury arcs, varying greatly in ultraviolet radiant energy output, were used during the investigation. Approximately 20 cc. of the egg albumin solutions were irradiated in quartz test-tubes (20 × 130 mm.), 19.5 cm. from the light source. The irradiation vessels were placed in a constant temperature water-bath held at 25°. Crystalline egg albumin was prepared by the method of Cole[5] and recrystallized twice Salts were removed, using the apparatus described by Bernhart, Arnow and Bratton.[6] About 10 cc. of a concentrated egg albumin solution, stored at 5° and preserved with a toluene paraffin oil layer, was measured accurately and diluted to 100 cc. with distilled water and a definite volume of hydrochloric acid or sodium hydroxide solution. The pH of this solution was measured with the glass electrode. Fresh solutions were prepared from the stock solution immediately before each irradiation. In one series of irradiations a nitrogen atmosphere was obtained by alternately evacuating and bubbling nitrogen through the solution (plus 0.02 cc. of *n*-heptyl alcohol to inhibit foaming) contained in the irradiation tube. The glass tubing employed was then sealed off and the stopper sealed. *n*-Heptyl alcohol (0.02 cc.) in 20 cc. of 0.01 *M* phosphate buffer (pH 6.5 were irradiated for forty-eight hours under nitrogen; this procedure caused no change in the pH of the mixture. In the other series of irradiations free access of air was obtained by fitting the stoppers of the quartz tubes with bent glass tubing. After each irradiation the pH of the solution was again determined.

Results

Change in pH as a Function of Initial pH.—The data obtained after forty-eight hours of irradiation are shown in Fig. 1. The results show

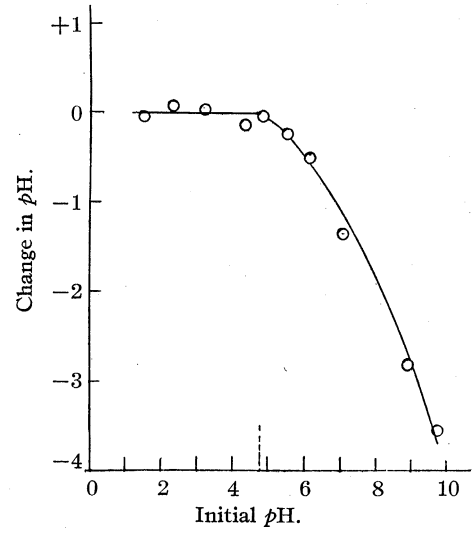

Fig. 1.—Change in pH of egg albumin solutions caused by forty-eight hours irradiation with arc 1W. 0.64 g. egg albumin per 100 cc. solutions irradiated in contact with air. The broken line, pH 4.8, indicates the isoelectric point of egg albumin.

that under the experimental conditions employed, a drop in pH occurs when the initial pH is above the isoelectric point of egg albumin (pH 4.8) and no significant change occurs when the initial pH is below the isoelectric point. A straight line relationship was found between the initial pH of the irradiated solution and the difference in base bound by egg albumin (Cohn[7]) at the pH values

(1) The data in this paper are taken from a thesis submitted by the author (present address: Department of Biochemistry, Tulane University, New Orleans, Louisiana) to the Graduate School of the University of Minnesota in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

before and after irradiation. This relationship is shown in Fig. 2. The difference in base bound

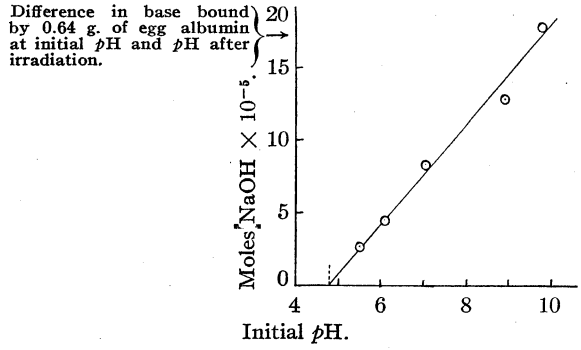

Fig. 2.—The difference in base bound by 0.64 g. egg albumin per 100 cc. at *p*H values before and after irradiation, as a function of the initial *p*H of the irradiated solutions. Experimental data same as Fig. 1.

by the egg albumin is a measure of the strong acid necessary to lower the *p*H to the same extent that it was lowered by irradiation. The data indicate that the photochemical reaction or reactions responsible for the drop in alkalinity of egg albumin solutions irradiated by ultraviolet light are catalyzed either directly or indirectly by the hydroxyl ion concentration of the solution. The change in *p*H observed is correlated with 90 to 98% denaturation of the egg albumin present. The extent of denaturation was determined by bringing the irradiated solution to the isoelectric point, then filtering, washing, drying, and weighing the precipitated protein.

Change in *p*H as a Function of the Time Irradiated.—The results obtained are shown in Fig. 3. The data show that after long periods of irradiation a slight rise in *p*H occurs in solutions whose initial *p*H is below the isoelectric point. Irradiation under nitrogen of a solution (*p*H 6.40) results in a rise of *p*H instead of the drop observed when the solutions are irradiated in air. This indicates that the reaction or reactions responsible for the decreases in *p*H require oxygen.

Discussion.—The data are in agreement with the work of Mond,[2] who concluded that the *p*H values of protein solutions tend to approach the isoelectric point under irradiation. The conclusion of Stedman and Mendel,[4] who believed that the drop in *p*H of irradiated protein solutions is due to a change in the solvent water, is untenable. Assuming the correctness of the methods by which

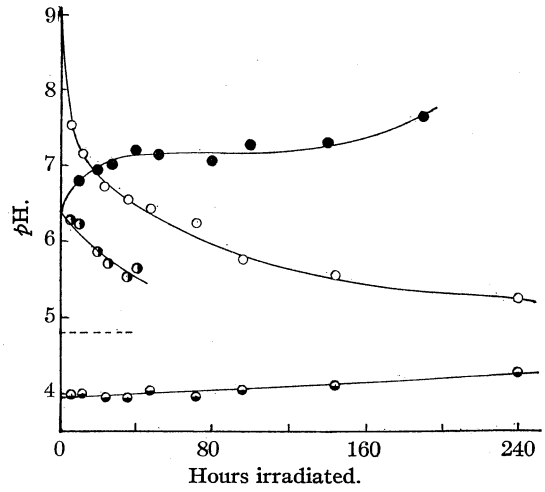

Fig. 3.—The change in *p*H of egg albumin solutions with the time irradiated: ○, 0.81 g. egg albumin per 100 cc., arc 1W, initial *p*H 9.03, irradiated in contact with air; ◒, 0.81 g. egg albumin per 100 cc., arc 1W, initial *p*H 3.94, irradiated in contact with air; ●, 0.76 g. egg albumin per 100 cc., arc 2S, initial *p*H 6.40, irradiated under nitrogen; ◑, 0.76 g. egg albumin per 100 cc., arc 2S, initial *p*H 6.40, irradiated in contact with air.

decreases in *p*H in unbuffered distilled water were found, the extent of the change which they observed corresponds to a very small fraction of the acid formation necessary to reduce the *p*H of a protein–buffer solution. The largest *p*H change of distilled water resulting from ultraviolet irradiation, observed by Stedman and Mendel,[4] is from *p*H 7 to 5.8. The acid necessary to change the *p*H of 100 cc. of distilled water from *p*H 7 to 5.8 is approximately 0.14×10^{-5} mole of hydrochloric acid. In order to change the *p*H of 100 cc. of a solution containing 0.64 g. of egg albumin from *p*H 7 to 5.8, approximately 8×10^{-5} mole of hydrochloric acid is required.

Summary

The change in *p*H caused by ultraviolet irradiation of egg albumin solutions was studied with the glass electrode. The *p*H of egg albumin solutions irradiated in contact with air decreases when the *p*H is above the isoelectric point and rises slightly when the initial *p*H is below the isoelectric point. The *p*H of egg albumin solutions which are alkaline in respect to the isoelectric point increases during irradiation under nitrogen.

The Oxidation of Ethyl Disulfide by Hypobromite Ion. The Rate of the Reaction

BY H. A. YOUNG AND M. B. YOUNG

The reaction between ethyl disulfide and hypobromite ion is more complicated than the corresponding one between the disulfide and bromine.[1] Whereas a dilute solution of bromine oxidizes the disulfide quantitatively to ethyl sulfonate, a dilute solution of sodium hypobromite produces some sulfate ion in addition to the sulfonate. In the present investigation, as in the previous ones, the oxidation system consisted of two phases, the solvents being carbon tetrachloride and water. Also, as previously, the primary object of the investigation was the study of the initial reaction between the sulfur compound and the oxidizing agent, particularly with reference to evidence for or against the formation of a "sulfenic" acid according to the reaction

$$RSSR + H_2O = RSH + RSOH$$

Consequently, all of the organic products of the oxidation were not traced, although the principal one, ethyl sulfonic acid, was identified in the manner previously described.[1a]

The possibility of a hydrolytic cleavage of the sulfur–sulfur linkage of disulfides, as described in the above equation, has been the subject of many investigations, the most recent of which have been those of Schöberl and his co-workers.[2]

Stoichiometry

The experiments were carried out as follows. The disulfide was weighed in a weighing ampoule and added to a known volume of carbon tetrachloride in a 1-liter bottle with a tightly fitting ground-glass stopper. The analyzed hypobromite solution, freshly prepared by adding bromine to a solution of sodium hydroxide of known concentration, was then pipetted into the bottle and the mixture shaken violently in a mechanical shaker until samples of the hypobromite layer taken at suitable time intervals showed no appreciable further loss of oxidizing power. A blank experiment containing the same volumes of carbon tetrachloride and hypobromite solutions was run with each experiment, and the results corrected accordingly. The blank corrections were small in every case. The hypobromite was determined iodimetrically by analyzing 10-cc. samples of the aqueous layer; the sulfate was determined gravimetrically as barium sulfate after separation of the carbon tetrachloride layer. Table I is a summary of seventeen experiments.

Examination of the ratio of moles of hypobromite ion used to moles of ethyl disulfide used, column 11, indicates that although the experimental error is larger than might be wished (approximately 2%), there is a variation in this ratio which is too great to be attributed entirely to this cause. From a comparison of the results of Expts. 1, 2, 3, 10, and 11, with those of Expt. 7, and of Expts. 4 and 6, with those of Expt. 9, it is apparent that this variation is independent of the disulfide concentration. In addition, the ratio seems to increase with increased hypobromite ion concentration and decrease with increasing hydroxide ion concentration, other factors remaining constant. These facts indicate that the value of the ratio depends in some manner upon the concentration of hypobromous acid present.

The initial hypobromous acid (Column 7) was obtained using Shilov's[3] value of 2.06×10^{-9} for the dissociation constant of hypobromous acid. In calculating the final concentration of hypobromous acid, it was assumed that the reduction of two moles of hypobromite ion required one mole of hydroxide ion. That this assumed ratio of 2 to 1 is reasonable but possibly somewhat low will be shown by an examination of the equations for the oxidation of disulfide to sulfonic acid and to sulfates. An attempt to measure the ratio during the iodimetric determination of the hypobromite ion was made by using a measured volume of standardized acid and back-titrating with standardized sodium hydroxide solution after the thiosulfate titration. The results obtained for the ratio varied between 2 and 2.5, but the error involved in the method of determination is necessarily large. Fortunately, a value as high as 2.5 does not materially change the conclusion of the present work. The concentrations of hypobromous acid at the end of each experiment, calculated from the above assumption, are given in

[a] Shaking stopped and solution analyzed before reaction was complete. Values of the ratio of moles of hypobromite used to moles sulfate ion produced are respectively 17.5, 17.0, 17.9.

Column 8. In Column 9 are the average concentrations of the acid.

An examination of the plot of average hypobromous acid concentration against the values of moles hypobromite ion used per mole of disulfide oxidized (Fig. 1) shows that within the limits of experimental error the relationship is a linear one.

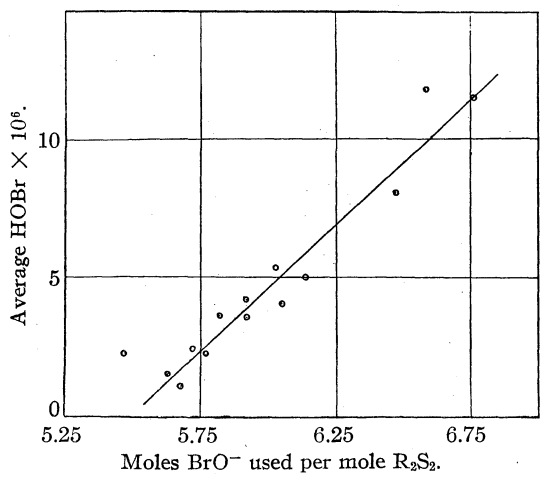

Fig. 1.—Dependence of hypobromite ion requirement upon concentration of HOBr.

In column 12 are given the values of moles of sulfate ion produced per mole of disulfide oxidized, and it is seen that they increase as the hypobromite–disulfide ratios increase. The plot of the values of the sulfate–disulfide ratio against average hypobromous acid concentration is shown in Fig. 2, and again the relationship appears to be a linear one.

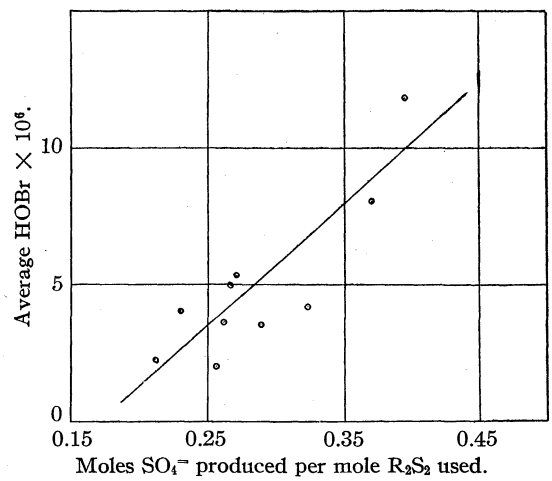

Fig. 2.—Dependence of sulfate production on concentration of HOBr.

The fact that values of the ratio of moles of hypobromite ion used to moles of disulfide used did not increase over those tabulated, even though some of the experiments were allowed to shake for many hours, is evidence that the sulfate ion production is an independent rather than a follow reaction to the production of sulfonate. This conclusion is strengthened by the results of Expts. 15, 16, and 17, in which the reaction was stopped when the values of moles of hypobromite used per mole of disulfide were approximately 2, 3, and 4,

respectively. The resulting values of moles hypobromite used per mole of sulfate ion produced were constant within the limits of error, being 17.5, 17.0, and 17.9, respectively.

The Rate of the Reaction

Experimental.—The rate of disappearance of hypobromite ion during the early stages of the reaction was measured by the following experiments. Freshly prepared hypobromite solutions were pipetted into the reaction vessel, consisting of an indented 500-cc. round-bottomed Pyrex flask, fitted with a mercury-sealed glass stirrer and a side neck of small diameter for withdrawing samples. Freshly prepared solutions of ethyl disulfide, made by dissolving weighed amounts of disulfide in a known volume of carbon tetrachloride, were added by means of a pipet, and the electric stirrer started. The stirring was at constant speed and sufficiently fast to emulsify the two layers. At various times the stirrer was stopped, the carbon tetrachloride layer allowed to settle out, a 10-cc. sample of the water layer removed by means of a pipet, and the hypobromite determined iodimetrically. This procedure of sampling seemed justified, since experiments indicated that there was no decrease in the hypobromite ion concentration when there was no stirring.

The temperature at which the rate experiments were carried out was 25.0 ± 0.1°, maintained by a water thermostat. All reagents were brought to reaction temperature before each experiment by immersion in the thermostat.

Results.—Preliminary experiments showed that the decomposition of hypobromite ion to bromate ion could be neglected if the concentration of hydroxide ion was kept reasonably high. Experiments in which the hydroxide ion concentration at any time became appreciably lower than 0.03 N gave low results for both stoichiometric and rate measurements. Consequently, in the later experiments it seemed advisable to adopt the concentration of 0.03 N as the lower limit for hydroxide ion. That the rate of decomposition of hypobromite ion to bromate ion increases sharply with decreasing hydroxide ion has been shown by Liebhafsky and Makower[4] and more recently by Skrabal and Skrabal.[5]

The experiments indicated that the rate of disappearance of hypobromite ion was proportional to the concentrations of disulfide and hypobromite ion and inversely proportional to the hydroxide ion concentration.

If the stoichiometric relationship may be represented by the equation $L\ BrO^- + L/2OH^- + R_2S_2 \longrightarrow$, where L is a function of the hypobromous acid concentration and is known from the stoichiometry experiments, the following formulation may be made for any one time interval. Let the initial concentrations of hypobromite, disulfide, and hydroxide be a, b, and c, respectively. Then if the volumes of the aqueous layer and of the carbon tetrachloride layer are V and V_1, respectively, and x is the concentration of hypobromite ion at time t, the concentration of disulfide at time t will be $b - \frac{(a-x)}{L}\left(\frac{V}{V_1}\right)$ and that of hydroxide ion will be $c - (a-x)/2$.

The rate law may then be expressed as

$$-\frac{dx}{dt} = \frac{k[x]\left[b - \frac{a-x}{L}\left(\frac{V}{V_1}\right)\right]}{\left[c - \frac{a-x}{2}\right]}$$

or more simply

$$-\frac{dx}{dt} = \frac{k(x)\ (D + Ex)}{F + Gx}$$

where

$$D = b - \frac{a}{L}\frac{V}{V_1} \qquad E = \frac{1}{L}\frac{V}{V_1}$$

$$F = c - \frac{a}{2} \qquad G = \frac{1}{2}$$

Integration of dx between the limits a and x, and of dt between 0 and t leads to the expression

$$kt = \frac{F}{D}\ln\left(\frac{D + Ex}{x}\right) - \frac{G}{E}\ln(D + Ex) - \frac{F}{D}\ln\left(\frac{D + Ea}{a}\right) + \frac{G}{E}\ln(D + Ea)$$

A plot of

$$\left[2.303\frac{F}{D}\log\frac{D + Ex}{x} - 2.303\frac{G}{E}\log(D + Ex)\right.$$

(denoted H) as ordinate against time as abscissa should then be a straight line for each time interval. Because of the variation in V, the results of a single experiment would result in a series of line segments with the initial abscissa of each differing from the final abscissa of the preceding one. If the rate law is correct, translation of each line segment by an amount equal to the summation of the preceding differences should result in a single straight line. That such is the case is shown in Fig. 3, where are plotted the results of two typical experiments. The details of calculation are in Table II.

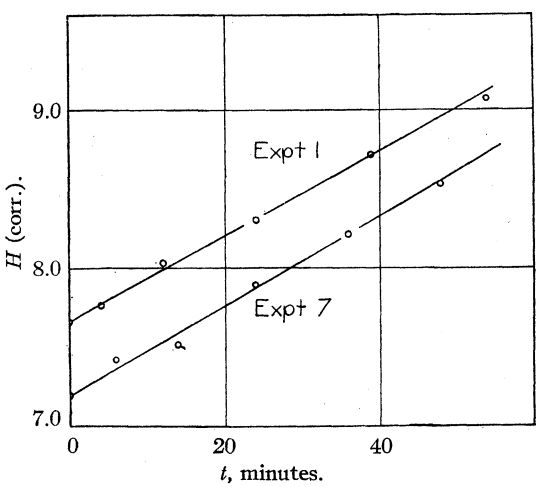

Fig. 3.—Typical rate results. Corrected value of H plotted against time in minutes.

Discussion of Results

An explanation for the above stoichiometric and rate results would be a reaction system which has, as a single rate-determining step, a reaction between disulfide and hypobromous acid. This rate-determining step is probably followed by several rapid reactions, among which must be two competing ones of comparable rates, the first involving hypobromous acid and eventually leading to sulfate ion, the second involving water and leading to sulfonate ion.

Although the authors realize the need for caution in interpreting the results obtained in such a complicated reaction system, it is felt that these experiments seem to prove that the principal rate determining step is not the hydrolysis of the disulfide. The possibility of the establishment of a rapid equilibrium involving water and disulfide as a precursor to further oxidation also seems to be remote, since not only is the solubility of ethyl disulfide in water not materially affected by hydroxide ion, but experiments in which carbon tetrachloride solutions of disulfide were stirred with water for several minutes resulted in water layers which did not reduce hypobromite ion. Any sulfenic acid formed in the latter experiments might reasonably be expected to be in the water layer, and, because of solubility relations, in appreciable quantities.

The conclusion that sulfenic acid formation is not involved in the primary oxidation is in accord with the results of Shinohara and Kilpatrick,[6] who have shown that the rate determining step in oxi-

(6) Shinohara and Kilpatrick, THIS JOURNAL, **56**, 1466 (1934).

dation of cystine by iodine is a simple second order reaction between cystine and iodine (or triiodide ion). Since Shinohara and Kilpatrick worked entirely in acid solution, however, their results do not preclude the possibility of the establishment of a rapid equilibrium involving cystine and water and the formation of a sulfenic acid. But also, the above conclusion is not contradictory to the work of Schöberl and his colleagues. They have shown that symmetrical disulfides which contain a carboxyl group and the sulfur atom attached to the same carbon atom decompose to yield the corresponding sulfhydryl compound, a keto acid, and hydrogen sulfide when heated in alkaline or, in some cases, neutral, solutions.

$$[RCH(COOH)S]_2 + H_2O \longrightarrow RCH(COOH)SH + RCO(COOH) + H_2S$$

For this result, the assumption of an alkaline cleavage of the original disulfide leads to a satisfactory and reasonable mechanism, as they have pointed out. However, the authors feel that there is at present a regrettable tendency in the chemical literature to assume that all disulfides undergo cleavage in alkali. Aside from the evidence of the present paper that such a cleavage is not of importance in the oxidation of ethyl disulfide, Schöberl has pointed out two other disulfides, both of which contain carboxyl groups but only one of which is in the proper position, which do not show any tendency to decompose upon heating with alkali[2] (p. 1187).

If the two over-all reactions for the oxidation of ethyl disulfide are written

$$R_2S_2 + 5\ BrO^- + 2\ OH^- = 2\ RSO_3^- + 5\ Br^- + H_2O$$
$$R_2S_2 + M\ BrO^- + \quad = 2\ SO_4^= + Br^- +$$

values of M may be determined from the stoichiometry measurements of Table I, since it may be readily shown that

$$M = \frac{\left(\frac{BrO^-}{R_2S_2}\right) - 5 + \frac{5}{2}\left(\frac{SO_4^=}{R_2S_2}\right)}{\frac{1}{2}\left(\frac{SO_4^=}{R_2S_2}\right)}$$

where BrO^-/R_2S_2 = moles hypobromite used per mole R_2S_2 used, and $SO_4^=/R_2S_2$ = moles sulfate ion produced per mole R_2S_2 used.

TABLE III

7	.150	.288	.0421	2.60	2.30	2.45	5.8	.028
8	.0992	.288	.0421	1.72	1.43	1.58	5.7	.029
9[a]	.0730	.288	.0421	1.27	0.97	1.12	5.6	.030
10[a]	.0989	.292	.0650	1.69	1.28	1.49	5.7	.030
11	.0988	.292	.0365	1.69	1.35	1.52	5.7	.031
12	.0977	.392	.0365	1.25	1.04	1.15	5.6	.029

[a] These experiments unfortunately embraced concentration ranges in which D became zero, resulting in a singularity in the integrated expression. However, in the neighborhood of the singularity, the rate constants could be determined by using the simplified rate law—$dx/dt = k(x)(Ex)/(F + Gx)$. Such calculations were made and the rate constants so determined did not differ appreciably from those determined in the usual manner.

Although the values of M (column 14, Table I) vary quite widely, it is observed that, except for Expts. 4 and 5, the values lie between 10.70 and 13.50. The average value of M, 12.1, is at least suggestive of the equation

$$R_2S_2 + 11BrO^- + 6OH^- = 2CH_3COO^- + 2SO_4^= + 11Br^- + 5H_2O$$

Conclusion

1. The oxidation of ethyl disulfide by hypobromous acid involves at least two independent reactions, one of which produces ethyl sulfonate ion and the other sulfate ion.

2. The rate of oxidation has been studied at 25° and the following rate law obtained

$$-\frac{d\ BrO^-}{dt} = \frac{k(R_2S_2)(BrO^-)}{(OH^-)}$$

where k has the value of 0.028 ± 0.002.

3. These experiments give no evidence for the formation of a sulfenic acid by the hydrolysis of the disulfide.

Reaction of Olefins with Solid Cuprous Halides

BY E. R. GILLILAND, J. E. SEEBOLD, J. R. FITZHUGH[1] AND P. S. MORGAN[2]

That olefins react with cuprous salts in solution has long been known. Berthelot[3] observed that ethylene was absorbed by hydrochloric acid solutions of cuprous chloride. Manchot and Brandt[4] found that ethylene at atmospheric pressure was absorbed by such a solution to the extent of one mole for each mole of cuprous chloride, forming a metastable compound which is empirically $CuCl \cdot C_2H_4$. Ethylene is also known to react with ammoniacal cuprous solutions, several patents[5] having been granted for the recovery of ethylene by absorption in ammoniacal solution.

One case of the reaction of an olefin with a solid cuprous halide has been reported by Tropsch and Mattox.[6] They found propylene did not react. Ethylene was selectively recovered from mixtures of ethylene and ethane and of ethylene and propylene, but in a great deal less than stoichiometric proportion. Chavastelon[7] obtained a similar acetylene compound, $Cu_2Cl_2 \cdot C_2H_2$, and reports equilibrium pressures substantially lower than those for ethylene.

The work reported in this paper summarizes the results obtained employing other systems of olefins and solid cuprous salts.

Experimental

Procedure.—The high variation of the equilibrium pressure of the addition compounds with temperature made it desirable to separate the experimental work into two parts, high pressure and low pressure.

In the high pressure work an accurately known quantity of a powdered cuprous salt was mixed with small mesh pumice and introduced into a steel autoclave. The reactor was then charged with ethylene at about 60 atmospheres pressure for twelve hours at 0°, after which the ethylene was bled from the reactor until the pressure fell just below the vapor pressure of liquid ethylene at 0°. The remaining ethylene was then removed at constant temperature by releasing successive portions of known volume. Sufficient time was allowed between the successive proportions of the gas to obtain pressure equilibrium. These equilibrium pressures were plotted *versus* the volume of the gas withdrawn and the curve gave a plateau at the dissociation pressure of the addition compound; the volume of gas corresponding to the length of the plateau represented the amount of olefin combined with the cuprous salt.

The procedure for measuring the equilibrium dissociation pressure as a function of temperature was identical with that outlined above except that the extraction of gas was discontinued when the constant pressure period was reached. The temperature was then increased in steps, and the corresponding equilibrium pressures were recorded.

The low pressure apparatus was constructed of glass, but the operation was similar to that outlined for the high pressure work.

The operation for the study of mixtures consisted of treating the cuprous salt at constant temperature and pressure with a known gas mixture. Analyses and volume measurements were made of both the unabsorbed portion of the gas and of the gas obtained on decomposing the addition compound.

Pressure measurements were, in general, more accurate than temperature measurements for both the low and high pressure apparatus. Pressure measurements at a given temperature checked to within 3 mm. for the low pressure apparatus, and to within 20 mm. for the high pressure apparatus. Temperatures, however, were read with a calibrated thermometer and are subject to an estimated maximum error of 1 °C.

Results

The results show that such reactions are not limited to ethylene and solid cuprous chloride. Propylene combines mole for mole with solid cuprous chloride yielding a highly dissociative compound which may be written empirically as $CuCl \cdot (C_3H_6)$. Isobutylene forms a similar compound which probably is $CuCl \cdot i\text{-}C_4H_8$, although in this case complete saturation of the cuprous chloride was not obtained, presumably due to the fact that equilibrium was not reached. In one experiment 0.62 mole of isobutylene reacted per mole of solid cuprous chloride in contact with liquid isobutylene at −50°. The molal ratios measured are given in the following table.

TABLE I

Olefin	Mole olefin	Mole CuCl	Mole olefin/mole CuCl

[a] Vapor pressures of liquid isobutylene.

The equilibrium data obtained are given in Table II and Fig. 1. The data obtained for the cuprous chloride–ethylene compound agree well with those of Tropsch and Mattox.[6]

At low temperatures where all three olefins (ethylene, propylene and isobutylene) react with cuprous chloride, the equilibrium pressure curves are almost identical. The propylene and isobutylene curves are practically coincident and the ethylene curve shows only a slight deviation from these two, indicating that the reaction is characteristic of the unsaturated structure and is not markedly influenced by molecular weight. At higher temperatures, molecular weight plays a much more important part in the behavior of the olefins toward solid cuprous chloride than does the unsaturated structure in the molecule. Ethylene has been found to combine with solid cuprous bromide mole for mole, according to the formula $CuBr \cdot C_2H_4$, indicating that the reaction is not limited to the chloride. The bromide has been found to have different properties from the chloride, but these may be described and explained on the same basis as the chloride.

A consideration of Fig. 1 shows that a gaseous olefin cannot react with the solid cuprous salts at temperatures higher than correspond to the intersection of the dissociation pressure curve with that of the vapor pressure curve of the olefin in question. These maximum reaction temperatures are approximately 20° for propylene with cuprous chloride and −18° for isobutylene with cuprous chloride. Tropsch and Mattox observed that no propylene was absorbed by cuprous chloride at 23° and 11 atmospheres absolute. This point is very close to the maximum reaction temperature under which condition reaction of the gas would be difficult to observe. Had they operated at a lower temperature reaction no doubt would have been detected.

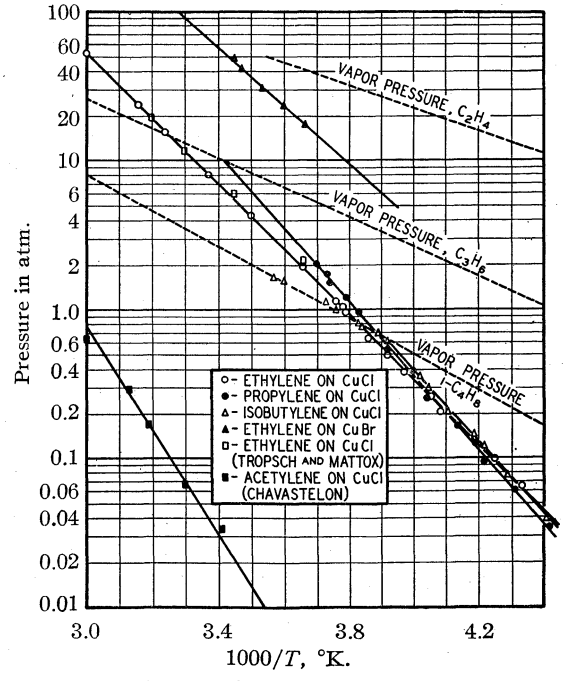

Fig. 1.—Dissociation pressures.

The slopes of the lines of Fig. 1 together with P–V–T data permit the calculation of the heat of reaction at various temperatures. These calculated values of the heat of reaction varied from 10,000 to 11,000 cal. per gram mole at low tem-

peratures down to approximately 7000 cal. per gram mole at the highest temperatures employed.

Under suitable conditions olefins may be recovered from gaseous or liquid mixtures by the use of solid cuprous halides. Consider a gaseous mixture of ethylene and ethane over solid cuprous chloride. Using the Lewis and Randall fugacity rule,[8] the addition equilibrium relation for the mixture can be expressed as

$$yf = f_s$$

where y is the mole fraction of ethylene in the gas phase, f the fugacity of ethylene at the total pressure and temperature of the mixture and f_s the fugacity of ethylene in the equilibrium with the solid complex at the total pressure and temperature. If the difference in volume between the cuprous chloride and the addition compound be neglected, f_s is independent of pressure. Using these assumptions the recovery of ethylene from a given mixture under definite conditions of pressure and temperature may be computed from this equation using the fugacity data given by Lewis and Kay.[9]

Tropsch and Mattox[6] passed a mixture of 60% ethylene and 35% propylene over an excess of cuprous chloride at a pressure of 17.7 atmospheres. They found that "of the 13 liters of ethylene passed only four liters was absorbed, 0.35 mole for each mole of cuprous chloride." Assuming a temperature of 25° the equilibrium value of the recovery calculated as outlined is 4 liters. This calculation is based on an assumed temperature since the authors failed to report the temperature of their observation. These investigators observed that practically no reaction was obtained in the case of a 61% ethylene–35% ethane mixture at 39 atmospheres. The temperature is not reported. Assuming a temperature of approximately 25°, reaction should have proceeded. This is borne out by the success of the present work when dealing with a mixture of ethylene and ethane containing 48% ethylene. Ethylene was recovered from this mixture to the extent of 0.515 mole per mole of cuprous chloride and concentrated to a purity of 98%. This reaction was carried out at 20° and 50 atmospheres absolute pressure. After the reaction had ceased, the ethylene mixture bled from the reactor in successive portions yielded analyses which checked values that were computed by the fugacity method. In similar fashion, ethylene was also recovered from a mixture of hydrogen and ethylene containing 42% ethylene at a temperature of 20°. Here again saturation was not reached, 0.693 mole of ethylene being combined with each mole of cuprous chloride. In like manner, analysis of the gas bled from the reactor checked the equilibrium values calculated. In this case the purity of the removed ethylene was 97%.

Liquid phase reaction was carried out at atmospheric pressure and temperatures lower than that of the intersection of the vapor pressure curve with the addition-compound curve using a mixture of propane and propylene containing 48% propylene, and employing about 50% excess of cuprous chloride. 86% of the propylene was recovered as compared to a computed maximum recovery of 91% for the conditions of the experiment. The liquid mixture was allowed to remain in contact with the solid for about fifteen minutes and the container was not agitated. The purity of the recovered propylene was 98%.

Summary

Ethylene, propylene and isobutylene are absorbed by solid cuprous chloride and ethylene is absorbed by solid cuprous bromide, indicating that the reaction is characteristic of the olefins and the cuprous halides. Except for isobutylene, approximately one mole of olefin is absorbed for one mole of cuprous halide. Olefins have been absorbed from several mixtures and concentrated by the use of these salts and a method for calculating the theoretical maximum recovery is outlined.

Evidence for Ring Structure in Certain Aliphatic Organic Compounds

BY HILTON A. SMITH AND J. P. MCREYNOLDS

In connection with the study of the rate of esterification of organic acids, the postulation has been made that acids with a chain involving four or more carbon atoms have a ring structure. The purpose of this paper is to use this as a basis for explaining a number of properties of organic acids and other organic compounds which might have such a structure.

I. Esterification

The rates of the catalyzed esterification of normal aliphatic acids in methyl alcohol have been studied recently.[1] Figure 1 shows the effect of the length of the carbon chain on the values of the rate constant at 25°. From this figure, it is obvious that increasing the chain length of the acid produces a definite effect when there are less than four carbon atoms in the chain. Starting with butyric acid, however, lengthening of the chain produces no effect. These facts were explained by postulating that the chain of butyric and higher acids was not straight, but that the first four carbon atoms including that in the carboxyl group formed a ring.

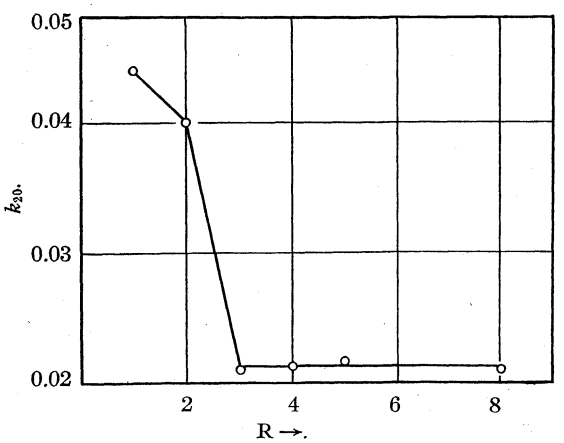

Fig. 1.—Effect of acid chain length on the reaction $CH_3OH_2^+ + RCOOH \rightarrow CH_3COOR + H_3O^+$.

In a subsequent paper[2] it was shown that the rates of the catalyzed esterification of methyl and phenyl substituted acids in methanol substantiated this theory.

(2) Smith, *ibid.*, **61**, 1176 (1939).

II. Saponification

The effect of the length of the carbon chain of the acid group on the rate of the alkaline hydrolysis of saturated aliphatic esters was studied by Evans, Gordon and Watson.[3] These workers found that the values of the reaction rate constants decreased with increasing chain length until ethyl butyrate was reached. Further increase in the chain length had no effect. They attributed the decreasing values of k in the early members of the series to an increase in the activation energy of the reaction. This idea has been modified[4] and it has been shown that within experimental error the activation energy does not change with increasing chain length. The change is rather a change in the steric factor in the equation $k = sZe^{-E/RT}$.

Figure 2 shows the effect of the length of the carbon chain on the reaction velocity constants for the saponification of the ethyl esters of normal aliphatic acids at 25°. The data of Smith and Levenson were used for the first three points on this graph, while subsequent points were obtained from the data of Evans, Gordon and Watson.

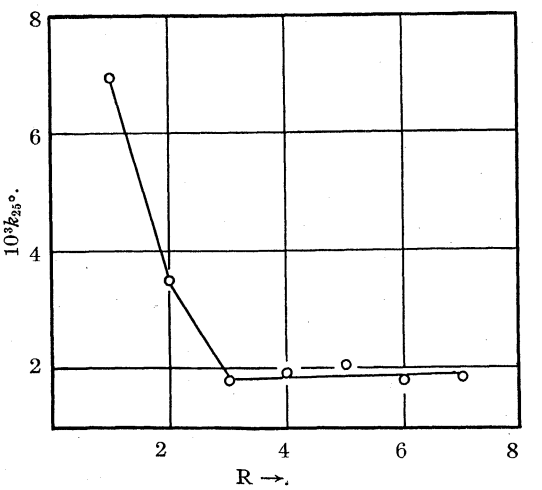

Fig. 2.—Effect of acid radical chain length on the reaction $NaOH + RCOOC_2H_5 \rightarrow RCOONa + C_2H_5OH$.

This figure shows that, as in the case of esterification, the effect of increasing the length of the

(3) Evans, Gordon and Watson, *J. Chem. Soc.*, 1439 (1938).
(4) Smith and Levenson, THIS JOURNAL, **61**, 1172 (1939).

carbon chain is quite different before and after a total of four carbon atoms are present. These results readily may be explained on the basis of the ring theory. The ring will be formed in the ethyl esters of butyric and higher acids.

Evans and co-workers included in their studies the rate of saponification of the ethyl esters of several methyl-substituted acids. Here also the results are readily explainable on the basis of the ring theory. Thus, substitution of a methyl group on the third carbon of butyric acid gives a smaller rate constant than the substitution of a similar group on the second carbon of propionic acid. This is evidenced by the fact that the values of k for ethyl isovalerate are lower than the corresponding values for ethyl isobutyrate.[5] Also the values of k for the saponification of the ethyl ester of methylethylacetic acid are smaller than the corresponding values for isobutyric acid. This shows the effect of the ring formation caused by completion of the four carbon atom chain.

The saponification of the ethyl ester of diethylacetic acid is particularly interesting. This ester gives the lowest values of k and also the highest activation energy of any of the esters studied by Evans, Gordon and Watson. It behaves very similarly to trimethylacetic acid ester. Evans and co-workers were unable to offer any explanation of the results with ethyl diethylacetate. The postulation of a ring structure gives such an explanation. In this ester, there are two rings formed, and the terminal methyl groups are brought into such a position that the screening of the carboxyl group is even greater in the case of the diethylacetate than in that of the trimethylacetate. Evans and co-workers found that branching on the α-carbon atom leads to a lower probability factor in the case of the ethyl esters of isobutyric and trimethylacetic acids. While their conclusion is correct, their low value of the activation energy of isobutyric acid[5] is responsible for their very low value of "s" for this acid.

Hinshelwood and Legard[6] demonstrated that substitution in the α-position often causes an increase in the activation energy. While this increase is found for the esters of trimethylacetic acid, methylethylacetic acid, and isovaleric acid, it is not found for the isobutyric ester. This same effect was found in esterification studies.[7] It may be that in the case of trimethylacetic and diethylacetic acids the reacting molecules must possess an added amount of energy at the time of collision in order to break through the force field set up around the carboxyl group by the several close methyl groups.

(5) In this connection, Evans and co-workers state among other conclusions that "ethyl isobutyrate gives a value of E which is smaller than that for ethyl n-butyrate." This conclusion apparently results from a mistake in calculation. A re-plotting of their reaction rate constants against inverse temperature resulted in an activation energy of 15,000 cal. per mole in each case. These values were checked by the method of least squares. The results gave 15,023 for isobutyric acid and 14,968 for its normal isomer. These are certainly the same within experimental error.

Acid Dissociation Constants

The dissociation constant of an organic acid may be considered as the representation of an equilibrium between the release of protons by the acid and the reaction between the H_3O^+ ion and the acid radical. The effect of increasing the chain length of the acid may have a different effect on each of these, thus causing a shift in the value of the dissociation constant. The latter reaction is very similar to the catalyzed esterification of an acid with an alcohol. One might, therefore, expect to find much the same results when the effect of chain length on the two properties is studied.

The acid dissociation constants of a number of aliphatic acids have been studied by Dippy.[8] The effect of the length of the carbon chain on the dissociation constant of a normal aliphatic acid is shown in Fig. 3. It will be noted that the general effect of increasing the carbon chain is to lower the value of the dissociation constant. In the case of the shift from propionic to butyric acids, however, there is an increase in the value of K. The recent work of Belcher[9] is in accord with Dippy's findings. Bennett and Moses[10] compared the dissociation constants of propionic, butyric, and heptoic acids; they attributed the high value in the case of butyric acid to the fact that the end methyl in this group, being free to move, occasionally came into close proximity to the carboxyl group and facilitated ionization. Dippy, on the

(7) The activation energy of the catalyzed esterification of isobutyric acid with methyl alcohol was found to be the same as that for normal acids. "E" for the same reaction with methylethylacetic acid was higher. In the case of trimethylacetic acid the activation energy is also greater. The results with this latter acid have not yet been published. In the case of isovaleric acid, the activation energy had about the same value (10,000 cal./mole) as that for normal acids. The value of k at 50° for this acid appears to be somewhat low, and may account for this result. However, this point was checked several times, all runs agreeing within the limits of experimental error.

(9) Belcher, THIS JOURNAL, **60**, 2744 (1938).

(10) Bennett and Moses, *J. Chem. Soc.*, 2364 (1930).

other hand, explains the high dissociation constant of butyric acid by stating that after the proton has left the acid, the anion forms a ring of the type here postulated for the acid itself. The idea that the ring is present in the anion only seems untenable for two reasons. In the first place, the same general effect is found in the study of esterification of the acids, and also of saponification of the corresponding esters. In neither instance is the ion involved in the reaction, but rather the acid or ester molecule itself. In the second place, butyric acid hardly can be regarded as an exception. The dissociation constant of valeric acid is also higher than that of propionic acid, while that of hexoic acid is almost the same. It appears that butyric and higher acids follow one curve, while acids of shorter chain length follow another. Evidently the same effect which is found in butyric acid persists in higher normal acids. These facts can be explained by postulating ring formation for butyric and higher acids both in the undissociated molecule and in the anion. Of course, the ring must be more stable in the anion than in the acid.

Dippy feels that the possibility of explaining the dissociation constants by steric hindrance is rendered less likely by the absence of abnormality in the phenyl-substituted acids.[11] This already has been discussed in connection with the esterification of these acids[2] where it has been shown that the lack of such an abnormality may be readily accounted for by ring structures.

It would appear that the change in the dissociation constants of normal aliphatic acids may be explained on the assumption that increase in the chain length involves two opposing factors. The first may be assigned to a decrease in the ability of the proton to leave the acid when chain length is increased, and results in a decrease in the dissociation constant. This effect becomes smaller with increasing chain length. The second may be due to the fact that the number of effective collisions between the H_3O^+ ion and the COO^- group of the anion is lessened with increasing chain length up to butyric acid. This results in an increase in the value of the dissociation constant. The shape of this curve will be essentially the inverse of that shown in Fig. 1 for the case of esterification. The shape of the curve in Fig. 3 results from the combination of these two curves. The sudden drop in the dissociation constant from octoic to nonoic acids was not explained by Dippy, nor can it be explained here.

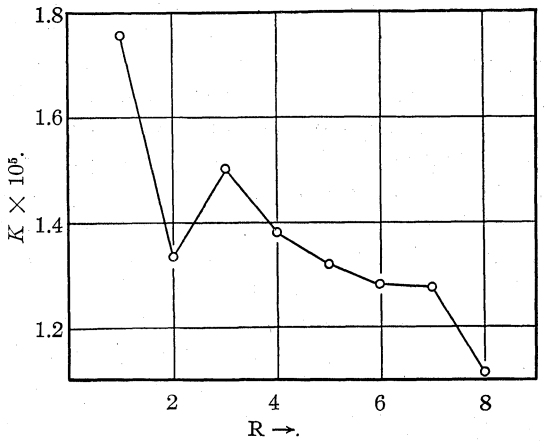

Fig. 3.—Effect of acid chain length on ionization constants.

The high dissociation constants found for isovaleric and diethylacetic acids are readily explainable on the basis of the ring theory; also the fact that isobutyric acid has essentially the same K as propionic acid. The very low value of the dissociation constant for trimethylacetic acid is unexpected, and can be explained only by assuming that some factor comes into play here which decreases the ability of the proton to leave the acid.

Dippy and Lewis[11] also find that the dissociation constant for *cis*-cinnamic acid is considerably higher than that for the *trans* form. This is readily explainable on the basis of the ring theory. In the *cis* isomer the ring will be formed, while in the *trans* isomer this is structurally impossible. For this reason, the solid angle within which H_3O^+ ions may approach the carboxyl group in order to have reaction occur is much greater in the *trans* than in the *cis* form. In fact, it is often found that when organic acids are capable of existing in two geometrical isomers of this type, the *cis* form will have the higher dissociation constant. This generality may be explained by the fact that in the *trans* form the solid angle from which H_3O^+ ions may approach the anion in order to collide with the carboxyl group, is considerably greater than the corresponding solid angle for the *cis* form.

Certain recent evidence may be considered to be opposed to this theory. For instance, dielectric constant data indicate that the length of an amino acid increases regularly with the number of carbon atoms between the charged groups, despite the

(11) Dippy and Lewis, *J. Chem. Soc.*, 1008 (1937).

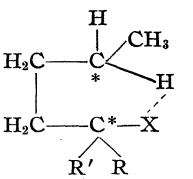
fact that these groups are of opposite sign.[12] Nevertheless, the dipole distances calculated assuming a zig-zag chain structure are considerably larger than those actually found, thus indicating that the charged portions of the molecule actually are closer than might be expected. Then, too, the effect of ring formation has not been observed either for the saponification of the esters of dibasic acids,[13] or in the ionization constants of certain substituted acids.[14] This is, however, not surprising since the effect of substitution of —COOH, —Cl or similar groups gives rise to changes which are of a completely different type and order of magnitude from the effects under consideration here. For instance, substitution of a chlorine atom, or carboxyl group in the alpha position changes the dissociation constant of acetic acid from 1.8×10^{-5} to about 10^{-3}, while the corresponding substitution of a methyl group causes a change which is not only of smaller magnitude (K for propionic acid is approximately 1.3×10^{-5}) but is also in the opposite direction. The work of Ingold[13] when compared with that of Evans, Gordon and Watson[3] also shows that the effects due to increasing chain length are quite different when one is dealing with a dibasic acid as compared to a monobasic acid.

Optical Rotatory Power

The preceding three sections have dealt with the explanation of the effect of the length of the carbon chain of an acid or related compound on certain chemical reactions. The argument may be raised that all of these may be explained on some other basis than that of physical structure. In order to forestall such criticism, a study has been made of the correlation of optical rotatory power of acids and related compounds with their structures as predicted by the ring theory already outlined. This property is known to depend on molecular structure.

Pickard and Kenyon[15] found evidence of irregularities in optical rotatory power for the series of alcohols EtCHOHR which could be interpreted as evidence for the suggested spiral structure of Frankland.[16] This scheme indicates an irregularity when R = 5 or 6, and again when R = 9 or 10.

The explanation of irregularities in a homologous series of optically active compounds is much more satisfactory when these irregularities are interpreted in the light of a ring formed through a hydrogen bond. The introduction of such a ring into a compound already containing an asymmetric atom should produce certain effects upon the optical activity. (1) The increment of change $\Delta[M]_D$ in the molecular rotation for added CH_2 groups should show a variation when enough groups are added to close a ring. The effect of the added CH_2 group and the effect of the ring closure are superimposed. That ring closure does have a marked effect upon optical activity is well known from the lactones of sugar acids. (2) The introduction of a further CH_2 group after the ring is closed will introduce an asymmetric carbon atom into the ring as shown in I. Due to this increase in the number of asymmetric carbon atoms a change in $\Delta[M]_D$ should be found for the addition of this group. (3) Additional CH_2 groups should show uniform effects. The increment may well be quite small since the change in structure is so far removed from the center of asymmetry that it should show little effect.



I (* asymmetric carbon atom)

The introduction of an asymmetric atom into such a ring does not necessarily demand that such an ester as methyl *n*-valerate be resolvable into optical antipodes. The ring must, by its very nature, be quite unstable. This would prevent isolation of the two diastereoisomers by use of an active resolving agent. A kinetic resolution would occur yielding only one diastereoisomer, followed by immediate racemization upon liberation of the free compound. Thus, the esterification of *n*-valeric acid with an optically active alcohol would direct the structure of the asymmetric carbon in the acid ring preferentially to one or the other possible asymmetric structures.

A sufficiently complete series of esters is found in those of structural formula  (R^1 from CH_3 through C_6H_{13}, and R from CH_3 through C_8H_{17}). The values for the specific rotation were taken from the "International Critical Tables"[17] and converted to molecular rotation through multiplication by one-hundredth of the molecular weight. The molecular rotations are given in Table I. Figure 4 makes use of the data

in this table. In 4 A, $[M]_D$ is plotted against the number of carbon atoms in R (R^1 constant) and in 4 B $[M]_D$ is plotted against the number of carbon atoms in R^1 (R constant).

TABLE I

	$[M]^{20}D$				
Acid	*d*-β-Butyl	*d*-β-Amyl	*d*-β-Hexyl	*d*-β-Heptyl	*d*-β-Octyl
Acetate	29.50	22.31	14.44	13.00	11.76
Propionate	31.01	22.23	15.42	14.40	12.98
Butyrate	31.64	24.92	18.20	18.85	17.90
Valerate	32.74	27.53	20.76	20.52	19.60
Hexoate	32.09		21.68	21.34	20.43
Heptoate	32.31		22.17	21.73	20.79
Octoate	32.28			21.95	21.12
Nonoate	32.16		22.70	22.27	21.49
Dodecoate		28.19			

The essential factor which would be affected by an increase in either R or R^1 according to the treatment under consideration may be called $\Delta[M]_D$ which represents the change in molecular rotation when the number of carbon atoms in the optically active molecule is increased by one.

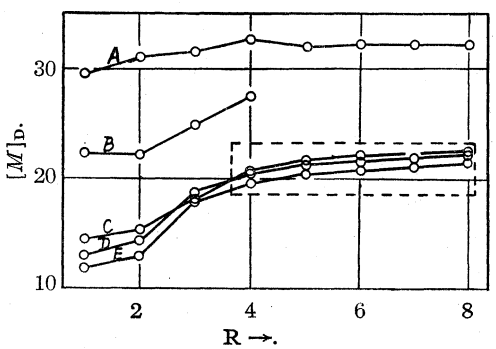

Fig. 4A.—Effect of chain length on molecular rotation of $R^1C(CH_3)(H)-O-C(=O)-R$, R variable: A, *d*-β-butyl; B, *d*-β-amyl; C, *d*-β-hexyl; D, *d*-β-heptyl; E, *d*-β-octyl.

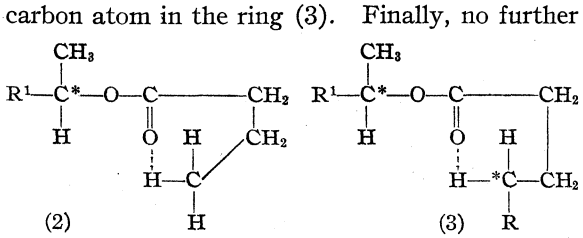
In Fig. 4A the postulated ring structure would predict that $\Delta[M]_D$ for the increase in R from 2 to 3 should show a significant change due to the appearance of a ring structure (2). It would also indicate a significant change in $\Delta[M]_D$ between R = 3 and 4 due to the appearance of an asymmetric carbon atom in the ring (3). Finally, no further marked changes in $\Delta[M]_D$ should appear beyond R = 4. The data plotted in Fig. 4A agree with this treatment with the exception of the $\Delta[M]_D$ between R = 4 and 5 in curve A. Since such an irregularity does not appear in any of the other curves which could be plotted in this range, no explanation can be offered for this apparent irregularity. In Fig. 4B the significant changes in $\Delta[M]_D$ should appear between $R^1 = 1$ and $= 2$ and between $R^1 = 2$ and $= 3$. Substantial agreement is found. The most striking feature of the curves in Figs. 4A and 4B is the exceedingly small effect of changes in either R or R^1 within the areas enclosed within the dotted lines. The esters within this area are of such nature that the ring structure treatment would indicate no significant changes in $\Delta[M]_D$ for additions of CH_2 groups to either the acid (R) or the alcohol (R^1) portions.



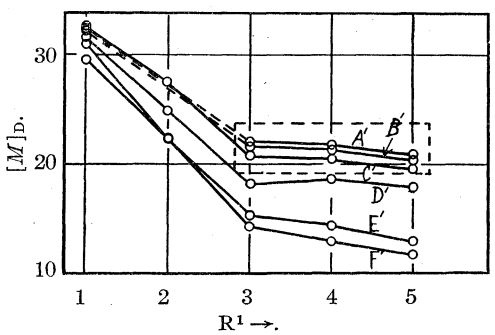


Fig. 4B.—Effect of chain length on molecular rotation of $R^1C(CH_3)(H)-O-O-C(=O)-R$, R^1 variable: A', heptoates; B', hexoates; C', valerates; D', butyrates; E', propionates; F', acetates.

The structure was applied only to acids in the earlier kinetic treatment, but from the above discussion it seems to be independent of the functional group as long as that group contains a donor atom.

In support of this conclusion three homologous series of alcohols are discussed. Data are given in Table II and plotted in Fig. 5. The appearance of the ring should be indicated by $\Delta[M]_D$ from R = 2 to 3, and the asymmetric carbon in the ring by $\Delta[M]_D$ from R = 3 to 4; $\Delta[M]_D$ values for higher R values should be essentially constant. In curve A for γ-isopropyl carbinols $\Delta[M]_D$ values are in good agreement with the theory particularly from R = 4 through higher R

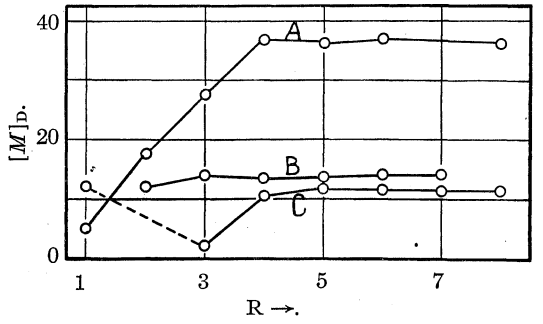

Fig. 5.—Effect of chain length on molecular rotation of *d*-β-methyl, *d*-γ-ethyl, and *d*-γ-isopropyl carbinols: A, isopropyl carbinols; B, methyl carbinols; C, ethyl carbinols.

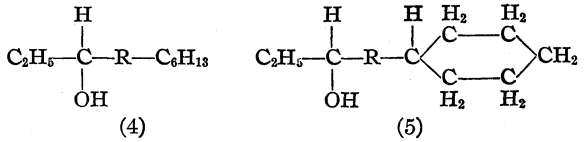
values. Curve B for *d*-β-methylcarbinols shows the expected trend after R = 4. The Δ[*M*]D values in this series are quite small, and so no significant conclusions may be drawn. Curve C for *d*-γ-ethylcarbinols does not give any information for Δ[*M*]D before the interval R = 3 to 4 since the compound corresponding to R = 2 does not contain an asymmetric atom, and would therefore show an [*M*]D value of zero. The values of Δ[*M*]D beyond R = 3 do show excellent agreement with the postulated effects of a ring structure.

TABLE II

R	[*M*]D R—C(H)(OH)—CH_3	R—C(H)(OH)—C_2H_5	R—C(H)(OH)—$CH(CH_3)_2$
CH_3		12.20	4.95
C_2H_5	12.20		17.47
C_3H_7	13.97	2.28	27.62
C_4H_9	13.42	10.57	36.71
C_5H_{11}	13.73	11.83	36.10
C_6H_{13}	14.06	11.66	36.90
C_7H_{15}	14.02	11.49	
C_8H_{17}		11.62	36.10

An example of the effect of ring formation is seen in the parallel series of alcohols of the type shown in 4 and 5, where R varies from 0 to 2. The optical activity of these series was determined by Kuhn and Biller.[18] The curves for these series as given by Fig. 6 show that very little change takes place in the hexyl, heptyl, and octyl derivatives. This is in agreement with the ring



structure, as the ring is closed and contains the same asymmetric atoms in all three compounds, as

(18) Kuhn and Biller, *Z. physik. Chem.*, **B29**, 1 (1935).

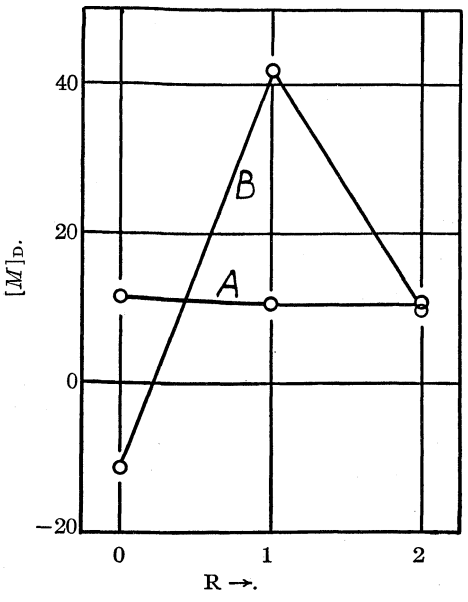


Fig. 6.—[M]D for $C_2H_5CHOHRC_6H_{13}$ and $C_2H_5CHOHRC_6H_{11}$ from R = 0 to R = 2: A, $C_2H_5CHOHRC_6H_{13}$; B, $C_2H_5CHOHRC_6H_{11}$.

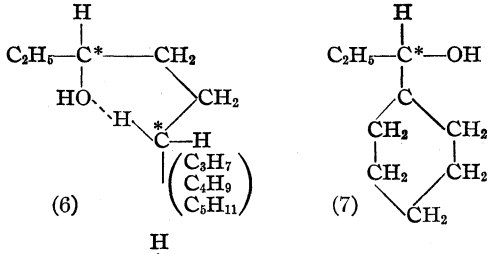
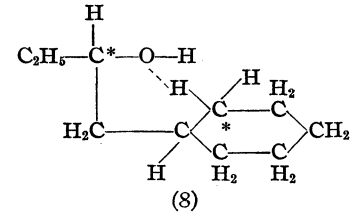
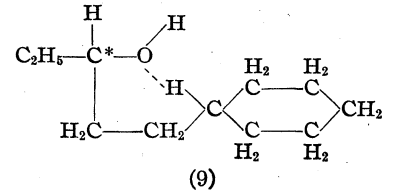
is shown in 6. The changes in the cyclohexyl compounds of the same number of carbon atoms arise from a difference in the structure due to ring formation. In the first member, no ring is possible, as shown in 7. In the second case, ring formation is possible, and results in the formation of a second asymmetric atom. This is shown in 8. In the third member, ring formation is also possible. However, in this structure as given by 9, there is

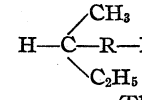






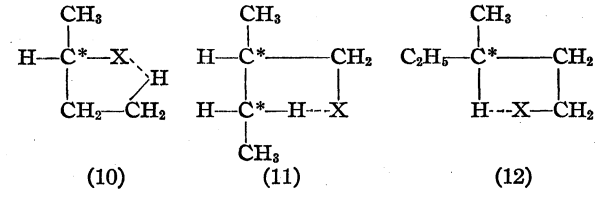
only one asymmetric carbon atom, and the ring structure is much the same as that in the normal series. Figure 6 shows the results of these structures on the optical rotatory power.

That this type of ring formation is quite general seems fairly well supported by the curves in Fig. 7. These represent optical activities of azides, aldehydes, and acids of the general formula



where X is the particular functional group. The values used for acids are by Levene, Rothen and Marker[19]: those for aldehydes by Levene and Rothen[20]; and those for the azides are by the same authors.[21] The three examples of each type contain the same ring structures.

As shown by Fig. 7, the trend of the three curves is quite analogous in all respects, except that the azide curve is inverted. Such inversion offers no difficulties, since an asymmetric carbon may contribute either a positive or negative effect to the total rotation. Whatever structure is used to explain the trend in one series must be used to explain the trend in all three. Possible structures for these series are given by 10, 11, and 12, where X may represent —COOH, —CHO, or $—CH_2N_3$.



(10) (11) (12)

In 10, there is but one asymmetric atom. In 11, there are two such atoms. In 12, there is still the same ring as in 10 and 11, but it contains only one asymmetric carbon.

Unquestionably other data related to optical activity may be explained on the basis of ring structure. However, in most cases, insufficient data are available to warrant further discussion.

It is thus possible to explain not only the effect of the character of the carbon chain on esterification, saponification, and dissociation constants, but also its effect on optical activity, by assuming that certain ring structures may be formed. Probably this type of ring structure may explain other anomalies which now appear in the literature, particularly the peculiar effect which the ethyl group often exerts. This anomaly has been pointed out by Evans and co-workers.[3] The effect of the nature of the carbon chain on the rate of both the base catalyzed[22] and the acid catalyzed[23] prototropy of phenyl alkyl ketones may be explained by the formation of a ring containing four carbons quite as easily as by the three carbon containing ring postulated by the authors. The three-carbon ring must be under a great strain, while that containing four C atoms would be essentially strainless. In this connection, Huggins[24] has pointed out that in general hydrogen bonds are more stable when distances through which the bond operates are small.

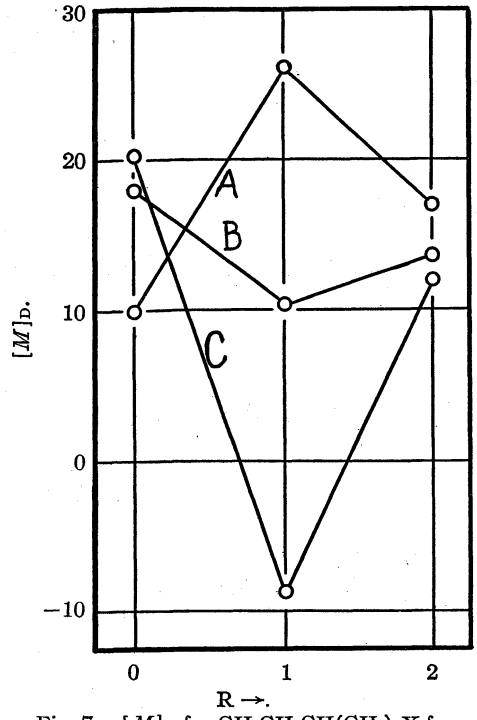


Fig. 7.—$[M]_D$ for $CH_3CH_2CH(CH_2)_nX$ from CH_3 | n = 0 to n = 2: X = COOH, CHO, or CH_2CN_3; A, azides; B, acids; C, aldehydes.

It is probably unnecessary to point out that the ortho effect found in many organic compounds is probably due to this same type of ring formation. That such rings are formed in salicylic acid, *o*-toluic acid, *o*-chlorobenzoic acid, and similar compounds has already been postulated.[25] In all these cases the bonding hydrogen atom completes

(25) See, for instance, Dippy, Evans, Gordon, Lewis and Watson, *J. Chem. Soc.*, 1421 (1937). It should be noted that these authors postulate that this ring formation takes place only in the anion of the acid. It seems preferable to consider that the bond is also present in the un-ionized acid since reactions such as esterification do not depend on ionization of the acid, but show a marked dependence on the ortho effect.

a six-membered ring similar to that postulated for the normal acids.

Summary

The effect of the character of an alkyl side chain on the processes of esterification and saponification, on acid dissociation constants, and on optical activity has been discussed. It has been shown that ring formation similar to that already postulated to explain the effect of the alkyl chain length of normal aliphatic acids on their velocity of esterification in methanol gives a satisfactory explanation of these phenomena.

The same structure may be used to explain other reactions. It is pointed out that the ortho effect is unquestionably due to the same type of structure.

Chlorine. The Heat Capacity, Vapor Pressure, Heats of Fusion and Vaporization, and Entropy

BY W. F. GIAUQUE AND T. M. POWELL

This paper presents the results of a low temperature calorimetric investigation of chlorine. The entropy of chlorine has been calculated previously[1] from band spectrum data and the principal purpose of the present work is to compare the value obtained by means of the third law of thermodynamics with the accurately known spectroscopic value. No difficulty with false equilibrium at low temperatures, such as has been found with a few other substances, was anticipated in the case of a molecule like chlorine. Thus it was expected and has been found that the two methods of obtaining the entropy are in excellent agreement.

The measurements were made in a calorimeter which has been described as Gold Calorimeter II.[2] A detailed description of a similar calorimeter has been given previously.[3]

Chlorine reacts slowly with gold at ordinary temperatures and before the gold calorimeter was used for chlorine the reactivity was investigated by immersing a sheet of gold in liquid chlorine at its boiling point. The sheet had an area of 58.5 cm.^{2} and was boiled in nitric acid, washed in alcohol and heated before weighing after each removal from the chlorine. During the first twenty-four hours the gold lost 0.0140 g. but subsequent immersion for four days caused an additional decrease of only 0.0087 g. Since the calorimetric investigation required that the liquid chlorine be at temperatures near the boiling point for a comparatively short period, the reaction could not occur to any appreciable extent. Moreover, the data on the rate of solution of gold were obtained with undried commercial liquid chlorine whereas the chlorine used to fill the gold calorimeter was carefully dried and purified. Presumably the reaction between gold and very dry chlorine would be much slower than that recorded above. When measurements were not in progress, the chlorine was solidified and kept near the temperature of liquid air.

The resistance thermometer was calibrated during the measurements against a copper–constantan thermocouple with the laboratory designation W.[4] Small corrections to this standard thermocouple were recently determined by Stephenson and Giauque.[5] Following the present research the standard thermocouple was compared with the vapor pressures of hydrogen and agreement with the corrections of Stephenson and Giauque was found.

Preparation of the Chlorine.—The chlorine was prepared by dropping 3 *M* HCl on manganese dioxide. The small amount of hydrogen chloride in the gas was removed by water and the chlorine was dried with concentrated sulfuric acid and finally with phosphorus pentoxide.

Chlorine prepared as above was placed in the calorimeter and measurements of the heat effect associated with premelting in the solid showed it to contain an impurity of about 5 parts in 10,000 on a molal basis. The material was removed from the calorimeter and fractionated in a vacuum jacketed column. Subsequent premelting

measurements in the temperature range a few degrees below the melting point showed that the liquid-soluble solid-insoluble impurity had been reduced to about 3 moles in 100,000.

The Vapor Pressure of Chlorine.—The vapor pressure of chlorine was measured with a mercury manometer using carbon dioxide as a buffer in the manner described previously[6] for nitrogen tetroxide. The measurements were made with the calorimetric apparatus since it permitted excellent temperature control. A system of capillaries and mixing bulbs was so arranged that the less dense carbon dioxide could not enter the calorimeter or the connecting lines adjacent to it. To guard against slow diffusion a small amount of chlorine was pumped from the calorimeter before each vapor pressure observation. Heat was then added until the desired temperature was reached. The results of two series of observations on the triple point are given in Table I.

TABLE I

TRIPLE POINT DATA FOR CHLORINE (0°C. = 273.10°K.)

Series	% melted	T, °K. Thermocouple	T, °K. Resistance Ther.	$P_{inter.}$ cm. Hg
I	25	172.13	172.111	1.044
I	50	172.12	172.109	1.046
II	7	172.13	172.109	1.052[a]
II	30	172.14	172.120	1.046
II	80	172.11	172.115	1.042
Values accepted		172.12		1.044

[a] This value deviates by more than the error of measurement and is given no weight.

The results starting at the triple point are represented by the equation

Triple point 172.12 to 240.05°K.

$$\log_{10}P_{(inter.\ cm.)} = \frac{-1414.8}{T} - 0.01206\ T + 1.34 \times 10^{-5}\ T^2 + 9.91635 \quad (1)$$

The observed values of the vapor pressure are given in Table II where they are compared with Equation 1. The temperatures are given to thousandths of degrees in order that the high relative accuracy may be used in obtaining temperature coefficients. Near the triple point an error in pressure of 0.001 cm. corresponds to 0.01° and since the accuracy of the pressure measurements is about 0.002 cm. deviations of the order of 0.02° are within the limit of error. At the higher temperatures the larger dP/dT makes temperature measurement the limiting factor. The standard acceleration of gravity was taken as 980.665 cm. sec.$^{-2}$ and for this location g = 979.973 cm. sec.$^{-2}$.

The Calorimetric Data.—The heat capacity results are presented in Table IV and results taken from a smooth curve through the observations are given in Table V. A small pressure of helium gas was used to assist thermal equilibrium in the solid at low temperatures. A correction was applied for vaporization into the small gas space due to changing vapor pressure in the liquid range. This correction was made with the assistance of density measurements on liquid chlorine by Pellaton,[11] who gives the equation

$$D = 1.468 - 2.89 \times 10^{-3}t - 5.3 \times 10^{-6}t^2 \quad (2)$$

where t is the centigrade temperature. Since the vapor pressure and heat of vaporization were known accurately, there was no appreciable error involved in the small vaporization correction.

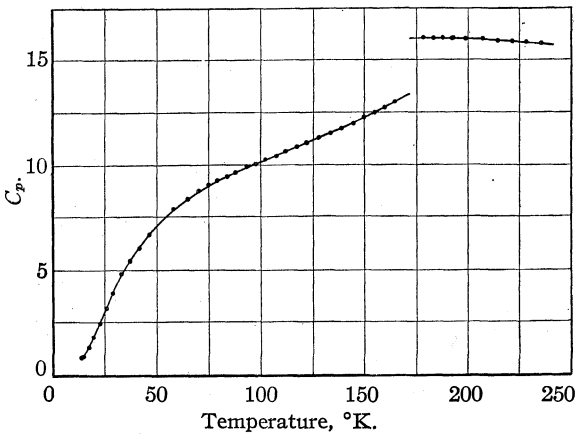

Fig. 1.—Heat capacity in calories per degree per mole of chlorine.

It is estimated that a smooth curve through the data represents the heat capacity to 0.1–0.2% at all temperatures above 35°K. The percentage accuracy decreases near the boiling point of hydrogen due to the rapidly decreasing heat capacity and the rapid decrease in the temperature coefficient of the resistance thermometer in this region.

The inaccuracy is estimated to be within 1% at 20°K. but the error may easily be several per cent. at 15°K. In calculating energy 1 calorie (15°) was taken as 4.1832 international joules.

The heat capacity of chlorine has been measured by Eucken and Karwat[13] and their results have been compared with the present work in Table V. The weight of the chlorine used for the heat capacity measurements was found by condensing the material in a steel container with a valve and weighing the liquid at room temperature. 165.829 g. or 2.3385 moles of chlorine were used for the measurements.

The heat of fusion was measured in the usual manner; heat input was started at a temperature somewhat below the melting point and ended several degrees above. The known heat capacity of each phase permitted accurate correction. The results are presented in Table VI.

TABLE VI

HEAT OF FUSION OF CHLORINE

Melting point, 172.12°K. Molecular weight, 70.914

Run	ΔH cal. mole^{-1}
1	1530.5
2	1529.8
3	1531.1
4	1530.7
Average	1531 ± 1
Eucken and Karwat[13]	1615

The heat of vaporization was measured by attaching an absorption bulb, filled with a solution which contained 2 M sodium hydroxide and 1.7 M potassium iodide, to the calorimeter. In order to prevent the solution from being sucked back,

the entrance tube was immersed in a small amount of mercury at the bottom of the absorption bulb. The iodide was added to prevent clogging of the opening when a small portion of the chlorine reacted with the mercury. Heat was introduced so slowly that vaporization could proceed quietly from the surface. The results for the heat of vaporization at the boiling point are given in Table VII.

TABLE VII

HEAT OF VAPORIZATION OF CHLORINE

Boiling point, 239.05°K. Molecular weight, 70.914

Moles evapd.	Time of energy input, min.	ΔH cal. mole^{-1} at 760 mm.
0.16916	40	4881
.17280	40	4884
.17289	40	4876
.17148	40	4874
	Average	4878 ± 4

From vapor pressure equation, $\Delta H = 4851$

The value for the heat of vaporization calculated from the vapor pressure measurements, 4851 cal. mole^{-1}, agrees within the limit of accuracy of the data but is given no weight compared to the reliable calorimetric value. In calculating the heat of vaporization from dP/dT we made use of data of state observations on chlorine gas. Measurements have been made near the boiling point by Eucken and Hoffmann,[15] who also summarize the measurements of other observers. They represent the volume of chlorine gas by the equation

$$V = \frac{RT}{P} + 39 - \frac{8.5 \times 10^8}{T^{2.6}} \text{ cm.}^3\text{/mole} \qquad (3)$$

In many previous researches in this Laboratory the gas volume at the boiling point has been estimated by means of Berthelot's equation of state in order to calculate the heat of vaporization from the vapor pressure. It is of interest to note that in the case of chlorine Berthelot's equation gives a gas volume and therefore heat of vaporization only 0.1% less than Equation (2) at the boiling point. The volume of liquid chlorine at the boiling point was obtained from the density equation of Pellaton[11] mentioned above.

The Entropy of Chlorine.—The calculation of the entropy of chlorine from the calorimetric data is summarized in Table VIII. The correction of the entropy to the ideal gas state was made by means of the thermodynamic equation

$$(\partial S/\partial P)_T = -(\partial V/\partial T)_P$$

and Berthelot's equation of state. The critical constants were taken as $P_c = 76.1$ atm.,[11] $T_c = 417$°K.[11]

$$\Delta S = S_{\text{ideal}} - S_{\text{actual}} = 27RT_c^3P/32T^3P_c$$
$$= 0.12 \text{ cal. deg.}^{-1} \text{ mole}^{-1} \text{ at the boiling point.}$$

We have used Berthelot's equation in preference to Equation (3) in making the above calculation because the data used in obtaining Equation (3) are not sufficiently complete to determine temperature coefficients at the boiling point.

TABLE VIII

THE ENTROPY OF CHLORINE

0–15°K., Debye function $hc\nu/k = 115$	0.331	
15–172.12°K., graphical	16.573	
Fusion 1531/172.12	8.895	
172.12–239.05°K., graphical	5.231	
Vaporization 4878/239.05	20.406	
Entropy of actual gas at boiling point	51.44	
Correction for gas imperfection	0.12	
Entropy of ideal gas at boiling point	51.56	cal. deg.$^{-1}$ mole^{-1}

The calculation of the entropy of chlorine from spectroscopic data has been carried out by Giauque and Overstreet,[1] who have considered the effect of the three isotopic molecular species in considerable detail. We have used their equations and constants to calculate the entropy at the boiling point, 239.05°K. The value for the entropy of the ideal gas at this temperature and 1 atmosphere is found to be 51.55 cal. deg.$^{-1}$ mole^{-1}.

The calorimetric and spectroscopic values of the entropy are compared in Table IX.

TABLE IX

COMPARISON OF CALORIMETRIC AND SPECTROSCOPIC VALUES FOR THE ENTROPY OF CHLORINE

	Entropy in cal. deg.$^{-1}$ mole^{-1}		
	Calorimetric data		
T, °K.	Actual gas	Ideal gas	Spectroscopic
239.05	51.44	51.56	51.55
298.10	...	53.32	53.31

The entropy calculated from spectroscopic data does not include the entropy of isotopic mixing or that due to the nuclear spin of Cl^{35} and Cl^{37} since both of these effects cancel in chemical reactions with a high degree of accuracy. The molecular constants for each of the three isotopic molecular forms of chlorine were of course considered in the calculation. The symmetry number was taken as two in calculating the values given in the last column of Table IX. The value given for the ideal gas at 298.1 was obtained by using the band spectrum data for the gas above the boiling point.

(15) Eucken and Hoffmann, *Z. physik. Chem.*, **B5**, 442 (1929).

The excellent agreement of the entropies calculated from calorimetric and from molecular data supports the third law of thermodynamics and also adds to the substantial evidence that only protons or deuterons may cause molecular rotation in the solid state at the temperatures of liquid hydrogen.

We thank Dr. R. A. Ruehrwein for assisting with the measurements.

Summary

The heat capacity of solid and liquid chlorine has been measured from 14°K. to the boiling point.

The melting and boiling points were found to be 172.12 and 239.05°K., respectively (0°C. = 273.10°K.).

The heat of fusion is 1531 cal. mole^{-1} and the heat of vaporization at the boiling point is 4878 cal. mole^{-1}.

The vapor pressure of liquid chlorine has been measured and the results represented by the equation: triple point 172.12 − 240°K., $\log_{10} P$ (int. cm. Hg) = $-(1414.8/T) - 0.01206\ T + 1.34 \times 10^{-5}\ T^2 + 9.91635$.

The observed triple point pressure was found to be 1.044 cm.

The entropy of chlorine was found to be 51.56 and 53.32 cal. deg.$^{-1}$ mole^{-1} at 239.05 and 298.10° K., respectively, for the ideal gas by means of the third law of thermodynamics.

The data are in excellent agreement with a calculation based on band spectrum data giving 51.55 and 53.31 cal. deg.$^{-1}$ mole^{-1} at the two temperatures.

The Ternary Systems $KBrO_3$–$KClO_3$–H_2O at 25° and $NaBrO_3$–$NaClO_3$–H_2O at 25 and 50°[1]

BY THEODORE SWENSON AND JOHN E. RICCI

These systems have been investigated for the purpose of finding and studying other examples of the type of solid solution previously suggested[2] as a possible addition to the types in the usual Roozeboom classification, namely, the formation of a single incomplete or limited series of solid solutions between two salts without any experimentally measurable degree of mutual solubility for one of the components. Such solid solutions were noted between potassium chlorate and potassium nitrate[3] and between sodium bromate and sodium sulfate.[2] The combinations of potassium bromate and chlorate, and of sodium bromate and chlorate, were therefore studied, as ternary systems with water, using the usual phase rule methods for the investigation of the solubility relationships.

Experimental

High grade (99.9%) potassium bromate was used without recrystallization, while sodium bromate was purified by recrystallization. The chlorates both contained small amounts of the corresponding bromates; this bromate content was in each case determined, by the method described below, and the necessary corrections were then made when the dry chlorates were weighed out for the preparation of the ternary complexes.

The solubility determinations were made according to the usual procedure described in similar investigations, insofar as method of stirring, sampling, filtering, density determination and temperature control are concerned. Starting with complexes of known composition, and analyzing the saturated solutions at equilibrium, the solid phases were then determined by the usual methods of graphical or algebraic extrapolation, besides occasional analyses of wet and centrifuged residues.

The analytical method for the saturated solutions depended on the determination of the combined percentage of the two salts concerned, by evaporation, and iodometric titration of the bromate with thiosulfate, thus allowing the calculation of the percentage of the second salt by difference. This simple scheme involves the difficulty of titrating small quantities of bromate in the presence of large and varying amounts of chlorate. A preliminary investigation of this analytical problem was therefore necessary.

Iodometric Titration of Bromate in Presence of Chlorate.—The determination of bromate by iodometry, in the presence of chlorate, depends on the proper regulation of the acidity, the concentration of iodide, and the time allowed for reaction and titration. Conditions for the differential titration were first given by Junck,[4] chiefly

(1) The material of this paper is taken from the thesis of Mr. T. Swenson presented to the Graduate School of New York University in partial fulfilment of the requirements for the degree of Master of Science.

from the point of view of the detection and estimation of bromate present as impurity in a chlorate. The literature was reviewed by Taradoire,[5] studying the problem for the same purpose, and employing many refinements in technique for the exact determination of traces of bromate in chlorates. Barneby,[6] studying the general problem of the differential titration of the halogenates in mixtures, described the determination of 0.1 g. of potassium bromate in the presence of 0.1 g. of potassium chlorate. The problem of much larger relative amounts of chlorate, however, such as are found in the present solubility measurements, was not touched upon, and the actual conditions required had therefore to be determined by experiment.

The conditions finally adopted, allowing the titration of up to 0.1 or 0.2 g. of potassium bromate in the presence of as much as 20 g. of sodium chlorate, in a volume of about 100 ml., were the following: sodium iodide, 5 g. (20 ml. of 25% solution), giving a concentration of 0.33 *N* after dilution to 100 ml.; 1.5 ml. of concd. hydrochloric acid (0.18 to 0.2 *N* after dilution); titration with 0.2 *N* sodium thiosulfate to be started one and one-half minutes after addition of the acid, and to be finished in five minutes, inclusive. The above acidity was found to be approximately the minimum for the complete and reasonably fast reaction of the bromate; the large quantity of iodide is required to keep the iodine well in solution. Tests showed these conditions to give complete reaction of the bromate, in the absence of chlorate, with an accuracy of one part in two thousand. When chlorate was added, two corrections had to be made. The first is a constant one depending on the quality and quantity of the chlorate, being caused by the bromate content of the latter. This was therefore determined by previous titration of the chlorate alone according to the method just described and taking account of the second correction too, which is an effect of the slow oxidation of iodide by chlorate under the conditions of the titration. This second effect, which was found to be approximately directly proportional to the chlorate concentration and to the time, was evaluated by measuring the continued liberation of iodine from various initial weights of chlorate, by successive titration with a very dilute thiosulfate solution, and plotting the total volume of thiosulfate used against the time.

Tested on known mixtures, the procedure described, involving two corrections, gave an average error of only one part in two thousand, in six determinations of about 0.2 g. of sodium bromate in the presence of 10 g. of sodium chlorate of known bromate content. The same conditions, moreover, using a 0.02 *N* sodium thiosulfate solution for titration, and applying the time correction indicated, can be used for the detection of quantities as small as 0.001 (±0.0005)% of bromate in chlorate.

Results.—The results of the solubility determinations are shown in Tables I and II, which list the composition of original complexes, the composition (and density, for some) of saturated solutions, and, in the last column, the composition of the solid phase calculated by the extrapolation of tie-lines, on the assumption of an anhydrous solid.

Discussion

Both systems reveal solid solution formation. In the potassium salt system there are two series of limited solid solutions, one of potassium chlorate in potassium bromate (S.S. I) with a limit at 3% potassium chlorate, the other with a limit of 5% potassium bromate in potassium chlorate (S.S. II), (both limits estimated from the diagram). The isothermally invariant liquid solution in equilibrium with these two mutually saturated solid solutions has the composition 4.94%

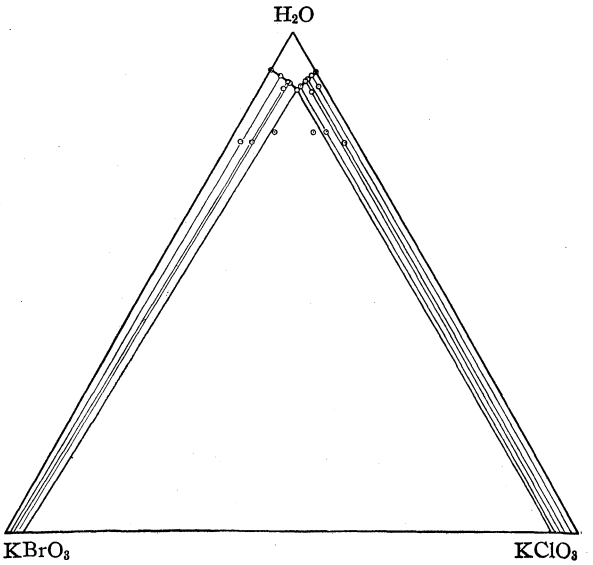

Fig. 1.—System $KBrO_3$–$KClO_3$–H_2O at 25°.

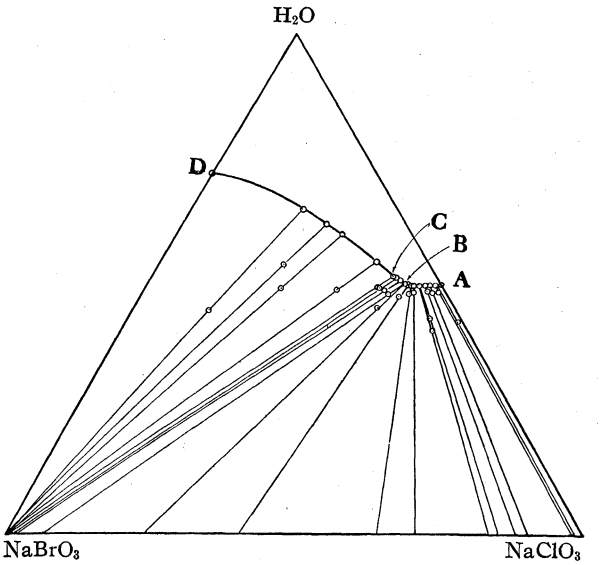

Fig. 2.—System $NaBrO_3$–$NaClO_3$–H_2O at 25°.

potassium bromate and 6.54% potassium chlorate. In one or two experiments the composition of the solid was determined by direct analysis of the dried residue, checking the values obtained by algebraic extrapolation of tie-lines. The time allowed for equilibrium was fourteen days, repeated analysis of saturated solutions having shown this time to be sufficient, when small amounts of solid were used.

The interpretation of the sodium salt system from the data collected is more difficult; perhaps more complete isotherms at both temperatures would be required for a complete interpretation. The chief difficulty in the experiments was the very long time required for the attainment of equilibrium in the formation of the solid solutions here involved; some of the complexes were stirred for periods of one or two months before analysis, some of them still showing small changes going on.

Considering the results at 25°, there is no indication of a break in the solubility curve starting with a solution (point A, Fig. 1) of sodium chlorate alone, until the liquid solution reaches the composition (point B) 6% sodium bromate and 44% sodium chlorate (approximately, as estimated from the diagram). The corresponding solid phase in equilibrium with these liquid solutions changes continuously from pure sodium chlorate, through a wide range of continuous solid solution composition up to 60–65% sodium bromate. A break in the liquid curve at point B (and therefore a corresponding discontinuity in the solid phase) is strongly suggested by the shape of the curve. The solid phase saturating the remaining liquid solutions from B to D seems, however, to be not simply a corresponding solid solution of low sodium chlorate content, but apparently pure sodium bromate over a large part of the curve. For the portion of the curve from D to C (C being an estimated point) the saturating solid is apparently sodium bromate or at most a solid solution of negligible concentration of sodium chlorate in sodium bromate. The appearance of the solid in this region was always quite identical with that of the pure salt, equilibrium was very rapidly attained, and the extrapolation of the tie-lines gave an average algebraic deviation of −0.05% sodium chlorate and an average absolute deviation of 0.41% sodium chlorate, from the point representing pure sodium bromate. Within the experimental variation of the extrapolations, therefore, the phase here is not a solid solution. Beyond C, however, or between C and B, it is possible that a third solid phase is formed, a very finely divided milky solid, slow to settle and slow to come to equilibrium, with compositions, estimated from the disposition of the tie-lines, ranging from very low sodium chlorate content (if not actually pure sodium bromate) to about 5–10% sodium chlorate. This interpretation of three different solid phases would of course involve the existence of two isothermally invariant points for liquid solutions saturated with two adjacent solid phases. These, suggested as points B and C, were not determined; the limits of solid solution com-

position, in view of the slowness in the attainment of equilibrium, would be very difficult to fix.

An alternative possibility is that the two salts form a single solid solution, theoretically continuous from one pure salt to the other, but that the distribution of the salts between the solid and liquid phases is very uneven. The wide divergence of the tie-lines for complexes giving solutions containing approximately 6% sodium bromate (point B) would then simply indicate a marked tendency toward the formation of an isothermally invariant point, because of a tendency toward discontinuity in the solid phase. The observed curvature at the point B, however, suggests actual discontinuity, so that the latter interpretation, while not impossible, seems rather unlikely.

The solid phases are therefore suggested as being pure sodium bromate from D to C, solid solution of some sodium chlorate in sodium bromate (S.S. I) from C to B, and a solid solution (S.S. II) of wide range of proportions of the salts, up to pure sodium chlorate, from B to A. If this interpretation is correct, this system might then be taken as another example of the type of solid solution formation suggested as possible in connection with a study of the system $NaBrO_3$–Na_2SO_4–H_2O[2]; that is, a system in which the miscibility of the salts is such that while solid solutions are formed, a pure salt may still constitute one of the solid phases by itself.

The same general characteristics were noted for the system in the results of a partial isotherm at 50°, also shown in Table II.

Summary

1. In the system $KBrO_3$–$KClO_3$–H_2O, studied at 25°, the two salts dissolve to a limited extent in each other, forming two solid solutions containing up to 3% potassium chlorate in potassium bromate and up to 5% potassium bromate in potassium chlorate.

2. The salts in the system $NaBrO_3$–$NaClO_3$–H_2O studied at 25° (and incompletely at 50°) form a series of solid solutions which, though the evidence is not altogether conclusive, is apparently discontinuous. The solubility curve at 25° appears to be divided into three portions corresponding to the following solid phases: (1) pure sodium bromate, (2) a sodium bromate solid solution containing up to about 5–10% sodium chlorate, (3) a sodium chlorate solid solution containing from 0 to 60–65% sodium bromate.

3. Conditions for the differential iodometric titration of bromate in the presence of very large amounts of chlorate are examined; with proper correction for the slow reaction of chlorate with iodide in acid solution, small amounts of bromate (0.1–0.2 g.) can be determined accurately in the presence of up to 20 g. of chlorate.

The Electrostatic Effect of Substituents on the Dissociation Constants of Organic Acids. IV. Aromatic Acids[1]

BY F. H. WESTHEIMER

I

In 1923 Bjerrum[2] advanced the hypothesis that, except for a statistical factor, the effect of a substituent on the ionization constant of an organic acid is electrostatic in origin. Recently, a more satisfactory mathematical formulation of Bjerrum's hypothesis has been advanced by Kirkwood and the author.[3] This treatment differs from the old essentially in that the solute molecules are regarded as cavities of low dielectric constant within the solvent. Shookhoff and the author[4] have applied the new equations with considerable success to a large number of saturated aliphatic acids, and have shown that it will account not only for the ratio of the first to the second dissociation constants of straight-chain dibasic acids, but also, in contrast to the equations of Bjerrum and of Eucken,[5] for the ratio of the dissociation constants of alkylated dibasic acids and for the effect of dipolar substituents on the ionization constants of monobasic acids.

The purpose of the present paper is to apply the new treatment to aromatic acids.

The equations from which the effect of substituents on the ionization constants of acids can be computed are given below. For dibasic acids

$$\text{Log } K_1/\sigma K_2 = \frac{e^2}{2.303kTRD_E} = \Delta pK$$

and for dipole substituted acids

$$\text{Log } K_1/\sigma K_2 = \frac{eM \cos \zeta}{2.303kTR^2D_E} = \Delta pK$$

In the first equation K_1 and K_2 are the first and second ionization constants of the dibasic acid, e the electronic charge, and R the distance between the ionizable protons. σ, the statistical factor, is equal to four for the dibasic acids and to two in the comparison of hydroquinone with phenol; in the other cases considered in this paper it is unity. In the second equation, K_1 is the dissociation constant of the acid with a polar substituent, K_2 that of the unsubstituted acid, M the dipole moment of the substituent, ζ the angle the dipole makes with the line joining its center with the ionizable proton, and R the distance between the dipole and the proton. D_E, the "effective" dielectric constant, has been evaluated in the previous papers of this series only for spheres and for prolate ellipsoids of revolution in which the substituent and the dipole are at the foci. While neither a sphere nor a prolate ellipsoid of revolution is a good model for aromatic compounds, the ellipsoid will serve as a first approximation for the para substituted benzene derivatives; obviously neither the ortho nor meta compounds can be treated quantitatively. That meta substituted carboxylic acids are, in general, similar to the para, follows from the work of Dippy and Watson.[6] The author is aware of the peculiarities of ortho substituted acids,[7] and hopes to discuss these at a later date.

In the previous publications, the interprotonic or proton–dipole separation has been computed from the known ionization constants, and this length compared with molecular dimensions. In the present instance, it is more advantageous to assume a reasonable distance for the interprotonic or proton–dipole separation, and to compute ΔpK, the difference between the pK values of the two acids (less the logarithm of the statistical factor), a difference which can then be compared with the experimental value. The lengths chosen are, in all cases, reasonable ones. However, variation of 0.2 Å. will, in the case of the benzoic acids, cause a change of ΔpK of 20%. Since the equation employed is not ideally adapted to benzenoid compounds, and since the lengths chosen for R are somewhat arbitrary, values of ΔpK have been given only to the nearest 0.05 unit. The molecular volumes, necessary for the computations, have been estimated from Traube's rule.[8] The internal dielectric constant[3] has been set equal to 2.00, as in previous papers of this series.

II

The limited data available for dibasic acids are summarized in Table I.

TABLE I

DIBASIC AROMATIC ACIDS

$V = 190$ Å.^{3} $R = 7.5$ Å. $D_E = 76$

Acid	ΔpK (obsd.)	ΔpK (calcd.)
Terephthalic acid[a]	(0.70)	0.40
Benzoic acid *p*-sulfonamide[b]	0.35	0.40
Benzoic acid *p*-sulfonate		

[a] Due to its insolubility, the first dissociation constant of terephthalic acid has never been measured in water. The estimate in parentheses is that of Kuhn and Wasserman, *Helv. Chim. Acta*, **11**, 44 (1928). [b] The assumption is made that the ionization constant of benzoic acid *p*-sulfonamide is equal to the ionization from the carboxyl group, were it possible to measure it, of benzoic acid *p*-sulfonic acid. The data are given in Landolt–Börnstein, "Physikalisch–chemische Tabellen."

Inspection of this table reveals that the electrostatic effect, while it may not be the exclusive factor, is the major one in determining the effect of a charged group on the strength of an aromatic carboxylic acid.

Since the benzene ring itself introduces complications absent in the aliphatic series, a purely electrostatic treatment will be expected to apply best to the phenylacetic acids, in which a methylene group separates the carboxyl from the ring. The data are collected in Table II. The differences between the dipole moment of the substituents and the hydrogen moment are those given by Smyth[9] for aromatic compounds, and are assumed to be located in the bond between the ring and the substituent. The calculated value for the *p*-methoxy acid has been placed in parentheses because the angle and location of the methoxyl moment is still in doubt.[10] The calculations have

(8) Traube, *Samml. chem. chem.-tech. Vortr.*, **4**, 255 (1899).

(9) Smyth, *J. Phys. Chem.*, **41**, 209 (1937).

(10) Cowley and Partington, *J. Chem. Soc.*, 1257 (1933); Bennett and Glasstone, *Proc. Roy. Soc.* (London), **145A**, 71 (1934); Bennett, *Trans. Faraday Soc.*, **30**, 853 (1934); Hampson and Sutton, *Proc. Roy. Soc* (London), **140A**, 562 (1933); Sutton and Hampson, *Trans. Faraday Soc.*, **31**, 945 (1935).

been made on the assumption that the value of Marsden and Sutton[11] is correct, namely, that the methoxyl moment is at an angle of 76° with the ring to oxygen bond, with the negative end of the dipole toward the ring. While this seems to be the best available estimate, it indicates considerable interaction between the methoxyl group and the ring, causing a complex charge distribution which is poorly represented by a point dipole.

TABLE II

PHENYLACETIC ACIDS

$V = 210$ Å.^{3} $R = 6.6$ Å. $\cos\zeta = 0.90$ $D_E = 10.9$

Acid	ΔpK (obsd.)	ΔpK (calcd.)
p-Chlorophenylacetic acid[a]	0.10	0.15
p-Bromophenylacetic acid[a]	.10	.15
p-Iodophenylacetic acid[a]	.15	.15
p-Nitrophenylacetic acid[a]	.45	.40
p-Methoxyphenylacetic acid[a]	− .05	(− .05)

[a] Dippy and Williams, *J. Chem. Soc.*, 161 (1934); 1888 (1934).

It is apparent that the electrostatic effect alone is adequate to account for the effect of substituents on the ionization constants of phenylacetic acids.

The data for the substituted benzoic acids are summarized in Table III. *p*-Aminobenzoic acid is not included because, since an unknown percentage of the acid is present as a dipolar ion (zwitterion), the value of ΔpK is not known.

TABLE III

BENZOIC ACIDS

$V = 180$ Å.^{3} $R = 5.9$ Å. $D_E = 9.4$

Acid	ΔpK(obsd.)	ΔpK(calcd.)
p-Toluic acid[a]	−0.15	−0.05
p-Fluorobenzoic acid[a]	.10	.25
p-Chlorobenzoic acid[a]	.25	.25
p-Bromobenzoic acid[a]	.25	.25
p-Cyanobenzoic acid[b]	.70	.70
p-Nitrobenzoic acid[a]	.80	.65
p-Anisic acid[a]	− .30	(− .05)
p-Hydroxybenzoic acid[b]	− .25	(− .00)

[a] Dippy and Williams, *J. Chem. Soc.*, 1888 (1934); Dippy, Williams and Lewis, 343 (1935); Dippy and Lewis, 644 (1936). [b] Landolt–Börnstein, "Physikalisch-chemische Tabellen."

Inspection of Table II shows that the electrostatic effect, if not the only one, is at least the major cause of the differences in acidity among the benzoic acids, except for the cases of the hydroxy and methoxy substituted acids.

The close correspondence between the predictions of the electrostatic theory and experiment does not apply to the phenols and anilines. The data for the substituted phenols are presented in Table IV.

TABLE IV

SUBSTITUTED PHENOLS

$V = 160$ Å.^{3} $R = 5.1$ Å. $D_E = 6.5$

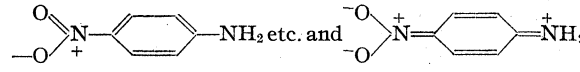
Phenol	ΔpK (obsd.)	ΔpK (calcd.)	$M_{int.}$ in D
p-Cresol[a]	−0.25	−0.10	0.00[b]
p-Chlorophenol[a]	.50	.50	− .03[b]
p-Hydroxybenzaldehyde[a]	1.30	.45	Large[c]
p-Cyanophenol[a]	2.05	1.30	Probably large[d]
p-Nitrophenol[a]	2.80	1.25	0.71[b]
Hydroquinone[a]	−0.70	−0.05	

[a] Landolt–Börnstein, "Physikalisch-chemische Tabellen." [b] Marsden and Sutton, ref. 11. [c] The observed moment in solution of *p*-hydroxybenzaldehyde of 4.19 D (Pearce and Berhenke, *J. Phys. Chem.*, **39**, 1005 (1935)) considerably exceeds 3.20, the moment calculated on the basis of free rotation of both groups. [d] While no value for the interaction moment is available for *p*-cyanophenol, the interaction moment for *p*-cyanodimethylaniline is known. While exceeded by that of *p*-nitrodimethylaniline (1.86 D) it is none the less large (0.71 D).

In the case of the phenols, while the electrostatic theory adequately accounts for the effect of halogen substituents, the effect of the nitro group, for example, in increasing the strength of phenol, is much greater than can be accounted for on the basis of the group moment alone.

It is an interesting and significant fact that, in the majority of cases in which the electrostatic theory is inadequate, the dipole moment of the molecule is not equal to the vector sum of the constituent dipoles. When there is no interaction of the substituent groups, such a summation is valid.[12]

The classical case of interaction of substituent groups is that of para nitroaniline, where the dipole moment of the compound is greater than the absolute sum of the constituent dipoles. Such an enhanced moment has been explained by the assumption that para nitroaniline is a resonance hybrid[13] of the following structures



The last column of Table IV gives the interaction moment for the substituted phenols. The correspondence between the interaction moment and the deviations from the electrostatic theory are apparent.

It is reasonable to assume that resonance is more pronounced in the substituted phenolate ion than

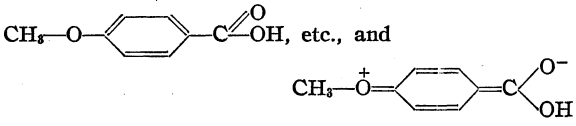
(11) Marsden and Sutton, *J. Chem. Soc.*, 599 (1936).

(12) Höjendahl, *Physik. Z.*, **30**, 391 (1929).

(13) Kumler and Porter, THIS JOURNAL, **56**, 2549 (1934).

in the phenol itself. On this basis, it can be anticipated that, in those cases in which there is interaction of the groups in para positions, the substituent will increase the acid strength of phenol more than can be predicted from a purely electrostatic treatment.

A similar explanation can be advanced to account for the large decrease of acidity caused by a methoxyl or hydroxyl substituent in benzoic acid. The resonating forms of the para methoxy acid are the following



Here it is reasonable to assume that resonance is more important in the acid than in the corresponding ion. As yet, there are no dipole moment data available to support the assumption of resonance in para methoxybenzoic acid. Further, no explanation of the anomalous behavior of hydroquinone can be offered at this time.

Table V contains the data for substituted anilines, regarding anilinium ion as an acid according to the Brönsted definition. Included are the cases of benzidine and *p*-phenylenediamine, in which the substituent is a charged group.

TABLE V

SUBSTITUTED ANILINES

Aniline	V in Å.^{3}	R in Å.	D_E	ΔpK (obsd.)	ΔpK (calcd.)	$M_{int.}$
p-Phenylene-diamine	190	5.6	34	2.90	1.25	
p-Benzidine	250	9.9	94	0.60	0.25	
p-Toluidine	165	5.1	6.2	−0.50	−0.10	0.00
p-Chloroaniline	165	5.1	6.2	.50	.50	.06
p-Bromoaniline	165	5.1	6.2	.35	.50	.05
p-Nitroaniline	165	5.1	6.2	3.45	1.25	.95
p-Anisidine	165	5.1	6.2	− .70	− .10	

While it is at once obvious that the electrostatic equations are quite inadequate to account for the base strength of the substituted anilines, it seems likely that differences in resonance energy can account for many of the observed effects.

Finally, it is interesting to consider the computations in this paper in the light of Hammett's[14] empirical equation

$$\log K = \log K^0 + sr$$

where K is any rate or equilibrium constant for a substituted benzene derivative, K^0 is the corresponding constant for the unsubstituted benzene derivative, s is a constant characteristic of the substituent, and r, a constant characteristic of the reaction, has been set equal to unity for the case of the ionization of substituted benzoic acids. Hammett's equation is of much broader scope than the present treatment, and includes both those effects ascribed to resonance and the purely electrostatic ones. It is interesting that a special value of s was reserved for the *p*-nitro group in aniline and phenol, cases in which the interaction ascribed to resonance is especially large. The present treatment can predict the s values of Hammett's equation with moderate accuracy for those substituents for which no large resonance effects have been observed. The calculated constants are the computed values of ΔpK for the benzoic acids. They have the proper sign, are in the correct sequence and of the right order of magnitude; while the agreement is far from perfect, it is significant that a theoretical treatment based on the electrostatic theory can even approximate these constants.

TABLE VI

VALUES OF s

Para substituent	s (Hammett)	s (calcd.)
CH_3	−0.17 ± 0.05	−0.06
F	+ .06 ± .07	+ .24
Cl	+ .23 ± .04	+ .27
Br	+ .23 ± .04	+ .26
NO_2	+ .78 ± .07	+ .65
CN	+1.00 ± .04	+ .68

Summary

The electrostatic effect of substituents on the dissociation constants of para substituted phenyl acetic acids, benzoic acids, phenol and anilines has been computed by the method of Kirkwood and Westheimer. It is found that the electrostatic effect is the predominant factor in determining the strength of the carboxylic acids with the exception of the para hydroxy and methoxy benzoic acids. The electrostatic effect is an important but subordinate cause of the variation of acidity among substituted phenols and anilinium ions. The difference between the electrostatic and the total effect of a substituent is greatest in those cases in which resonance interaction of the groups has already been indicated by considerations of dipole moment data.

The Free Radicals of the Type of Wurster's Salts

BY L. MICHAELIS, M. P. SCHUBERT AND S. GRANICK

The univalent oxidation products of the aromatic *p*-diamines, or Wurster's salts,[1] are free radicals which may polymerize in a sufficiently concentrated solution and at low temperature or in the solid state.[2] This paper is concerned with their properties, especially their stability and color, in dilute solution where they appear only as free radicals. They are in general much more stable than the corresponding quinone diimines although the latter are not radicals. The absorption spectra of these radicals show a very distinct pattern of bands in the visible range of wave lengths varying according to substitutions of the hydrogen atoms either at the amino groups or at the ring. The influence of substitutions at the amino groups has been described by Piccard. This study will be extended here, and a study of the effect of substitutions at the ring will be added.

1. Stability.—The study of stability in the dissolved state is complicated by the fact that it is impossible to obtain any pure solution of these radicals at all. They exist only in equilibrium with one molecular species at a lower level of oxidation, the diamine, and another at a higher level of oxidation, the diimine. Since the latter are very unstable compounds, liable to undergo irreversible changes, such a system may undergo irreversible changes, which are not directly due to any lability of the radical itself. For this reason the criteria for stability or lability of the radical should be discussed first. Stability in general may be conceived as the reluctance to undergo chemical reactions. One is faced with an obvious ambiguity with respect to the definition and measurement of stability, because the tendency to enter into a chemical reaction depends also on the nature of the substance with which the substance in question is to react. This is true for all reactions except those which are strictly monomolecular such as radioactive decompositions. Among the various chemical reactions which a radical is inclined to undergo there are three types which might be chosen as criteria for stability.

(1) R. Willstätter and J. Piccard, *Ber.*, **41**, 1458 (1908); J. Piccard, *ibid.*, **46**, 1843 (1913); E. Weitz, *Z. Elektrochem.*, **34**, 538 (1928); L. Michaelis, THIS JOURNAL, **53**, 2953 (1931); L. Michaelis and E. S. Hill, *ibid.*, **55**, 1487 (1933).

(2) J. Piccard, *Ann.*, **381**, 351 (1911); *Ber.*, **59**, 1438 (1926).

If we designate, as previously, the three levels of oxidation–reduction by R, S, and T (the diamine, the semiquinone radical, and the diimine), and the dimerized radical as D, the stability of the radical may be measured either by the equilibrium constant of the reversible reaction

$$R + T \rightleftarrows 2S \qquad (1)$$

or by the equilibrium constant of the reversible reaction

$$2S \rightleftarrows D \qquad (2)$$

or (3) by the rate at which the free radical undergoes any irreversible reaction. The kind and rate of such a reaction depends on the solvent and on the nature of the substance with which the radical is to react.

The study of each such reaction will lead to a different notion of the stability of the radical. If we choose the equilibrium constant of reaction (1) as criterion for stability and compare the stabilities of various radicals of the homologous series, not only S is varied but also R and T. If we choose the constant of reaction (2), not only S is varied but also D. So the best comparison available of stabilities of the radicals among themselves seems to be a reaction of the type (3) as standard method, chosen in such a way that only the radical is varied, and the substance with which it reacts is always the same, namely, nothing else but a properly chosen solvent. Thus it seems to be the fairest and most natural method for measuring the stability of the radical just to measure its lifetime in a properly chosen solvent. This criterion of stability is preferable furthermore because the equilibrium constant of reaction (1) cannot be measured (except for diamino-durene) on account of the lability of the quinone diimine, and the process (2) from left to right does not take place to any measurable degree in dilute solution.

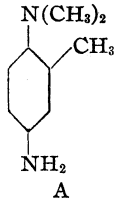
The criterion for stability, then, will be the lifetime of the radical in a properly chosen solvent. There is only one difficulty involved in this procedure which must be first overcome. It is characteristic of the systems to be investigated in this paper that the free radicals (the S forms, Wurster's salts in the present case) are much more resistant to irreversible changes when exposed to a solvent, than are the T forms, the quinone-di-

imines, though the latter are not free radicals. It is known that quinone diimines in all solvents not entirely water free, are very unstable; whereas some of the free radicals such as Wurster's blue, are very stable compounds even in an aqueous solution. Consequently, if in some particular case a radical in a certain solution has only a short lifetime, it cannot be decided directly whether the irreversible disappearance of the radical is due to its own lability, or to the lability of the diimine with which it is in equilibrium. How much of the labile diimine is present in equilibrium with the radical depends on the thermodynamical constant of the equilibrium $R + T \rightleftarrows 2S$. This constant need not show any simple relation to the tendency of the radical to undergo irreversible reactions. Hence we have to find a method to distinguish what may be designated as the *direct*, and the apparent or *indirect*, lability of the radical. The aim is to measure the direct lability of the radical. The lifetime of the radical in a properly chosen solvent will be taken as a measure of its stability provided the lability of the radical under the experimental conditions is a direct one, and not an indirect one. In order to show how this idea can be used in practice we shall describe four typical cases.

First Case.—If a solution of tetramethyl-*p*-phenylenediamine bihydrochloride, about 0.01 *M*, in an aqueous acetate buffer, *p*H 4.6, is oxidized with a very small amount of bromine, say not more than 1 atom of bromine to 50 or 100 molecules of the diamine, the intense blue color of the radical developed is stable for practically any length of time. It is known that the quaternary diimonium compound derived from this diamine is a compound extremely unstable in water. According to Willstätter even in the solid state it readily decomposes with production of formaldehyde. This experiment shows that the amount of the diimonium compound formed under the conditions chosen in equilibrium with the blue radical is vanishingly small, and the radical itself is very stable.

Second Case.—When the same experiment is performed with *p*-phenylenediamine instead of its tetramethylated derivative, the result is quite different. When aqueous acetate buffer is chosen as a solvent, the yellow color of this radical primarily formed on addition of bromine, turns pink in a few minutes. The rate at which this irreversible reaction takes place greatly depends on the initial concentration of the diamine. When this is varied, keeping constant the amount of bromine used for the oxidation, the rate of the irreversible reaction is greatly diminished as the concentration of the diamine is increased. According to reaction (1) the amount of diimine formed is decreased as the concentration of the diamine is increased. This experiment shows that the irreversible reaction is caused essentially by the irreversible changes of the diimine present and that the free radical is much more stable in this solvent than is the diimine. The diimines which have been prepared by Willstätter[3] are all extremely unstable in organic solvents not perfectly water free. When methanol—even containing as much as 20% water—is chosen as a solvent, the life-time of the radical is much longer, but also here the lifetime of the radical is increased as the initial concentration of the diamine is increased. The concentrations of the diamine and of bromine being properly chosen, the lifetime of the radical may be extended to more than a whole day. By extrapolation we may infer that the direct lifetime of this radical is very long, and its apparent lability for the greatest part is due to the fact that the equilibrium constant of the reaction (1) is such as to cause the two steps of oxidation greatly to overlap. This is a case where the direct lifetime proper of the radical can be proven to be quite long, although at first glance the radical may have the appearance of being very labile.

Third Case.—When the same experiment is performed with the diamine (formula A) the radical has a half lifetime of about ten minutes in an aqueous acetate buffer. In this case the lifetime is not influenced at all by varying the initial concentration of the diamine. This radical itself has a restricted lifetime and its breakdown is not caused indirectly by the diimine which may be in equilibrium with it. The direct disappearance of the radical is so fast that the rate of the indirect breakdown, if there be any, plays no role.



A

Fourth Case.—When the same experiment is performed with symmetrical dimethyldiaminodurene, no radical is formed under any conditions. In this case the corresponding diiminium compound, although not perfectly stable for any

(3) R. Willstätter and E. Mayer, *Ber.*, **37**, 1494 (1904); R. Willstätter and A. Pfannenstiehl, *ibid.*, **37**, 4605 (1904); R. Willstätter and H. Kubli, *ibid.*, **42**, 4135 (1909).

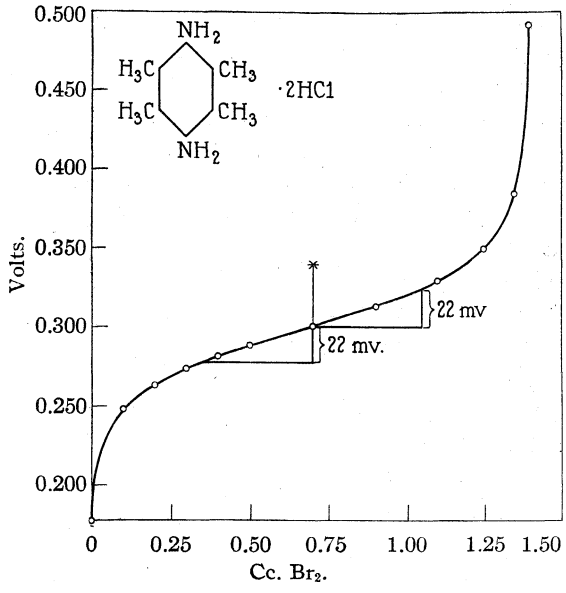


Fig. 1.—Durene diamine bihydrochloride, 50 cc. of 0.001 *M* in a solvent consisting of 8 volumes of methanol + 2 volumes of aqueous acetate buffer of *p*H 4.62 (apparent *p*H of the mixture is 6.21) is titrated with aqueous bromine. Potentials are constant throughout the titration. The titration curve indicates a two-step oxidation with the formation of an intermediate radical (which is yellow). The curve is symmetric, the index potential 22 mv. Hence, the semiquinone formation constant $k = 1.0$; maximum ratio of semiquinone to total substance is 0.33. In this case both the radical and the diimine are stable, at any rate within the period necessary for titration. The initial solution is colorless; it turns yellow during the titration and fades out again at the end-point of titration.

length of time, is yet stable enough to allow a satisfactory potentiometric titration in 80% methanol. The shape of the titration curve confirms that there is no intermediate radical formed at all. Here it is meaningless to speak of the lifetime of the radical. The fact that it is never formed to any measurable extent is itself an expression of its utmost instability, although it must be conceded that here the term "instability" has not precisely the same meaning as in the other cases.

These four examples cover all cases which may be actually encountered. Using critically such tests for stability, the results obtained may be summarized as follows:

The radical derived from *p*-phenylenediamine may be considered as the parent substance. Considering its stability proper according to the above criterion, it is a rather stable compound. Its well-known instability in aqueous solution is essentially an indirect one. Its direct stability can be modified by substitutions. These may be either at the amino groups or at the ring. Considering first compounds with the amino groups unsubstituted, it can be generally stated that substitution of the H atoms in the ring by methyl groups has no influence on the stability exceeding the limits of error of the method. Comparing the compounds not methylated at the ring but methylated at the amino groups, methyl groups appear to increase the stability. The tetramethylamino compound is the most stable of the series. There is, however, no cogent proof that these differences may not be due to differences of the indirect labilities. When both the amino groups and the H atoms of the ring are substituted, the effect largely depends on the particular structure. A methyl group at the ring in ortho position to an unmethylated amino group has sometimes very little effect, sometimes more, and, if any at all, a destabilizing effect. However, if a methyl group is in ortho position to a methylated amino group, it always has a distinct destabilizing effect; two

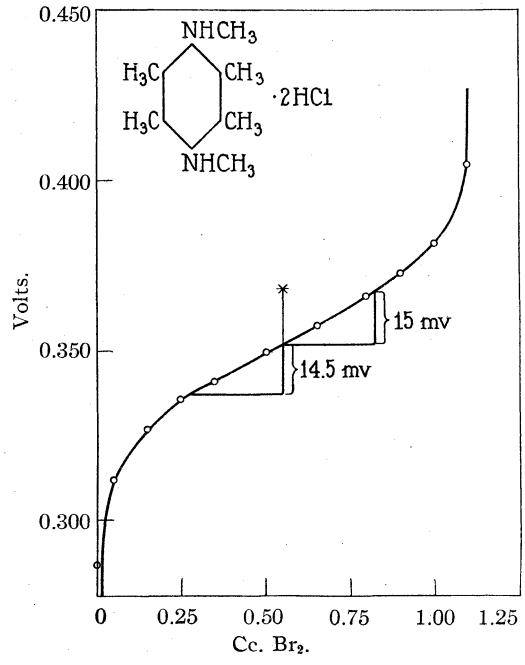

Fig. 2.—Symmetrical dimethyldurene diamine bihydrochloride. Conditions of titration the same as in Fig. 1. Here also a full titration curve is obtained. The index potential is between 14 and 15 mv., indicating that no intermediate radical is formed, in agreement with the fact that no trace of any intermediate colored compound is visible during the titration. The point * in this and all the other curves marks the end of the first step, where 1 atom of bromine per molecule of the diamine has been added.

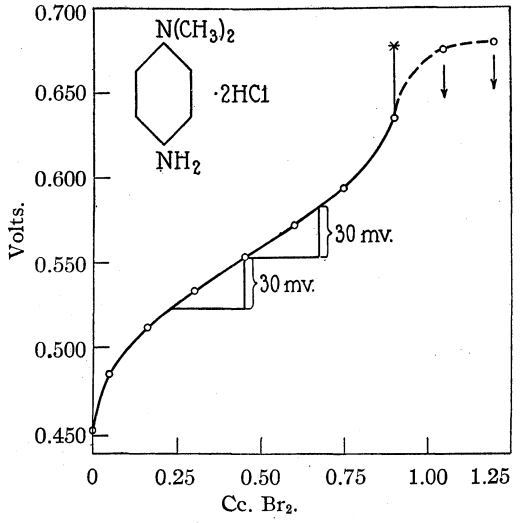

Fig. 3.—Unsymmetrical dimethyl-*p*-phenylenediamine bihydrochloride, 50 cc. of 0.001 *M* solution in a mixture of 8 volumes of methanol and 2 volumes of 0.05 *M* aqueous acetic acid (apparent *p*H of mixture is 3.1) are titrated with aqueous bromine. Potentials are nearly steady only to the end of the first step which is marked with a star (*). During the second step, potentials show considerable drift, as indicated by arrows. Since there is a slight jump at the end of the first step this first step can be treated approximately as a univalent step with no overlapping. The index potential of this univalent step should be 28.6 mv. It is found to be 30 mv., which is in sufficiently good agreement considering the limits of accuracy under the conditions prevailing. Hence, the curve suggests two successive univalent steps of oxidation with no, or very little, overlapping; the first step is reversible; the second step is irreversible due to the spontaneous breakdown of the diimonium compound.

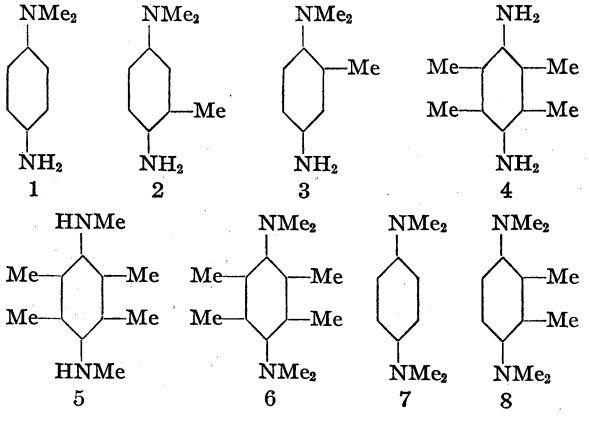
methyl groups, especially if both are ortho to a methylated amino group, decrease the stability to an enormous extent. It may be added that the lifetime of any of these compounds is not affected by diffuse daylight.

To give some examples, the radical derived from 1 (Wurster's red) is a very stable one; 2 is almost as stable; but 3 has a half-lifetime only of less than five minutes in an aqueous solution; the radical derived from 4 is very stable; 5 and 6 do not establish any radicals at all; 7 gives a very stable radical, perhaps the most stable of all; whereas the radical derived from 8 fades out in an aqueous solution within a few minutes.



Substitutions of one single H atom at the ring other than by methyl such as by OCH_3, Cl, SO_3H, all have a distinct destabilizing effect.

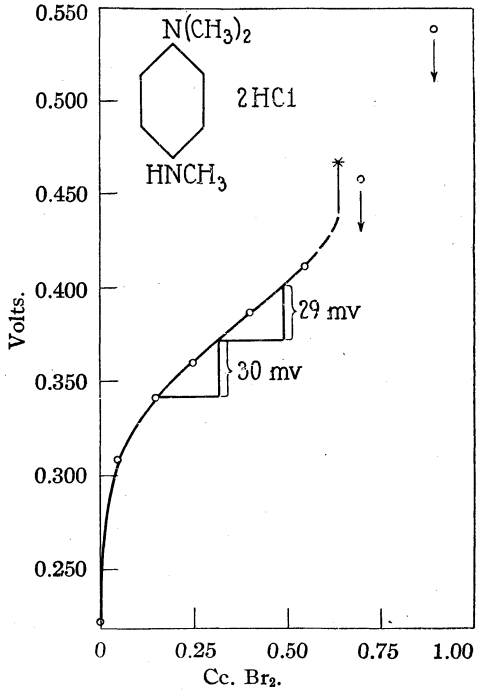


Fig. 4.—Trimethyl-*p*-phenylenediamine dihydrochloride. Conditions of titration similar to those of Fig. 3. Potentials are fairly stable during the first step of oxidation; the index potential corresponds practically to a univalent oxidation (theoretically, 28.6 mv.) and no overlapping with the second step. During the second step of oxidation potentials drift rapidly, showing the instability of the diimine.

The decay of the radical can be observed most easily from the change of its color. In some cases the color simply fades out, in others a new dyestuff may be formed due to condensations. In addition, potentiometric measurements give some indications as to the stability of the radical. If both the radical and the diimine are stable, a potentiometric titration of the diamine with bromine gives a full reproducible potentiometric titration curve up to the end-point of titration. Diaminodurene is the only example of this kind among the

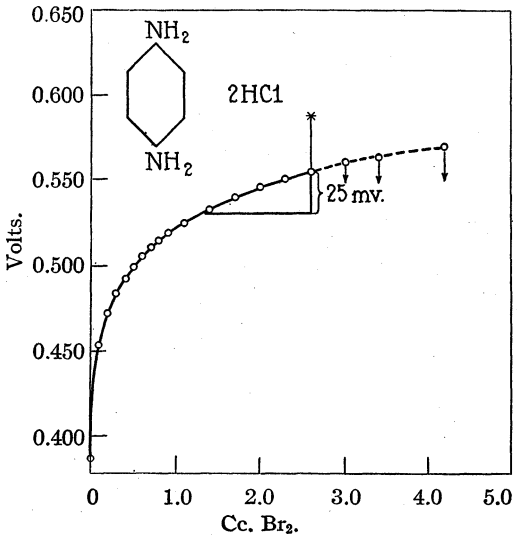

Fig. 5.—*p*-Phenylenediamine dihydrochloride. Conditions of titration similar to those of Fig. 3. The potentials are almost, although not perfectly, steady in the first part of the titration and then begin to drift rapidly.

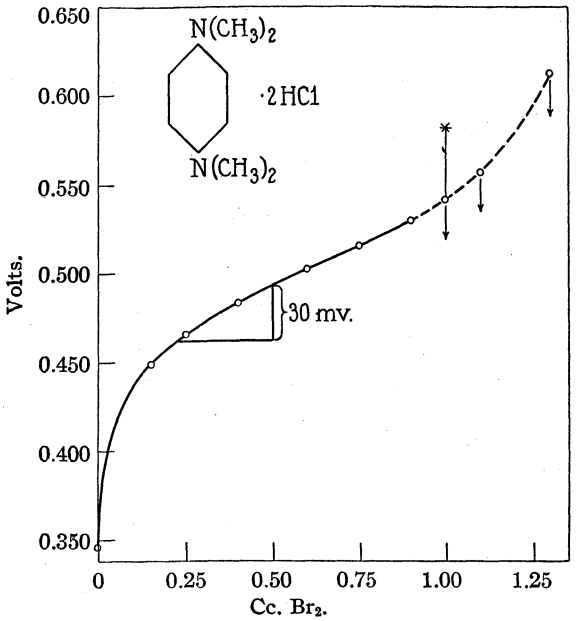

Fig. 6.—Symmetrical tetramethyl-*p*-phenylenediamine dihydrochloride under the same conditions as in Fig. 3. This curve is similar to that of Fig. 3 except that the potentials begin to drift a little earlier.

compounds investigated.[4] If the radical is stable and the diimine is unstable, steady potentials are obtained only in the first stages of the titration as long as there is no appreciable overlapping of the two steps of oxidation. If the radical itself is unstable, the potentials will not be steady even in the first stages of the titration. Many examples of these types of titration curves were obtained, and some are reproduced graphically in the experimental part. Thus a critical discussion of the potentiometric titration curves gives an indication as to the comparative stability of various radicals. The results of the two methods never showed any discrepancy. The limiting case of instability of a radical is the case where no radical is formed at all. If in such a case the diimine happens to be a relatively stable compound, the titration curve should have the shape of a reversible bivalent titration without any intermediate step. Such a case is realized for symmetric dimethyldiaminodurene. If a radical is not formed, and the corresponding diimine compound is not stable either, no steady potentials can be obtained at all during the titration. Such a case is realized in tetramethyldiaminodurene.

2. Absorption Spectra.—The absorption bands for the radicals of the diamines substituted in the amino group, but not in the ring, have been described by Piccard. There are two distinct bands and, if the amino groups are in part or all methylated, a third less conspicuous one toward the shorter wave lengths. Each methyl group substituted in the amino group has a bathochromic effect, displacing the bands toward longer wave lengths. The molar absorption is distinctly greater for the tri- and tetramethyl compounds than for the others. There is scarcely any dif-

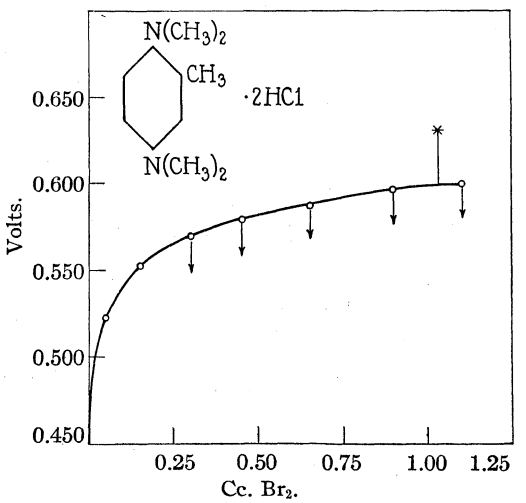

Fig. 7.—Symmetrical tetramethyldiaminotoluene dihydrochloride. Same conditions as in Fig. 3. This curve is one example for a much more unstable radical than Figs. 5 or 6. Potentials drift even in the first stages of titration.

(4) Another example of this kind is symmetrical diphenyl-*p*-phenylenediamine [Michaelis and Hill, THIS JOURNAL, **55**, 1481 (1933)]. Aromatic substituents are not included in the present paper.

ference in the effect of methyl and ethyl; however, carboxymethyl (CH_2COOH) has a stronger bathochromic effect.

Comparing compounds not methylated at the amino groups, the effect of gradually attaching methyl groups at the ring is no bathochromic effect at all, but consists in changing the pattern of the bands as follows (Fig. 8). Without any methyl in the ring the first peak (the one toward the shorter wave lengths) is higher than the second; with one methyl, the two peaks are blurred into one; with two and more methyls, the first peak is decreased in height, the second increased; this effect is greatest in the durene compound.

Comparing the effect of substitutions at the ring in compounds with one or more methyls at the amino groups, the effect of one methyl in the ring consists usually in blurring the pattern; the two bands overlap to a greater extent (Figs. 10, 11, 13). Two methyl groups in the ring make the absorption pattern rather diffuse, (Figs. 9, 13) showing a weak, broad, blurred band. As the bands are blurred the total molar absorption is diminished.

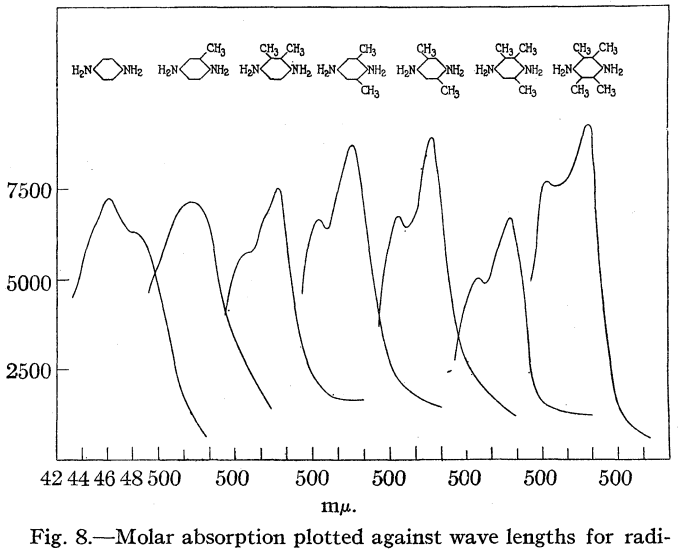

Fig. 8.—Molar absorption plotted against wave lengths for radicals of diamines methylated at the ring, but not at the amino groups. In reality all the curves overlap. All curves should be imagined as displaced horizontally to the left so that the points marked "500 mμ" coincide.

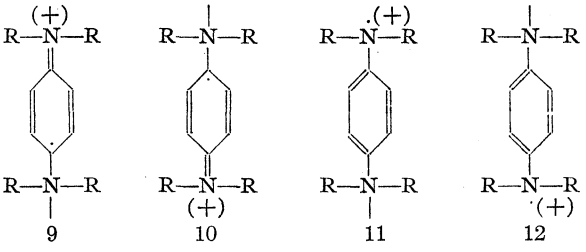
3. Interpretation.—The fact that such radicals are capable of existence at all can be attributed to a particular symmetry of structure resulting in resonance. The molecule has an odd number of electrons; the electrons may be paired in various ways, leaving always one unpaired electron. The odd electron has no fixed place, but there is resonance among various limiting states. Each of them may be considered as contributing a share to the resonating or mesomeric state but none of them can exist as a separate, tautomeric structure for any conceivable length of time. Those two limiting states which may be considered as the main contributors to the resonating state may be symbolized[5] by 9 and 10. There are more configurations of which 11 and 12 are examples.



Resonance among these various structures can take place only if the six carbon atoms of the ring, the two nitrogen atoms and the four atoms attached to the two nitrogen atoms, all are located in one plane. Structures such as 9 or 10 resemble a quinone structure with an odd electron at a carbon atom, while structure 11 or 12 represents a benzenoid structure with an odd electron at a nitrogen atom. Radicals of this type may be designated as semiquinones. The ambiguity as to the benzenoid and the quinonoid structure, or the meriquinoid character which is responsible for the color, lies within a single ring,[6] in contrast to ordinary organic dyestuffs, such as indophenols or triphenylmethane dyes, which are not radicals, and in which this ambiguity is distributed over two (or three) rings. It is the aim of this paper to show that all those radicals showing little stability possess a structure which counteracts a coplanar arrangement such as would be necessary for resonance.

Although not all, yet some of the effects of substitution may be accessible to a rational interpretation at the present time. It is very remarkable that methyl groups in the ring have such a strong destabilizing effect on the radical if the amino groups also are methylated. This effect can be accounted for as follows. In the resonating state, the bond between N and C is

(5) In these formulas letters are atomic kernels, dashes are pairs of electrons, which represent a chemical bond only if they connect two kernels, and the dot is a single electron.

(6) G. Schwarzenbach and L. Michaelis, THIS JOURNAL, **60**, 1667 (1938).

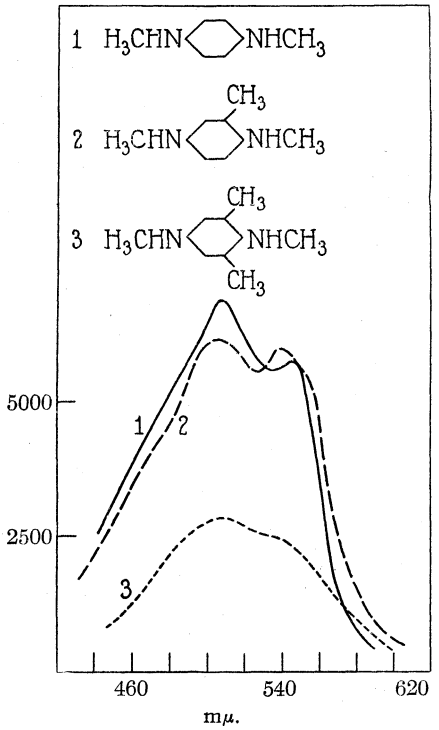


Fig. 9.—Molar absorption plotted against wave lengths for radicals of three symmetrical dimethyl diamines differing by substitution at the ring.

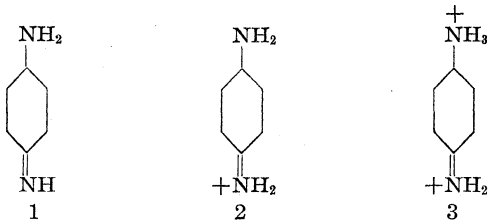
something intermediate between a single and a double bond. The properties of such a quasi double bond will approach those of a double bond and restrict the free rotability of the amino group around this bond as the axis. The two atoms linked by the double bond and the four atoms attached to them must lie in one plane. This plane must be also the plane of the benzene ring. If such a coplanar arrangement requisite for resonance is hampered, stability is diminished.[7]

Some Additional Remarks on the Solvent and on *p*H.—The stability of all of these radicals depends on *p*H. Even the most stable radicals are stable only within a certain *p*H range, which in aqueous solution is usually from *p*H 3.5 to 6. Outside this range all of these radicals become unstable. This is easily accounted for by taking into consideration that among the three possible states of ionization of the radical only formula 2 can exhibit the resonance necessary for the stability. This state, or rather the resonance system of which formula 2 is one of the limiting states, secures whatever stability may be inherent in such an unsaturated compound. A *p*H very suitable

(7) Compare: L. Pauling and G. W. Wheland, *J. Chem. Phys.*, **1**, 362 (1933); E. Hückel, *Z. Physik*, **83**, 632 (1933); *Z. Elektrochem.*, **43**, 752 and 827 (1937).



for stability in most compounds in aqueous solution is 4.6; in 80% methanol it is about *p*H 3 for most of the compounds, and about *p*H 6 for the durene compounds. One easily understandable exception is the radical derived from tetracarboxymethyl-*p*-phenylenediamine, which has its best stability in aqueous solution at *p*H 7. At a lower *p*H, not all of the four carboxyl groups are ionized. If there be any asymmetry with respect to the free electrical charges at these carboxyl groups, resonance will be counteracted.

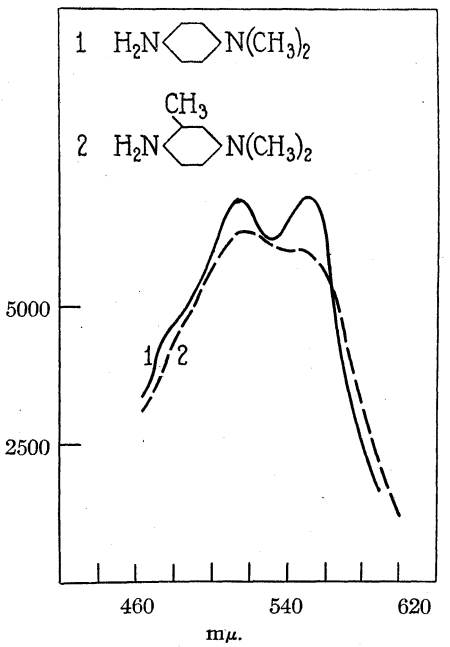


Fig. 10.—Another example of the influence of substitution at the ring upon the pattern of the absorption spectrum.

It has been pointed out before that the radical of *p*-phenylenediamine is very much more stable in methanol than in water. As the amino groups are progressively methylated, the difference of the stability in aqueous and in alcoholic solutions becomes much smaller, and in the tetramethyldiamino compound the radical is perfectly stable both in water and in alcohol. This is quite different from the behavior of the diimines which are all quite unstable in water, and even in alcohol if not

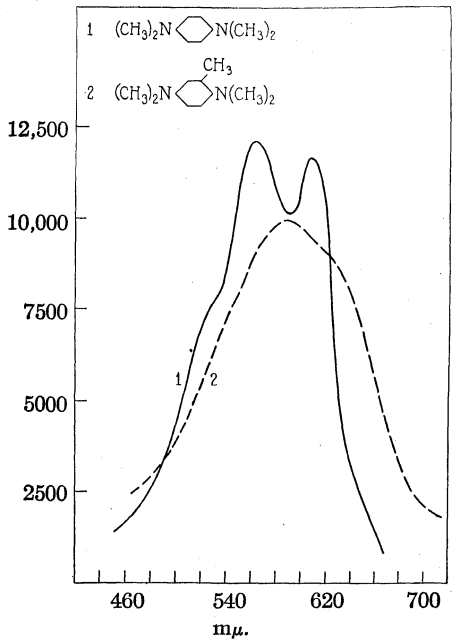

Fig. 11.—A further example of the influence of substitution at the ring upon the pattern of the absorption spectrum.

quite water free; whereas the stability of the radicals in methanol is scarcely diminished even if the alcohol contains 20% of water. The only diimines which in such a solvent have a sufficient stability to allow reproducible potentiometric titration curves throughout both steps of oxidation are the diimine compounds derived from diaminodurene and symmetrical dimethyldiaminodurene.

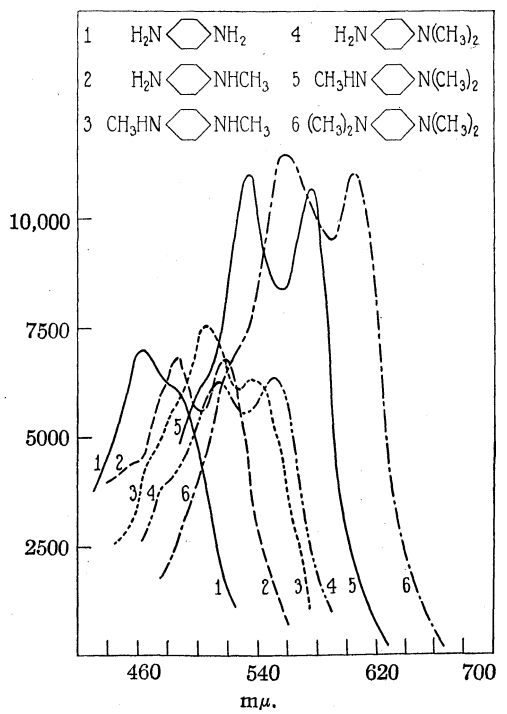

Fig. 12.—Molar absorption plotted against wave lengths for radicals derived from diamines substituted at the amino group but not at the ring. The tetracarboxymethyl derivative is not included in this graph. It is shown in Fig. 13, the last curve, dotted line.

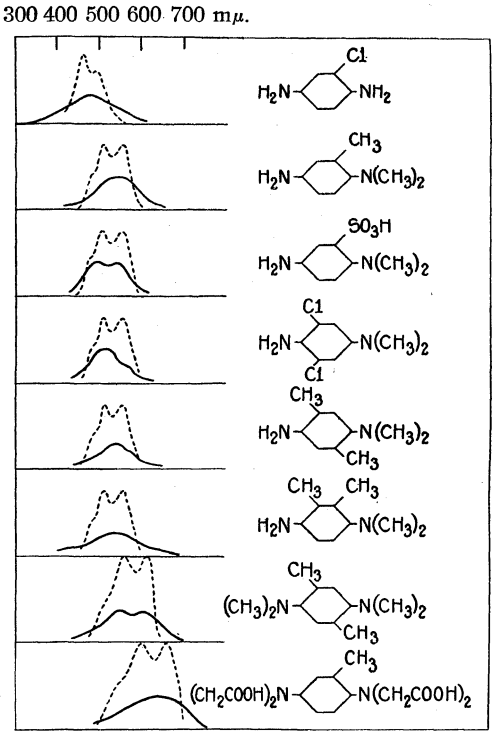

Fig. 13.—Rough sketches of absorption spectra of some compounds substituted at the benzene ring which are not stable enough for accurate measurements of the absorption (drawn out curves). They are obtained by comparing in the hand spectroscope the freshly prepared solutions with those obtained by the homologous, more stable compound with no substitution at the ring. The latter is always plotted in the dashed curve, reproduced from the accurate measurements with the spectrophotometer.

The authors are greatly indebted to Professor Linus Pauling for comments and advice with respect to some of the theoretical discussions.[8]

Experimental

1. Preparation of the Compounds.—All of the *p*-diamines used in this work were prepared as the dihydrochlorides. 1,4-Diaminobenzene, 1,4-diamino-2-methylbenzene and 1-amino-4-dimethylaminobenzene were obtained as commercial preparations and purified by dis-

(8) Professor L. Pauling has drawn our attention to the following analogous case of steric hindrance on resonance: Birtles and Hampson [*J. Chem. Soc.*, 10 (1937)] show that the magnitude of the electric dipole moment of nitrobenzene can be accounted for by resonance due to coplanar arrangement of the NO_2 group and the benzene ring. In nitrodurene this effect of the NO_2 group is strongly diminished.

solving in boiling methanol or boiling methanol containing 10% of water. The solution is decolorized with Darco G. 60 and the hydrochlorides reprecipitated by addition of 5 to 10 volumes of acetone and about 5% volume of concentrated hydrochloric acid.

The symmetrical N,N'-dimethyl derivatives, 1,4-di-(methylamino)-benzene, 1,4-di-(methylamino)-2-methylbenzene, 1-4-di-(methylamino)-2,6-dimethylbenzene and 1,4-di-(methylamino)-2,3,5,6-tetramethylbenzene were all prepared similarly. For example, 12 g. of 1,4-diaminobenzene dihydrochloride in 50 cc. of dry pyridine is heated with 26 g. of toluenesulfonyl chloride at 100° for one and one-half hours. The product is precipitated by pouring the mixture into water and is recrystallized by dissolving in dilute sodium hydroxide solution and adding acetic acid. This ditosyl derivative is methylated in aqueous alkali by the use of excess dimethyl sulfate and the crystalline product is filtered off and washed with dilute alkali. The tosyl groups are removed by warming this product at 90° in a mixture of 30 cc. of acetic acid and 60 cc. of concentrated sulfuric acid until a clear solution results and then for about two hours more. The mixture is diluted with water, made alkaline and extracted with ether. The base is dissolved in 300 cc. of acetone and the dihydrochloride precipitated by the addition of 6 cc. of concentrated hydrochloric acid. It is recrystallized by dissolving in hot methanol and adding 5% volume of concentrated hydrochloric acid and 5 volumes of acetone.

1-Amino-4-methylaminobenzene was prepared from methylacetanilide (55 g.) by nitration in a cold solution of 55 cc. of acetic acid and 110 cc. of sulfuric acid with 19 cc. of fuming nitric acid (d. 1.5); reduction of this nitro compound with stannous chloride in concentrated hydrochloric acid and hydrolysis of the resulting product by heating in this acid mixture under reflux for five hours. The base is separated and the dihydrochloride precipitated from acetone as above.

1-Methylamino-4-dimethylaminobenzene was prepared from 1-amino-4-dimethylaminobenzene by tosylating, methylating and hydrolyzing as for the N,N'-dimethyl derivatives.

A number of the desired compounds were prepared by coupling the appropriate amino compound with diazotized sulfanilic acid, recrystallizing the resulting azo compound and reducing it in boiling water containing a trace of acid by means of zinc dust.[9] By this method there were prepared 1-amino-4-dimethylamino-3-methylbenzene, 1-amino-4-dimethylamino-2-methylbenzene, 1,4-diamino-2,5-dimethylbenzene, 1-amino-4-dimethylamino-2,5-dimethylbenzene, 1,4-diamino-2,6-dimethylbenzene, 1,4-diamino-2,3-dimethylbenzene and 1-amino-4-dimethylamino-2,3-dimethylbenzene.

Pseudocumene was prepared in pure form from a technical product by the method of Jacobsen.[10] The pseudocumene sulfonic acid was recrystallized twice by dissolving in water and adding an equal volume of concentrated hydrochloric acid. The pseudocumene, b. p. 166–167°, obtained from this sulfonic acid was nitrated by the method of Schultz[11] and reduced to pseudocumidine. The subsequent transformation to 1,4-diamino-2,3,5-trimethylbenzene followed the method of Smith.[12]

Most of the N,N'-tetramethyl compounds were prepared either from 1,4-diamino or 1-amino-4-dimethylamino dihydrochlorides by heating with approximately a 50 to 100% excess of methanol in a sealed tube at 150° for eight hours. The free bases were separated in ether or chloroform and distilled at about 1 mm. pressure. In most cases no attempt was made to crystallize the resulting oily bases but these were converted directly in acetone to their dihydrochlorides.

Methylation of diaminodurene with methanol at 150° led, however, to the symmetrical N,N'-dimethyl derivative (m. p. of the base 93°) identical with that obtained by the method described above for preparing N,N'-dimethyl derivatives. This N,N'-dimethyldiaminodurene with nitrous acid in aqueous acid solution gives a dinitroso derivative quite smoothly (m. p. 212°). However, by refluxing diaminodurene in a methanol–water mixture with methyl iodide and sodium carbonate, tetramethyldiaminodurene can be obtained directly (m. p. of the base 67°).

1,4-Tetraethyldiaminobenzene and 1-dimethylamino-4-diethylaminobenzene were prepared from 1,4-diaminobenzene and 1-dimethylamino-4-aminobenzene, respectively, by heating 8 g. of the hydrochlorides in sealed tubes with 15 cc. of absolute ethanol, 1 g. of calcium chloride, 1 g. of cuprous chloride and 1 g. of sodium bromide. The bases are distilled and the hydrochlorides recrystallized from acetone as usual.

2,5-Diaminobenzenesulfonic acid monohydrochloride was prepared by reduction of 2-amino-5-nitrobenzenesulfonic acid with stannous chloride and recrystallization of the product by dissolving in boiling water and precipitating with an equal volume of concentrated hydrochloric acid.

2-Dimethylamino-5-aminobenzenesulfonic acid monohydrochloride was prepared by heating 1-chloro-5-nitrobenzenesulfonic acid with dimethylamine at 100° for two hours and reducing the resulting product with stannous chloride. The tin is removed with hydrogen sulfide and the hydrochloride is recovered by evaporation. It is recrystallized by dissolving in a methanol–water mixture and precipitated with acetone.

The tetracarboxymethyl compounds were prepared as described previously.[13]

2. Compounds not Methylated at the Amino Groups.—The properties of the radicals derived from *p*-phenylenediamine and its homologs substituted at the ring but not substituted at the amino groups are summarized in Table I.

These compounds are more difficult to judge than the others, because they show a greater overlapping of the two steps of oxidation. If the diimine is relatively stable (as in no. 7), the radical is perfectly stable also. If the diimine is very unstable (as in no. 1), it is always obvious that the radical is at least very much more stable than the diimine. The apparent instability of the radical is either in part or entirely an indirect one as can be proved for all these compounds with the "concentration test" described above. Using a higher concentration of the diamine, but

[a] Dissolved in 8 volumes of methanol + 2 volumes aqueous acetate buffer, *p*H 4.6. [b] Dissolved in aqueous acetate buffer, *p*H 4.6. In all other cases, where no letter is indicated, the solvent is 8 volumes of methanol + 2 volumes of 0.005 *N* aqueous solution of acetic acid. [c] Curve for a simple bivalent oxidation without intermediate step. [d] In absence of O_2, color and intensity change relatively slowly. After five days, the intensity had diminished appreciably, while the intensity of Wurster's blue and the trimethyldiamine had not changed under the same conditions. In aqueous acetate buffer (*p*H 4.6) even in the absence of oxygen, the solution turns to a dirty violet color in one day, the original bands being just visible. [e] Potential jumps to second step, and becomes unstable. [f] Indistinguishable from the tetramethyl compound. [g] Aqueous phosphate buffer at *p*H 7.26. [h] The potentials are, of course, never steady in the strictest sense of the word. There is also a certain arbitrariness in the stage of oxidation where a potential begins to show a distinct drift. The indications in this column can, however, be used for comparative purposes.

the same amount of bromine, the life-time is considerably longer than given in the table.

As the yellow color of these radicals disappears in time it either may be replaced by a different color due to condensation (*e. g.* in no. 1), or simply fade out if such condensations are inhibited owing to substitutions at the benzene ring (as in no. 3 or 7). If a condensation to a colored substance (pink or violet, according to the particular compound) takes place, the lifetime of the radical may be greatly underestimated since its yellow color is superseded by the deeper color of the secondary reaction product. The duration of the yellow color is greatest in pure methanol. However, in order to make possible a variation in *p*H so as to find out its optimum condition, and also in order to make possible the maintenance of a given *p*H during the corresponding potentiometric titration experiment as shown in the last column, the experiments as tabulated were performed in a solvent consisting of 80% methanol and 20% of an aqueous buffer. The latter was chosen so as to give the greatest stability. It was 0.05 *M* aqueous solution of acetic acid, producing in the mixture an apparent *p*H of about 3, for the compounds nos. 1 to 5; it was acetate buffer (*p*H 4.6) producing an apparent *p*H about 6 for compounds nos. 6 and 7.

In order to demonstrate how much the two steps of oxidation overlap in these compounds, the potentiometric titration curve for no. 7 (Fig. 1) may be chosen, which shows steady potentials throughout both steps of oxidation. From this curve it can be derived[14] that the semiquinone formation constant is equal to 1.0. Hence, in the mid-point of titration, where the concentration of the radical is maximum, not more than 33% of the substance exists as radical. When only 0.1 atom of bromine is added to 1 molecule of the diamine, 8% of the substance is present as radical, and still almost 1% as diimine: there is always appreciable overlapping. In aqueous solution the overlapping seems to be even greater, although definite figures cannot be given on account of the instability of the potentials.

So it is evident that the direct stability of the radicals nos. 1 and 7 is much greater than the lifetime in column III seems to indicate. Whether the differences of lifetime within this group are real differences in direct stability or indirectly caused by differences in the stabilities of the diimines, is difficult to decide. There is no doubt that the diimines, although all of them are unstable, differ greatly in stability among themselves according to the number and positions of the methyl groups at the ring which influence the ease and possibility of secondary reactions. For instance, the diimine no. 7 should be, and really is, much more stable than no. 1. It is not certain whether this difference is reflected also in the corresponding radicals.

In contrast, in the compounds 8 to 11, the lifetime of the radical is so short under any condition that the radical itself must be considered as unstable.

3. Compounds Methylated at the Amino Groups (Table I, from no. 12 to the end). **(a) Benzene Derivatives.**—The common feature of these compounds is the fact that the difference between the stability in aqueous and in alcoholic solution is much less conspicuous. This difference becomes smaller as the number of methyl groups at the nitrogen is increased. In the extreme case, for the tetramethylamino compound, the difference between water and alcohol as a solvent vanishes entirely. The fact that these radicals are much more stable in an aqueous solution than the unmethylated ones, may be attributed essentially to the fact that the overlapping of the two steps of oxidation is smaller. As a consequence the indirect lability of the whole system due to the hydrolysis of the diimine in aqueous solution is almost eliminated. Although full potentiometric titration curves cannot be obtained because of the lability of the diimines, such a curve as Figs. 3 and 4 indicates that in spite of the rapid drift of the potentials in the negative direction during the second half of titration, there appears a transient potential jump in the mid-point of titration. This is possible only when the semiquinone formation constant is essentially larger than 16, whereas in the unmethylated diaminodurene mentioned before this constant is 1.0.

The most suitable solvent to combine a sufficient stability of the potentials with a sufficient buffer capacity in order to maintain a constant *p*H during the titration is 8 volumes of methanol and 2 volumes of 0.05 *M* aqueous acetic acid (apparent *p*H of the mixture, 3.1) but the stability is quite satisfactory also in an aqueous acetate buffer *p*H 4.6. Under proper conditions, all of these radicals are stable at least for several days. In the tri- and tetramethylamino compounds the radical does not fade out even over a period of many days; on the contrary, the color increases somewhat, in part due to further oxidation by exposure to the air, and to a slight extent even in the strict absence of oxygen, due to secondary dismutation of the traces of the diimine present. The nature of this peculiar decomposition of the diimine is of no interest for the present purpose.[15] At any rate, all of these radicals are very stable compounds in great contrast to their corresponding diimines.

(b) Compounds Substituted both at the Ring and at the Amino Groups.—A single methyl group at the ring has no, or at least no conspicuous, effect on the stability of the radical, if it is ortho to an unmethylated amino group; however, it has a very decided destabilizing effect when it is ortho to a methylated amino group. This effect is a direct one and is not caused indirectly by the interference of the diimine, as can be shown by the test described before. In the ψ-cumene and durene compounds, no radical is established at all if the amino groups are methylated. This is true whether the corresponding di-

(14) Regarding the method of calculation see Michaelis and Schubert, *Chem. Rev.*, **22**, 437 (1938).

(15) For the understanding of this peculiar process it will suffice to describe the following observations. When a solution of dimethyl-*p*-phenylenediamine in acetate buffer is titrated very rapidly with just enough bromine to cause the red color of the radical to disappear again, and when the colorless solution is allowed to stand, the color of the radical reappears in a short time. The same is true for tri- and for tetramethyl-*p*-phenylenediamines. In the tetra compound there is a remarkable difference insofar as the radical which is secondarily reëstablished is, according to its spectrum, that of the tri, instead of the tetra compound. This again is in conformity with Willstätter's observation that the tetramethyldiimonium compound, even in the solid state, easily loses one methyl group in the form of formaldehyde. The radical itself of the tetramethyl compound (Wurster's blue), has not the slightest tendency to lose a methyl group. This shows once more how much more stable is the radical than the diimonium compound.

imine is stable or labile. In the symmetrical dimethyldiaminodurene, the diimine is rather stable in 80% methanol; in tetramethyldiiminodurene it is extremely labile, yet, in both cases, no radical is formed at all.

Of the many details presented in this table one item is worth special attention. No. 18 is considerably more labile than 17; correspondingly no. 26 is more labile than 25, but no. 26 is much more stable than 18. While in unsymmetrical dimethyldiaminobenzene the introduction of one CH_3 group in the ring ortho to the methylated amino group has a strong destabilizing effect, this effect is smaller for a corresponding substitution in tetramethyldiaminobenzene. In the latter case, the introduction of two methyl groups in the ring is necessary to exert a really strong destabilizing effect. Compare also the difference of this effect according to the position of the two methyl groups (nos. 27 and 28).

4. Absorption Spectra.—Ten cc. of a 0.01 *M* solution of the dihydrochloride in the same solvent as indicated in the tabulation, was mixed with 1 cc. of 0.001 *N* aqueous solution of bromine. The concentration of the radical was calculated according to the amount of bromine added, neglecting the overlapping of the two steps, which causes no appreciable error if the excess of unoxidized diamine is as large as in these experiments. A König–Marten's spectrophotometer was used for the readings.

Summary

The radicals derived from aromatic *p*-diamines as modified by substitutions at the amino groups and at the benzene ring, by univalent oxidation, are compared with each other with regard to stability and color. The stability is measured approximately in terms of the lifetime in a properly chosen solvent. A distinction has to be made as to whether the disintegration is due to the direct breakdown of the radical ensuing from interaction with the solvent, or is caused indirectly by the lability of the diimine with which it always is in equilibrium. The indirect lability is most obvious in compounds not methylated at the amino groups. It may make the radicals appear to be much more labile than they really are. The direct spontaneous lability of the radicals is increased whenever there is a steric hindrance preventing the coplanar arrangement of the molecule necessary for resonance. This is the case when one or two methyl groups substituted in the benzene ring are in ortho position to a methylated amino group. Direct observations of changes in color are supported by potentiometric oxidative titrations of the diamines. The absorption spectra are recorded. It is especially noteworthy that diamino durene forms a very stable radical, but that any methylation of its amino groups entirely prevents the formation of a radical, due to the steric hindrance preventing coplanar arrangement of the molecule.

Studies on the Wolff–Kishner Reduction of Steroid Ketones[1]

BY JAMES D. DUTCHER AND O. WINTERSTEINER

In connection with a problem related to the steroid compounds of the adrenal cortex we had occasion, in a practice experiment, to reduce the semicarbazone of cholestanone by the method of Wolff and Kishner. However, the usual agent, sodium ethylate, as well as the benzylate modification described by Ruzicka and Goldberg,[2] yielded not the expected hydrocarbon, cholestane, but α- and β-cholestanol as the sole reaction products. This unusual result prompted us to study the behavior of other ketonic steroids in the Wolff–Kishner reduction, in order to learn whether constitutional or experimental factors were primarily involved.

A search of the literature revealed only two cases in which a similar atypical course of the Wolff–Kishner reduction had been observed. According to Eisenlohr and Polenske,[3] β-decalone semicarbazone yielded, besides the hydrocarbon, 33% of β-decalol. When the experiment was repeated under strictly anhydrous conditions, the yield of alcohol was but little lower, 25%. A complete failure to obtain the normal product had been reported by Reindel and Niederländer,[4] who after treating the semicarbazone of acetyl-nor-lithocholyl methyl ketone with sodium ethylate at 200° were able to isolate only the corresponding carbinol. The formation of secondary alcohols from cyclic steroid ketones

has not, to our knowledge, previously been observed.[5]

Methods.—The usual method of heating the semicarbazones with sodium ethylate in a bomb tube was employed in preference to the benzylate procedure of Ruzicka and Goldberg,[2] since in the latter some benzoic acid is always formed, and this interfered with the isolation of the reduction products in the experiments with bile acids.

In order to obtain quantitative information as to the ratio of carbinols and non-alcoholic products formed, the reaction products were treated with an excess of succinic anhydride in pyridine. The acid succinates of the alcohols can be extracted readily from ether with dilute sodium carbonate solution, a property not possessed by the acid phthalates with which we at first experimented. Both types of acid esters are easily crystallizable and have served in some instances for the identification of the alcohols formed. In the experiments with bile acids the reduced acids had to be converted into the ethyl esters prior to the esterification with succinic acid in order to retain the non-alcoholic products in the ether phase on extraction with sodium carbonate.

Table I summarizes the results obtained with seven ketonic sterols and bile acids. It is immediately apparent from the data that compounds with a semicarbazone group in position 3 are reduced preponderantly to the corresponding C_3-carbinols; semicarbazone groups at positions 7 and 12, on the other hand, do not exhibit this abnormal behavior. Dehydrocholic acid trisemicarbazone and dehydrodesoxycholic acid disemicarbazone consequently yield a high percentage of lithocholic acid (3-hydroxycholanic acid). It is also evident that the observed anomaly is not dependent upon the configuration of carbon atom 5, since it is exhibited by members of both the cholestane and coprostane series.

As was to be expected, the C_3-carbinols produced in the reaction were epimeric mixtures. In accordance with the observations of Windaus[6] on the epimerization of sterols with alkali at high temperature, the epimer with the hydroxyl group in *trans* position to the hydrogen on C_5 is the main product. Thus cholestanone yields chiefly β-cholestanol (dihydrocholesterol) besides some α-cholestanol (*epi*-dihydrocholesterol); coprostanone, on the other hand, gives preponderantly the *epi* compound, α-coprosterol. A small amount of the β-epimer undoubtedly was present but could not be isolated. The ketonic bile acids, which correspond sterically to coprostanone, are reduced to mixtures of α- and β-lithocholic acids, in which the α-epimer likewise preponderates.

The proportion of C_3-carbinol to the normal C_3-methylenic reduction product depends largely on the nature of the ketone reduced and less so on experimental factors. Under standard conditions the saturated C_3-monoketones (cholestanone, coprostanone, dehydrolithocholic acid) give the highest yields of carbinols (70–80%). With the di- and triketo acids the yields of normal reduction product (cholanic acid) are increased, but always fall short of that of the C_3-carbinol (lithocholic acid). No evidence was obtained, in the latter cases, for the presence of polyhydroxy acids which might be formed by an abnormal reduction of the C_7 or C_{12} keto groups. This point was further checked by experiments with 3-hydroxy-12-ketocholanic acid semicarbazone which were thought to provide a better chance for isolating a dihydroxy acid. No compound of this description could be isolated, but some of the original 3-hydroxy-12-ketocholanic acid was recovered besides the normal reduction product, lithocholic acid. The same acid, 3-hydroxy-12-ketocholanic acid, was also invariably found to be present, to the extent of 8–10%, among the reduction products of dehydrodesoxycholic acid disemicarbazone. Since the nitrogen content of the two semicarbazones in question was close to the theoretical value, the possibility that they contained material in which the 12-keto group was left free appears remote. It seems rather that under the conditions of the reaction the semicarbazone group in position 12 undergoes partial hydrolysis, with regeneration of the free ketone.

The reduction of the semicarbazone of the α,β-unsaturated ketone, cholestenone, follows a more complex course. Besides the normal reduction product, Δ_4-cholestene (pseudocholestene), a large proportion of alcohols is formed. One of the steps in the abnormal reaction is probably the formation of the epimeric α,β-unsaturated alcohols, the *allo*-cholesterols. The presence of these com-

(5) After this work had been completed Marker and Lawson [THIS JOURNAL, **61**, 852 (1939)] reported that pregnanol-20(α)-one-3-semicarbazone on reduction by the Wolff-Kishner method yielded almost exclusively pregnanediol-3(α), 20(α), and Marker and Rohrmann [*ibid.*, **61**, 1284 (1939)] reported that the reduction of the semicarbazone of sarsasapogenone, a C_3 ketone (see Marker and Rohrmann, [*ibid.*, **61**, 943 (1939)]), yielded chiefly the carbinol, sarsasapogenin. These results are entirely in harmony with our observations on the reduction of saturated C_3-monoketones.

TABLE I

WOLFF–KISHNER REDUCTION OF STEROID KETONES

Reaction time eight hours, temperature 200° unless indicated otherwise in Column 1. The melting points in Column 4 are those of the products for which the yield is given; the figures in brackets are the melting points of the pure compounds. When the yield given pertains to a crude fraction, reference is made in Column 4.

Compound reacted	Reaction products	Yield, % of theory	Remarks
Cholestanone semicarbazone (at 180°)	α-Cholestanol β-Cholestanol	90	Weighed as crude carbinol fraction. Both epimers isolated in pure form. Hydrocarbon fraction negligible
Cholestanone semicarbazone (at 200°)	α-Cholestanol β-Cholestanol	75	Weighed as crude succinates. Both epimers isolated in pure form.
	Cholestane	13	M. p. 80° (81°).
Cholestanone semicarbazone + hydrazine	Cholestane	75	M. p. 80–81° (81°).
Cholestanone hydrazone	(α + β)-Cholestanols	82	Weighed as crude succinates.
	Cholestane	15	M. p. 78–80° (81°).
Cholestanone hydrazone + hydrazine	Cholestane	93	M. p. 81° (81°).
Cholestanone ketazine	(α + β)-Cholestanols	75	Weighed as crude succinates.
	Cholestane	18	Crude hydrocarbon fraction.
Cholestanone ketazine + hydrazine	Cholestane	98	M. p. 81° (81°).
Coprostanone semicarbazone (at 180°)	α-Coprostanol	64	M. p. 116–118° (118°).
	β-Coprostanol	Small amount	Indicated by digitonin precipitate. Hydrocarbon fraction negligible.
Cholestenone semicarbazone (at 210°)	α-Coprostanol β-Cholestanol Cholesterol	35	Weighed as crude succinates. Saturated alcohols isolated in pure form; cholesterol indicated by color reaction.
	allo-Cholesterols	Small amount	Isolated as $\Delta_{3,5}$-cholestadiene.
	Δ_4-Cholestene	40	Weighed as crude hydrocarbon fraction. Pure compound (m. p. 79°) isolated.
Cholestenone ketazine + hydrazine	Δ_4-Cholestene	64	M. p. 77° (79°).
Dehydrocholic acid trisemicarbazone	α-Lithocholic acid	38	M. p. 188° (188°).
	β-Lithocholic acid	Small amount	Not isolated.
	Cholanic acid	22	M. p. 161° (164°); part isolated as ethyl ester, m. p. 93° (93°).
Dehydrodesoxycholic acid disemicarbazone	α-Lithocholic acid β-Lithocholic acid	38	M. p. 188° (188°). M. p. 179° (179°).
	Cholanic acid	31	M. p. 164° (164°).
	(α + β)-3-Hydroxy-12-ketocholanic acid	9	M. p. 157°; pure α-epimer (m. p. 164°) and derivatives prepared.
Dehydrolithocholic acid semicarbazone	(α + β)-Lithocholic acid	73	Isolated as crude ethyl lithocholate acid sucinnate, m. p. 140–145° (147°).
	Cholanic acid	7.7	Isolated as ethyl ester, m. p. 93° (93°).
3(α)-Hydroxy-12-ketocholanic acid semicarbazone	(α + β)-Lithocholic acid	70	M. p. 172–176°.
	(α + β)-3-Hydroxy-12-ketocholanic acid	10	M. p. 157° (9 parts α, 1 part β).

pounds, indicated by a strong Rosenheim reaction, was proved by their conversion on acid treatment to the doubly unsaturated hydrocarbon melting at 79° of Schoenheimer and Evans,[7] later shown to be $\Delta_{3,5}$-cholestadiene by Stavely and Bergmann.[8] The *allo*-cholesterols, under the conditions of the Wolff–Kishner reduction, may be partially transformed into the corresponding epimeric β,γ-unsaturated alcohols. Cholesterol could not be isolated as such, but its presence in the digitonin precipitable portion of the carbinol fraction was indicated by a strong Liebermann–Burchard reaction. Reduction of the double bond, as evidenced by the isolation of α-coprosterol and

(7) Schoenheimer and Evans, *J. Biol. Chem.*, **114**, 567 (1936).
(8) Stavely and Bergmann, *J. Org. Chem.*, **1**, 567 (1937).

β-cholestanol, also takes place. Since no saturated hydrocarbons could be found in the hydrocarbon fraction, it appears that double bond reduction does not occur once the keto group has been eliminated.

These results confirm and amplify those of Lettré,[9] who found pseudo-cholestene, cholesterol and a saturated alcohol which he believed to be β-cholestanol, among the reduction products of cholestenone semicarbazone. They also accord with those of Stange,[10] who reduced the disemicarbazone of 3,6-diketocholestene with sodium ethylate and obtained a small amount of Δ_4-cholestene, presumably together with other reduction products. When the 3-monosemicarbazone was subjected to the reaction, cholestanediol-3,6 was obtained.

Influence of Experimental Conditions.—The results discussed so far were obtained under standard conditions. The influence of the reaction time was studied in the case of dehydrodesoxycholic acid. The results recorded in Table II indicate that the proportion of normal and abnormal reduction products does not vary greatly when the period of heating is extended from 4.5 to 8, 10 and 22 hours. No trend is discernible in the figures; the fluctuations observed are probably fortuitous.

TABLE II

REDUCTION OF DEHYDRODESOXYCHOLIC ACID DISEMICARBAZONE; REACTION TIME VARIED

1.0 g. of disemicarbazone yielded the products listed in the percentage given.

Reaction time, hrs.	Cholanic acid		Lithocholic acid		3-Hydroxy-12-keto-cholanic acid	
	Mg.	%	Mg.	%	Mg.	%
4.5	274	38	263	35	71	9
8	238	33	293	39	62	8
10	285	40	224	30	72	9
22	265	36	248	33	64	8

Since the practicable temperature range for the reaction is comparatively narrow (180–210°), the influence of this factor was not systematically investigated. From the first two experiments with cholestanone semicarbazone recorded in Table I it would appear that raising the temperature from 180 to 200° favors slightly the production of the hydrocarbons.

That the addition of 10% of water to the reaction mixture or the exclusion of oxygen do not perceptibly alter the proportion of normal and abnormal reaction products was ascertained in separate experiments with cholestanone semicarbazone.

A profound effect, however, is exerted by the presence of an added excess of hydrazine hydrate. The abnormal reaction is entirely suppressed and a practically quantitative yield of hydrocarbon is obtained. The hydrazone and ketazine of cholestanone, which under standard conditions react in the same way as the semicarbazone to give high yields of carbinol, are also reduced in the normal manner when hydrazine is present.

Among C_3-ketonic steroids of known structure, only the two unsaturated ketones studied by Lettré and by Stange, and a few saturated bile acids previously have been subjected to the reaction. The reduction of the trisemicarbazone of dehydrocholic acid to cholanic acid has been described by Borsche and Hallwass,[11] but no yield was reported, and other products may well have been present. An instance of complete reduction in the presence of hydrazine is found in the paper of Wieland and Kapitel,[12] who obtained good yields of 7-hydroxycholanic acid from the disemicarbazone of 3,12-diketo-7-acetoxycholanic acid. The experiment of Wieland and Jacobi,[13] on the other hand, in which a mixture of the mono- and disemicarbazones of 3,7-diketocholanic acid was reduced to lithocholic acid, can, in the light of our experience, be interpreted as an instance of reduction of the semicarbazone grouping at C_3 to carbinol and that at C_7 to methylene. Fieser,[14] commenting on the anomaly of this result, suggests that the lithocholic acid was formed from the 7-monosemicarbazone by elimination of the C_7-keto group and reduction of the free C_3-keto group to carbinol. In all probability both reactions occurred simultaneously.

In all other instances recorded in the literature, reduction of keto groups other than on C_3 are involved. It is evident from these reports that the reaction proceeds in the normal manner on keto groups at C_6,[15] C_7,[16] C_{12}[16,17] and C_{17}.[18]

No satisfactory explanation can be offered at present as to why the C_3-keto group displays this unique resistance to complete reduction. It may be classed with other known differences between the chemical reactivity of C_3-hydroxyl or keto groups and that of similar groups in other positions of the steroid molecule. The C_3-keto groups can be reduced selectively to carbinol catalytically or with sodium and alcohol, and to methylene by the Clemmensen method. Acylation as well as ester saponification proceeds faster at C_3 than at C_7, C_{12}, C_{17} and C_{20}.

For the abnormal reaction the following mechanism is suggested: Wolff[19] believed that the course of the normal reaction from the semicarbazone to the methylene compound proceeded with the intermediate formation of the hydrazone, followed by its decomposition to the methylene compound as shown by Reaction 1. This view is supported by the fact that hydrazones are readily reduced by this method.

Reaction 1

$$>C{=}N{-}NH{-}CO{-}NH_2 \xrightarrow{H_2O} \underset{(I)}{}$$

$$>C{=}N{-}NH_2 + NH_3 + CO_2 \xrightarrow{NaOEt} >CH_2 + N_2$$
$$(II) \qquad\qquad (III)$$

The first step in the abnormal reduction is probably the same as I to II in Reaction 1. The subsequent step, involving the production of a hydroxyl group, can best be explained by the assumption that the hydrazone is hydrolyzed to the free ketone and hydrazine base (II to IV). The regenerated keto group reacts then by oxidation–reduction with sodium ethylate, giving the secondary alcohol and acetaldehyde (IV to V). This reaction can be demonstrated by treating cholestanone itself with sodium ethylate at 180°. The epimeric cholestanols are obtained in good yield. The acetaldehyde which should be formed presumably undergoes further changes such as condensation or oxidation.

Reaction 2

$$>C{=}N{-}NH_2 + H_2O \longrightarrow >C{=}O + H_2N{-}NH_2$$
$$(II) \qquad\qquad (IV)$$

$$>C{=}O + C_2H_5OH \longrightarrow >CH{-}OH + CH_3CHO$$
$$(IV) \qquad\qquad (V)$$

If the postulated equilibrium between free ketone and hydrazine on the one hand and hydrazone on the other actually exists, then the introduction of an excess of hydrazine should keep the concentration of free ketone at a low level and thereby promote the normal reaction (Reaction 1). This is indeed the case, since in the presence of hydrazine the reduction to the hydrocarbon is quantitative. Splitting of the semicarbazone occurs to a measurable extent only at comparatively high temperatures since refluxing with sodium ethylate at 90° does not regenerate the ketone or any other ether-soluble material.

(19) Wolff, *Ann.*, **394**, 86 (1912).

Experimental

The conditions were, in the majority of runs, those customarily employed. The amount of sodium dissolved in absolute alcohol was equal to the weight of the semicarbazone; the temperature was 200° and the reaction time usually eight hours, except in experiments designed to test the influence of the last two variables. Deviations from the standard procedure, such as the addition of hydrazine hydrate, will be referred to in the text.

In the ensuing account, all melting points are uncorrected.

Semicarbazones of Cholestanone and Coprostanone.—These were obtained in quantitative yield as colorless, amorphous powders by refluxing an alcoholic solution of the ketone for two hours with twice its equivalent of semicarbazide acetate. Cholestanone semicarbazone decomposed at 238° after sintering at 227°; coprostanone semicarbazone decomposed at 192° after sintering at 178°.[20]

Anal. Calcd. for $C_{28}H_{49}ON_3$: N, 9.5. Found: N, 9.4, 9.4.

β-Cholestanol Acid Phthalate.—This was prepared by boiling a pyridine solution containing the alcohol and a large excess of phthalic anhydride (10 mols) for one hour. It could neither be extracted with sodium carbonate solution, nor adsorbed on solid sodium carbonate, from its solution in ether or petroleum ether; needles from alcohol, m. p. 160°.

Anal. Calcd. for $C_{35}H_{52}O_4$: C, 78.4; H, 9.7; mol. wt., 537. Found: C, 78.4; H, 9.7; neut. equiv., 535, 536.

α-Coprostanol Acid Phthalate.—This was isolated from the reduction products of coprostanone after treatment with phthalic anhydride in pyridine. It likewise did not possess the desired solubility properties; needles from alcohol, m. p. 218–220°.

Anal. Calcd. for $C_{35}H_{52}O_4$: C, 78.4; H, 9.7; mol. wt., 537. Found: C, 78.3; H, 9.5; neut. equiv., 537.

β-Cholestanol Acid Succinate.—The treatment of β-cholestanol with succinic anhydride in the ratio of 1 to 5 mols in pyridine yielded a mixture of acid ester and di-ester. Only when a ratio of 1 to 10 was employed was the acid ester quantitatively formed; plates from dilute alcohol or ether–methanol, m. p. 171°.

Anal. Calcd. for $C_{31}H_{52}O_4$: C, 76.2; H, 10.7. Found: C, 76.4; H, 10.8.

Reduction of Cholestanone and Coprostanone Semicarbazones.—A mixture of 400 mg. of cholestanone semicarbazone with a solution of 400 mg. of sodium in 15 cc. of absolute alcohol was heated in a bomb tube at 180° for

(20) Dorée and Gardner, *J. Chem. Soc.*, **93**, 1630 (1908).

eight hours. The contents of the tube were poured into water, neutralized with hydrochloric acid and extracted with ether. The ethereal residue (361 mg.) was refluxed with 1.4 g. of succinic anhydride and 5 cc. of pyridine for one hour, poured into water and extracted with ether. The ether layer was then washed several times with dilute sulfuric acid and finally with dilute sodium carbonate solution. The ether, which retained the neutral fraction (hydrocarbon), was washed with water, dried and evaporated, leaving 22 mg. of oily, non-crystallizable material. The sodium carbonate solution was acidified with hydrochloric acid and extracted with ether. This ether solution, containing the acid esters of the alcohols, was washed, dried and evaporated (413 mg.).

The succinates were saponified with methyl alcoholic potassium hydroxide at room temperature, yielding 316 mg. of alcohols; 150 mg. of the latter was treated with digitonin in 80% alcohol, and precipitate and filtrate worked up in the usual manner: 102 mg. of β-cholestanol, m. p. 140°, $[\alpha]_D$ +29° (ethanol); and 27.2 mg. of α-cholestanol, m. p. 181°, $[\alpha]_D$ +34° (ethanol), were thus obtained and identified by specific rotations and mixed melting point determinations with authentic samples. β-Cholestanol[21] has m. p. 141°, $[\alpha]_D$ +28.8° (ether). α-Cholestanol[22] has m. p. 181°, $[\alpha]_D$ +33.95° (alcohol).

Four hundred mg. of coprostanone semicarbazone, reduced under the same conditions, yielded 17.4 mg. of non-crystalline material in the hydrocarbon fraction, and 269 mg. of alcohols. The latter yielded on treatment only a small amount of digitonide which was not worked up. From the digitonin filtrate 225 mg. of α-coprostanol was recovered, m. p. 116–118°, unchanged when mixed with an authentic sample; $[\alpha]_D$ +30° (alcohol); Dorée and Gardner[20] report $[\alpha]_D$ +31.3°.

In another experiment 1.2 g. of the semicarbazone was treated with sodium ethylate (1 g. of sodium in 15 cc. of alcohol) at 200° for ten hours, and the ether-soluble reaction products (1.034 g.) separated with succinic anhydride. The weight of the ester fraction (1.04 g.) indicated that 75% of the sterol portion of the semicarbazone had been converted to alcohols. One hundred mg. of the recrystallized succinate (m. p. 155–160°) was saponified. The precipitate obtained with digitonin yielded 40 mg. of β-cholestanol, m. p. 142°, and the digitonin filtrate 24 mg. of α-cholestanol, m. p. 181–182°.

The hydrocarbon fraction (204 mg.) was recrystallized from alcohol–ether, giving 136 mg. of plates melting at 80°, $[\alpha]_D$ +25° (chloroform); cholestane,[23] m. p. 80°; $[\alpha]_D$ +24.4°.

The lack of effect of water and of oxygen was shown by the following experiment. Each of three bomb tubes (a, b, c) was charged with 300 mg. of the semicarbazone, and with ethylate prepared from 300 mg. of sodium and 5 cc. of absolute alcohol. Tube a served as control; to tube b, 0.5 cc. of water was added; in tube c the air was replaced by nitrogen. After six hours at 200° the contents of the tubes were subjected to the usual fractionation procedure. The weights of the hydrocarbon fractions were (a) 15.7 mg., (b) 14 mg., (c) 10 mg.; those of the carbinol fractions (calculated from the weights of the ester fractions) (a) 252 mg., (b) 252 mg., (c) 241 mg.

Hydrazine hydrate had a marked effect: 434 mg. of the semicarbazone was reduced with sodium ethylate at 200° in the presence of 0.5 cc. of 100% hydrazine hydrate. The crystalline material (330 mg.) obtained by ether extraction of the reaction products yielded on recrystallization 273 mg. (75%) of cholestane, m. p. and mixed m. p. 80–81°.

Reduction of Cholestanone Hydrazone.—The hydrazone was prepared by refluxing 1 g. of the ketone with 1.0 cc. of hydrazine hydrate in 50 cc. of absolute alcohol. Water was added to the hot solution to incipient cloudiness. After standing overnight the hydrazone had precipitated out quantitatively; light yellow needles, m. p. 248° (dec.) after softening at 230°.

Anal. Calcd. for $C_{27}H_{48}N_2$: N, 7.0. Found: N, 7.1.

The reduction of 300 mg. of this compound under standard conditions (300 mg. sodium, 5 cc. alcohol, 200°, eight hours) yielded 280 mg. of ether-soluble material, which was separated into alcoholic (300 mg. of acid succinate) and hydrocarbon (42 mg.) fractions. The crude ester after one recrystallization from dilute alcohol melted at 155–160°, showing that it consisted of a mixture of α- and β-cholestanol acid succinates. The hydrocarbon fraction gave on recrystallization cholestane melting at 78–80°, mixed m. p. with cholestane (m. p. 81°) 80°; yield of alcohols, computed from weight of crude succinates, 80%; of hydrocarbon, 15%.

The same experiment, repeated with the addition of 0.5 cc. of hydrazine hydrate, yielded 260 mg. (93%) of cholestane, m. p. 81°, $[\alpha]_D$ +24.6° (chloroform).

Reduction of Cholestanone Ketazine.—When acetic acid was used to precipitate the cholestanone hydrazone from the above alcoholic solution, the ketazine, an amorphous white powder decomposing at about 200°, was obtained. *Anal.* Calcd. for $C_{54}H_{92}N_2$: N, 3.7. Found: N, 3.8. The reduction of 500 mg. of this compound, carried out under standard conditions, yielded 87 mg. (18%) of hydrocarbon and 477 mg. of acid succinate, corresponding to a 75% yield of alcohols.

When the reduction was carried out in the presence of 0.5 cc. of hydrazine hydrate, 500 mg. of the ketazine yielded 475 mg. (98%) of cholestane, m. p. 82°.

Reduction of Cholestenone Semicarbazone.—The semicarbazone of cholestenone was prepared by the pyridine–alcohol method to be described in the section on bile acids. The amorphous material which formed within an hour after mixing crystallized in clumps of needles after standing at room temperature for twenty-four hours, m. p. 215–235° (dec.).[24] The yield was quantitative.

Anal. Calcd. for $C_{28}H_{47}ON_3$: N, 9.5. Found: N, 9.5.

One and one-half grams of semicarbazone was treated with a solution of 1.5 g. of sodium in 25 cc. of absolute alcohol in a bomb tube at 210° for eight hours. The contents of the tube were poured into water, and the resulting alkaline solution extracted with ether. (Some material remained in the alkaline solution from which it was later extracted with ether after neutralization.) The crude residue (1.08 g.) from the ether was treated with 1.0 g. of

(21) Willstätter and Mayer, *Ber.*, **41**, 2199 (1908).
(22) Windaus and Uibrig, *ibid.*, **47**, 2384 (1914).

succinic anhydride in 5 cc. of pyridine at room temperature for twenty-four hours.[25] The hydrocarbon fraction (500 mg.) after two recrystallizations from acetone–water and one from ether–methanol, yielded Δ_4-cholestene, m. p. and mixed m. p. 79°; $[\alpha]_D$ +65.0° (chloroform).

The virtual absence of saturated hydrocarbons was established in the following way. The material from the mother liquor was dissolved in ether and treated with a solution of bromine in acetic acid, and as much of the dibromide (m. p. 117°) as possible was removed by crystallization. The residue of the mother liquor was dissolved in carbon tetrachloride and treated with acetic anhydride and sulfuric acid according to Anderson and Nabenhauer.[26] The Δ_4-cholestene dibromide was decomposed completely by these reagents. The carbon tetrachloride on evaporation left only 3 mg. of an oily residue, which still gave a positive Liebermann–Burchard reaction.

The acid ester fraction (580 mg.) was saponified with a 20% solution of potassium hydroxide in 50% methanol. On cooling, a crystalline mass formed which was filtered off, washed with dilute methyl alcohol and water and dried *in vacuo*. This crude alcoholic fraction (450 mg.) gave a strongly positive Liebermann–Burchard reaction (presence of cholesterol) and a negative Rosenheim reaction (absence of Δ_4-alcohols). Treatment with 1.0 g. of digitonin in 85% alcohol gave 1.2 g. of digitonide. This, when decomposed with pyridine and ether, yielded 290 mg. of material which on repeated crystallization from 95% ethanol and from aqueous methanol gave a fraction (100 mg.), m. p. 141°. This material gave a negative Liebermann–Burchard reaction and showed no depression of its melting point when mixed with β-cholestanol. The material which remained in the mother liquors still gave an intense Liebermann–Burchard reaction but could not be separated into pure compounds. It probably consisted of cholesterol mixed with some β-coprostanol.

The digitonin filtrate was evaporated to dryness and extracted with ether. The extract after several recrystallizations from aqueous acetone melted at 117–118° and was identified as α-coprostanol. No α-cholestanol could be isolated from the mother liquors.

The acidic fraction (137 mg.), obtained on neutralization of the alkaline solution of the original reaction mixture, showed an intense Rosenheim reaction and contained 4.3% of nitrogen. After recrystallization from boiling 95% ethanol it formed long needles (50 mg.). The Rosenheim reaction was negative. *Anal.* Calcd. for $C_{28}H_{43}ON_3$: C, 76.9; H, 9.9; N, 9.6. Found: C, 77.2; H, 10.0; N, 9.6. This compound is probably identical with a substance of similar properties and composition (C, 77.07; H, 10.19; N, 9.66) which Stange[10] obtained as a by-product from the Wolff–Kishner reduction of Δ_4-cholestenedione-3,6 monosemicarbazone.

Since the residue from the mother liquors (70 mg.) still gave a very strong Rosenheim reaction, indicative of the presence of *allo*-cholesterols, it was dissolved in 50 cc. of alcohol containing a few drops of concentrated sulfuric acid, and the solution boiled for four hours. The solution was then poured into water and extracted with ether. The ether after repeated washings with dilute sodium carbonate solution, yielded 13 mg. of a crystalline residue. On recrystallization from dilute alcohol long needles melting at 78° and exhibiting a specific rotation in benzene, $[\alpha]_D$ −113°, were obtained. $\Delta_{3,5}$-Cholestadiene[7] has m. p. 78–79°, $[\alpha]_D$ −112.5° (benzene).

Reduction of Cholestenone Ketazine in Presence of Hydrazine.—The ketazine was prepared in the same manner as the corresponding compound from cholestanone. It is an amorphous, yellow powder decomposing above 190°. It was dried *in vacuo* at 110° for analysis.

Anal. Calcd. for $C_{54}H_{88}N_2$: N, 3.7. Found: N, 4.0.

The reduction of 500 mg. of the ketazine (500 mg. of sodium, 10 cc. of alcohol, 0.5 cc. of hydrazine hydrate, 200° for eight hours) yielded 490 mg. of ether-soluble material from which no alcohols could be isolated by the succinic anhydride procedure. On recrystallization from aqueous acetone 310 mg. of needles, m. p. 77°, was obtained. Several recrystallizations from alcohol gave Δ_4-cholestene, m. p. and mixed m. p. 78–79°.

Reduction of Dehydrodesoxycholic Acid Disemicarbazone.—The customary method of preparing semicarbazones by refluxing the ketonic compound with an alcoholic solution of semicarbazide acetate proved to be unsatisfactory in the case of the polyketonic bile acids. Although Borsche and Hallwass[11] had used this method for preparing the trisemicarbazone of dehydrocholic acid, we were unable to obtain a preparation with the required nitrogen content, no matter whether their procedure was employed in its original form or whether the conditions were varied in respect to the time of heating and the amounts of reagent used. In the preparation of the semicarbazone of 3-hydroxy-12-ketocholanic acid by this method the yield was very low, and the product was pigmented. Better results were obtained by the use of butyl alcohol as solvent. However, the method of Haller and LaForge,[27] employing semicarbazide acetate in a pyridine–alcohol solution, gave very satisfactory results, especially when the mixture was allowed to stand at room temperature for several days instead of being refluxed for a shorter period.

Five grams of commercial dehydrodesoxycholic acid, m. p. 186°, was dissolved in a mixture of 50 cc. of absolute alcohol and 50 cc. of dry pyridine. To this was added a solution of semicarbazide acetate, prepared by dissolving 5.0 g. of semicarbazide hydrochloride in 15 cc. of water and 5.0 g. of potassium acetate in 50 cc. of absolute alcohol, mixing, and filtering off the precipitated potassium chloride. After the addition of 10 cc. more water the solution was allowed to stand at room temperature for several days. The gelatinous mass which had formed was broken up, poured into a large volume of cold water, filtered and washed as thoroughly as possible to remove pyridine. After drying *in vacuo* at 110° a nearly colorless amorphous product was obtained in theoretical yield; decomposition point 215° after discoloration beginning at 190°.

Anal. Calcd. for $C_{26}H_{42}O_4N_6$: N, 16.7. Found: N, 16.7.

Five grams of disemicarbazone was heated with a solution of 2.0 g. of sodium dissolved in 25 cc. of absolute alcohol at 200° for ten hours. The reaction mixture was

(25) Considerable amounts of pigment and resinous material were formed at 130°.

(26) Anderson and Nabenhauer, THIS JOURNAL, **46**, 1957 (1924).

(27) Haller and LaForge, *J. Org. Chem.*, **1**, 38 (1936).

diluted with water, acidified and extracted with ether. The ether residue was esterified with absolute alcohol and sulfuric acid and fractionated with succinic anhydride as previously described: succinic half-esters, 2.40 g.; cholanic acid ester, 1.58 g.

The neutral fraction (1.58 g.) was crystallized from absolute alcohol, yielding 1.0 g. of ethyl cholanate, colorless needles, m. p. and mixed m. p. 93°. The mother liquors, saponified with potassium hydroxide in methyl alcohol, yielded 200 mg. of crystalline cholanic acid, m. p. 164°. The over-all yield of cholanic acid from the disemicarbazone was 31%.

A small amount of 3-hydroxy-12-ketocholanic acid was isolated from the acid succinate fraction by the following procedure. The esters (2.4 g.) were saponified with alcoholic potassium hydroxide at room temperature for twelve hours. The solution was poured into water, acidified with hydrochloric acid and extracted with ether. The ether solution was washed with water and repeatedly extracted with 0.067 *M* disodium phosphate solution, which was acidified and again extracted with ether. The two ether fractions were again washed, dried and evaporated.

The material remaining in the first ether solution (1.43 g.) was crystallized from aqueous ethyl alcohol. Colorless plates, m. p. 175–177°, were obtained; 100 mg. of this fraction was treated with digitonin in 90% ethyl alcohol; 73 mg. of digitonide was obtained, indicating that the epimeric mixture contained 17.5% of the β-compound. Decomposition of the digitonide yielded material which on crystallization from aqueous ethanol gave colorless plates, m. p. 179°; $[\alpha]_D$ +25.1° (alcohol). β-Lithocholic acid[28] has m. p. 180° and $[\alpha]_D$ +25° (alcohol).

The filtrate from the digitonin precipitation yielded α-lithocholic acid which crystallized from ether–petroleum ether in colorless plates, m. p. 188°. *Anal.* Calcd. for $C_{24}H_{40}O_3$: C, 76.6; H, 10.6. Found: C, 76.7; H, 10.4. $[\alpha]_D$ +33.6° (95% alcohol). α-Lithocholic acid[11] has $[\alpha]_D$ +32.7°. The ethyl ester melted at 92°. Ethyl α-lithocholate[29] has m. p. 92–93°. *Anal.* Calcd. for $C_{26}H_{44}O_3$: C, 77.3; H, 10.9. Found: C, 77.4; H, 10.6. The acetyl derivative melted at 169°. Acetyl α-lithocholic acid[29] has m. p. 169°.

The product recovered from the phosphate solution (0.36 g.), after crystallization from aqueous acetone, melted at 157°. It was shown to be a mixture of α- and β-3-hydroxy-12-ketocholanic acids similar to that obtained by Kyogoku[30] by the biological reduction of dehydrodesoxycholic acid. *Anal.* Calcd. for $C_{24}H_{38}O_4$: C, 74.0; H, 9.8. Found: C, 74.1, 74.1; H, 9.8, 9.9. The acetyl derivative formed needles from aqueous acetic acid; the melting point, 198°, is that reported by Kyogoku, and was not depressed by admixture with authentic α-3-acetoxy-12-ketocholanic acid. *Anal.* Calcd. for $C_{26}H_{40}O_5$: C, 72.2; H, 9.3. Found: C, 72.2; H, 9.2. The acid succinate of the ethyl ester formed colorless prisms or needles from aqueous alcohol, m. p. 170°; $[\alpha]_D$ +96.3° (ethanol); neutralization equivalent found, 517, 529. The melting point was unchanged on admixture with the acid succinate ($[\alpha]_D$ +95.7° in alcohol) prepared from an authentic sample of ethyl α-3-hydroxy-12-ketocholanate.

(28) Reindel and Niederländer, *Ber.*, **68**, 1245 (1935).
(29) Reindel and Niederländer, *ibid.*, **68**, 1969 (1935).
(30) Kyogoku, *Z. physiol. Chem.*, **246**, 99 (1937).

Saponification of the acetyl derivative yielded free α-3-hydroxy-12-ketocholanic acid, m. p. 164°, mixed m. p. 165°.[30] The ethyl ester of this had m. p. and mixed m. p. 132–133°.

The yields of crystalline products from 5.0 g. of semicarbazone were: cholanic acid, 1.13 g., 31%; (α + β)-lithocholic acids, 1.43 g., 38% of the theory; 3-hydroxy-12-ketocholanic acids (90% α-, 10% β-), 0.36 g., 9.2%.

To determine whether the time of reduction influenced the nature or proportion of the products, the following experiment was carried out. Each of four tubes was charged with 1.0 g. of disemicarbazone and 0.75 g. of sodium dissolved in 20 cc. of absolute alcohol. The tubes were placed in the oven at 210° and removed at intervals of 4.5, 8.0, 10.0 and 22 hours. The contents of the tubes were poured into water, acidified and extracted with petroleum ether. The petroleum ether was repeatedly extracted with 0.067 *M* disodium phosphate solution to remove the 3-hydroxy-12-ketocholanic acid present. The residue obtained on evaporating the petroleum ether was then subjected to the succinic anhydride procedure. The distribution of the material in the three fractions is recorded in Table II.

Reduction of 3-Hydroxy-12-ketocholanic Acid.—The acid was prepared by the method of Kaziro and Shimada,[31] m. p. 161° with sintering at 113–115°; $[\alpha]_D$ +110° (alcohol); acetyl derivative, m. p. 198–199°; ethyl ester, m. p. 133°. The semicarbazone, which was obtained in quantitative yield by the pyridine–alcohol procedure, melted at 240° with decomposition.

Two grams of the semicarbazone was reduced under standard conditions. The reaction mixture was diluted with water, acidified and extracted with ether. A small amount of unreacted semicarbazone (80 mg.) collected at the interphase and was removed by filtration. The ether phase was washed with water and extracted with 0.067 *M* disodium phosphate solution. From the material contained in the phosphate solution (229 mg.) 3-hydroxy-12-ketocholanic acid, m. p. 157°, $[\alpha]_D$ +84° (alcohol), was recovered. These properties are those of a mixture of 9 parts of α- and 1 part of β-acid.[30] The acid succinate of the ethyl ester was prepared (m. p. 169°) and identified by mixed melting point determination with the corresponding compound from the pure α-epimer (m. p. 170°); yield of crude acid, 10%.

The residue of the ether solution (1.215 g.) yielded on crystallization from dilute alcohol, lithocholic acid, m. p. 172–176°. Treatment of a small sample with digitonin showed the presence of 18% of β-compound in the epimeric mixture; yield of crude acid, 70%.

Reduction of Dehydrolithocholic Acid Semicarbazone.—Dehydrolithocholic acid (m. p. 140°) was obtained by oxidation of lithocholic acid with chromic acid by the method of Reindel and Niederländer.[28] The semicarbazone was prepared in the usual manner with semicarbazide acetate in alcohol. The colorless, semicrystalline product melted at 230° with decomposition.

Anal. Calcd. for $C_{25}H_{41}O_3N_3$: N, 9.7. Found: N, 9.8.

Five hundred mg. of semicarbazone was treated with 500 mg. of sodium dissolved in 10 cc. of absolute alcohol in a bomb tube at 200° for seven and one-half hours. The

(31) Kaziro and Shimada, *Z. physiol. Chem.*, **249**, 220 (1937).

reaction mixture was worked up in the usual manner. The acid succinate fraction weighed 425 mg., and the cholanic ester fraction 35 mg. This represents a lithocholic acid yield of 73% and of cholanic acid 7.7%. The succinic acid ester melted at 140–145°. For comparison the acid succinate of ethyl α-lithocholate was prepared from an authentic sample of ethyl α-lithocholate. It crystallized from ether–petroleum ether solution in large, hexagonal plates, m. p. 147°; neutralization equivalent calcd. 504; found, 505. On saponification of the succinic ester fraction, m. p. 140–145°, with alcoholic potassium hydroxide, a mixture of α- and β-lithocholic acids was obtained, m. p. 175–177°. Precipitation of a small sample with digitonin showed that approximately 15% of the β-epimer was present.

The neutral fraction on crystallization from absolute alcohol yielded needles of ethyl cholanate, m. p. and mixed m. p. 93°.

Reduction of Dehydrocholic Acid.—Recrystallized dehydrocholic acid, m. p. 236°, was used. The trisemicarbazone was obtained in theoretical yield by the alcohol–pyridine method. The nearly colorless, amorphous product melted above 290° with decomposition. The material was dried *in vacuo* at 110° for analysis.

Anal. Calcd. for $C_{27}H_{43}O_5N_9$: N, 22.0. Found: N, 21.9.

One gram of the semicarbazone was treated with a solution of 1.0 g. of sodium in 15 cc. of absolute alcohol at 200° for eight hours. The highly pigmented contents of the tube were poured into water, acidified with hydrochloric acid and extracted with ether. The residue from the ether solution (525 mg.) was dissolved in 90% acetic acid; 50 mg. of crystalline material, melting at 161°, deposited after prolonged standing. Recrystallization from acetone gave cholanic acid, m. p. and mixed m. p. 164°. The remaining oily material was esterified and the ester fraction (463 mg.) subjected to the succinic anhydride procedure in the usual way. The neutral fraction yielded 100 mg. of ethyl cholanate which after two recrystallizations from absolute alcohol showed m. p. and mixed m. p. 93°. From the sodium carbonate solution 397 mg. of succinic acid esters was obtained. Crystallization from aqueous methanol and aqueous acetone yielded plates melting at 140–145°. This material was therefore similar to the mixture of α- and β-lithocholic ester acid succinates obtained from the reduction of dehydrodesoxycholic acid disemicarbazone. Saponification at room temperature with alcoholic potassium hydroxide yielded, after two recrystallizations from aqueous acetone, colorless plates (250 mg.) of α-lithocholic acid, m. p. and mixed m. p. 188°; $[\alpha]D$ +33.6° (alcohol). The acetate melted at 169°. α-Lithocholic acid[29] has m. p. 188°; $[\alpha]D$ +33.5° (alcohol); acetate, m. p. 169°. The over-all yields from dehydrocholic acid were: cholanic acid, 142 mg., 22%; α-lithocholic acid, 250 mg., 38%.

The majority of the microanalyses reported in this paper were carried out by Mr. William Saschek.

Summary

The products found in the Wolff–Kishner reduction of the semicarbazone of cholestanone, coprostanone, cholestenone, dehydrocholic acid, dehydrodesoxycholic acid, dehydrolithocholic acid and 3-hydroxy-12-ketocholanic acid have been investigated. When the usual conditions are employed, the semicarbazone group at carbon atom 3 yields mainly the corresponding C_3-epimeric carbinols besides smaller amounts of the normal C_3-methylenic reduction products. Semicarbazone groups at C_7 and C_{12} are reduced in the normal manner to methylene. In this way lithocholic acid, in addition to cholanic acid, may be obtained in good yield from the ketonic bile acids. The occurrence of the abnormal type of reduction is not dependent on the configuration of carbon atom 5 in the C_3-ketone used.

The hydrazone and ketazine of cholestanone behave in the same manner as the semicarbazone, yielding on reduction mainly the epimeric cholestanols.

The abnormal reduction to carbinol is completely suppressed by the addition of an excess of hydrazine hydrate to the reaction mixture. Under these conditions a quantitative yield of cholestane was obtained from the semicarbazone, hydrazone and ketazine of cholestanone.

The reduction of cholestenone semicarbazone yields chiefly α-coprostanol, β-cholestanol, and Δ_4-cholestene. Evidence for the formation of *allo*-cholesterol and cholesterol has been obtained. No saturated hydrocarbons are produced in the reaction.

A possible mechanism for the abnormal type of reduction is suggested.

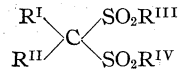
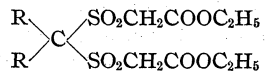
Dialkyl *bis*-(Carbethoxymethanesulfonyl)-methanes

BY R. L. SHRINER, J. M. CROSS AND ELMER H. DOBRATZ

One class of compounds which are useful for their hypnotic and sedative action is that of the dialkyl *bis*-(alkylsulfonyl) methanes represented by the type formula I. To this class belong such



I

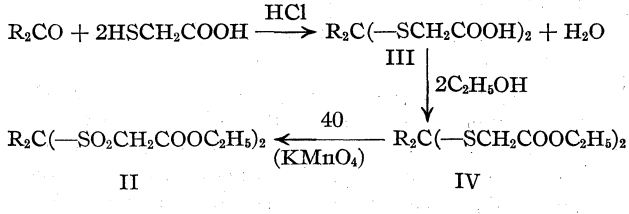


II

well-known compounds as sulfonal, trional and tetronal. These compounds are rather toxic and cannot be used in certain cases of impairment of cardiac or renal function. They also have a very limited solubility in water, tetronal, the most active hypnotic, being only very slightly soluble. Many different alkyl groups have been inserted[1] in an effort to improve the pharmacological action. The effect of introducing other functional groups into the alkyl residues has been studied in a few cases for R^{I} and R^{II} but not at all for R^{III} and R^{IV}. This modification of structure has been made in the present investigation in which the synthesis of a series of dialkyl *bis*-(carbethoxymethanesulfonyl)-methanes of formula II is described.

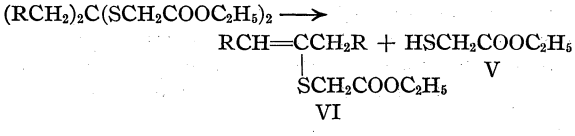
The detoxifying action of a carboxyl or ester group is well known and it was hoped that its presence would eliminate some of the toxic effects. The compounds of formula II should also be more soluble in the alkaline body fluids since they contain two active methylene groups which are capable of forming salts.[2]

These compounds were synthesized by condensing ketones with mercaptoacetic acid in the presence of hydrogen chloride.



The thioketals (III) were then esterified by treatment with absolute alcohol and hydrogen chloride in the presence of anhydrous magnesium sulfate which was used to absorb the water formed, thus preventing excessive hydrolysis of the thioketals. In order to isolate these esters (IV) it was necessary to dissolve the reaction mixture in absolute ether and, after the magnesium sulfate was filtered off, to wash this solution rapidly with ice water and dilute alkali. This removal of the acid was necessary to prevent hydrolysis of the thioacetal linkage in IV. The esters were then obtained in good yields by distilling off the ether and removing the last traces of ether by gentle heating *in vacuo*.

Only the dimethyl thioketal could be distilled *in vacuo* without decomposition. The diethyl, di-*n*-propyl and di-*n*-butyl derivatives were found to split out ethyl mercaptoacetate (V) during distillation with the formation of the corresponding carbethoxymethylmercaptoalkenes (VI), according to the general reaction



The oxidation of the thioketal (IV) to the disulfone (II) proved rather difficult owing to the sensitivity of the compounds to both acids and alkalies. Oxidations by hydrogen peroxide, chromic oxide, and neutral or alkaline permanganate were not successful. The disulfones were finally obtained in yields of 30–40% by adding a carbon tetrachloride solution of the thioketal (IV) to a 10% sulfuric acid solution into which powdered potassium permanganate was sifted so that an excess of permanganate was always present. Although the acid caused some hydrolysis of the thioketal, part of the latter was oxidized to the disulfone. The disulfones corresponding to formula II were prepared in which the alkyl groups were varied from methyl to *n*-butyl. Their analyses and physical properties and the intermediates are given in the experimental part. These sulfones were all soluble in sodium hydroxide solution but insoluble in sodium bicarbonate solution. They were soluble to a limited extent in 2% sodium carbonate solution.

Through the courtesy of the Lilly Research Laboratories the pharmacological action of these

(1) See Fränkel, "Die Arzneimittel Synthese," Verlag von Julius Springer, Berlin, 1927, pp. 526–530.

(2) Ashley and Shriner, THIS JOURNAL, **54**, 4410 (1932).

compounds was studied. It was found that they were comparatively non-toxic as compared to sulfones of type I, which indicates the detoxifying effect caused by the introduction of the carbethoxy group. However, regardless of the mode of administration, oral, intravenous or intraperitoneal injection, none of these disulfones caused hypnosis in the experimental animals. Evidently the presence of the salt forming methylene groups caused too great a shift in the oil–water distribution ratio which is necessary for hypnotic action.

Experimental

Mercaptoacetic Acid.—In order to prepare the thioketals in good yields it was necessary to have the pure anhydrous acid. Eastman Kodak Co. technical mercaptoacetic acid (thioglycolic acid) was mixed with an equal volume of toluene and the mixture subjected to distillation. After the water and toluene had distilled the residual oil was distilled under reduced pressure. The fraction boiling 87–90° at 4 mm. was collected and used.

Dialkyl *bis*-(Carboxymethylmercapto)-methanes (III).—A mixture of 50 g. of the anhydrous mercaptoacetic acid and 50 g. of each of the anhydrous ketones was saturated with dry hydrogen chloride. The flask was stoppered and chilled in an ice–salt mixture until crystallization was complete. The crystals were filtered, washed with petroleum ether, then with cold water and dried in a vacuum desiccator. Table I summarizes their properties.

TABLE I

$R_2C(—SCH_2COOH)_2$

R	M. p., °C. (corr.)	Yield, %	Molecular formula	S Analyses, % Calcd.	Found
CH_3	134–135	82	$C_7H_{12}O_4S_2$	28.57	28.57
C_2H_5	125–126	96	$C_9H_{16}O_4S_2$	25.39	25.11
n-C_3H_7	133–134	92	$C_{11}H_{20}O_4S_2$	22.85	22.56
n-C_4H_9	86–87	94	$C_{13}H_{24}O_4S_2$	20.80	21.01

Dialkyl *bis*-(Carbethoxymethylmercapto)-methanes (IV).—Fifty grams of each of the above acids was dissolved in 600 ml. of absolute ethanol in a two-liter, three-necked flask fitted with a mercury-sealed stirrer and protected by a calcium chloride tube. The flask was immersed in an ice-bath and 75 g. of anhydrous magnesium sulfate was added. Dry hydrogen chloride was passed over the vigorously stirred suspension for six hours. Six hundred milliliters of absolute ether was then added. The magnesium sulfate was removed by filtration and washed with a small amount of absolute ether. The combined filtrate and washings were poured into ice-cold, dilute sodium hydroxide and shaken thoroughly. The ether layer was separated and washed again with ice-cold sodium hydroxide and twice with ice water. An emulsion formed upon washing with ice water. It was broken by adding a few grams of sodium sulfate and shaking thoroughly. After drying over sodium sulfate the ether was distilled and the last traces removed by gentle heating (not over 60°) *in vacuo*. The properties of these esters are summarized in Table II.

Upon distillation *in vacuo* the diethyl, di-*n*-propyl and di-*n*-butyl-*bis*-(carbethoxymethylmercapto)-methanes were found to decompose. After distillation from a Claisen flask the combined fractions obtained from each compound were separated by distillation through a column packed with glass helices.[3]

The lowest boiling fraction from the three compounds was found to boil at 25° at 1.8 mm. and possessed d^{20}_{20} 1.0980; $n^{20}D$ 1.4578. The M_D calculated for ethyl mercaptoacetate was 30.02 and the found value, 29.85. The solid derivatives of this ester mentioned in the literature are the chloromercuri derivatives which Wislicenus[4] mentioned as melting somewhere under 100°, and a nickel complex[5] which melted at 101°. The ethyl chloromercurimercaptoacetate was prepared by adding an alcoholic solution of the ester to an excess of mercuric chloride dissolved in alcohol. The white amorphous reaction

$$HSCH_2COOC_2H_5 + HgCl_2 \longrightarrow ClHgSCH_2COOC_2H_5 + HCl$$

product was removed by filtration and recrystallized from alcohol. Fine, colorless needles melting sharply at 105° were obtained.

Anal. Calcd. for $C_4H_7O_2SHgCl$: S, 9.01; Hg, 56.49. Found: S, 9.12; Hg, 56.59.

For comparison purposes, mercaptoacetic acid was esterified and the properties of the synthetic ethyl ester found to check those recorded above. The chloromercuri derivative was also made and found to melt at 105° and its melting point was not depressed by addition of the above sample.

The second fraction obtained corresponded to the carbethoxymethylmercaptoalkenes (VI). Their properties and analyses are as follows:

3-Carbethoxymethylmercaptopentene-2.—B. p. 78.5° at 2 mm., d^{20}_{20} 1.0127, $n^{20}D$ 1.4797; M_D calcd. 52.82; found, M_D 52.73.

Summary

A series of dialkyl *bis*-(carbethoxymethanesulfonyl)-methanes has been prepared by oxidizing dialkyl *bis*-(carbethoxymethylmercapto)-methanes. The latter were obtained by esterification of the corresponding acids which were produced by the reaction between mercaptoacetic acid and the simple ketones. These disulfones possessed no hypnotic activity.

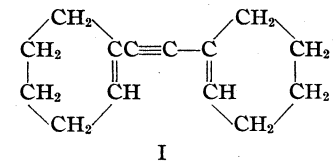
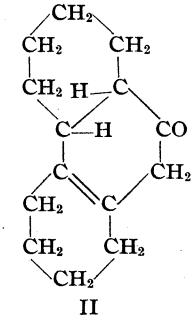
Cyclization of Dienynes. VII.[1] Dehydrogenation of *trans*-Dodecahydrophenanthrene and a Further Study of *trans*-3,4-Dialkyloctalones

BY C. S. MARVEL, RALPH MOZINGO[2] AND E. C. KIRKPATRICK[3]

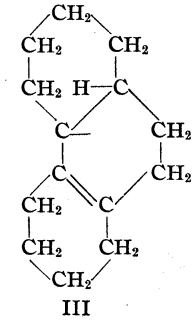
In an attempt to prepare phenanthrene derivatives[4] it was found that the cyclization of di-Δ^1-cyclohexenylacetylene (I) gave a ketone described as Δ^{11}-dodecahydro-9-phenanthrone (II), which on Clemmensen reduction yielded a hydrocarbon considered to be Δ^{11}-dodecahydrophenanthrene (III). Attempts to dehydrogenate these compounds with selenium did not give phenanthrene or a phenanthrol. The hydrocarbon (III) was converted by this treatment to a compound which appeared to be identical with the *trans-as*-octahydrophenanthrene (IV) reported by van de Kamp and Mosettig.[5] Moreover, reduction of the hydrocarbon (III) gave a product with physical properties which checked closely those of tetradecahydrophenanthrene obtained by the hydrogenation of phenanthrene.[4] These facts seemed to establish the phenanthrene structure and pointed to the conclusion that selenium does not dehydrogenate fused *trans* ring systems.



I



II



III

Recently, however, Cook, Hewett and Robinson[6] have shown that van de Kamp and Mosettig's *trans-as*-octahydrophenanthrene contains also the *cis*-isomer (V) and the spiran (VI).

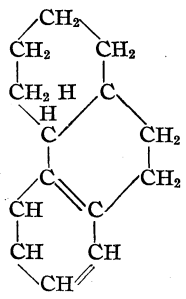
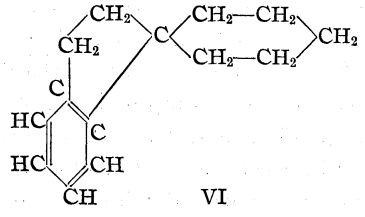
IV



V



VI

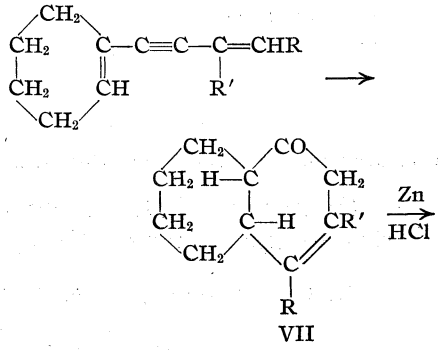
This result coupled with the fact that all comparisons of physical properties in this series had been made on liquids has made it seem desirable to reconsider the structures which have been assigned previously to compounds II and III.

The spiran, cyclohexanespirocyclopentane, has been shown by Clemo and Ormston[7] to be largely decomposed into unidentified fragments when it is heated with selenium although some of it does yield naphthalene, a completely aromatized compound. Since our hydrocarbon (III) is only partially dehydrogenated and not seriously attacked otherwise when heated with selenium, it obviously cannot be the hydrogenated spiran related to VI.

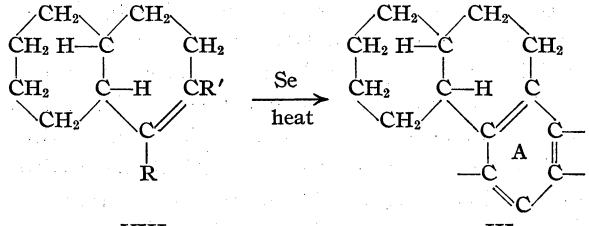
That our hydrocarbon (III) is a phenanthrene derivative has now been established definitely by dehydrogenation over a platinum on charcoal catalyst[8] at 300–320° to give phenanthrene as the only product. This leaves only the question of the position of the double union in the hydrocarbon to be determined.

The fact that dehydrogenation of this dodecahydrophenanthrene with selenium gives octahydrophenanthrene indicates that the double union is at the 11-position. Further evidence of this was sought by ozonolysis of the unsaturated cyclic ketone (II). However, only a mixture of products resulted. These results are similar to those reported by Durland and Adkins,[9] who found that unsaturated hydroaromatic compounds are attacked by ozone–oxygen mixtures at other points as well as at the double bond. Confirmation of the 11-position for the double bond was obtained by hydrogenation of the cyclic ketone (II) over Raney nickel.[10] While this hydrogenation has been reported as giving a non-crystalline alcohol[4b] a solid alcohol has now been obtained. The reduction was more difficult to accomplish than would have been the case if the carbon–carbon double bond had been in an exposed position since a temperature of 185° at 100–200 atmospheres was needed to bring about the addition of hydrogen.

Another case where selenium failed to dehydrogenate a *trans*-bridge has been reported from this Laboratory.[11] An octahydronaphthalene derivative (VIII) was prepared by the following reactions. The structure of the intermediate cyclic



VII



VIII IX

ketone (VII, R = *n*-propyl, R′ = *n*-butyl) was established by ozonolysis to yield a keto acid which could be distilled at 120–125° (2 mm.), without decomposition. If the ring closure had produced a spiran (X), the product of ozonolysis would have been a β-keto acid (XI) and certainly would have decomposed with the loss of carbon dioxide at this temperature. Hence, the hydrocarbon obtained by the Clemmensen reduction of

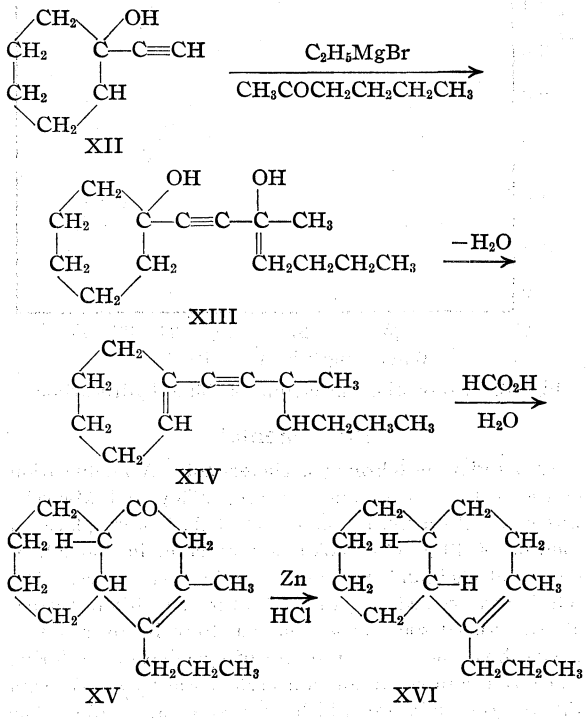
the ketone (VII) was assigned the octalin structure (VIII). Attempts to dehydrogenate this hydrocarbon with selenium led to mixtures of hydrocarbons but ultraviolet absorption spectrum evidence indicated no naphthalene derivative. A new aromatic ring (IXA) was apparently formed from the other alkyl groups. It should be noted here that the crude dehydrogenation product was blue in color.

In order more definitely to establish this ring formation from 1,2-dialkyl groups in a Δ^1-octalin derivative, we have now synthesized the compound corresponding to VIII (in which R is *n*-propyl and R′ is methyl) by the following reactions.



When the methyl *n*-propyl octalin (XVI) was heated with selenium, a bluish mixture of hydrocarbons was obtained. Fractional distillation removed the blue color but the colorless product was still a mixture of hydrocarbons. The ultraviolet absorption spectrum of this mixture showed definite bands of the same character and in the same region as the bands shown by tetralin and other hydrocarbons having an alicyclic ring fused to a benzene ring.[12]

Figure 1 shows the ultraviolet absorption curves of the octalin derivative (XIV), its selenium dehydrogenation product and a sample of *trans-as*-octahydrophenanthrene prepared by the method of van de Kamp and Mosettig.[5] Figure 2 shows the curves of the selenium dehydrogenation product from the octalin mixture and for tetralin.[12]

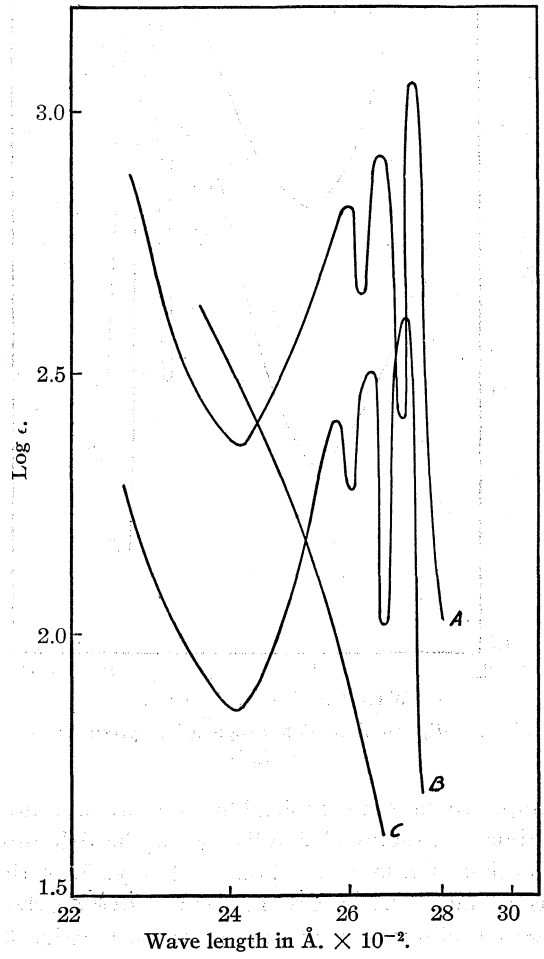


Fig. 1.—*A*, *as*-octahydrophenanthrene; *B*, selenium dehydrogenation products; *C*, octalin derivative (XIV).

The very close similarity between absorption curves B[12a] and A in Fig. 1 shows that they must be produced by the same basic ring structure calculating from Beer's law, the position of B on the log ϵ axis indicates that the concentration of *trans-as*-octahydrophenanthrene in the dehydrogenation product amounts to about 35–40%.

In order to complete the identification of the supposed octalin (XVI), an attempt was made to dehydrogenate it over a platinum–charcoal catalyst to yield the naphthalene in the same way that the dodecahydrophenanthrene (III) had been converted to phenanthrene. However, this at-

(12) Morton and de Gouveia, *J. Chem. Soc.*, 916 (1934).

(12a) To calculate the molal concentration to draw this curve, a molecular weight of 186 was used.

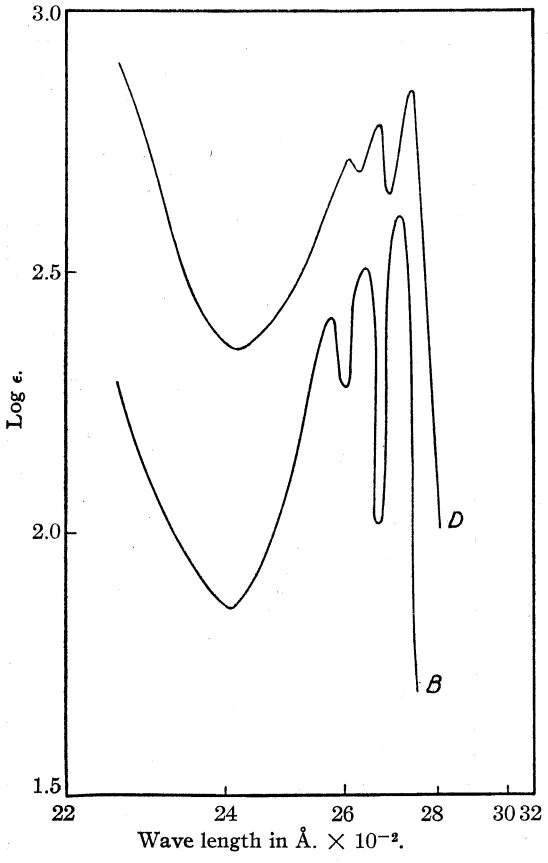

Fig. 2.—*B*, selenium dehydrogenation product; *D*, tetralin.[12]

tempt produced a complex blue mixture of hydrocarbons. Fractional distillation of the dehydrogenation mixture gave about a 19% yield of the deep blue hydrocarbon. This hydrocarbon showed absorption in the ultraviolet (Fig. 3) similar to that shown by known azulene derivatives.[13] The octalin mixture before dehydrogenation gave the characteristic deep blue color with bromine and acetic acid which has been reported for azulene-yielding compounds.[14]

The exact structure of this new azulene has not been established. Its formation, however, shows that the supposed octalin (XVI) contains a hydrocarbon which can be dehydrogenated to give the azulene structure in which a seven-membered ring is fused to a five-membered ring with two carbons in common. Since the ozonization of the ketone (XV) gave evidence of the hydronaphthenone structure, the rearrangement to a seven–five system must have occurred during the Clemmensen[15] reduction. It should be pointed out that no azulenes were noted in the dehydrogenation of the dodecahydrophenanthrene (III) and hence the rearrangement during the Clemmensen reduction must not have occurred in the phenanthrene series.

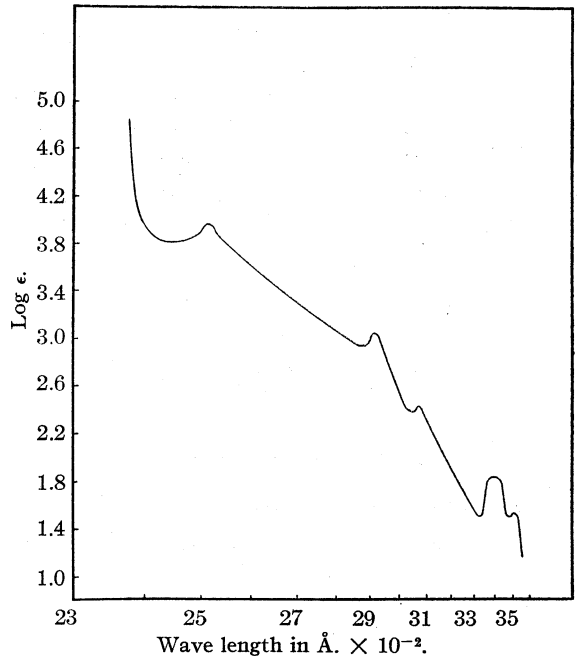

Fig. 3.—Absorption spectrum of blue hydrocarbon.

Experimental

Preparation of 1-Ethynylcyclohexanol.—A modification of the method of Pinkney, Nesty, Wiley and Marvel[4a] was used. In a 2-liter three-necked flask were placed a solution of 40 g. (1.0 mole) of potassium in 400 ml. of *t*-amyl alcohol and 800 ml. of anhydrous ether. The solution was cooled to −15° and saturated with acetylene. To the stirred solution was added dropwise over ten to twelve hours 300 g. (3.0 moles) of cyclohexanone during which time a rapid stream of acetylene was passed through the reaction mixture which was kept at −15°. The solution was stirred for six hours after the addition of all of the cyclohexanone and the acetylene shut off. The reaction mixture was poured into 90 ml. of concentrated hydrochloric acid and 200 g. of ice. The acetylenic alcohol was extracted from the water with ether and fractionated, after removing the unreacted ketone with sodium bisulfite solution. The pure product, b. p. 77–78° (17 mm.), $n^{25}D$ 1.4790, weighed 260 g. (2.1 moles, 69% based on the ketone used).

Preparation of 1-(3-Hydroxy-3-methyl-1-heptynyl)-cyclohexanol.—To the Grignard solution prepared from 79 g. (3.30 gram atoms) of magnesium and 380 g. (3.48 moles) of ethyl bromide in 1.5 liters of anhydrous ether was added with stirring 186 g. (1.50 moles) of 1-ethynylcyclohexanol. The addition was carried out as rapidly as possible without loss of ether and after all the acetylenic

(14) Baber and Smith, "A Research on Eucalypts," Sydney, 1920, p. 417; Haworth, *Ann. Reports*, **34**, 393 (1937).

(15) Clemmensen, *Ber.*, **46**, 1837 (1913).

alcohol had been added the solution was stirred for one hour at room temperature. To the stirred solution was then added 165 g. (1.65 moles) of 2-hexanone and the mixture stirred for two hours. The reaction mixture was poured into 600 g. of ice to which had been added 150 ml. of concentrated hydrochloric acid. The organic layer was separated and the water layer extracted twice with ether. The ether solution was dried over magnesium sulfate, the ether removed and the product fractionated through a modified Widmer column under reduced pressure. The glycol boiled at 124–126° (1 mm.) and did not crystallize on standing. The yields in two runs were 214 g. (61%) and 207 g. (59%), respectively. Some dehydration during distillation evidently occurred because the analysis was high in carbon.

Anal. Calcd. for $C_{14}H_{24}O_2$: C, 75.00; H, 10.71. Found: C, 75.43; H, 10.76.

Dehydration of 1-(3-Hydroxy-3-methyl-1-heptynyl)-cyclohexanol.—Two hundred and seven grams of the glycol was heated to 190–200° with 20 g. of anhydrous potassium bisulfate for thirty minutes. Most of the water which was produced in the dehydration distilled out as it was produced and the remainder was removed under reduced pressure. The residue was fractionated through a Widmer column under reduced pressure. The 1-(3-methyl-3-hepten-1-ynyl)-cyclohexene boiled at 143–148° (21 mm.) and amounted to 154 g. (89%). On standing in the air this hydrocarbon rapidly absorbed oxygen, which accounts for the poor analysis.

Anal. Calcd. for $C_{14}H_{20}$: C, 89.36; H, 10.64. Found: C, 88.14; H, 10.97.

Cyclization of 1-(3-Methyl-3-hepten-1-ynyl)-cyclohexene.—A mixture of 131 g. (0.7 mole) of the dienyne and 900 ml. of 87% formic acid was refluxed for thirty hours. The dark colored mixture was diluted to 2 liters with water and 100 g. of sodium carbonate added to partly neutralize the formic acid. The organic layer was separated and the water layer extracted with ether in portions until the ether no longer became colored. The ether solution was neutralized with sodium bicarbonate and after removal of the ether the product was fractionated under reduced pressure. The first fraction consisted of the dienyne, b. p. 90–93° (1 mm.), and amounted to 15 g. The ketone distilled at 107–108° (1 mm.). The yield after refractionation was 48 g. (38% based on the dienyne not recovered); $n^{25}D$ 1.5022.

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.55; H, 10.63. Found: C, 80.77, 80.60; H, 10.75, 10.64.

The 2,4-dinitrophenylhydrazone, prepared according to the method of Brady,[16] melted at 124–125°.

Anal. Calcd. for $C_{20}H_{26}O_4N_4$: C, 62.18; H, 6.73. Found: C, 61.95; H, 6.85.

Clemmensen Reduction of *trans*-3-Methyl-4-propyl-1,2,4a,5,6,7,8,8a-octahydro-1-naphthalenone.—To a solution of 15 g. of the ketone in 250 ml. of acetic acid were added 100 g. of amalgamated zinc and 90 ml. of 18% hydrochloric acid. The mixture was refluxed one hour and then 60 ml. of concentrated hydrochloric acid added in the course of two hours. The solution was refluxed for twelve hours longer. The organic material was extracted with ether. Fractionation of the ether extract gave 9 g. of hydrocarbon boiling at 115–120° (14 mm.).

Anal. Calcd. for $C_{14}H_{24}$: C, 87.50; H, 12.50. Found: C, 87.20; H, 12.49.

Platinum–Charcoal Dehydrogenation of the Clemmensen Reduction Product.—Four grams of the product from the Clemmensen reduction was passed over platinum–charcoal dehydrogenation catalyst[8] at 300–320°. After repeated passage of the compound over the catalyst until evolution of hydrogen ceased, the product was washed from the dehydrogenation apparatus and subjected to fractional distillation. The lower boiling portion consisted of 0.66 g. of material boiling at 123–128° (20 mm.). An intermediate fraction amounting to 0.32 g. boiling at 128° (20 mm.) to 111° (2 mm.) was colored blue. The fraction boiling at 111–125° (2 mm.) was very dark blue and amounted to 0.75 g. (19% of the theoretical). A brown residue remained.

Azulene Test.—Three drops of the Clemmensen reduction product was dissolved in 10 ml. of acetic acid and enough bromine added to make the solution faintly yellow. After standing for two hours, an intense blue color developed, indicating the presence of a hydroazulene in the reduction product. The blue color was destroyed by allowing the sample to stand in the air for several days.

A similar positive test for azulenes was obtained when the mixture of hydrocarbons obtained in the dehydrogenation was treated with bromine in acetic acid.

Selenium Dehydrogenation of the Clemmensen Reduction Product.—Four grams of the hydrocarbon was heated with 20 g. of powdered selenium under an air condenser for twenty-eight hours at 390–400°. After this time the evolution of hydrogen selenide became slow. The organic material was removed by extraction with ether. After distillation the product, which boiled at 115–123° (17 mm.), amounted to 2.1 g. No attempt was made to fractionate the material, but comparison of the ultraviolet absorption spectrum with *trans-as*-octahydrophenanthrene[5] indicated that the mixture contained about 35–40% of this compound.

In another run the hydrocarbon (15 g.) was heated with selenium (30 g.) for forty-two hours at 390–400°. The product was blue and analyzed for a hydrocarbon.

Anal. Calcd. for $C_{14}H_{24}$: C, 87.50; H, 12.50. Calcd. for $C_{14}H_{18}$: C, 90.32; H, 9.68. Found: C, 88.69; H, 11.41.

Ultraviolet Absorption Spectra.—The spectra were taken with a Bausch and Lomb ultraviolet spectrograph. A hydrogen discharge tube operating on 15,000 volts gave a continuous ultraviolet source and the Hα, Hβ, and Hγ lines served to calibrate the wave length scale of the spectrograph. The pictures were taken with a slit opening 60μ × 5 mm. and a 1.0 cm. quartz cell. Eastman double coated orthochromatic plates were used with a three-minute exposure. The absorption coefficient was determined by comparison with the blackness of a trace due to a 10^{-4} molar solution of naphthalene. The concentrations used were varied from 10^{-2} to 10^{-5} for each sample. Alcohol was used as the solvent.

Ozonization of 3-Methyl-4-propyl-1,2,4a,5,6,7,8,8a-octahydronaphthalen-1-one.—Two ozonolysis reactions were carried out using 10-g. samples of the ketone in carbon

(16) Brady, *J. Chem. Soc.*, 756 (1931).

tetrachloride solution. In the first the reaction was interrupted after six hours and, in the second, after twelve and a half hours. Both gave acidic fractions boiling from 90–180° (1 mm.), but no pure product was isolated. The boiling point changed continuously. The ozonization was not complete in either case. The acidic fraction amounted to 2.1 g. boiling below 100° (1 mm.) and 3.2 g. boiling from 100–180° (1 mm.) with some residue, when the ozonization was carried out for twelve and a half hours. The acid fraction gave no 2,4-dinitrophenylhydrazone.

Preparation of Δ^{11}-Dodecahydro-9-phenanthrone.—This ketone was prepared by the formic acid cyclization of dicyclohexenylacetylene.[4a] The ketone was fractionated to give a fraction boiling at 135–136° (2 mm.) with the refractive index $n^{25}D$ 1.5296. The refractive index of the sample did not vary during distillation.

Hydrogenation of Δ^{11}-Dodecahydro-9-phenanthrone to Tetradecahydro-9-phenanthrol.—A solution of 22.2 g. of the ketone in 120 ml. of ethyl alcohol was hydrogenated at 185° under a pressure of 100–200 atmospheres of hydrogen using Raney nickel[10] as the catalyst. Four hours were required for complete reduction to the saturated alcohol. The product from the hydrogenation was filtered and the solvent distilled. The residue was fractionally distilled through a modified Widmer column. The portion boiling at 136–138° (2 mm.) solidified to a waxy solid on standing for a few hours. The product did not give a sharp melting point and it has not been possible to purify it by recrystallization. The wide melting range indicates that the tetradecahydro-9-phenanthrol is a mixture of *cis–trans* isomers.

Anal. Calcd. for $C_{14}H_{24}O$: C, 80.77; H, 11.54. Found: C, 80.87; H, 11.38.

Δ^{11}-Dodecahydrophenanthrene.—The reduction of Δ^{11}-dodecahydro-9-phenanthrone to the corresponding unsaturated hydrocarbon was carried out by the method of Clemmensen[15] in the manner previously described.[4a]

Dehydrogenation of Δ^{11}-Dodecahydrophenanthrene.—Four and two-tenths grams of Δ^{11}-decahydrophenanthrene was passed repeatedly over platinum–charcoal catalyst[8] until the material was solid. The dehydrogenation product was removed from the apparatus with acetone and filtered. On recrystallization of the solid, after evaporation of the acetone, phenanthrene separated. The noncrystalline portion which remained in the solvent was recovered and again dehydrogenated and the product recrystallized. The phenanthrene amounted to 2.3 g. and melted at 97–98°. No other dehydrogenation product was isolated.

Anal. Calcd. for $C_{14}H_{10}$: C, 94.38; H, 5.62. Found: C, 94.20; H, 5.90.

Summary

1. Evidence has been presented to show that the cyclization of di-Δ^{11}-cyclohexenylacetylene yields Δ^{11}-dodecahydro-9-phenanthrone and not a spiran derivative.

2. Further evidence to support the view that cyclization of dienynes produces ring systems with the *trans*-configuration has been described.

3. Clemmensen reduction of *trans*-3-methyl-4-propyl-1,2,4a,5,6,7,8,8a-octahydro-1-naphthalenone has been found to cause a partial rearrangement of the carbon skeleton to a seven-five fused ring system which yields azulene derivatives on dehydrogenation.

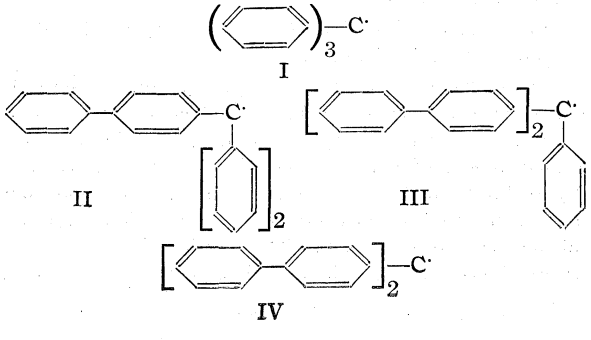
Effect of Substitution on the Dissociation of Hexaarylethanes. VII.[1] Meta and Para Phenyl Groups

BY C. S. MARVEL, MAX B. MUELLER AND EMANUEL GINSBERG

A comparison of the degree of dissociation of hexaarylethanes which have phenyl groups substituted for hydrogen atoms in the meta and para positions with respect to their attachment to the ethane carbon atoms is of considerable interest in testing the resonance theory of dissociation of hexaarylethanes.[2]

It has been pointed out previously[2] that in triphenylmethyl (I) the odd electron can resonate among ten positions, in diphenyl-*p*-biphenylmethyl (II), among thirteen positions, in di-*p*-biphenylphenylmethyl (III), among sixteen positions and in tri-*p*-biphenylmethyl (IV) among nineteen positions.



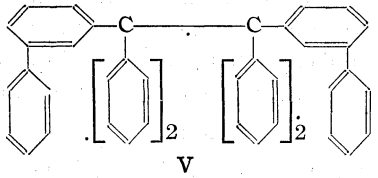
I II III IV

(1) For the sixth communication in this series see THIS JOURNAL, **61**, 77 (1939).

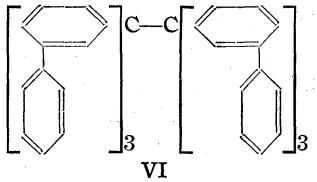
(2) Pauling and Wheland, *J. Chem. Phys.*, **1**, 362 (1933); **2**, 482 (1934); Wheland, *ibid.*, **2**, 474 (1934); Hückel, *Trans. Faraday Soc.*, **30**, 40 (1934); see also Gilman, "Organic Chemistry," Vol. II, John Wiley and Sons, Inc., New York, N. Y., 1938, p. 1850.

Accurate measurements[3] have shown that hexaphenylethane and hexa-*p*-biphenylethane dissociate to the extent of 2–3% and 100%, respectively, in one-tenth molar benzene solutions of the ethane at 20°. Hence, the introduction of the para phenyl group has the effect predicted on the resonance theory of increasing markedly the dissociation of the hexaarylethane.

The introduction of a phenyl group into a meta position of triphenylmethyl would not be expected to increase the number of resonance forms. Hence if this factor is the most important one in determining dissociation it would be expected that such ethanes as tetraphenyldi-*m*-biphenylethane (V) and hexa-*m*-biphenylethane (VI) would exhibit approximately the same degree of dissociation as hexaphenylethane.



V



VI

Recently it was reported from this Laboratory that hexa-*m*-biphenylethane (VI) was dissociated to the extent of about 60% in a 2.5% solution in benzene at 25°. We have now prepared the tetraphenyl-di-*m*-biphenylethane (V) and find by measurement of its magnetic susceptibility that it is dissociated to the extent of 11–12% in a 3.6% solution of the ethane in benzene at 25°. A determination of the magnetic susceptibility of the corresponding *p*-biphenyl derivative (II) has also been made under the same conditions. This hydrocarbon exists to the extent of 13–14% as the free radical in a 3.6% solution. As would be expected, the dissociation in 7% solution is only 10%.

It is very significant that the degree of dissociation of the mono-*m*-phenyl and mono-*p*-phenyl derivatives of triphenylmethyl should fall so close together and that hexa-*m*-biphenylethane should be dissociated to the extent of 60% which approaches the complete dissociation shown by the corresponding para isomer. In view of these values it is evident that the number of resonance forms of the free radical must play a rather minor part in determining the degree of dissociation of these hexaarylethanes.

Another interesting fact has been observed in this study of the meta and para phenyl substituted hexaphenylethanes. Whereas Schlenk, Weikel and Herzenstein[4] have shown that progressive substitutions of pairs of *p*-phenyl groups in hexaphenylethane produces a shift in the color of the solution from the characteristic yellow of this hydrocarbon to orange-red, red and violet, the substitution of two phenyl groups in the meta position gives only a yellow-orange color and six phenyl groups in the meta position give only an orange-red color although the dissociations of the two series of ethanes seem to be of the same general order. It is thus evident that the depth of color of a free radical solution is not a reliable index of the degree of dissociation. The color of the free radical solution is partly a characteristic of the groups present and their positions and not of the degree of dissociation alone.

Experimental

Diphenyl-*m*-biphenylcarbinol.—The Grignard reagent was prepared from 30 g. of *m*-bromobiphenyl and 3.4 g. of magnesium in 200 cc. of dry ether. The reaction was started by addition of a little ethylmagnesium bromide. To this Grignard reagent was added, with stirring, 25 g. of benzophenone dissolved in 100 cc. of dry ether during about three hours. The solution was then refluxed and stirred another hour. The reaction mixture was treated with a solution of ammonium chloride and cracked ice and then steam distilled. The solid residue was dissolved in an excess (400 cc.) of petroleum ether (b. p. 90–110°) and dried with calcium chloride. The yellow solution was filtered from the calcium chloride and concentrated. The light yellow solid which separated on cooling was recrystallized from hot petroleum ether. The yield was 32 g. (80%) of white crystals melting at 104–105°.

Anal. Calcd. for $C_{25}H_{20}O$: C, 89.24; H, 6.00. Found: C, 89.24; H, 6.05.

Diphenyl-*m*-biphenylcarbinol Ethyl Ether.—To a solution of 5 g. of the carbinol in 150 cc. of dry ether was added 5 g. of calcium chloride and then dry hydrogen chloride was passed into the mixture until it was saturated. The solution was filtered from the calcium chloride and was concentrated under reduced pressure to a brown viscous sirup. This residue was washed with petroleum ether (b. p. 30–60°) to remove much of the tarry impurity and then dissolved in 100 cc. of hot absolute ethanol. On concentration and cooling 5 g. (94%) of white prismatic needles melting at 78–79° was obtained.

Diphenyl - *m* - biphenylchloromethane.—Twenty-five grams of the pure carbinol (or ethyl ether) was dissolved in 100 cc. of hydrogen chloride-free acetyl chloride and the solution refluxed for two hours in an all-glass apparatus. After standing a few hours the dark brown solution was filtered through a sintered glass funnel to remove any tarry material. The filtrate was concentrated and cooled to 0°. The crystals which separated in the course of twenty-four hours were collected and recrystallized from acetyl chloride. The yield was 21 g. (80%) of white crystals melting at 86–87°.

Anal. Calcd. for $C_{25}H_{19}Cl$: Cl, 10.00. Found: Cl, 9.95.

Diphenyl-*m*-biphenylmethyl Peroxide.—A solution of 0.786 g. of diphenyl-*m*-biphenylchloromethane in 25 cc. of dry, thiophene-free benzene was shaken with 3 g. of molecular silver for ten hours in the evacuated measuring apparatus already described. After determining the magnetic susceptibility of the solution, it was transferred as completely as possible to an open beaker. The color disappeared completely within ten minutes. The colorless solution was evaporated to dryness. The slightly colored crystalline residue was recrystallized by dissolving it in 10 cc. of dry benzene followed by the addition of 20 cc. of absolute ethanol. The white crystalline material which separated over a period of twenty-four hours was collected, dried, and weighed: yield, 0.489 g. (66%); m. p. 164–165°.

Magnetic Susceptibility Measurements.—The general procedure used for the determination of the dissociation of hexaarylethane has been described previously.[3b] The results for di-*p*-biphenyltetraphenylethane and di-*m*-biphenyltetraphenylethane are summarized in the table.

Summary

1. Di-*m*-biphenyltetraphenylethane has been prepared in benzene solution.

2. Magnetic susceptibility measurements show that in a 3.6% benzene solution, di-*m*-biphenyltetraphenylethane is 11–12% dissociated while di-*p*-biphenyltetraphenylethane is 13–14% dissociated.

3. It is suggested that the number of resonance forms of the free radical plays a rather minor part in determining the degree of dissociation of an hexaphenylethane.

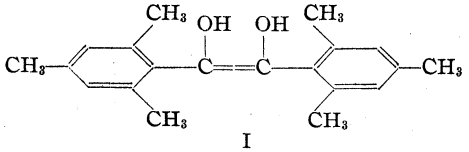
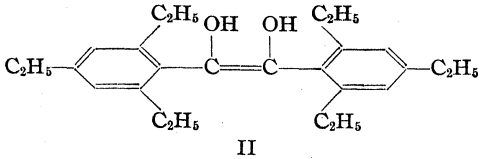
1,2-Diarylacetylene Glycols. II. An Enediol from Hexaethylbenzil

BY REYNOLD C. FUSON, JOSEPH CORSE AND C. H. MCKEEVER[1]

The remarkable stability of the enediol, 1,2-dimesitylacetylene glycol (I),[2] is even more pronounced in its ethyl analog 1,2-di-(2,4,6-triethylphenyl)-acetylene glycol (II).



I



II

The latter, for example, is much more stable in air; it can be exposed to the atmosphere for hours without appreciable change. The methyl compound, on the other hand, is so readily oxidized that it is extremely difficult to purify.

(1) Röhm and Haas Research Assistant.

(2) Fuson and Corse, THIS JOURNAL, **61**, 975 (1939).

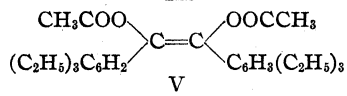
Considerable practical advantage is gained, therefore, by working with the ethyl compound.

The new enediol (II) was made by the action of the binary mixture, Mg + MgI_2,[3] on 2,4,6-triethylbenzoyl chloride and by the method of Thompson[4]—catalytic hydrogenation of the corresponding benzil (III). Both synthetic products melted at 154–155.5° and a mixed melting point showed no lowering.

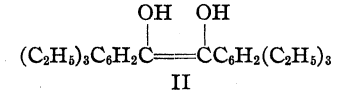
The action of acetic anhydride gave a diacetate (IV), melting at 189–190°—probably the *trans* form. A second diacetate (V) forms when the benzil is hydrogenated in acetic anhydride solution. This isomer—assigned the *cis* configuration—melts at 133.5–134°.

$(C_2H_5)_3C_6H_2COCOC_6H_2(C_2H_5)_3$

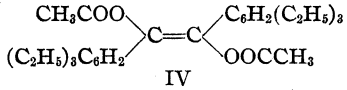
III



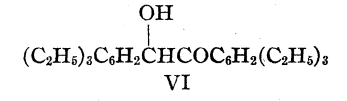
V



II



IV



VI

A mixture of two dibenzoates was formed by the action of benzoyl chloride in pyridine. These melt at 124.5° and 235–236° and presumably possess, respectively, the *cis* and *trans* configurations; treatment with alcoholic potassium hydroxide converts them to the benzil (III).

Like the methyl analog the new glycol (II) can be caused to rearrange slowly to the corresponding benzoin (VI) by heating in a methanol solution containing hydrogen chloride. The benzoin is stable in air and shows no tendency to revert spontaneously to the glycol. In this respect the new enediol and the benzoin appear to differ from ordinary keto–enol pairs; these compounds are not readily interconvertible.

Another property which distinguishes this enediol from ordinary enols is its neutral character. This behavior suggests that vinyl alcohols in general may prove to be neutral substances and that they take on an acidic character only when conjugated with a negative group such as the carbonyl group. This point of view is supported by the observation that in reductone[5] and ascorbic acid[6] the β-hydroxyl group is acidic while the α-hydroxyl group is neutral. The enediol shows infrared absorption maxima at 2.78 and 2.83 μ which may be interpreted to indicate the presence of two hydroxyl groups. Maxima in this region are normally indicative of acidic hydroxyl groups. The double peak observed here is similar to those of compounds in which two hydroxyl groups are held by the same atom. The benzoin, on the other hand, shows a single absorption maximum at 2.85 μ—presumably due to one hydroxyl group.

The authors are indebted to Professors A. M. Buswell and W. H. Rodebush and to Mr. J. R. Downing for the determination and interpretation of the infrared absorption data.

Experimental

2,4,6-Triethylbenzoyl Chloride.—Consistently high yields of this acid chloride were obtained by the thionyl chloride method. This procedure is preferable to that using phosphorus pentachloride[7] since the latter occasionally gave low yields. To 30 g. of 2,4,6-triethylbenzoic acid which had been dried for twelve hours at 60° over phosphorus pentoxide was added, all at once, 21 cc. of thionyl chloride. The reaction started immediately. The mixture was allowed to stand for four hours at room temperature. The excess thionyl chloride was removed under diminished pressure and the acid chloride distilled *in vacuo*. There was obtained 27.5 g. (85% of the theoretical amount) of 2,4,6-triethylbenzoyl chloride, b. p. 108–110° (2 mm.).

1,2-Di-(2,4,6-triethylphenyl)-acetylene Glycol.—A binary mixture of magnesium and magnesium iodide was prepared from 9 g. of magnesium and 46 g. of iodine according to the method of Gomberg and Bachmann.[3] A stream of dry nitrogen was passed through the vessel throughout the period of reaction.

A solution of 32.6 g. of 2,4,6-triethylbenzoyl chloride in 30 cc. of dry ether was added dropwise to the binary mixture. The reaction mixture was stirred for twenty-four hours before nearly all the magnesium had gone into solution. The solution was decanted into a separatory funnel which contained 200 g. of cracked ice and 16 cc. of glacial acetic acid. The ether–benzene layer was separated and washed *rapidly* with three portions of a 10% solution of potassium bicarbonate, once with water, twice with a 5% solution of sodium thiosulfate and twice more with water. The benzene and ether were removed as rapidly as possible under diminished pressure, using a nitrogen-filled capillary tube. The residue was a mixture of white and yellow crystals. The yellow benzil was separated

(3) Gomberg and Bachmann, THIS JOURNAL, **49**, 236) 1927).

(4) Thompson, *ibid.*, **61**, 1281 (1939).

(7) Fuson and Corse, THIS JOURNAL, **60**, 2063 (1938).

from the mixture by washing with low-boiling petroleum ether. The enediol could be recrystallized by dissolving it in a small amount of ether, evaporating this solution to a small volume and adding low-boiling petroleum ether. There was obtained 8 g. of the enediol, m. p. 148–152° (with decomposition) in an open capillary and 154–155° in a nitrogen-filled capillary.

Anal. Calcd. for $C_{26}H_{36}O_2$: C, 82.05; H, 9.53. Found: C, 81.71; H, 9.79.

The low-boiling petroleum ether solution was allowed to stand at room temperature. After several hours the 2,4,6,-2′,4′,6′-hexaethylbenzil started to crystallize; yield, 5 g. From the potassium bicarbonate washings there was obtained 1.5 g. of triethylbenzoic acid.

The enediol did not dissolve in cold 40% aqueous sodium hydroxide solution. It reduced Tollens' reagent as well as ferric chloride and cupric acetate at 0°, and gave a positive test with 2,6-dichlorobenzeneoneindophenol. Oxidation converts it to the benzil.

The glycol was prepared also by hydrogenation of the benzil on methyl alcohol according to the procedure of Thompson[4] for the methyl analog.

The enediol was recrystallized from ether–petroleum ether mixture. The melting point in an open capillary was 149–151°, with decomposition. In a nitrogen-filled capillary the melting point was 154–155.5°. The melting point of a mixture of this product with the sample prepared from the acid chloride showed no depression.

In later experiments it was found more convenient to use low-boiling petroleum ether as the solvent in the reduction. The enediol precipitated as it was formed. The reaction mixture was filtered and the enediol dissolved in a small amount of ether. This solution was filtered to remove the catalyst and the enediol reprecipitated by evaporating most of the ether and adding low-boiling petroleum ether.

Diacetate (Low-Melting).—When the benzil was hydrogenated in acetic anhydride according to the method of Thompson[4] a diacetate was formed. It crystallized from methyl alcohol in glistening white columns melting at 133.5–134°.

Anal. Calcd. for $C_{30}H_{40}O_4$: C, 77.55; H, 8.68. Found: C, 77.49; H, 8.21.

Diacetate (High-Melting).—One-half gram of the enediol was washed with low-boiling petroleum ether, then added to 3 cc. of acetic anhydride, and the solution refluxed gently for three hours. The light brown reaction mixture was poured into water and heated on the steam cone for a few minutes to decompose the excess acetic anhydride. It was extracted with ether, the ether extracts washed with three portions of a 10% solution of potassium carbonate, then with water. The ether was removed and the solid recrystallized from ethyl alcohol. There was obtained 0.2 g. of white needles which melted at 188–190°, and a very small amount of light yellow oil.

Anal. Calcd. for $C_{30}H_{40}O_4$: C, 77.55; H, 8.68. Found: C, 77.64; H, 8.83.

Dibenzoates.—A mixture of 1.8 g. of the enediol, 30 cc. of pyridine and 5 cc. of benzoyl chloride was refluxed gently for three and one-half hours. The reaction mixture, now red, was allowed to stand at room temperature for three hours, then poured into 100 cc. of water. It was extracted with 70 cc. of benzene, the benzene extract washed three times with a 10% solution of potassium bicarbonate, then acidified with dilute hydrochloric acid, washed several times with large portions of very dilute hydrochloric acid, and finally washed with water. The benzene was removed by an air blast. The white solid which remained was partially soluble in alcohol. It was recrystallized from a benzene–absolute alcohol mixture, m. p. 235–236°.

Anal. Calcd. for $C_{40}H_{44}O_4$: C, 81.6; H, 7.53. Found: C, 81.82; H, 7.82.

The filtrate was evaporated to dryness. There remained 0.8 g. of a compound which crystallized readily from 95% alcohol, m. p. 124–124.5°.

Anal. Calcd. for $C_{40}H_{44}O_4$: C, 81.6; H, 7.53. Found: C, 81.35; H, 7.40.

2,4,6,2′,4′,6′-Hexaethylbenzoin.—To 40 cc. of methyl alcohol saturated with dry hydrogen chloride was added 1.8 g. of the enediol. The solution was refluxed for two and one-half hours. The reaction vessel was stoppered tightly and allowed to stand overnight at room temperature. The reaction mixture was then poured into water and extracted with ether; the ether extracts were washed and dried over calcium chloride. After the ether had been removed, there remained 1.6 g. of a light yellow mixture of compounds. By washing this mixture with small portions of low-boiling petroleum ether the yellow color was removed. From these washings a small amount of 2,4,6,2′,4′,6′-hexaethylbenzil was obtained. The benzoin was recrystallized from low-boiling petroleum ether, m. p. 64–65.5°.

Anal. Calcd. for $C_{26}H_{36}O_2$: C, 82.05; H, 9.53. Found: C, 82.37; H, 9.23.

The benzoin did not reduce Tollens' reagent or copper acetate. It gave a negative test with 2,6-dichlorobenzeneoneindophenol. Oxidation with chromic anhydride, however, converted it to the benzil.

Summary

A new enediol, 1,2-di-(2,4,6-triethylphenyl)-acetylene glycol (II), has been synthesized and characterized.

It yields two diacetates and two dibenzoates, and can be caused to rearrange to the corresponding benzoin.

It is readily oxidized, but is not soluble in aqueous alkali.

Researcles on Thiazoles. XXIII. The Synthesis of Certain Benzothiazoles Structurally Related to Quinoline Antimalarials

BY H. HERBERT FOX AND MARSTON T. BOGERT

Of the numerous synthetic organic compounds tested as possible antimalarials, Plasmoquine and Atebrine generally have been regarded as among the most useful. The former of these is a 6-methoxy-8-(δ-diethylamino-α-methyl-butyl) aminoquinoline (XXVI), the latter a 2-chloro-7-methoxy-5-(δ-diethylamino-α-methyl-butyl)-aminoacridine (XXVII).

At the time our research was initiated, no work had been reported, at least so far as we could discover, on the synthesis of benzothiazoles structurally related to Plasmoquine, for the purpose of investigating them as possible antimalarials. It was not until the latter part of March, 1938, when most of our work had been completed, that we learned that Knunyantz and Benevolenskaya[1] had been conducting studies also in this field and had found that 6-methoxy-4-(γ-diethylaminopropyl)-aminobenzothiazole and its 2-methyl derivative were devoid of antimalarial effect. It seems unlikely, therefore, that the 6-methoxy-4-(and 7)(β-diethylaminoethyl)-aminobenzothiazoles, described in the following pages, will exhibit any antimalarial properties.

The methods used by us in these syntheses were quite different from those employed by Knunyantz and Benevolenskaya. The latter prepared their benzothiazoles from thiamides by the familiar Jacobson[2] reaction, whereas we utilized the Herz process[3] as applied to *p*-substituted aromatic amines with a free *o*-position. The various steps in our syntheses are shown on the Flow Sheets.

Experimental

Series A

2-Amino-5-methoxyphenylmercaptan (III).—The Herz reaction product (II) was prepared as described by Ast and Bogert,[4] except that it was found possible to reduce by 40% the proportion of sulfur monochloride to *p*-anisidine hydrochloride without loss of yield. As reported by them, it formed a reddish brown microcrystalline solid, melting with decomposition at 168° (corr.), when crystallized from a mixture of ligroin and chloroform.

From the crude Herz reaction product, a clear colorless aqueous solution of the *sodium salt* of the 2-amino-5-methoxyphenylmercaptan was obtained by the Ast and Bogert[4] technique (except that sodium hydroxide was used instead of the bicarbonate), which was likewise followed in the preparation of the corresponding *zinc salt* (IV).

Hydrochloride.—A cold concentrated aqueous solution of the above sodium salt was neutralized carefully with dilute acetic acid. There resulted a yellow precipitate or suspension. The mixture was extracted with ether, the ether extract dried with anhydrous magnesium sulfate and treated with a current of dry hydrogen chloride. The precipitated hydrochloride was collected, dried, and crystallized from a mixture of absolute ethanol and dry benzene. It formed small yellow needles, m. p. in sealed tube, 210–211° (corr.), with decomposition and previous darkening; yield of crude product, 41%, calculated to the initial *p*-anisidine hydrochloride. It was soluble in water, in excess of aqueous caustic alkali, or in alcohol, but not in benzene.

Anal. Calcd. for $C_7H_{10}ClNOS$: C, 43.8; H, 5.3; N, 7.3. Found: C, 43.6; H, 4.9; N, 7.6.

2,2′-Diamino-5,5′-dimethoxydiphenyl Disulfide (V).—A suspension of 3 g. of the zinc salt of the mercaptan (IV) in 100 cc. of concentrated ammonium hydroxide solution was treated for four hours with a vigorous current of air. A red precipitate replaced the suspended salt. The solid material was removed, extracted with alcohol, the alcoholic extract decolorized with Norite, concentrated, treated with three times its volume of water, and allowed to stand. Long yellow needles separated, which were crystallized repeatedly from 25% ethanol, and then melted at 73–73.5° (corr.). The product was insoluble in water or aqueous caustic alkali, but dissolved in the usual organic solvents.

Anal. Calcd. for $C_{14}H_{16}O_2N_2S_2$: C, 54.5; H, 5.2. Found: C, 54.5; H, 4.9.

6-Methoxybenzothiazole (VI).—A mixture of 15.4 g. of the zinc mercaptide (IV), sufficient glacial acetic acid to dissolve it (about a liter), an excess of anhydrous formic acid, and some metallic zinc, was refluxed for four hours. The bulk of the acid was then distilled off, the residue made alkaline with sodium hydroxide and distilled with steam, giving an 82% yield (11.1 g.) of the crude thiazole. Crystallized from petroleum ether, it was obtained in glistening colorless plates, m. p. 72.5–73° (corr.); freely soluble in carbon bisulfide, alcohol, ether, or benzene, moderately soluble in petroleum ether or hot water, and practically insoluble in cold water.

Anal. Calcd. for C_8H_7ONS: C, 58.1; H, 4.3; N, 8.5. Found: C, 58.1; H, 4.1; N, 8.3.

This compound was prepared also from the aminomercaptan hydrochloride (III) and anhydrous formic acid, in the presence of zinc. The yield was 46%. The method

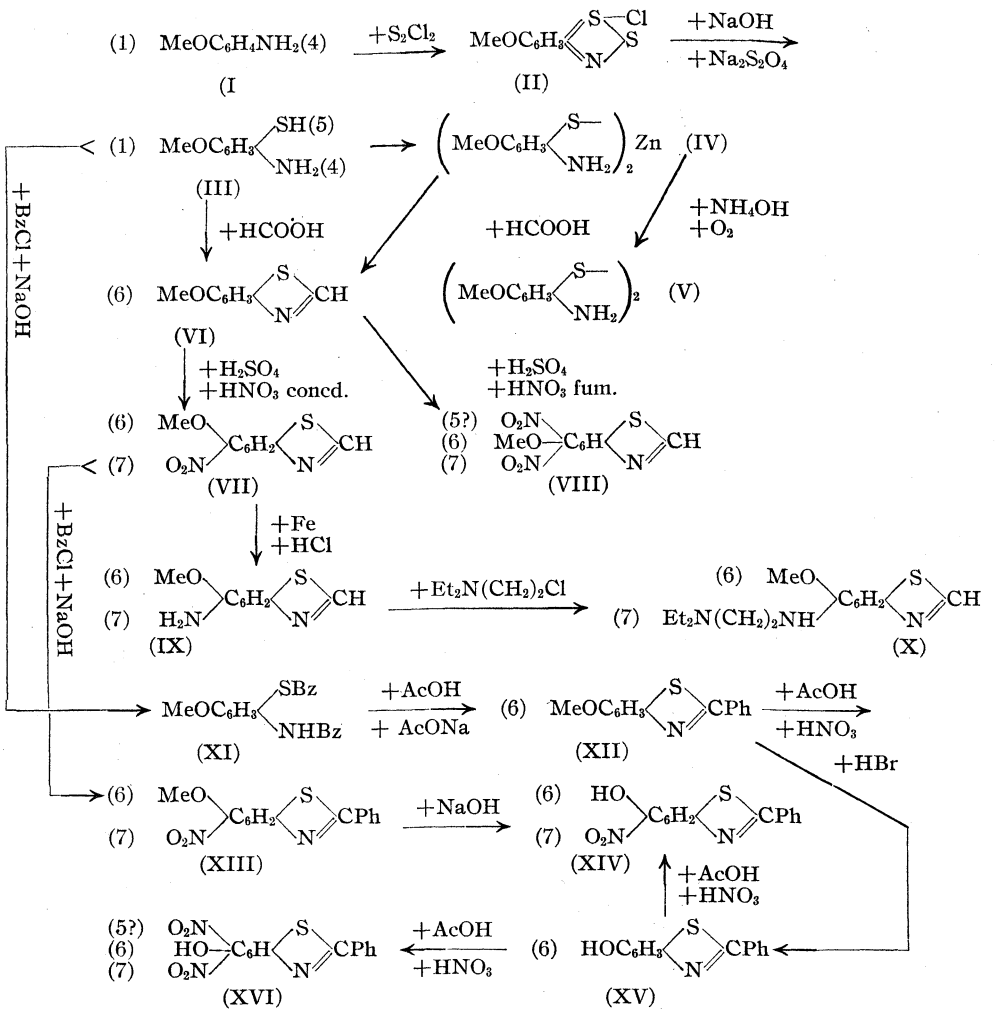
FLOW SHEET—SERIES A



was less satisfactory, because the isolation of the pure aminomercaptan hydrochloride was rather troublesome.

6-Methoxy-7-nitrobenzothiazole (VII).—A solution of 1.5 g. of 6-methoxybenzothiazole in 6 cc. of concentrated sulfuric acid was treated gradually with 6 cc. of concentrated nitric acid, the solution being maintained at room temperature for five minutes and then poured upon ice. The precipitated nitro derivative was collected, washed with water, and crystallized from alcohol. The product formed pale yellow plates, m. p. 202–203.5° (corr.); yield, 1.5 g. or 78%. In subsequent runs, the yields were nearly that calculated.

Anal. Calcd. for $C_8H_6O_3N_2S$: C, 45.7; H, 2.9; N, 13.3. Found: C, 45.6; H, 3.1; N, 13.1.

The same product was obtained by treating a solution of the thiazole in concentrated phosphoric acid with a slight excess of fuming nitric acid; but for all of our subsequent work the first method of preparation was preferred.

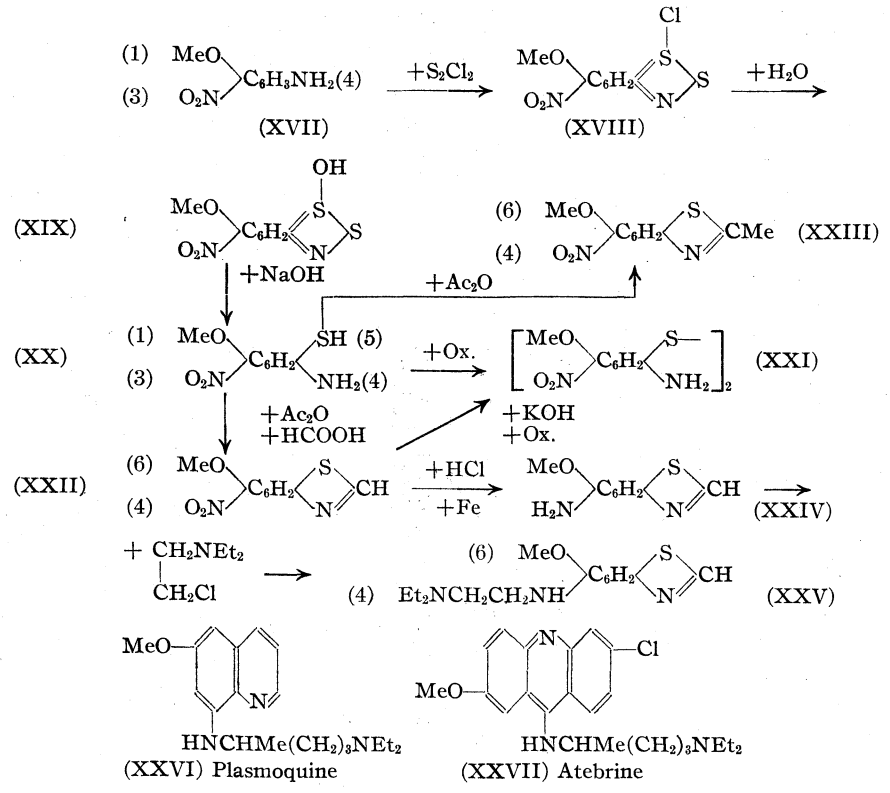
6-Methoxy-5(?),7-dinitro-benzothiazole (VIII).—To a solution of 1 g. of the thiazole (VII) in 6 cc. of concentrated sulfuric acid, there was added dropwise 4 cc. of fuming nitric acid, the mixture being kept for five minutes at 45° and then poured upon ice. The yellow precipitate, when crystallized from alcohol, formed very long needles, of an exceedingly pale yellowish tinge, m. p. 161–162.5° (corr.).

Anal. Calcd. for $C_8H_5O_5N_3S$: C, 37.6; H, 2.0. Found: C, 37.9; H, 2.0.

Since, in what follows, evidence is submitted that the first nitro group is attached to C^7, it seems probable that the second one is on C^5.

6-Methoxy-7-aminobenzothiazole (IX).—A suspension of the corresponding nitro derivative in hot dilute hydrochloric acid was reduced by successive additions of iron powder, and the mixture refluxed until the reaction was complete. The cold mixture was made strongly alkaline with sodium carbonate and filtered hot. As the filtrate cooled, a tan precipitate of the amine separated which was filtered out. The filtrate from this was added to the iron oxide residue and the whole extracted with benzene. The benzene extract was dried over anhydrous sodium sulfate and dry hydrogen chloride passed in, to precipitate the amine hydrochloride. This precipitate was dried, dissolved in water and the aqueous solution made slightly

FLOW SHEET—SERIES B



alkaline with sodium carbonate. The free amine so recovered was added to that obtained from the first alkaline filtrate from the iron oxide, and the whole was purified by solution in dilute acid and reprecipitation by alkali; yield 62%. Purified by repeated crystallization from hot water, it formed tan plates, m. p. 130.5–131.5° (corr.).

Another portion was sublimed *in vacuo*, and the white sublimate crystallized from "Skellysolve D." Nearly white plates were thus secured, m. p. 130–131° (corr.), with previous softening.

Anal. Calcd. for $C_8H_8ON_2S$: C, 53.3; H, 4.5; N, 15.6. Found: C, 53.2; H, 4.6; N, 16.0.

HCl Salt.—Nearly colorless transparent flakes (from alcohol), melting with decomposition and previous darkening at 223–224° (corr.) (sealed tube).

Anal. Calcd. for $C_8H_8ON_2S \cdot HCl$: 0.0992 g. requires 1.055 cc. of 0.434 *N* NaOH. Found: 1.068 cc.

6 - Methoxy - 7 - (β - diethylaminoethyl) - aminobenzothiazole (X).—A mixture of 5 g. of the above amine (IX), 6 g. of β-diethylaminoethyl chloride hydrochloride, and 15 cc. of absolute ethanol was heated at 110° for fifty-six hours under a short air condenser carrying a calcium chloride guard tube, to permit the distillation of the alcohol without ingress of moisture. The reaction product was dissolved in hot water, the reddish-brown solution cooled and a large excess of potassium carbonate added. The solution separated into two layers. The upper viscous dark brown oily one was taken up in ether, the ether solution dried over potassium carbonate, filtered, and the ether boiled off. The residue was distilled at a pressure of about 0.0001 mm. and gave, in addition to some unchanged initial material, a light yellow viscous oily fraction at 140–145°, which darkened rapidly on exposure to the air, and was the compound sought (X); $n^{25}D$ 1.5792.

Anal. Calcd. for $C_{14}H_{21}ON_3S$: C, 60.2; H, 7.6. Found: C, 60.0; H, 7.7.

2 - Benzoylamino - 5 - methoxybenzoylphenylmercaptan (XI) was prepared from the sodium mercaptide (III) and benzoyl chloride, as described by Ast and Bogert[4] and a similar product obtained (m. p. 162–163°, corr.).

2-Phenyl-6-methoxy-benzothiazole (XII), obtained from the foregoing dibenzoyl derivative by the action of acetic anhydride and fused sodium acetate, as described by Ast and Bogert,[4] formed fine long colorless needles, m. p. 114–114.5° (corr.), as reported by them.

2-Phenyl-6-methoxy-7-nitrobenzothiazole (XIII).—To a mixture of 2.4 g. of the above thiazole (XII) with 10 cc. of glacial acetic acid, there was added 2 g. of nitric acid (sp. gr., 1.4) in 4 cc. of glacial acetic acid. There resulted a red solution, which was warmed for a short time at 60°, then cooled and poured into water. The yellow precipitate which formed was collected, washed with water and dried; yield 2.5 g., or 82%. Recrystallized from glacial acetic acid, it formed small yellow needles, m. p. 210–211°.

Anal. Calcd. for $C_{14}H_{10}O_3N_2S$: C, 58.7; H, 3.5. Found: C, 58.6; H, 3.7.

To a hot solution of 2 g. of 6-methoxy-7-nitrobenzothiazole in 5 cc. of benzoyl chloride,[5] an excess of 10% sodium hydroxide solution was added slowly and carefully, and

(5) *Cf.* Reissert, *Ber.*, **38**, 3432 (1905).

the heating continued for a short time longer. The solution was filtered hot and the gummy precipitate thus removed was crystallized repeatedly from glacial acetic acid first and then from ethanol. The purified product formed small yellow needles, m. p. 210–211° (corr.).

Anal. Calcd. for $C_{14}H_{10}O_3N_2S$: C, 58.7; H, 3.5. Found: C, 59.0; H, 3.6.

The product from this second method was apparently identical with that obtained by the direct nitration of the phenylmethoxythiazole (XII) as described above. A mixture of the two melted at 210–211° (corr.).

2-Phenyl-6-hydroxybenzothiazole (XV).—A mixture of 3 g. of 2-phenyl-6-methoxybenzothiazole with 40 cc. of 48% hydrobromic acid was refluxed for six hours, cooled, and made alkaline with dilute sodium hydroxide. A dirty white precipitate separated at first, but soon redissolved, giving a solution with a strong green fluorescence. This solution, after decolorization with Norite, was acidified with excess of dilute acetic acid. A whitish gummy solid precipitated and soon became crystalline. Recrystallized from dilute ethanol, it formed white needles which melted, with previous softening, at 227–227.5° (corr.); yield, nearly that calculated.

Fries and Buchler[6] prepared this compound in much the same way, except that they used glacial acetic acid saturated with hydrogen bromide and heated the mixture for eighteen hours at 100° in sealed tubes. They reported the m. p. of their product as 227°.

2-Phenyl-6-hydroxy-7-nitrobenzothiazole (XIV).—1.01 g. of the above crude hydroxythiazole was nitrated as described by Fries and Buchler.[6] The long orange needles so obtained melted at 170–171° (corr.).

In another experiment, 1 g. of 2-phenyl-6-methoxy-7-nitrobenzothiazole was refluxed for seven hours with an excess of 10% sodium hydroxide solution. The mixture, consisting of a red solution containing a red precipitate, was filtered hot. The red precipitate was extracted by boiling with dry benzene, which recovered a large amount of unchanged initial thiazole. The small quantity of red solid undissolved by the benzene was taken up in hot alcohol, the alcohol solution acidified with hydrochloric acid, decolorized with Norite, and precipitated by careful dilution of the hot solution. Orange needles separated which, when recrystallized from dilute alcohol, melted at 171° (corr.). A mixture of this product with that obtained by the method described in the first paragraph, melted at 170.5–171° (corr.).

Anal. Calcd. for $C_{13}H_8O_3N_2S$: C, 57.3; H, 3.0. Found: C, 57.5; H, 3.0.

2-Phenyl-6-hydroxy-5(?),7-dinitrobenzothiazole (XVI).—A solution of 0.4 g. of 2-phenyl-6-hydroxybenzothiazole in 5 cc. of glacial acetic acid was treated with a solution of 1 cc. of nitric acid (sp. gr., 1.4) in 2 cc. of glacial acetic acid. The red mixture was warmed gently for a short time, then poured into water, the precipitate collected, washed with water, dried, and crystallized from glacial acetic acid. Long fine deep yellow needles were thus obtained, m. p. 194.5–196° (corr.).

Anal. Calcd. for $C_{13}H_7O_5N_3S$: C, 49.2; H, 2.2. Found: C, 49.4; H, 2.4.

(6) Fries and Buchler, *Ann.*, **454**, 240 (1927).

Series B

2-Amino-3-nitro-5-methoxyphenylmercaptan (XX).—The Herz reaction as applied to *p*-anisidine proved very unsatisfactory with *m*-nitro-*p*-anisidine, because of the sensitivity to moisture of the hydrochloride of the latter, and other complications. Recourse was had, therefore, to a modification of the Herz process described in a later German Patent, no. 367,346.[3]

A suspension of 150 g. of *m*-nitro-*p*-anisidine (XVII) in 900 cc. of glacial acetic acid, at 20°, was treated with 440 cc. (750 g.) of previously cooled sulfur monochloride. After being stirred for some time at room temperature, it was heated slowly to 75–80° and maintained at that point until the evolution of hydrogen chloride ceased (about five hours). After a brief additional heating at 90°, the mixture was cooled to room temperature, the orange-yellow precipitate collected, washed with dry benzene, and dried in the air; yield 170 g.

Some of this crude product, purified by crystallization from a mixture of benzene and glacial acetic acid, yielded a yellowish orange microcrystalline solid (XVIII), 1-chloro-4-nitro-6-methoxyisobenzo-1,2,3-dithiazole, which melted with decomposition at 220° (corr.), with previous darkening. However, if heated suddenly at any temperature above 190°, melting and decomposition ensued almost immediately. The compound was soluble in water, alcohol, or glacial acetic acid, but insoluble in benzene. Its aqueous solution, however, soon underwent hydrolysis on standing, with separation of a voluminous flocculent precipitate, which crystallized from absolute ethanol in long yellow needles of the corresponding *hydroxyl derivative* (XIX), which decomposed at 162.5° (corr.) with preliminary darkening; yield, 68%, based on the initial nitroanisidine.

Anal. Calcd. for $C_7H_6O_4N_2S_2$: C, 34.1; H, 2.5. Found: C, 34.3; H, 2.6.

This product easily was converted by caustic alkali into the sodium amino mercaptide (XX), as described for the 2-amino-5-methoxyphenylmercaptide, except that the solution so obtained was blood-red instead of colorless.

The zinc salt, prepared from the aqueous solution of the sodium mercaptide and zinc sulfate, by the Ast and Bogert[4] technique, was obtained in small red needles (from a mixture of ethanol and benzene), freely soluble in ethanol or glacial acetic acid, only slightly soluble in chloroform, and practically insoluble in water or benzene; yield, 40%, calculated to the *m*-nitro-*p*-anisidine.

2,2′-Diamino-3,3′-dinitro-5,5′-dimethoxydiphenyl Disulfide (XXI).—The aqueous alkaline solution of the sodium mercaptide (XX) was acidified with hydrochloric acid. A red flocculent precipitate separated, which was removed, washed with water, and crystallized from ethanol. Beautiful bright red needles were thus obtained, m. p. 171° (corr.).

Anal. Calcd. for $C_{14}H_{14}O_6N_4S_2$: C, 42.2; H, 3.5; mol. wt., 396. Found: C, 42.2; H, 3.7; mol. wt. (Rast), 392.

In the above reaction, the free mercaptan, which separated first, rapidly oxidized in the air to the disulfide. The presence of the mercaptan in the freshly precipitated material was demonstrated easily by its solubility in dilute alkali.

4-Nitro-6-methoxy-benzothiazole (XXII).—All attempts to obtain this thiazole by the action of anhydrous formic acid upon either the freshly precipitated mercaptan (XX), or its zinc salt, proved futile.

To a solution of the sodium mercaptide (XX) obtained by hydrolysis of 100 g. of the Herz reaction product, there was added all at once 140 cc. of crude formic–acetic anhydride, prepared as described by Béhal.[7] The whole was shaken vigorously, and then allowed to stand for five to ten minutes with occasional shaking. A yellow solid precipitated. This was collected, washed with water, and crystallized from dilute ethanol, giving long glistening yellow flat needles, m. p. 150–152°; yield 23.5 g.; or 21%, calculated to the nitroanisidine. Knunyantz and Benevolenskaya,[1] who prepared this compound in another way, gave its m. p. as 151°.

Anal. Calcd. for $C_8H_6O_3N_2S$: C, 45.7; H, 2.9; N, 13.3. Found: C, 45.7; H, 2.8; N, 13.2.

2-Methyl-4-nitro-6-methoxybenzothiazole (XXIII).—A few cc. of the aqueous alkaline solution of the sodium mercaptide (XX) was treated with sufficient acetic anhydride to redissolve the precipitate which first appeared. The solution was warmed and allowed to stand as long as crystals continued to separate. These small yellow needles were removed, washed with water and recrystallized from dilute ethanol. The first recrystallization yielded large intense yellow glistening plates, but all subsequent recrystallizations gave long yellow needles, m. p. 147° (corr.). Knunyantz and Benevolenskaya[1] prepared this compound by a different method and found its m. p. as 149–150°.

Anal. Calcd. for $C_9H_8O_3N_2S$: C, 48.2; H, 3.5; N, 12.5. Found: C, 48.1; H, 3.5; N, 12.4.

4-Amino-6-methoxybenzothiazole (XXIV).—A suspension of 60 g. of the corresponding nitro derivative (XXII) in dilute hydrochloric acid (50 cc. of concentrated acid to 500 cc. of water) was reduced by the gradual addition of 60 g. of iron powder. After refluxing the mixture for two and one-half hours, it was extracted with benzene and the filtered extract distilled. After the removal of the benzene, the residue was crystallized from absolute ethanol, after decolorization by Norite. The crystals obtained varied in form with the rate of cooling, the concentration, and probably other factors, being lightly tinted transparent plates, thick spikes, or long needles in rectangular clusters. The m. p. remained constant at 145.5–146° (corr.), even after the carefully purified material had been sublimed in a vacuum. Knunyantz and Benevolenskaya,[1] who reduced the nitro derivative by stannous chloride and crystallized their product from dilute alcohol, obtained long needles, m. p. 151°.

(7) Béhal, *Ann. chim.*, [7] **20**, 417 (1900).

Anal. Calcd. for $C_8H_8ON_2S$: C, 53.3; H, 4.5; N, 15.5. Found: C, 53.3; H, 4.6; N, 15.3.

Hydrochloride.—Long colorless needles, from concentrated hydrochloric acid, melting with decomposition, in a sealed tube, at 207–209° (corr.) (literature,[1] m. p. 206–208°).

Anal. Calcd. for $C_8H_8ON_2S\cdot HCl$: 0.1 g. requires 1.061 cc. of 0.434 *N* NaOH; found, 1.069 cc.

4-(β-Diethylaminoethyl)-amino-6-methoxybenzothiazole (XXV) was prepared from the foregoing amine and β-diethylaminoethyl chloride hydrochloride in essentially the same way as the 7-(β-diethylaminoethyl) isomer (X) was obtained from the corresponding amine, except that no ethanol was used in the mixture. Distillation of the crude product, at a pressure of 5–6 mm., in an atmosphere of nitrogen, yielded two fractions. One, b. p. 188–215°, consisted mainly of unchanged initial amine; and the other, b. p. 215–217°, was a yellow viscous oil, which darkened rather less rapidly on standing than its isomer (X); $n^{25}D$ 1.5978.

Anal. Calcd. for $C_{14}H_{21}ON_3S$: C, 60.2; H, 7.6. Found: C, 60.2; H, 7.3.

Acknowledgments.—Our grateful thanks are due to E. I. du Pont de Nemours & Co., Inc., of Wilmington, Delaware, and to the National Aniline and Chemical Co., Inc., of New York, for a generous supply of *p*-anisidine and of *m*-nitro-*p*-anisidine, for use in these investigations.

We are indebted also to Mr. Saul Gottlieb, of these Laboratories, who carried out the analyses recorded in this paper.

Summary

1. 6-Methoxy-4(and 7)-(β-diethylaminoethyl)-aminobenzothiazoles have been synthesized from *p*-anisidine in the one case, and from 3-nitro-4-aminoanisole in the other.

2. It was planned to study these compounds as possible antimalarials, but work recently published in Russia, on some closely related benzothiazoles, makes it seem unlikely that they will prove of any value in that direction.

3. From *m*-nitro-*p*-anisidine, 4-amino-6-methoxybenzothiazole is easily prepared.

4. Nitration of 6-methoxy, or of 2-phenyl-6-methoxybenzothiazole, substitutes the H in position 7.

NEW YORK, N. Y. RECEIVED MAY 13, 1939

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY, COLUMBIA UNIVERSITY]

Calculation of Base Rate Constants from Acid Rate Constants

BY SAMUEL H. MARON[1] AND VICTOR K. LA MER

For the protolytic equilibrium

$$N + B \underset{k_A}{\overset{k_B}{\rightleftharpoons}} R^- + A \qquad (1)$$

where N is acid substrate which ionizes to yield a proton to a base, B is base (proton acceptor), R^- is conjugate base of N, and A is conjugate acid of B, the equilibrium constant, K, is given by

$$K = \frac{k_B}{k_A} = \frac{[R^-]\,[A]}{[N]\,[B]} \qquad (2)$$

However, the ionization constant of N, K_N, corresponding to the reaction

$$N + H_2O = H_3O^+ + R^- \qquad (3)$$

is given by

$$K_N = [R^-]\,[H_3O^+]/[N] \qquad (4)$$

while the ionization constant of A, K_A, corresponding to the reaction

$$A + H_2O = H_3O^+ + B \qquad (5)$$

is given by

$$K_A = [B]\,[H_3O^+]/[A] \qquad (6)$$

Dividing now (4) by (6)

$$\frac{K_N}{K_A} = \frac{[R^-]\,[H_3O^+]}{[N]} \cdot \frac{[A]}{[B]\,[H_3O^+]} = \frac{[R^-]\,[A]}{[N]\,[B]} = K \qquad (7)$$

by eq. (2). And hence

$$\frac{K_N}{K_A} = \frac{k_B}{k_A} \qquad (8)$$

Knowing any three of the four constants K_N, K_A, k_B, k_A in (8), the fourth may be calculated. It is proposed to apply these equations to the prototropic isomerization of nitroparaffins to calculate k_B from available values of K_N, K_A, and k_A.

The primary and secondary nitroparaffins are acids which react with bases (defined in the general sense of Brönsted[2]) to yield an aci-nitroparaffin ion and a conjugate acid[3] according to the general scheme

$$\begin{matrix} R \\ R' \end{matrix}\!\!>\!CHNO_2 + B \xrightarrow{k_B} \begin{matrix} R \\ R' \end{matrix}\!\!>\!C=NOO^- + A \qquad (9)$$

The mechanism of this reaction has been discussed before.[4] Again, the reisomerization of aci-nitroparaffin to the nitro form has been shown to be, under the proper conditions, a reaction between the aci-nitroparaffin ion and an acid[5] (in the general sense) according to the scheme

$$\begin{matrix} R \\ R' \end{matrix}\!\!>\!C=NOO^- + A \xrightarrow{k_A} \begin{matrix} R \\ R' \end{matrix}\!\!>\!CHNO_2 + B \qquad (10)$$

If (9) and (10) be combined, we have the equilibrium condition:

$$\begin{matrix} R \\ R' \end{matrix}\!\!>\!CHNO_2 + B \underset{k_A}{\overset{k_B}{\rightleftharpoons}} \begin{matrix} R \\ R' \end{matrix}\!\!>\!C=NOO^- + A \qquad (11)$$

with equilibrium constant

$$K = \frac{\left[\begin{matrix} R \\ R' \end{matrix}\!\!>\!C=NOO^-\right][A]}{\left[\begin{matrix} R \\ R' \end{matrix}\!\!>\!CHNO_2\right][B]} = \frac{k_B}{k_A} \qquad (12)$$

Equation (12) is exactly analogous to equation (2), and hence it follows from (8) that

$$K = \frac{k_B}{k_A} = \frac{K_N}{K_A} \qquad (13)$$

where K_N is according to (3) and (4) the constant for the nitroparaffin dissociation

$$\begin{matrix} R \\ R' \end{matrix}\!\!>\!CHNO_2 + H_2O \rightleftharpoons \begin{matrix} R \\ R' \end{matrix}\!\!>\!C=NOO^- + H_3O^+ \qquad (14)$$

and

$$K_N = \frac{\left[\begin{matrix} R \\ R' \end{matrix}\!\!>\!C=NOO^-\right][H_3O^+]}{\left[\begin{matrix} R \\ R' \end{matrix}\!\!>\!CHNO_2\right]} \qquad (15)$$

while K_A is the ionization constant of the acid used and is defined by equations (5) and (6).

The ionization constants K_N of the nitro forms of nitromethane and nitroethane can be obtained from some measurements of Junell.[6] Junell determined what he terms the "scheinbare Dissoziationskonstante" of these two substances by

(6) Junell,[3] Dissertation, pp. 114–124.

determining at high pH's the total concentration of aci form and calculating the ratio

$$K'_N = [H_3O^+]\,[\text{aci form}]/[\text{nitro form}] \quad (16)$$

The highest H_3O^+ concentration used for the nitromethane measurements was 1.41×10^{-9}, while the highest concentration of H_3O^+ for nitroethane was 5.38×10^{-9}. Now, since the ionization constant of aci-nitromethane is given by Junell[7] as 6×10^{-4} while that of nitroethane has been shown to be 4.1×10^{-5},[8] it follows that the ratios of aci ion to aci acid at equilibrium must be

$$\frac{[R^-]}{[R\,H]} = \frac{6 \times 10^{-4}}{1.41 \times 10^{-9}} = 4.3 \times 10^5 \text{ for nitromethane}$$

and

$$\frac{[R^-]}{[R\,H]} = \frac{4.1 \times 10^{-5}}{5.38 \times 10^{-9}} = 7.6 \times 10^3 \text{ for nitroethane}$$

From these ratios it is seen that compared to the concentrations of aci ion present the concentrations of aci acid are negligible, and hence (16) is essentially

$$K_N' = \frac{[H_3O^+]\,[R^-]}{[N]} = K_N \quad (17)$$

the ionization constants of the nitro forms. For nitromethane Junell reports from five measurements $K_N = (2.6 \pm 0.2) \times 10^{-11}$, while for nitroetnane he gives as a result of four measurements $K_N = (2.7 \pm 0.2) \times 10^{-9}$. These are the values of K_N employed in all calculations.

Table I gives the observed quantities and calculations for nitromethane at 0°. Columns (1), (2) and (3) give the acids used, their ionization constants, and the rate constants, respectively, for the reaction (10)

$$CH_2{=}NOO^- + A \longrightarrow CH_3NO_2 + B$$

These data are due to Junell.[7] Column (4) gives the equilibrium constant K calculated by Eq. (13), while column (5) gives the rate constant, k_B, calculated by (12) for the reaction: $CH_3NO_2 + B \longrightarrow CH_2{=}NO_2^- + A$ where B is the conjugate base of the particular acid.

It is possible to compare several of the calculated values of k_B with observed results. Although no rate data are available for 0°, kinetic measurements are extant for the reaction with the bases H_2O, monochloroacetate, and acetate ions at several temperatures, so that extrapolation to 0° and comparison with the calculated constants are possible. The data available for this purpose are summarized in Table II. A

35.0	1.38×10^{-2}	Reitz[3]

plot of log k_B *vs.* $1/T$ and extrapolation to 0° yields the constants given in column (6) of Table I. The agreement between calculated and observed results, columns (5) and (6), is good.

In case of the acid H_3O^+ the procedure was reversed and k_A calculated from the values of k_B at 0° measured by Maron and La Mer.[4]

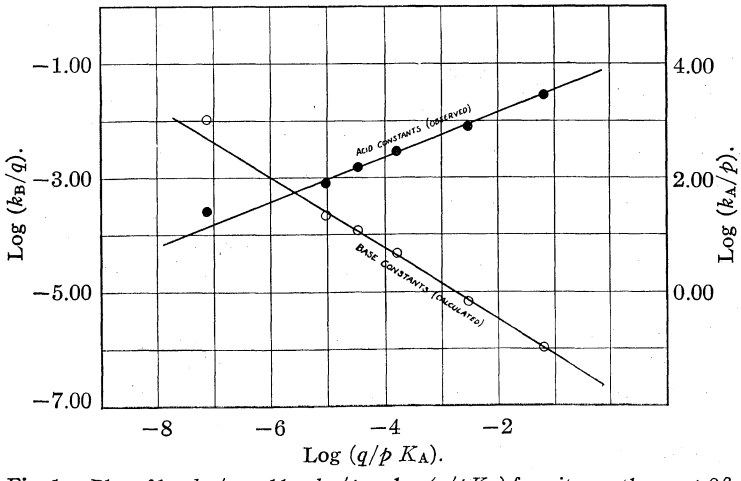

Fig. 1.—Plot of log k_B/q and log k_A/p *vs.* log (q/pK_A) for nitromethane at 0°.

It is possible to make the comparison between observed and calculated constants in two other ways, namely, by calculation of K and K_A from observed data. From equation (13), $K = k_B/k_A$. Using the observed values of k_A and k_B given in columns (3) and (6) of Table I, $K_{obsd.}$ have been calculated and are given in column (7). These values are to be compared with those given in column (4), and calculated from $K_{calcd.} = K_N/K_A$. The agreement again is good. And, finally, also by equation (13), $K_A = K_N k_A/k_B$; values of K_A thus calculated are given in column (8), and again show as good agreement with the observed values of K_A in column (2) as can be expected.

Table III gives the results of similar calculations for nitroethane. These calculations are again based on Junell's values for k_A, and on his value of $K_N = 2.7 \times 10^{-9}$ for nitroethane. Columns (1), (2) and (3) have the same significance as before except that now the reaction involved is

$$CH_3CH_2NO_2 + B \underset{k_A}{\overset{k_B}{\rightleftarrows}} CH_3CH{=}NOO^- + A$$

while columns (4) and (5) give the calculated equilibrium constants of the reaction ($K_{calcd.}$) and the rate constants for the forward reaction (k_B). Unfortunately no extended data on the forward reaction are available to permit comparison of calculated and observed results in this case. The only value of k_B available at 0° is $k_{OH^-} = 39.1$ and due to Maron and La Mer,[4] but no k_A observed is known to permit a calculation of k_B. Hence again the procedure was reversed and the known value of k_{OH^-} was used to calculate the value of k_{H_2O} in column (3).

However, a test of the calculated values of k_B can be obtained in another way. Junell showed that for both nitromethane and nitroethane a plot of log k_A/p *vs.* log (qK_A/p) is essentially linear, as would be expected if the Brönsted relation log $k_A/p = \log G_A + \alpha \log (q/pK_A)$ were obeyed. p and q are the statistical factors to correct the respective measured acid and base constants K_A and K_B to a uniform basis (see ref. 1). The values assigned p and q are given in Tables I and III. On theoretical grounds it may be anticipated that a plot of log k_B/q *vs.* log q/pK_A should also yield a straight line but with slope $= -\beta$ and y intercept $= \log G_B$. Further $\alpha + \beta$ should equal unity. The plot of both log k_A/p and log k_B/q *vs.* log q/pK_A for nitromethane at 0° is shown in Fig. 1. The expected linearity for log k_B/q *vs.* log q/pK_A is verified. Whenever a point is off the curve, the discrepancy is traceable to the corresponding value of k_A, which is also off

the curve. Further, from this plot we obtain $G_A = 8200$, $G_B = 1.98 \times 10^{-7}$, $\alpha = 0.39$ and $\beta = 0.62$, and hence $\alpha + \beta = 0.39 + 0.62 = 1.01$ as against the expected sum of unity.

A similar plot for nitroethane is shown in Fig. 2. Again the linear relation is obtained between log k_B/q and log q/pK_A. In this case $G_A = 32$, $G_B = 1.05 \times 10^{-7}$, $\alpha = 0.36$, $\beta = 0.65$ and $\alpha + \beta = 0.36 + 0.65 = 1.01$.

From the deductions of this paper may be derived another very interesting and quite general relationship. For reactions of the type discussed here, and which lead to an equilibrium, we have in general

$$k_A/p = G_A(q/pK_A)^\alpha \text{ and } k_B/q = G_B(p/qK_B)^\beta$$

where $K_B = 1/K_A$, *i. e.*, the ionization constant for the base conjugate to A. With these equations we obtain finally for log k_B/k_A

$$\log k_B/k_A = [1 - (\alpha + \beta)] \log q/p + \log \frac{G_B}{G_A} - (\alpha + \beta) \log K_A \quad (18)$$

But $k_B/k_A = K$ and $(\alpha + \beta) = 1$. Hence

$$\log \frac{k_B}{k_A} = \log K = \log \frac{G_B}{G_A} - \log K_A \quad (19)$$

However, according to (8) $\log K + \log K_A = \log K_N$. Therefore

$$\log K_N = \log G_B/G_A$$

and

$$K_N = G_B/G_A \quad (20)$$

According to (20) the ratio G_B/G_A should be the ionization constant of the substrate involved in the basic reaction. This relation can be tested easily by utilizing the values of G_B and G_A found at 0° for nitromethane and nitroethane. For nitromethane $G_B/G_A = 1.98 \times 10^{-7}/0.82 \times 10^4 = 2.4 \times 10^{-11}$, as against the observed value of $K_N = 2.6 \times 10^{-11}$. Similarly, for nitroethane $G_B/G_A = 1.05 \times 10^{-7}/32 = 3.3 \times 10^{-9}$ as against the experimental value $K_N = 2.7 \times 10^{-9}$. Considering the uncertainties in drawing the straight lines in Figs. 1 and 2 the agreement is satisfactory.

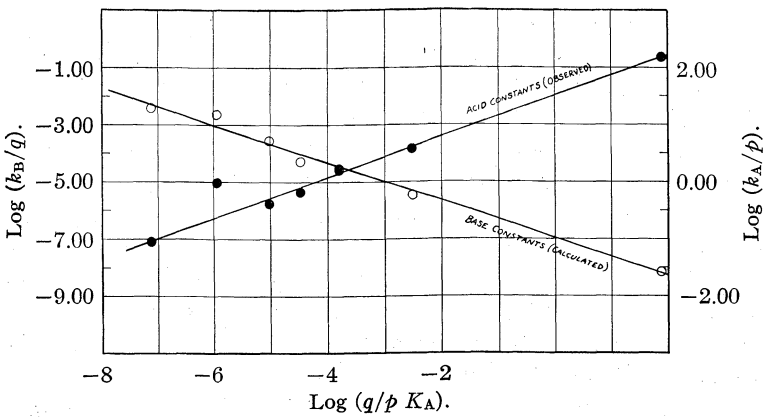

Fig. 2.—Plot of log k_B/q and log k_A/p *vs.* log (q/pK_A) for nitroethane at 0°.

Summary

1. Equations are deduced for calculating rate constants from certain kinetic and thermodynamic data.

2. These equations are applied to calculate the base rate constants for the isomerization of nitromethane and nitroethane to the aci forms.

3. Wherever comparison between calculated and observed values is possible, the agreement is good.

4. The calculated constants obey the Brönsted relation (log $k_B/q = G_B(p/qK_B)^\beta$.

5. An equation is derived relating acid strength of the substrate to the constants G_A and G_B in the Brönsted equations. The equation is shown to be valid for the cases discussed.

The Cobalt Ammine Salts of 12-Molybdophosphoric Acid

BY HAROLD A. HORAN

The recent work of Keggin and others[1] has shown that many salts of 12-molybdophosphoric acid are derived from the anion $PMo_{12}O_{40}^{-3}$. The structures of the alkali and ammonium salts have been determined and in general the composition of the anhydrous salts may be represented as $M_3PMo_{12}O_{40}$ while the hydrates have the composition $M_3PMo_{12}O_{40}\cdot 2H_2O$. Many salts of this heteropolyacid with the alkaline earth and heavier metals are known.[2] With the divalent cations the salts generally may be represented by $M_3(PMo_{12}O_{40})_2\cdot xH_2O$, while the salts involving the trivalent cations conform to the general formula $M(PMo_{12}O_{40})\cdot xH_2O$.

The complex cations of the cobaltic and chromic ammine series form characteristic precipitates with 12-molybdophosphoric acid.[3,4] The compositions of these salts have not in general been determined. By analogy to the simple cations we would expect a trivalent complex cation such as the hexammine cobaltic ion to form a salt of the type $[Co(NH_3)_6]PMo_{12}O_{40}\cdot xH_2O$. With the divalent complex cations of the pentammine series we would expect a salt such as $[Co(NH_3)_5X]_3(PMo_{12}O_{40})_2\cdot xH_2O$, where X is Cl, Br, NO_3, etc.

The precipitation of the nitratopentammine salt of 12-molybdophosphoric acid has been proposed for the gravimetric determination of phosphates[4] and as a result of a partial analysis of the salt the formula $[Co(NH_3)_5NO_3]HPMo_{12}O_{40}\cdot H_2O$[5] was suggested. This would indicate salts of the type $[Co(NH_3)_5X](HPMo_{12}O_{40})$, where X is Cl, Br, NO_3, etc. These would be acid salts of the acid, $H_3PMo_{12}O_{40}$. Acid salts of this acid involving the simple mono and divalent cations do not exist.

It is known that the pentammine cations undergo reaction in aqueous solution,[6] namely

$$Co(NH_3)_5X^{++} + H_2O = Co(NH_3)_5(H_2O)^{+++} + X^-$$

The rate and extent of this reaction depend, among other factors, on what X is. Evidence will be presented in this paper to show that due to this reaction the salts formed with the various pentammine cations and 12-molybdophosphate are all of the same composition, namely, $[Co(NH_3)_5(H_2O)]PMo_{12}O_{40}\cdot 4H_2O$. The normal or acid salts mentioned above are not formed. Probably the size of the cation involved is a determining factor in the formation of normal salts of the type, $M_3(PMo_{12}O_{40})_2$, and with large complex cations this structure cannot build up. As for acid salts there is no reason to expect these with the complex cations any more than with the simple ones.

Evidence will also be presented to show that the salt formed with the hexammine cobaltic ion may be represented as $Co(NH_3)_6(PMo_{12}O_{40})\cdot 3H_2O$. It is probable in both cases that part or all of the water of crystallization is lattice water.[7]

Experimental

Materials.—Chloropentammine, aquapentammine and hexammine cobaltic chlorides were prepared and purified by the methods of Biltz.[8] After purification, the salts were washed free of hydrochloric acid with 95% alcohol and finally with small portions of ether. The aquapentammine was air dried, while the chloropentammine and hexammine were dried in an oven, the former at 60° and the latter at 130°. The composition and purity were checked in all cases by Kjeldahl ammonia determinations, and in addition by gravimetric chloride determinations in the case of the aquapentammine and hexammine chlorides. The results were: calcd. for $[Co(NH_3)_5Cl]Cl_2$: NH_3, 34.00. Found: NH_3, 34.15. Calcd. for $[Co(NH_3)_5(H_2O)]Cl_3$: NH_3, 31.72; Cl, 39.62. Found: NH_3, 31.80; Cl, 39.69. Calcd. for $[Co(NH_3)_6]Cl_3$: NH_3, 38.20; Cl, 39.76. Found: NH_3, 38.29; Cl, 39.68.

The nitratopentammine cobaltic nitrate was prepared by the method of Jörgensen.[9] After purification, it was washed thoroughly with 95% alcohol and then with ether. It was dried in an oven at 50°. It was analyzed for ammonia and total ammonia plus nitrate, the former being done by Kjeldahl and the latter by a modified Kjeldahl method.[10] Calcd. for $[Co(NH_3)_5NO_3](NO_3)_2$:

NH_3, 25.79; NH_3 + NO_3 as N, 33.95. Found: NH_3, 25.70; N, 33.84.

Two standard phosphate solutions were employed. One was prepared and standardized by the method of Furman and State.[4] The other was prepared by weighing out a definite amount of twice recrystallized potassium dihydrogen phosphate (Merck reagent grade) which had been dried to constant weight at 100° and dissolving and making up to a definite volume. The phosphorus content of this solution was checked by double precipitation as magnesium ammonium phosphate and ignition to the pyrophosphate. These solutions will be designated as A and B, respectively. Solution A contained 0.2956 mg. of phosphorus per ml. and solution B contained 0.3196 mg. of phosphorus per ml.

Acid sodium molybdate was prepared immediately prior to use according to Furman and State,[4] using Merck reagent grade molybdic acid. This solution is approximately 1.4 molar.

The potassium permanganate solution used in the molybdenum determinations was standardized against the best obtainable sodium oxalate.

The ferric alum used in the molybdenum determinations was Merck reagent grade. A blank on this and the Jones reductor used was quite small and consistent, 0.10–0.12 ml. of 0.1 *N* potassium permanganate.

The sulfuric acid and sodium hydroxide used were the ordinary C. P. reagents.

Precipitations.—The precipitates were formed, filtered, washed and dried according to the directions of Furman and State.[4] The above-mentioned pentammines were used as precipitants. Solutions of these were prepared immediately prior to use and were approximately 0.025 molar in all cases.

The procedure follows. To the phosphate contained in a volume of approximately 8 ml. and free of nitric and hydrochloric acids but containing approximately 36 milliequivalents of sulfuric acid add 1 ml. of acid sodium molybdate solution for each milligram of phosphorus present. After heating the solution to near boiling, slowly add the pentammine solution. The rates of formation of precipitates increased in the order chloropentammine, nitratopentammine, aquapentammine. This is in agreement with known rates of conversion of the acido ions to the aquapentammine ion. Sufficient precipitant was added in all cases to color the supernatant liquid pink and then an excess of 2–3 ml. in the aqua and nitrato cases. Complete precipitation could not be obtained in the case of the chloropentammine unless an excess of 6–8 ml. of precipitant was used. In all cases the solutions were kept near the boiling point for five to ten minutes to ensure complete precipitation. Longer digestion, fifteen to twenty minutes, was found necessary in the case of the chloropentammine. The volume of solution in all cases was approximately 20 ml. After cooling to room temperature the solutions were filtered through a porous porcelain crucible. The precipitates were washed free of sulfuric acid with 0.3 *N* nitric acid and then once with a small portion of water. The crucibles and contents were washed with 95% alcohol followed by ether. Air was drawn through the crucible for five minutes. The outside of the crucible was wiped with a lintless cloth and the former was placed in an evacuated desiccator over calcium chloride. The crucibles were weighed after thirty minutes. The results of some of the precipitations with the pentammine reagents are given in Table I.

Precipitations were carried out in a similar manner using hexammine cobaltic chloride as the precipitant. This solution was made up approximately 0.025 molar. It was found necessary in these cases to double the amount of sulfuric acid present in order to prevent the precipitation of the molybdate of the ammine. A small excess, 2–3 ml., of precipitant beyond that necessary to color the supernatant liquid orange was used. Table II contains the results of precipitations with the hexammine reagent.

The theoretical weights of precipitate according to the proposed formula for the cobaltic aquapentammine molybdophosphate are given in Table I. Similar data are given in Table II for cobaltic hexammine molybdophosphate.

B	25.01	7.993	.5271	.5258
B	49.98	15.97	1.055	1.051
B	49.98	15.97	1.057	1.051

[a] The theoretical values are calculated from the amount of phosphorus taken and the formula $[Co(NH_3)_6]PMo_{12}O_{40}\cdot 3H_2O$.

Method of Analysis of Precipitates.—Samples for analysis were prepared and dried as mentioned above. Ammonia was determined by distillation from a sodium hydroxide solution into an excess of standard hydrochloric

acid, the excess being titrated with standard sodium hydroxide using methyl red as an indicator.

In the case of precipitates formed using the nitratopentammine reagent, total ammonia plus nitrate determinations were carried out using a modified Kjeldahl method.[10] This method was tested successfully on samples composed of pure potassium nitrate and the molybdophosphate precipitated with the aquapentammine reagent, the combined ammonia and nitrate value being known in these samples.

Molybdenum was determined in samples which were dissolved in a minimum of sodium hydroxide solution and warmed until all ammonia had been expelled. The cobaltic hydroxide thus formed dissolved on the addition of 10 ml. of concentrated sulfuric acid. The solution was evaporated to the fumes of sulfur trioxide and fumed for three to five minutes. This served to destroy any hydrogen peroxide, nitrate and chloride. After dilution the solution was passed through a Jones reductor and the reduced solution was caught under an excess (5-fold) of ferric alum. After the addition of a few ml. of phosphoric acid the solution was titrated with standard potassium permanganate solution. A blank was run on all reagents, including appropriate amounts of cobalt and phosphorus, and the proper correction made. This was never more than 0.12 ml. of 0.1 *N* potassium permanganate solution.

Cobalt and phosphorus determinations were not carried out since the amounts of these constituents are so small that nothing definite would be established by them. Furman and State[4] determined these constituents in the precipitate formed with the nitratopentammine reagent. Their values agree closely with the theoretical values of these constituents on the basis of the formula proposed above for the aquapentammine molybdophosphate.

The precipitates formed using the aquapentammine and chloropentammine reagents were tested qualitatively for chloride. This constituent was found in small amounts. Its presence is probably due to occlusion or post-precipitation.

Results of Analysis.—Some typical results on the precipitate formed using the aquapentammine precipitant follow.[11] Found: NH_3, 4.16, 4.18; Mo, 55.87, 55.91. For the precipitate formed using the nitratopentammine precipitant: Found: NH_3, 4.15, 4.17; Mo, 56.05, 56.15; Total $NH_3 + NO_3$, calcd. as NH_3, 4.16, 4.17. For the precipitate formed using the chloropentammine precipitant: Found: NH_3, 4.19, 4.17; Mo, 55.85, 56.03. The theoretical values according to the proposed formula for the aquapentammine molybdophosphate: calcd. for $[Co(NH_3)_5(H_2O)]PMo_{12}O_{40}\cdot 4H_2O$: NH_3, 4.14; Mo, 55.99; Total N as NH_3, 4.14.

With the precipitate formed using hexammine cobaltic chloride as the precipitant the following are some typical results. Found: NH_3, 4.96, 4.99; Mo, 56.46, 56.63. Calcd. for $[Co(NH_3)_6]PMo_{12}O_{40}\cdot 3H_2O$: NH_3, 5.02; Mo, 56.51.

(11) During the progress of the work which Professor Horan reports in the present paper, he communicated his conclusions regarding the complete aquation of the nitratopentammine salt to us, and these were confirmed by one of us (H. M. S.) and forwarded to Dr. Horan in August of 1938. Although qualitative tests for nitrate may sometimes be obtained, State's quantitative estimations made in 1938 by the Devarda alloy reduction method and subsequent distillation of ammonia gave the same value for total nitrogen as did the direct distillation of the ammonia after adding alkali alone.—[N. H. FURMAN and H. M. STATE.]

Discussion[11]

The results of precipitations and analysis of the salt formed using the nitratopentammine reagent agree closely with those of Furman and State.[4] However, these authors did not determine total ammonia and nitrate and assumed the presence of the latter. The above analysis shows definitely the absence of nitrate. The above results also show definitely that the compound formed with the different pentammine reagents is always the same.

The hexammine and aquapentammine molybdophosphates are similar in composition. The former apparently has three moles of water of crystallization per mole of the salt, while the latter apparently has four. The direct determination of water is not reliable due to decomposition of the salts at temperatures sufficiently high to drive off all of this constituent. We would expect a close similarity between the two salts due to the similar structures of the cations, $Co(NH_3)_5(H_2O)^{+++}$ and $Co(NH_3)_6^{+++}$.

The precipitation of phosphate in the form of such complex compounds is the basis of a satisfactory gravimetric determination of this constituent. Hexammine cobaltic chloride would seem to be the best precipitant. Furman and State[4] claim the nitratopentammine reagent gives the most satisfactory precipitate for analytical purposes. They mention the difficulty of filtering and washing the hexammine precipitate. This difficulty is not apparent except when dealing with very large amounts of precipitate, 1 g. or more, and in such cases the method is scarcely applicable. In view of the comparative ease of preparation and purification as well as stability of solutions, the hexammine precipitant would seem preferable to the nitratopentammine. An additional disadvantage of the nitratopentammine is its low solubility, approximately 8.5 g. per liter. This necessitates the use of large volumes of reagent in many cases, causing unnecessary dilution of the solution. The hexammine reagent easily can be made up ten times as strong as the nitrato reagent. The former has been used successfully in other gravimetric determinations.[12,13]

Conclusions

The compositions of the cobaltic pentammine and hexammine salts of 12-molybdophosphoric acid have been determined. The divalent acido cations do not directly form salts with this acid but react with water forming a trivalent ion which then reacts with the molybdophosphate.

The compositions of the cobaltic hexammine molybdophosphate and the cobaltic aquapentammine molybdophosphate are quite similar.

Suggestions have been made concerning the use of hexammine cobaltic chloride as a reagent in the quantitative determination of phosphates.

The Protium–Deuterium Ratio and the Atomic Weight of Hydrogen

BY JOHN A. SWARTOUT AND MALCOLM DOLE

On the basis of a protium–deuterium ratio in normal water[1] of 5000, the International Committee on Atomic Weights[2] recently changed the accepted atomic weight of hydrogen from 1.0078 to 1.0081; no reference to the source of this ratio, 5000, was given and the Committee apparently overlooked the work of Gabbard and Dole[3] who found 6900 and of Hall and Jones[4] who found 6500. It is the purpose of this paper to demonstrate by a new exchange reaction method the validity of the Gabbard–Dole ratio of 6900, and to point out that the chemical atomic weight of hydrogen is probably closer to 1.0080 than to 1.0081. At the same time we shall also reinvestigate the density of water made from atmospheric oxygen as compared to normal water inasmuch as the published data in the literature vary from 6.0 to 8.6γ[5] for this important constant of nature. We use methods presumably free of isotopic errors, or uncertainties inherent in electrolytic separation, in combustion, in dubious extrapolations or corrections to the data and in isotopic exchange equilibria which are functions of temperature. Furthermore, a modified float method of measuring densities sensitive to $\pm 0.1\ \gamma$ or better and improved techniques throughout increase the reliability of the final observations.

In principle the new method consists in the continued elimination of all the heavy hydrogen from normal water through repeated exchange reactions $H_2 + HOD \rightleftarrows HD + HOH$, without affecting the isotopic composition of the oxygen, until the density of the water has been reduced to a constant minimum value. From the γ-value of this water the protium–deuterium ratio in normal water can be calculated. By burning deuterium-free hydrogen in excess with oxygen of the air, the relative atomic weight of atmospheric oxygen can be calculated from the appropriate combination of the above data.

We have also measured the protium–deuterium ratio in Atlantic Ocean water in order to investigate the influence of the source of the water on this ratio.

Experimental

Preparation of Deuterium-free Water Containing Atmospheric Oxygen.—The deuterium-free water which served as a source of D-free hydrogen was prepared by the fractional electrolysis of water using the cells of Gabbard and Dole.[3] The complete elimination of deuterium was proved by combining the hydrogen from each successive electrolysis with atmospheric oxygen, the hydrogen always being in excess, and by measuring the density of the resulting water. When a minimum value of the density had been attained, the water was assumed to be D-free. Data obtained in this work are given in Table I and plotted in Fig. 1, where the rapidity with which deuterium is eliminated by electrolytic fractionation (factor equal to 5.2) is readily seen. In this plot the diameter of the circles is twice as great as the experimental error.

TABLE I

DATA FOR DENSITIES OF WATER MADE FROM HYDROGEN ON SUCCESSIVE ELECTROLYTIC FRACTIONATION AND ATMOSPHERIC OXYGEN

No. electrolytic fractionations	γ

2	−7.5
3	−8.9
4	−8.9 ± 0.1
5 (Gabbard and Dole[3])	−9.0 ± 0.3
4 (Hall and Jones[4])	−8.9 ± 0.3

(1) We define the term "normal water" in this paper as signifying purified Lake Michigan water.

(2) G. P. Baxter, O. Hönigschmid and P. LeBeau, THIS JOURNAL, **60**, 737 (1938).

(3) J. L. Gabbard and M. Dole, *ibid.*, **59**, 181 (1937). For references to earlier results see this paper.

(4) N. F. Hall and T. O. Jones, *ibid.*, **58**, 1915 (1936).

(5) γ is defined as the excess density of the water in question over that of normal water in parts per million. A negative sign for γ means that the water is lighter than normal.

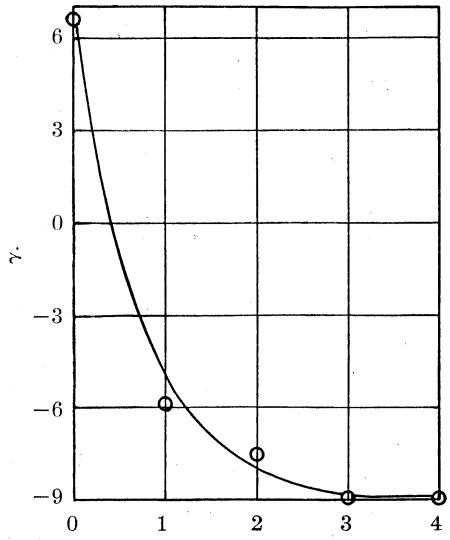

Fig. 1.—Density of water produced from the combustion of hydrogen from successive electrolyses with air oxygen.

Considering the excellent agreement between these independent measurements of the γ-value of D-free water containing atmospheric oxygen, there seems to be little reason to doubt the reliability of our final value of $-8.9\ \gamma$.

Preparation of Deuterium-free Water Containing Normal Oxygen.—In order to prepare water containing normal Lake Michigan oxygen and D-free hydrogen, the D-free hydrogen produced by five electrolytic cells operating at ten amperes current was first purified by passing over hot copper to remove all oxygen, dried over calcium chloride, then bubbled through a sample of Lake Michigan water at 85°. The mixture of water vapor and hydrogen in a ratio of 1:2 was passed through a tube, 60 × 2.8 cm., containing platinized asbestos as a catalyst, and heated to 450°. Following the isotopic exchange, the water vapor was condensed in a water condenser, followed by a carbon dioxide–acetone trap. The exchanged hydrogen was conserved by burning with air over a copper catalyst.

Since equilibrium was reached during the passage of the vapors over the platinum, it was necessary to make a number of runs with each sample in order to reduce the deuterium concentration to a negligible value. The number of repetitions necessary for this was estimated from the equilibrium constant for the reaction at 450° 0.825, which was obtained by extrapolation of the data of Jones and Sherman.[6] According to this calculation, the density of the sample should be within 0.1 p. p. m. of D-free water after seven runs.

In order to test this experimentally, an exploratory set of experiments was made, in which the density of the sample was measured after each equilibration. In these and all following experiments the D-free hydrogen was conserved by using hydrogen from the second electrolysis in the first three runs, that from the third electrolysis in the fourth and fifth runs, and that from the fourth electrolysis in all succeeding runs. The final result of this exploratory set can be given no weight because, first, a portion of the sample was lost during the density measurements; second, the temperature measurements at which floating equilibrium occurred were made with a Beckmann instead of a platinum thermometer; third, no extreme precautions were made in the purification of the samples, being distilled only from alkaline permanganate in Pyrex apparatus; and, fourth, the hydrogen in the final runs may not have been D-free, since no check was made upon it. A 150-ml. sample of normal Lake Michigan water was taken and six runs made. The data for the densities as measured after each equilibrium are collected in Table II and plotted in Fig. 2.

TABLE II

DATA FOR THE DENSITIES OF THE WATER OBTAINED IN THE EXPLORATORY TEST OF THE EXCHANGE FRACTIONATION

2	− .036	− 9.2
3	− .047	−12.0
4	− .054	−13.8
5	− .057	−14.5
6	− .057	−14.5

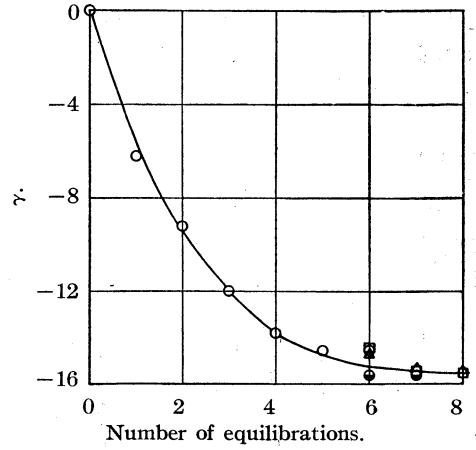

Fig. 2.—Decrease in density for each run through equilibrator: ○, exploratory expt.; □, sample 1; △, sample 2; ◒, sample 3.

Following this work three new sets of experiments were made to determine the concentration of deuterium in three samples of Lake Michigan water. One sample of 300 ml. was taken directly from Lake Michigan while one of 300 ml. and one of 100 ml. were taken from the laboratory distilled water supply. Measurements showed that the laboratory distilled water has the same density as that in the Lake within $\pm 0.1\ \gamma$. Six equilibrations were made on each sample under the same conditions as in the exploratory sample. The original sample and the condensate after each run were weighed to determine any loss of water which might have occurred. In no case was the loss greater than 0.6%. After the sixth equilibration the water was purified and the density determined by the improved method. Repeated exchange equilibrations were then made until the density of the resulting water had been reduced to a minimum value (within the experimental error).

TABLE III

DENSITY OF WATERS AFTER EQUILIBRATION WITH D-FREE HYDROGEN

Equilibration no.	γ
Sample 1	
1–6	−14.4
7	−15.4
8	−15.5
Sample 2	
1–6	−14.6
7	−15.2
8	−15.4
Sample 3	
1–6	−15.6
7	−15.6

A blank was run using nitrogen instead of hydrogen in order to make certain that no factor other than the removal of deuterium such as a possible change in the oxygen isotopic ratio caused the decrease in density. Nitrogen was passed through the apparatus in exactly the same way as was the hydrogen. Two evaporations and condensations of normal water were made, then the density was compared to that of the original water. No difference in density could be detected.

A 100-ml. sample of water taken from the Atlantic Ocean 45 miles east of Cape Ann, Massachusetts, was subjected to the same number of equilibrations as was the Lake Michigan water. Table IV gives the results of density measurements made upon this sample.

TABLE IV

DATA FOR THE DENSITY OF DEUTERIUM-FREE ATLANTIC OCEAN WATER

Equilibrations	γ
1–6	−13.6
7	−14.0
Normal ocean water	+ 1.7

From the last value of γ given in Table IV it is evident that normal ocean water is 1.7 p. p. m. heavier than normal Lake Michigan water, and that ocean water from which all deuterium has been removed is 14.0 p. p. m. lighter than normal lake water. This indicates that the difference between normal ocean water and ocean water with no deuterium is equal to: 14.0 + 1.7 = 15.7 p. p. m. Another equilibration might have been made on the ocean water, since the difference between the density of the water after equilibrations six and seven is slightly outside the experimental error, but by analogy to the other experiments seven equilibrations should have been sufficient to remove all the deuterium.

The difference in concentration of the oxygen isotopes in air can be calculated from the difference between the densities of water containing air oxygen and no deuterium (Table I) and water containing normal Lake Michigan oxygen and no deuterium (Table III). The density difference of these two waters is $-15.5 - (-8.9) = -6.6$ γ.

Purification of Water Samples and Density Measurements.—The modified density measuring apparatus employing a platinum resistance thermometer and the new purification techniques were built and worked out by Mr. R. L. Slobod in a study of the isotopic composition of oxygen in carbonate rocks. This work will be submitted shortly for publication. It is sufficient to state here that every attempt was made to reduce all errors in the relative density measurements to less than 0.1 γ; since repeated determinations usually agreed with each other within this range, we believe that our results are reliable, at least as far as the density measurements are concerned, to this small error.

Discussion

The Protium–Deuterium Ratio.—The average value for the difference between the densities of normal Lake Michigan water and water having the same oxygen isotopic content and no deuterium is given by the average of the data of Table III, or -15.5 ± 0.1 γ. From this value the H/D ratio in normal water was found making use of the recent value for the density of pure deuterium oxide recently published by Stokland, Tronstad and Ronaess,[7] 1.10764, and still more recently by Johnston,[8] 1.10763. The mole fraction of deuterium oxide was calculated with aid of the equation published by Swift[9]

$$N_{D_2O} = \frac{9.257 \times 10^{-6}\,\gamma}{1 - 3.3 \times 10^{-8}\,\gamma}$$

Since the H/D ratio is given by the ratio N_{H_2O}/N_{D_2O} (here H_2O refers to pure protium oxide) our final result is 6970/1 or in round numbers 7000 ± for the H/D ratio.

In Table V we have collected for purposes of comparison previous estimates of this ratio.

TABLE V

DENSITY DIFFERENCES BETWEEN DEUTERIUM-FREE WATER AND NORMAL WATER FROM VARIOUS INVESTIGATORS

	Source of water	γ	H/D ratio
This investigation	Lake Michigan	−15.5	6970
	Atlantic Ocean	−15.7	6880
Gabbard and Dole[3]	Lake Michigan	−15.4	7020
Hall and Jones[4]	Lake Mendota	−16.5	6550
Johnston[10]	Columbus, Ohio	−18.3	5900
Morita and Titani[11]	Osaka, Japan	−17.1	6320
Tronstad, Nordhagen,[12] and Brun	Rjukan, Norway	−18.5	5840
Tronstad and Brun[13]	Rjukan, Norway	−20.0	5400

From a study of this table it is evident that our results for both Atlantic Ocean and Lake Michigan water give a smaller amount of deuterium in water than any of the other results. Indeed our

(8) H. L. Johnston, THIS JOURNAL, **61**, 878 (1939).

(9) E. Swift, *ibid.*, **61**, 198 (1939).

(10) H. L. Johnston, *ibid.*, **57**, 484, 2737 (1935).

(11) N. Morita and T. Titani, *Bull. Chem. Soc. Japan*, **13**, 419 (1938).

(12) L. Tronstad, J. Nordhagen and J. Brun, *Nature*, **136**, 515 (1935).

(13) L. Tronstad and L. Brun, *Trans. Faraday Soc.*, **34**, 766 (1938).

method of analysis of the water is such that it should give such a minimum value; that is, we know that there is at least as much heavy hydrogen in water as we find because our chief sources of error all tend to make the H/D ratio larger. Thus if we have not eliminated all the deuterium in our preparation of D-free water by either method, if any oxygen of the air leaked into our exchange apparatus, if our D-free water became contaminated in any way with ordinary water, the density of the D-free water would be greater than it should be and the amount of deuterium found correspondingly too small. But the reduction of the density of normal water to a constant minimum value, and the fact that no water was gained or lost in the exchange experiments, seem to rule out the first two possibilities. Five cc. of ordinary water mixed with 100 cc. of our water of γ value equal to -15.5 would produce an error of 1 p. p. m., but we estimate that the amount of ordinary water gained by the light water in the course of a density determination was 0.1 cc. or less since the distilling flask, condenser, receiver, and density measurement tube were always dried out before introducing the light water. The Pyrex float was the only object covered with a film of ordinary water that came into contact with the sample under investigation.

We believe that our method, eliminating as it does all uncertainty in regard to the isotopic composition of the oxygen, yields a reliable result. Furthermore since no great difference was found by us for the H/D ratio in Lake Michigan and Atlantic Ocean water, we disagree with the conclusion of Tronstad and Brun[13] that the varying results of the different investigators indicate varying concentrations of deuterium in waters of different localities. As pointed out before by one of us[14] slight differences in density of water from various natural sources are due primarily to variations in the oxygen isotope ratios. A further indication of the reliability of our H/D ratio is given in the following paragraph.

The Relative Atomic Weight of Atmospheric and Water Oxygen.—From the data of Tables I and III it is evident that the difference in density between normal water and water made from oxygen of the air is 6.6 γ, the latter water being the heavier. In Table VI this value is given along with previous determinations by other investigators.

(14) M. Dole, *J. Chem. Phys.*, **4**, 778 (1936).

TABLE VI

DIFFERENCES IN DENSITY BETWEEN NORMAL WATER AND WATER MADE FROM ATMOSPHERIC OXYGEN AND NORMAL HYDROGEN

	γ
This investigation	6.6
Dole[15]	6.0
Greene and Voskuyl[16]	6.0
Hall and Johnston[17]	6.6
Jones and Hall[18]	6.1
Morita and Titani[19]	7.0
Smith and Matheson[20]	8.6

With the exception of Smith and Matheson's result of 8.6 γ, all the data of Table VI, although obtained by several methods, are in satisfactory agreement. The average of all the data of Table VI excluding the Smith and Matheson figure is 6.4 γ, which when added to 8.9 γ (from Table I) gives 15.3 γ for the difference in density between normal water and deuterium-free water, a value in close agreement with our experimental data of Table III. Thus the data of Table III are consistent with the data of Tables I and VI; this is an important criterion of the accuracy of the γ values from which the H/D ratio is calculated.

The atomic weight of oxygen in the air is 0.000119 atomic weight units greater than the atomic weight of oxygen in water.

The Chemical Atomic Weight of Hydrogen.—Using our new value for the H/D ratio for normal water in calculating the chemical atomic weight of hydrogen by the same method as that of the International Committee on Atomic Weights[2] we obtain 1.0080 instead of the present accepted value of 1.0081.

Note Added to Proof.—Although we had intended to reserve the detailed discussion of the experimental techniques of water purification for the forthcoming publication with Mr. R. L. Slobod, the appearance of the paper by Greene and Voskuyl [THIS JOURNAL, **61**, 1342 (1939)] prompts us to state that possibly the data of Tables I, II, III, and IV may be as much as 0.25 γ too positive because of the fact that in our distilling apparatus there may have been a greater fractionation and decrease in density of our normal water than of our D-free water. We were unsuccessful in an attempt to demonstrate this difference in the distilling properties of the two types of water, probably because the slight difference expected is about equal to our experimental error. Additional

discussion of the work of Greene and Voskuyl, which overlaps ours to a certain extent, will be given later.

Acknowledgments.—We wish to acknowledge gratefully a grant from the Alexander Dallas Bache Fund of the National Academy of Sciences which made possible the use of the platinum resistance thermometer for measuring temperature. We are also indebted to Mr. R. L. Slobod and Mr. J. L. Gabbard for experimental coöperation.

Summary

1. Water containing normal Lake Michigan oxygen and pure protium has been prepared by an exchange reaction in the gas phase: $H_2 + HOD = HD + HOH$. The density of this water has been found to be 15.5 ± 0.1 p. p. m. lighter than normal Lake Michigan water. From this the ratio of hydrogen atoms to deuterium atoms was calculated to be 6970.

2. Water containing normal Atlantic Ocean oxygen and pure protium was prepared by the same method. The difference in density between this and normal Atlantic Ocean water was found to be 15.7 ±0.2 p. p. m., corresponding to a H/D ratio of 6900.

3. Deuterium-free hydrogen was burned with atmospheric oxygen and the density of the water produced was compared with that of water containing normal Lake Michigan oxygen and pure protium. The atmospheric oxygen water was found to be 6.6 p. p. m. heavier, which corresponds to a greater atomic weight of oxygen in air of 0.000119 ± 0.000002 atomic weight units.

4. The chemical atomic weight of hydrogen as calculated from our new H/D ratio is 1.0080 instead of the value of 1.0081 recently adopted by the International Committee on Atomic Weights.

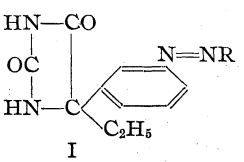
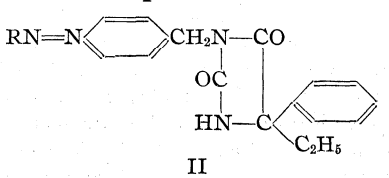
The Synthesis of Colored Derivatives of Nirvanol. II. N-Benzyl Azo Compounds[1]

BY SHIRLEY POWELL LINGO[2] WITH HENRY R. HENZE

Last year there was reported[3] an attempt to convert the soporific called Nirvanol into colored derivatives (I) possessing dyestuff properties. Since it is generally believed that the activity of soporifics is related, at least in part, to the alkyl or aryl groups present in a molecule, it follows that attachment of an azo linkage might so affect the influence of the phenyl group in Nirvanol as to reduce or completely alter its activity. Therefore it was decided to leave intact the phenyl and ethyl groups at the 5-position of the hydantoin nucleus, and to introduce the azo grouping through attachment to a benzyl group linked to the amidic nitrogen of the heterocycle (II).



I



II

In this investigation the sodium salt of Nirvanol was condensed with *p*-nitrobenzyl chloride and the product reduced catalytically to form 3-*p*-aminobenzyl-5-ethyl-5-phenylhydantoin. The latter was diazotized and coupled, in turn, with dimethylaniline, β-naphthylamine, phenol, salicylic acid, α- and β-naphthol, and 1,5-dihydroxynaphthalene, respectively, to form colored azo derivatives. From alkaline solution the dyes derived from phenol, α-naphthol and salicylic acid impart a yellow or orange color, and the 1,5-dihydroxynaphthalene derivative a purple color, to silk or wool. The β-naphthol azo compound is too insoluble in dilute alkali to serve as a dyestuff for these fibers. Likewise, the β-naphthylamine derivative is too little soluble even in concentrated hydrochloric acid to impart color, whereas the azo dyestuff derived from dimethylaniline dyes silk or wool from an acid bath a light purple which is changed to yellow by contact with alkali.

Experimental

Preparation of *p*-Nitrobenzyl Chloride.—This compound was prepared in satisfactory yield by nitration of benzyl chloride following the procedure of Alway[4]; m. p. 72.5–72.8°.

Preparation of 3-(*p*-Nitrobenzyl)-5-ethyl-5-phenylhydantoin.—A solution of sodium methylate was prepared by action of 23 g. (1 gram atom) of freshly cut sodium with 200 cc. of methanol. To this was added 204 g. (1.0 mole) of Nirvanol[3] (m. p. 198.0–198.5°) dissolved in about 1300 cc. of hot methanol, and the mixture was heated for fifteen hours to accomplish complete reaction. Then, to the clear but slightly yellow colored solution was added 171.5 g. (1.0 mole) of *p*-nitrobenzyl chloride; at first the color of the mixture turned to green, then darkened to a deep brown without turbidity. This solution was heated for seven hours; precipitation of solid material, first noticed at the end of one hour, continued during the next three hours. After standing for twenty-four hours, the solid was separated, washed free of sodium chloride, and dried. The alcoholic solution when diluted with water yielded additional reaction product as well as 9.0 g. of unchanged Nirvanol. The total yield (319 g.) of the nitro compound, of m. p. 170–170.5°, represented 98.5% of the theoretical quantity based on the Nirvanol which reacted. The product was recrystallized from ethyl alcohol and acetone, yielding broad, transparent, colorless needles of m. p. 177.0–177.5° (corr.). The nitrobenzyl derivative is insoluble in water, only slightly soluble in methyl and ethyl alcohols, and is fairly soluble in acetone.

Anal. Calcd. for $C_{18}H_{17}N_3O_4$: N, 12.38. Found: N, 12.16.

The configuration of 3-(*p*-nitrobenzyl)-5-ethyl-5-phenylhydantoin is predicated on the analogous conversion of 5-ethyl-5-phenylhydantoin into 3-methyl-5-ethyl-5-phenylhydantoin.[5]

Preparation of 3-(*p*-Aminobenzyl)-5-ethyl-5-phenylhydantoin.—From 33.9 g. of 3-(*p*-nitrobenzyl)-5-ethyl-5-phenylhydantoin (partially dissolved in 100 cc. of ethanol) was obtained 29.8 g. of the pure amine (96% yield) by reduction using hydrogen under twenty atmospheres pressure with Raney nickel as catalyst at 100°. The 3-(*p*-aminobenzyl) derivative was obtained in the form of colorless, diamond-shaped platelets by adding water to a hot alcohol–acetone solution; m. p. 171.7° (corr.).

Anal. Calcd. for $C_{18}H_{19}N_3O_2$: C, 69.88; H, 6.19; N, 13.59. Found: C, 70.07; H, 6.06; N, 13.53.

Preparation of 3-(Dimethylaniline-*p*-azobenzyl)-5-ethyl-5-phenylhydantoin.—Three and nine-hundredths grams (0.01 mole) of 3-(*p*-aminobenzyl)-5-ethyl-5-phenylhydantoin was dissolved in 100 cc. of water containing 6 cc. of concd. hydrochloric acid; this solution was cooled in ice and treated with a cold solution of 0.69 g. (0.01 mole) of sodium nitrite dissolved in the least volume of water, and the whole mixture allowed to stand for thirty minutes. Then 0.60 g. (0.01 mole) of urea was added to destroy any unreacted nitrous acid and the mixture was stirred during twenty minutes.

To this diazotized solution was added 1.21 g. (0.01 mole) of freshly distilled dimethylaniline causing a yellow color to develop. Ethyl alcohol (about 90 cc.) was added in quantity sufficient to make the solution homogeneous; the solution developed a blood-red color. The addition of about 7 g. of sodium acetate caused an orange-colored solid to separate; the mixture stood overnight.

The solid was filtered, washed with water, and dried in an oven at 105°. The dried material was a very bulky orange powder with a tendency to develop a static electrical charge; yield 4.1 g. (93%). A portion of the solid was dissolved in hot acetone, to which water was added to incipient cloudiness. Set aside to cool, shiny plates separated; filtered, and dried at 105°, 3-(dimethylaniline-*p*-azobenzyl)-5-ethyl-5-phenylhydantoin melts at 228.5–229.0° (corr.). The configuration of this dyestuff is predicated upon the normal tendency of dimethylaniline to form azo derivatives by coupling in the position para to nitrogen. Difficulty was experienced in determining nitrogen by the micro Dumas method until a minute quantity of lead dioxide was added to the sample; neither copper oxide nor potassium chlorate was satisfactory.

Anal. Calcd. for $C_{26}H_{27}N_5O_2$: C, 70.72; H, 6.16; N, 15.87. Found: C, 70.58; H, 6.07; N, 15.73.

Preparation of 3-(β-Naphthylamine-*p*-azobenzyl)-5-ethyl-5-phenylhydantoin.—A solution of 3.09 g. (0.01 mole) of 3-(*p*-aminobenzyl)-5-ethyl-5-phenylhydantoin in 80 cc. of water containing 6 cc. of concd. hydrochloric acid was cooled in ice and diazotized with 0.69 g. (0.01 mole) of sodium nitrite; after twenty minutes the excess of the nitrite was destroyed by addition of 0.60 g. of urea. The diazotized amine was coupled with 1.43 g. (0.01 mole) of β-naphthylamine dissolved in 50 cc. of ethyl alcohol; a bright red solid separated immediately but the mixture was allowed to stand overnight. The product was filtered, washed with water, dried, and then weighed 4.60 g. (99% yield).

The unpurified dyestuff in a melting point tube undergoes a darkening in color and superficial fusion at about 100°, is tarry at about 110°, and is melted with evolution of gas at about 120°. A solution of the azo derivative in glacial acetic acid was poured into ice water to yield a semi-colloidal precipitate that could be coagulated by addition of a few drops of hydrochloric acid. The melting point behavior of the material was unchanged by this treatment. The dyestuff was dissolved in glacial acetic acid, to which some concd. hydrochloric acid had been added, and was reduced by addition of zinc dust. The reduction product was recrystallized from dilute methyl alcohol and from water–acetone mixture; m. p. 170°; mixed melting point with authentic sample of 3-(*p*-aminobenzyl)-5-ethyl-5-phenylhydantoin 171°.

A portion of the original product was heated in an evaporating dish over a free flame until the solid melted to a clear dark red liquid and the evolution of gas had ceased; on cooling a glass-like solid remained. The latter was pulverized and analyzed. Another portion of this heated material was dissolved in glacial acetic acid and reduced with zinc dust and concd. hydrochloric acid. After recrystallization from water–acetone, the melting point was 169°; mixed melting point with an authentic sample of 3-(*p*-aminobenzyl)-5-ethyl-5-phenylhydantoin 170–171°. Qualitative evidence of the recovery of 1,2-diaminonaphthalene from the fusion residue was obtained.

(4) Alway, THIS JOURNAL, **24**, 1060 (1902).
(5) German Patent 611,057

Anal. Calcd. for $C_{28}H_{25}N_5O_2$: C, 72.55; H, 5.44; N, 15.15. Found: C, 72.82; H, 5.39; N, 15.21.

The structural configuration of this azo derivative is predicated upon the usual tendency of β-naphthylamine to couple in the α-position.

Preparation of 3-(Phenol-*p*-azobenzyl)-5-ethyl-5-phenylhydantoin.—This compound could be obtained by coupling the diazotized amine with a solution of phenol in sodium hydroxide and neutralizing the hydrochloric acid formed by means of sodium carbonate, but a slightly better yield of purer product was obtained by proceding similarly to the preparation of the dimethylaniline analog. Thus, 3.09 g. (0.01 mole) of 3-(*p*-aminobenzyl)-5-ethyl-5-phenylhydantoin was diazotized, the excess nitrite decomposed with urea, and to the mixture was added 0.94 g. (0.01 mole) of redistilled phenol, causing the production of a light yellow color. Seven grams of sodium acetate was added and a dull yellow solid separated, but the mixture was allowed to stand overnight before filtration. The solid was washed with water and dried at 105°; the yield was 3.73 g., representing 90% of the theoretical. The dyestuff could be crystallized from acetone–water in the form of clusters of needle-like platelets, m. p. 245–247° (corr.), with gas evolution subsequent to fusion.

Anal. Calcd. for $C_{24}H_{22}N_4O_3$: C, 69.55; H, 5.35; N, 13.52. Found: C, 69.59; H, 5.35; N, 13.46.

The structure assigned to this azo dyestuff is based upon the normal tendency of phenol to couple para to the hydroxyl group.

Preparation of 3-(α-Naphthol-*p*-azobenzyl)-5-ethyl-5-phenylhydantoin.—Diazotization of 3.09 g. (0.01 mole) of 3-(*p*-aminobenzyl)-5-ethyl-5-phenylhydantoin was carried out as usual and the solution poured into one of 1.04 g. (0.01 mole) of α-naphthol in 200 cc. of water containing 4.0 g. of sodium hydroxide. The deep-red colored solution was permitted to stand for one hour before adding a mixture of 15 cc. of concd. hydrochloric acid in 300 cc. of water, with stirring, to precipitate the azo compound. A purple-red flocculent mass was obtained by filtration, which, after washing and drying at 105°, weighed 4.36 g. (94% yield).

The dyestuff behaved as follows upon heating in a melting point tube: began to change color and to sinter at about 120°, formed a tarry sirup at about 140°, had melted sufficiently at 148° to begin a viscous flow down the side of the tube, at about 150° gas evolution began, causing pronounced expansion in volume of the mass. The solid was purified, without change in melting point behavior, by solution in benzene from which it was precipitated by petroleum ether addition. It is a brilliant red substance in finely powdered form, but is much darker in appearance in larger particles. The azo derivative is soluble in the common organic solvents, except petroleum benzine, insoluble in water, and dissolves slowly in 5% sodium hydroxide solution.

Anal. Calcd. for $C_{28}H_{24}N_4O_3$: C, 72.40; H, 5.21; N, 12.06. Found: C, 71.94; H, 5.17; N, 12.17.

The configuration assigned to this compound is based on the usual coupling behavior of α-naphthol, which is para to the hydroxyl group.

Preparation of 3-(β-Naphthol-*p*-azobenzyl)-5-ethyl-5-phenylhydantoin.—The method for preparation of this compound followed that of the phenol derivative. From 3.09 g. (0.01 mole) of the amine and 1.44 g. (0.01 mole) of β-naphthol in alcohol, 4.36 g. (94% yield) of bright red dyestuff was obtained. The product was recrystallized from diluted acetone and from ethyl acetate in the form of dark red crystals, m. p. 212–213° (corr.). Here, too, difficulty was had in analyzing for nitrogen content until a trace of potassium chlorate was incorporated with the sample.

Anal. Calcd. for $C_{28}H_{24}N_4O_3$: C, 72.40; H, 5.21; N, 12.06. Found: C, 72.54; H, 5.22; N, 11.99.

Since it is normal for β-naphthol to form azo compounds by coupling in the α-position, that structure is assigned to this derivative.

Preparation of 3-(1,5-Dihydroxynaphthalene-*p*-azobenzyl)-5-ethyl-5-phenylhydantoin.—Diazotization of 3.09 g. (0.01 mole) of the amine, dissolved in 90 cc. of water containing 7 cc. of concd. hydrochloric acid, was accomplished in the usual manner with 0.76 g. (0.011 mole) of sodium nitrite. The diazotized material was poured into an alkaline solution of 1,5-dihydroxynaphthalene (m. p. 259–260°); the latter was obtained by dissolving 1.60 g. (0.01 mole) in 200 cc. of water containing 4 g. of sodium hydroxide, an amount slightly in excess of that of the hydrochloric acid used for diazotization so that the coupling occurred in basic solution. The development of color was immediate and quite intense, yielding finally a solution so deeply red as to be nearly opaque. The azo dyestuff was precipitated by dropwise addition of the basic solution to a mixture of 300 cc. of water and 20 cc. of concd. hydrochloric acid, utilizing mechanical stirring. A flocculent precipitate resulted, which was filtered, washed, and dried at 105° to a hard, red-black cake weighing 4.85 g. (100% yield).

Attempts at purification of the product were not very satisfactory; in general, an ether solution was shaken repeatedly with water, concentrated, and diluted with petroleum ether to reprecipitate the dyestuff. After drying over calcium chloride, the solid when heated darkened at about 140°, sintered at about 148–158° forming small tarry globules, the latter began a viscous flow at about 168°, and apparently became liquid at about 194°, above which temperature gas evolution caused pronounced expansion; after many and tedious attempts to dissolve out the more soluble portions of material, incipient fusion did not occur below 194° but decomposition with evolution of gas took place at 196°. Material of this latter melting point behavior was analyzed.

Anal. Calcd. for $C_{28}H_{24}N_4O_4$: C, 69.99; H, 5.03; N, 11.66. Found: C, 69.60; H, 5.07; N, 11.51.

The structure of this azo derivative is based upon the behavior of 1,5-dihydroxynaphthalene in coupling in the 2-position in forming azo dyes such as Diamond Black PV.

Preparation of 3-(Salicylic Acid-*p*-azobenzyl)-5-ethyl-5-phenylhydantoin.—A solution was made by dissolving 3.09 g. (0.01 mole) of 3-(*p*-aminobenzyl)-5-ethyl-5-phenylhydantoin in 80 cc. of water containing 7 cc. of concd. hydrochloric acid, cooled in ice and treated with 0.76 g. (0.011 mole) of sodium nitrite dissolved in 5 cc. of cold water. After standing for thirty minutes, the solution of diazonium salt was added with stirring to 1.38 g. (0.01

mole) of salicylic acid dissolved by 4 g. of sodium hydroxide in 200 cc. of water. The azo dyestuff was precipitated by dropping its alkaline solution slowly into a solution of 20 cc. of concd. hydrochloric acid in 300 cc. of water; vigorous stirring caused the separation of a flocculent precipitate. The latter was filtered, washed, and dried *in vacuo* for twenty-four hours. The weight, 4.4 g., represents a yield of 96% of the theoretical.

The resulting dyestuff was a light tan-colored solid which developed an extreme electrical charge when reduced to an amorphous powder by grinding. It exhibited the following behavior when heated: namely, its color deepened at 80–90°, and the solid began to melt at about 110° to a gummy solid. Above this temperature there was progressive softening, and at about 125–130° the material evolved a gas causing much expansion of the mass. No definite melting point or decomposition point could be recognized.

This azo derivative could not be recrystallized from any of the common organic solvents by dilution with water, for such addition of water caused separation of a gum which would not harden subsequently. It fuses in hot water at about 80°. The dyestuff was recrystallized from tetralin, yielding yellow-orange colored microscopic crystals. The latter could be dried at 110° and melted at 133–134°, although darkening occurred at about 125°; gas evolution took place above the melting point. Analysis was made of the recrystallized azo compound.

Anal. Calcd. for $C_{25}H_{22}N_4O_5$: C, 65.49; H, 4.84; N, 12.22. Found: C, 65.88; H, 4.77; N, 12.10.

It is assumed that salicylic acid couples para to the hydroxyl group in forming this derivative in analogy to its behavior in forming Crumpsall Yellow.

Summary

1. Nirvanol has been converted into colored derivatives. The latter contain a substituted aryl-azo-benzyl grouping attached to the nitrogen in the 3-position of the heterocycle.

Sulfanilamido Derivatives of Heterocyclic Amines[1]

BY RUSSEL J. FOSBINDER AND L. A. WALTER

Since the discovery by Domagk[2] that compounds containing the sulfanilamido structure are more or less effective in combating streptococcic infections in animals, hundreds of modifications of the parent structure have been prepared and tested for anti-bacterial activity.

This paper describes sulfanilamido derivatives of the pyridine and thiazole series, some of which were prepared before the especially interesting announcement by Whitby[3] that 2-sulfanilamidopyridine was effective against pneumococcic infections.

Through the kindness of Dr. Ralph Mellon and Mr. Frank B. Cooper at Western Pennsylvania Hospital, Pittsburgh, several of the compounds were tested pharmacologically in mice to determine their anti-streptococcic and anti-pneumo-

coccic activity as compared to the action of sulfanilamide and sulfapyridine. A sulfonamidophenylazopyridine derivative also tested, is included in Table II.

The observations on chemotherapeutic efficacy are of interest and justify a detailed study of the toxicological properties of the most active compounds. The results seem to indicate that heterocyclic amino compounds, other than 2-aminopyridine, may be coupled with the sulfanilyl radical without great change in physiological activity.

Experimental

2-Aminothiazole and 2-amino-4-methylthiazole were prepared by treating thiourea with α,β-dichloroethyl ether, and with chloroacetone, respectively.[4]

The nitro and acetamino sulfonamides were prepared by treating two moles of heterocyclic amine with one mole of the required sulfonyl chloride in ethyl acetate or dioxane solution, as shown in the following preparation.

2 - *p* - Nitrobenzenesulfonamido - 6 - aminopyridine.—Twenty-one and eight-tenths grams of 2,6-diaminopyridine in 200 cc. of ethyl acetate was poured into a solution of 22.1 g. of *p*-nitrobenzenesulfonyl chloride in 75 cc. of ethyl acetate. The solution was kept in cold water for several hours with an occasional shaking and then let stand overnight at room temperature. The solvent was distilled on a steam-bath and the oily residue shaken with 200 cc. of cold water until it crystallized. The product was filtered off and recrystallized from alcohol with the use of a little decolorizing charcoal. The yield was 22 g. It was soluble in dilute alkalies.

2 - Sulfanilamido - 6 - aminopyridine. 1.—Twenty-two grams of the above nitro compound was stirred with 200 cc. of 10% hydrochloric acid and an excess of finely divided tin. The mixture was kept at 50° for half an hour, filtered while still warm and diluted with water. The tin salts were precipitated with hydrogen sulfide and the filtered solution neutralized with sodium bicarbonate to precipitate the sulfanilamide. The crude material was recrystallized from alcohol, yield 15.5 g. (80%). It was soluble in dilute acids and dilute alkali.

2.—Attempts to hydrolyze the acetyl group from 2-N^4-acetylsulfanilamido-6-aminopyridine by refluxing with 10% hydrochloric acid gave chiefly sulfanilic acid. The acetyl group was removed with practically quantitative yields of the desired sulfanilamide by refluxing with ten times its weight of 5–10% sodium hydroxide for forty-five minutes.

Sulfanilamidothiazoles.—Reduction of 2-*p*-nitrobenzenesulfanilamido-4-methylthiazole with tin and hydrochloric acid as described for the pyridine compound gave only 30% of 2-sulfanilamido-4-methylthiazole.

The acetyl group was hydrolyzed from the 2-N^4-acetylsulfanilamidothiazole by refluxing with ten times its weight of 10% hydrochloric acid for half an hour. The yield of 2-sulfanilamidothiazole was about 70%. Longer refluxing gave a much lower yield. The 2-sulfanilamido-4-methylthiazole was also prepared in this manner. The sulfanilamidothiazoles were soluble in dilute acids and dilute alkali.

Summary

Some 2-sulfanilamido thiazoles and pyridines have been prepared and their chemotherapeutic activity against experimental streptococcic and pneumococcic infections in mice has been determined.

Several of the compounds appear to possess anti-streptococcic and anti-pneumococcic efficacy comparable to sulfanilamide and sulfapyridine, respectively.

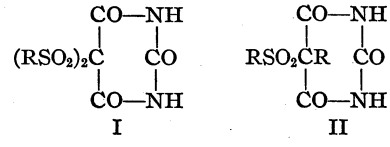
5-Sulfonylbarbituric Acids[1]

BY EDMOND L. D'OUVILLE,[2] FREDERICK J. MYERS AND RALPH CONNOR

α-Sulfonylamides[3] were effective enough as hypnotics to encourage a continued investigation of compounds containing the sulfone group combined with other groups that are present in some of the common hypnotics. Attention was naturally directed toward the synthesis of 5,5-disulfonyl (I) and 5-alkyl-5-sulfonyl (II) derivatives of barbituric acid.



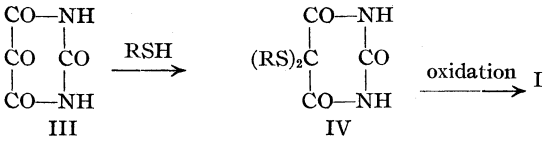
I II

The reactivity of the carbonyl group in alloxan (III) suggested that it might react with thiol compounds to give mercaptols (IV) which could be oxidized to the desired products (I).

(1) A portion of the communication is abstracted from a thesis submitted by Edmond L. d'Ouville in partial fulfilment of the requirements for the degree of Doctor of Philosophy at the University of Pennsylvania in June, 1937.

(2) Chemical Foundation Fellow.

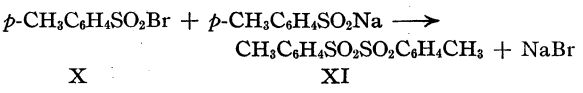
(3) d'Ouville and Connor, THIS JOURNAL, **60**, 33 (1938).



III IV I

With benzyl mercaptan in dry dioxane and using dry hydrogen chloride as a catalyst the product was the hemi-mercaptol, 5-hydroxy-5-(benzylthio)-barbituric acid (V); in glacial acetic acid–acetic anhydride solution 5-acetoxy-5-(benzylthio)-barbituric acid (VI), the acetylation product of V, was formed. Under the conditions tried it was not possible to carry the reaction further to the mercaptol stage. In addition to V, dibenzyl disulfide (VII) was produced; this must involve the reduction of alloxan, presumably to dialuric acid, although the reduction product was not isolated. With *p*-thiocresol in dioxane or glacial acetic acid as solvent and anhydrous hydrogen chloride, sulfuric acid or zinc chloride as catalysts, no condensation with alloxan occurred.

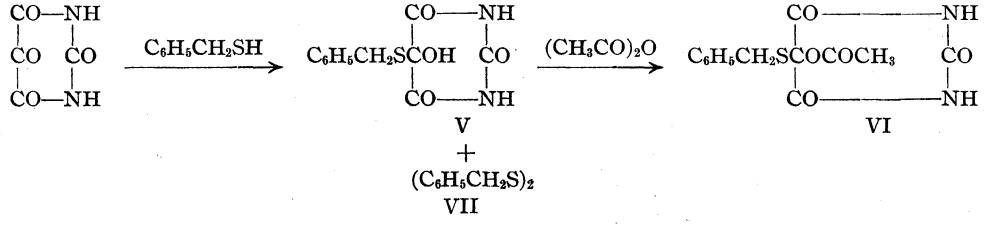
While X was not isolated, di-*p*-tolylsulfone (XI) was obtained; this is evidence for the formation of X since disulfones are readily formed[4] by the reaction of sulfonyl halides with the salts of sulfinic acids. Attempts to avoid the oxidation–re-



X XI

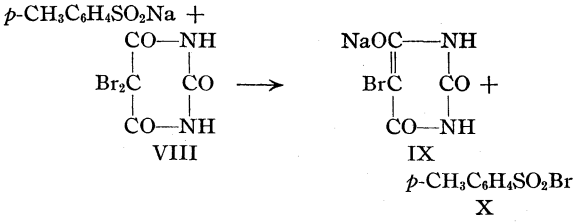
duction reactions in the preparation of disulfonylbarbituric acids were abandoned when the monosulfonyl derivatives (II) had been prepared and found to have properties which indicate that I would probably be very unstable and of no hypnotic value.

5-Ethyl-5-*p*-tolylsulfonylbarbituric acid (XII) and 5-ethyl-5-*p*-tolylsulfonyl-2-thiobarbituric acid (XIII) were prepared by the reaction of sodium *p*-toluenesulfinate with 5-ethyl-5-bromobarbituric acid and with 5-ethyl-5-bromo-2-thiobarbituric acid. Better yields of the metathesis



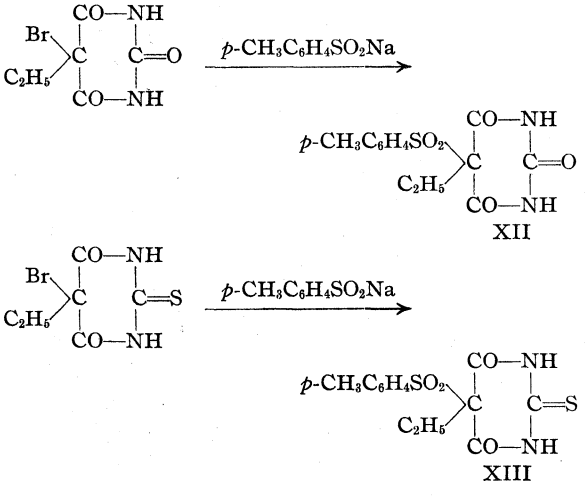
V + $(C_6H_5CH_2S)_2$ VII VI

A second possible synthesis of the disulfonylbarbituric acids was the reaction of 5,5-dibromobarbituric acid (VIII) with salts of sulfinic acid. With sodium *p*-toluenesulfinate a reaction occurred very readily at room temperature but none of the desired product (I, R = *p*-$CH_3C_6H_4$–) was obtained. The reaction appeared to be quite complex and the physical properties of the products made their separation and purification very difficult. The product isolated in the largest amount was the sodium salt of 5-bromobarbituric acid (IX), which was isolated in an amount corresponding to about 40% of the theoretical. The reduction of the dibromobarbituric acid implies that the first step in the reaction is the formation of IX and *p*-toluenesulfonyl bromide (X).



VIII IX X

products were obtained when the reactions were carried out without heating; for example, the yield of XII was 20% at 25° as compared with



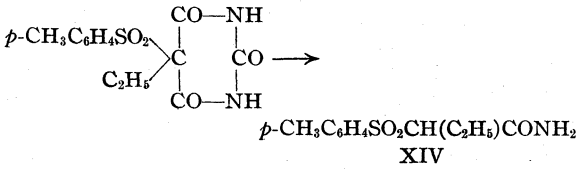
XII XIII

8% at 64°. This influence of temperature has been reported previously[3] and undoubtedly is due to the fact that higher temperatures favor the oxidation–reduction reaction. In the prepara-

(4) Kohler and MacDonald, *Am. Chem. J.*, **22**, 222 (1899).

tion of XII a by-product was the disulfone XI, showing that oxidation–reduction does occur.[5]

The yield of sulfonyl barbituric acid isolated was by no means a true gage of the amount of metathesis. A portion of the metathesis product underwent cleavage to give α-*p*-tolylsulfonyl-*n*-butyramide (XIV).



p-$CH_3C_6H_4SO_2CH(C_2H_5)CONH_2$

XIV

This cleavage of 5-sulfonylbarbituric acids is not surprising in view of other indications that the introduction of a sulfone group into active methylene compounds gives a structure labile to alcoholysis.[7]

It also appears likely that the acidity of the barbituric acids introduces a third complication in these reactions by liberating some of the sulfinic acid from its salt.

The 5-sulfonyl derivatives of the barbituric acids studied were relatively unstable. They dissolved readily in sodium carbonate solution but were slowly converted, even by water alone, to the cleavage product XIV. This, combined with the analytical data, establishes the structures of the products. Of the barbituric acids prepared, XII was the more stable and when pure could be stored satisfactorily in the dark; XIII could not be kept and its melting point was lowered over 35° by standing for three weeks. Preliminary pharmacological tests on XII, carried out through the kindness of Dr. Robert S. Shelton of the Wm. S. Merrell Company, indicated that it was without value as a hypnotic. Because of this report and the instability of the compounds, no further representatives of the series were prepared.

Experimental Part[8]

5-Hydroxy-5-(benzylthio)-barbituric Acid (V).—A mixture of 16 g. (0.1 mole) of alloxan monohydrate, 23 g. (0.19 mole) of benzyl mercaptan and 200 ml. of dioxane was cooled in an ice–salt bath and saturated with dry hydrogen chloride. After standing in the ice–salt bath overnight, the solution was resaturated with hydrogen chloride. White needles began to separate. After two days the solid (22 g., m. p. 135–140 dec.) was removed by filtration and recrystallized successively from alcohol and benzene. The purified product weighed 12.2 g. (46%), m. p. 169–174° dec. It turned deep red if allowed to stand in contact with air.

Anal. Calcd. for $C_{11}H_{10}O_4N_2S$: N, 10.54; S, 11.97. Found: N, 10.51, 10.81; S, 11.88.

Dilution of the mother liquor with water gave 5 g. of dibenzyl disulfide which after one recrystallization from alcohol melted at 70°.

5-Acetoxy-5-(benzylthio)-barbituric Acid (VI).—A mixture of 32 g. (0.2 mole) of alloxan monohydrate, 50 g. (0.4 mole) of benzyl mercaptan, 100 ml. of glacial acetic acid and 40 ml. of acetic anhydride was cooled in an ice–salt mixture and saturated with dry hydrogen chloride. The reaction mixture was kept at 0° for twelve hours and at room temperature for an additional twelve hours; the solid was removed by filtration and washed successively with water, alcohol and ether. The combined washings and mother liquor were diluted to 1.5 liter with water, filtered and the semi-solid residue washed with dilute alcohol. The combined solids weighed 19 g., m. p. 90–100°. Three recrystallizations from alcohol gave 5 g. (9.5%) of a white crystalline solid which turned pink at 190°, later became orange and finally melted with decomposition between 210° and 235°. Dilution of the mother liquors from the recrystallizations gave 4.5 g. of what appeared to be the same product in a less pure state.

Anal. Calcd. for $C_{13}H_{12}O_5N_2S$: N, 9.09; S, 10.39. Found: N, 9.17, 9.34, 9.33; S, 10.25.

Attempted Condensation of *p*-Thiocresol with Alloxan.—Using both glacial acetic acid and dioxane as solvents, reactions were carried out with alloxan hydrate and *p*-thiocresol under conditions similar to those described above. Dioxane was used as a solvent with sulfuric acid and zinc chloride, both alone and together, as catalysts in the cold and at 100°. In all cases no reaction product was isolated and unreacted *p*-thiocresol was obtained.

5,5-Dibromobarbituric Acid with Sodium *p*-Toluenesulfinate.—A suspension of 14.3 g. (0.05 mole) of 5,5-dibromobarbituric acid[9] and 21.4 g. (0.10 mole) sodium *p*-toluenesulfinate dihydrate[10] in 200 ml. of absolute methanol was allowed to stand at room temperature for four days. The crystalline solid (0.8 g.) was removed by filtration and recrystallized from benzene. The purified material became discolored at 200° and melted with decomposition at 207°. An authentic sample of di-*p*-tolyldisulfone[4] behaved similarly, both alone and when mixed with the reaction product.

The methanol filtrate was allowed to stand for seven days at room temperature and the solid that appeared removed by filtration. There was obtained 4.3 g. (38%) of the sodium salt of monobromobarbituric acid. Heating with 40% sulfuric acid solution gave 5-bromobarbituric acid, m. p. 200° (dec.), which was identified by a mixed

(5) Other investigators[6] have reported the formation of sodium benzenesulfonate and the unhalogenated active methylene compound when sodium benzenesulfinate was allowed to react with ethyl α-chloroacetoacetate, ethyl chloromalonate and diacetylchloromethane.

melting point with an authentic sample[11] and by conversion with 1:1 hydrochloric acid[9] to 5-chlorobarbituric acid, m. p. 273° (dec.). The latter gave no depression of the melting point when mixed with a sample of 5-chlorobarbituric acid prepared in a similar manner from 5-bromobarbituric acid.

The filtrate obtained after removal of sodium bromobarbiturate gave additional solid material but it appeared to be a mixture that could not be separated. The presence of an additional quantity of sodium bromobarbiturate was shown by the formation of 5-chlorobarbituric acid when a sample of the solid was heated with 1:1 hydrochloric acid.

5-*p*-Tolylsulfonyl-5-ethylbarbituric Acid (XII).—A mixture of 21 g. (0.10 mole) of sodium *p*-toluenesulfinate dihydrate and 20 g. (0.085 mole) of 5-bromo-5-ethylbarbituric acid[12] in 250 ml. of absolute methanol was allowed to stand for eight days at room temperature. The solvent was then removed by evaporation, the residue washed with ether and the solid remaining treated with dilute sodium hydroxide solution. Recrystallization of the alkali-insoluble material from alcohol gave α-*p*-tolylsulfonyl-*n*-butyramide (XIV).[3] Acidification of the alkaline solution with concentrated hydrochloric acid gave a bulky white precipitate which was filtered, dried and recrystallized from alcohol. The yield of pure XII was 5.5 g. (20%), m. p. 200.5–203.5° (dec.).

Anal. Calcd. for $C_{13}H_{14}O_5N_2S$: mol. wt., 310; N, 9.03; S, 10.32. Found: mol. wt., 316, 312; N, 9.08, 9.24; S, 10.25, 10.50.

After the removal of XII, evaporation of the acidic solution gave 12 g. of solid. The material was extremely soluble in water and on ignition charred and gave an alkaline ash. A small portion was refluxed with thionyl chloride[13] but the product was impure, m. p. 58–61°. With *p*-toluenesulfonyl chloride (m. p. 69°) the mixed melting point was 67°.

In another experiment the solid precipitated in the reaction mixture was separated by filtration, washed with water, dried and recrystallized from benzene. The product weighed 2.3 g. (18%), m. p. 204–208° (dec.), and was identified as di-*p*-tolyldisulfone by a mixed melting point.

5-*p*-Tolylsulfonyl-5-ethyl-2-thiobarbituric Acid (XIII).—Twenty-eight grams (0.13 mole) of sodium *p*-toluenesulfinate dihydrate was added to 250 ml. of absolute methanol, the mixture cooled to 5° and 25.6 g. (0.1 mole) of 5-bromo-5-ethyl-2-thiobarbituric acid[14] added. The solution was stirred vigorously and kept below 5° for one and one-half hours. The solution was allowed to come to room temperature and stand for eight days. It was then poured over ice, filtered and the solid washed with water. The product was almost entirely soluble in sodium carbonate solution. This solution was filtered, acidified with concentrated hydrochloric acid and the product recrystallized from dilute alcohol. The yield of pure XIII was 6.5 g. (20%), m. p. 179.9–180°. The product decomposed on standing three weeks, m. p. 141–145°.

Anal. Calcd. for $C_{13}H_{14}O_4N_2S_2$: mol. wt., 326; N, 8.59. Found: mol. wt., 320; N, 8.75, 8.77.

Summary

Attempts to synthesize 5,5-disulfonyl derivatives of barbituric acid were unsuccessful. *p*-Thiocresol did not react with alloxan while benzyl mercaptan gave 5-hydroxy-5-(benzylthio)-barbituric acid in dioxane as a solvent and 5-acetoxy-5-(benzylthio)-barbituric acid in acetic acid–acetic anhydride. Sodium *p*-toluenesulfinate with 5,5-dibromobarbituric acid gave sodium 5-bromobarbiturate, accompanied by oxidation products of the sulfinate.

The reaction at room temperature of sodium *p*-toluenesulfinate with 5-ethyl-5-bromobarbituric acid and with 5-ethyl-5-bromo-2-thiobarbituric acid gave 5-*p*-tolylsulfonyl-5-ethylbarbituric acid and 5-*p*-tolylsulfonyl-5-ethyl-2-thiobarbituric acid. The by-products show that the yields of metathesis products are lowered by oxidation–reduction reactions and by the ease of alcoholysis of the product.

Composition of Cottonseeds. I. Solubility of Nitrogenous Constituents

BY H. S. OLCOTT AND T. D. FONTAINE

Approximately 3,000,000 tons of cottonseeds are produced annually in the United States. At present, after removal of the hulls, the oil is recovered by pressing and the residual meal is used as a source of protein in stock foods. Depending upon the source of the seed and the efficiency of the pressing operation, the protein content of the meal varies from 45 to 55%. Commercial cottonseed meal is adjusted with hull bran to a protein content of 41% .

Inasmuch as proteins are becoming increasingly important as industrial raw materials, it appeared of interest to investigate the possibility of isolating and utilizing the proteins of the cottonseed. The work to be described is part of a general research program along these lines and deals particularly with the efficiency of extraction by aqueous solutions of salts, acids, and alkalies.

The proteins of the cottonseed were first investigated by Osborne and Vorhees.[1] Jones and Csonka[2] subsequently separated and characterized several of the fractions. There has been, however, no detailed study of their solubility behavior.

Experimental

In the procedure used for obtaining cottonseed oil commercially, the meats are first rolled, then cooked for twenty to forty minutes in an atmosphere of steam. After removal of the oil by pressing, the cake is broken and ground. The resultant cottonseed meal of commerce is not suitable for the preparation of protein. The yields are low because of denaturation of the protein by the heat treatment, and the product is dark, the color resulting from a combination of the pigments with the protein. For these reasons, most of the observations recorded refer to cottonseed meal from which the oil was removed by solvent extraction and which was never exposed to a temperature higher than 50°.

Whole cottonseed meats[3] were ground in a burr mill to 16-mesh-size particles, and extracted with ethyl ether in a large continuous extractor of the Soxhlet type for thirty-six to seventy-two hours. Approximately 10 kg. of ground meats could be accommodated in one extraction. The extraction chamber was fitted with a copper coil through which, at the end of the extraction period, warm water (45–50°) was passed to evaporate most of the entrained ether. The residual meal was air-dried, reground in the burr mill, and sieved through a 60-mesh screen to remove most of the hull particles with which the meats were originally contaminated.

One large sample of the light yellow meal so obtained was used for all the determinations. The following analytical data were obtained by the usual methods.

Constituent	Percentage
Water	9.0
Nitrogen	8.6
Lipids	0.5 (ether extraction)
Lipids	2.0 (chloroform extraction)
Ash	7.5

Five-gram portions of the meal were weighed into 8-ounce (240 cc.) centrifuge bottles. Because the meal is difficult to wet, it was stirred up thoroughly with 10 to 20 cc. of the extracting solution. The remainder (total, 200 cc.) was then added, the bottles were shaken thoroughly, and allowed to stand at room temperatures (23 to 28°).

As shown in Table I, continued agitation was unnecessary for complete extraction, and three hours was sufficient time to establish equilibrium. In some series of runs the meal suspensions were allowed to stand for twenty-four hours. The differences between these results and those obtained with the shorter experimental periods were within the limits of error.

In order to determine the amounts of nitrogenous compounds dissolved or peptized, the bottles were centrifuged and aliquots of the supernatant solutions were filtered and analyzed for nitrogen by a semimicro modification of the Kjeldahl–Gunning method (5–20 mg. nitrogen). The results, corrected to 200 cc., are expressed in terms of percentage of total nitrogen.

Table I also illustrates the effect of temperature on the efficiency of extraction by water and by 0.5 normal sodium chloride solution. The differences between the amounts

extracted at 25 and at 50° were sufficiently small to indicate that attempts to carry out the extractions at constant temperature were unnecessary.

An unaccountable variation in the results of different runs prevents the assignment of absolute accuracy within 3 to 5%. However, the duplicability of determinations in a single run was well within 1%. Thus, although the amounts of nitrogen extracted by 0.5 normal solutions of sodium sulfate and sodium sulfite do not differ by more than 0.3%, in the several runs in which they were compared directly, they were invariably efficient in the same order. For this reason, the data in each series of determinations except those of Table II) are those of a single representative run.

A portable glass electrode was used for the determination of *p*H. In the *p*H range above 9, a correction has been applied to the reading, depending upon the concentration of salt present.

Results and Discussion

The principal protein in cottonseed is a globulin. In the experiments of Jones and Csonka,[2] 84.6% of the nitrogen of cottonseed meal was soluble in 10% sodium chloride solution, and an additional 10.3% could be extracted by alkali. The non-protein nitrogen in their extracts amounted to 10.1% of the total. In the present investigation, it was found that 25 to 30% of the nitrogen was extractable with water and that, of this, a large part was present in the form of a hitherto undescribed protein. This fraction has been isolated and will be described in a later publication.

In the discussion which follows, it has been assumed that the water-soluble protein and non-protein nitrogen fractions are soluble in most of the solutions used, and that the variations in amount of nitrogen extracted may be interpreted in terms of the behavior of the globulin and glutelin fractions.

The peptizing activity of a number of inorganic salts is outlined in Table II. In the majority of cases 0.5 normal solutions extracted practically as much nitrogen as could be extracted by higher concentrations. The lyotropic series effect is less marked than that noted by Gortner and his co-workers[4] in the extraction of the proteins from wheat flour.

Sodium and potassium fluorides extracted smaller amounts of protein than did the other neutral salts. The relatively high yields obtained with calcium and magnesium halides as compared with those extracted by sodium dihydrogen phosphate suggest that, at least within a limited range, *p*H is not an important factor in salt peptization. On the alkaline side of neutrality, disodium phosphate and sodium bicarbonate were no more effective extractants than the neutral salts.

In Table III, the effect of concentration on the peptizing activity of sodium chloride and sodium sulfite is outlined in greater detail. The denaturation of cottonseed proteins which have been subjected to the cooking process is shown in the decreased yields from commercial meal.

4.0	76.6	..	..
5.0	73.2	38.1	..

Figure 1 illustrates the data outlined in Table IV concerning the solubility of cottonseed proteins in acid and alkali solutions. The results with ether-extracted meal are compared with those obtained in the presence of 0.5 normal sodium chloride solution, with commercial cottonseed meal, and with the behavior of soybean meal as demonstrated by Smith and Circle.[5] The cottonseed proteins differ from those of the soybean in being less soluble in water; the isoelectric range of the most abundant protein is 1.5 to 2 *p*H units higher than that of the soybean protein.

In the presence of 0.5 normal sodium chloride, the amount of protein extracted is constant throughout most of the alkaline range. Only above *p*H 11.0 does the curve rise slightly. Apparently, in the presence of salt, the solubility of the glutelin fraction is depressed. The effect of salt in depressing the *p*H of cottonseed protein solutions, especially in the alkaline range, is marked. The phenomenon also has been noted in experiments with soybean.[5,6]

At least one variable responsible for the difficulty in checking results has been traced to the effect of time on the nitrogenous constituents of cottonseed meal. Over a period of weeks and months, successive runs have demonstrated a gradual slight increase in solubility. The increase could not be correlated with changes in moisture content. A more detailed investigation of these changes is in progress. With soybean, the solubility of the proteins decreases on standing.[5,7]

The Pressure–Area and Pressure–Temperature Relations of Expanded Monolayers of Myristic and Pentadecylic Acids

BY GEORGE C. NUTTING AND WILLIAM D. HARKINS

1. Introduction

At 25° when spread on water which contains 0.01 *N* hydrogen ion, margaric ($C_{16}H_{33}COOH$) and higher saturated fatty acids form films which condense rather abruptly at pressures of about 0.5 dyne per cm. to slightly viscous, slightly compressible liquids whose area per molecule extrapolated to zero pressure varies only from about 23 to 24.5 sq. Å.

Lower members, specifically myristic and pentadecylic acids, exhibit a widely different behavior on compression. The limiting area at zero pressure is 46 sq. Å. per molecule. The compressibility is high and the pressure–area plots instead of being linear have a marked concave curvature upward. At a pressure characteristic of the particular acid a break occurs in the pressure–area curve such that the decrement of area per unit increase in pressure increases greatly; that is, the compressibility becomes very high. The curve above the break passes finally into a form characteristic of condensed films. A film which acts in this way is designated below the kink as an expanded film, and above it, until the area per molecule is about 23 sq. Å., as a transition or intermediate film.

The higher fatty acids give similar expanded and intermediate films at higher temperatures. The existence of the expanded state was recognized and investigated by Labrouste[1] and films of this type have been investigated in great detail by Adam and others.[2]

2. Apparatus and Materials

Pressure–area measurements were made with a film balance closely similar to one described by Harkins and Myers.[3] Subsolutions were contained in a shallow trough of stainless steel equipped with a false bottom through which water from a large reservoir was circulated. The trough and film balance were contained in a metal box with a front of plate glass. The top of this box was hollow, and water from the same thermostat was circulated through it in order to keep the temperature the same as that of the trough. This box was surrounded by an air thermostat kept as closely as possible at the temperature of the inner box. Thermocouples were installed just above and just below the film and when the air and the subsolution temperatures were equal it was assumed that the film also was at the same temperature.

In all of the experiments the films were spread on 0.01 *N* sulfuric acid prepared from water redistilled from alkaline permanganate and condensed in tin.

The myristic and pentadecylic acids were generously provided by Professor E. E. Reid of the Johns Hopkins University. The preparation and purification of the acids has been described by Reid and Meyer.[4] The acids were dissolved in purified ligroin (b. p. 60–70°) and spread from a precision pipet devised by Harkins and Anderson.[5] After spreading, a period of from fifteen to forty-five minutes was allowed before compression, during which it was assumed that any micro-crystals present would spread into a monolayer.

3. Pressure–Area Measurements

The pressure–area relations of myristic acid at seven temperatures from 6.7 to 25° are exhibited in Fig. 1 and Table I. So far as is possible, all experimental points are included, except that in the area interval 26–33 sq. Å. of Curve 4 and in a few other places, one-half the points have been omitted in order to avoid too great crowding. The time interval between adjacent points was never less than one minute, and except at the highest temperatures was commonly two to five minutes in the intermediate region. Area decrements also were not uniform but their magnitude may be judged from the curves.

It will be shown later that the rate of compression has a marked influence upon the pressure of

the intermediate film at any given temperature and molecular area. In the work of Adam and Jessop[6] the rate seems to have been much higher than that used in the present work. In the two investigations the pressures found for the transition Expanded → Intermediate film, are in good agreement, but our molecular areas for the transitions are about 10% lower than theirs. The total time (t) of a compression from the highest to the lowest area varied in our work from 39 minutes at 21.7° to 293 minutes at 9.5°.

The shape of Curve 7 in Fig. 1 is distorted by a spurious effect which causes it to be displaced toward lower areas, and decreases the pressure at the highest pressures. This is due to the solubility of the myristic acid which at 25° removes a part of the material from the film. Since the solubility increases with increase of film pressure as well as temperature the slope of the curve in the intermediate region is much too small.

4. The Rate of Compression

In order to determine the effect of the rate of compression on the form and position of pressure–area curves of expanded and intermediate films a series of experiments was carried out with both pentadecylic and myristic acids at several temperatures. The results are shown in Figs. 2, 3, 4, and 5, and in Tables I and II.

Comparing first the two acids, there is remarkable similarity between the curves for pentadecylic and those for myristic acid at a temperature

	15	1.05	46.1	32.8	8.3	7

11° lower. The principal difference is in the extent of minor irregularities in the intermediate region.

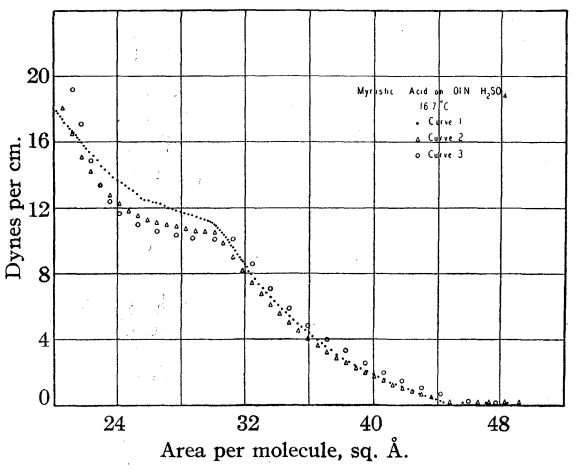

Fig. 2.—Effect of rate of compression on pressure–area relations of myristic acid films. Time of compression from limiting area at zero pressure to 20 dynes per cm.: Curve 1, 159 min.; Curve 2, 22 min.; Curve 3, 6 min.

The general rule is that a decrease in the rate of compression of an intermediate film causes: (1) an increase of molecular area at a given pressure; or (2) an increase of pressure at a given molecular area.

In Fig. 3 this effect is masked in the case of myristic acid by its relatively high solubility at 25° (Curves 1 and 2).

Results in reasonable accord with those reported in this paper for rapid compression have been obtained for myristic acid on 0.002 *N* hydrochloric acid by Dervichian,[7] who used the Wilhelmy method for measuring film pressures. The film was compressed at a very high, constant rate by a motor drive so that the total time of an experiment amounted to only about two or three minutes.

(7) D. G. Dervichian, Thesis, Paris, 1936.

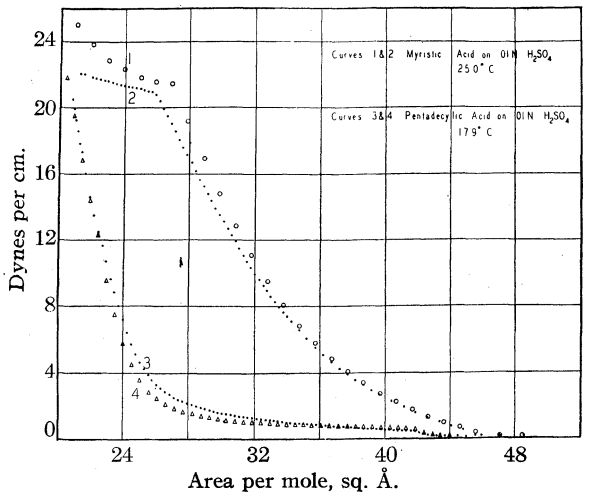

Fig. 3.—Effect of rate of compression on pressure–area relations of myristic and pentadecylic acids. Time of compression: Curve 1, 7.5 min.; Curve 2, 77 min.; Curve 3, 44 min.; Curve 4, 11 min. Curve 2 is depressed below Curve 1 by the solubility of myristic acid at 25°, so these two curves do not give the proper relations due to the effect of time on the film itself.

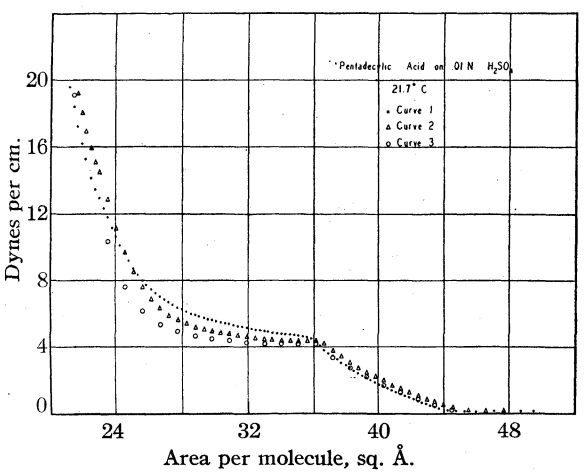

Fig. 4.—Pressure–area relations of pentadecylic acid at 21.7° at different rates of compression. Time elapsed between limiting area at zero pressure and 20 dynes per cm.: Curve 1, 44 min.; Curve 2, 12 min.; Curve 3, 5.5 min.

5. Pressure–Temperature Measurements

Pressure–temperature measurements have been made on monolayers of myristic acid spread on 0.01 *N* sulfuric acid at four molecular areas and on pentadecylic acid films at three molecular areas. Before beginning an experiment the apparatus and subsolution were cooled to the lowest

temperature desired (2° for myristic, 5° for pentadecylic acid), the surface of the subsolution was cleaned thoroughly and the acid was spread from ligroin solution. The area available per molecule at the time of spreading was always considerably greater than the area at which the measurements were to be made. A period of thirty to fifty minutes intervened between spreading and commencement of the slow compression to the selected molecular area. As soon as the temperature above and below the film differed by only a few hundredths of a degree, determinations of the pressure were begun. Several measurements were made at each temperature and the mean value is reported. The temperature interval was not uniform, amounting to 0.2 to 0.3° at the lowest temperatures and about 0.1° near the transition temperature. Temperatures were read to 0.01°. The experiments were performed slowly, and at such a rate that a period of from four to six hours was used in each experiment.

Each curve in Fig. 6 represents the change with temperature of the pressure of a monolayer of either myristic or pentadecylic acid (Table IV) at a definite, constant molecular area, *e. g.*, 33.2 sq. Å. for myristic acid. At the lowest temperature the pressure is also low for any area investigated, and remains constant to ±0.03 dyne per cm., so the f–T relation is given by a line which is almost horizontal, and represents a film of two dimensional vapor and the islands of aggregated molecules with which it is in equilibrium. At 6.5° the myristic acid film begins to exhibit a rapid rise of pressure with temperature, and a value of $(\partial p/\partial T)_a$ of 0.81. The film is here of the intermediate type. The similar change for pentadecylic acid occurs at 17° and the slope is 1.21 for a = 31.3 sq. Å.

This discontinuity between the pressure of the vapor and that of the intermediate film is in all cases rather sharp and for the three pentadecylic acid films is localized in a small temperature interval near 17.2°. The corresponding discontinuity in myristic acid occurs at a temperature about 11° lower.

Any one of the curves which represents an intermediate film approximates a straight line so closely that the derivative of the slope with respect to temperature may be taken as zero. In the curves of Fig. 6, especially those for smaller areas, departures from linearity are evident, but they are as much in one direction as another and the maximum deviation of the experimental points from the best straight line is of the order of 0.05 dyne per cm.

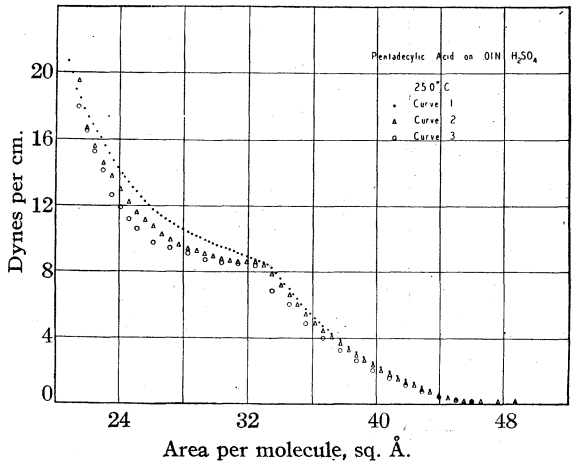

Fig. 5.—Pressure–area relations of pentadecylic acid at 25.0°. Time of compression from limiting area to 20 dynes: Curve 1, 79 min.; Curve 2, 14 min.; Curve 3, 7 min.

The transition Intermediate → Expanded film occurs at a higher temperature and pressure, and seems in some instances to extend over a range of the order of a degree of temperature and a dyne of pressure, but this is dependent upon the rate at which the temperature is increased.

The slope varies from about 0.8 to 1.2 for the intermediate films, but is very much smaller, 0.15 to 0.2, for the expanded films. The f, T relation appears to be linear near the transition region to 0.01 or 0.02 dyne per cm. except where the slope is caused to decrease by the solubility of the film, which increases with both rising temperature and pressure. The solubility effect is exhibited particularly by the myristic acid films above 18°, and especially by the expanded film of this acid at a molecular area of 29.2 sq. Å., since the true positive slope is changed into a fictitious negative one by the increase of solubility.

The slopes $(\partial f/\partial T)_a$ for the intermediate films increase somewhat as the molecular area for a given acid decreases, and are slightly greater for pentadecylic acid, which may be due to the greater solubility of the myristic acid.

The data for the pressure–temperature relations are exhibited in Table III. The temperatures and pressures of transition have been obtained by an extrapolation of the best straight lines which represent the data of the adjacent types of film.

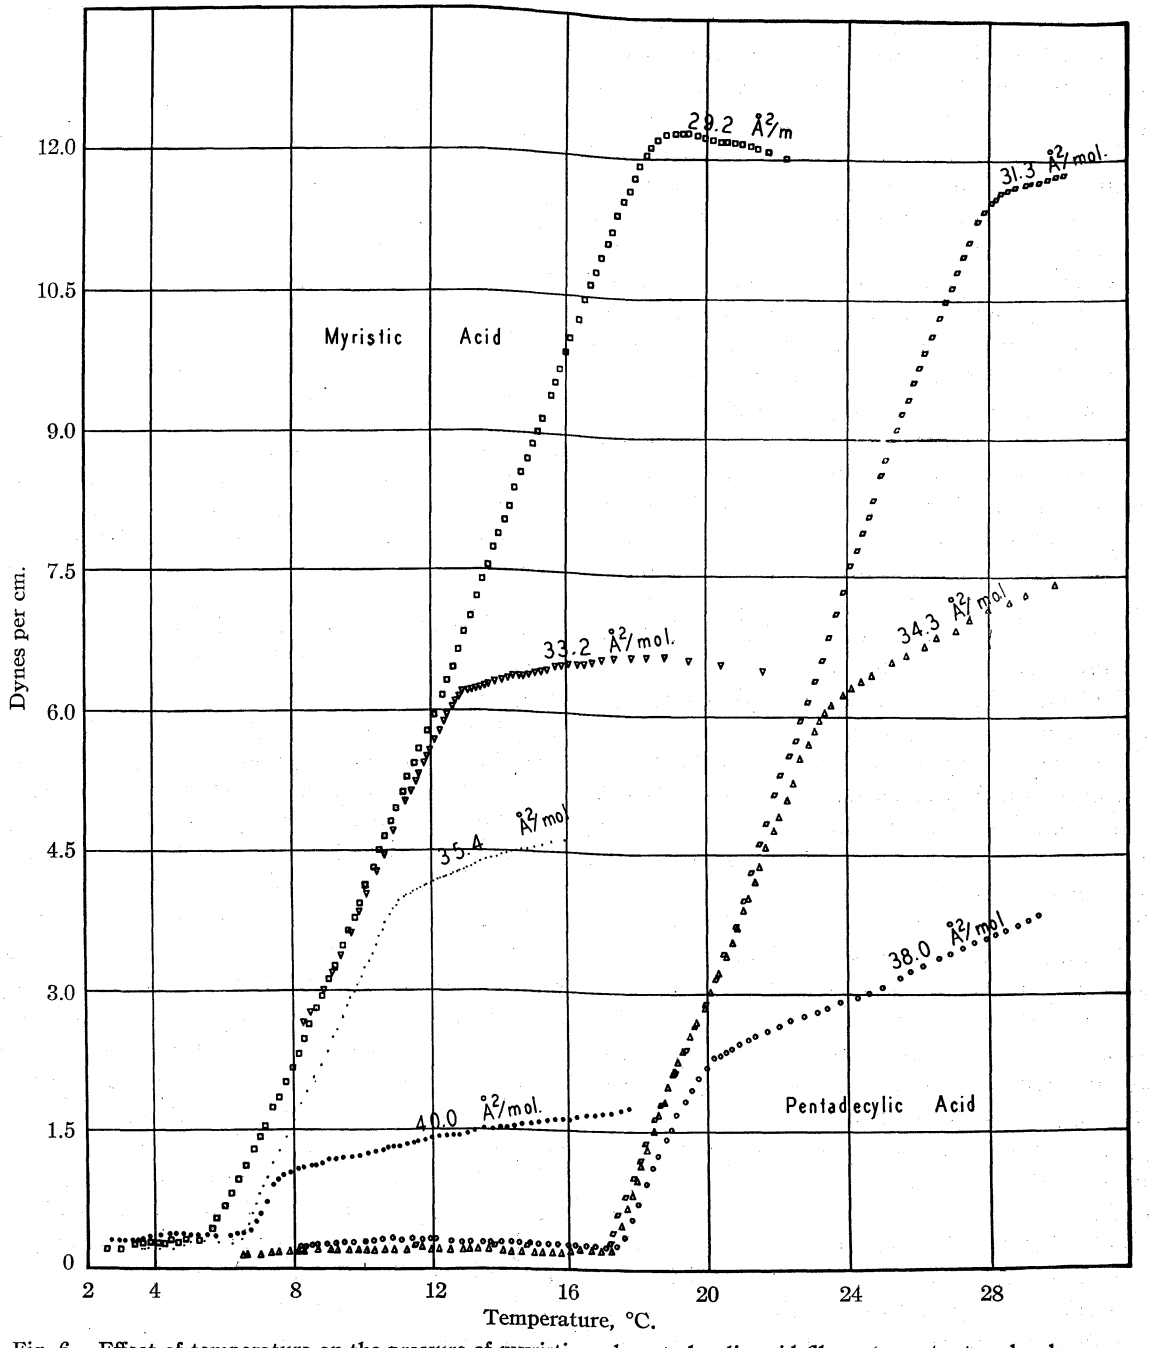

Fig. 6.—Effect of temperature on the pressure of myristic and pentadecylic acid films at constant molecular areas (on 0.01 *N* sulfuric acid).

6. Transformation of an Intermediate into a Condensed Liquid and into a "Plastic Solid" Film

For many years workers in surface chemistry have assumed that the intermediate may be transformed into a condensed film by increase of pressure, but no such transformation could be detected in the pressure–area plots. However, Harkins and Myers[8] discovered by viscosity measurements that pentadecylic acid undergoes a transformation Condensed Liquid → "Plastic Solid" at 21 sq. Å. and about 23 dynes per cm. No well-defined transformation was apparent in the *f*, *a* curves reported in this paper but Boyd and Harkins found that an extremely great in-

crease in viscosity with pressure occurs at a pressure of 21.2 dynes per cm. if the temperature is 25°. After this the pressure–area data were plotted on a different scale (Fig. 7) which revealed the fact that the two straight lines have their intersection at just this point.

The figure seems also to exhibit several additional kink points, but it is unsafe to assume that they represent phase transformations until this assumption has been tested by determinations of the viscosity of these films. Most of the data obtained thus far indicate that there is probably no definite point at which intermediate films are transformed into condensed liquid films.

7. Relation to Theory

Since additional work, with a theoretical bearing, other than that presented here is in progress in this Laboratory, the general discussion of the theory of the expanded and intermediate states will be deferred until later. However, two connections with theory are of moment here.

Langmuir[9] has proposed that the equation of state of an expanded film may be expressed by a van der Waals expression, simplified to the form

$$(f - f_0)(a - a_0) = kT \qquad (1)$$

Here f and a are, respectively, the measured film pressure and molecular area of the monolayer, and the term $-f_0$ is assumed to represent the spreading coefficient (f_S) of Harkins and Feldman[10] for the hydrocarbon oil which would be formed if the polar groups of the substance of the film were to be replaced by hydrogen atoms. For example, if the film is formed from myristic acid, the spreading coefficient should be that for tetradecane. The value of (f_S) is given by

$$f_S = \gamma_w - \gamma_0 - \gamma_{ow} \qquad (2)$$

in which γ represents the surface on interfacial tension and w and o represent water and oil, respectively.

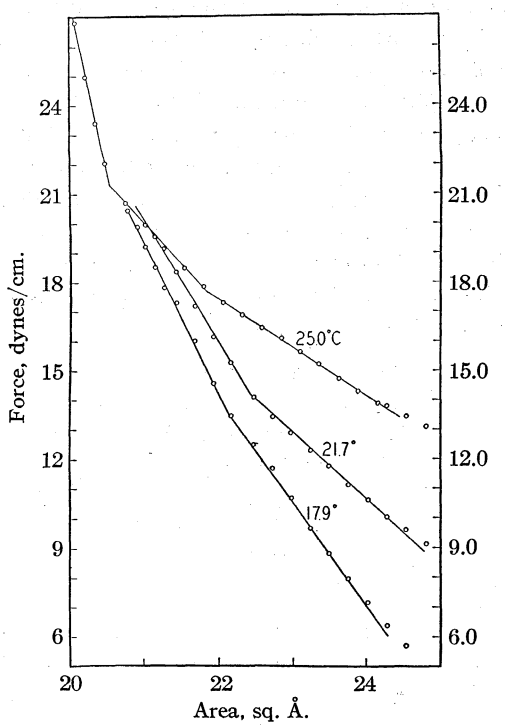

Fig. 7.—Pressure–area relations of pentadecylic acid between 20 and 25 sq. Å. at 25°. Exhibits a phase transition from Condensed Liquid → "Plastic Solid" at 25°, 21.3 dynes per cm., and 20.54 sq. Å. as confirmed by measurements of viscosity.

The values of f_0 which are calculated from the experimental data are seen to vary from 12.3 to 13.0 dynes per cm. for myristic acid, and from 12.4 to 13.5 for pentadecylic acid. While no very accurate determinations of the spreading coefficient have been made, the value for tetradecane obtained by extrapolation from values for the 6 and 8 carbon atom straight chain paraffins

(9) I. Langmuir, *J. Chem. Phys.*, **1**, 756 (1933).

(10) W. D. Harkins and A. Feldman, THIS JOURNAL, **44**, 2665 (1922).

is about 9, while Langmuir's experimental result is 5.7.

Thus the value of f_0 seems actually to correspond much more closely to the spreading coefficients of long paraffin chains of 17 or 18 carbon atoms in length. The value of the spreading coefficient may be given by another form of Eq. (2) which is

$$f_S = w_A - w_{C_0} \qquad (3)$$
