Comparison of Synthetic *d*-Isoequilenin with 14-*epi*-Equilenin.—Dr. O. Wintersteiner kindly made a comparison of our *d*-isoequilenin and its acetate with his 14-*epi*-equilenin,[24] prepared from equilin, and its acetate. The melting points of the isoequilenin and 14-*epi*-equilenin were taken in capillary tubes evacuated to approximately 0.1 mm. He reported the following melting points: *d*-isoequilenin, 263–264°; 14-*epi*-equilenin, 262–263°; mixed sample 261–264°; all melting points are corrected. In all cases there was previous softening before the melting point was reached.

The acetate of 14-*epi*-equilenin, prepared by Dr. Wintersteiner with acetic anhydride in pyridine at room temperature, had a melting point of 126–127.5°; later it melted fairly sharply at 148–149° (after another recrystallization, 148.5–149.5°) with slight softening around 126°. The higher melting point was observed after the sample had been dried at 100° for analysis (Calcd. for $C_{20}H_{20}O_3$: C, 77.88; H, 6.54. Found: C, 77.63; H, 6.73). Our recrystallized *d*-isoequilenin acetate melted at 149–149.5° with slight softening at 148°. A mixture of the two acetates melted at 149.5° after softening at 148°; the sample resolidified after some time and the solid now melted at 127–128°. From this it is clear that the acetate exists in two forms. The compounds possessed the following specific rotations: 14-*epi*-equilenin acetate, $[\alpha]^{24}D$ +137±7° (0.635% in absolute alcohol); *d*-isoequilenin acetate, $[\alpha]^{22}D$ +129.4° (0.307% in absolute alcohol). The margin of error is probably smaller in the latter case because the readings, which were determined using a 2 dcm. tube, were sharper.

***l*-Isoequilenin.**—The mixture of methyl-*l*-menthyl esters of the α-acid (2.35 g.) which remained after removal of the *l*-methyl-*l*-menthyl ester was hydrolyzed to the dicarboxylic acids by heating with a solution of 24 g. of potassium hydroxide (85%) in 60 cc. of methanol for three hours. After removal of the methanol in a current of air, the product was dissolved in water and the menthol was extracted with benzene. The acid (1.58 g.) which precipitated on acidification of the aqueous solution was converted to the dimethyl ester by means of diazomethane. A benzene solution of the ester was boiled with Norite, the solution was filtered and concentrated to a small volume and the residue was dissolved in hot methanol. On cooling the solution deposited fairly large prisms of the racemic dimethyl ester of the α-acid (0.73 g., m. p. 125.5–126°). With luck these can be filtered from the solution by suction before the active (*d*-) dimethyl ester precipitates. Ordinarily it is safer to decant the clear solution from the heavy crystals. The active ester crystallizes in fine colorless plates which dissolve more rapidly and are more soluble than the coarse prisms of the racemic ester. Even when both crystallize out at the same time, one can effect a separation by warming the mixture to dissolve the fine crystals and decant the solution from the coarse prisms. Still another method, which works well after the bulk of the racemic ester has been removed, is to allow the crystallizing solution to stand for ten hours or longer so that the prisms can grow larger; the latter can then be separated by picking them out of the fine crystals by hand. **The *d*-dimethyl ester of α-7-methoxy-2-methyl-2-carboxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid** (0.8 g.) melted at 108–109°, and it was obtained sometimes as high as 110–110.5°. The lower melting point is probably due to a small amount of the racemic ester, but the product is sufficiently pure for the steps which follow. A mixture of equal parts of the *d*-ester (m. p. 110–110.5°) and the *l*-ester (m. p. 110–110.3°) was recrystallized from acetone–methanol; from the solution was obtained prisms of the racemic ester which melted at 126–126.5°, alone and when mixed with the original racemic ester.

The *d*-dimethyl ester was carried through the remaining steps in the manner described for its antipode, the yields of the products being about the same. The product of the Arndt–Eistert reaction, **d-dimethyl ester of α-7-methoxy-2-methyl-2-carboxy-1,2,3,4-tetrahydrophenanthrene-1-propionic acid,** was quite free from its antipode, for it possessed a melting point of 103–103.5° and a specific rotation $[\alpha]^{29}D$ +122° (antipode, m. p. 103–103.5°, $[\alpha]^{28}D$ −123°). A mixture of equal parts of the antipodes recrystallized from methanol yielded crystals of the racemic ester; m. p. 89–89.5°, alone and when mixed with the racemic ester. Cyclization, followed by hydrolysis of the product, yielded the ***l*-isoequilenin.** The latter melted at 272–273° (vac.) when first obtained from its sodium salt by acidification, but after two recrystallizations from acetone–alcohol it formed large colorless plates, which melted at 257–258° (vac.). A mixture of equal parts of the *d*- and *l*-isoequilenin recrystallized from acetic acid yielded the racemic isoequilenin; m. p. 223–224°, alone and when mixed with the original racemic compound.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.2; H, 6.8. Found: C, 81.1; H, 6.9. *Rotation.* 30.7 mg. made up to 2 cc. in dioxane gave a rotation of −2.26°; *l*, 1; $[\alpha]^{28}D$ −147°. In absolute ethanol (7.9 mg. made up to 2 cc.) a specific rotation $[\alpha]^{28}D$ −162° was observed.

Summary

The total synthesis of the sex hormone equilenin and its three stereoisomers is described.

The Halogenation of Unsymmetrical Diphenylethane[1]

BY F. E. SHEIBLEY AND C. F. PRUTTON

When 1,1-diphenylethane at 100° in sunlight is treated with chlorine, hydrogen chloride is evolved and a yellow colored, liquid product results. From this material, on distillation, there was isolated unchanged diphenylethane, stilbene, and 1,1-diphenyl-2,2-dichloroethylene. The failure of the product to undergo any appreciable hydrolysis with caustic alkalies, and the absence in it of detectable amounts of 1,1-diphenylethylene and 1,1-diphenyl-2-chloroethylene, indicate that the over-all reaction is a result of stepwise additions of chlorine to intermediate unsaturates produced by the loss of hydrogen chloride.

IV

$$(C_6H_5)_2C{=}CCl_2$$
V

The chloride (II), prepared from the corresponding carbinol, has been described[2] as an uncrystallizable oil which slowly reverts to 1,1-diphenylethylene (III) at ordinary temperatures. The ethylene (III) was observed by Hepp[3] to react vigorously with chlorine at low temperatures giving a product which yielded 1,1-diphenyl-2,2-dichloroethylene (V) on distillation. The initial chlorination, I → II, is, therefore, the slowest reaction and constitutes the rate determining step.

Bromination mixtures, similarly prepared and distilled, gave only small amounts of 1,1,4,4-tetraphenylbutadiene-1,3 and stilbene.

The presence of stilbene in the halogenation mixtures from 1,1-diphenylethane parallels the experience of Kharasch and Clapp[4] who obtained this substance in excellent yields by heating 2,2-diphenylethanol with phosphorus pentoxide, and recognized the change as another case of the Wagner rearrangement. 1,1-Diphenyl-2-chloroethane is known[5] to give stilbene on distillation, and a similar observation has been recorded for 1,1-diphenyl-2-chloroethylene[6] (IV).

1,1-Diphenyl-2,2-dichloroethylene (V) is a remarkably stable substance and requires the action of alcoholic potassium hydroxide at 150° in order to effect its complete hydrolysis. The product, diphenylacetic acid, was similarly prepared by Fritsch and Feldmann,[7] who employed alcoholic sodium ethylate in a sealed tube and describe the removal of unreacted dichloro compound. A diphenoxy derivative was obtained by using sodium phenate in phenol at 225°. The composition of this product, m. p. 111.5°, indicates that hydration of the double bond has occurred to give the diphenylacetal of benzilic aldehyde,[8] since the alternative structure, $(C_6H_5)_2CHC(OH)(OC_6H_5)_2$, might be expected to lose phenol and give the phenyl ester of diphenylacetic acid.[9]

The pyrolysis of 1,1-diphenylethane in a silica tube at 700° gave benzene, toluene, and styrene in small amounts. Goldschmiedt[10] effected this pyrolysis in a pumice-filled tube and reported stilbene as a product, most of the diphenylethane being unchanged.

Experimental Part

1,1-Diphenyl-2,2-dichloroethylene.—Fifty grams of 1,1-diphenylethane[11] in a quartz flask at 100–150° was treated with a slow stream of chlorine during ten hours, the mixture being exposed to sunlight and finally to the light of an electric lamp. The increase in weight was 16 g. The product on distillation evolved abundant fumes of hydrogen chloride and yielded, at 277–308°, 50.8 g. of distillate which soon turned yellow. On adding solid calcium chloride, 1,1-diphenyl-2,2-dichloroethylene crystallized. The mixed solids were collected, freed of adhering oil by suction and pressing, washed with alcohol, and suspended in water. The undissolved material, 13.1 g., was crystallized from alcohol yielding 11.0 g. of 1,1-diphenyl-2,2-dichloroethylene, m. p. 78–79.5°.

The dark yellow oil, 29 cc., remaining from the crystallization with calcium chloride, was rectified at 1 mm. At

(9) *Cf. ibid.*, **68**, 2137, 2139, 2144, 2151 (1935).

(10) Goldschmiedt, *ibid.*, **6**, 1503 (1873).

(11) The 1,1-diphenylethane, b. p. 273–274° cor. at 744 mm., used in these experiments was obtained from the Dow Chemical Company. It has an odor remindful of mushrooms.

88° 14.6 cc. of colorless 1,1-diphenylethane, saturated toward bromine water, was recovered. At 113° 3.4 cc. of material passed over and partially crystallized; the crystals, recrystallized from a large volume of boiling alcohol, formed white, glistening plates, m. p. 121–123°, identified as stilbene by comparison with an authentic specimen and by conversion to the dibromide. The residue in the still consisted of crude diphenyldichloroethylene and solidified on cooling.

Bromination of 1,1-Diphenylethane. Stilbene.—To 25 cc. of 1,1-diphenylethane at 100° in a quartz flask suspended in the light from an electric lamp, 18 cc. of bromine was added slowly during three hours. The brown reaction mixture yielded copious fumes of hydrogen bromide on distillation and, at 290–310°, 15 cc. of distillate which crystallized on standing. The crystals were sucked free of oil and recrystallized from alcohol to give 0.4 g. of large plates, m. p. 122–124° alone and when mixed with a known sample of stilbene.

1,1,4,4-Tetraphenylbutadiene-1,3.—1,1-Diphenylethane 25 cc., was brominated as described above but only 10 cc. of bromine was used. Distillation of the product gave a fraction, 277–325°, which slowly crystallized. The crystals, sucked free of oil and recrystallized from acetone–alcohol, gave long, white, flat, glistening needles exhibiting a pale violet fluorescence in diffused daylight, m. p. 204–205° cor. An identical product was obtained from a bromination conducted at 65–70°.

Anal. Calcd. for $C_{28}H_{22}$: C, 93.81; H, 6.19; mol. wt., 358.5. Found: C, 93.45; H, 6.52; mol. wt. (Rast), 364, 361.

The melting point was not changed when the product was mixed with an authentic specimen of 1,1,4,4-tetraphenylbutadiene-1,3.[12]

1,1-Diphenyl-2,2-dichloroethylene crystallizes readily from alcohol in long, white, glistening needles, m. p. 79–80° cor. Melting point depression measurements, using naphthalene and *p*-dibromobenzene as solutes, gave for the cryoscopic constant of the compound respective values of 10.0° and 10.2° (mole/kg.), corresponding to a heat of fusion of 24.7 cal. per g.

Anal. Calcd. for $C_{14}H_{10}Cl_2$: C, 67.49; H, 4.05; mol. wt., 249. Found: C, 68.04; H, 4.51; mol. wt. (Rast), 271.

Diphenylacetic Acid.—Hydrolysis of 1,1-diphenyl-2,2-dichloroethylene was not effected by twenty-four-hour periods of treatment with alcoholic sodium hydroxide at 100° or aqueous sodium hydroxide at 150°. One gram of diphenyldichloroethylene, 3 g. of potassium hydroxide, and 17 cc. of alcohol were heated in a 38-cc. stainless steel bomb at 150° during twenty-four hours. The reaction mixture was diluted with water, boiled to remove alcohol, and extracted with ether. Acidification of the aqueous portion gave a precipitate of diphenylacetic acid, 0.62 g. (73%), m. p. 144.5–145°; crystallization from 325 cc. of boiling water yielded 0.56 g., m. p. 145–145.5°; recrystallized, m. p. 147–148° cor. The presence of phenol in a methyl alcoholic reaction mixture did not alter the product of hydrolysis.

Anal. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70. Found: C, 78.97, 79.24; H, 5.64, 5.62.

Benzilic Aldehyde Diphenylacetal.—Three-tenths gram of sodium dissolved in 6 g. of warm phenol, and 0.7 g. of diphenyldichloroethylene were heated at 225° during twenty-four hours. The cold reaction mixture, treated with dilute sodium hydroxide solution, left a yellow gummy mass which was washed with water, air-dried, and crystallized from alcohol, yielding 0.09 g. of a brown-tinted mass of small, opaque, chlorine-free prisms, m. p. 111.5–112° cor. The compound is insoluble in hot aqueous sodium hydroxide or hot concentrated hydrochloric acid.

Anal. Calcd. for $C_{26}H_{22}O_3$: C, 81.65; H, 5.80. Found: C, 82.34, 81.97; H, 5.60, 5.51.

Pyrolysis of 1,1-Diphenylethane.—The hydrocarbon, 340 cc., was slowly fed into an electrically heated, baffled silica tube at 676–702° during one hour and forty-five minutes. Carbon dioxide, 1.25 cubic feet (35.4 liters) was introduced with the charge, and 2.02 cubic feet (57.2 liters) of mixed gas, containing unsaturated material, resulted. The less volatile products amounted to 308 cc., 311 g., of dark colored oil and on distillation gave, at 71–153°, 64 cc. of a mixture consisting principally of benzene, toluene, and styrene. The viscous black residue, b. p. 258–300°, contained much unchanged diphenylethane and, possibly, some 1,1-diphenylethylene. The benzene–toluene–styrene mixture was cooled and treated with bromine until absorption ceased. The product yielded on distillation 52 cc. of distillate and a black residue which crystallized on cooling. Analysis of the distillate in a column still indicated approximately 42% benzene and 58% toluene. The black residue, freed from oil by suction and pressing, was crystallized from alcohol to give glistening plates, m. p. 71.5–72.5° alone or mixed with an authentic specimen of styrene dibromide.

(12) Valeur, *Bull. soc. chim.*, (3) **29**, 685 (1903).

Summary

The photochemical chlorination of 1,1-diphenylethane at 100°, followed by distillation of the product, gives 1,1-diphenyl-2,2-dichloroethylene and small amounts of stilbene.

The analogous bromination of 1,1-diphenylethane yields stilbene and 1,1,4,4-tetraphenylbutadiene-1,3 in small amounts.

The hydrolysis of 1,1-diphenyl-2,2-dichloroethylene to diphenylacetic acid requires the action of hot alcoholic caustic alkali under pressure.

The pyrolysis of 1,1-diphenylethane yields benzene, toluene, and styrene.

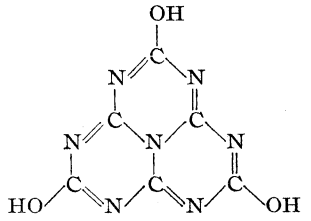
Some Derivatives of Cyameluric Acid and Probable Structures of Melam, Melem and Melon

BY C. E. REDEMANN AND H. J. LUCAS

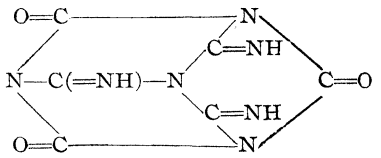
Since it has been shown recently that the structure proposed by Pauling and Sturdivant for the cyameluric acid nucleus,[1] I, accounts more satisfactorily for the acidic strength and for the products of hydrolysis[2] than any other proposed structure, and because of the prediction made by these authors[1] that there should be a group of cyameluric compounds analogous to the cyanuric compounds, attempts have been made to prepare some of these analogs.

Cyameluric acid forms a blue-lavender cupric ammonium salt, $CuNH_4(C_6N_7O_3)NH_3$, entirely analogous to that of cyanuric acid,[3] $CuNH_4(C_3N_3O_3).NH_3$. The insoluble cupric ammonium cyamelurate is useful in purifying cyameluric acid since the acid is readily regenerated from the salt by suspending it in water and acidifying with hydrochloric acid.



Pauling and Sturdivant

I



Franklin

II

In the case of the mercuric salts the parallelism is not so satisfactory. While Hantzsch[4] reported two different mercuric cyanurates with the formula $Hg_3(C_3N_3O_3)_2$, one called an oxygen salt, the other a nitrogen salt, specimens of mercuric cyamelurate, $Hg_3(C_6N_7O_3)_2$, obtained under conditions shown by Hantzsch to give different salts with the former gave only a single salt with the latter. This salt gave an immediate precipitate of yellow mercuric oxide with aqueous sodium hydroxide, hence it would be called the oxygen salt from the Hantzsch point of view. Although in this case the analogy with cyanuric acid is not complete, nevertheless the behavior of the mercury salt favors structure I rather than structure II, for of the latter only a nitrogen salt is possible. This argument is, however, open to criticism, for if the N–Hg bond has sufficient ionic character the salt would be expected to react with sodium hydroxide.

Cyanuryl trichloride, $C_3N_3Cl_3$, and cyameluryl trichloride, $C_6N_7Cl_3$, are completely analogous. Hydrolysis of the two chlorides is similar except that cyameluryl chloride hydrolyzes more rapidly, as might be expected since it is the acid chloride of the stronger acid.[2] When heated with acetic acid each acid chloride yields the respective acid and acetyl chloride; upon alcoholysis each yields the respective acid and an alkyl chloride.

Esters of cyameluric acid are more difficult to prepare than are those of cyanuric acid. Two series of esters are known for the latter: the oxygen esters, and the nitrogen esters. Potassium cyamelurate does not react readily with alkyl halides at room temperature. After standing with methyl iodide for nineteen months, only a small amount of iodide ion was formed and no ester could be isolated. Likewise, cyameluryl trichloride with sodium methoxide (or benzoxide) failed to give the ester. Potassium cyamelurate and allyl bromide gave an allyl derivative at 100° which was not obtained pure. A tribenzyl ester was obtained from benzyl chloride and potassium cyamelurate at 156°. This ester is a nitrogen ester since it gave benzylamine and no benzyl alcohol upon hydrolysis. Cyanuric acid[5] also forms the nitrogen ester at elevated temperatures.

From cyameluric acid and diazomethane was obtained a mixture of monomethyl esters with the nitrogen ester predominant, and also a trimethyl ester which was entirely a nitrogen ester.

(5) Hantzsch and Bauer, *Ber.*, **38**, 1009 (1905).

Cyanuryl chloride and cyameluryl chloride both react with ammonia, the former to produce a monochlordiamide and a triamide, melamine, and the latter to produce a diamide and apparently some triamide, although not pure.

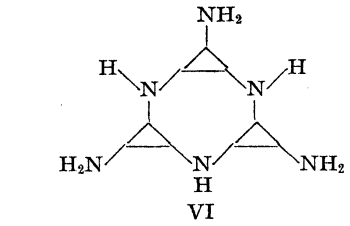
The resemblance of the derivatives of cyameluric acid to the corresponding derivatives of cyanuric acid indicates that cyameluric acid contains hydroxyl groups and suggests that formula I, or $C_6H_7(OH)_3$, is the one which most closely resembles $C_3N_3(OH)_3$.

On the basis that cyameluric acid is represented by I, satisfactory structures can be assigned to melam, melem and melon. Melam,[6] empirical formula $C_6H_9N_{11}$, is probably tetraaminodicyanurimide,[7] III. This structure accounts for the feebly basic property of melam, and is supported by the behavior of melam with 30% aqueous ammonia[8] at elevated temperatures to yield melamine and ammeline; also by Liebig's[6] observation that when boiled with nitric acid melam yields cyanuric acid and ammonium nitrate.

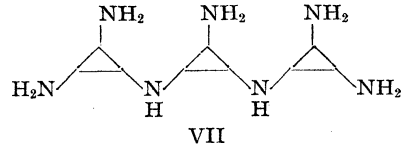
Melem,[6] empirical formula $C_6H_6N_{10}$, is probably cyameluryl triamide, IV. This structure satisfactorily accounts for the formation of large quantities of ammelide upon hydrolysis, and for the fact that melem is more resistant to hydrolysis than melam. Structures III and IV account satisfactorily for the observation that melam is a stronger base than melem, for the latter is derived from much the stronger acid.

$[3.5\text{-}(NH_2)_2C_3N_3]_2NH$	$C_6N_7(NH_2)_3$	$(HN{=}C_3H_3)_2NH$
Melam	Melem	Melon; Franklin
III	IV	V

Melon, with empirical formula $C_6H_3N_9$,[9,10] was assigned structure V by Franklin.[7b] But since melon gives good yields of cyameluric acid upon alkaline hydrolysis[11] a satisfactory structure for melon must involve the planar nucleus characteristic of cyameluric acid, I. Such a structure results from melem, IV, by the loss of ammonia from two or more molecules. One possibility is that shown by structure VI, where three molecules of ammonia have been split out from three molecules of cyameluric triamide. This compound, the molecule of which has three cyameluric nuclei, has the formula $C_{18}H_9N_{27}$, three times $C_6H_3N_9$, the accepted formula for melon. Here the side chains are $-NH_2$ groups, the =NH group forming part of a new ring. Larger molecules of the compact type, where the maximum number of ring closures had taken place would have a higher carbon, lower hydrogen and lower nitrogen content. In such a molecule hydrogen is found only along the periphery. The symmetrical triangular molecule with six cyameluric nuclei is $C_{36}H_{12}N_{52}$ or more simply $C_6H_2N_{8^2/_3}$. As condensations extend indefinitely the empirical formula approaches asymptotically the limit C_3N_4, Franklin's carbonic nitride. Another type of condensation product, in which the cyameluric nuclei, except for the two terminal ones, are joined to only two other nuclei (structure VII), would approach $C_6H_3N_9$ if extended indefinitely.



VI



VII

Melon[12]

On this basis it is possible to account for the lack of constancy of composition of melon observed by Liebig, Franklin and others. The hydrogen content of Franklin's preparations varied from 1.1 to 2.0%, while for the accepted formula, $C_6H_3N_9$, the hydrogen content is 1.5%. By taking extreme precautions to dry mercuric thiocyanate at 150° in the vacuum of a mercury vapor pump before decomposing it to melon, Franklin was able to obtain a product with a hydrogen content of only 0.6%. This corresponds closely to a compact condensation product, triangular in form, with twenty-one nuclei, and molecular formula $C_{126}H_{21}N_{175}$ or more simply $C_6HN_{8^1/_3}$ with a hydrogen content of 0.5%. Franklin's material was probably composed of both larger and smaller units, giving an average value corresponding to the above figures. It is probably incorrect to assign any one structure to melon, for it is more than likely a mixture of

(12) In VI and VII, each triangle represents C_6H_7, the cyameluric nucleus.

molecules of different sizes and shapes. This gives rise to its amorphous character.

It is seen that there is a formal resemblance between melon and graphite, in that the molecules are infinitely large and planar. The formal resemblance becomes even more pronounced if in the molecule of melon the void between the three cyameluric nuclei is filled by writing in three atoms of carbon and one of nitrogen. Taking the density of graphite as 2.25 and neglecting the hydrogen, we can predict a density for melon of less than 1.7. An observed value is 1.40 at 25°, which value may differ considerably with different preparations. Anhydrous cyameluric acid, which is not predicted to have large void spaces in its structure corresponding to those in melon, is found to have a density of 1.75 at 25°. The high stability of melon, like that of graphite, may be explained in terms of the enormous number of resonating forms contributing to the structure of the compound.

Experimental

Cupric Ammonium Cyamelurate.—To a solution of 2 g. of cyameluric acid trihydrate in 200 ml. of hot 0.5 *N* ammonium hydroxide, there was added an excess of cupric ammonium sulfate solution. After cooling, the resulting lavender precipitate was filtered off, washed and air dried. The color changed to a very blue shade of lavender upon drying, probably due to the loss of either ammonia to form a less amminated compound, or to the loss of water of crystallization.

Anal. Calcd. for $CuNH_4(C_6H_7O_3)\cdot NH_3$: Cu, 20.08. Found: Cu (iodometrically), 19.84, 20.13.

This salt is much less soluble than the one obtained from cyanuric acid under the same conditions.

Mercuric Cyamelurate.—Two samples of mercuric cyamelurate were prepared under conditions which Hantzsch[4] found to yield two different types of salts in the case of cyanuric acid. (A) To a solution of 2 g. of pure potassium cyamelurate in 50 ml. of boiling water was added a slight excess of a boiling solution of mercuric chloride. The white flocculent precipitate of the mercury salt which separated immediately was well washed with water and dried.

Anal. Calcd. for $(C_6N_7O_3)_2Hg_3$: Hg, 57.99. Found: Hg, 58.31, 58.33. The high values for mercury probably are due to adsorption of mercury by the semi-gelatinous precipitate.

(B) The same procedure was followed except that mercuric chloride was replaced by mercuric acetate, and the solutions were ice-cold. Both salts looked alike and gave immediate precipitates of yellow mercuric oxide when treated with a cold 1 *N* sodium hydroxide. Upon standing overnight, nearly colorless crystals of trisodium cyamelurate separated in each case.

Cyameluryl Trichloride.—(A) From tripotassium cyamelurate. Thirty grams of the salt dried at 150° for forty-eight hours and 60 g. of phosphorus pentachloride were ground to a fine mixture in a mortar. This was sealed in a large bomb-tube and heated in a boiling water-bath for seven hours. The tube was opened to relieve the pressure, then after resealing heated for an additional nine hours at 139° (*m*-xylene vapor-bath). After phosphorus oxychloride had been removed by letting stand in a desiccator over flake sodium hydroxide in a thin layer, the residue was crushed into a coarse powder and slowly sprinkled into and well stirred with an ice–water mixture to remove potassium chloride and any remaining phosphorus compounds. The light yellow solid was filtered off and dried in a vacuum desiccator over concentrated sulfuric acid. The yield of light yellow crystalline powder, which under the microscope was seen to consist of thin pale yellow platelets, was 23 g. (93%).

Cyameluryl trichloride is highly insoluble in all organic solvents tested, which included chloroform, anisole, nitrobenzene, acetonitrile, *o*-dichlorobenzene and glacial acetic acid (with which it reacted giving acetyl chloride and cyameluric acid). The compound was shown to be essentially free from inorganic salts by ignition upon platinum foil where no ash remained. No melting was observed, but the compound gradually disappeared by a combination of oxidation and perhaps sublimation. Attempts to secure purification by sublimation at atmospheric pressure and under high vacuum were unsuccessful. Analyses were finally run on the dry material without further purification.

Anal. Calcd. for $C_6N_7Cl_3$: N, 35.44; Cl, 38.49. Found: N (Kjeldahl), 35.76, 35.32; Cl (Carius), 32.83, 37.4, 37.4.

Results of the analysis indicate that the compound was slightly impure cyameluric trichloride. When completely decomposed by digesting with nitric acid, the solution gave but a faint test for phosphorus with ammonium molybdate.

(B) From cyameluric acid. Two grams of the acid which had been dried for several days at 150° and six grams of phosphorus pentachloride were ground and intimately mixed. The mixture was sealed in a heavy walled bomb-tube and heated to 218° (naphthalene vapor-bath) for thirty-six hours. The tube was opened periodically to relieve the pressure. The contents of the tube were worked up, as in A. The yield was 2.3 g. (92%) of product closely resembling that prepared from tripotassium cyamelurate.

N-Tribenzyl Cyamelurate.—A mixture of 5 g. of anhydrous trisodium cyamelurate and 17 ml. of freshly distilled benzyl chloride in a sealed bomb-tube was heated for twenty-three hours in a boiling water-bath. As little reaction appeared to take place at this temperature, heating was continued for an additional twelve hours in a vapor-bath at 156° (boiling bromobenzene). The contents were transferred to a Soxhlet extractor and extracted for four hours with boiling benzene. Following removal of volatile compounds by distillation under 18 mm. pressure, the residue was crystallized from boiling benzene; 4.2 g. (36%). After two additional recrystallizations from ethyl alcohol very small white needles melting at 283–284° (cor.) were obtained.

Anal. Calcd. for $C_{27}H_{21}N_7O_3$: mol. wt., 491; N, 19.96;

C, 65.96; H, 4.31. Found: mol. wt. (Rast camphor), 497; N (Kjeldahl), 19.54, 19.57; C, 65.46; H, 4.46.

Saponification of 0.2 g. of tribenzyl cyamelurate by refluxing for one hour with 10 ml. of aqueous 6 *N* potassium hydroxide, followed by distillation of the reaction mixture, gave a faintly cloudy distillate with an odor suggestive of ammonia. Extraction of this with ethyl ether following acidification with hydrochloric acid gave no trace of benzyl alcohol. However, extraction of the aqueous solution with ether after the addition of an excess of sodium hydroxide gave a few drops of a viscous residue which reacted readily with benzoyl chloride. The resulting solid after crystallization from aqueous ethyl alcohol melted at 105.5–106.0°, and melted at the same temperature when mixed with an authentic sample of N-benzylbenzamide, m. p. 105°. This shows that benzylamine but not benzyl alcohol is formed when tribenzyl cyamelurate is saponified and that the tribenzyl compound is a nitrogen, not an oxygen ester.

Action of Cyameluryl Trichloride on Benzyl Alcohol.—A mixture of 1.0 g. of cyameluryl trichloride and 1.5 g. of dry benzyl alcohol reacted spontaneously. The mixture became very hot and the yellow color of the cyameluryl trichloride changed to a pure white. The mixture was then boiled for one minute, cooled and 2 ml. of benzene added. The solid was removed by filtration and the filtrate was fractionally distilled. The fraction boiling between 170–190° had an unmistakable odor of benzyl chloride. This was confirmed by converting into the *p*-bromobenzenesulfon-*p'*-anisidide, m. p. 169.5–170.0° (uncor.), after recrystallizing from ethanol. The melting point was 170.0–0.5 when mixed with a known sample, m. p. 170–171°.[13]

The white residue was shown to be cyameluric acid by its solubility in sodium bicarbonate solution, from which the trisodium salt was precipitated in characteristic colorless needles upon adding an excess of strong sodium hydroxide solution.

Methyl Cyamelurate from Cyameluric Acid and Diazomethane.—An excess of an ethereal solution of diazomethane was added to 1.7 g. of very finely powdered cyameluric acid. The evolution of gas, vigorous at first, soon became rather slow. A strong yellow color from excess diazomethane was still present after standing for three days in the refrigerator, although the evolution of gas had become quite slow. The solid was filtered off and dried over concentrated sulfuric acid. The dry pale yellow solid thus obtained weighed 1.8 g. No melting was observed in a capillary tube; no solvent was found from which the material could be purified without some decomposition.

Anal. Calcd. for $C_6H_2N_7O_3(CH_3)$: C, 35.7; H, 2.12; CH_3, 6.38. Found: C, 35.4, 35.1; H, 3.22, 3.05; CH_3 (methoxyl), 0.58, 0.62; CH_3 (methylimide) 6.95, 6.48.

Analysis indicates slightly more than one methyl group per nucleus and some methylation of the hydroxyl groups.

The partially methylated product from the above experiment after fine pulverization was treated again with an excess of diazomethane at room temperature for four days. Since all apparent reaction had ceased, the solid was filtered off, dried over concentrated sulfuric acid, and analyzed.

Anal. Calcd. for $C_6N_7O_3(CH_3)_3 \cdot 1^1/_2H_2O$: C, 36.72; H, 4.12; H_2O, 9.18; CH_3, 15.3. Found: C, 36.22; H, 4.14; H_2O, 9.13; CH_3 (methoxyl), 0.060, 0.062.

When heated on platinum foil the anhydrous compound melted. In a capillary tube no melting was observed up to 290°, but instead extensive charring.

Attempts to Prepare Cyameluric Triamide.—(1) On adding 25 ml. of 15 *N* ammonium hydroxide to 1.19 g. of cyameluryl chloride, a very vigorous reaction took place immediately. The light yellow color of the cyameluryl chloride disappeared and a white flocculent precipitate took its place. After standing for one hour this was filtered off, washed well with cold water and dried in the oven at 75°; weight 0.88 g. As no solvent was found from which this material could be recrystallized, the sample was analyzed without further purification.

Anal. Calcd. for $C_6N_7(NH_2)_3$: N, 64.2; for $C_6N_7(NH_2)_2Cl$: N, 53.1; Cl, 14.93; for $C_6N_7(NH_2)_2OH$: N, 57.6. Found: N (Kjeldahl), 54.28, 54.17; Cl (Carius), 3.32, 3.50.

The analytical data indicate an impure mixture largely composed of one or both diamides, cyameluryl monochlorodiamide, and cyameluryl diamide.

(2) Two grams of cyameluryl chloride was suspended in 100 ml. of anhydrous ethyl ether into which was passed gaseous ammonia until the solution was saturated. It was then allowed to stand for two hours and again saturated with ammonia gas and allowed to stand overnight. Twenty-five ml. of water was then added and the mixture was vigorously shaken. The precipitate was separated by filtration, washed with concentrated ammonium hydroxide, and air dried. It was then crushed and digested with 100 ml. of warm 1 *N* ammonium hydroxide for thirty minutes, filtered, and dried at 100° for one hour. *Anal.* Found: N, 59.88, 60.01.

Since this analytical result agreed most nearly with a possible monohydrate of the triamide or the ammonium salt of the acid diamide the compound was dried for twenty-six hours at 150°. A loss in weight of 4.52% took place, with but little change in the analysis, but the material still appeared to be impure. *Anal.* Found: N, 60.20, 61.96.

(3) Two grams of cyameluryl chloride was sealed in a bomb-tube with anhydrous liquid ammonia and left for twenty hours at room temperature. The tube was opened and the ammonia allowed to evaporate. The residue was extracted with cold water to remove the ammonium chloride. The flocculent solid was collected upon a filter and dried at 100° for four hours. *Anal.* Found: N, 60.34, 60.01.

None of these preparations has a nitrogen content as high as that for the triamide (64.2%), but the purification is hampered because no satisfactory solvent has been found from which the compound can be crystallized.

Summary

1. Cyameluric acid has been shown to form a group of compounds entirely analogous to those of cyanuric acid. The analogy is complete for

(13) Gillespie, THIS JOURNAL, **56**, 2740 (1934), gives 167.5°, which is too low.

the cupric ammonium salts, the trichlorides, and the nitrogen esters formed by the reaction of benzyl chloride with the respective alkali salts at elevated temperature. The analogy is less exact for the diamides, the mercuric salts and the oxygen esters.

2. The existence of a trichloride and of an oxygen ester indicates that hydroxyl groups are present in the molecule of cyameluric acid.

3. The analogy with cyanuric compounds and the presence of hydroxyl groups substantiate the planar ring structure for cyameluric acid proposed by Pauling and Sturdivant.

4. Melam is probably dicyanurylimide and melem, cyameluryl triamide.

5. It is proposed that melon is a condensation product of cyameluryl triamide, and that the resulting very large molecules consist of planar cyameluryl rings joined through nitrogen atoms.

The Ionization Constants of Weak Acids at 25° from Conductance Measurements. A Method of Extrapolating the Data[1]

BY BLAIR SAXTON[2] AND LAWRENCE S. DARKEN[3]

A large number of investigations[4-14] have been conducted in recent years on the determination of ionization constants of weak acids by the conductance method. At the lower concentrations the degree of ionization is determined accurately from conductance data alone by use of the additive law that the specific conductance of the weak acid is equal to the specific conductance of the hydrogen ion and the acid ion as determined from the conductance of the sodium or the potassium salt of the acid, sodium or potassium chloride and hydrochloric acid at the corresponding ionic concentration. The salts and hydrochloric acid are considered completely ionized. The degree of dissociation of the weak acid is set equal to Λ/Λ_ϵ where Λ_ϵ is the equivalent conductance of the theoretical completely dissociated acid at the same ionic concentration. Values of Λ/Λ_ϵ are obtained by a method of successive approximations from the above-mentioned data. From the degree of dissociation of the acid a so-called mass law ionization constant is determined directly according to the relation

$$k = \alpha^2 c/(1 - \alpha) = c_i^2/c_u$$

where α is the degree of dissociation, c is the stoichiometric concentration of the weak acid, c_i is the ionic concentration, and c_u is the concentration of undissociated weak acid. At finite concentrations

$$K = y_\pm^2 k$$

where K is the thermodynamic ionization constant as usually written, and $y_\pm$ is the mean ionic activity coefficient. Several investigators[4-14] have shown that at extremely low concentrations the variation of k with concentration is in good agreement with that predicted by the Debye–Hückel[15] theory of interionic attraction which at low ionic concentrations reduces to this relation

$$\log y_\pm = -A\sqrt{c_i}$$

which combined with the previous equation gives

$$\log K = \log k - 2A\sqrt{c_i}$$

Unfortunately, the range over which this equation holds within an experimental error of one part in a thousand (to give a constant value of log K) is below an ionic concentration of about 0.003 (depending on the acid). Hence, extrapolating to obtain the limiting value of log K from a plot of log k *versus* $\sqrt{c_i}$ is not a convenient method in that it demands high accuracy at low concentrations. It will be shown that the true thermodynamic ionization constant may be determined

conveniently and accurately by extrapolating to infinite dilution a plot of log $k - 2A\sqrt{c_i}$ *versus* c_u. Such a plot has been found to be linear up to a concentration of almost one molal.

Experimental

The conductance measurements were made with the apparatus and technique used in our earlier work[6,10] and the ionization constants were calculated by the method there described. Jena glass cells and a silica cell were used. The cell constants were determined by use of both 0.01 and 0.1 demal potassium chloride solutions and all conductivities here reported are based on Jones and Bradshaw's[16] determination of the conductivities of these solutions. In the case of formic acid, half of the measurements were made with bright electrodes while the remainder were made with platinized electrodes. In the latter case, special care was taken to remove carbon dioxide and oxygen by bubbling nitrogen through the solutions. These measurements were made a year apart on samples of acid which had been independently purified and analyzed.

Kahlbaum cyanoacetic acid was recrystallized several times from conductivity water. The results checked those obtained with acid recrystallized from an ether–chloroform mixture and then twice from conductivity water. Formic acid was freshly distilled and standardized just before each run. Eastman *n*-butyric acid was purified by partially crystallizing three times and discarding the unfrozen liquid. The stock solution of each acid was analyzed by titrating with sodium hydroxide solution which had been standardized with potassium acid phthalate certified by the Bureau of Standards. In each analysis the titration was finished with standard base one-tenth the concentration of that used for the major part of the titration. The results usually showed deviations of about 0.01% from the average.

Sodium salt solutions were made by adding the calculated quantity of pure sodium carbonate to the acid solution. Carbon dioxide was removed by treating with nitrogen. The potassium butyrate stock solution was prepared by neutralizing a butyric acid solution with the theoretical amount of potassium hydroxide solution (the same potassium hydroxide solution which had previously been used for conductance measurements and with which the titer of the acid was determined). To suppress hydrolysis about 0.25% excess acid was added. The cell concentration was based on the amount of alkali used.

Densities were determined with a pyknometer. The following equations express the results over the concentration range covered

Formic acid: $d = 0.99704 + 0.012089c - 0.000690c^{3/2}$
Cyanoacetic acid: $d = 0.99704 + 0.023m$
Sodium cyanoacetate: $d = 0.99704 + 0.057m$
Butyric acid: $d = 0.99704 + 0.00362m$
Potassium butyrate: $d = 0.99704 + 0.0496m$

Densities for sodium formate solutions were taken from the "International Critical Tables" (m = gram moles per kilogram; c = gram moles per 1000 cc.).

The equivalent conductances of the salts follow Shedlovsky's[17] extension of Onsager's[18] equation and are given by

$Na^+ + CNCH_2COO^-$:
$$\Lambda = 91.91 - 80.79\sqrt{c_i} + 76c_i(1 - 0.2276\sqrt{c_i})$$
$Na^+ + HCOO^-$:
$$\Lambda = 104.69 - 83.69\sqrt{c_i} + 86c_i(1 - 0.2276\sqrt{c_i})$$
$K^+ + C_3H_7COO^-$:
$$\Lambda = 105.39 - 83.76\sqrt{c_i} + 110c_i(1 - 0.2276\sqrt{c_i})$$

The experimental data are given in Table I. Combining these equations with the equation for $\Lambda_{(H^+)} - \Lambda_{(Na^+)}$ given in an earlier paper,[6] the equations for the sums of the equivalent conductances of the ions of the weak acids as functions of their ionic concentrations, c_i, become

$H^+ + CNCH_2COO^-$:
$$\Lambda_e = 391.71 - 148.98\sqrt{c_i} + 151c_i(1 - 0.2276\sqrt{c_i})$$
$H^+ + HCOO^-$:
$$\Lambda_e 404.50 - 151.88\sqrt{c_i} + 161c_i(1 - 0.2276\sqrt{c_i})$$
$H^+ + C_3H_7COO^-$:
$$\Lambda_e = 381.69 - 146.57\sqrt{c_i} + 180c_i(1 - 0.2276\sqrt{c_i})$$

The measured equivalent conductances of the acids and the thermodynamic ionization constants calculated with the aid of these equations are given in Table II.

Discussion

The values of the mass law constant, k, follow the theoretical slope of the limiting Debye–Hückel law up to an ionic concentration of approximately 0.003 demal. This concordance has been demonstrated conclusively by earlier investigations.[4–14] The increase of the experimental error at these lower concentrations where the limiting law of Debye and Hückel holds is quite pronounced; hence it would be highly de-

sirable to employ a method of extrapolation which would make use of measured conductances at the higher concentrations where the error is much smaller. With this in view various methods of extrapolating were tried and it was found that the various extensions of the limiting law of Debye and Hückel did not account satisfactorily for the observed departures. These departures of K from constancy are such that log K is linear with the concentration of undissociated acid. It is also true that the plot of log K is essentially linear with the total concentration. It was hoped that the data on cyanoacetic acid, which is the most highly dissociated of the acids considered here, would show clearly whether log K is linear with c_u or with c. Although in the case of this acid the difference between c_u and c is pronounced, neither plot shows decided departure from linearity, but slight evidence is offered in favor of the plot against c_u. The extrapolation is shorter in the case log K *versus* c_u than in the case log K *versus* c. These plots are shown in Fig. 1.

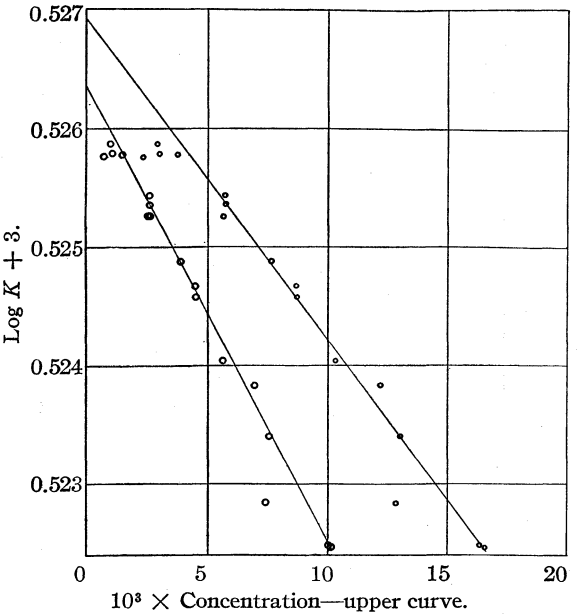

Fig. 1.—Log K *versus* c (upper curve) and c_u (lower curve) for cyanoacetic acid at 25°.

The data on formic acid were extended up to the region of the constant boiling mixture of this acid with water in order to determine the upper limit to which the linearity of log K *versus* c_u prevails. Although at the higher concentrations the ionic concentrations and hence k and K calculated by this method are meaningless, they are included in Table II as formal functions resulting from the application of the method. The linearity persists up to a concentration of about 0.7 demal; the deviation amounting to less than 0.5% in the demal solution. The data on formic acid up to 1.2 demal are represented by the top curve in Fig. 3, the scale being such that the deviations mentioned above are not perceptible. The first set of experiments on formic acid in which bright electrodes were employed yielded a value of the ionization constant (1.825×10^{-4}) which differed considerably from that obtained by Harned and Embree[19] from e. m. f. measurements of cells with buffered solutions (1.767×10^{-4}) (a figure obtained by multiplying their published value by the density of water to convert from molality to demality). As their results check the previous results of Harned and Owen[20] obtained similarly with unbuffered solutions, it was deemed advisable to repeat the work. This was done about a year later using lightly platinized electrodes and taking care to exclude oxygen. The agreement with the previous year's results is satisfactory. The discrepancy between our value and that resulting from e. m. f. measurements seems inexplicable. Previous work on acetic[4] and chloroacetic[6] acids has shown satisfactory agreement between the two methods.

Our value for the ionization constant of butyric acid agrees well with that obtained from e. m. f. measurements by Harned and Sutherland.[21] The agreement with Belcher's[14] measurements by essentially the same method is not as good as might be anticipated, as may be seen from Fig. 2, where Belcher's experimental points would appear as a cluster near log $K = -5.177$–8 and $c_u = 0.000 - 0.005$. The 0.7% discrepancy in K_0 (the extrapolated value of K) is due in part (0.3%) to differences in the measured conductances of the acid, and in part (0.4%) to differences in the measured conductances of the salt, which are reflected in Λ_0 for butyric acid. The disparity in the results of the three investigators is shown in the following table

	Saxton and Darken	Belcher[14]	Harned and Sutherland[21] Measured	Harned and Sutherland[21] From smoothed curve
$K_0 \times 10^5$ (25°C.)	1.518	1.508	1.510	1.518
Λ_0	381.69	382.40		

(19) Harned and Embree, THIS JOURNAL, **56**, 1042 (1934).

(21) Harned and Sutherland, *ibid.*, **56**, 2039 (1934).

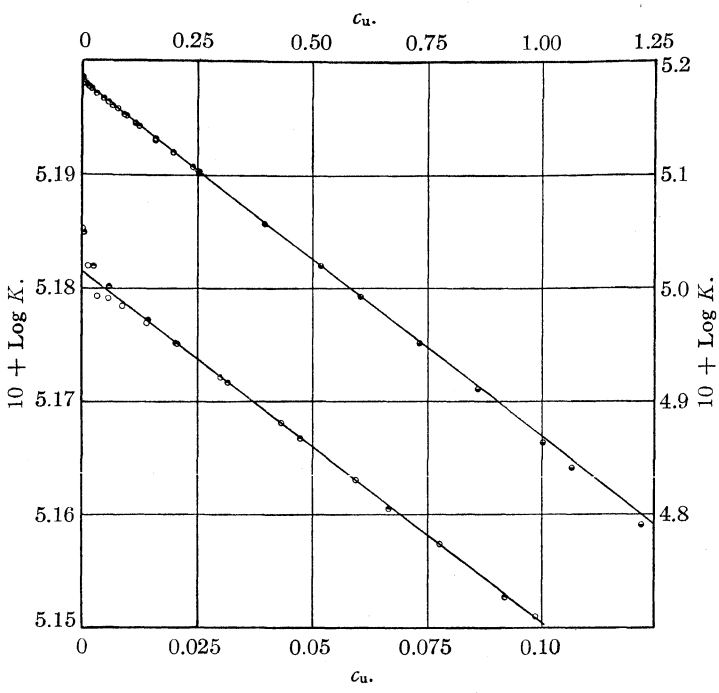

Fig. 2.—Log K *versus* c_u for butyric acid at 25°: concentration ranges, 0–0.1 (lower curve) and 0–1.25 (upper curve).

The extrapolated values from the log K *versus* c_u plots shown in Figs. 1 and 2 and the top curve of Fig. 3 correspond to 3.360×10^{-3}, 1.825×10^{-4}, and 1.518×10^{-5} for the ionization constants of cyanoacetic, formic and butyric acids, respectively.

Plots of log K *versus* c_u are shown in Fig. 3. The results of all available precise conductance measurements on aqueous solutions of weak acids (at 25°) are here shown in such a manner that the proper relative slopes of the lines are maintained, although the coördinate scales vary by large factors. From top to bottom the acids represented are: formic, acetic,[4] propionic,[14] monochloroacetic,[6] cyanoacetic, lactic,[13] and benzoic.[10] In order to avoid confusion, points corresponding to extremely low concentrations have been omitted.

Interpretation of the linearity of the plot of log K against c_u is complicated by the number of assumptions made in the evaluation of log K. In the series of equations

$$\log K_0 = \frac{-\Delta F^\circ}{2.3026\ RT} = \log \frac{a_\pm^2}{a_u} = \log \frac{c_i^2}{c_u}\frac{\gamma_\pm^2}{\gamma_u} = \log k + 2A\sqrt{c_i} + Bc_u = \log K + Bc_u$$

the first three equalities result from definition, ΔF° being the free energy of formation of one mole of undissociated acid (HA) from one mole of positive ion (H^+) and one mole of negative ion (A^-) at infinite dilution in pure water. It will be noted that the use of the third equality requires a method of measuring c_i and c_u. In the construction of Table II it is assumed that c_i and c_u can be obtained validly from conductance data. The fourth equality involves definition of k, introduction of the Debye–Hückel limiting law and statement of the linear c_u effect, while the fifth is merely another definition. The constant "A" is calculated on the assumption that the dielectric constant of the solution is that of pure water.

The reasons that log K varies with the concentration may be grouped in three classes:

1. Improper interpretation of the conductance data. In the calculation of Λ_ϵ the effect of the presence of undissociated acid on the equivalent conductance of the dissociated portion of the acid, due to changes in viscosity and dielectric constant, has been neglected. Reliable measurements of the viscosity and dielectric constant of weak acid–water solutions are at present unavailable.

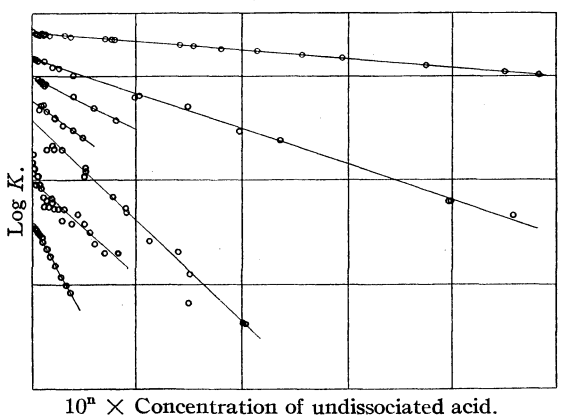

Fig. 3.—Log K *versus* c_u for aqueous solutions at 25° of: formic acid, acetic acid, propionic acid, chloroacetic acid, cyanoacetic acid, lactic acid, benzoic acid.

2. Errors introduced by use of the simplified form of the Debye–Hückel expression for the ionic activity coefficient. The authors have found that inclusion of extended terms in the Debye–Hückel relation does not improve the constancy of "K" but rather makes the deviations appear more complex. The error in the constant "A"

(caused by the assumption that the ion solvent is pure water, whereas it is really an aqueous solution of undissociated acid) is undoubtedly small.

3. Deviation of the activity coefficient of undissociated acid (γ_u) from unity. The determination of the activity coefficient of the undissociated portions of weak acids in a binary system, weak acid–water, according to the various possible experimental methods has not been investigated to any great extent. The activity coefficients of acetic acid from freezing-point lowerings show a rather pronounced maximum about 0.1 molal at 0°.[22,23] The effect in this region is complicated by the presence of a relatively large concentration of ions. Since the conductance data of MacInnes and Shedlovsky[4] on acetic acid (Fig. 3, second curve from top, covering the range up to 0.23 demal) show no such abnormality, it would seem either that conditions at 25° are significantly different from those at 0°, or that the interpretation of the freezing point measurements is erroneous, or that there is some compensating factor involved in the conductance data so that the maximum does not appear. Above 0.5 molal, freezing point data indicate an almost linear relationship between the activity coefficient of the undissociated portion of the acid and the molality (or any other common concentration function) for formic, acetic, propionic, and butyric acids.[21,22] Values of d log γ_u/dm at one molal obtained from freezing point measurements are compared in Table III with values of d log K/dc_u from conductance measurements at 25°, as shown in Fig. 3. Activity coefficients of weak acids in water from distribution experiments are not available at the present time, since the activity coefficients of these acids in solvents other than water are not known. The seemingly direct determination of activity coefficients from vapor pressure measurements is complicated by the polymerization of vapor acid molecules. In the case of acetic acid the extent of this polymerization has been investigated and the activity coefficients of undissociated acid in the aqueous phase, corrections being made for dimerization in the vapor phase, are tabulated in Landolt–Börnstein.[24] A plot of the log of these activity coefficients against the molality has a slope of about −0.12 at 1 molal. This compares favorably with d log K/dc_u read from the curve for acetic acid in Fig. 3 (−0.14). Similar data for formic acid are not available except at 80°, at which temperature the data in Landolt–Börnstein[24] yield a value for d log γ_u/dm of −0.007, which is considerably lower than d log K/dc_u read from the curve for formic acid in Fig. 3 (−0.035).

TABLE III

Acid	$-d \log \gamma_u/dm^{19}$ (freezing point)	$-\Delta \log \gamma_u/dm^{20}$ (freezing point, m = 0.2–0.5)	$-d \log \gamma_u/dm$ (vapor pressure)	$-d \log K/d c_u$ (conductance) 25°C.

Butyric	.094	..	..	.31

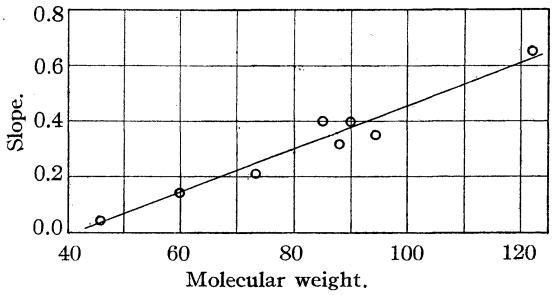

Fig. 4.—Slopes of (log K *versus* c_u) *versus* molecular weights of acids.

Hildebrand[25] has presented an equation relating the activity coefficient of one component of a "regular" binary solution to the mole fraction. At lower concentrations it reduces to the simple expression log $\gamma_2 = \alpha N_2$, in which the constant "α" is a function of the partial molal volumes and energies of vaporization of the two components. Since the ion concentrations are quite small at the higher concentrations of acids treated in this paper, the variation of activity coefficient of undissociated acid with concentration might be determined approximately from Hildebrand's equation by considering the solution to consist of two non-electrolytes, water and undissociated acid, forming "regular" solution. Unfortunately, "α" cannot be evaluated in the cases under consideration because of the polymerization of water and other departures from "regularity" as well as the uncertainty of the data available. However, it is interesting to observe that "α" and "B" have the same sign, and that, since the partial molal volumes are roughly in inverse order

of molecular weight for the acids considered, it would be expected on the basis of Hildebrand's equation that the "B"'s would be in the order of the molecular weights. This is in accordance with experimental finding, shown graphically in Fig. 4.

Summary

A method of extrapolating ionization constants determined by the conductance method has been suggested. The method consists of plotting the logarithm of the ionization constant, which includes the ion activity coefficient calculated by the Debye–Hückel limiting law, against the concentration of undissociated electrolyte. The validity of the method is based mainly on empirical evidence which indicates the linearity of such a plot up to high concentrations in the case of the organic acids considered.

The thermodynamic ionization constants of cyanoacetic, formic, and butyric acids in aqueous solution at 25° have been measured by the conductance method and found to be

Cyanoacetic acid	3.360×10^{-3}
Formic acid	1.825×10^{-4}
Butyric acid	1.518×10^{-5}

Polarographic Study of the Reduction of Chromate Ion at the Dropping Mercury Electrode

BY JAMES J. LINGANE AND I. M. KOLTHOFF

The purpose of this study was to investigate the reduction of chromate ions at the dropping mercury electrode by means of the polarographic technique.[1] The only previous study of the reduction of chromate at the dropping electrode is found in a recent paper of Thanheiser and Willems,[2] which appeared after the present investigation was begun. These authors studied the reduction of chromate only in sodium hydroxide medium, with particular reference to the polarographic determination of chromium in steel. We have investigated the reduction of chromate in unbuffered solutions and in the presence of buffers, as well as in strongly alkaline medium, and have discovered several new and interesting phenomena.

Experimental

The current–voltage curves (polarograms) were obtained and photographically recorded by means of a standard Heyrovsky polarograph.[1] Most of the polarograms were obtained by using an external saturated calomel electrode as anode, rather than the customary stationary pool of mercury on the bottom of the cell, in order to minimize contact of the chromate solutions with mercury. The H-cell and dropping electrode arrangement described by Lingane and Laitinen[3] was used. The cell was kept in a water thermostat at 25 ± 0.1°, and air was displaced from the solutions with nitrogen. Reagent grade chemicals and conductivity water were used in preparing all solutions.

In most of the experiments the pressure on the dropping mercury, hereinafter designated by h, was maintained at 72.0 ± 0.2 cm. of mercury. The amount of mercury flowing from the dropping electrode per sec. under a pressure of 72 cm. designated by m, was determined by the method already described.[1,4] Two different capillaries were used, for which the values of m were, respectively, 1.54 and 1.58 mg. sec.$^{-1}$ at h = 72 cm.

The drop time, in dilute potassium chloride solution with the dropping electrode disconnected from the polarizing e. m. f., was 4.2 ± 0.1 sec. The drop time occasionally became erratic, especially in neutral or slightly acid chromate solutions. This probably was caused by the wetting of the interior of the capillary by the chromate solution when the mercury thread retracts momentarily into the lumen after each mercury drop falls. This erratic behavior was eliminated by dipping the tip of the capillary into concentrated nitric acid, and then washing with water, while the mercury was issuing from the tip. The erratic dropping also could be eliminated by simply polarizing the dropping electrode cathodically for a few seconds at a potential of about −1.5 v.

The current-recording galvanometer of the polarograph was calibrated carefully by the method already described.[4]

Reduction of Chromate in Alkaline Medium.—In unbuffered solutions of potassium chromate, with potassium chloride as the supporting electrolyte, the c. v. curve of chromate consists of several waves as shown by curve 1 in Fig. 1.

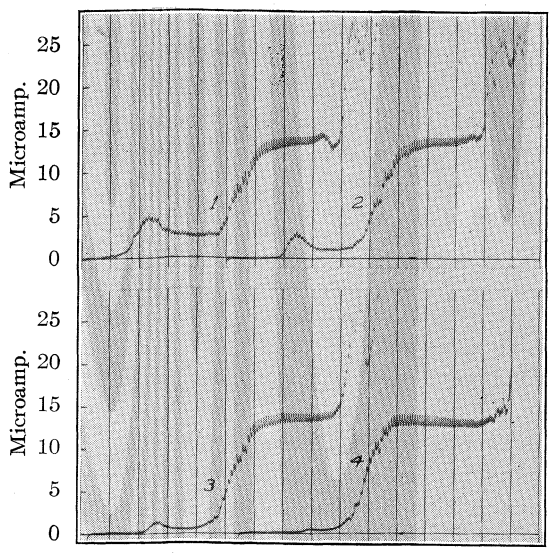

Fig. 1.—Current–voltage curves of 1.42×10^{-3} M potassium chromate in 0.1 N potassium chloride with various concentrations of sodium hydroxide: (1) no NaOH, (2) 0.002 N NaOH, (3) 0.013 N NaOH, (4) 0.2 N NaOH.

(In this and following polarograms, $E_{d.e.}$ signifies the potential of the dropping electrode against the saturated calomel electrode.) Addition of small amounts of sodium hydroxide to the solution decreases the first wave at −0.3 v., and it finally disappears when the concentration of sodium hydroxide is greater than about 0.2 N.

It will be noted that the height of the second wave at −1.0 v. is unaffected by the addition of sodium hydroxide, but the third ill-defined wave at −1.8 v. is, like the first wave, eliminated in 0.2 N sodium hydroxide.

C. v. curves of various concentrations of potassium chromate in 1 N sodium hydroxide as supporting electrolyte are shown in Fig. 2, and the corresponding values of the diffusion currents are given in Table I. The diffusion currents recorded in Table I have been corrected for the residual current that was obtained with the 1 N sodium hydroxide solution alone[1,4] (curve 1 in Fig. 2).

It will be noted that only one wave is obtained in 1 N sodium hydroxide solution, whose half-wave potential is at −0.85 v. *vs.* the S. C. E. The half-wave potential is practically constant and independent of the chromate concentration. The diffusion current is directly proportional to the concentration of chromate ions, as shown by the

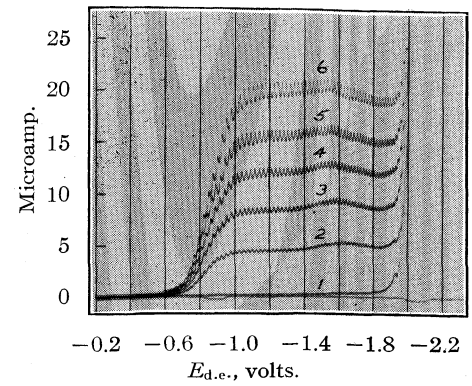

Fig. 2.—Various concentrations of potassium chromate in 1 N sodium hydroxide (see Table I).

TABLE I

RELATION BETWEEN THE DIFFUSION CURRENT AND THE CONCENTRATION OF CHROMATE IONS IN 1 N SODIUM HYDROXIDE

Diffusion currents measured at $E_{d.e.} = -1.2$ to -1.4 v. (see Fig. 2). $h = 72.1$ cm.; $m = 1.54$ mg. sec.$^{-1}$; $t = 3.36$ sec.; and $m^{2/3}t^{1/6} = 1.63$ mg.$^{2/3}$ sec.$^{-1/2}$ at $E_{d.e.} = -1.2$ v.

K_2CrO_4, millimoles per liter	i_d,[a] microamp.	i_d/C, microamp. per m mole per liter
0.473	4.35	9.20
0.901	8.40	9.33
1.298	12.00	9.25
1.667	15.52	9.32
2.100	20.08	9.55
		Av. 9.33 ± 0.09
Calcd. for $n = 3$ (Eq. 3)		9.66

[a] Corrected for the residual current.

satisfactory constancy of the ratio i_d/C given in the last column of Table I.

According to the Ilkovic equation the diffusion current should be given by [1,4]

$$i_d = 605nCD^{1/2}m^{2/3}t^{1/6} \text{ (microamperes)} \qquad (1)$$

where n is the number of faradays of electricity required per mole for the reduction, C is the concentration of the reducible substance in millimoles per liter, t is the drop time in sec., and D is the diffusion coefficient of the reducible substance in the units cm.^{2} sec.$^{-1}$. The general validity of this equation has been demonstrated in previous papers,[1,4] and it has also been shown that the effective diffusion coefficient of a reducible ion in the presence of an excess of supporting electrolyte can be calculated with satisfactory accuracy from the relation

$$D = \frac{RT\lambda_i^0}{zF_y^2} = 2.67 \times 10^{-7}\frac{\lambda_i^0}{z} \text{ (cm.}^2 \text{ sec.}^{-1}\text{)} \qquad (2)$$

where R, T, and F_y are, respectively, the molar gas constant, the absolute temperature, and the

faraday, λ_i^0 is the equivalent conductance of the reducible ion at infinite dilution and z is its valence. The equivalent conductance of the chromate ion at infinite dilution is 80.0 ohm^{-1} $cm.^2$, and hence from Eq. 2 its diffusion coefficient is 1.07×10^{-5} $cm.^2$ $sec.^{-1}$ at 25°.

Since the value of the product $m^{2/3}t^{1/6}$ for the capillary used to obtain the data in Table I was 1.63 $mg.^{2/3}$ $sec.^{-1/2}$ we find from Eq. 1 that the ratio i_d/C with this capillary should be a function of n according to

$$i_d/C = 3.22\ n \qquad (3)$$

The observed value of i_d/C from the data in Table I is 9.33 microamp. per millimole per liter, corresponding to $n = 3$. Hence in alkaline medium the reduction of $CrO_4^=$ ions at the dropping electrode takes place according to

$$CrO_4^= + 4H_2O + 3e \longrightarrow Cr(OH)_3 + 5OH^- \qquad (4a)$$

or

$$CrO_4^= + 2H_2O + 3e \longrightarrow CrO_2^- + 4OH^- \qquad (4b)$$

the latter reaction predominating in strongly alkaline medium in which the solubility of $Cr(OH)_3$ is appreciable.[5]

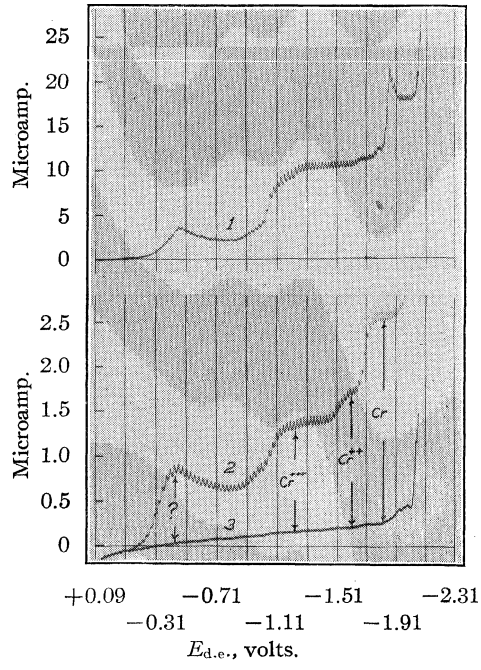

Fig. 3.—Increase of the relative height of the first wave with decreasing concentration of chromate in neutral unbuffered medium: (1) 1.10×10^{-3} M K_2CrO_4 in 0.1 N potassium chloride; (2) 1.19×10^{-4} M K_2CrO_4 in 0.1 N KCl; (3) residual current of 0.1 N KCl alone (see Table II).

(5) R. Fricke and O. Windhausen, *Z. anorg. allgem. chem.*, **132**, 273 (1924).

From the free energy data listed by Latimer[6] the reversible potentials for reactions 4a and 4b are, respectively, −0.37 v. and −0.42 v. in 1 N sodium hydroxide against the saturated calomel electrode. From the curves in Fig. 2 it is seen that the observed reduction potential is several tenths of a volt more negative than the reversible potentials, and hence the reduction of $CrO_4^=$ ions at the dropping electrode is irreversible and requires a considerable overvoltage in strongly alkaline medium.

Reduction of $CrO_4^=$ does not proceed farther than the +3 oxidation state in strongly alkaline medium apparently because the potential actually required for $CrO_2^- \longrightarrow Cr^{+2}$, or $CrO_2^- \longrightarrow Cr^0$, is more negative than the potential at which sodium ions are discharged.

Reduction of Chromate in Unbuffered Solutions.—It was thought at first that the first wave at −0.3 v. in unbuffered solutions of potassium chloride as supporting electrolyte might be due to the reduction of $CrO_4^=$ ions to some oxidation state between +6 and +3. However, this hypothesis is invalidated by the fact that *the relative height of the first wave in unbuffered medium increases markedly with decreasing concentration of chromate.* This is demonstrated by the polarograms in Fig. 3, and the diffusion current data in Table II.

TABLE II

DIFFUSION CURRENTS OF THE THREE WAVES OF CHROMATE IN UNBUFFERED 0.1 N POTASSIUM CHLORIDE SOLUTION AS A FUNCTION OF THE CHROMATE CONCENTRATION

The three diffusion currents were measured at potentials of −0.8 v., −1.4 v., and −1.9 v., respectively (see Fig. 3). h = 72.0 cm., m = 1.58 mg. $sec.^{-1}$, and $m^{2/3}t^{1/6}$ was equal to 1.71, 1.66, and 1.60 $mg.^{2/3}t^{-1/2}$ at the foregoing three potentials.

K_2CrO_4, millimoles per liter	i_d, microamp.[a] at voltages			i_d/C, microamp. per m mole. per liter at voltages

[b] Maxima present and diffusion current not well defined.

(6) W. M. Latimer, "The Oxidation States of the Elements and their Potentials in Aqueous Solutions," Prentice-Hall, Inc., New York, 1938.

With concentrations of chromate smaller than 0.001 molar the last wave at −1.8 v. becomes well-defined (compare curve 1 of Fig. 1 with curve 2 of Fig. 3). It will be shown later that this last wave is due to the complete reduction of chromate ions to metallic chromium.

With concentrations of chromate less than about 2×10^{-4} M a fourth wave appears at −1.5 v. (curve 2, Fig. 3). The total diffusion current at −1.6 v. is very close to 4/3 the diffusion current at −1.3 v., and hence it corresponds to the reduction of chromate ion to chromous hydroxide according to

$$CrO_4^{=} + 4e + 4H_2O \longrightarrow Cr(OH)_2 + 6OH^- \qquad (5)$$

This same conclusion follows by application of the Ilkovic equation. The value of m for the capillary used to obtain the curves of Fig. 3 was 1.58 mg. sec.$^{-1}$ and t was equal to 3.00 sec. at $E_{d.e.} = -1.6$ v. Hence the product $m^{2/3}t^{1/6}$ was 1.63 mg.$^{2/3}$sec.$^{-1/2}$, and from Equations (1), (2) and (3) the calculated ratio of i_d/C for $n = 4$ is 12.9 microamp. The concentration of chromate used to obtain curve 2 of Fig. 3 was 0.119 mmoles per liter and the observed (corrected) diffusion current was 1.50 microamp. Hence the observed ratio of i_d/C is 1.50/0.119 = 12.6 microamp., in good agreement with the calculated value for $n = 4$.

In Table II are listed the data obtained for the diffusion currents, corresponding to the three waves at −0.3 v., −1.0 v., and −1.8 v., of various concentrations of potassium chromate in unbuffered 0.1 N potassium chloride solution. The diffusion currents have been corrected for the residual current obtained with the 0.1 N potassium chloride solution alone.[1,4] The observed ratios of i_d/C for each of the three waves are listed in the last three columns, and the values of this ratio calculated from Eq. 1 for $n = 3$ and $n = 6$, respectively, are given at the bottom of the last two columns.

It will be noted that the diffusion currents of the second and last waves are directly proportional to the concentration of chromate, and the average values of i_d/C correspond very closely to values for n of 3 and 6, respectively. Hence the second wave is due to the reduction $CrO_4^{=} \longrightarrow Cr(OH)_3$, as in alkaline medium (Eq. 4), and the last wave corresponds to the complete reduction of $CrO_4^{=}$ ions to metallic chromium, according to the equation

$$CrO_4^{=} + 6e + 4H_2O \longrightarrow Cr^0 + 8OH^- \qquad (6)$$

It will be noted that the ratio of i_d/C for the first wave was not constant, but increased with decreasing concentration of chromate. It should also be mentioned that the peculiar rounded maximum shown by the first wave was neither suppressed by methyl red nor by gelatin. It is evident, from this fact, that the maximum is not a typical "adsorption" maximum,[1] but is due to some other cause.

In 1 N potassium chloride solution the first wave is well defined and does not show a maximum. However, just as in 0.1 N potassium chloride solution, the relative height of the first wave increases markedly with decreasing concentration of chromate.

When a relatively small concentration of a magnesium salt is added to a chromate solution in 0.1 N potassium chloride, the c. v. curve shows only a single wave starting at about −0.3 v., but the diffusion current is not well defined and it increases continuously with increasing applied e. m. f. This peculiar effect of magnesium ions is demonstrated in Fig. 4.

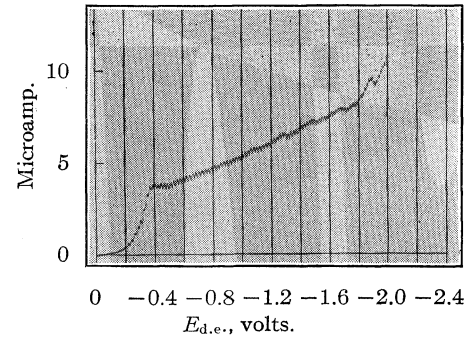

Fig. 4.—Influence of magnesium ions on the c. v. curve of chromate: 1.10×10^{-3} M K_2CrO_4 in 0.1 N KCl plus 0.01 M $MgCl_2$.

Reduction of Chromate in Buffered Solutions.—Typical c. v. curves of chromate reduction in two ammonia–ammonium chloride buffers of the same pH (8.7) but of different buffer capacity are shown in Fig. 5. Curve 1 was obtained with a 0.005 N and curve 2 with a 0.05 N buffer, and an excess of potassium chloride (0.1 N) was present in both cases. The most pronounced effect of the buffer was that it caused the first and second waves to coalesce into a single wave at −0.2 v. In the more concentrated buffer, the height of this wave corresponds to an n-value of 3 and hence reduction of chromate to chromic ions. The last wave at −1.6 v.

corresponds to the reduction of chromate ions to metallic chromium, as shown by the fact that the diffusion current corresponds to the value calculated from the Ilkovic equation for $n = 6$.

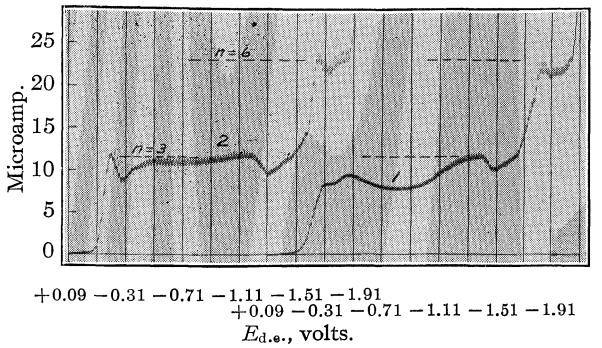

Fig. 5.—1.21 × 10^{-3} M K_2CrO_4 in 0.1 N KCl plus (1) 0.005 N NH_4Cl–NH_4OH buffer of pH 8.7, (2) 0.05 N NH_4Cl–NH_4OH buffer of pH 8.7. The short horizontal dotted lines indicate the diffusion currents calculated from the Ilkovic equation for values of n of 3 and 6, respectively.

From Eq. 4 it is evident that the concentration of hydroxyl ions formed at the electrode surface by the reduction will be between four and five times larger than the chromate ion concentration, depending on whether CrO_2^- or $Cr(OH)_3$ is formed. Hence in the reduction of the 1.21 × 10^{-3} M chromate solution, the concentration of hydroxyl ions liberated at the electrode surface was between about 0.005 and 0.006 N, when the diffusion current was reached. With the most dilute ammonium chloride–ammonia buffer (0.005 N, curve 1) the buffer capacity was not great enough to prevent a considerable change in the pH at the electrode surface, and this accounts for the fact that curve 1 has a shape intermediate between that of a c. v. curve in a completely unbuffered potassium chloride solution (compare Fig. 3) and that in a well-buffered ammonium chloride–ammonia solution. There was no significant change in the shape of the c. v. curve with increasing concentration of the ammonium chloride–ammonia buffer between 0.05 and 1 N.

The characteristics of the c. v. curve were also practically the same in various ammonia–ammonium chloride buffers of constant ammonium chloride concentration (0.1 N) but of different pH values between about 7.5 and 10. The reduction potential of the first wave was only shifted by a few hundredths of a volt, from −0.10 to −0.17 v., when the pH of a 0.1 N ammonium chloride–ammonia buffer was varied from 8 to 10. C. v. curves of 0.001 molar potassium chromate in 0.1 N ammonium chloride as supporting electrolyte (pH about 5) were similar to curve 2 in Fig. 5, except, as was to be expected, the reduction began at a more positive potential (+0.1 v.) and the slope of the first wave was smaller. The smaller slope was undoubtedly due to the poor buffer capacity of the pure ammonium chloride solution, and the consequent change in pH at the electrode surface with increasing current.

We also investigated the effect of diethylammonium chloride–diethylammonium hydroxide buffers of various pH values. Since the dissociation constant of diethylamine, 1.3 × 10^{-3}, is about one hundred times larger than that of ammonia it was possible to study the c. v. curves in these buffers up to a pH of about 12, and compare the characteristics of the curves with those obtained in dilute (*ca.* 0.01 N) sodium hydroxide solutions of about the same pH. The characteristics of the c. v. curve of chromate in a 0.1 M diethylammonium chloride–diethylammonium hydroxide buffer at a pH of about 10 are practically the same as those in an ammonium chloride–ammonia buffer of the same pH. At a pH of 10 only two waves were obtained at −0.35 v. and −1.8 v., as shown in Fig. 6. However, as the

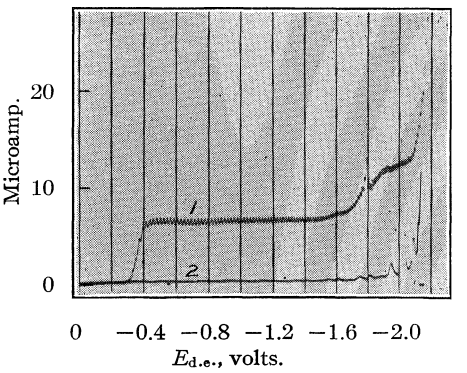

Fig. 6.—(1) 7 × 10^{-4} M potassium chromate in 0.1 M diethylammonium chloride–diethylamine buffer of pH 10.2. (2) Residual current of buffer alone.

pH was shifted from 10 to 12 the reduction potential of the first wave ($CrO_4^= \longrightarrow Cr^{+++}$) was shifted markedly from −0.35 v. to −1.1 v., and the second wave at −1.8 v. ($CrO_4^= \longrightarrow Cr$) disappeared at a pH of 12. At a pH of 12 in a diethylammonium chloride–diethylamine buffer the c. v. curve showed only a single wave which closely resembled the single wave in dilute solutions of sodium hydroxide, both in the magnitude

of the diffusion current and the value of the reduction potential. There was also a slight indication of a "pre-wave" in the diethylammonium chloride–diethylamine buffers of *p*H 11 and 12, just as in the dilute sodium hydroxide solutions.

In a 0.1 *N* solution of borax in 0.1 *N* potassium chloride (*p*H about 9) only a single well-defined wave was obtained at −0.3 v., and the diffusion current corresponded to $CrO_4^{=} \longrightarrow Cr^{+++}$. There was some indication of a second wave at −1.8 v., about twice as large as the first wave, but it was not well defined.

Discussion

The most interesting phenomenon observed in the reduction of chromate at the dropping electrode is the first wave at −0.3 v. in unbuffered solutions (Fig. 1 and Fig. 3). The most logical explanation of this wave appears to be that it is due to the reduction of $CrO_4^{=}$ ions, but that its height does not correspond to $n = 3$ because of the formation of a film of either chromic hydroxide, or basic chromic chromate, at the electrode surface which interferes with the further reduction.

The formation of basic chromic chromate at solid cathodes, presumably as a stable film impervious to chromate ions, is the usual explanation given to account for the low current efficiency in technical chromium plating.[7] According to Müller and Ekwall[8] the formula of the chromic chromate precipitated at a platinum or carbon cathode is $Cr_2(OH)_4CrO_4$, or $Cr(OH)_3 \cdot CrOH\text{-}CrO_4$. A variety of different "chromic chromates" probably can be formed depending on the experimental conditions, particularly the *p*H at the electrode surface.

Quantitative interpretation of the first wave in the present experiments, and the effect of *p*H on the reduction potential, is not possible at the present time because the detailed mechanism of the reduction is unknown. In this connection it should be emphasized that Equations 4a and 4b are intended to represent merely the *net* reaction, and not the actual mechanism of the reduction.

Qualitatively, however, the observed effects indicate that the formation of a film on the surface of the mercury drops increases the overvoltage necessary to obtain complete reduction of $CrO_4^{=}$ to Cr^{+3}. In neutral unbuffered solutions complete reduction to the +3 state does not start until a potential of about −1.0 v. is reached. When sodium hydroxide is added to the solution the first wave is decreased and shifted to a more negative value, but the second wave ($CrO_4^{=} \longrightarrow Cr^{+3}$) is shifted to a more positive value, and in 1 *N* sodium hydroxide solution it starts at about −0.7 v. (Fig. 1 and Fig. 2). Apparently the film of basic salt is not formed in strongly alkaline solution, because the chromic chromium remains in solution as chromite ion (CrO_2^{-}).

There seems to be a critical range of hydroxyl ion concentration in which the film formation occurs, which is to be expected from the amphoteric nature of the chromic ion. Apparently the film does not form in buffer solutions of *p*H less than 10 or 10.5, since in such solutions the height of the wave corresponds to $n = 3$. Under the present experimental conditions, the film appears to be stable only over a *p*H range from about 10.5 to 13 or 13.5.

In alkaline buffers the reduction potential shifts to more negative values with increasing *p*H, but the interpretation of the shift is complicated by the fact that it depends on the kind of buffer used as well as on the *p*H.

Summary

The reduction of chromate at the dropping electrode has been investigated in neutral unbuffered solutions, in buffer solutions of *p*H between 8 and 12, and in strongly alkaline medium.

With 1 *N* sodium hydroxide as supporting electrolyte the current–voltage curve consists of only a single well-defined wave, with a half wave potential of −0.85 v. *vs.* the saturated calomel electrode which is independent of the concentration of chromate. The height of the wave, which is directly proportional to the chromate concentration, corresponds to the reduction of $CrO_4^{=}$ to the +3 oxidation state (CrO_2^{-} in strongly alkaline medium).

In unbuffered solutions of potassium chloride the c. v. curve consists of four distinct waves at −0.3 v., − 1.0 v., −1.55 v., and −1.8 v., *vs.* the S. C. E. It was shown that the last three waves correspond, respectively, to $CrO_4^{=} \longrightarrow Cr^{+3}$, $CrO_4^{=} \longrightarrow Cr^{+2}$, and $CrO_4^{=} \longrightarrow Cr$. From the fact that the *relative* height of the first wave at −0.3 v. increased markedly with decreasing concentration of chromate, it was concluded that this wave was not due to the reduction of

$CrO_4^=$ to some oxidation state between +6 and +3, but that the limiting current is governed by the formation of a film of chromic hydroxide, or basic chromic chromate, at the electrode surface, which interfered with the further reduction. When the solution was well-buffered at a *p*H between 8 and 10 the diffusion current at −0.3 to −0.4 v. corresponded to the reduction $CrO_4^= \longrightarrow Cr(OH)_3$. Apparently the film of basic salt is only stable under the conditions of the present experiments over a *p*H range from about 10.5 to 13.5.

From an analytical viewpoint, 1 *N* sodium hydroxide is the most suitable supporting electrolyte for the polarographic determination of chromate.

Ternary Systems. XXIV. Some Further Solid Solutions of Alums, at 25°[1]

BY ARTHUR E. HILL, NORMAN O. SMITH AND JOHN E. RICCI

This is a report of experiments continuing an investigation, conducted in this Laboratory, of ternary systems involving the formation of solid solutions between isomorphous double salts in equilibrium with aqueous solution. The general purpose of the investigation is the accumulation of reliable data on which to base, ultimately, speculations on the formation of solid solutions between such salts. In this respect it has been of interest especially to study the distribution of the two salts between the conjugate liquid and solid solutions, and to attempt to relate this distribution with the aqueous solubilities of the individual salts. On the basis of results, already published, on the formation of such solid solutions in a series of picromerites, studied as ternary systems of pairs of double salts with water,[2a] and in a number of alum pairs,[2b] an empirical equation has already been suggested[2a] for the relation between the mole fraction of a component in the liquid phase and its mole fraction in the solid phase; the degree of success toward a theoretical interpretation of the observed relation will be presented in a forthcoming publication from this Laboratory, making use of the present and additional data collected on this type of system.

Alums crystallize as regular octahedra and provided the lattice dimensions be not greatly different they would be expected to form solid solutions with one another. Early work with alums had been done by Hollmann[3] with the alum pairs $KFe(SO_4)_2$–$KAl(SO_4)_2$ and $KCr(SO_4)_2$–$KAl(SO_4)_2$, and by Fock[4] with the pair $KAl(SO_4)_2$–$TlAl(SO_4)_2$. In addition Hill and Kaplan[2] have studied the pairs $NH_4Al(SO_4)_2$–$KAl(SO_4)_2$, $NH_4Fe(SO_4)_2$–$NH_4Al(SO_4)_2$ and $NH_4Al(SO_4)_2$–$NaAl(SO_4)_2$. Complete miscibility between the alums was found in all these pairs studied, with the exception of the last mentioned, the sodium alum–ammonium alum pair, which formed no solid solution at all at the temperature of the measurements, 25°. The present paper describes similar measurements for the following pairs of alums in equilibrium with aqueous solutions at 25°: $TlAl(SO_4)_2$–$NH_4Al(SO_4)_2$, $TlAl(SO_4)_2$–$KAl(SO_4)_2$, $NH_4Cr(SO_4)_2$–$KCr(SO_4)_2$ and (partially) the pair $NH_4Fe(SO_4)_2$–$KAl(SO_4)_2$; complete miscibility was found to prevail for all these pairs at the temperature studied. Included also in this report is the ternary system for the formation of thallium alum from its component salts and water at 25°. This was desirable in view of the fact that thallium alum was to be prepared for use in solid solutions with other alums.

As has been emphasized in the preceding papers of this series, the present measurements are distinguished by the fact that special attention has been given to the question of attainment of equilibrium, inasmuch as the uncertainty about equilibrium generally vitiates the older results on the solubilities of such mixed salts. The procedure followed, for this purpose, already has been described,[2] the essential point being that

[a] n is probably 17.

equilibrium is approached, for every solubility determination, from opposite sides as follows. Complexes are made up in duplicate from weighed amounts of the two alums and water in 50-ml. glass-stoppered solubility tubes and brought to equilibrium by rotation in a thermostat at 25 ± 0.02°; each solubility tube also contained two glass marbles which by their rolling motion kept the solid phases well ground. Following the usual procedure the duplicates differed only in the order of addition of the components, so that in one tube one of the two alums was dissolved completely and the second then added in solid form; in the duplicate tube the order of addition of the salts was reversed. Agreement between the duplicates upon analysis of the liquid and solid phases after rotation is proof that the measurements represent equilibrium, a factor of prime importance for our ultimate purpose.

Thallium Alum at 25°.—Complexes were made up from weighed amounts of recrystallized Eimer and Amend thallous sulfate, Merck hydrated aluminum sulfate and water. The thallous sulfate was found to be 99.61% pure by precipitation as the chromate. The composition of the aluminum salt, as a result of efflorescence, did not correspond exactly to that of a single hydrate, being always somewhat less hydrated than the usually accepted formula $Al_2(SO_4)_3 \cdot 18H_2O$; the analytically determined composition was therefore always used in calculating the compositions of the complexes. We may point out that similar observations on the low hydration of aluminum sulfate (low compared to the formula $Al_2(SO_4)_3 \cdot 18H_2O$) were being made at the same time by Horan and Skarulis,[5] who in fact offer serious evidence for doubting the usually accepted value for the hydration, and suggest the possibility of the formula $Al_2(SO_4)_3 \cdot 17H_2O$ for the hydrate in equilibrium with solution at 0°. Although it seems likely, on the basis of the work of Horan and Skarulis and of further investigations now being conducted by one of us (Dr. N. O. Smith), that the formula may be $Al_2(SO_4)_3 \cdot 17H_2O$, we are temporarily not assigning any definite formula to this hydrate in the present paper. Similar uncertainty exists for the degree of hydration of the corresponding chromic sulfate, for which the hepta-decahydrate formula also has been suggested.[6]

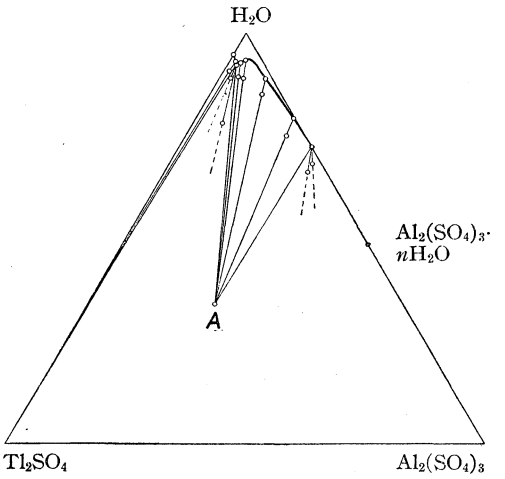

Fig. 1.—The system Tl_2SO_4–$Al_2(SO_4)_3$–H_2O at 25°; A = $TlAl(SO_4)_2 \cdot 12H_2O$.

Solubility equilibrium was found to be reached in this simple system within twenty-four hours, provided that the thallous sulfate was dissolved in the water before the addition of the aluminum sulfate. Only the liquid phases were analyzed. Thallium was determined volumetrically by the method of Zintl and Rienäcker[7] in which thallous ion is oxidized to thallic ion by standard bromate in 5% hydrochloric acid solution at 80° using methyl orange as indicator. In order to determine aluminum it was necessary first to remove thallium by precipitation as the sulfide in hot solution made alkaline with sodium hydroxide to retain the aluminum. After removal of sulfur the fil-

trate was analyzed for aluminum by precipitation with 8-hydroxyquinoline according to the gravimetric method of Kolthoff and Sandell.[8]

Table I shows the results, which are plotted in Fig. 1. The solubilities listed for the pure salts, thallous sulfate and hydrated aluminum sulfate, are averages from closely agreeing measurements from both under- and super-saturation (these approaches to equilibrium are marked U and S, respectively, in this and subsequent similar tables). That for thallous sulfate, 5.213%, is in good agreement with the figures of Berkeley[9] (5.21% by interpolation), and of Noyes and Stewart[10] (5.22%); the figure for the aluminum salt, 27.86%, is in fair agreement with the determinations of Poggiale[11] (27.6%), Wirth[12] (27.82%), Britton[13] (27.70%) and Hill and Kaplan[2] (27.39%). The solid phase over the greater part of the diagram is shown by algebraic extrapolation[14] to be the hydrated double sulfate, thallium alum, and the small average absolute deviation (= 0.24%) between the extrapolated and the theoretical percentage of thallous sulfate in the solid phase is indicative of the experimental accuracy. The solubility curve of the hydrated aluminum sulfate as solid phase is of course too short to be represented on the diagram. Inspection of the figure shows that at 25° the alum is congruently soluble to an extent of about 7% of anhydrous salt (see also Table II).

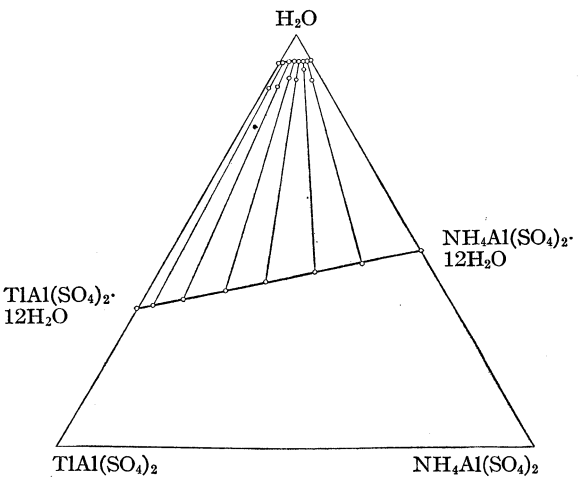

Fig. 2.—The system $TlAl(SO_4)_2$–$NH_4Al(SO_4)_2$–H_2O at 25°.

Thallium Alum, Ammonium Alum, Water at 25°.—Inasmuch as an attempt will be made to relate the distribution of the isomorphous salts between aqueous and crystalline phases, to the molar solubilities, this particular alum pair is of special interest because of the considerable difference in the molecular weights of the pair. Both alums were prepared by mixing solutions of equimolecular quantities of the component salts (analyzed grades) at about 60° and allowing the solution to cool with prolonged stirring. In the case of the ammonium alum this procedure gave a product of composition corresponding to the theoretical value. The thallium alum so prepared, however, as if, apparently, incongruently soluble at higher temperatures, was contaminated with excess thallous sulfate; this difficulty was therefore overcome by returning the crystals to the mother liquor, adding a considerable excess of aluminum sulfate, heating to dissolve the solid, and cooling with stirring for twenty hours. The solubilities of the individual alums were determined from under- and super-saturation

and the complexes were made from the two alums and water in duplicate as described above. In Table II the complexes marked A were made with thallium alum and those marked B with ammonium alum as the original solid phase. After two or three weeks in the thermostat both liquid and solid phases were analyzed for thallium (volumetrically as described above) and for ammonium by distilling the ammonium liberated by potassium hydroxide into standard acid and titrating the excess acid with standard base. The solid phases were centrifuged and air-dried before being analyzed. The results of analysis are shown in Table II and plotted in Fig. 2.

For comparison with the solubility here reported for thallium alum at 25°, 6.989%, we note that Fock[4] gives 7.07%, Locke[15] 6.97% and Berkeley,[9] by interpolation, 7.19%. The solubility of ammonium alum, 6.15%, which is an average (from both under- and super-saturation) of both ammonium and aluminum analyses, is in satisfactory agreement with the recent determination of Hill and Kaplan,[2] 6.19%. The fact that the ternary results from the duplicate tubes (A and B) are in agreement is proof that they are results at equilibrium. Figure 2 shows that the two alums form a complete series of solid solutions, and the directions of the tie-lines indicate that the concentration of ammonium alum in the liquids (neglecting water content) is always greater than that in the conjugate solids. The over-all accuracy of the analytical procedure was again checked by extrapolating algebraically the tie-lines joining the compositions of the original complexes and the liquid solutions, to the straight line on the diagram joining the points representing the single alums; the average absolute deviation between the observed and the extrapolated compositions of the solid phases was only 0.19%.

Thallium Alum, Potassium Alum, Water at 25°.—This system is one already studied by Fock[4] but as his analyses appear to be of doubtful accuracy it was thought desirable to repeat the work. It may be observed that thallium alum and potassium alum have very similar solubilities by weight but quite different solubilities in molar units, a fact of some interest in connection with interpreting their behavior ultimately.

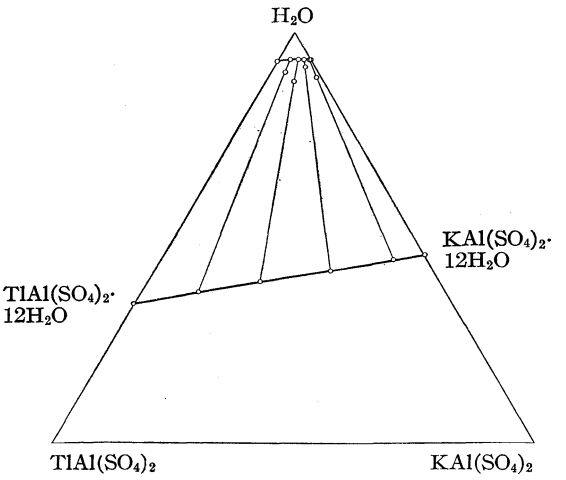

Fig. 3.—The system $TlAl(SO_4)_2$–$KAl(SO_4)_2$–H_2O at 25°.

The complexes were made up in duplicate according to the procedure for the preceding system, the A tubes (Table III) having thallium alum and the B tubes potassium alum present as the initial solid phase. The potassium alum used was recrystallized Baker Analyzed material. After four weeks rotation in the thermostat the equilibrium liquids and solids were analyzed for both thallium and aluminum as described above, the solids being first centrifuged and air-dried. Table III gives the resulting data, which are shown graphically in Fig. 3.

The solubility of potassium alum here reported (6.58%) is again in close agreement with the determination of Hill and Kaplan[2] (6.60%). As shown in Fig. 3, the two alums are completely mutually soluble, the proportion of potassium alum being greater in the liquids than in the conjugate solids, concentrations being on the dry basis. When Fock's figures for this isotherm are plotted on such a triangular diagram, the liquid curve shows considerable irregularity.

The internal agreement in the present data can again be judged by the small average absolute deviation (of only 0.09%) between the extrapolated and the observed compositions of the solid phases.

Ammonium Chrome Alum, Potassium Chrome Alum, Water at 25°.—Hydrated chromic salts in general are known to exist in both violet and green forms, but in the case of the (solid) chrome alums only the violet forms appear to have been prepared. A solution of the violet form becomes green on heating, and there is evidence[16,17] that an equilibrium exists in the liquid between the dissolved violet and green forms. In the determinations of the solubility of a chrome alum an abnormally long time is required for complete equilibrium to be reached, the reason for this undoubtedly being related to the additional equilibria involved.

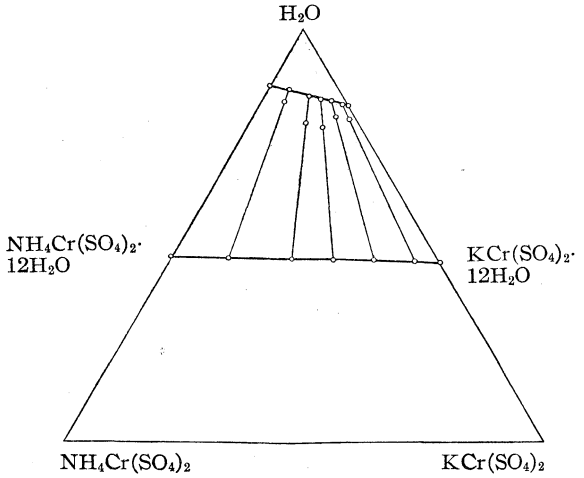

Fig. 4.—The system $NH_4Cr(SO_4)_2$–$KCr(SO_4)_2$–H_2O at 25°.

(17) Koppel, *Ber.*, **39**, 3738 (1906).

Baker and Adamson chemicals were used in the present work. After recrystallization from water (maximum temperature 60°) the alums were dried in a desiccator over the corresponding partly dehydrated salts. Analysis of the ammonium chrome alum for both ammonium and chromium content showed agreement with theory. The potassium chrome alum, as a result of efflorescence, changed slightly in composition during the preparation of the complexes; this change was taken into consideration in the calculation of the composition of the original complexes listed in Table IV. The complexes were made up in duplicate as already described, the A tubes with potassium chrome alum and the B tubes with ammonium chrome alum as the original solid. Three months of rotation in the thermostat was necessary for equilibrium to be reached as shown by successive analyses of tubes containing the separate alums and water when their single solubilities were being determined from under- and from super-saturation. At the end of such a period of rotating, both the liquid and the solid phases were analyzed for ammonium and chromium content, the former by the ammonia distillation method and the latter by oxidation to chromate with sodium peroxide followed by reduction with iodide and titration with thiosulfate.[18] The solids were centrifuged and air-dried for a short time before analysis. The results are given in Table IV and shown graphically in Fig. 4.

Our figure for the solubility of ammonium chrome alum (13.66%) is in agreement with the value of 13.2% interpolated from Koppel's data[17] but very far from that of Locke[15] (9.63%), whose measurements were made after only a few hours. Locke's figure for potassium chrome alum (11.01%) is subject to the same error, and is consequently very different from the solubility here reported, of 18.78%. As the diagram shows, the alums of this system are completely miscible in the solid state, and again the proportion of the potassium alum in the liquids is seen always to exceed that in the conjugate solids, provided concentrations are taken on the dry basis. average absolute deviation between the analytical and the extrapolated compositions of the solid phases in this system was 0.37%.

Ferric Ammonium Alum, Potassium Alum, Water at 25°.—This pair of alums, not containing a common cation, constitutes with water a quaternary system, but only that portion of the system was examined where the total compositions can be expressed in terms of the two alums and water. The complexes were again made up in duplicate from weighed amounts of potassium alum (recrystallized Baker Analyzed), ferric ammonium alum (recrystallized Baker and Adamson) and water, as in the preceding systems. As in the case of potassium chrome alum mentioned above, the composition of the ferric ammonium alum changed during manipulation as a result of efflorescence, and a correction for the change was applied in calculating the compositions of the complexes, by means of a time extrapolation. After one month of rotation in the thermostat, both liquid and solid phases were analyzed, as follows, for ammonium, iron and total iron and aluminum: for ammonium by the ammonia distillation method, for iron by the Zimmermann–Reinhardt reduction followed by titration with standard ceric sulfate, for combined iron and aluminum by the simultaneous precipitation of both cations by 8-hydroxyquinoline.[8,19] The accuracy of the latter procedure was found to be satisfactory by preliminary tests.

These determinations are sufficient for the determination of the complete composition of the phases, provided it can be assumed that in any phase the number of moles of trivalent sulfates equals the number of moles of univalent sulfates, whereupon the remaining constituents can be calculated. This assumption is justified so long as the system remains quaternary, or so long as no hydrolytic products are formed. Actually a very small amount of a finely-divided insoluble solid was formed in all the tubes. This was probably a basic iron complex, but being present in such small quantity it was not analyzed. The liquids were analyzed without interference by waiting long enough for the settling of all solids, before sampling. The main solid phase itself was also easily obtained free of this hydrolytic precipitate because the latter passed through the finest filter paper, so that the main solid was washed free of it by the supernatant liquid. The main solid phases were sucked dry on filters and analyzed while moist.

The results are presented in Table V, in which the A complexes began with ferric ammonium alum and the B complexes with potassium alum as the only solid. The figure for the solubility of ferric ammonium alum (31.20%), which is the average of both iron and ammonium analyses, is slightly higher than the reports of Locke[15] (30.7%) and of Hill and Kaplan[2] (30.85%).

The analytical results are shown calculated in terms of the three alums ammonium–iron, potassium–aluminum, and potassium–iron; the difference, water, is shown, for the solid phases, in the last column, as moles of water per mole of total double sulfate in the solid. The agreement of these figures with the theoretical number 12 required for alums supports the assumption that the solids are all quaternary solid solutions or mixed alums. The internal consistency of the results was further checked by methods of algebraic extrapolation,[14] in which by assuming the theoretical alum hydration for the solids, any one of the three percentages listed under "the solid phase" could be calculated by extrapolation, for comparison with the observed value. The average error found, testing all three columns, was only 0.37%. In these averages, however

tubes 2A and 2B were not included; these two tubes were found to contain considerably more of the above-mentioned hydrolytic precipitate than any of the other complexes. The very same method of algebraic extrapolation, however, showed that even in this case the main solid phase was evidently quaternary, although the basic solid and consequently also the liquid solution must be of higher order. Extrapolation further indicated that the basic solid contained neither ammonium nor aluminum.

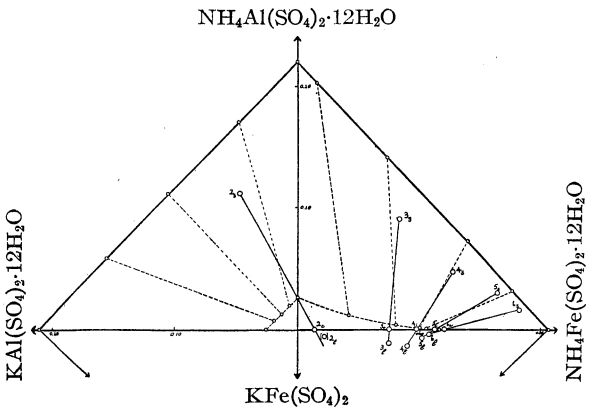

Fig. 5.—Part of the system $KAl(SO_4)_2$–$NH_4Fe(SO_4)_2$–H_2O at 25°. Units: moles of salt per 100 g. of mixture or phase. Subscripts l, c, s denote liquids, complexes and solids, respectively.

The data of Table V were recalculated, using the averages for the duplicate tubes, to moles per 100 g. of mixture, and listed as such in Table VI. Using the graphical method of extrapolation for such reciprocal quaternary systems of Ricci and Loucks[20] the results, in these units, are plotted in Fig. 5, which is a projection on the base of the isothermal tetrahedral pyramid model for the quaternary system. The points are numbered in accordance with the table. It may be pointed out, in elucidation of the figure, that inasmuch as the original complexes were made up from water and the two alums $KAl(SO_4)_2$ and $NH_4Fe(SO_4)_2$, the compositions of the complexes all fall, in this projection, on the horizontal axis connecting these alums. The units of the diagram are moles of the respective salts per 100 g. of mixture (including water), the water being plotted, in the solid model, on a vertical axis perpendicular to the base pictured, at the intersection of the axes joining the reciprocal alums. The ends (not shown) of the four horizontal axes would represent the number of moles of the respective (anhydrous) alums in 100 g. of the pure salt. The dashed curves and tie-lines show the results of Hill and Kaplan on two of the ternary systems making up the main quaternary system. If the complete quaternary system were to be studied, the isothermal model, except for regions of quinary behavior, would probably consist of two surfaces bounded by four edges, the one a curved surface representing liquid and the other also a curved surface representing the saturating solid solutions. The data of Hill and Kaplan, in Fig. 5, therefore give two edges of each surface, and our data some points on these surfaces. Point 2 is in doubt for reasons stated above. Further information concerning the trend in direction of the tie-lines, and general relations between the liquids and the solids in the quaternary system, was obtained by projecting the points and lines of the solid model onto the two diagonal planes of the pyramid passing through

the vertical water axis; these projections however are not shown, for reasons of space-saving. Some of the significant aspects of the distribution of the salts between the liquid and solid phases, however, are shown below, together with similar information on the simpler systems studied.

Distribution between Liquid Solution and Solid Solution.—In order to interpret some of the above data in terms of the Roozeboom[21] classification of solid solutions, the concentrations have been recalculated into mole fractions of the two alums, disregarding water, in the two phases. The results, showing for each system the mole fraction of the more soluble alum, are listed in Table VII, and are plotted in Fig. 6, where the Y values represent the mole fraction of the more soluble alum in the liquid phase and X its mole fraction in the solid phase.

All three ternary systems studied apparently belong to Class I of Roozeboom's classification, in which there is complete miscibility in the solid phase and in which one of the components is present in higher proportion in the liquid than in the conjugate solid phase throughout the series of solid solutions. It is conceivable of course that this relation may not hold true at the extreme edges of the diagram, for which there are no data, but in the light of further theoretical work not yet published such a possibility appears unlikely These curves, it may be noted, all follow the equation previously suggested, $y = x^m$, with m a constant for each system. For the present we observe merely that the component present in greater concentration in the liquid than in the solid is that component with the greater aqueous molar solubility; for example, though ammonium and potassium alums both have smaller weight solubilities than thallium alum, their molar solubilities

(21) Roozeboom, *Z. physik. Chem.*, **8**, 521 (1891); **30**, 385 (1899).

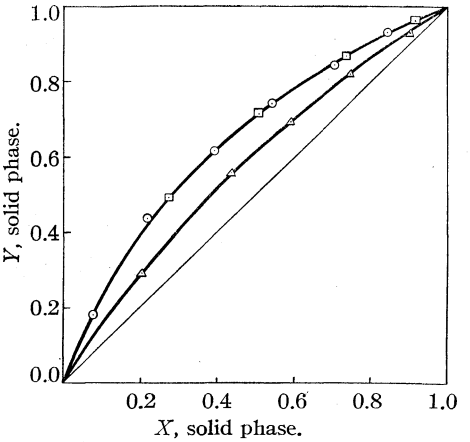

Fig. 6.—Distribution of alums between liquid solution and solid solution at 25°: circles, ○, $TlAl(SO_4)_2$–$NH_4Al(SO_4)_2$; squares, □, $TlAl(SO_4)_2$–$KAl(SO_4)_2$; triangles △, $NH_4Cr(SO_4)_2$–$KCr(SO_4)_2$.

are much greater, a fact to be taken into account in considering the observed distribution.

Similar (partial) calculations are shown in Table VIII, for part of the quaternary system $NH_4Fe(SO_4)_2$–$KAl(SO_4)_2$–H_2O. The table lists the number of moles of $^1/_2K_2SO_4$ and $^1/_2Fe_2(SO_4)_3$ per mole of total double sulfate in both liquid solutions (Y) and solid solutions (X). Although these figures may be interpreted as indicating that the proportion of potassium alum (ferric

or aluminum) is greater in the liquid than in the solid solutions, and the same for (potassium or ammonium) ferric alum, the results do not of course have the significance of those shown above in Table VII and Fig. 6, since Roozeboom's classification applies only to ternary systems.

Summary

1. The system Tl_2SO_4–$Al_2(SO_4)_3$–H_2O has been studied at 25° and the isotherm found to consist of the three solubility curves of Tl_2SO_4, $TlAl(SO_4)_2 \cdot 12H_2O$, and $Al_2(SO_4)_3 \cdot nH_2O$, respectively (n being probably 17).

2. The 25° isotherms for the ternary systems consisting of water and the three alum pairs thallium alum–ammonium alum, thallium alum–potassium alum and ammonium chrome alum–potassium chrome alum have been studied. In all three a complete series of solid solutions has been found, and their assignment to Roozeboom's Class I demonstrated.

3. That part of the quaternary system ferric ammonium alum–potassium alum–water, where the total compositions can be expressed in terms of $NH_4Fe(SO_4)_2$, $KAl(SO_4)_2$ and H_2O, has been studied at 25°. Where the concentration of $KAl(SO_4)_2$ relative to that of $NH_4Fe(SO_4)_2$ in the total composition is large, the behavior becomes that of a system of more than four components, apparently because of slight hydrolysis; all the quaternary solids, however, are solid solutions of alums.

NEW YORK, N. Y. RECEIVED JANUARY 23, 1940

Some Properties of Sodium Palmitate Curd as Studied in the Centrifuge

BY JAMES W. McBAIN AND T. FOSTER FORD

Soap curd[1] is a felt of hydrated crystalline fibers enmeshing a mother liquor that is slightly alkaline water with almost no soap. The fibers, although exceedingly fine,[2] yield good X-ray patterns as has been shown by Thiessen and others, and they are strikingly visible in the ultramicroscope. Ordinary solutes diffuse and sediment freely through their interstices.[3] The mechanical structure of the felt is sufficiently firm that sodium palmitate curd more concentrated than 0.2 M does not sediment or crush in a centrifugal field of 250,000 times gravity. Incidentally, this is likewise true of household soap, liquid crystalline sulfonic acid solution of 2 M, and of a potassium coconut oil liquid crystalline neat soap.

The densities of sodium palmitate curds at 20° with and without added salt, referred to water at 20° as 0.99820, are given in Table I. Compositions are given in true weight %.

TABLE I

Wt. % NaP	Wt. % NaCl	Wt. % H_2O	Density of curd
1.39	0	98.61	1.0000
2.105	0	97.895	1.0014
2.78	0	97.22	1.0014
2.065	1.92	96.0	1.0136
2.025	3.77	94.2	1.0269
2.725	1.91	95.3	1.0130
2.67	3.74	93.5	1.0194

The density of the hydrated curd fibers themselves was found by adding sodium palmitate solution to saturated sodium chloride solution until the curd fibers just began to sediment, instead of having a tendency to float. The result, 1.15, agrees fairly well with that calculable from Table I.

Observations in the Air-Driven Spinning Top.—For observation of sedimentation in the one-piece rotor the effective arrangement shown in Fig. 1 was devised. By looking obliquely down into the top, as shown by the arrow, it is possible to see directly the separation of water from curd. Calibration was by observation when known weights of water were added to the empty top, the internal radius of which was 0.80 cm., with opening of radius 0.5 cm., height of annular space 0.26 cm., and volume of annular space 0.32 cc. Forty seconds are required for the 20 mm. rotor to attain its full speed of 2650 r. p. s. at 80 lb. (5 atm.) pressure of air.

Separation of curd from water occurred so rapidly, in about one minute, that sedimentation velocity of curd fibers has not yet been accurately

measured. However, s is about 5×10^{-11}. The method of using a scraping tool was found inadmissible for soap curds as this may press water out of the structure.

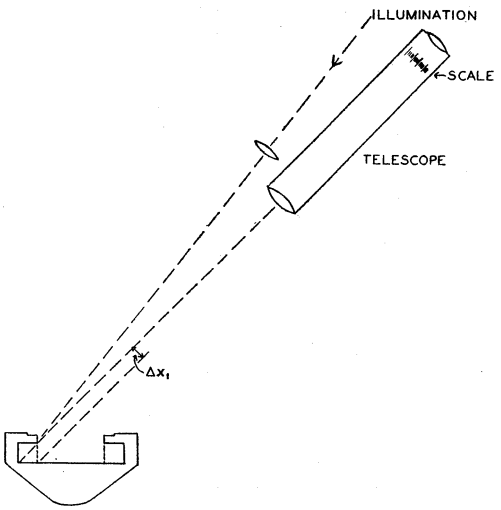

Fig. 1.

Tenth normal sodium palmitate curd shows no sedimentation at 2650 r. p. s.; one-fifteenth normal curd begins to collapse at 1500 r. p. s.; and one-twentieth normal at 1000 r. p. s. A curd collapsed at a high speed does not noticeably rebound when the speed is reduced, although in most cases a slight blurring of the originally sharp boundary between curd and separated water is noticed. This is due perhaps to the Brownian motions and slight diffusion of the curd fibers, but possibly also to a collision effect of molecules that are diffusing back after displacement in the high centrifugal field.

The amount of collapse increases as the centrifugal force increases, but it takes an observable time. The time lag must be due to friction of the water forced through the interstices of the curd structure. With the usual Poiseuille formula for membranes, idealized as consisting of parallel equal capillaries, the radius r of these equivalent capillaries was deduced from the measurements. For example, with a ring of 0.05 N curd of average radius 0.68 cm., 0.32 cc. of curd contained 0.0045 g. of sodium palmitate, of which the effective weight (above that of the aqueous medium) is 0.00067 g., the centrifugal force exerted on the periphery at 2000 r. p. s. is therefore $4\pi^2$ (0.00067) $(0.68)(2000)^2 = 42{,}000$ dynes. The rate of collapse at twenty seconds from the beginning of the experiment calculated from the slope of the collapse curve is 0.0234 g. H_2O/sec. The inner cylindrical surface of the curd being 1.11 sq. cm., by assuming that 1 sq. cm. of this is total pore cross section, it follows that the flow is equivalent to that through twenty-six million capillaries, each 0.3 cm. long and 0.00022 cm. in diameter. The initial calculated pore size is somewhat greater and that at forty seconds somewhat smaller, but the cessation of collapse is not due to the interstices becoming too small to permit capillary flow, but because the structure is stronger. A similar measurement at 800 r. p. s. gave also 0.00022 cm. for the effective pore diameter.

An alternative approach is to evaluate the diameter of the fibers themselves, or much more probably bundles of fibers, from the approximate sedimentation velocity constant, $s = 5 \times 10^{-11}$. Whereas for spheres this would correspond to a radius of about 390 Å., for very long cylinders the diameter would be about 400 Å. Judging by the well-known ultramicroscopic appearance of sodium palmitate curds, this is an effective diameter due to bundling of the parallel individual fibers which, according to the sorption of methylene blue,[2] are much less than 100 Å. in diameter.

Fig. 2a.—N sodium palmitate curd.

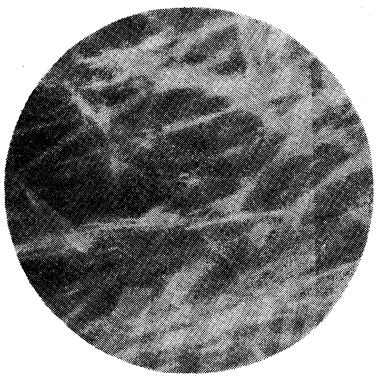

Fig. 2b.—0.25 N sodium palmitate curd.

Photographs of N and 0.25 *N* sodium palmitate curd as seen in the cardioid ultramicroscope are shown in Fig. 2, clearly showing that we are dealing with discrete bundles of fibers.

In Table II is given the final radial thickness, *d*, of the ring of water separated from 0.05 *N* sodium palmitate curds in experiments carried out in triplicate at 10, 20, 40 and 80 lb./sq. in. air pressure, respectively. In all cases the original thickness of the ring of curd was 0.30 cm. In Table III, glycerol was added in two experiments, raising the density to 1.0268, but separations at the higher pressures were greater than without glycerol despite the greater buoyancy of the medium.

TABLE II

FINAL THICKNESS, *d*, OF WATER LAYER SEPARATED FROM 0.30 CC. OF CURD

Lb./sq. in.	(R. p. s.)^2 × 10^{-6}	A	B	C
10	1.117	0.014	0.008	0.005
20	2.66	.052	.034	.030
40	4.92	.078	.052	.052
80	7.02	.090	.070	.070

TABLE III

FINAL THICKNESS, *d*, OF AQUEOUS GLYCEROL LAYER SEPARATED FROM 0.30 CM. OF CURD

Lb./sq. in.	(R. p. s.)^2 × 10^{-6}	D	E
10	1.17	...	...
20	2.66	0.030	0.045
40	4.92	.090	.170
80	7.02	.125	.180
100	8.4	.160	...

Since the properties of sodium palmitate curds depend upon their structure, the exact procedure used in their preparation is important. Thus if the soap solution has been cooled sufficiently that it has already begun to form curd fibers before placing in the top, it forms a soft "mushy" curd yielding considerably more water on collapse than if it were introduced while clear but just above the melting point and allowed to form and set in the slowly rotating top.

The mat separated from mush curd remains in one piece whereas the ordinary curd usually breaks into about seven equal segments in the rotor used owing to radial collapse of the inner circumference. This indicates that the mush curd possesses less oriented structure which agrees with the fact that more free water may be mechanically squeezed from such a mat than from a stiff curd collapsed to an equal extent.

When a curd refuses to collapse further at a given speed, the strength of the structure in the peripheral layer just balances the centrifugal force exerted by the unbalanced mass of the upper (or inner) layers of curd upon this peripheral layer. This pressure exerted inward radially by the outermost or peripheral layer is known as the swelling pressure, although here there is no marked tendency to swell but chiefly a tendency to resist further collapse.

This is a clear case where the origin of the swelling pressure[4] is mechanical rather than osmotic, whereas for many jellies and gels the two factors have not been distinguished in recording swelling pressures and the thermodynamically related vapor pressures. The data are collected in Table IV.

TABLE IV

FINAL THICKNESS, *d*, OF WATER LAYER FROM 0.30 CM. OF VARIOUS CURDS OF SODIUM PALMITATE AND THE SWELLING PRESSURES, *P*, IN DYNES/SQ. CM.

Description of curd	(R. p. s.)^2 × 10^{-6}	*d*	*P* × 10^{-4}
0.05 *N* NaP curd formed in top from soap soln. in which crystals just beginning to form, least collapse obtained	2.66	0.04	4.7
0.05 *N* NaP curd formed from soap soln. just above m. p., least collapse obtained	4.92	0.05	8.7
0.05 *N* NaP curd formed from soap soln. just barely melted clear, least collapse obtained	7.02	0.08	12.8
N/15 NaP curd formed from soap soln. just above melting point, least collapse obtained	7.02	0.038	17.0

Curds were made from 0.05 *N* sodium palmitate solutions with additions of sodium chloride and glycerol, respectively, in such amounts as to make the two curds equal in density. Compared with the original curd in water alone, the glycerol curd collapsed faster and to a greater extent. However, the sodium chloride curd was too rigid to collapse and showed a coarse radial structure yielding water readily upon cutting. The cut curd then collapsed. Since the glycerol medium has a higher viscosity, it is clear that the effect is one of structure and possibly of reduced hydration rather than any retardation of "capillary" flow.

Summary

The behavior of soap curd in the centrifuge is in accord with its brush heap structure with greater or less orientation depending upon previous history; the effective diameter of the interstices between the ultramicroscopic fibers being 10^{-4} cm., that of the fibers, or more probably fiber

(4) J. W. McBain and R. F. Stuewer, *Kolloid-Z.*, **74**, 10 (1936).

bundles, themselves 400 Å.; and the swelling pressure from a chiefly mechanical origin being 10^5 dynes/sq. cm. for 0.05 *N* sodium palmitate curd.

Glycerol softens the curd whereas sodium chloride makes it more rigid.

Dialkyl Adipates

BY ROBERT A. FEAGAN, JR., AND J. E. COPENHAVER[1]

This work was carried out because of the growing commercial importance of the higher alcohols and adipic acid, as well as to study the type of melting point curve exhibited by the esters of this dibasic acid. This investigation covers the normal alkyl esters from pentyl to eicosyl. Since the first four have been described previously, they were not prepared in this series but for completeness they are included in the curve.

The esters up to and including dinonyl were colorless liquids at room temperature and above that compound they were white waxy solids. The melting points are given in Table I and plotted in Fig. 1. The alternation between the esters of the even and odd carbon alcohols was very slight, the odd esters exhibiting the unusual property of being a little above the mean curve. It will be noted that there is an even number of carbon atoms in all of these compounds.

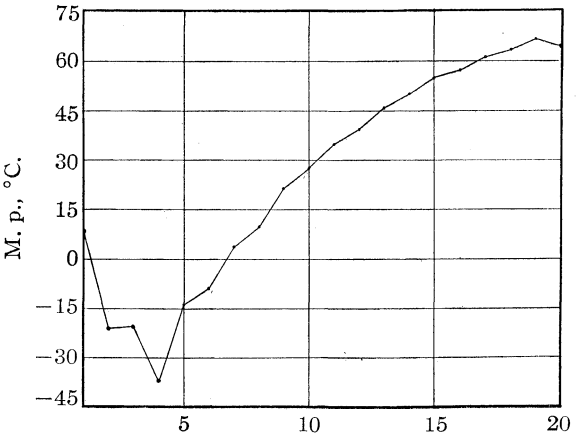

Fig. 1.—Melting points of the dialkyl adipates.

Experimental

Two methods were used for their preparation, *viz.*, the action of the alcohols on the acid or on adipyl chloride. In several cases, both methods were used and the products checked. A slight excess of the acid or the acid chloride was used above the theoretical quantity necessary for the formation of the diester. When adipic acid was used, the reaction mixture was heated at 150–155° for several hours, whereas with adipyl chloride, only slight warming was necessary.

The crude product from either method was dissolved in ether and thoroughly washed with 10% sodium carbonate. The recovered ester was recrystallized from

(1) Presented in part before the Organic Division of the American Chemical Society at its 97th meeting, Baltimore, Maryland, April, 1939.

acetone, in which the higher derivatives were almost insoluble, while the corresponding alcohols were very soluble. Cooling with dry-ice was necessary to remove from solution the esters below tetradecyl.

The melting points were taken, with mechanical stirring, in a 200-cc. bulb, fitted with a side-arm for the thermometer and melting point tube. Standard Anschütz thermometers were used so the melting points may be regarded as corrected.

This problem was suggested by Dr. E. Emmet Reid, Research Adviser, University of South Carolina, and to him the authors wish to express their appreciation for his valuable help. The alcohols from decyl to octadecyl were furnished by Dr. Reid and were from those prepared by Meyer and Reid.[2] Thanks also are due E. I. du Pont de Nemours and Company for furnishing the adipic acid.

Summary

The diesters of adipic acid from *n*-pentyl to *n*-eicosyl alcohols were prepared and the melting points determined. The melting points show slight alternation, the esters of the odd carbon alcohols being slightly higher than the even on the mean curve.

The Synthesis of 5-Methylchrysene and Related Compounds

BY MELVIN S. NEWMAN[1,2]

In a previous publication,[3] the author pointed out the desirability of synthesizing methyl derivatives of chrysene and described a new synthesis by which chrysene and 6-alkylchrysenes could be prepared readily. In order to explore the generality of this method for the preparation of various chrysene derivatives desired for biological testing in connection with the cancer problem, further work has been done. In this paper, the syntheses of 5-methylchrysene, 5-ethylchrysene and 5,6-dimethylchrysene are described, together with a new and more generally applicable procedure for the preparation of α,γ-diphenylbutyric acid, an important intermediate.

The α,γ-diphenylbutyric acid previously[3] used was prepared in five steps, of which the first was the condensation of benzaldehyde with acetophenone. The second step involved 1,4-addition of hydrogen cyanide to the chalcone thus produced. It was feared that in certain projected syntheses, the corresponding chalcones (bearing alkyl groups on the α-carbon) might prove difficult to prepare or purify and also that conditions for the addition of hydrogen cyanide might be difficult to find.[4] In the present work α,γ-diphenylbutyric acid was prepared by the alkylation of benzyl cyanide with phenethyl bromide using sodium amide.[5] The α,γ-diphenylbutyronitrile thus produced was hydrolyzed to the corresponding acid in excellent yield. Inasmuch as a variety of substituted phenethyl bromides and of substituted benzyl cyanides is easily prepared, the new approach is seen to be quite general.

The cyclization of the acid chloride of α,γ-diphenylbutyric acid by aluminum chloride was further improved (94% yield) by decreasing the time of reaction.[3] It was also determined that if the volatile phosphorus compounds formed when the acid was treated with phosphorus pentachloride were not removed prior to the treatment with aluminum chloride, the yield was decreased to 77%. The remaining steps in the synthesis are indicated in the chart.

The Reformatsky condensations of 1,2,3,4-tetrahydro-1-keto-2-phenylnaphthalene, I, with ethyl α-bromopropionate and ethyl α-bromobutyrate proceeded smoothly and the corresponding unsaturated acids, II (R = CH_3 and C_2H_5), were isolated in fair yields. The double bond is placed in the ring instead of the alternate position of conjugation with the carboxyl group as in the analogous case of 3,4-dihydro-2-phenyl-1-naphthaleneacetic acid.[3] It is interesting to note that from the neutral fraction of the reaction products (after dehydration and hydrolysis) con-

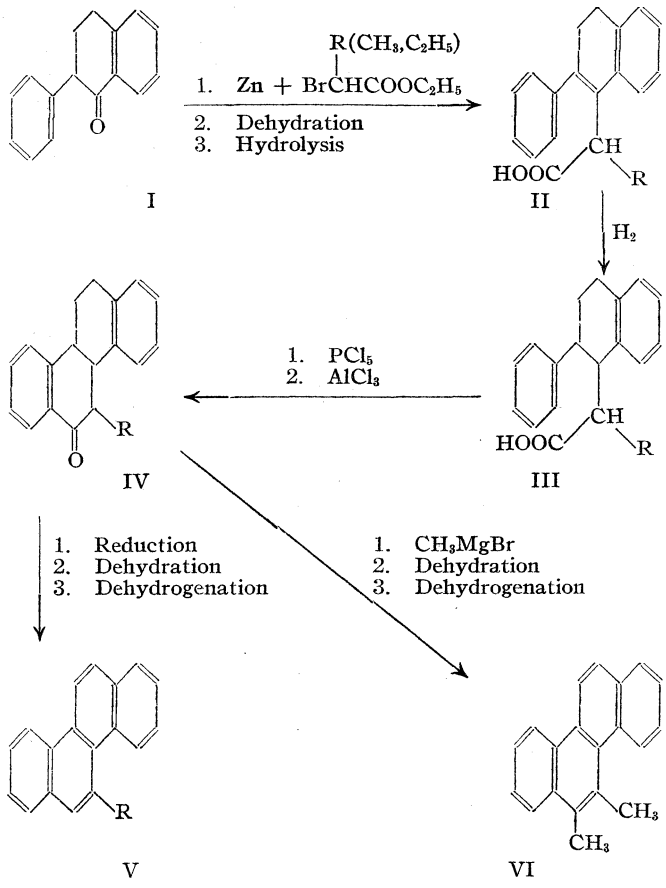
(3) Newman, THIS JOURNAL, **60**, 2947 (1938).

(4) Michael and Weiner, *ibid.*, **59**, 744 (1937), cite no instance of the addition of hydrogen cyanide to unsaturated ketones containing an alkyl group on the α-carbon.

(5) See Bergstrom and Fernelius, *Chem. Rev.*, **12** 138 (1933), and **20**, 455 (1937), for reviews of the use of sodium amide in alkylation studies.



siderable amounts of starting ketone, I, were recovered in spite of varying the amount of excess reagents used in the Reformatsky reactions. In an experiment using ethyl α-bromobutyrate and zinc with I, it has been shown that at least part of the recovered unchanged ketone results from the reaction of its enolic form with the postulated organozinc intermediate according to the equation

$$\underset{\text{I}}{\text{R—COCHR}} + \text{BrZnCH(C}_2\text{H}_5\text{)COOC}_2\text{H}_5 \longrightarrow \underset{\text{Ia}}{\text{R—C(OZnBr)=CR}} + \text{C}_2\text{H}_5\text{CH}_2\text{COOC}_2\text{H}_5$$

Upon hydrolysis, the bromozinc enolate, Ia, regenerates I. This explanation is supported by the isolation (in 15% yield) of ethyl butyrate from the reaction products. Such behavior of a ketone in the Reformatsky reaction has its analogy in similar reactions of ketones with Grignard reagents.[6]

Another interesting observation had to do with the use of iodine for initiation of the reaction. If strictly anhydrous conditions were carefully observed and sandpapered zinc foil[7] used, the reactions always started easily without the use of iodine. However, the yield of desired product was better if a small amount of iodine was used to initiate the reaction. Thus, in comparable runs using I and ethyl α-bromopropionate, the yield of unsaturated acid, II (R = CH_3), was 23.0% when no iodine was used and 37.6% when it was.

Difficulty was again encountered in the reduction of the unsaturated acids, II. Reduction was finally accomplished by high pressure hydrogenation over a copper-barium chromite catalyst[8] at 200°. A small amount of decarboxylation also took place but at lower temperatures reduction was incomplete. The reduction of the esters over a nickel catalyst supported on kieselguhr was also tried but at 200° saturation of the double bond was incomplete and it was feared that at higher temperatures the aromatic rings might have been hydrogenated.

No attempts were made to separate in a pure condition the stereoisomeric reduced acids, III, although in one case a separation into crystalline and non-crystalline fractions was made. Both fractions yielded the same end-products when put through the remaining steps of the synthesis. No crystalline ketone corresponding to IV was isolated. To form the 5-alkylchrysenes, the crude ketones were reduced to the alcohols using the aluminum isopropylate procedure.[9] The alcohols were dehydrated by heating with a trace of iodine and the tetrahydrochrysenes dehydrogenated by heating with sulfur. The hydrocarbons, 5-methylchrysene, m. p. 117.2–117.8°, and 5-ethylchrysene, m. p. 91.4–92.4°, were obtained in fair yields. In connection with the latter, it should be pointed out that the ethylchrysene, m. p. 236°, prepared from the acetylchrysene, m. p. 254°, is not the 5-derivative as tentatively advanced.[10]

After treating IV (R = CH_3) with methylmagnesium bromide, followed by dehydration and

dehydrogenation, a mixture of hydrocarbons was obtained. By fractional crystallization of the picrates formed from this mixture followed by adsorption of the picric acid on alumina, 5,6-dimethylchrysene, VI, was obtained. The nature of the impurity has not been determined positively but it is probably 5-methylchrysene, since the melting point of the mixture of hydrocarbons obtained was not depressed by the addition of 5-methylchrysene.

The new hydrocarbons are being tested for biological activity. Unpublished results would indicate a very slight carcinogenic activity for 6-methylchrysene[3] as it has produced one sarcoma in twenty mice during eighteen months.[11]

Experimental[12,13]

α,γ-Diphenylbutyric acid.—To 39 g. of powdered sodium amide[14] under 500 cc. of dry sulfur-free benzene in a three-necked flask fitted with mercury-sealed stirrer, reflux condenser, gas inlet tube, and dropping funnel was added 106 g. of benzyl cyanide[15] with stirring and cooling, the air in the system having been displaced with dry nitrogen. Ammonia was evolved copiously and the benzene took on a deep red color. The mixture was refluxed for one hour and on cooling a light colored complex separated from a deep red solution. Owing to the vigorous exothermic reaction two hours were required for the addition (with cooling) of 156 g. of phenethyl bromide. After three hours of stirring at room temperature, during which time the color became light brown and much white solid appeared, the mixture was refluxed for thirty minutes, cooled, and treated with an excess of dilute hydrochloric acid. The benzene layer was washed and the product distilled to give 114 g. (61%) of a clear yellow viscous oil, b. p. 147–151 at 0.5–1 mm. A fairly large higher boiling residue accounted for the low yield. In spite of several modifications of procedure, the yield varied from 56 to 63%. In a typical hydrolysis, 165 g. of nitrile was refluxed with 600 cc. of acetic acid and 100 cc. of 70% sulfuric acid for two days to yield 170 g. (95%) of acid, m. p. 70–72°. Alkaline hydrolysis of the nitrile was not as satisfactory.

1,2,3,4-Tetrahydro-1-keto-2-phenylnaphthalene. I.—The yield of this ketone was increased to 94% when the directions previously given[3] were modified to include in the following order: one-half hour for addition of aluminum chloride at room temperature; one-half hour each at 40 and at 60°; and a final cooling to room temperature during one-half hour before decomposition. In a comparable experiment in which the acid chloride was treated directly with aluminum chloride without removing any of the volatile phosphorus compounds formed in the reaction of the acid with phosphorus pentachloride, the yield fell to 77%.

The Reformatsky Reactions.—Considerable experimentation upon the Reformatsky reaction was carried out, the best conditions found being illustrated by the following description: to a hot solution of 44.4 g. (0.2 mole) of I and 54 g. (0.3 mole) of ethyl α-bromopropionate in 250 cc. of dry sulfur-free benzene contained in a 1-liter flask fitted with a ground-in condenser was added 20 g. (0.3 mole) of zinc foil which had been freshly sandpapered[7] and about 0.2 g. of iodine. After the initial reaction moderated the benzene was kept gently refluxing for three hours. The solid complex which separated was decomposed with dilute hydrochloric acid. The organic reaction products were heated at 230° with a small crystal of iodine to effect dehydration and then distilled at 2 mm. The fraction boiling from 180 to 210° was refluxed for sixteen hours with alcoholic potassium hydroxide. From the neutral portion of the hydrolyzed products was isolated 12.3 g. of I (27.3%) and from the acid fraction, by crystallization from benzene–ligroin, 20.92 g. (37.6%, or 52.5% if allowance for recovered ketone is made) of **3,4-dihydro-α-methyl-2-phenyl-1-naphthaleneacetic acid, II** (R = CH_3), m. p. 204–210°. A sample recrystallized for analysis separated as small colorless dense prisms, m. p. 210.2–210.6°.

Anal. Calcd. for $C_{19}H_{18}O_2$: C, 81.99; H, 6.52. Found: C, 82.15; H, 6.52.

In decomposing the insoluble complex formed in the Reformatsky reaction, there was always a certain amount which was not easily decomposed by shaking with dilute acid at room temperature. In a run using 0.1 mole of ketone, this insoluble complex was collected by filtration and decomposed by boiling with dilute hydrochloric acid and a little alcohol. On cooling 3.2 g. of organic matter crystallized. This crystalline material proved to be ethyl 1,2,3,4 - tetrahydro - 1 - hydroxy - α - methyl - 2 - phenyl-1-naphthaleneacetate, m. p. 90.4–91.4°, as shown by analysis and by dehydration and hydrolysis to II (R = CH_3).

Anal. Calcd. for $C_{21}H_{24}O_3$: C, 77.75; H, 7.46. Found: C, 77.49; H, 7.51.

In a comparable reaction using 44.4 g. of I, 58.5 g. of ethyl α-bromobutyrate, 20 g. of zinc, and 0.2 g. of iodine, there was isolated 21.4 g. (48%) of unchanged ketone and 16.0 g. (27.6% or 53.4% if allowance for recovered ketone is made) of a mixture of isomeric unsaturated acids, m. p. 151–168°, designated as **3,4-dihydro-α-ethyl-2-phenyl-1-naphthaleneacetic acid.** No attempt was made to separate pure isomers and the portion for analysis, crystallized from benzene–ligroin, melted at 156–169°.

Anal. Calcd. for $C_{20}H_{20}O_2$: C, 82.16; H, 6.90. Found: C, 82.39; H, 6.88.

Isolation of Ethyl Butyrate.—In an exactly similar reaction using 0.1 mole of ketone, the organic reaction products were extracted with benzene and after washing, the benzene removed in an insulated column packed with glass helices. The remaining material was distilled with steam and after salting out the distillate with ammonium chloride, the non-aqueous layer was dried over sodium sulfate

(13) The author acknowledges the valuable assistance of Mr. O. Woolfolk in the preparation of several intermediates and of Mr. J. H. Walker who performed the semi-micro analyses. Their assistance was made possible by The Ohio State W. P. A. Project No. 65-1-42-89.

(14) The sodium amide used was prepared by Dr. M. Orchin essentially according to the method of Dennis and Browne, THIS JOURNAL, **26**, 587 (1904), using ammonia from a tank.

(15) The benzyl cyanide was purified according to Johnson, "Organic Syntheses," Vol. 16, John Wiley and Sons, Inc., New York, p. 89.

and distilled. A forerun, b. p. 80–121°, was discarded and 1.7 g. of ethyl butyrate, b. p. 121.2–121.5°, was obtained. On hydrolysis, butyric acid was identified by odor and by its *p*-bromphenacyl ester,[16] m. p. and mixed m. p. 62.6–63.0°.

The Reduced Acids. III.—After several methods of reduction had been attempted unsuccessfully, the acids were reduced smoothly in dioxane over catalyst 37KAF[8] under an initial hydrogen pressure of 1900 lb. (127 atm.). A temperature of 200° was necessary, as at lower temperatures reduction was incomplete. The reduced acids, III, contain three asymmetric carbon atoms and no attempt was made to separate pure isomers. By the reduction of 10.0 g. of II (R = CH_3) there was obtained 5.91 g. of colorless needles, m. p. 143–148°, of **1,2,3,4-tetrahydro-α-methyl-2-phenyl-1-naphthaleneacetic acid, III** (R = CH_3), by a single crystallization from benzene–ligroin. On evaporation of the mother liquors to dryness, 4.06 g. of a pale yellow viscous oil was obtained which consisted of a mixture of isomeric acids. A small amount of the crystals was recrystallized from benzene–ligroin to yield colorless rosets of needles, m. p. 147.6–148.8°.

Anal. Calcd. for $C_{19}H_{20}O_2$: C, 81.40; H, 7.19. Found: C, 81.42, 81.44; H, 6.94, 6.92.

In the case of the corresponding acid, III (R = C_2H_5), no crystalline fraction was obtained and the pale colored oil obtained in over 90% yield was used directly for the succeeding steps.

5-Methylchrysene, V(R = CH_3).—Either the crystalline or non-crystalline acid III (R = CH_3) could be used for the preparation of 5-methylchrysene. In a typical experiment, 2.00 g. of acid III (R = CH_3) in 10 cc. of benzene was treated with 1.5 g. of phosphorus pentachloride. After refluxing for several minutes, all volatile compounds were removed under reduced pressure at 80°. The pale yellow residue was dissolved in 15 cc. of dry sulfur-free benzene and 1.0 g. of aluminum chloride added in three portions with cooling. After swirling at room temperature until the evolution of hydrogen chloride slackened, the reaction mixture was warmed slowly to 50°. The bromine colored solution was cooled after thirty minutes and was decomposed by adding dilute hydrochloric acid. The benzene solution was washed with acid and alkali and the organic matter remaining after the evaporation of the solvent was pale brown in color. This crude ketone IV (R = CH_3) was suitable for the further steps described below. A solution of the above ketone in isopropanol containing aluminum isopropylate (from 0.5 g. of aluminum) was distilled slowly until no further test for acetone was given by the distillate.[9] The reaction mixture was treated with dilute hydrochloric acid and the organic product dehydrated by heating at 230° for ten minutes under reduced pressure after the addition of a crystal of iodine. The residue was dehydrogenated by heating at 240 to 250° for forty minutes with 0.23 g. of sulfur. After vacuum distillation from a small amount of zinc dust, the hydrocarbon was isolated by crystallization from benzene–alcohol as almost colorless needles, m. p. 115–117°, in 36% yield (0.621 g.). A sample purified for biological testing and analysis by recrystallization of the picrate followed by chromatographic adsorption on alumina formed colorless needles, m. p. 117.2–117.8°, with brilliant blue-violet fluorescence in ultraviolet light.

Anal. Calcd. for $C_{19}H_{14}$: C, 94.18; H, 5.82. Found: C, 94.04, 93.96; H, 5.96, 5.59.

5,6-Dimethylchrysene. VI.—A solution of the ketone, IV (R = CH_3), prepared as above from 4.26 g. of acid, III (R = CH_3), in 25 cc. of benzene was refluxed with an excess of ethereal methylmagnesium bromide for thirty minutes. The alcohol thus formed was dehydrated by heating at 220° under reduced pressure and then distilled at 10 mm. The pale yellow distillate (3.60 g.) was heated with 0.89 g. of sulfur at 230–240° for one hour, when the evolution of hydrogen sulfide had ceased. The product was distilled from a small amount of zinc dust and, since the solids obtained by crystallization had an unsharp melting point (118–125°), the entire product was treated with picric acid. After fractional crystallization of the picrates from benzene–alcohol followed by chromatographic adsorption on alumina, there was obtained 1.06 g. of colorless **5,6-dimethylchrysene, VI**, m. p. 128.6–129.8°, having intense blue-violet fluorescence in ultraviolet light. If a benzene–alcohol solution of the hydrocarbon were cooled rapidly, thin plates, m. p. 128.0–129.0°, were obtained. On slow cooling needles of m. p. 128.6–129.8° separated. From other fractions of the picrates, 0.71 g. of a hydrocarbon mixture, m. p. 118–128°, was obtained and no depression of melting point was noticed on mixing in some 5-methylchrysene, m. p. 117°.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.71; H, 6.29. Found: C, 93.47, 93.61; H, 6.15, 6.20.

The **picrate** crystallized from benzene–alcohol in red needles, m. p. 134.4–135.4° with decomposition.

Anal. Calcd. for $C_{26}H_{19}O_7N_3$: C, 64.33; H, 3.95; N 8.66. Found: C, 64.52; H, 3.82; N, 8.34.

The ***s*-trinitrobenzene derivative** crystallized from benzene–alcohol in bright orange needles, m. p. 158.6–159.4°.

Anal. Calcd. for $C_{26}H_{19}O_6N_3$: C, 66.52; H, 4.08; N, 8.95. Found: C, 66.66; H, 3.88; N, 9.11.

5-Ethylchrysene, V(R = C_2H_5).—No crystalline acid corresponding to III (R = C_2H_5) was isolated. A solution of 4.16 g. of acid III (R = C_2H_5) in 20 cc. of benzene was treated with 3.0 g. of phosphorus pentachloride. The acid chloride was cyclized in benzene solution using 2.0 g. of aluminum chloride, the ketone reduced, the alcohol dehydrated, and the residue dehydrogenated as above to yield a total of 1.15 g. (32%) of **5-ethylchrysene**, m. p. 88–90°. A sample purified for analysis by crystallization of the picrate and chromatographic adsorption on alumina formed colorless needles, m. p. 91.4–92.4°, having an intense blue-violet fluorescence in ultraviolet light.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.71; H, 6.29. Found: C, 93.49, 93.39; H, 6.16, 6.10.

The **picrate** crystallized from benzene–alcohol in red needles, m. p. 99.2–100.6°.

Anal. Calcd. for $C_{26}H_{19}O_7N_3$: C, 64.33; H, 3.95; N, 8.66. Found: C, 64.33; H, 3.61; N, 8.46.

The ***s*-trinitrobenzene derivative** crystallized from benzene–alcohol in orange rectangular prisms, m. p. 125.2–125.8°.

Anal. Calcd. for $C_{26}H_{19}O_6N_3$: C, 66.52; H, 4.08; N, 8.95. Found: C, 66.45; H, 3.82; N, 8.76.

Summary

The synthesis of 5-methylchrysene, 5-ethylchrysene, and 5,6-dimethylchrysene is described, together with a new and more generally applicable synthesis for α,γ-diphenylbutyric acid.

The recovery of a considerable amount of 1,2,3,4-tetrahydro-1-keto-2-phenylnaphthalene from the Reformatsky reaction between this ketone and ethyl α-bromobutyrate despite a large excess of reagents is noted. An explanation is offered involving reaction of the enol form of the ketone with an organozinc intermediate to produce a bromozinc enolate and ethyl butyrate. This explanation is supported by the isolation of ethyl butyrate from the reaction mixture.

The Condensation of Esters with Aromatic Hydrocarbons by Means of Aluminum Chloride

BY JAMES F. NORRIS AND PAUL ARTHUR, JR.[1]

Preliminary results of the study of the condensation of ethyl acetate and of phenyl acetate with benzene were given in a recent paper[2] from this Laboratory. The work was continued because the reaction appeared to give a new and valuable method for the preparation of aromatic ketones. When the investigation was about completed, an abstract of a German patent,[3] bearing on the subject, was published. Our results are not in accord with certain statements in the patent; these will be considered in the experimental part of this paper.

In a communication by Bowden[4] on the alkylation of benzene by esters by the Friedel–Crafts reaction one phase of the condensation is described. In our work special attention was paid to acylation and the study of the conditions to be used to produce alkylation alone or simultaneous alkylation and acylation.

A study of possible mechanisms of the reactions involved was made in order to gain information to be used as a guide in directing the syntheses. The results led to the following steps in the case of methyl acetate

(1) $CH_3COOCH_3 + AlCl_3 \xrightarrow{\text{cold}} CH_3COOCH_3.AlCl_3 \xrightarrow{\text{hot}} CH_3COOAlCl_2 + CH_3Cl$

(2) $CH_3Cl + C_6H_6 + AlCl_3 \longrightarrow C_6H_5CH_3 + C_6H_4(CH_3)_2$ etc. $+ HCl$

(3) $CH_3COOAlCl_2 + C_6H_6(C_6H_5CH_3$, etc.) $+ AlCl_3 \longrightarrow C_6H_5COCH_3 + C_6H_4CH_3COCH_3$ (etc.) $+ AlOCl$

From work to be discussed later it is probable that a third step is involved in the alkylation, namely, the formation of an intermediate which contains three components, the hydrocarbon, the alkyl chloride and aluminum chloride.

One mole of aluminum chloride dissolves in one mole of methyl acetate and forms a compound which melts at about 60°. When this was heated it was stable at 132°, decomposed moderately rapidly at 143°, and rapidly at 170°. The yield of methyl chloride isolated was 0.7 mole. The solid residue ($CH_3COOAlCl_2$) obtained after the pyrolysis of the complex made from ethyl acetate and aluminum chloride, was condensed with benzene by aluminum chloride; the yield of acetophenone was 42% of the theoretical.

When methyl acetate, toluene, and aluminum chloride were heated, the products were dimethyl- and trimethylbenzene and a 60% yield of a mixture of methyl acetophenones. Since all of the dimethyl acetophenones have not been described, it was necessary to synthesize certain isomers by methods which gave evidence in regard to structure. The product obtained contained mostly 2,4-dimethylacetophenone; a smaller amount of 4-methylacetophenone was shown to be present.

In the case of ethyl acetate, alkylation alone took place at room temperature; at 90° both alkylation and acylation occurred. By control of the temperature it was possible to obtain as the chief product of the reaction either *m*-diethylbenzene or ethyl derivatives of acetophenone.

Alkylation of benzene was effected by the use of methyl and ethyl formates. Attempts to acylate with these reagents and thus form aldehydes were not successful.

Details of Experiments

Pyrolysis of Molecular Compounds of Esters and Aluminum Chloride.—The pyrolysis was effected in a tube with a side-arm connected to a U-tube containing enough water to cover the bend and to absorb the hydrogen chloride formed. The other gases, after passing through a drying tube, entered a spiral condenser cooled by dry-ice. The condensate was collected in a graduated tube placed in a toluene-bath kept cold by two test-tubes filled with dry-ice. Any permanent gases formed were collected. The tube in which pyrolysis took place was heated by the vapor of a boiling liquid which was selected according to the temperature required.

It has been shown that the compound formed from aluminum chloride and ethyl benzoate contains its components in the molecular ratio of 1:1. One mole of aluminum chloride dissolves in one mole of methyl acetate, with the evolution of heat. The compound solidifies and begins to melt at 60°. When more chloride was added it did not dissolve in the melted complex and no appreciable amount of heat was evolved. A compound was prepared from 4.5 cc. of methyl acetate and 7.8 g. of aluminum chloride (mole ratio 1:1). No methyl chloride was formed when it was heated for fifty minutes at 110°. At 143° in fifty minutes 0.05 mole was collected. When the temperature was held at 170° for two and one-half hours the total yield of methyl chloride was 0.7 mole. Heating was continued at 184° and 220° until the evolution of hydrogen chloride ceased (0.38 mole). No acetyl chloride was found. The titration of the acid and the determination of chloride ion by precipitation gave the same results.

Since ketones are formed from esters, it appeared possible that a compound of acetyl chloride and aluminum chloride was formed along with methyl chloride as the result of pyrolysis. A search for acetyl chloride was made. Combes[5] has shown that under certain conditions acetyl chloride is converted in part by aluminum chloride into acetylacetone as the result of the loss of hydrogen chloride. The test for the ketone with ferric chloride was applied. The color produced was the same, but not so strong as that produced by a sample of acetylacetone. The behavior was tested of a mixture of acetyl chloride and aluminum chloride when heated to the temperature used in the pyrolysis. No acetyl chloride was recovered, but the product gave a test with ferric chloride. No acetylacetone was separated by using copper sulfate or dinitrophenylhydrazine. It is probable that a compound of the composition $CH_3COOAlCl_2$ is involved in the ketone synthesis, which is similar to a compound derived from benzoic acid and is the intermediate in the formation of benzophenone from the acid.

Pyrolysis of the Compound $CH_3COOC_2H_5 \cdot AlCl_3$.—The compound began to decompose slowly at 139°; in 9.7 hours 0.67 mole of ethyl chloride was obtained. At 170° there were obtained 0.5 mole in two hours and 0.85 mole in 6.3 hours.

The residue from the pyrolysis (14.1 g.) which appears to have the formula $CH_3COOAlCl_2$ was heated on a steam-bath for three hours with benzene and aluminum chloride (mol ratio 1:2:1.2, respectively). The yield of acetophenone melting at 17.5–18° was 42% of the theoretical.

Pyrolysis of the Compound $CH_3COOC_4H_9(n) \cdot AlCl_3$.—The compound has been studied.[6] It is liquid at 0°. When it was heated at 132° hydrogen chloride and a permanent gas were formed fairly rapidly. The liquid formed at 170° was shown to be *n*-butyl chloride (5%); the hydrogen chloride was 1.26 moles. The chief products were evidently butylenes and hydrogen chloride.

Pyrolysis of the Compounds Containing Methyl and Ethyl Formate and Aluminum Chloride.—The compound containing methyl formate decomposed slowly at 110°. When heated at 143°, as long as methyl chloride was formed, the yield of the latter was 88% of the theoretical. The residue when heated at 185° gave practically equivalent amounts of hydrogen chloride and carbon monoxide. The residue obtained at 143° appeared to have the same composition as the compound made from formic acid and aluminum chloride as the result of the loss of hydrogen chloride. The compound prepared in this way, when heated at 185°, yielded carbon monoxide and hydrogen chloride. This residue, obtained at 143°, should condense with benzene to give benzaldehyde, provided it behaved as the analogous residue obtained from an acetate. For this reason it was studied. Zinc chloride lowered the temperature of its pyrolysis to 140°; cuprous chloride had no effect. It did not yield an aldehyde when an attempt was made to condense it with benzene. When anhydrous formic acid was dropped into phosphorus trichloride at room temperature, a steady stream of carbon monoxide was produced.

The compound of ethyl formate and aluminum chloride gave 82% of the theoretical yield of ethyl chloride when heated at 110° for one and one-quarter hours. Subsequent heating at 184° yielded 0.93 mole of hydrogen chloride and 0.43 mole of carbon monoxide.

Alkylation of Aromatic Hydrocarbons with Esters.—The pyrolysis of compounds of esters and aluminum chloride showed that the alkyl–oxygen bond broke at a lower temperature than the acyl–oxygen bond; that the compounds which contained ethyl esters decomposed at a lower temperature than those containing methyl esters. It was shown also that one molecular quantity of aluminum chloride is used in the formation of the alkyl halide and as a result an additional mole of aluminum chloride is required for the condensation in which ketones are formed. These facts made it possible to select experimental conditions for the syntheses. The molecular ratios of the reactants used were kept constant in order to determine the influence of factors other than concentration on the products of the reactions.

Ethylation of Benzene with Ethyl Acetate.—Aluminum chloride (117.3 g.) was added slowly to a mixture of 39.2 cc. of ethyl acetate and 71 cc. of benzene in a flask placed in ice water. The mixture stood at room temperature for about twenty-five hours and was shaken occasionally. After decomposition with ice, the dried product was fractionated through a V-packed column equivalent to 17 theoretical plates. There were obtained 33 cc. of benzene, 6 cc. of ethylbenzene, 16 cc. of *m*-diethylbenzene; 12.3% of the ester was converted into ethylbenzene and 51.3% into diethylbenzene. The latter was shown to be the meta isomer by comparing it and its derivatives with those of an authentic sample, obtained from the Eastman Kodak Company, which furnished details of the method used in its purification. These included fractional sulfonation of the diethylbenzene made from ethylene and benzene, recrystallization of the barium sulfonate, hydrolysis of the sulfonic acid, and distillation of the hydrocarbon. The physical constants obtained are given below: the constants of the *m*-diethylbenzene from the Eastman Kodak Company are given in parentheses and those reported in the literature in brackets: b. p. 181.6° at 751 mm. (181–182°) [180.5°]; m. p. $<-55°$ ($<-55°$) [$<-20°$]; $n^{25}D$ 1.4922 (1.4922) [1.4926]; tetrabromo derivative, m. p. 77.8–78.2° (77.8–78.2°) [74°]. Mixed melting point showed no depression. The tetrabromo derivative of *o*-diethylbenzene melts at 64.5° and that of the para compound at 112°. Benzoylbenzoic acid by condensation with phthalic anhydride, m. p. 121.5–123° (120–121°) [114–116° (uncor.)]; neutralization equivalent of acid 281.2 (theoretical 282).

These results are not in accord with the patent, previously mentioned, which states that the para isomer is formed on alkylation of an aromatic nucleus with which an alkyl group is combined. The method appears to be the best for the preparation of *m*-diethylbenzene because it does not involve a tedious treatment to remove isomers.

Agitation of the reactants during the course of the experiment affects the relative proportions of the products formed. With very little agitation 12.2% of the ester was converted into ethylbenzene, 29% into *m*-diethylbenzene, and 17.8% into triethylbenzene. In an experiment in which the reactants were stirred for eleven hours, the corresponding figures were 18.5% ethylbenzene, 48.5% *m*-diethylbenzene and 8% triethylbenzene.

Ethylation with Ethyl Formate.—The formate was condensed with benzene under the conditions used with ethyl acetate; 11.9% of the ester was converted into ethylbenzene, 24% into diethylbenzene and 23.7% into triethylbenzene. The index of refraction of the diethylbenzene was $n^{20}D$ 1.4958; that of the meta isomer is $n^{20}D$ 1.4947. Benzene was ethylated with ethyl formate under the conditions favorable for the formation of *s*-triethylbenzene. The mole ratios used were benzene 1, aluminum chloride 5, ethyl formate 3. The reagents were mixed at the temperature of an ice-bath and then slowly heated during one hour to 70°, and finally at 94° for forty minutes. The hydrocarbon obtained was distilled with steam and fractionated; only 0.5 cc. boiled between 60 and 201°. The yield of *s*-triethylbenzene, boiling at 208–209° (uncor.), was 50.5%. The index of refraction of the part boiling at 209° was $n^{25}D$ 1.4925. The value is in accord with the index of a sample of *s*-triethylbenzene purified by sulfonation, etc.

Methylation with Methyl Acetate.—An experiment was made under the condition used with ethyl acetate. No alkylation took place; the result was the same when hydrogen chloride was passed into the reactants or when they were heated at 60° for two and one-half hours. At 90–96° both alkylation and acylation occurred (see later).

Methylation with Methyl Formate.—Benzene and methyl formate yielded only 5% of toluene when condensed at room temperature. The ester was condensed with toluene. To 139.4 g. of aluminum chloride suspended in 88.4 cc. of toluene was added a mixture of 44.2 cc. of toluene and 25 g. of methyl formate (mole ratio methyl formate 1, aluminum chloride 2.5, toluene 3). To the mixture was added 5 g. of cuprous chloride. The mixture stood for 107 hours and then was heated for two periods of one-half hour each at 60° and at 80°. The products recovered were benzene 0.1 mole, toluene 1.7 moles, *m*-xylene 0.45 mole. The xylene was shown to be the meta isomer by condensing it with phthalic anhydride; the aroylbenzoic acid melted at 222–224°, which is the melting point for the compound made from *m*-xylene. This condensation appears to be a good method for preparing *m*-xylene free from its isomers.

Methyl formate was condensed with benzene under favorable conditions for the preparation of mesitylene (mol ratio: C_6H_6 1, aluminum chloride 5, methyl formate 3; time of heating was one hour at 70–85° and four hours on the steam-bath). The yield of mesitylene (b. p. 165.5–166°) was 46% of the theoretical. No benzene, toluene, or xylene was obtained.

Acylation of Aromatic Hydrocarbons by Means of Esters.—Acylation with esters requires a higher temperature than alkylation. The effect of the molecular ratio of aluminum chloride to the ester was studied in the case of methyl acetate. With the ratio 1 CH_3COOCH_3 to 0.62 aluminum chloride, the yield of ketones was 19% and with 1 CH_3COOCH_3 to 2.2 aluminum chloride, 51% of the theoretical.

Methyl Acetate and Toluene.—To a cooled mixture of 96 cc. of methyl acetate and 266 cc. of toluene, contained in a 1-liter flask provided with a return condenser and a wide tube, was added slowly 366 g. of aluminum chloride (mol ratio: 1:2:2.2, respectively). The mixture was heated on a steam-bath for two hours; it was left at room temperature for ten hours and finally heated for five and one-half hours. The product, after decomposition with ice and drying, was distilled through a column equivalent to 16 theoretical plates. The fractions up to 180° were collected at atmospheric pressure, the next at 50 mm. up to 180°, and finally at 2 mm. The moles of the products from 1 mole of methyl acetate were as follows: benzene 0.25, toluene 0.36, xylene 0.05, $C_6H_3(CH_3)_3$ 0.13, ketones 0.60; 9 cc. of high boiling liquids and 2 g. of solid materials were also obtained.

The fraction boiling at 80° was shown to be benzene by its melting point, 4.5–5°. The fraction boiling at 137–139° was condensed with tetrachlorophthalic anhydride; the melting point of the product was 206–215°, showing that it consisted principally of *m*-xylene. The fraction at 164° was nearly pure mesitylene (b. p. 165°). The crude compound prepared from it and phthalic anhydride melted at 200–211°, and after recrystallization at 210–212°, the recorded melting point is 211–212°.

That part of the ketone fraction (b. p. 135–138°) which boiled at 136° was studied. A part was treated with sodium hypochlorite. The neutralization equivalent of the acids obtained was 147.2. Since the equivalent of toluic acid is 136 and dimethylbenzoic acid 150, it appeared that the fraction examined contained about 80% of dimethylacetophenone. A sample of the mixed ketones was treated with 2,4-dinitrophenylhydrazine. Two hydrazones crystallized from the reaction mixture separately, the *p*-methyl derivative first. One compound had the same melting point (174.2–175.2° (cor.)) as the 2,4-dinitrophenylhydrazone prepared from a pure sample of 2,4-dimethylacetophenone. The quantity of hydrazone obtained showed that the original mixture of ketones contained about 80% of 2,4-dimethylacetophenone. When *p*-nitrophenylhydrazine was used, a small amount of the hydrazone of *p*-methylacetophenone was isolated. It melted at 192–193° (cor.). These results are not in accord with the patent mentioned before, which states that the ketone formed from an alkylbenzene and a simple ester is the 2,5-dialkylated ketone.

Methyl Acetate and Benzene.—The moles of reactants used were benzene 2, methyl acetate 1, aluminum chloride 2.2. The mixture was heated at 60–70° for one hour; at 70–80° for one hour, and at the reflux temperature for six and one-half hours. There was obtained a 45% yield of a mixture of ketones of which about 83% was *p*-methylacetophenone; the latter was identified by the melting point of its 2,4-dinitrophenylhydrazone and the mixed melting point of the compound and an authentic sample; the rest of the mixture was principally 2,4-dimethylacetophenone.

Ethyl Acetate and Benzene.—The mole ratio used was benzene 2; ethyl acetate 1; aluminum chloride 2.2. The mixture was heated gradually to 90° and refluxed for 2.6 hours. The yield of mixed ketones was 48%. The fraction boiling at 242–243° contained 70% *p*-ethylacetophenone; the fraction boiling at 252–262° contained 25% *p*-ethylacetophenone; the higher boiling ketone was not identified.

Phenylhydrazones Used in Identification.—Several of these derivatives, some of which have not been described, were prepared from ketones synthesized by methods that furnished evidence of structure.

4-Nitrophenylhydrazone of 2,4-Dimethylacetophenone.—The compound was prepared from a sample of the ketone, made in this Laboratory by Dr. J. N. Ingraham by condensing pure *m*-xylene with acetyl chloride. The hydrazone prepared in the usual way consisted of bright yellow crystals. The product was recrystallized from a mixture of dichloromethane and petroleum ether and melted at 154.6–154.8° (cor.). % N found, 14.9 and 14.8; theory, 14.83.

2,4-Dinitrophenylhydrazone of 2,4-Dimethylacetophenone.—After crystallization from alcohol and water, the compound was obtained as long needles that matted together; m. p. 174.2–175.2°; % N found, 16.8 and 16.8; theory, 17.07.

4-Nitrophenylhydrazone of 2,5-Dimethylacetophenone.—The ketone was prepared from *p*-xylene, acetyl chloride, and aluminum chloride. The reaction took place at 15°, with stirring for two and one-half hours, and standing at 25° for twenty minutes. That no rearrangement of the alkyl groups took place was shown by the fact that the hydrocarbon recovered was *p*-xylene which melted at 11–12°. The 4-nitrophenylhydrazone prepared from the ketone melted at 159.8–160.1° (cor.); % N found, 14.95 and 14.83; theory, 14.83. The mixed melting point of this compound with the corresponding derivative of 2,4-dimethylacetophenone (m. p. 154.4–154.8°) was 135–142°.

2,4-Dinitrophenylhydrazone of 2,5-Dimethylacetophenone.—The compound was recrystallized from alcohol; m. p. 174.2–175.2° (cor.); % N found, 17.0 and 16.9; theory, 17.07. The melting point of a mixture of this compound and the 2,4-dinitrophenylhydrazone of 2,5-dimethylacetophenone (m. p. 174.2–175.2°) was 155–162°.

2,4-Dinitrophenylhydrazone of 3,4-Dimethylacetophenone.—The ketone was prepared from *o*-xylene, acetyl chloride and aluminum chloride in the presence of carbon disulfide; the time of reaction was forty minutes at room temperature. The index of refraction of the ketone was $n^{20}D$ 1.5390 (literature 1.5388). The 2,4-dinitrophenylhydrazone of the ketone melted at 255.2–255.8° (cor.). A mixed melting point with the 2,4-dinitrophenylhydrazone of 4-methylacetophenone (258.6–259.4°) gave 245–250° with decomposition.

Summary

1. The condensations of methyl and ethyl formates and acetates with benzene and toluene by means of aluminum chloride have been investigated. At lower temperatures alkylation alone takes place; at higher temperatures the acetates yield derivatives of acetophenone, the structures of which have been determined.

2. The pyrolysis of the compounds of the esters and aluminum chloride has been studied. The first decomposition yielded alkyl chlorides with excellent yields. The residue obtained in this way from ethyl acetate gave acetophenone when it was condensed with benzene.

3. A number of new 4-nitro- and 2,4-dinitrophenylhydrazones of 2,4-, 2,5- and 3,4-dimethylacetophenones have been prepared and used in the identification of the ketones formed from methyl acetate.

Monothioacetals of Galactose

BY M. L. WOLFROM AND D. I. WEISBLAT

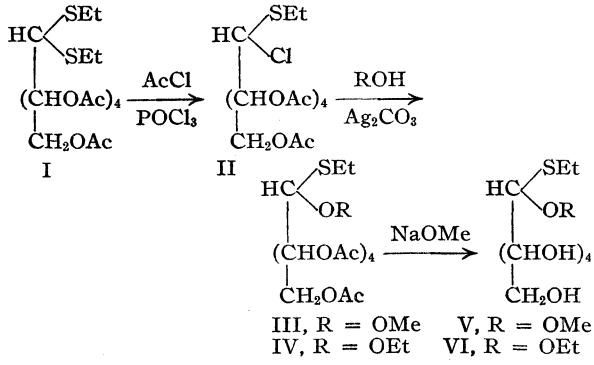
Geuther and Bachmann[1] treated the diethyl acetal of acetaldehyde with phosphorus pentachloride and obtained the 1-chloro-1-ethoxyethane (α-monochlorodiethyl ether), previously synthesized by Wurtz and Frapolli[2] from acetaldehyde, ethanol and hydrogen chloride. Blaise[3] and recently Post[4] postulated the probable formation of this same halogen compound in the reaction of acetaldehyde diethyl acetal with benzoyl chloride.

As thioacetals and acetals of the simple alcohols are available in the sugar series, we were interested in the possible extension of the above reactions to these carbohydrate derivatives. We have found that galactose dimethyl acetal reacts readily with acetyl chloride with the replacement of one methoxyl group by chlorine to form 1-chloro-1-methoxy-galactose pentaacetate. This general type of derivative is the open chain analog of the well-known acetohalogen sugars. Such a derivative had been prepared in the arabinose series by Montgomery, Hann and Hudson[5] through halogen replacement of the 1-acetate in the two isomeric *aldehydo*-1-methoxy-arabinose pentaacetates obtained by the acetolysis of the methyl arabinopyranosides. A corresponding galactose derivative had been obtained in this Laboratory[6] by halogen replacement of the 1-acetate in 1-ethoxy-galactose hexaacetate obtained by the acetylation of *aldehydo*-galactose pentaacetate ethyl hemiacetal.

We have found that galactose diethyl mercaptal pentaacetate (I) reacts with a mixture of acetyl chloride and phosphorus oxychloride to replace one ethylmercapto group with chlorine. The resulting *aldehydo*-1-chloro-1-ethylmercapto-galactose pentaacetate (II) reacts with methanol or ethanol to produce the monothioacetal pentaacetate (III and IV) from which the monothioacetals (V and VI) can be obtained by saponification. No evidence was obtained for the presence of more than one form of these derivatives in any of our reactions, although such a result is a possibility on stereochemical grounds. The halogen in the above halogen compounds is extremely reactive and the halogen derivatives are difficult to obtain in pure form. Montgomery, Hann and Hudson[5] likewise report the same experience with the arabinose derivative which they also used for acetal synthesis.

These monothioacetals of galactose and their pentaacetates are beautifully crystalline substances and are formed in high yield from the chloro compound. Such mixed oxygen, sulfur acetals have been postulated by Green and Pacsu[7] as a probable intermediate in the reaction of sugar mercaptals with mercuric chloride in alcoholic solution in the presence of mercuric oxide.

Work is in progress in this Laboratory on the extension of these reactions to other sugar structures and on the study of the behavior of the monothioacetals under ring-closure conditions.



Experimental

***aldehydo*-1-Chloro-1-ethylmercapto-*d*-galactose Pentaacetate (II).**—*d*-Galactose diethyl mercaptal pentaacetate[8] (30 g.) was dissolved in 20 cc. of freshly distilled acetyl chloride and the solution heated to boiling. Phosphorus oxychloride (10 cc.) was added to the boiling solution under reflux until a reddish-brown coloration began to develop (two to five minutes). The flask was then stoppered, quickly immersed in an ice-bath and the whole placed in an icebox. Crystallization in rosets of small needles began in a few hours and after standing overnight at icebox temperature the crystals were removed by filtration and washed thoroughly with a mixture of petroleum ether (5 parts) and ether (1 part). This crude material was re-

crystallized rapidly from benzene by the addition of anhydrous ether; yield 13–18 g., m. p. 108–111°. The material at this stage of purity still decomposed rapidly and evolved ethyl mercaptan. After two more recrystallizations from four parts of benzene by the addition of approximately seven parts of dry ether, pure material was obtained; yield 7–7.5 g., m. p. 111–113°, spec. rot. −27° (22°, *c* 3.7, abs. $CHCl_3$).[9] Due to the instability of the compound, the constants recorded are probably not quite the maximum.

In absolute chloroform the rotation changed slowly in the *dextro* direction. In one experiment the specific rotation was −13° after fifteen hours. At this point the solution had darkened somewhat and an odor of ethyl mercaptan was distinctly noticeable. It is believed that this mutarotation represents decomposition, probably by reaction with traces of moisture.

The substance was readily soluble in the common organic solvents but was practically insoluble in cold ether, petroleum ether and water. It reduced Fehling's solution and evolved ethyl mercaptan on boiling with dilute alkali or acid. The substance was found to be stable only when kept in a vacuum desiccator over soda lime. An investigation of mother liquors yielded no other definite substance or any methanol reaction product different from that described below (III).

Anal. Calcd. for $C_8H_{12}O_5(CH_3CO)_5SCl$: Cl, 7.5; saponification value (six equivalents), 12.8 cc. 0.1 *N* NaOH per 100 mg. Found: Cl, 6.9; saponification value, 12.9 cc.

d-Galactose S-Ethyl O-Methyl Monothioacetal Pentaacetate (III).—*aldehydo*-1-Chloro-1-ethylmercapto-*d*-galactose pentaacetate (II, 10 g.) was added to a previously cooled suspension of 20 g. of Drierite (anhydrous calcium sulfate) and 10 g. of silver carbonate in 50 cc. of anhydrous methanol in a three-necked flask equipped with a mercury-sealed mechanical stirrer and a drying tube. The reaction was then allowed to run at room temperature for approximately sixteen hours. The inorganic salts were removed by filtration through a bed of Super-cel (Johns-Manville) and the clear, colorless filtrate was made just opalescent with water. The product crystallized on standing at icebox temperature; yield 5.6 g., m. p. 114–117°, spec. rot. +42.5° (abs. $CHCl_3$). Pure material was obtained on recrystallization (92–95% return) from five parts of hot methanol containing a few drops of pyridine; m. p. 119–120°, spec. rot. +42.5° (19°; *c*, 3.3; abs. $CHCl_3$).

The substance crystallized in beautiful diamond-shaped plates and was readily soluble in chloroform, ether, acetone and warm alcohol but was practically insoluble in water and petroleum ether. It showed no reduction toward hot Fehling's solution and evolved ethyl mercaptan on heating with dilute hydrochloric acid.

Anal. Calcd. for $C_9H_{15}O_6(CH_3CO)_5S$: S, 6.87; CH_3CO, 10.7 cc. 0.1 *N* NaOH per 100 mg. Found: S, 7.08; CH_3CO, 10.8 cc.

d-Galactose Diethyl Monothioacetal Pentaacetate (IV).—This substance was synthesized from *aldehydo*-1-chloro-1-ethylmercapto-*d*-galactose pentaacetate (II, 10 g.) exactly as described for the synthesis of the corresponding methoxy compound (III) except that 60 cc. of absolute ethanol was substituted for the methanol. The product was isolated from the reaction mixture in the same manner; yield 5.3 g., m. p. 102–102.5°, spec. rot. +50° (abs. $CHCl_3$). Pure material was obtained on recrystallization (93–95% return) from six parts of hot absolute ethanol containing a few drops of pyridine; m. p. 104–105°, spec. rot. +50° (20°; *c*, 3.5; abs. $CHCl_3$).

The substance crystallized in beautiful prisms and exhibited properties and solubilities similar to those of the corresponding methoxy compound (III).

Anal. Calcd. for $C_{10}H_{17}O_6(CH_3CO)_5S$: S, 6.67; CH_3CO, 10.4 cc. 0.1 *N* NaOH per 100 mg. Found: S, 6.62; CH_3CO, 10.4 cc.

d-Galactose S-Ethyl O-Methyl Monothioacetal (V).—*d*-Galactose S-ethyl O-methyl monothioacetal pentaacetate (III, 8.5 g.) was dissolved at room temperature in 20 cc. of anhydrous methanol, 4 cc. of 0.2 *N* sodium methylate added and the solution cooled rapidly in an ice-bath. Crystallization occurred immediately upon shaking. After a few hours of standing the crystalline material was removed by filtration and washed thoroughly with ether; yield 4.6 g. (98%), m. p. 144–146°, spec. rot. +48° (H_2O). Pure material was obtained on recrystallization (90–95% return) from six parts of hot anhydrous methanol; m. p. 146–147°, spec. rot. +50° (20°; *c*, 3; H_2O).

The substance crystallized in the form of elongated prisms. It showed no reduction toward hot Fehling's solution but on acid hydrolysis ethyl mercaptan was liberated and the hydrolyzate was reducing. The material was soluble in water and warm methanol and was practically insoluble in ether, acetone and chloroform.

Anal. Calcd. for $C_9H_{20}O_6S$: C, 42.13; H, 7.87; S, 12.51. Found: C, 41.86; H, 7.70; S, 12.28.

d-Galactose Diethyl Monothioacetal (VI).—*d*-Galactose diethyl monothioacetal pentaacetate (IV, 9.6 g.) was dissolved in 30 cc. of warm ethanol and to the warm solution 5 cc. of 0.2 *N* sodium methylate was added. The solution was immediately immersed in an ice-bath and crystallization began immediately. After a few hours of standing the material was removed by filtration and washed with ether; yield 5.2 g. (93%), m. p. 155–156°, spec. rot. +53° (20°; *c*, 3; H_2O). The product was pure and identical constants were obtained on material after four recrystallizations from 14 parts of hot absolute ethanol from which it could be obtained in 94% return.

The substance crystallized in elongated prisms exhibiting a beautiful pearly luster and showed properties and solubilities similar to those of the corresponding methoxy compound (V).

Anal. Calcd. for $C_{10}H_{22}O_6S$: S, 11.86. Found: S, 11.82.

***aldehydo*-1-Chloro-1-methoxy-*d*-galactose Pentaacetate.**—*d*-Galactose dimethyl acetal pentaacetate[10] (1 g.) was dissolved in 3.5 cc. of boiling, freshly distilled acetyl chloride and the stoppered container placed in the icebox, whereupon the product crystallized. After several hours the product was removed by filtration and washed with ether; yield 0.9 g., m. p. 140–145°. Pure material was obtained on recrystallization from dry benzene by the addi-

(9) All specific rotations are recorded to the D-line of sodium light; 22° is the temperature; *c* is the concentration in g. per 100 cc.

tion of ligroin; m. p. 155–156°; spec. rot. −38° ⟶ +15° (25°; *c*, 5; abs. $CHCl_3$, 24 hrs.); spec. rot. −53° ⟶ −42.5° (26°; *c*, 5; dry benzene; 10 hrs.).

Anal. Calcd. for $C_7H_{10}O_6(CH_3CO)_5Cl$: Cl, 8.04; saponification value (six equivalents), 13.6 cc. 0.1 *N* NaOH per 100 mg. Found: Cl, 7.96; saponification value, 13.7 cc.

We are indebted to Mr. John Walker (W. P. A. Project 18062) for assistance rendered in the analytical determinations. We also acknowledge the assistance of Mr. Irving Auerbach (N. Y. A. Project O. S. U. 167).

Summary

1. *aldehydo*-1-Chloro-1-methoxy-*d*-galactose pentaacetate was synthesized by the action of acetyl chloride upon *d*-galactose dimethyl acetal pentaacetate.

2. *aldehydo*-1-Chloro-1-ethylmercapto-*d*-galactose pentaacetate (II) was synthesized by the action of a mixture of acetyl chloride and phosphorus oxychloride upon *d*-galactose diethyl mercaptal pentaacetate.

3. *d*-Galactose diethyl monothioacetal and *d*-galactose S-ethyl O-methyl monothioacetal and their pentaacetates have been synthesized from II.

The Thermal Decomposition of Diacetyl

BY W. D. WALTERS

In a previous investigation[1] the rate of decomposition of diacetyl in the range 424–470° was obtained by pressure measurements and the products of the reaction analyzed. Since diacetyl can be determined quantitatively by conversion to dimethylglyoxime, which, on addition of a nickel salt, precipitates as nickel dimethylglyoxime, it is possible to analyze for the amount of diacetyl remaining after the decomposition has been allowed to proceed for a definite time. The present work was undertaken to investigate the kinetics of the decomposition by this method, thereby avoiding any assumptions regarding the relation between the pressure increase and the amount of decomposition. The effect of propylene on the rate of decomposition and the variation of the ketene concentration during the decomposition also were studied.

Experimental

The diacetyl, obtained from the Eastman Kodak Company, was dried over calcium sulfate and purified by four fractional distillations under vacuum, the middle two-thirds being used for each subsequent operation. The diacetyl used in this investigation was analyzed quantitatively, as indicated later, and found to be pure within the limits of error of the method, ±0.1%. The diacetyl was protected from light and between runs kept at −80°. The propylene, obtained from the Ohio Chemical Company, was of 99.5% purity.

The cylindrical Pyrex vessel, 75 × 120 mm., was contained in a furnace similar in design to the one previously used.[1] By means of a chromel–alumel thermocouple located at the center of the reaction vessel, the temperature was determined to within 0.1°. A temperature control of ±0.25° was obtained by causing light reflected from the mirror of a galvanometer in the thermocouple-potentiometer circuit to fall on a photoelectric cell, which controlled additional heating current. All thermocouples were standardized at the boiling point of sulfur and the absolute accuracy of the temperatures measured should be at least ±0.5°. In runs 29–50 inclusive, from which the activation energy was determined, a new thermocouple, standardized before use at the sulfur boiling point and after use against a standard thermocouple, was used every day.[2]

In order to obtain a pressure of diacetyl in the reaction vessel higher than its vapor pressure at room temperature, a small side arm was connected to the line leading from the storage bulb to the reaction vessel. This T-section was separated by a stopcock I from the reaction vessel and separated by another stopcock II from the line leading to the storage bulb. To introduce a sample into the reaction bulb, stopcock I was closed and stopcock II opened. Using dry-ice–acetone mixture the desired amount of diacetyl was condensed in the lower part of the side arm. After stopcock II was closed and I opened, the dry-ice-bath was replaced by a heated liquid-bath, vaporizing the diacetyl within fifteen seconds. The external tubing adjacent to the reaction bulb was heated with resistance wire to approximately 85° to prevent condensation of diacetyl. Stopcocks I and II which were also heated were "no-lube" stopcocks ground for high vacuum, and to these it was necessary to apply only a small amount of high vacuum grease. The diacetyl storage bulb was fitted with a small stopcock and ground glass joint so that it could be removed, the grease wiped off the

joint with ether, and the bulb weighed without admitting air. These weighings were reproducible to within at least 0.4 mg. To ensure that no trace of air entered the reaction bulb, the diacetyl was outgassed at −80° in the storage bulb and again in the side arm before every run. Moreover, blank determinations showed that under the conditions used no diacetyl was lost. In the runs with propylene the same procedure was followed except that the desired amount of propylene was placed in the furnace prior to the introduction of the diacetyl.

Before using a new reaction vessel, or after contact with air, it was flushed out at an elevated temperature with several charges of diacetyl, one of which was allowed to remain in the vessel overnight. A similar treatment was given the packed bulb, which was filled with thin-walled Pyrex tubes. The reaction bulb was evacuated to a pressure less than 10^{-3}–10^{-4} mm. before every run.

After a definite time in the reaction vessel, the products of the reaction, as well as diacetyl, were removed by expansion into a condensing apparatus consisting of two long spirals of 8-mm. tubing, a trap fitted with a ground glass joint, and a U-tube in series, all of which could be immersed in a dry-ice–acetone mixture. Since undecomposed diacetyl, which is readily condensable, represented the major portion of the gas in most of the runs, about 85% of the charge could be removed within a few seconds. Then after forty seconds the remainder of the gas in the reaction bulb was led through the condensing apparatus by connecting the U-tube to the pumping system. At −80° all the diacetyl condensed out and the permanent gases and ketene were removed. No diacetyl could be detected in the effluent gases. By noting the pressure in the reaction vessel during removal, a correction could be applied for the decomposition occurring as the charge was being removed. This usually corresponded to about twenty seconds' additional heating. All the diacetyl was distilled into the removable trap, which was then taken off and kept at −80° while a solution of hydroxylamine hydrochloride and nickel chloride was added. Then this bulb was fitted with a ground glass cap and allowed to warm up to 0°. The rest of the analysis for diacetyl was a modification of the method described by Schmalfuss and Rethorn.[3] To precipitate quantitatively any nickel dimethylglyoxime remaining in solution after the first filtration, a second period of heating of the filtrate with simultaneous evaporation and subsequent addition of ammonium hydroxide was necessary.

To follow the reaction and determine the time of removal, pressure measurements were made using a heated click gage calibrated before and after every run. The volume of the click gage together with external tubing amounted to about 1% of the total volume. The extrapolated and calculated initial pressures ordinarily agreed to within 1%.

The determination of ketene was accomplished by its reaction with water to form acetic acid, which could be titrated with dilute alkali. The gases from the reaction vessel were removed by expansion into an evacuated 2-liter bulb, which was connected to the apparatus by a ground glass joint so that it could be rotated. At the time the gases entered, ice at −80° was contained in a finger attached to the bulb. By quickly melting the ice and rotating the bulb, the water, which ran into the bulb, would cover a large part of the inner surface of the bulb, thus facilitating the reaction between the ketene and the water. In the presence of diacetyl an excess of alkali must be avoided, since in alkaline solutions reactions involving diacetyl apparently destroy a portion of the alkali. However, with continuous stirring the titration of acetic acid in the presence of diacetyl to the brom thymol blue end-point with dilute alkali could be used satisfactorily. Blank determinations using standard acetic acid and diacetyl showed that a small correction of about 1% was necessary.

(3) Schmalfuss and Rethorn, *Z. Untersuch. Lebensm.*, **70**, 233 (1935).

Results

To determine whether diacetyl undergoes some reaction at low temperatures, a few preliminary experiments with initial pressures in the neighborhood of 150 mm. were made at 114, 242, 304, and 346° with reaction times of sixty-six minutes or more. Within the limits of experimental error no reaction could be detected either from the pressure measurements or from the analyses for diacetyl. The results of experiments at higher temperatures where decomposition does occur are given in Table I. The majority of runs were carried to only small amounts of decomposition, 20% or less, so as to avoid as much as possible any interference by the products. The data from the runs at 408° with initial pressures from 147 to 287 mm. indicate that the fraction decomposed within a certain time is practically independent of the initial pressure. Since similar results over a wider range of initial pressures were obtained in the previous investigation using pressure measurements, first order constants were calculated for all the runs and they are given in the last column of Table I.

In the runs near 418 and 436° which were carried to larger amounts of decomposition, the first order constants decrease as the percentage decomposition increases, indicating that probably the reaction is complex and inhibited to some extent by the products. From the measured pressure increases and the amounts of diacetyl disappearing, it was possible to correlate the pressure increase with the fraction of diacetyl decomposed at 418 and 436°, as shown in Fig. 1. These curves could then be used to transform the pressure measurements during a run into percentages of decomposition. During a single run at either of these temperatures, although the first order

[a] Surface to volume ratio increased eighteen-fold.

constants fall off as the reaction proceeds, the decrease from the initial value does not exceed 5% until more than 25% of the diacetyl has decomposed. However, to fit the experimental results fairly satisfactorily over the whole decomposition, a 1.6 order would be required at 436° and a 1.5 order at 418°.

The results from experiments on the packed bulb with the surface to volume ratio increased by a factor of 18 are also shown in Table I. The rate at 425.5°, although somewhat slower, is essentially in agreement with the rate in the unpacked bulb. At the lower temperatures the rate is slightly faster than the rate in the unpacked bulb, but even at the lowest temperature, 383.1°, where the heterogeneous reaction would be expected to become more important, the rate in the packed bulb is only 20% greater than the rate in the unpacked bulb, indicating about 1% of heterogeneous reaction.

The activation energy was obtained, as shown in Fig. 2, from runs with initial pressures near 200 mm. in which the amount of decomposition was low and approximately constant, averaging about 16%. This procedure will tend to eliminate any errors arising from the falling off of the rate constants as the reaction proceeds, since, as already mentioned, this effect is not appreciable until more than 25% decomposition has occurred. Using the value of 63,200 cal. for the activation energy, the reaction rate constant can be expressed as

$$k = 8.7 \times 10^{15} e^{-63200/RT}\ \text{sec.}^{-1}$$

It is known that ketene is produced during

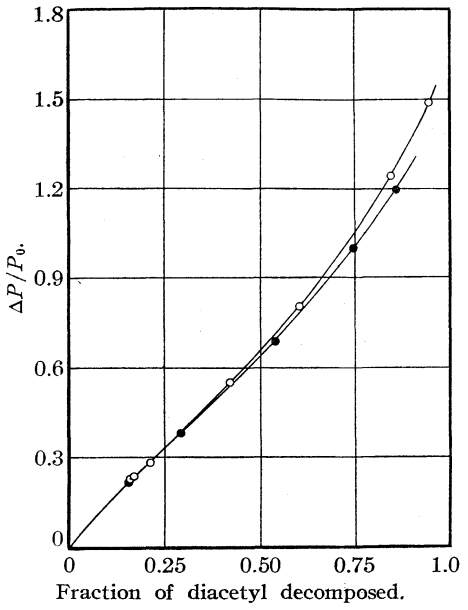

Fig. 1.—Plot of pressure increase against fraction of diacetyl decomposed: ●, 418°; ○, 436°.

the decomposition of diacetyl,[1,4] and the reaction which has been proposed for its formation is

$$CH_3COCOCH_3 \longrightarrow CH_4 + CO + CH_2{=}CO$$

Assuming the correctness of this equation, a comparison of the pressure increases in Table I with the amounts of diacetyl decomposed indicates that polymerization of the ketene is occurring. Moreover, the rise of the curves in Fig. 1 near the end of the decomposition points to the presence of an intermediate which decomposes with an increase in volume. Apparently ketene undergoes decomposition as well as polymerization.[5] However, it is uncertain whether the polymerization and the decomposition are competing reactions, or, as Hurd and Williams[6] suggest, the polymerization to acetylketene occurs first, followed by the decomposition of the acetylketene. In any case, it is to be expected that if diacetyl does decompose according to the equation given above, the yield of ketene will increase as the percentage of diacetyl decomposed decreases. The results of the analyses for ketene are shown in Table II and Fig. 3. The percentages of decomposition were obtained from pressure increases using the data shown in Fig. 1 and Table I.

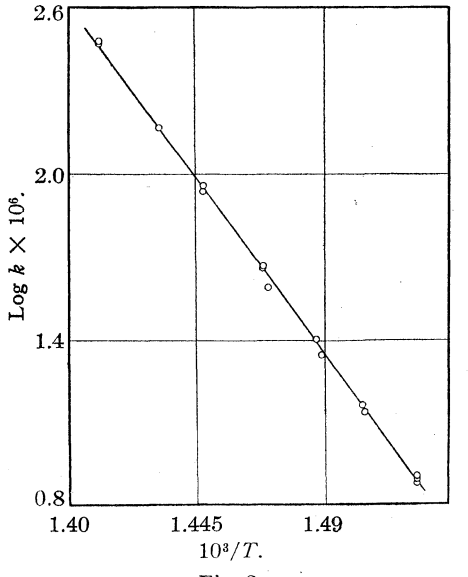

Fig. 2.

204.7	1140	6.1	4.2	2.8	67
195.6	2340	12.2	9.0	4.0	44

Although the highest yield of ketene at 436° was found to be 67% at 8.6% decomposition, the yield of ketene is increasing rapidly and will presumably extrapolate to some value close to 100% at zero decomposition. At the lower tem-

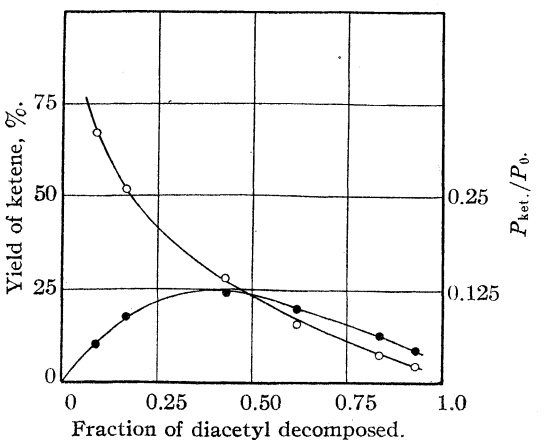

Fig. 3.—Ketene present during the decomposition of diacetyl at 436°: ●, $P_{ket.}/P_0$; ○, % yield of ketene.

(6) Hurd and Williams, *ibid.*, **58**, 962 (1936).

perature for the same percentage decomposition a somewhat smaller yield of ketene was obtained. In this connection, it can be seen from the data in Table I and Fig. 1 that as the temperature decreases the pressure increase corresponding to a given amount of decomposition of diacetyl decreases. This fact together with the smaller yield of ketene at the lower temperature may be explained by the increasing importance of the polymerization of ketene as the temperature decreases.

Inhibition by Propylene.—For a number of chain reactions it has been demonstrated that unsaturated compounds, particularly propylene[7] and also ethylene,[8] inhibit the decomposition. In cases where nitric oxide is not satisfactory as an inhibitor, such as the decompositions of aldehydes and ketones, inhibition by propylene has been regarded as an indication of a chain reaction. Therefore, the effect of propylene on the decomposition of diacetyl was investigated and the results of successive runs with and without propylene are shown in Table III.

[a] Calculated from pressure increases instead of analyses.

The first two runs, on which only pressure measurements were made, indicated that propylene was definitely an inhibitor. However, to avoid the possibility that the slower pressure increase might be due to some cause other than the slower decomposition of diacetyl, analyses for the amount of diacetyl present, as well as pressure measurements, were carried out in the succeeding runs. For comparison the results of run 32 which had been made earlier are given in the last line of the table. The analytical results, which show that the rate of decomposition is approximately 35% slower in the presence of 150 mm. of propylene, are in agreement with the pressure measurements.

Discussion

On the basis of the inhibition with propylene and also the kinetics of the ordinary decomposition, it would appear that the decomposition of diacetyl is probably a chain reaction. Moreover, the fact that small amounts of diacetyl can promote the chain decomposition of other compounds,[9] such as diethyl ether, acetaldehyde, and acetone, gives evidence that free radicals are produced when diacetyl decomposes. Although the experimental results do not exclude the possibility that some decomposition occurs through intramolecular rearrangement, it is probable that the major portion of the decomposition is a chain reaction. Therefore, as in the previous investigation, the following simplified chain mechanism for the decomposition of diacetyl, designated by M_1, will be assumed.

$$M_1 \longrightarrow 2R_1 \quad (1)$$

$$R_1 + M_1 \longrightarrow R_1H + R_2 \quad (2)$$

$$R_2 \longrightarrow R_1 + M_2 \quad (3)$$

$$R_1 + R_2 \longrightarrow R_1R_2 \quad (4)$$

Under conditions where the amount of decomposition according to reaction (1) can be neglected in comparison with the chain decomposition, the rate of decomposition has been shown to be[10]

$$\frac{d(M_1)}{dt} = -\sqrt{\frac{k_1k_2k_3}{k_4}}(M_1) \quad (I)$$

In the presence of an inhibitor, such as propylene, which acts by removal of radicals R_1[11]

$$R_1 + M_3 \longrightarrow X \quad (5)$$

the rate equation[12] becomes

$$\frac{d(M_1)}{dt} = -\left[\left(\frac{k_1k_2k_3}{k_4}(M_1)^2 + \frac{k_5^2k_3^2}{16k_4^2}(M_3)^2\right)^{1/2} - \frac{k_5k_3}{4k_4}(M_3)\right] \quad (II)$$

That unsaturated compounds are present in the products was shown in the previous investigation, in which the unsaturates were determined as a group including ethylene. From the retarding effect of propylene, these unsaturated products would be expected to exert an inhibiting influence. If the inhibitor, M_3, in reaction (5) can be identified with one of the products which increases as the amount of decomposition increases, the rate of reaction during a single run would reduce to

$$dx/dt = (k_A^2(1-x)^2 + k_B^2x^2)^{1/2} - k_Bx \quad (III)$$

(11) For discussion of possible mechanisms for the removal of radicals by propylene, see Ref. 7.

(12) This equation is similar to equation (36) derived by Rice and Polly.

where x is the fraction decomposed and k_A and k_B are constants. At low percentages of decomposition equation III will approach the value given in equation I. Actually the experimental results during a single run at 418 or 436° can be expressed to within 5% by an empirical equation of the above type. This, of course, is a necessary, but not a sufficient, condition to prove the validity of the above equations. The deviation is greatest near the beginning where the rate does not fall off as rapidly as would be predicted from the equation.

Comparison of the fractional times from the pressure measurements for runs at 436° (with initial pressures near 200 mm.) shows that the rates of decomposition in the earlier work[1] are on the average about 9% slower than those obtained in the present study. Most of this difference may be due to a slight difference in temperature scales since a variation of 1° causes a change of approximately 7% in the rate. The present value of 63.2 kcal. for the activation energy is almost within the limits of experimental error of the value 66.5 ± 3 kcal. obtained previously at higher temperatures by pressure measurements, corrected for the change in the pressure increase with temperature. At present it is not possible to state whether the difference is due in part to an increase of activation energy with temperature or is entirely the result of the fact that different methods were used to measure the rate. Although the frequency factor of 8.7×10^{15} is somewhat lower than the earlier value, it is still higher than that found in most decompositions, one outstanding exception being azomethane[13] with a frequency factor of 3.5×10^{16}.

Assuming that expression (1) is correct, a high frequency factor might be due to a high frequency factor for one or more of the rate constants in the numerator, or to a small frequency factor for a rate constant in the denominator. On the basis of the Eyring theory[14] of absolute reaction rates, a high frequency factor for a rate constant in the numerator would result if the reaction involved a large entropy of activation.

That there is restricted rotation around the bond joining the two carbonyl groups in diacetyl has been shown by Zahn[15] using dipole measurements, and a similar effect might be expected in a radical with adjacent carbonyl groups. In the detailed scheme[1] for the decomposition of diacetyl

$$CH_3COCOCH_3 \longrightarrow 2CH_3CO \quad (1')$$

or

$$\longrightarrow CH_3 + CH_3COCO \quad (1'')$$

$$CH_3CO \longrightarrow CH_3 + CO \quad (1'a)$$

$$CH_3COCO \longrightarrow CH_3 + 2CO \quad (1''a)$$

$$CH_3 + CH_3COCOCH_3 \longrightarrow CH_4 + CH_2COCOCH_3 \quad (2')$$

$$CH_2COCOCH_3 \longrightarrow CH_2{=}CO + CH_3CO \quad (3')$$

$$CH_3 + CH_2COCOCH_3 \longrightarrow CH_3CH_2COCOCH \quad (4')$$

reactions (3′) and (1′), assuming for the moment that (1′) is the primary reaction, will involve the breaking of the bond joining the carbonyl groups. In both of these reactions a contribution to the entropy of activation would result from the free rotation around this bond in the activated complex. However, with a reasonable estimate of the potential barrier from the dipole data, the entropy of activation, using Pitzer's values,[16] although appreciable, does not appear to be sufficient to account entirely for the high experimental frequency factor. By analogy with acetone,[17] any entropy of activation corresponding to free rotation of the methyl groups in the activated complex probably would be small. Moreover, other reasons for a high frequency factor in a chain reaction[18] do not seem applicable to the decomposition of diacetyl.

In trying to decide whether reaction (1′) or reaction (1″) is more probable, an attempt was made to estimate the strength of the carbon–carbon bond joining the two acetyl groups using the heats of combustion of diacetyl,[19] acetone[20] and ethane.[21] The energy necessary to dissociate diacetyl into two acetyl groups was found to be $A + (A - E) - 7$ with a possible error of ±6 kcal., where A is the energy of dissociation of acetone into a methyl and acetyl radical, and E, the energy of dissociation of ethane into two methyl radicals. On account of the variations in the values assigned by different investigators to these carbon–carbon bonds, an attempt to evaluate numerically the above expression at the present time does not seem justified. However, unless there is a large difference in the carbon–carbon bond in acetone and ethane, the middle carbon–bond in diacetyl will have a value near that of acetone, in other words, approximately the strength of an ordinary single bond. On the

other hand, LuValle and Schomaker's observations[22] of a shortening of 0.07 Å. in the bond between the adjacent carbonyl groups would indicate that this middle bond is somewhat stronger than a single carbon–carbon bond. Although it is difficult to make any decision as to which primary step actually occurs, on the basis of this latter evidence, reaction (1″) would seem to be more probable than reaction (1′).

Summary

1. The kinetics of the decomposition of diacetyl between 383 and 436° have been investigated by analyzing for the diacetyl present after different time intervals. The pressure increases corresponding to the different amounts of decomposition have been determined.

2. With variation of the initial pressure the reaction is first order, but during a run the first order constants fall off.

3. The first order rate constant can be expressed as $k = 8.7 \times 10^{15} e^{-63,200/RT}$ sec.$^{-1}$.

4. Determinations of the amount of ketene present during the decomposition show that the yield of ketene increases as the percentage of decomposition decreases.

5. Addition of propylene retards the decomposition of diacetyl.

The Heat Capacity and Entropy, Heats of Fusion and Vaporization and the Vapor Pressure of Methyl Chloride[1]

BY G. H. MESSERLY AND J. G. ASTON

This paper presents the results of a low temperature calorimetric investigation of methyl chloride. The work was begun several years ago to permit a comparison between the third law entropy and the value calculated from molecular constants for an organic compound containing methyl groups uncomplicated by the question of restricted rotation. The measurements had to be discontinued, however, because of the destruction by fire of a considerable portion of the Cryogenic Laboratory and have only recently been completed. Egan and Kemp have since published low temperature calorimetric data on methyl bromide and found good agreement between the calorimetric and "spectroscopic" entropy.[2] Our data on methyl chloride confirm the results of Egan and Kemp with methyl bromide.

Purification of Methyl Chloride.—A commercial sample was used as the starting material. About 150 cc. of liquid was distilled in the absence of air through an efficient vacuum-jacketed low temperature fractionating column (section 1 × 70 cm. packed with glass helices). An 80-cc. middle portion was redistilled and the middle cut of about 50 cc. after drying over P_2O_5 and removal of the last traces of air, was condensed in a weighed glass sample bulb. Vapor pressure measurements taken on the first and last portions of the final sample as the distillation proceeded had shown that no further purification of the material could be effected by fractionation. Two samples from different batches of starting material were prepared in this way. The second of these was used for all measurements. Only the melting point of the first sample was determined.

The Apparatus.—When the first sample prepared was being cooled to liquid hydrogen temperatures in the apparatus previously described[3] most of the apparatus was destroyed by a fire in the laboratory. The rebuilt apparatus was similar to the one destroyed except that the calorimeter itself was made entirely of gold and somewhat larger (present capacity 47 cc.) than the original gold-plated copper calorimeter. Heat conduction was provided for by eight radial vanes instead of the horizontal copper disks previously used. The single standard thermocouple at the bottom of the old calorimeter was replaced by two standard thermocouples which were fastened into horizontal platinum wells gold-welded on the top and bottom of the new calorimeter. The hydrogen liquefier that was an integral part of the old apparatus has been eliminated; liquid hydrogen produced in the laboratory liquefier and other refrigerants are added to the dewar surrounding the cryostat can through a vacuum jacketed german silver transfer tube. The present calorimeter is thus practically identical with the one described by Giauque and Egan.[4] It will hereafter be designated calorimeter C. The earlier calorimeter, only the winding of which was destroyed, is designated calorimeter

A. Calorimeter C was used in all the thermal measurements reported.

At the time that this apparatus was being rebuilt, data upon the performance of the adiabatic calorimeter[5] had not yet been obtained. It was for this reason that the destroyed isothermal calorimeter was replaced with one of the same type rather than the adiabatic apparatus, which has shown itself capable of greater accuracy than the isothermal calorimeter above 190 °K.

The Heat Capacity Measurements.—The method, temperature scale, and accuracy were as already described.[3] Standard thermocouples S-4 and S-7 were used for all temperature measurements. Their calibration was checked at the freezing and boiling points of hydrogen and oxygen, and at the upper transition point of oxygen. There was satisfactory agreement with the original scale.[6] The results of this and other similar comparisons made in this Laboratory from time to time will be discussed in a forthcoming paper. Standard thermocouple S-2 was used for the melting point determination in sample one.

One defined calorie was taken as equal to 4.1835 international joules. The density of liquid methyl chloride was obtained from the data of Timmermans.[7a] The heat capacity results are given in Table I and plotted in Fig. 1, where are also plotted some earlier heat capacity data on methyl chloride by Eucken and Hauck.[7b] These latter data may be seen to be unsuitable for third law calculations. The series number in Table I designates to which set of continuous measurements the particular measurement belongs.

The Vapor Pressure Measurements.—The measurements were made as already described,[3] and the results are given in Table II. Except for the lowest pressures the accuracy depends only upon the temperature. Column 1 gives the temperature as read by standard thermocouple S-7; column 2 the observed pressure and column 3 the difference between the observed pressure and that calculated from equation (1). Column 4 gives the temperature difference corresponding to the pressure difference in column 3.

10[a]	175.436	175.436	175.448
19	175.437	175.438	175.450
41	175.437	175.433	175.447
80	175.438	174.440	175.452
Melting point	175.44	175.44	175.45

[a] This observation taken one hour after the previous one.

Triple Point.—At the bottom of Table II are given the determinations of the triple point pressure.

The Melting Point.—The equilibrium temperature of both samples was observed over periods of fifteen and eighteen hours with increasing fractions of the sample melted as determined by the heat input. From these results and the heat of fusion, the solid insoluble impurity for both samples was found to be 0.002 ± 0.001 mole per cent. Tables IIIA and IIIB summarize the data.

Values of the melting point were obtained with two different samples and three different standard thermocouples. The value on sample I with thermocouple S-2 was obtained with calorimeter A. The values on sample II were obtained with the rebuilt apparatus.

The final value taken for the melting point was 175.44 ± 0.05°K. (−97.72°C.). Other values given in the literature for the melting point of methyl chloride are: −102.9,[8] −97.6,[9] −91.5,[10] −93[11] (all in °C.).

By solving equation (1) for one atmosphere 248.94 ± 0.02°K. (−24.22°C.) is obtained for the normal boiling point of methyl chloride. Other values given by earlier investigators for the normal boiling point are: −23.73,[12] −24.09,[13] −23.7,[14] −23.7,[7a] −23.8[15] (all in °C.). The values of the physical constants indicate that methyl chloride would be a suitable material for thermometric fixed points. It is curious that the values obtained in this research seem to be the only reliable ones for such a common substance.

The Heats of Fusion and Vaporization.—The heats of fusion were measured as already described, and the results are given in Table IV. The heat of vaporization at the boiling point has

been calculated from our vapor pressure equation and the equation of state data of Holst,[14] with the liquid density mentioned already. A direct experimental result has been published by Shorthose.[15] These values are compared in Table V. To obtain a final value, the experimental value of Shorthose was averaged with the one derived from the data of Holst. Double weight was given to the latter value. The heat of vaporization also has been calculated assuming a modified Berthelot equation of state for the gas with critical constants cited by Centnerszwer.[16] The agreement obtained justifies the later use of the Berthelot equation in calculating the entropy to the ideal gas state. This comparison could equally well have been made between the gas volumes, but in this case the experimental data of Shorthose would have received no weight.

TABLE V

THE HEAT OF VAPORIZATION OF METHYL CHLORIDE AT THE BOILING POINT

B. p., 248.94°K.; mol. wt., 50.495

		ΔH, cal./mole
(1)	Calculated from eqn. (1) and state data Holst[14] (1914)	5138 ± 10
(2)	Measured (Shorthose,[15] 1924)	5166 ± 20
	Average (2 × (1) + (2))/3	5147 ± 15
(3)	Calculated from eqn. (1) and modified Berthelot eqn. T_c = 143.2°C.;[16] P_c = 65.7 atm.[16]	5157

The Entropy from Thermal Data.—The calculation is summarized in Table VI. The entropy of the gas at 298.16°K. has been obtained by extrapolation using the spectroscopic data discussed by Stevenson and Beach.[17] The corrections for gas imperfection are based upon a modified Berthelot equation of state for the gas. For completeness the entropy of the superheated liquid has been estimated at 298.16°K.

The Entropy from Molecular Data.—Stevenson and Beach[11] have calculated the entropy of methyl chloride to be 55.99 e. u. for the ideal gas

The agreement between the entropy calculated from calorimetric and from molecular data further confirms the validity of applying the third law to organic compounds.

We gratefully acknowledge the help of the Research Corporation in providing a grant-in-aid which made the work possible. We wish to thank Mr. S. C. Schuman and Mr. R. M. Kennedy for help with the experimental work. We are indebted to Mr. C. W. Brouse for the execution of the fine mechanical work in the apparatus and the supervision of its construction.

Summary

The heat capacity of methyl chloride has been measured from 12°K. to the boiling point.

The melting and boiling points of methyl chloride are 175.44 and 248.94°K. respectively (0°C. = 273.16°K.).

The heat of fusion is 1537 cal./mole and the heat of vaporization is 5147 cal./mole at the boiling point.

The vapor pressure of methyl chloride is represented from the triple point to the boiling point by the equation, $\log_{10} P_{mm.} = -(1822.60/T - 9.287119 \log_{10} T + 0.00555556 T + 31.07167$.

The triple point pressure is 6.57 int. mm.

The entropy of methyl chloride in the ideal gas state has been found from calorimetric data to be 54.27 e. u. and 55.94 e. u. at 284.94 and 298.16°K., respectively. The corresponding values calculated from spectroscopic and molecular data are 54.31 e. u. and 55.98 e. u.

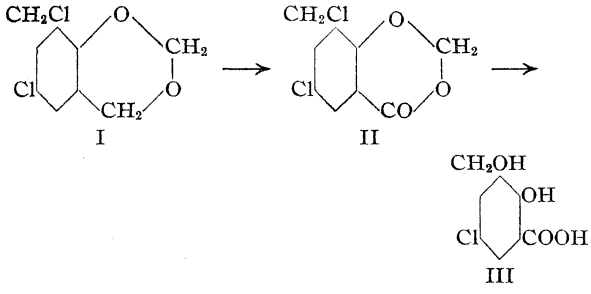
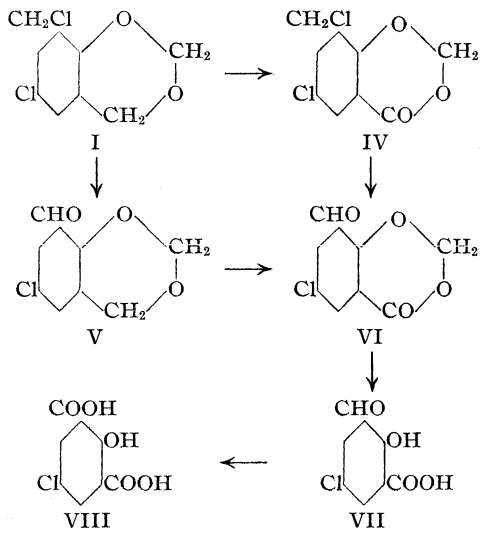
Proof of Structure of 6-Chloro-8-chloromethyl-1,3-benzodioxane by Oxidation[1]

BY C. A. BUEHLER, B. CALVIN BASS, ROBERT B. DARLING AND MILTON E. LUBS

In studying the action of formaldehyde on *p*-chlorophenol[2] in the presence of hydrochloric acid, a compound (I) thought to be 6-chloro-8-chloromethyl-1,3-benzodioxane was obtained. That the condensation product was a dioxane was shown by oxidation with chromium trioxide in acetic acid by the method of Borsche and Berkhout.[3] The 6-chloro-8-chloromethyl-1,3-benzodioxane-4-one, II, thus obtained gave, on alkaline hydrolysis, 2-hydroxy-3-methylol-5-chlorobenzoic acid, III.



To prove the structure of the original dioxane, I, a new oxidizing mixture, potassium permanganate in acetic acid, was tried and it was found that complete disruption of the dioxane ring was possible in one step. In this oxidation five products, IV, V, VI, VII and VIII, were isolated. Considering the effect of time and concentration of oxidizing agent on the amounts of the products obtained, we are inclined to support the oxidation sequence as indicated below. Of the first-formed products, IV appears in greater amounts than V although the former apparently is consumed more rapidly as the oxidation proceeds.



The 6-chloro-8-chloromethyl-1,3-benzodioxane-4-one, IV, and 6-chloro-8-aldo-1,3-benzodioxane, V, were isolated only in small quantities. The former, identical with II, gave the corresponding alcohol on alkaline hydrolysis while the latter was identified by conversion into its phenylhydrazone.

Of all the oxidation products, perhaps 6-chloro-8-aldo-1,3-benzodioxane-4-one, VI, is the most interesting because of the ease with which the dioxanone ring is broken. Not only does this opening occurs on standing and on titration with standard alkali, since the neutral equivalent is fairly satisfactory and 2-hydroxy-3-aldo-5-chlorobenzoic acid, VII, may be recovered from the titration mixture, but catalytic reduction, in which

(1) Presented at the 99th meeting of the American Chemical Society, Cincinnati, Ohio, April, 1940.

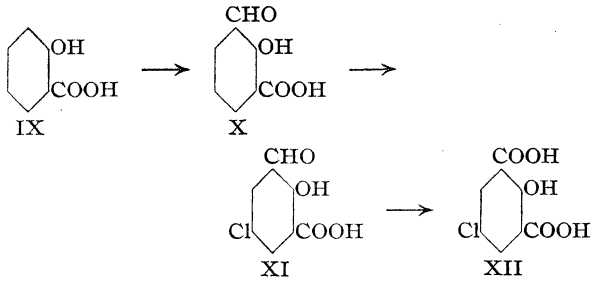
(2) For a similar reaction of phenol, see *Chem. Zentr.*, **103**, I, 2997(1932).

(3) Borsche and Berkhout, *Ann.*, **330**, 92 (1904).

the product is purified from slightly acidified water, gives 2-hydroxy-3-methylol-5-chlorobenzoic acid, III, rather than the expected 6-chloro-8-methylol-1,3-benzodioxane-4-one. Of indefinite melting point, this unstable dioxanone reacts positively with Tollens' reagent, a test which serves to distinguish it clearly from its decomposition product, 2-hydroxy-3-aldo-5-chlorobenzoic acid, VII, which does not affect this reagent.

2-Hydroxy-3-aldo-5-chlorobenzoic acid, VII, formed an oxime and could be oxidized readily to 2-hydroxy-5-chloroisophthalic acid, VIII, a compound which is fluorescent in ultraviolet light. The latter formed a diethyl ester.

None[4] of the oxidation products is recorded in the literature. To establish their constitution the synthesis below was carried out



Salicylic acid, IX, was converted into the known 2-hydroxy-3-aldobenzoic acid, X, by the Reimer–Tiemann reaction. On chlorination X gave a chloro derivative, XI, identical with VII. From an examination of the oxidation and synthetic series of reactions it is apparent that this identity could occur only if the formula for VII and XI was that of 2-hydroxy-3-aldo-5-chlorobenzoic acid. As further proof of structure, XI was oxidized with potassium permanganate in acetic acid to give the dicarboxylic acid, XII, which proved to be identical with VIII.

Experimental

Preparation of 6-Chloro-8-chloromethyl-1,3-benzodioxane.—To a mixture of 500 cc. of concentrated hydrochloric and 15 cc. of concentrated sulfuric acid warmed to 40°, 20 g. of Eastman Kodak Co. practical *p*-chlorophenol and 80 cc. of U. S. P. 40% formaldehyde were added. Hydrogen chloride was bubbled rapidly through the stirred mixture, kept at 40°, for one and one-half hours, at which point the solution had clarified with the separation of some solid. This crude solid, 30 g., was crystallized three times from methanol and gave 18.5 g. melting at 103°.

Anal. Calcd. for $C_9H_8O_2Cl_2$: Cl, 32.37; mol. wt., 219.1. Found: Cl, 32.31, 32.42; mol. wt. (cryoscopic, benzene), 217, 218.

Oxidation of 6-Chloro-8-chloromethyl-1,3-benzodioxane to 6-Chloro-8-chloromethyl-1,3-benzodioxan-4-one.—The dioxane, 3 g., was oxidized by the method of Borsche and Berkhout.[2] The crude benzodioxanone, washed with water until free from color, was crystallized from 95% ethanol, on the addition of water, in white, glistening plates, 1 g., melting at 181–182°. The compound gave a positive test for chlorine with aqueous silver nitrate, but no coloration was produced with ferric chloride nor was there any fluorescence in ultraviolet light.

Anal. Calcd. for $C_9H_6O_3Cl_2$: Cl, 30.43; mol. wt., 233.1. Found: Cl, 30.48, 30.22; mol. wt. (cryoscopic, acetic acid), 238, 242.

Hydrolysis of the Benzodioxanone to 2-Hydroxy-3-methylol-5-chlorobenzoic Acid.—6-Chloro-8-chloromethyl-1,3-benzodioxane-4-one, 1 g., was warmed with sodium hydroxide solution and then acidified as recommended by Borsche and Berkhout. The crude product when crystallized from 95% ethanol, upon the addition of water, gave a white powder, 0.5 g., melting at 165.5–166°. The pure acid produced a mulberry-purple color with ferric chloride and a bluish-green fluorescence in ultraviolet light.

Anal. Calcd. for $C_8H_7O_4Cl$: Cl, 17.50, neut. equiv., 202.6. Found: Cl, 17.61, 17.64; neut. equiv., 206.

Oxidation of 6-Chloro-8-chloromethyl-1,3-benzodioxane with Potassium Permanganate.—To a solution of 3 g. of 6-chloro-8-chloromethyl-1,3-benzodioxane in 100 cc. of glacial acetic acid there was added 160 cc. of distilled water, which causes considerable precipitation, and 9 g. of potassium permanganate. This mixture was refluxed vigorously for two hours while a stream of air was introduced to prevent bumping. After partial cooling, sulfur dioxide was bubbled through the solution to remove the color and dissolve the suspended material. To prevent resinification the resulting amber colored solution, having a greenish-blue fluorescence, was evaporated in a stream of air to one-half its volume or until organic material began to separate. Twice the volume of distilled water was then added, and the mixture was allowed to stand for three to four hours when about 0.2 g. of 6-chloro-8-aldo-1,3-benzodioxane, usually mixed with a smaller amount of 6-chloro-8-chloromethyl-1,3-benzodioxane-4-one, separated out. The total solid was dissolved in about 10 cc. of methanol and then thrown out by the addition of 50 to 75 cc. of cold water as 6-chloro-8-aldo-1,3-benzodioxane, a white solid melting at 138–138.5°.

After the removal of the crude 6-chloro-8-aldo-1,3-benzodioxane, concentrated hydrochloric acid was added to the filtrate until the amber color just disappeared. At the same time the solution became cloudy, and the fluorescence changed to blue-violet. This mixture was allowed to stand, usually twelve hours or more, until about 0.3 g. of 2-hydroxy-3-aldo-5-chlorobenzoic acid separated out. This product, when crystallized from water three or four times, gave 0.1 g. of long needles melting at 213.5–215.5°. More of the compound may be recovered by the addition of hydrochloric acid to the filtrate.

The filtrate obtained on removing the aldo acid was extracted with about 75-cc. portions of ether four times, the aqueous layer being discarded. On evaporating the com-

(4) German Patent 216,924 refers to a product, melting at 201°, which was thought to be 2-hydroxy-3-aldo-5-chlorobenzoic acid.

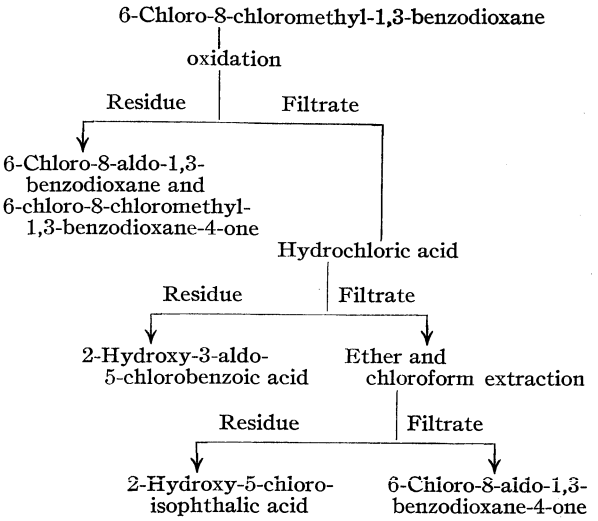
bined ether extractions to dryness, a mixture of about 1 g. of 6-chloro-8-aldo-1,3-benzodioxan-4-one and 2-hydroxy-5-chloroisophthalic acid, containing small amounts of 2-hydroxy-3-aldo-5-chlorobenzoic acid, was recovered. This residue was extracted with two 75-cc. portions of chloroform, and the combined chloroform solutions were then evaporated to about 90 cc., during which process some solid separated. This solid was removed and added to that remaining from the two chloroform extractions.

The chloroform filtrate was evaporated to about 25 cc., and the solid separating, about 0.4 g., which was removed by filtration, was crude 6-chloro-8-aldo-1,3-benzodioxan-4-one. This compound proved to be difficult to purify by the usual methods. Our best product was obtained by recrystallization twice from chloroform, in which process the first crystals, consisting largely of 2-hydroxy-5-chloroisophthalic acid, were discarded. The fact that 2-hydroxy-5-chloroisophthalic acid was fluorescent in ultraviolet light was of great assistance in this purification. Because of its instability the melting point of the 6-chloro-8-aldo-1,3-benzodioxan-4-one obtained, about 0.3 g., was indefinite. If heated rapidly, it melted in the neighborhood of 165–170°, then solidified, and finally sublimed around 190–200°. If heated slowly, the compound did not melt, but began to sublime around 175°, the process being complete near 200°.

The residue, about 0.3 g., remaining from the chloroform extractions was crude 2-hydroxy-5-chloroisophthalic acid. It was purified by solution in hot water followed by cooling in an ice-bath. After removing some 2-hydroxy-3-aldo-5-chlorobenzoic acid, which separated out first as an impurity, by filtration, concentrated hydrochloric acid was added to the filtrate and 2-hydroxy-5-chloroisophthalic acid precipitated. This compound, after five crystallizations, gave about 0.1 g. of a white, hair-like product melting at 238–240°.

Either varying the time or concentration of oxidizing agent exerted an influence on the amounts of the oxidation products. For instance, in a forty-five minute oxidation, fairly pure 6-chloro-8-chloromethyl-1,3-benzodioxan-4-one separated at the point at which impure 6-chloro-8-aldo-1,3-benzodioxane normally appeared. This dioxanone, after crystallization from methanol, weighed 0.25 g. and melted at 178–181°. A three-hour oxidation, in which the 6-chloro-8-aldo-1,3-benzodioxane-4-one produced was converted into 2-hydroxy-3-aldo-5-chlorobenzoic acid during the purification of 2-hydroxy-5-chloroisophthalic acid, gave 0.4 g. of the aldo acid. Likewise, a five and one-half hour oxidation gave 0.3 g. of 2-hydroxy-5-chloroisophthalic acid.

The scheme of separation employed for the oxidation products of 6-chloro-8-chloromethyl-1,3-benzodioxane may be represented diagrammatically as shown



Oxidation Products and Derivatives

(1) 6-Chloro-8-chloromethyl-1,3-benzodioxan-4-one.—This dioxanone, m. p. 178–181°, was identical with that previously described as melting at 181–182°. On hydrolysis it gave 2-hydroxy-3-methylol-5-chlorobenzoic acid also previously described.

(2) 6-Chloro-8-aldo-1,3-benzodioxane.—This compound, a white powder, m. p. 138–138.5°, gave negative tests with aqueous silver nitrate, ferric chloride, litmus and ultraviolet light.

Anal. Calcd. for $C_9H_7O_3Cl$: Cl, 17.85. Found: Cl, 17.82, 17.96.

(a) The phenylhydrazone separated from an alcoholic solution on the addition of water as pale yellow needles, m. p. 152.5–155°.

Anal. Calcd. for $C_{15}H_{13}O_2ClN_2$: Cl, 12.28. Found: Cl, 12.31, 12.21.

(3) 6-Chloro-8-aldo-1,3-benzodioxan-4-one.—The melting point of this dioxanone is of little significance as has been indicated above. The compound did not affect aqueous silver nitrate nor fluoresce in ultraviolet light, but it gave a mulberry-purple color with ferric chloride and a deposit of silver with Tollens reagent. In hot alkali it was sufficiently soluble for a neutral equivalent determination. Conversion to 2-hydroxy-3-aldo-5-chlorobenzoic acid was accomplished on standing or by heating in neutral or alkaline solution.

Anal. Calcd. for $C_9H_5O_4Cl$: Cl, 16.68; neut. equiv., 212.6. Found: Cl, 16.71, 16.88; neut. equiv., 202, 198.

(a) The oxime of 2-hydroxy-3-aldo-5-chlorobenzoic acid was obtained from the dioxanone and hydroxylamine hydrochloride in 10% sodium hydroxide solution. By the addition of water to an ethanol solution, it crystallized as a white, needle-like solid, m. p. 199.5–200.5°.

Anal. Calcd. for $C_8H_6ClNO_4$: Cl, 16.45; neut. equiv., 215.6. Found: Cl, 16.48; neut. equiv., 207.

(b) By reduction of the dioxanone in ethyl acetate with hydrogen (Raney catalyst) at 39 lb. (2.5 atm.) pressure followed by evaporation of the solvent and taking up the residue in warm water, 2-hydroxy-3-methylol-5-chlorobenzoic acid separated as the solution, slightly acidified with hydrochloric acid, cooled for several hours. Purification by the same process gave a product of m. p. 166.5–167°. The identity of this acid with that previously described was established by analysis and mixed melting point.

(4) 2-Hydroxy-3-aldo-5-chlorobenzoic Acid.—This aldo acid, one of the most abundant oxidation products, crystallized easily though not with a sharp melting point from

aqueous solution. The crude product, m. p. 208–214°, rose in melting point to 217–221° after ten crystallizations. The crystals separated in clusters from a dilute and in a hair-like mat from a concentrated solution. Aqueous silver nitrate reacted negatively, but ferric chloride gave a cherry-red coloration. In solution the substance gave a green fluorescence in reflected light, but there was no effect in the ultraviolet except on standing when fluorescence developed slowly due to the formation of 2-hydroxy-5-chloroisophthalic acid. Potassium permanganate in acetic acid converted the aldo acid to the corresponding dicarboxylic acid in good yield. The compound first formed was a monohydrate.

Anal. Calcd. for $C_8H_5ClO_4 \cdot H_2O$: Cl, 16.27; neut. equiv., 218.6. Found: Cl, 16.57, 16.49; neut. equiv., 208, 212.

Heating at 115–120° for three hours gave the anhydrous form.

Anal. Calcd. for $C_8H_5ClO_4$: Cl, 17.68; neut. equiv., 200.6. Found: Cl, 17.66, 17.80; neut. equiv., 201.

(a) The oxime, m. p. 199.5–200.5°, prepared in the usual manner, was shown by analysis and mixed melting point to be identical with that previously described. It gave a dark purple color with ferric chloride; its aqueous solution in reflected light produced a blue, while the solid in ultraviolet gave a yellowish-green, fluorescence.

(5) **2-Hydroxy-5-chloroisophthalic Acid.**—This dicarboxylic acid separated from water as a white mat resembling filter paper. When heated it shrank at about 225°, darkened at about 235°, and then melted with slight decomposition at 238–240°. Its aqueous solution in reflected light possessed a blue-violet, while the solid in ultraviolet gave a bright greenish-blue, fluorescence. Silver nitrate did not affect a solution of the acid, but ferric chloride produced a dark red color. The compound separating from water was a monohydrate.

Anal. Calcd. for $C_8H_5ClO_5 \cdot H_2O$: Cl, 15.11; neut. equiv., 117.3. Found: Cl, 15.23, 15.38; neut. equiv., 116, 115.

By heating for five hours at 115–120°, the anhydrous acid resulted.

Anal. Calcd. for $C_8H_5ClO_5$: Cl, 16.37; neut. equiv., 108.3. Found: Cl, 16.40, 16.42; neut. equiv., 115, 116.

(a) The diethyl ester was produced from ethanol and hydrogen chloride. By the addition of cold water to an ethanol solution, it crystallized as white needles, m. p. 50–51°. In ultraviolet light the solid produced a bluish-green fluorescence.

Anal. Calcd. for $C_{12}H_{13}ClO_5$: Cl, 13.00. Found: Cl, 13.04, 13.11.

Synthetic Products and Derivatives

(1) **2-Hydroxy-3-aldobenzoic Acid.**—This acid was prepared by the Reimer–Tiemann reaction[5] modified as follows. A solution of 200 g. of sodium hydroxide in 450 cc. of water was prepared and to 300 cc. of it at room temperature, containing 50 cc. of chloroform, there was added slowly, with constant stirring, 90 g. of salicylic acid. The resulting solution was placed in a three-necked, round-bottomed flask in which it was stirred while being refluxed on a water-bath at 80°. After the initial foaming and refluxing had subsided somewhat, another 50 cc. of chloroform and the remainder of the sodium hydroxide solution were added gradually through the condenser over a period of three hours. After another hour of stirring at 80°, the mixture was allowed to cool. Any chloroform layer was siphoned off, and 1:1 hydrochloric acid was added cautiously to the remainder of the reaction mixture until it became neutral, a fact indicated by its light, almost transparent appearance. After filtering off any resinous material present, 150 cc. more of 1:1 hydrochloric acid was added and a voluminous tan precipitate formed. This solid was permitted to settle while being cooled to about 20°, and then it was filtered off in a Büchner and washed five times with about 50-cc. portions of cold water.

The residue was now dissolved in an amount of 1:10 ammonium hydroxide sufficient to produce an orange to red solution. To this solution about 100 cc. of a 20% copper sulfate solution was added, with constant stirring, until the suspension which formed assumed a pea-green color. More 1:10 ammonium hydroxide, about 100 cc., was then added until the color became a much darker green.[6] After warming at 60° with constant stirring, the mixture was filtered, the green residue being washed three or four times with cold water.

In a solution of 15 cc. of concentrated sulfuric acid in 1200 cc. of water, the above residue was dissolved and, on stirring, the free 2-hydroxy-3-aldobenzoic acid separated as a flocculent white to yellow precipitate. So much resinous material was present, however, that the precipitate was redissolved in the mother liquor by heating barely to boiling, to avoid additional resinification, and the mixture was filtered rapidly. On cooling, tan crystals, melting at 167–173°, separated from the filtrate. For purification, the crude product was dissolved at room temperature in the least possible quantity of methanol, and this solution was poured several times through boneblack. Crystallization occurred after adding 3 volumes of water and cooling to 20°. Two more crystallizations from methanol gave 3 g. of tan needles melting at 178–179° (Reimer and Tiemann give 179°).

(2) **2-Hydroxy-3-aldo-5-chlorobenzoic Acid.**—Into a solution of 3.0 g. of 2-hydroxy-3-aldobenzoic acid in 75 cc. of glacial acetic acid surrounded with ice, dry chlorine was bubbled at the rate of 60 to 70 bubbles per minute until 1.3 g. of the gas had dissolved. After standing at room temperature for twenty-four hours, the reaction mixture was diluted with approximately three times its volume of distilled water. Upon cooling in a refrigerator for two hours, 2-hydroxy-3-aldo-5-chlorobenzoic acid had precipitated as a white, fluffy solid. By crystallization three times from water the acid, 2.7 g., melted at 226°. An analysis, as shown below, indicated that the compound was isomeric with the hydrated oxidation acid melting at 217–221°.

Anal. Calcd. for $C_8H_5ClO_4 \cdot H_2O$: Cl, 16.27; neut.

(5) Reimer and Tiemann, *Ber.*, **10**, 1563 (1877).

(6) The success of the experiment depends largely on the skill in arriving at the proper shade of color. Since the copper salts of 2-hydroxy-3-aldobenzoic and 2-hydroxy-5-aldobenzoic acids have different solubilities in ammonium hydroxide, a satisfactory separation is possible at the proper concentration. However, if the alkali is excessive, both isomeric salts dissolve.

equiv., 218.6. Found: Cl, 16.41, 16.61; neut. equiv., 212, 219.

That the two acids were identical was shown by a mixed melting of the oximes (synthetic aldoxime, m. p. 202°; oxidation aldoxime, m. p., 199.5–200.5°).

(3) **2-Hydroxy-5-chloroisophthalic Acid.**—To a solution of 1.2 g. of synthetic 2-hydroxy-3-aldo-5-chlorobenzoic acid in 40 cc. of glacial acetic acid, 64 cc. of distilled water and 4 g. of potassium permanganate were added. The mixture was stirred about a minute, until a noticeable reaction began, and then it was allowed to stand for two hours. After clarification with sulfur dioxide, evaporation to about half its volume, and then cooling, the crude 2-hydroxy-5-chloroisophthalic acid, which had separated, was removed. Upon purifying and heating as before, the anhydrous synthetic dicarboxylic acid melted at 245–246°. The analysis, as given below, indicated that the compound was isomeric with the anhydrous oxidation dicarboxylic acid whose hydrate melted at 238–240°.[7]

Anal. Calcd. for $C_8H_5ClO_5$: Cl, 16.37; neut. equiv., 108.3. Found: Cl, 16.48, 16.17; neut. equiv., 113, 113.

That the two dicarboxylic acids were identical was shown by a mixed melting point of the two diethyl esters (synthetic ester, m. p. 50°; oxidation ester, m. p. 50–51°).

(7) For both 2-hydroxy-3-aldo-5-chlorobenzoic and 2-hydroxy-5-chloroisophthalic acids the melting points of the hydrates do not differ appreciably from those of the anhydrous forms.

Summary

1. 6-Chloro-8-chloromethyl-1,3-benzodioxane has been obtained by the action of formaldehyde on *p*-chlorophenol in the presence of hydrochloric acid.

2. Oxidizing the above dioxane with potassium permanganate in acetic acid gave five products: 6-chloro-8-chloromethyl-1,3-benzodioxane-4-one, 6-chloro-8-aldo-1,3-benzodioxane, 6-chloro-8-aldo-1,3-benzodioxane-4-one, 2-hydroxy-3-aldo-5-chlorobenzoic acid and 2-hydroxy-5-chloroisophthalic acid.

3. The structure of 6-chloro-8-chloromethyl-1,3-benzodioxane was established through the identity of 2-hydroxy-3-aldo-5-chlorobenzoic and 2-hydroxy-5-chloroisophthalic acids with two isomeric acids synthesized from salicylic acid.

The Acetylation of alpha-Bromo Ketones and their Derivatives

BY R. P. BARNES AND VICTOR J. TULANE

In an attempt to obviate certain difficulties experienced with glacial acetic acid solutions of freshly fused potassium acetate as an acetylating agent for alpha haloketones, we turned to acetic anhydride solutions of the acetate instead. The results were so surprising that we decided to test further the power of this acetylating combination. Thus the following compounds were investigated: phenyl bromobenzyl diketone (I), bromodibenzoylmethane (II), desyl bromide (III), acetylbenzoin (IV) and benzoin (V).

$C_6H_5CHBrCOCOC_6H_5$ (I)

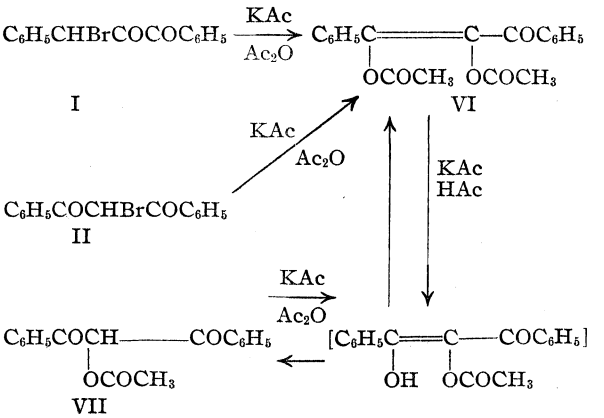
$C_6H_5COCHBrCOC_6H_5$ (II)

$C_6H_5CHBrCOC_6H_5$ (III)

$C_6H_5CH(OCOCH_3)COC_6H_5$ (IV)

$C_6H_5CHOHCOC_6H_5$ (V)

We have found that both bromo ketones (I) and (II) upon refluxing with a solution of freshly fused potassium acetate in acetic anhydride lead to the diacetate of phenylbenzoyl acetyleneglycol (VI). This diacetate, upon treatment with a solution of freshly fused potassium acetate in glacial acetic acid with subsequent distribution of the acetic acid by pouring into a large volume of water, is changed quantitatively into dibenzoylcarbinol acetate (VII). While other methods of acetylation fail,[1] dibenzoylcarbinol acetate is acetylated quantitatively by means of acetic anhydride–fused potassium acetate, giving the diacetate (VI).



(1) A. H. Blatt and W. Lincoln Hawkins, THIS JOURNAL, **58**, 81 (1936).

Neither phenyl bromobenzyl diketone (I) nor bromodibenzoylmethane (II) is enolic as indicated by alcoholic ferric chloride, and both are unaffected by acetic anhydride and by acetyl chloride. It is our experience that unless an alpha-bromo diketone is enolic, it is not acetylated by either of these reagents. It seems reasonable therefore that in these acetylations, bromine is first split out by metathesis with subsequent enolization and acetylation to the diacetate, since we have found[2] that compounds of the type R—C(OCOCH$_3$)=C(Br)—COR, which result from the acetylation of enolic bromo diketones, do not acetylate further under any known conditions.

We believe that these reactions give a feasible explanation of the behavior of the bromo diketones (I) and (II) on treatment with a solution of freshly fused potassium acetate in glacial acetic acid.[3]

The diacetate (VI) when dissolved in cold concd. sulfuric acid and poured onto finely crushed ice, gives the separation of a pale yellow solid. This solid oils out so rapidly that its melting point cannot be determined. However, its alcoholic solution gives with ferric chloride solution a deep greenish-blue color which fades rapidly, decolorizes iodine solution, and bleaches indophenol. These properties are characteristic of ene–diols. Thus the mesityl group in phenylmesitoylacetyleneglycol[4] and other ene–diols[4] does exert a stabilizing influence upon the ene–diol. On exposure to atmospheric oxygen the ene–diol (VIII) is changed to diphenyl triketone (IX).

$$C_6H_5C(OCOCH_3)\equiv C(OCOCH_3)—COC_6H_5 \xrightarrow{H_2SO_4}$$

VI

$$C_6H_5C(OH)\equiv C(OH)—COC_6H_5 \xrightarrow{O_2} C_6H_5COCOCOC_6H_5 + H_2O_2$$

VIII IX

In a similar manner, desyl bromide (III), acetyl benzoin (IV), and benzoin (V), are acetylated by acetic anhydride–fused potassium acetate to the alpha-diacetate of diphenyl acetyleneglycol[5] (X), whereas potassium acetate and acetic acid convert desyl bromide into acetyl benzoin.

(2) Unpublished graduate thesis.

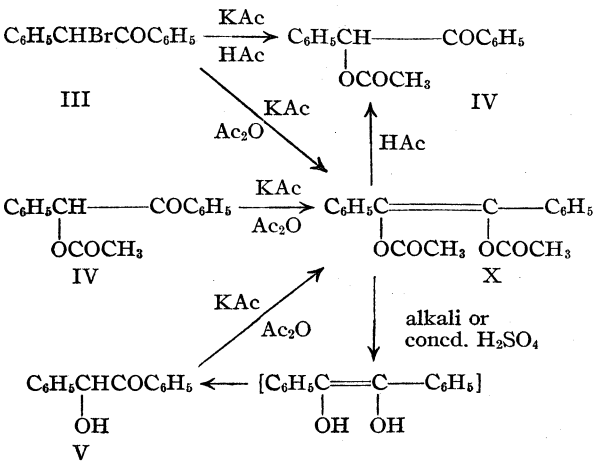
(4) R. P. Barnes and Leila S. Green, THIS JOURNAL, **60**, 1549 (1938); R. B. Thompson, *ibid.*, **61**, 1283 (1939); Reynold C. Fuson and Joseph Corse, *ibid.*, **61**, 975 (1939).

(5) Johannes Thiele, *Ann.*, **306**, 142 (1899).



The driving power in these reactions seems to be the concentration of potassium acetate. The diacetate (X) is hydrolyzed to acetylbenzoin by boiling acetic acid, and either aqueous alkali or concd. sulfuric acid converts the diacetate (X) to benzoin. Thus again the stabilizing effect of the mesityl group is manifested, since Thompson[4] and Fuson[4] have found that the two geometrically isomeric ene–diols resulting from the reduction of dimesitoyl are quite stable.

Experimental

Phenylbenzoylacetyleneglycol Diacetate (VI).—A solution of 10 g. of either phenyl bromobenzyl diketone or bromodibenzoylmethane in 50 cc. of acetic anhydride is refluxed gently for thirty minutes with 5 g. of freshly fused potassium acetate, after which it is poured into 500 cc. of cold water and stirred vigorously until the acetic anhydride is decomposed. The resulting yellow oil solidifies. It is filtered immediately, washed with water and dried, yielding a practically quantitative amount of crude material. It is recrystallized from hot methyl alcohol, and melts at 133°.

Anal. Calcd. for $C_{19}H_{16}O_5$: C, 70.3; H, 4.9. Found: C, 70.0; H, 4.8.

A solution of 10 g. of dibenzoylcarbinol acetate in 50 cc. of acetic anhydride with 5 g. of freshly fused potassium acetate is treated as described above, yielding a practically quantitative yield of phenylbenzoylacetyleneglycol diacetate, melting and mix-melting at 133°.

The Action of Glacial Acetic Acid on Phenylbenzoylacetyleneglycol Diacetate.—A solution of 5 g. of the diacetate in 25 cc. of glacial acetic acid is refluxed gently for thirty minutes with 2.5 g. of freshly fused potassium acetate and worked up as above. The product is recrystallized from methyl alcohol, melting and mix-melting with pure dibenzoylcarbinol acetate at 94°.

Phenyl bromobenzyl diketone and bromodibenzoylmethane are both recovered unchanged after refluxing for four hours with either acetyl chloride or acetic anhydride Neither gives any color with alcoholic ferric chloride.

Hydrolysis of Phenylbenzoylacetyleneglycol Diacetate.—Solution of 2.0 g. of the diacetate in 10 cc. of cold concd.

sulfuric acid produces a deep orange color. This solution is poured with stirring onto crushed ice. A light yellow solid separates out which soon becomes sticky. It cannot be crystallized from alcohol. Its alcoholic solution gives a deep greenish-blue color with ferric chloride, which color fades rapidly; it bleaches iodine and indophenol solutions instantly. On exposure to atmospheric oxygen, it changes to a yellow solid which is identified as diphenyltriketone, melting and mix-melting with an authentic sample at 70°.

Diphenylacetyleneglycol Diacetate (X).—Separate solutions of 10.0 g. each of desyl bromide, acetylbenzoin and benzoin in 50 cc. of acetic anhydride are refluxed gently with equal weights of freshly fused potassium acetate for thirty minutes. Each solution turns yellow to light brown. After cooling, they are poured into large volumes of cold water and stirred vigorously until the acetic anhydride is decomposed. A cream-colored granular solid separates out. The solid is filtered, washed with water, and dried over solid potassium hydroxide. It is then crystallized from methyl alcohol, yielding 3.0 g. of a crystalline solid, melting at 153° and 6.0 g. of material melting at 70°. The material melting at 70° mix-melts with acetylbenzoin at 70°, and is hydrolyzed quantitatively by alkali to benzoin. Repeated recrystallizations do not change the melting point of 70°. When refluxed with acetic anhydride and potassium acetate, it yields the 153° substance. It is a mixture of acetylbenzoin and diphenylacetyleneglycol diacetate. The diacetate, melting at 153°, is hydrolyzed quantitatively by both alkali and cold concd. sulfuric acid to benzoin, identified by its melting point and mixed-melting point. Hot glacial acetic acid converts the diacetate to acetylbenzoin.

Acetylbenzoin (IV).—A solution of 10.0 g. of desyl bromide in 50 cc. of glacial acetic acid is refluxed with 10.0 g. of freshly fused potassium acetate for thirty minutes, cooled and poured into a large volume of water. An oily solid separates, which is crystallized from methyl alcohol, melting and mix-melting with acetylbenzoin at 84°.

Summary

Herein is reported the use of an acetylating combination which seems to be more powerful than acetic anhydride in the presence of concd. sulfuric acid, converting certain compounds which have the group —CH(Br)— or —CH(OCOCH$_3$)— or —CH(OH)— adjacent to a >C=O group, into diacetates of acetyleneglycol.

The properties of the ene–diol, phenylbenzoylacetyleneglycol, resulting from the hydrolysis of its diacetate are given.

Further possibilities of this acetylating combination are now under investigation.

Sterols. XCV. Acid Isomerization of Pseudosapogenins to Sapogenins

BY RUSSELL E. MARKER AND EWALD ROHRMANN

The reaction of the sapogenins with acetic anhydride to yield the isomeric pseudosapogenins is now a well-established reaction which has been applied to sarsasapogenin,[1] *epi*-sarsasapogenin,[2] sarsasapogenone,[2] isosarsasapogenin,[2] tigogenin[3] and chlorogenin.[2] Although there may be some question concerning the structure of the pseudosapogenins all of the available evidence indicates the presence of an ethylenic linkage at C-16, C-17 and a reactive grouping at C-22 possibly as in I.[4]

In studying the reduction of pseudosarsasapogenone[2] by the Clemmensen method, it was observed that the essential reaction product was desoxysarsasapogenin and not desoxypseudosarsasapogenin. That this isomerization of the pseudosapogenin side chain to the sapogenin side chain is due to the presence of hydrochloric acid is clearly shown in succeeding experiments.

Pseudosarsasapogenin upon standing with aqueous ethanolic hydrochloric acid at 25° for one day is almost quantitatively converted into sarsasapogenin. Pseudotigogenin and pseudochlorogenin readily were converted into the corresponding sapogenins by short refluxing with aqueous ethanolic hydrochloric acid. It seems probable that this reaction involves the addition of hydrogen chloride to ethylenic linkages followed by elimination of hydrogen chloride and subsequent ring closure to yield the spiro ketal system. It is significant that dihydropseudosarsasapogenin[4] is unaffected by similar treatment.

In previous work we have shown that the side chains of tigogenin, chlorogenin and diosgenin and probably of gitogenin and digitogen differ in

configuration from the side chain of sarsasapogenin. This was shown by the conversion of sarsasapogenin to neotigogenin,[5,6] a substance differing from tigogenin only in the configuration of the side chain. That the configuration of the side chain of the sapogenins derived from the acid isomerization of the pseudosapogenins is determined largely by the configuration at C-5 is indicated by the fact that pseudosarsasapogenin (pseudoisosarsasapogenin[2]) yields largely sarsasapogenin rather than isosarsasapogenin, while pseudotigogenin yields largely tigogenin rather than neotigogenin. Thus it may be generalized that pseudosapogenins having the regular configuration at C-5 give rise to a spiro ketal side chain of the "sarsasapogenin configuration" (II), while those having the *allo*-configuration give rise to one having the "isosarsasapogenin configuration" (III). It seems most probable that these reactions are of an equilibrium nature and that the isomerization of pseudosarsasapogenin probably gives rise to small amounts of isosarsapogenin besides the sarsasapogenin. Likewise the isomerization of pseudotigogenin probably gives small amounts of neotigogenin in addition to the tigogenin.

The behavior of the pseudosapogenins on acid isomerization raises the interesting question concerning the structure of the side chains of unhydrolyzed saponins. It would appear that some of these substances such as tigonin[7] and amolonin,[8] the parent saponins of tigogenin, give rise to more sugar groups on acid hydrolysis than one would reasonably expect to be attached to a single hydroxyl group such as exists in tigogenin. This suggests that the nucleus of the saponins may be that of the pseudosapogenins (I) or more probably that of the keto-diol IV, which is the equivalent of a spiro ketal (II and III). Such substances, during the course of the acid hydrolysis necessary for the cleavage of the glycoside linkages, would be converted to spiro ketals (II and III). The existence of a nucleus such as I or IV, on the basis of the previously mentioned equilibrium, satisfactorily explains the existence of smilagenin[9,10,11] (isosarsasapogenin) and neotigogenin[6] among the hydrolysis products of the saponins.

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part[12]

Clemmensen Reduction of Pseudosarsasapogenone.—To a boiling solution of 200 mg. of pseudosarsasapogenone in 50 cc. of ethanol in the presence of 5 g. of 20-mesh zinc was added 8 cc. of concentrated hydrochloric acid over a period of two hours. Water was added and the precipitated solid taken up in ether and crystallized from acetone to give white plates, m. p. 214–216°. This gave no depression with a sample of desoxysarsasapogenin of m. p. 214–216°.

Anal. Calcd. for $C_{27}H_{44}O_2$: C, 80.9; H, 11.1. Found: C, 81.2; H, 11.1.

Isomerization of Pseudosapogenins. (a) **Pseudosarsasapogenin.**—To a solution of 500 mg. of pseudosarsasapogenin, m. p. 170–173°, in 100 cc. of 95% ethanol was added a mixture of 85 cc. of ethanol and 15 cc. of concentrated hydrochloric acid. After standing at 25° for twenty hours, water was added and the precipitated solid taken up in ether and crystallized from acetone to give 400 mg. of white needles, m. p. 199–201°. This gave no depression with a sample of sarsasapogenin, m. p. 199–201°.

With chromic anhydride at room temperature, this gave a neutral product which crystallized from acetone as white plates, m. p. 223–226°. This gave no depression with a sample of sarsasapogenone, m. p. 223–226°.

With hot acetic anhydride an acetate was formed which was crystallized repeatedly from acetone–methanol to give white plates, m. p. 125–127°. When mixed with a sample of sarsasapogenin acetate, m. p. 143–145°, the mixture melted from 126–144°. When seeded with a crystal of sarsasapogenin acetate, m. p. 143–145°, a product of m. p. 142–144° was obtained. This gave no depression with sarsasapogenin acetate.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.9; H, 10.1. Found: C, 75.8; H, 10.2.

Similar results were obtained when pseudosarsasapogenin was refluxed in ethanol solution with aqueous hydrochloric acid for ninety minutes.

Dihydropseudosarsasapogenin, m. p. 169°, was recovered unchanged after refluxing for two hours in aqueous ethanolic hydrochloric acid solution.

(b) **Pseudotigogenin.**—Pseudotigogenin when refluxed for one hour with aqueous ethanolic hydrochloric acid gave a good yield of a product which crystallized from acetone as white needles, m. p. 203–205°. This gave no depression with a sample of tigogenin, m. p. 204–206°.

With boiling acetic anhydride this yielded an acetate, m. p. 202–204°, which gave no depression with an authentic sample of tigogenin acetate, m. p. 202–204°.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.9; H, 10.1. Found: C, 75.7; H, 10.0.

(c) **Pseudochlorogenin.**—Pseudochlorogenin when treated as described for pseudotigogenin gave a good yield of a product which crystallized from acetone as white needles, m. p. 269–272°. This gave no depression with a sample of chlorogenin, m. p. 270–273°.

With boiling acetic anhydride this yielded a diacetate, m. p. 149–151°, which gave no depression with a sample of chlorogenin diacetate, m. p. 149–151°.

Anal. Calcd. for $C_{31}H_{48}O_6$: C, 72.05; H, 9.4. Found: C, 72.1; H, 9.3.

Summary

Pseudosarsasapogenin, pseudotigogenin and pseudochlorogenin are isomerized by hydrochloric acid to the original sapogenins.

Sterols. XCVI. *allo*-Pregnanediols from Tigogenin

BY RUSSELL E. MARKER AND EWALD ROHRMANN

In a recent publication[1] the conversion of sarsasapogenin to $\Delta^{16,17}$-pregnenedione-3,20 and the subsequent reduction of this to various pregnane derivatives was described. In the present work we have extended some of these reactions to tigogenin (I), a substance having the *allo*-configuration at C-5.

Tigogenin upon treatment with acetic anhydride at 200° is converted to pseudotigogenin which upon mild oxidation with chromic anhydride is converted to an unsaturated diketone of the composition $C_{21}H_{30}O_2$. This substance is undoubtedly $\Delta^{16,17}$-*allo*-pregnenedione-3,20 (II) a substance first reported by Butenandt, Mamoli and Heusner.[2] Their product was prepared from androsterone by conversion to the nitrile, reaction with methyl Grignard reagent and subsequent oxidation. The product was reported to melt at 205–208°, while our product from tigogenin melts at 210–212°.

Reduction of the unsaturated diketone with sodium and ethanol yields *allo*-pregnanediol-3(β),20(α) while reduction with Adams catalyst yields *allo*-pregnanediol-3(β),20(β). The ease of reduction with sodium and ethanol indicates the presence of an α,β-unsaturated ketone grouping.

Although data have been presented indicating that the configuration of the C-3 hydroxyl group in tigogenin is *beta*, none of this evidence can be considered conclusive inasmuch as it has been derived from digitonin precipitation data[3] and from reduction experiments on $\Delta^{4,5}$ unsaturated ketones,[4] reactions which might conceivably be influenced by the presence of the complex side chain.

(1) Marker and Rohrmann, THIS JOURNAL, **62**, 518 (1940).
(2) Butenandt, Mamoli and Heusner, *Ber.*, **72**, 1614 (1939).

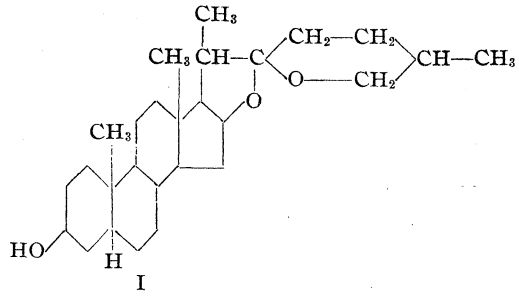
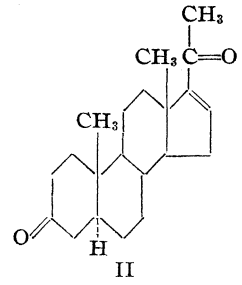
(4) Marker and Rohrmann, THIS JOURNAL, **61**, 1291 (1939).



I



II

The conversion of tigogenin to *allo*-pregnanediol-3(β),20(β) and *allo*-pregnanol-3(β)-one-20 by reactions in which the original C-3 hydroxyl group remains intact definitely proves that the configuration of the C-3 hydroxyl group is *beta*. Pseudotigogenin was acetylated and oxidized with chromic anhydride under relatively mild conditions, giving a non-crystalline product. Reduction of this with Adams catalyst followed by mild oxidation with chromic anhydride and subsequent hydrolysis yielded *allo*-pregnanol-3-(β)-one-20, while direct hydrolysis of the reduction product yielded *allo*-pregnanediol-3(β),20(β).

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Experimental Part

Pseudotigogenin.—A mixture of 3.6 g. of tigogenin and 25 cc. of acetic anhydride was heated at 195–200° for eight hours. The solvent was removed *in vacuo* and the residue hydrolyzed with ethanolic potassium hydroxide. The neutral material was crystallized from aqueous acetone to give white crystals, m. p. 193–196°. When mixed with tigogenin, m. p. 204°, it gave a depression in melting point to 180–186°, yield 3.1 g.

Anal. Calcd. for $C_{27}H_{44}O_3$: C, 77.8; H, 10.6. Found: C, 77.5; H, 10.5.

$\Delta^{16,17}$-*allo*-Pregnenedione-3,20 from Pseudotigogenin.—To a solution of 1.5 g. of pseudotigogenin in 100 cc. of acetic acid was added a solution of 1.5 g. of chromic anhydride in 25 cc. of 90% acetic acid. It was allowed to stand at 25–28° for two hours, poured into water and extracted with ether. The ethereal solution was washed with 2% sodium hydroxide solution and the product remaining after evaporation of the ether was sublimed in a high vacuum at 120–125°. This was crystallized from ether–pentane and finally from ether to give small white crystals, m. p. 210–212°. It gave a 25° depression with *allo*-pregnanedione-3,20, m. p. 210°; yield 425 mg.

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.2; H, 9.6. Found: C, 80.0; H, 9.5.

The substance was unchanged by refluxing with acetic anhydride.

***allo*-Pregnanediol-3(β),20(α) from $\Delta^{16,17}$-*allo*-Pregnenedione-3,20.**—To a solution of 200 mg. of $\Delta^{16,17}$-*allo*-pregnenedione-3,20 in 50 cc. of boiling absolute ethyl alcohol was added 4 g. of sodium in small pieces. After the sodium had dissolved, water was added and the product was extracted with ether. It was recrystallized from methanol and acetone, giving white crystals, m. p. 213–214°. It gave no depression in melting point when mixed with *allo*-pregnanediol-3(β),20(α), m. p. 214–217°; yield 160 mg.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.7; H, 11.3.

This product gave an acetate with hot acetic anhydride which was crystallized from methanol as white crystals, m. p. 166–168°. It gave no depression in melting point when mixed with the diacetate of *allo*-pregnanediol-3(β),20(α), m. p. 166–168°.

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.2; H, 10.0. Found: C, 74.0; H, 9.9.

***allo*-Pregnanediol-3(β),20(β) from $\Delta^{16,17}$-*allo*-Pregnenedione-3,20.**—A solution of 200 mg. of $\Delta^{16,17}$-*allo*-pregnenedione in 100 cc. of acetic acid was shaken with 100 mg. of Adams catalyst under a pressure of 45 pounds (3 atm.) of hydrogen for three hours. The product was crystallized from ethanol to give white crystals, m. p. 192–193°. It gave no depression in melting point when mixed with *allo*-pregnanediol-3(β),20(β), m. p. 192–194°.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.8; H, 11.3. Found: C, 78.6; H, 11.2.

Oxidation of Pseudotigogenin Acetate with Chromic Oxide.—A solution of 1.6 g. of pseudotigogenin in 10 cc. of acetic anhydride was refluxed for thirty minutes. The excess acetic anhydride was removed *in vacuo* and the residue was dissolved in 100 cc. of glacial acetic acid. To this was added 2 g. of chromic oxide in 10 cc. of 80% acetic acid. After standing at 28° for two hours, water was added and the precipitated solid taken up in ether. The acids were removed by washing with water and sodium carbonate solution. Upon evaporation of the ether the residue failed to crystallize from acetone or ethanol, probably due to some by-products of the oxidation. The total product was dissolved in acetic acid and shaken with hydrogen under 45 pounds (3 atm.) pressure in the presence of Adams catalyst for one hour. A portion of the reduction product was hydrolyzed by refluxing for thirty minutes with alcoholic potassium hydroxide solution. This product was crystallized from ethyl alcohol to give white crystals, m. p. 192–194°. Mixed with *allo*-pregnanediol-3-(β),20(β), m. p. 192–194°, it gave no depression in melting point.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.7; H, 11.3. Found: C, 78.4; H, 11.3.

The remainder of the reduction product was dissolved

in 20 cc. of acetic acid and oxidized by adding 1 g. of chromic anhydride in dilute acetic acid. The neutral fraction was refluxed for fifteen minutes with alcoholic potassium hydroxide, then crystallized from dilute ethanol to give a product melting at 192–193°. Mixed with *allo*-pregnanol-3(β)-one-20, m. p. 192–193°, it gave no depression in melting point.

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.2; H, 10.7. Found: C, 79.3; H, 10.6.

Summary

Tigogenin reacts with acetic anhydride to yield pseudotigogenin which on mild oxidation with chromic anhydride yields $\Delta^{16,17}$-*allo*-pregnenedione-3,20.

Reduction of $\Delta^{16,17}$-*allo*-pregnenedione-3,20 with sodium gives *allo*-pregnanediol-3(β),20(α) while reduction with Adams catalyst gives *allo*-pregnanediol-3(β),20(β). The configuration of the hydroxyl group in tigogenin is shown to be *beta*.

STATE COLLEGE, PENNA. RECEIVED JANUARY 2, 1940

[CONTRIBUTION FROM THE SCHOOL OF CHEMISTRY AND PHYSICS OF THE PENNSYLVANIA STATE COLLEGE]

Sterols. XCVII. Sarsasapogenin

BY RUSSELL E. MARKER AND EWALD ROHRMANN

We find that sarsasapogenin reacts with both ethylmagnesium bromide and methylmagnesium iodide to yield products which contain two esterifiable hydroxyl groups. Oxidation of the diacetate of the ethyl Grignard product with chromic anhydride at 90° gave 3-hydroxy-*etio*-bilianic acid.[1]

The dimethyl ester[1] of the 3-hydroxy-*etio*-bilianic acid readily was converted to a monomethyl ester by hydrolysis with one equivalent of alkali. This indicates that one of the carboxyl groups in the acid is hindered, as might be anticipated from the structure. This is also in accord with the results of Litvan and Robinson[2] concerning the analogous acid derived from *o*-methylestrone. The mono-methyl ester yielded a crystalline acetate which, upon treatment with thionyl chloride and diazomethane by the procedure of Arndt and Eistert,[3] yielded a nicely crystalline diazo ketone.

Attempts to convert the diazo ketone to a crystalline acid by treatment with silver oxide were unsuccessful. The non-crystallline acid obtained from this reaction was treated with acetic anhydride to give, after alkaline hydrolysis, a ketone of the composition $C_{19}H_{30}O_2$, m. p. 117–119°. For purposes of comparison we prepared *etio*-cholanol-3(β)-one-17 by the method used by Ruzicka and co-workers.[4] This product after purification melted at 117° when crystallized from pentane. Ruzicka reports his product to melt at 151–152°. Evidently this ketone, as in the case of many other sterol ketones, exists in several polymorphic forms with different melting points. This product did not depress in melting point when mixed with the product prepared from 3-hydroxy-*etio*-bilianic acid. Both products formed semicarbazones melting at 240–242° with decomposition.

As further proof of the identity of the above product, it was reduced by sodium in amyl alcohol and the 3-OH group epimerized to the α-form. This product was identical with *etio*-cholanediol-3(α),17(α) prepared by the reduction of *epi-etio*-cholanolone with sodium in ethanol. The *etio*-cholanediol-3(α),17(α) was converted into its diacetate and this subjected to partial hydrolysis with methanolic potassium hydroxide, followed by oxidation with chromic anhydride. The resulting product was then hydrolyzed to yield *etio*-cholanone-3-ol-20. This substance was converted readily to testosterone by bromination and subsequent removal of hydrogen bromide with pyridine.

We wish to thank Parke, Davis and Company for their generous assistance.

Experimental Part

Reaction of Sarsasapogenin Acetate with Ethylmagnesium Bromide.—To a Grignard reagent prepared from 6.1 g. of magnesium, 27.5 g. of ethyl bromide and 100 cc. of ether was added a solution of 5 g. of sarsasapogenin acetate in 200 cc. of ether. Most of the ether was distilled off and the residual liquid was refluxed for fifteen hours with 25 cc. of benzene. The mixture was decomposed with dilute hydrochloric acid and the solid taken up in ether. The product was crystallized from ethyl acetate–pentane as flaky white needles, m. p. 159–161.5°.

Anal. Calcd. for $C_{29}H_{50}O_3$: C, 77.9; H, 11.3. Found: C, 77.9; H, 11.2.

When refluxed with an excess of acetic anhydride the product yielded a diacetate which crystallized from aqueous methanol as white needles, m. p. 87.5–89°.

Anal. Calcd. for $C_{33}H_{54}O_5$: C, 74.7; H, 10.3. Found: C, 74.8; H, 10.1.

Reaction of Sarsasapogenin Acetate with Methylmagnesium Iodide.—This reaction was carried out as described above. The product was crystallized from ethyl acetate–pentane as white plates, m. p. 179–181.5°.

Anal. Calcd. for $C_{28}H_{48}O_3$: C, 77.7; H, 11.2. Found: C, 77.7; H, 11.2.

When treated with *p*-nitrobenzoyl chloride in pyridine at 60° the substance formed a **di-*p*-nitrobenzoate**, which crystallized from ether as white crystals, m. p. 192–194°.

Anal. Calcd. for $C_{43}H_{56}O_9N_2$: C, 69.3; H, 7.6. Found: C, 69.2; H, 7.6.

Oxidation of Diacetate of Ethyl Grignard Product.—To a stirred solution of 3 g. of the diacetate of the ethyl Grignard product in 60 cc. of acetic acid heated at 90° was added a solution of 7 g. of chromic anhydride in 40 cc. of 80% acetic acid over a period of one hour. The mixture was stirred for an additional hour at 90° when ethanol was added and the mixture concentrated *in vacuo* to about one-third volume. Water was added and the solid taken up in ether and washed with water and 3% sodium hydroxide. The alkaline water layer was heated on the steam-bath for twenty minutes, cooled, acidified with hydrochloric acid and the precipitated acid taken up in ether and crystallized from chloroform as small white crystals, m. p. 220–222°. This gave no depression with a sample of 3-hydroxy-*etio*-bilianic acid, m. p. 220–222°; yield 1.1 g.

Anal. Calcd. for $C_{19}H_{30}O_5$: C, 67.4; H, 8.9. Found: C, 67.2; H, 8.9.

Mono-methyl Ester of 3-Hydroxy-*etio*-bilianic Acid.—A solution of 2.68 g. of the dimethyl ester of 3-hydroxy-*etio*-bilianic acid in 25 cc. of methanol was refluxed for ninety minutes with a solution of 0.292 g. (1 mol) of sodium hydroxide in 8 cc. of water. The mixture was diluted with water, acidified with hydrochloric acid and the precipitated acid taken up in ether. The ethereal extract was washed with 0.5% potassium hydroxide solution. Evaporation of the ethereal solution gave approximately 1 g. of unchanged dimethyl ester.

The alkaline extract was acidified with hydrochloric acid and the precipitate taken up in ether and crystallized from ether–pentane as small compact white crystals, m. p. 211–213°.

Anal. Calcd. for $C_{20}H_{32}O_5$: C, 68.1; H, 9.2. Found: C, 68.3; H, 9.1.

When refluxed with an excess of acetic anhydride the monomethyl ester yielded an **acetate** which, after treatment in acetone with Norite, crystallized from aqueous acetone and aqueous methanol as compact white crystals, m. p. 181.5–183.5°.

Anal. Calcd. for $C_{22}H_{34}O_6$: C, 66.95; H, 8.7. Found: C, 67.0; H, 8.8.

Diazoketone from Monomethyl Ester.—A solution of 2 g. of the acetate of the monomethyl ester of 3-hydroxy-*etio*-bilianic acid in 10 cc. of dry benzene and 2 cc. of thionyl chloride (colorless) was refluxed on the steam-bath for two hours. The solvents were evaporated and the residual sirup was evaporated repeatedly *in vacuo* with dry benzene.

The acid chloride was not obtained crystalline. The product was dissolved in 60 cc. of ether and to this solution at 0° was added a cold ethereal solution of diazomethane (from 4 g. of methylnitrosourea). The solution was allowed to stand at room temperature for sixteen hours, when the solvent was evaporated. The residue was crystallized from ether–acetone–pentane as pale yellow needles, m. p. 159–160° dec. (gas); yield 1.2 g.

Anal. Calcd. for $C_{23}H_{33}O_5N_2$: C, 66.1; H, 8.0; N, 6.7. Found: C, 66.1; H, 8.1; N, 6.4.

Conversion of Diazoketone to *etio*-Cholanol-3(β)-one-17.—To a solution of 1 g. of the diazoketone in 25 cc. of absolute ethanol heated at 70–80° was added 2 g. of dry, freshly prepared silver oxide. The mixture was warmed at 70–80° for one hour, after which time the evolution of gas had ceased. The mixture was filtered and the filtrate diluted with water and the precipitated solid taken up in ether. Evaporation of the ether gave a non-crystalline sirup which was hydrolyzed with hot ethanolic potassium hydroxide. The resulting acid could not be crystallized. The sirup was refluxed with acetic anhydride for twenty-five minutes and the excess acetic anhydride was distilled off up to 250°. The residue was heated at 250° for one hour and then sublimed in high vacuum at 4 mm. pressure at 200–250°.

The sublimate was hydrolyzed with ethanolic potassium hydroxide and the neutral fraction treated with Girard reagent. The resulting ketonic material was sublimed in high vacuum and crystallized from ether–pentane as white needles, m. p. 117–119°.

Anal. Calcd. for $C_{19}H_{30}O_2$: C, 78.5; H, 10.4. Found: C, 78.2; H, 10.7.

When treated with semicarbazide acetate the product yielded a **semicarbazone** which crystallized from aqueous ethanol as white crystals, m. p. 241–242.5° dec.

Anal. Calcd. for $C_{20}H_{33}O_2N_3$: C, 69.1; H, 9.6. Found: C, 69.0; H, 9.3.

etio-Cholanolone was prepared by the oxidation of coprostanol by the method described by Ruzicka and coworkers.[5] It was isolated as the semicarbazone, m. p. 240–242°.

Anal. Calcd. for $C_{20}H_{33}O_2N_3$: C, 69.1; H, 9.6. Found: C, 69.0; H, 9.3.

A solution of 1 g. of the above semicarbazone was refluxed with 30 cc. of ethanol and 5 cc. of concentrated sulfuric acid in 10 cc. of water for three hours. The product was extracted with ether, the solvent removed and the residue was sublimed at 120–130° in a high vacuum. It was then crystallized from pentane giving white needles, m. p. 117–118°. It gave no depression in melting point when mixed with the same product obtained from 3-hydroxy-*etio*-bilianic acid.

Anal. Calcd. for $C_{19}H_{30}O_2$: C, 78.5; H, 10.4. Found: C, 78.4; H, 10.7.

***etio*-Cholanediol-3(α),17(α).**—To a solution of 200 mg. of *etio*-cholanolone in 80 cc. of amyl alcohol was added 5 g.

of sodium. The solution was refluxed for ten hours to ensure epimerization of the 3 hydroxyl group. The product was sublimed in high vacuum and crystallized from ethyl acetate, m. p. 233–235°. It gave no depression in melting point with an authentic sample of *etio*-cholanediol-3(α),17(α) prepared by the reduction of *epi-etio*-cholanolone.

Anal. Calcd. for $C_{19}H_{32}O_2$: C, 78.0; H, 11.0. Found: C, 78.1; H, 11.1.

With boiling acetic anhydride the product gave a diacetate which was crystallized from methanol as white crystals, m. p. 124–125°.

Anal. Calcd. for $C_{23}H_{36}O_4$: C, 73.4; H, 9.7. Found: C, 73.3; H, 9.8.

Ruzicka and co-workers[5] report a m. p. of 236–236.5° for the diol and of 124.5–125.5° for the diacetate.

Partial Hydrolysis of the Diacetate of *etio*-Cholanediol-3(α),17(α).—To a solution of 1.5 g. of the diacetate of *etio*-cholanediol-3,17 in 1 liter of absolute methanol was added 0.8 mol (titration) of potassium hydroxide in 100 cc. of methanol. After standing at room temperature for fifty hours, it was carefully neutralized with sulfuric acid and the methanol removed *in vacuo*. The residue was extracted with ether, washed well with water and the ether evaporated. The residue was dissolved in 25 cc of acetic acid, vacuum evaporated twice, and then dissolved in 25 cc. of acetic acid at room temperature. To this solution was added 700 mg. of chromic anhydride in 10 cc. of 80% acetic acid. After standing for forty-five minutes the mixture was diluted with water and extracted with ether. After washing with dilute sodium carbonate solution and water the ether was evaporated and the residue was dissolved in 50 cc. of ethyl alcohol. To this was added 2 g. of Girard reagent and the product was refluxed for twenty minutes. Water was added and the precipitated product extracted with ether. The aqueous layer was decomposed with hydrochloric acid and the solid product extracted with ether. The ether was evaporated and the residue dried with benzene. To the residue was added 1.5 g. of succinic anhydride and 5 cc. of pyridine and the mixture heated for ninety minutes. Ether was added and the pyridine removed by shaking with dilute hydrochloric acid. The ethereal extract was washed with potassium carbonate solution and the aqueous layer acidified and extracted with ether. Evaporation of the ether gave a residue which was hydrolyzed with ethanolic potassium hydroxide. The resulting product was treated with Norite in acetone and crystallized from ether–pentane (1:1). After standing overnight in a refrigerator the crystalline material was filtered. This product was not very soluble in ether, and was crystallized directly from this solvent, to give a small amount of a product melting at 145–148°, which gave no depression in melting point with *etio*-cholanone-17-ol-3(α), m. p. 149–150°.

The filtrate was evaporated and the residue crystallized from pentane to give white crystals, m. p. 139–141°. When mixed with *etio*-cholanone-17-ol-3(α) of a melting point of 148° it gave a depression of 24°. This product was *etio*-cholanone-3-ol-17.

Anal. Calcd. for $C_{19}H_{30}O_2$: C, 78.5; H, 10.4. Found: C, 78.2; H, 10.4.

Testosterone.—To a solution of 225 mg. of *etio*-cholanone-3-ol-17 in 20 cc. of glacial acetic acid acidified with hydrobromic acid was added 7.5 cc. of a 0.1 *M* solution of bromine in acetic acid. The solution was diluted with water and extracted with ether. The ethereal solution was shaken with dilute sodium bicarbonate solution, filtered, and the ether evaporated. The residue was crystallized from pentane–acetone. It melted over a range of 150–156°, but was not further purified.

To 100 mg. of this product was added 10 cc. of pyridine and the solution was refluxed for nine hours. Ether and water were added and the pyridine removed by shaking with dilute hydrochloric acid. The product was sublimed in a high vacuum and the sublimate crystallized from pentane to give white crystals, m. p. 149–151°, which gave no depression in melting point when mixed with an authentic sample of testosterone, m. p. 150–152°.

Anal. Calcd. for $C_{19}H_{28}O_2$: C, 79.1; H, 9.8. Found: C, 79.0; H, 9.7.

Summary

Sarsasapogenin has been converted into testosterone.

Glycofuranosides and Thioglycofuranosides. VII. Crystalline Alkyl Furanosides and Dimethylacetal of *d*-Mannose

BY ALLEN SCATTERGOOD[1] AND EUGENE PACSU

The general method of Pacsu and Green[2] for the preparation of glycofuranosides from the sugar mercaptals was applied to mannosediethylmercaptal which was previously obtained[3] from sirupy mannose by Fischer and from crystalline mannose by Levene and Meyer.[4] It was found that this starting material could be prepared conveniently and in good yield directly from the readily available α-methyl-*d*-mannopyranoside[5] by the action of hydrochloric acid and ethyl mercaptan. As was reported in a preliminary communication,[2f] the reaction between mannosediethylmercaptal and mercuric chloride in methyl alcoholic solution under neutral conditions resulted in a 60% yield of pure α-methyl-*d*-mannofuranoside (m. p. 118°; $[\alpha]^{20}D$ 108.4° in water solution) previously prepared by Haworth and co-workers through the dicarbonate[6] and direct from mannose[7] and methyl alcoholic hydrogen chloride. Green and Pacsu used pyridine to remove the excess mercuric chloride necessary to carry this type of reaction to completion. During the course of this work it was found that metallic mercury was also suitable for this purpose, the reaction being $Hg^{++} + Hg \rightarrow Hg_2^{++}$. On acetylation by acetic anhydride and sodium acetate, α-methyl-*d*-mannofuranoside readily gave a crystalline tetraacetate (m. p. 61–62°; $[\alpha]^{20}D$ 108.8° in chloroform solution) which was identical with the compound obtained[7a] by Haworth and co-workers by the pyridine method of acetylation. The substance had a specific rotation[8] of 105.3° in *trans*-dichloroethylene and 120.3° in *cis*-dichloroethylene.

When the sirupy residue of the mother liquor of α-methyl-*d*-mannofuranoside was treated with a saturated aqueous solution of calcium chloride, crystallization of a non-reducing, negatively rotating substance started immediately. After recrystallization by the addition of isobutyl alcohol to its concentrated methyl alcoholic solution, the substance had a specific rotation of −58.5° in water solution. It represented a calcium chloride addition compound of β-methyl-*d*-mannofuranoside with the composition of $C_7H_{14}O_6 \cdot CaCl_2 \cdot 3H_2O$. Subsequent investigation revealed that the sirupy residue of the mother liquor of α-methyl-*d*-mannofuranoside prepared according to Haworth and co-workers[7] would also combine with calcium chloride to yield the same addition compound. Furthermore, it was also obtained directly from mannose and methyl alcoholic hydrogen chloride at room temperature in the presence of calcium chloride. Considering the difficulties involved in the preparation of crystalline mannose, it is probably best to prepare this calcium chloride compound from the mercaptal. Removal of the calcium chloride from the addition compound by silver oxalate resulted in the pure β-methyl-*d*-mannofuranoside, which was obtained from ethyl acetate solution in long needles. Irvine and Burt[9] first suggested the existence of this substance as they believed that the "γ-methylmannoside" which they obtained in the sirupy condition was a mixture of two forms. Recently Haworth and co-workers obtained[10] β-methyl-*d*-mannofuranoside by the carbonate method but were unable to secure it in the crystalline condition. Our purest preparation which had been recrystallized three times from ethyl acetate melted at 47° and had a specific rotation of −112.6° in water solution as against −107° observed first[2f] on a slightly reducing sample. From the rotation of the calcium chloride compound (−58.5°) a rotation of −108.2° is calculated for the optically active portion of

this substance by multiplying by the formula weight ratio of 359/194. In a special experiment we found that addition of the calculated amount of calcium chloride to the aqueous solution of the pure furanoside changed the observed rotation from −6.65 to −6.40°. Further amounts of calcium chloride added to the solution did not appreciably change the rotation of the solution. This experiment clearly indicated that calcium chloride has a perturbing effect upon the rotation of the glycoside with which it is combined and that it is unsafe to calculate the rotation of a sugar or sugar derivative from the rotation of its calcium chloride compound by multiplying by the formula weight ratio.

By application of the furanoside synthesis to mannosediethylmercaptal in ethyl, normal propyl, and isopropyl alcohols, respectively, the corresponding α-alkyl mannofuranosides were obtained in the crystalline state. Table I contains the more important constants of the furanosides prepared in the course of the present work.

TABLE I

ALKYL MANNOFURANOSIDES WITH THEIR MELTING POINTS, OBSERVED AND CALCULATED ROTATIONS AND A_x'' VALUES

d-Manno-furanosides	Mol. wt.	M. p., °C.	$[\alpha]^{20}D$ in water	[M]	A_x'' [M] − $B_{\alpha\beta}$[a]	$[\alpha]_D$ calcd. from (A_x[b] + $B_{\alpha\beta}$[a] + F[c])
α-Methyl	194	118	108.4	21,030	21,455	...
β-Methyl	194	47	−112.8	−21,880	−21,455	...
α-Ethyl	208	90	105.0	21,840	22,265	105.4
α-n-Propyl	222	89	96.0	21,310	21,735	100.2
α-i-Propyl	222	82–84	96.7	21,470	21,895	100.8

[a] $B_{\alpha\beta}$ = −425, one-half the sum of the molecular rotation of α- and β-methyl-d-mannofuranoside. [b] A_x designates the following "normal" values for the aldoses: A_{OMe} = 18,700; A_{OEt} = 19,600; A_{OPr} = 19,925; $A_{Oi\text{-}Pr}$ = 20,060. [c] F = 2755 obtained from $A''_{OMe} - A_{OMe}$.

When the pentaacetate of mannosediethylmercaptal was submitted to the action of mercuric chloride in absolute methyl alcohol under neutral conditions, mannosedimethylacetal pentaacetate was formed. On deacetylation, this substance gave rise to crystalline mannosedimethylacetal with m. p. 101° and $[\alpha]^{20}D$ 0.6° in water solution. The dimethylacetal was stable in neutral and alkaline media but it suffered gradual hydrolysis at room temperature in a 0.05% hydrochloric acid solution. The specific rotation in the latter medium changed in forty-eight hours from the initial value of 0.6° to −34°. This change was probably due to the formation of a mixture of the α- and β-methylmannofuranoside from the dimethylacetal and the reaction followed a first order course with the velocity constant of 10^4k = 240. After the point of maximum levorotation had been reached, the rotation changed slowly to the final value of +12.8°, the approximate final rotation of d-mannose. This second change apparently represented the hydrolysis of the furanosides to methyl alcohol and mannose and it proceeded about one-twentieth as rapidly ($10^4 k$ = 11.8) as the first stage of the hydrolysis reaction.

Mannopyranose and its derivatives have been known for a long time to present a notable exception to the validity of van't Hoff's hypothesis of optical superposition as applied by Hudson to the sugars and certain of their derivatives. By the preparation of the crystalline β-methylmannofuranoside, it has now become possible to test Hudson's isorotation rules in the mannofuranose series also. It is seen in Table I that half of the rotational difference of the two mannofuranosides, A''_{OMe} = 21,455, is considerably larger than the "normal" value, A_{OMe} = 18,700, for the methylglycosides of the aldoses. It appears, therefore, that the isorotation rules do not hold for the furanoid derivatives of mannose just as they are not applicable directly to mannose and its pyranoid derivatives where the value of the same coefficient is A'_{OMe} = 14,225. In a recent communication[11] it has been shown that by introduction of a new term (F) in the simple equations used for the calculation of the rotations, correct values are obtained for d-mannose and l-sorbose and its pyranoid derivatives from the "normal" A_x and a_x coefficients for the aldoses and ketoses, respectively. The numerical value of F is calculated by subtraction of the value of any "normal" A_x coefficient from that of the corresponding "abnormal" coefficient. It represents a constant characteristic of a particular sugar and its derivatives in a certain solvent. Thus, F = −4475 was calculated from $A'_{OMe} - A_{OMe}$ (14,225 − 18,700) for d-mannopyranose and all its glycosidic derivatives in water solution. It is to be expected that by introduction of a similar constant for the mannofuranose series the calculated and observed rotations of the glycosidic derivatives will show satisfactory agreement. The pertinent data in Table I reveal that this, indeed, is the case. The value of the new term, F = 2755, represents the difference between the "abnormal" and the "normal" coefficients of

(11) Pacsu, THIS JOURNAL, 61, 2669 (1939).

$A''_{OMe} = 21{,}455$ and $A_{OMe} = 18{,}700$, respectively, and it remains practically constant for the different alkyl mannofuranosides.

As to the physical significance of F, it has been suggested[11] that this constant probably represents the numerical value of the contribution of a hitherto unrecognized optical factor, the ring conformation, to the total rotation of the molecule. In the furanose series, where the ring is almost certainly planar, large deviations from the isorotation rules should not be found if ring conformation were the only disturbing factor. However, it is quite certain that the B coefficient of the sugars and their derivatives consists of at least four optical factors without considering a possible solvent effect. These factors are the number (N) of the different atoms, the conformation (C) of the ring, the configuration (C_f) of the hydrogen atoms and hydroxyl groups around the asymmetric centers, and the orientation (O) about the C–O bonds of all the hydroxyl groups. The last factor is probably due to the formation of hydrogen bonds. Obviously these factors must have nearly constant values for both the α- and β-isomers of those pyranoid or furanoid sugars and sugar derivatives which obey the rules of isorotation in first approximation, since in such instances only will the difference between the B parts of the isomers be zero, and, consequently, the value of A_x be a constant quantity. On the other hand, in instances where the isorotation rules are not valid, the value of at least one of the factors must be different for the α- and β-forms, since the difference, in such cases, between the B parts of the α,β-isomers will not be zero and, consequently, the value of A_x will be modified by this difference. Of the four factors under consideration, factor N represents a constant characteristic of certain groups of sugars, such as pentoses, aldohexoses, ketohexoses, etc., and it must have the same value for both the ring and the α,β-isomers of any member within these groups. Similarly, the factor C_f should have a constant value characteristic of the individual members of the different groups of sugars and should not change either for the ring isomers or for the α,β-isomers of a particular sugar. With regard to factor C, any simple sugar molecule containing a strainless six-membered ring should, according to Haworth,[12] be theoretically capable of existing in two *trans* and six *cis* forms constituted on the Sachse principle. However, Pacsu[11] recently reported that attempts to build up these forms from the Fisher–Hirschfelder atom models resulted in the discovery that only one *cis* and one *trans* form could be constructed. The diameters of these atom models are the so-called collision diameters obtained from the kinetic theory or from a rule of Pauling that the collision diameter is equal to 3.2 times the covalent radius. Figures 1 to 8 represent the skeleton models of a pyranose molecule constructed from these atom models in the eight conformations advocated by Haworth.

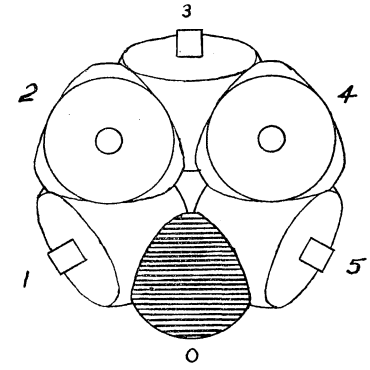

Fig. 1.—*trans*-Form, O above plane of paper, C_3 below plane of paper. A —CH_2OH group projecting outward on C_5 (*d*-form) would not interfere with groups attached to neighboring carbon atoms. This conformation is possible for the *d*-aldohexoses but not for the *l*-forms, which would have the —CH_2OH group on the lower valence of C_5 where it would block groups on the lower valences of C_1 and C_3. This does not mean that the *d*- and *l*-forms of an aldohexopyranose will not be mirror images. It simply indicates that the mirror image of the *d*-form will be derived from a different figure (Fig. 2).

It becomes evident by handling these models that *d*-hexopyranose molecules with conformations represented by Figs. 2, 4, 5, 6, 7, and 8 cannot be constructed because more or less obstruction occurs between certain atoms or atomic groups such as the hydrogen atom and the hydroxyl group of one or more ring carbon atoms and the —CH_2OH group which would be on carbon atom 5 of an aldohexose molecule. On the other hand, molecules with either of the two conformations represented by Figs. 1 and 3 can be constructed readily without obstructions occurring between any of the addenda of the ring. Since theoretical considerations[13] indicate that a *cis* form would be unstable and would pass over to the *trans* form because of large repulsion both in the ring and among the

(13) Gorin, Kauzmann and Walter, *J. Chem. Phys.*, **7**, 327 (1939).

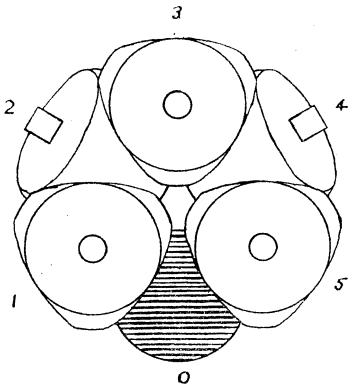

Fig. 2.—*trans*-Form, O below plane of paper, C_3 above plane of paper. Bottom view of Fig. 1. A $-CH_2OH$ group projecting upward on C_5 (*d*-form) partially covers the upper valences of C_1 and C_3. Even with hydrogen atoms on the two latter positions, there would be some interference. This conformation is possible for the *l*-aldohexoses but not for the *d*-forms. The *d*-form of a given aldohexose would be derived from Fig. 1 while the *l*-form, its mirror image, would be derived from Fig. 2.

subsidiary groups, there remains only one *trans* form (Fig. 1) from which all the *d*-hexopyranose molecules and their derivatives must be derived. In such a case factor C will have the same value for the α- and β-form of any pyranoid sugar or sugar derivative. Finally, factor O for the α-form (O_α) of any sugar may differ considerably from the same factor for the β-isomer (O_β) and, therefore, will not cancel out in the calculation of the numerical value of A_x. This appears to be the case in mannose, rhamnose, sorbose, etc., and their pyranoid derivatives where large deviations from the isorotation rules have been observed.

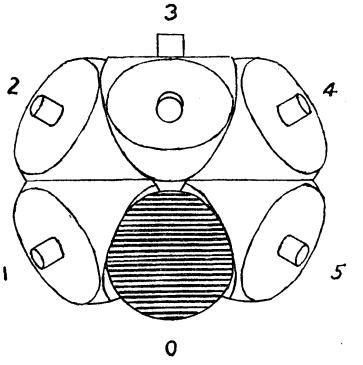

Fig. 3.—Symmetrical *cis*-form, O and C_3 above plane of paper. A $-CH_2OH$ group projecting outward on C_5 (*d*-form) would not interfere with groups of neighboring carbon atoms. This conformation is possible for the *d*-aldohexoses but not for the *l*-forms, which would have the $-CH_2OH$ group on the lower valence of C_5 where it would partially cover the lower valences of C_1 and C_4.

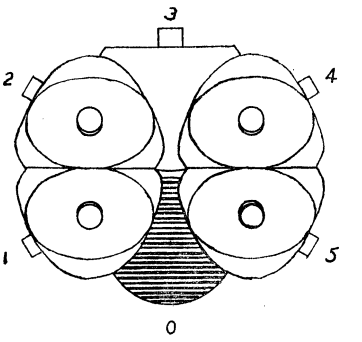

Fig. 4.—Symmetrical *cis*-form, O and C_3 below plane of paper. Bottom view of Fig. 3. A $-CH_2OH$ group projecting upward on C_5 (*d*-form) partially covers the upper valences of C_1 and C_4. This conformation is possible for the *l*-aldohexoses but not for the *d*-forms.

In the mannopyranose series $F = -4475$ represents, therefore, the numerical value of half of such difference $[(O'_\alpha - O'_\beta)/2]$. Since factor C is necessarily constant for all the furanosides (planar ring) any large deviation from the rules in this series must also be ascribed to the difference in the rotation values of the O factors for the α- and β-isomers. Obviously this is the case in the alkyl mannofuranosides where $F = 2725$ represents the numerical value of half of such difference $[(O''_\alpha - O''_\beta)/2]$. In both the pyranose and furanose series, therefore, the physical significance of F appears to be confined to the disturbing optical effect of the different orientation of the hydroxyl groups in the α- and β-isomers of certain sugars. As pointed out previously,[11] the occurrence of such disturbances at present cannot be predicted, neither can the effect be measured by physical or chemical methods. In many

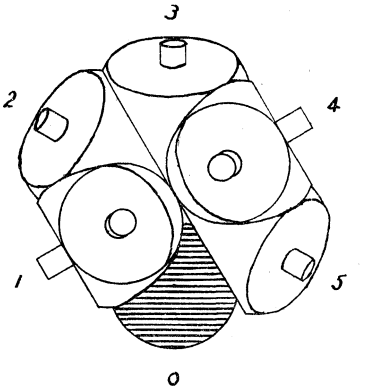

Fig. 5.—Asymmetrical *cis*-form, C_1 and C_4 above plane of paper. In both the *d*- and *l*-forms there would be interference between OH groups and H atoms on the upper valences of C_1 and C_4. Neither form can exist in this conformation.

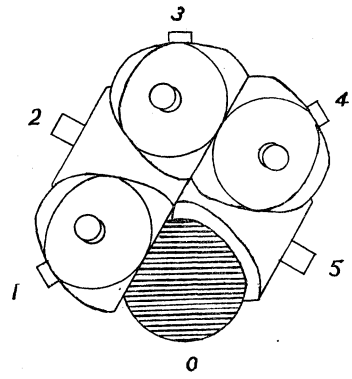

Fig. 6.—Asymmetrical *cis*-form, C_2 and C_5 below plane of paper. Bottom view of Fig. 5. In both the *d*- and *l*-forms there would be no interference on the top face of the molecule. However, on the bottom face of C_2 and C_5 there would always be interference. Neither form can exist in this conformation.

instances the optical effect of the orientation appears to be negligible (glucose-arabinose series) but for certain sugars (mannose, sorbose, etc.) it must be eliminated from the calculations by the introduction of term *F*, a characteristic constant for each of these sugars.

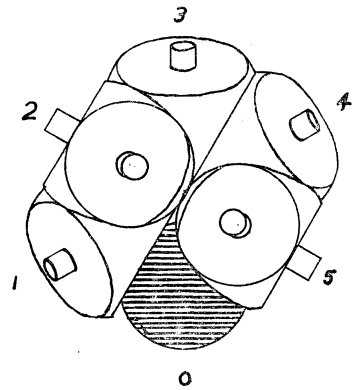

Fig. 7.—Asymmetrical *cis*-form, C_2 and C_5 above plane of paper. Mirror image of Fig. 5. A $-CH_2OH$ group projecting upward on C_5 (*d*-form) partially covers the upper valence of C_2. Even for the *l*-form, with H atoms on the upper valences of C_2 and C_5, there is interference. Neither form can exist in this conformation.

Experimental Part

Preparation of Mannosediethylmercaptal from α-Methyl-*d*-mannopyranoside.—One hundred cc. of ethyl mercaptan was added to 100 g. of crude α-methylmannopyranoside[5] in 100 cc. of concd. hydrochloric acid and the mixture was shaken for twenty hours at room temperature. At the end of this time the reaction product was treated with ice-cold water (150 cc.) and the crystals which soon formed were filtered and washed with small quantities of ice water. The crude product was purified by crystallization from water containing enough ammonia

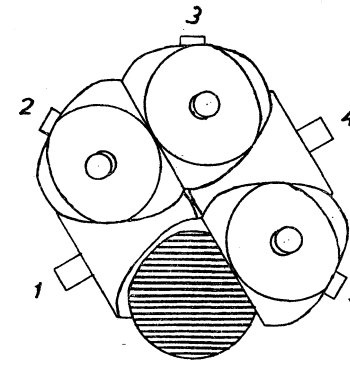

Fig. 8.—Asymmetrical *cis*-form, C_1 and C_4 below plane of paper. Bottom view of Fig. 7, mirror image of Fig. 6. A $-CH_2OH$ group projecting upward on C_5 (*d*-form) partially covers the upper valence of C_3. There would also be interference for both the *d*- and *l*-forms on the bottom valences of C_1 and C_4. Neither form can exist in this conformation.

to make the solution alkaline and decolorized by the use of activated carbon; yield, 54%; m. p. 131–133°.

Preparation of α-Methylmannofuranoside and its Tetraacetate.—A warm solution of 109 g. of mercuric chloride (0.4 mole) in 500 cc. of absolute methyl alcohol was added slowly to a suspension of 87 g. of yellow mercuric oxide in a solution of 57.6 g. of mannosediethylmercaptal (0.2 mole) in 500 cc. of absolute methyl alcohol. During the addition the mixture was either shaken mechanically or stirred. After the addition had been completed, the mixture was stirred or shaken for three hours. A test for the completion of the reaction was usually made after this time by heating the clear filtrate of a sample of the mixture with water. The reaction was complete if no precipitate of mercaptoethyl mercuric chloride would form. The insoluble mercury compounds were then filtered off and washed with methyl alcohol. The filtrate and washings contain mercuric chloride, which must be removed. This can be accomplished either by the use of pyridine according to Pacsu and Green[2] or by means of metallic mercury. In the latter procedure the united liquids were shaken with 7 cc. of mercury until the solution was free of chloride ion. This usually required four days of continuous shaking. After this time the mixture was filtered and the solution was evaporated *in vacuo* to a sirup which often crystallized spontaneously. If this was not the case then the sirup was dissolved in two or three times its volume of normal propyl alcohol and the solution was inoculated with seed crystals secured by evaporation of a methyl alcoholic solution of a small sample of the sirup in a stream of air. In either case the crystals were washed with cold normal propyl alcohol until the rotation of the washings became positive. Evaporation of the filtrate and washings *in vacuo* or in a stream of air gave a sirup which deposited more crystals on addition of an equal volume of normal propyl alcohol. After a thorough chilling the crystals were filtered and washed with ice-cold normal propyl alcohol in 10-cc. portions until the washings became positively rotating. The total yield of

the crude product was 25 g. or 64%. The strongly negative rotating filtrate and washings were saved for the preparation of the β-isomer. Haworth and co-workers[7a] used a mixture of methyl alcohol and ether to crystallize α-methylmannofuranoside. Six crystallizations were reported necessary with this combination of solvents. In the present work, normal propyl alcohol was found to be a better solvent, as pure material was obtained after two recrystallizations. The substance was dissolved in ten times its weight of normal propyl alcohol at 75°. The hot solution was filtered through a steam-jacketed funnel and the filtrate was kept in the icebox overnight. After the second recrystallization the substance had m. p. 118° and $[\alpha]^{20}D$ 108.4° in water solution, in agreement with the data of Haworth, Hirst and Wood.[7b]

Anal. Calcd. for $C_7H_{14}O_6$: OCH_3, 15.97. Found: OCH_3, 15.92.

For acetylation, 1 g. of α-methylmannofuranoside was boiled for two minutes with 5 cc. of acetic anhydride containing 0.25 g. of anhydrous sodium acetate. After the solution had been worked up in the usual manner, the product crystallized spontaneously from its chloroform solution upon evaporation in a stream of air. After recrystallization from aqueous alcohol it had m. p. 61–62° and $[\alpha]^{20}D$ 108.8° in chloroform (*c*, 1.23), 105.3° in *trans*-dichloroethylene (*c*, 1.56) and 120.3° in *cis*-dichloroethylene (*c*, 1.18). Haworth, Hirst and Webb[7a] prepared this substance by acetylation of the furanoside in pyridine at 0°. By the above procedure the acetate was secured in the crystalline condition without the difficulty which Haworth and co-workers encountered.

Preparation of the Calcium Chloride Compound of β-Methylmannofuranoside.—From the combined filtrate and washings of the α-methylmannofuranoside a strongly negatively rotating sirup was obtained by evaporation of the solution *in vacuo*. A saturated aqueous solution of 8 g. of calcium chloride was added to the sirup. Crystallization of the calcium chloride mannoside compound started within a few minutes, and was initiated by stirring. During the crystallization an equal volume of normal propyl alcohol was stirred in so that the mixture would not set to a solid. The crystalline slush was chilled in ice for several hours and then filtered with suction. The crystals were washed with cold absolute ethyl alcohol, in which they were insoluble. The substance was dried *in vacuo* over calcium chloride; yield, 8 g. or 13%. From the mother liquor, after the removal of the excess calcium chloride by means of silver oxalate, several small quantities of α-methylmannofuranoside were obtained. A careful search failed to reveal the presence of any mannosedimethylacetal.

The crude calcium chloride compound was dissolved in a minimum quantity (about 20 cc.) of cold methyl alcohol. The formation of the solution is a slow process and an excess of methyl alcohol is to be avoided. Isobutyl alcohol was then added to the solution, a few cc. at a time, until a total of 60 cc. had been added at room temperature. Crystallization started at this point and 20 cc. of isobutyl alcohol was added during the crystallization, making a total of 80 cc. The crystals were kept in the icebox overnight and then filtered and washed with isobutyl alcohol; yield, practically quantitative; $[\alpha]^{20}D$ −58.5° in water solution (*c*, 1.711). A similar process of recrystallization by the use of water instead of methyl alcohol and normal propyl alcohol instead of isobutyl alcohol was employed to prepare a sample of the substance for analysis, since the methyl alcohol method gave high values to the methoxyl content.

Anal. Calcd. for $C_7H_{14}O_6 \cdot CaCl_2 \cdot 3H_2O$: Ca, 11.16; Cl, 19.74; H_2O, 15.04; OCH_3, 8.64. Found: Ca, 11.08; Cl, 19.70; H_2O, 15.13; OCH_3, 8.70.

The compound was very soluble in water and methyl alcohol and almost insoluble in ethyl alcohol and higher alcohols. It was devoid of action toward Fehling solution. In testing the compound with Fehling solution it was found that an excess of the alkaline tartrate portion of the reagent would keep the calcium in solution as a complex ion during the test. The substance was hydrolyzed in 0.575 *N* hydrochloric acid at 19° in two days to give mannose with $[\alpha]D$ 14.0°.

The same substance was obtained from the mother liquor of the α-methylmannofuranoside prepared according to Haworth and co-workers.[7a] After several crops of the α-compound were removed, a sirup was obtained which was strongly negatively rotating. This was treated with an equal volume of a saturated aqueous solution of calcium chloride and the crystalline compound formed was filtered with some ethyl alcohol; yield, 0.5 g. from 10 g. of mannose.

The calcium chloride compound of β-methylmannofuranoside was also prepared direct from mannose in the following way. To 360 cc. of methyl alcohol containing 1% of dry hydrogen chloride, there was added 11 g. of calcium chloride (0.1 mole) and 18 g. of *d*-mannose (0.1 mole). The mixture was shaken on the machine until the mannose had all dissolved. After twenty hours of standing at room temperature the solution showed its lowest negative rotation. The acid was then neutralized by shaking the solution with silver carbonate. After filtration the solution was evaporated *in vacuo* to a sirup which was dissolved in 125 cc. of warm normal propyl alcohol. On inoculation with a crystal of the calcium chloride compound the product crystallized at 0°; yield 6 g. or 17%; $[\alpha]^{20}D$ −58.0° in water solution.

Preparation of β-Methylmannofuranoside from its Calcium Chloride Compound.—A solution of 3.6 g. of the calcium chloride compound in 50 cc. of water was shaken for thirty minutes with an equivalent quantity of silver oxalate, which was prepared by mixing 21 cc. each of normal solutions of potassium oxalate and silver nitrate and washing the resulting precipitate thoroughly by decantation. The reaction mixture was filtered, the filtrate was rendered alkaline by a few drops of ammonia, then evaporated *in vacuo* to a sirup which was repeatedly treated with alcohol, each time the solvent being evaporated *in vacuo* to ensure the removal of water. Seed crystals were secured by extraction of a small portion of the sirup with 25 cc. of hot ethyl acetate and slow evaporation of the solution in a vacuum desiccator. The main portion of the sirup was then extracted with warm ethyl acetate in several portions, which were kept in separate flasks. Each ethyl acetate extract deposited a small quantity of sirup at room temperature. The solutions were decanted into clean flasks and inoculated with crystals. The crystallization of the substance was slow and the flasks were al-

lowed to remain at 0° for several days. The furanoside was deposited in the form of buttons made up of fine needles. The crystals (1 g.) were filtered and shaken at room temperature with 25-cc. portions of ethyl acetate until all but a trace had dissolved. The combined solutions were kept in the icebox for three days. Well developed crystals of the β-furanoside were obtained; yield, 70%; m. p. 46–47°; $[\alpha]^{20}D$ −112.6° in water solution (*c*, 2.952). Further recrystallization did not change the rotation or the melting point.

Re-formation of the Calcium Chloride Compound from β-Methylmannofuranoside.—A solution of 0.1476 g. of β-methylmannofuranoside in 5 cc. of water gave an observed rotation of −6.65° in a 2-dm. tube. This corresponds to a specific rotation of −112.6°. To 3 cc. of this solution there was added 84 mg. of calcium chloride, a small excess over the calculated quantity to form the addition compound. The rotation of this solution was −6.40° which corresponds to a specific rotation of −108.4°. Thus the specific rotation of the furanoside is lowered 4.2° by the addition of calcium chloride. From the specific rotation of the crystalline calcium chloride addition compound (−58.5°) a rotation of −108.2° is calculated for the optically active portion of this substance by multiplying by the formula weight ratio 359/194. Further quantities of calcium chloride added to this solution did not appreciably change the rotation. Evaporation of this solution resulted in the formation of a crystalline substance which on recrystallization from methyl alcohol and isobutyl alcohol had $[\alpha]^{20}D$ −58.5° in water solution. This experiment indicates that the same calcium chloride compound may be re-formed from crystalline β-methylmannofuranoside.

Preparation of α-Alkylmannofuranosides.—A hot solution of 22.8 g. of mannosediethylmercaptal in the desired alcohol was made (200 cc. of ethyl alcohol, 400 cc. of either *n*- or *i*-propyl alcohol). To the cooled solution, 34 g. of yellow mercuric oxide[2b] was added. A warm solution of 43.6 g. of mercuric chloride in 200 cc. of ethyl alcohol, in 325 cc. of normal propyl alcohol or in 280 cc. of isopropyl alcohol was added under vigorous stirring to the mercaptal solution at room temperature. The mixture was shaken or stirred for the required period (three hours for isopropyl alcohol, six hours for ethyl alcohol and overnight for normal propyl alcohol) until a test showed that the reaction was complete. The reaction mixture was filtered and the filtrate and washings were treated by either of the procedures given for the preparation of α-methylmannofuranoside. The sirups obtained crystallized spontaneously. The products were recrystallized from ethyl acetate and showed the constants given in Table I.

Anal. Calcd. for $C_6H_{11}O_5(OR)$: OR, 21.6 (R, C_2H_5), 26.6 (R, C_3H_7). Found: OR, 21.2 (R, C_2H_5), 26.1 (R, *n*-C_3H_7), 25.4 (R, *i*-C_3H_7).

Preparation of Mannosedimethylacetal.—The starting material, mannosediethylmercaptal pentaacetate, was prepared by acetylation of the mercaptal with hot acetic anhydride containing anhydrous sodium acetate. It was identical with the substance previously prepared by Pirie,[14] who acetylated the mercaptal in pyridine. The demercaptalation of the acetate was carried out in an apparatus fitted with a separatory funnel, a reflux condenser and a mercury-sealed mechanical stirrer. A solution of 12 g. of the acetate in 120 cc. of methyl alcohol was gently refluxed and stirred for five hours with 6 g. of yellow mercuric oxide and a solution of 22.5 g. of mercuric chloride in 45 cc. of warm methyl alcohol. After this time, the mixture was stirred at room temperature overnight, then filtered and the filtrate and washings evaporated *in vacuo* to dryness. The chloroform extract of the residue contained, beside the mannosedimethylacetal pentaacetate, a small quantity of mercuric chloride. It was found in this investigation that metallic copper was an ideal reagent for removal of mercury in non-aqueous solvent. Moist bright copper turnings were added to the chloroform solution and the mixture was shaken until a sample no longer amalgamated a fresh copper turning. The reaction mixture was filtered and the combined filtrate and chloroform washings were evaporated *in vacuo* to a sirup. For deacetylation by the procedure of Zemplén and Pacsu[15] this sirup was dissolved in 50 cc. of absolute methyl alcohol and 2 cc. of 0.1 *N* sodium methylate in methyl alcohol was added to the solution. The mixture was kept at room temperature overnight, then the filtered solution was evaporated *in vacuo* to a sirup which crystallized spontaneously. The crude mannosedimethylacetal was then dissolved in a small volume of absolute ethyl alcohol and crystallized by the addition of isopropyl ether at 0°. The substance was then recrystallized twice from hot ethyl acetate; m. p. 101°; $[\alpha]^{20}D$ 0.6° in water solution (*c*, 6.86).

Anal. Calcd. for $C_6H_{12}O_5(OCH_3)_2$: OCH_3, 27.4. Found: OCH_3, 27.6.

The acetal is non-reducing but is easily hydrolyzed by dilute aqueous acids. A study of the rate of hydrolysis was made and the data are reported in Table II.

TABLE II

HYDROLYSIS OF A SOLUTION OF 0.074 G. OF MANNOSEDIMETHYLACETAL IN 2 ML. OF 0.05% HYDROCHLORIC ACID AT 23° IN A 2-DM. TUBE.

It will be noticed that the solution of the acetal became negatively rotating as the reaction proceeded. This is

(14) Pirie, *Biochem. J.*, **30**, 374 (1936).

(15) Zemplén and Pacsu, *Ber.*, **62**, 1613 (1929).

interpreted as evidence of the formation of a β-glycoside. Since the acetal eventually became hydrolyzed to mannose as shown by the final rotation, it was concluded that the intermediate must have been β-methylmannofuranoside or a mixture of this substance and its α-form. The formation of these intermediates from the acetal proceeded about twenty times faster than the hydrolysis of these intermediates into mannose and methyl alcohol.

Acknowledgment is made to Mr. Richard C. Johnson, a student at the Union Junior College, Roselle, New Jersey, for making the drawings of the models.

Summary

1. By application of the general method of Pacsu and Green to mannosediethylmercaptal prepared directly from α-methylmannopyranoside, crystalline β-methyl, α-ethyl, α-*n*-propyl and α-isopropyl mannofuranosides have been obtained. The β-methylmannofuranoside has been isolated from its crystalline calcium chloride addition compound, $C_6H_{11}O_5OCH_3 \cdot CaCl_2 \cdot 3H_2O$, which was obtained from the mother liquor of the α-methylmannofuranoside. The same calcium chloride compound also has been obtained directly from the reaction products of mannose and methyl alcoholic hydrogen chloride and from the mother liquor of α-methylmannofuranoside prepared according to Haworth and co-workers.

2. It has been found that calcium chloride has a perturbing effect upon the rotation of the β-methylmannofuranoside with which it is combined and therefore it is unsafe to calculate the rotation of a sugar or a sugar derivative from the rotation of its calcium chloride compound by multiplying by a formula weight ratio.

3. Crystalline mannosedimethylacetal has been prepared and its hydrolysis has been studied.

4. It has been shown that Hudson's rules of isorotation hold closely in the mannofuranose series provided that a factor F is introduced in the equations. The numerical value of F has been determined to be 2725 for the furanoid derivatives of mannose in water solution.

5. It has been suggested that the factor F probably represents the disturbing optical effect of the different orientation of the hydroxyl groups in the α- and β-isomers of certain sugars and their pyranoid or furanoid derivatives.

Disubstituted Aminoacetones Containing Two Unlike Substituents[1]

BY J. WM. MAGEE[2] WITH HENRY R. HENZE

Continuing our attempts to prepare compounds possessing satisfactory activity as soporifics, we reported[3] recently our synthesis of ten disubstituted aminoacetones which subsequently were converted into disubstituted aminohydantoins. The ketones thus employed were all of the simple type $CH_3COCH_2NR_2$ in which the two substituents are identical and are either alkyl or allyl. We have now been interested in obtaining examples of the less well-known type CH_3COCH_2NRR', in which the two substituents are different, since these compounds present greater opportunity for variation in the combination of the groups most usually present in useful sedatives.

We have completed the synthesis of ten disubstituted aminoacetones, six of which had not been reported previously, by interaction of bromoacetone and the appropriate mixed secondary amine.[3] Most of the amines employed were produced in almost quantitative yield by catalytic reduction of the appropriate Schiff base by high pressure hydrogenation in the presence of Raney nickel catalyst.

Experimental

Preparation of the Mixed Secondary Amines.—The monomethylaniline and monoethylaniline were redistilled immediately before use. Cyclohexylmethylamine was obtained by heating one mole of methylaniline for eight hours at 200° in the presence of Raney nickel catalyst and an initial hydrogen pressure of 3500 lb. (233 atm.). The product was of such purity as to permit use immediately upon filtration from the catalyst. In the other instances, one mole of benzaldehyde, or a derivative, was warmed on a steam cone with one mole of a primary amine for fifteen minutes. After cooling to room temperature and separating the water formed from the unsaturated base, the latter was reduced in thirty minutes at 75° under initial hydrogen pressure of 2000 lb. (133 atm.). Here, too, the mixed amines were obtained in excellent yield and in a state of practical purity.

Preparation of Disubstituted Aminoacetones.—The two general procedures previously described[3] for preparing dialkylaminoacetones were employed in this investigation. Thus 0.4 mole of methylaniline, ethylaniline, benzylmethylamine or benzylphenylamine, diluted with 400 cc. of ether was added to 0.2 mole of bromoacetone in 50 cc. of ether and cooled to aid in the separation of the hydrobromide of the secondary amine. After evaporation of the ether, it was found desirable to dissolve 90–95% of the keto amine by addition of 6 *N* hydrochloric acid, to extract the acid solution with ether before neutralizing with alkali and again extracting with ether. Upon distillation the aminoacetones were obtained in yields of 45–50% of the theoretical.

For the aminoacetones derived from the more expensive mixed secondary amines, slightly higher yields of product were obtained by suspending 0.2 mole of the amine in 150 cc. of water containing 0.2 mole of sodium carbonate and adding 0.2 mole of bromoacetone dropwise with efficient stirring. The sodium bicarbonate separating from solution was removed by suction filtration. A small amount of unreacted bromoacetone could be removed efficiently from the keto amine by extraction with 1 *N* hydrochloric acid. Fractionation under diminished pressure yielded these aminoacetones in about 50% yield.

The substituted aminoacetones prepared in this study are colorless oils when first prepared but develop a dark color quite quickly. But sparingly soluble in water, the keto amines are readily soluble in 6 *N* acid solutions and in the usual organic solvents. Data obtained by analysis or measurement of the physical properties of these ten compounds are listed in Table I. The surface tensions were measured by means of Cassel's[4] precision capillarimeter at 20°. In calculating the parachors, the atomic parachor values of Sugden[5] were used.

Preparation of Semicarbazones from the Substituted Aminoacetones.—Solid, crystalline semicarbazones were obtained readily and in good yield from each of the ten substituted aminoacetones, best by dissolving the ketone in dilute alcohol, adding slightly more than the equivalent quantity of semicarbazide hydrochloride and making the solution barely alkaline with sodium hydroxide solution. The derivatives were recrystallized from dilute alcohol.

The corrected melting points and the analytical data of the ten semicarbazones are to be found in Table II.

Summary

1. Ten disubstituted aminoacetones, CH_3COCH_2NRR', have been prepared from mixed secondary amines, this being the initial report of the synthesis of six of the amino ketones.

2. Catalytic hydrogenation of seven Schiff bases, derived from benzaldehyde, by the use of Raney nickel and hydrogen under pressure afforded an easy and convenient method of preparing the corresponding mixed secondary amines in good yield.

5,5-Dimethylhydantoins Containing a —NRR′ Substituent[1]

BY HENRY R. HENZE AND J. WM. MAGEE[2]

Recently we reported[3] the synthesis of ten 5,5-dimethylhydantoins containing a dialkylamino constituent. This synthesis was accomplished by adaptation of Bucherer's[4] procedure to the utilization of aminoacetone derivatives of the type $CH_3COCH_2NR_2$. In this manner, for example, we were able to convert dimethylaminoacetone into 5-dimethylamino-5-methylhydantoin despite the fact that this conversion had not been obtained by other investigators[5] using the closely related method of Bergs.[6]

It has been possible now to extend our investigation to the preparation of hydantoins from substituted aminoacetones of the type CH_3COCH_2NRR' in which R— and R′— represent different groupings. Further, since phenyl and benzyl groups are present in the structure of many anticonvulsants[7] and antispasmodics, one or both of these are present in all but one of the mixed secondary amines from which the substituted aminoacetones were prepared.

Experimental

For the preparation of the ten hydantoins included in this investigation, 0.1 mole of the appropriate substituted aminoacetone, whose synthesis has been reported previously,[8] 0.15 mole of potassium cyanide, 0.3 mole of ammonium carbonate and 7–8 volumes of 50% alcohol were warmed under a reflux condenser for about ten hours at 55–65°. After concentration of the solution to about one-half volume, cooling in an ice-bath caused separation of most of the hydantoin and only an additional small quantity was obtained upon neutralization of the filtrate with con-

(7) Through the courtesy of Eli Lilly and Company the 5-(di-*n*-butylaminomethyl)-5-methylhydantoin and the 5-(diethylaminomethyl)-5-methylhydantoin have been shown to possess approximately 50% and 40%, respectively, of the anticonvulsant value of 5,5-diphenylhydantoin.

(8) Magee with Henze, THIS JOURNAL, **62**, 910 (1940).

centrated hydrochloric acid. Because of their amino substituent, these hydantoins possess solubility in acid as well as the usual solubility in alkali.

The hydantoins were recrystallized readily from dilute alcohol, and are soluble in the ordinary organic solvents, and are insoluble in water. The compounds are stable, white, crystalline solids which melt without decomposition to clear straw-colored liquids. Analytical data and corrected melting points for the hydantoins are reported in Table I.

Summary

1. Ten examples have been prepared of a new type of disubstituted aminohydantoin in which the two substituents are not alike.

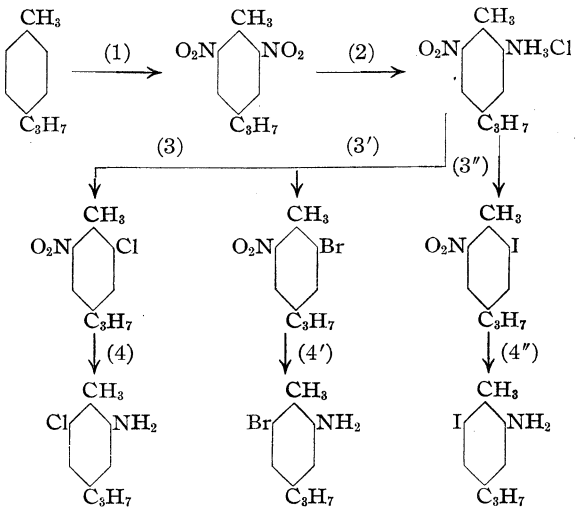
The Preparation and Properties of 6-Halogenated Carvacrylamines from *p*-Cymene

BY R. W. BOST AND GRANVIL C. KYKER[1]

The preparation of 6-halogenated carvacrylamines by a method which locates the position of the halogen has not been reported. Wheeler and Early[2] and Inoue and Horiguchi[3] independently obtained a product by the direct chlorination of 2-nitro-*p*-cymene from which a chloronitro-*p*-cymene was separated. In each case the substance was taken to be 2-chloro-6-nitro-*p*-cymene and the subsequent reduction product to be 6-chlorocarvacrylamine. The chlorination is accompanied by low yields and a mixture of difficultly separable products since positions 3, 5 and 6 are open to substitution and other chlorination products were recognized.[2] The method of these investigators[2,3] is not applicable to the preparation of analogous bromine and iodine compounds. A method for preparing 6-halogenated carvacrylamines from *p*-cymene which is equally applicable to chloro, bromo, and iodocarvacrylamines has been investigated. The steps in the process are shown in the diagram.



Steps (1) and (2) have been reported in a previous paper.[4]

Since the position of the substituents in 2,6-dinitro-*p*-cymene and 6-nitrocarvacrylamine have been established[5] an orientation of the substituent groups in 6-halogenated carvacrylamines is obtained.

Diazotized 6-nitrocarvacrylamine gave 2-chloro-6-nitro-*p*-cymene when treated with cuprous chloride according to the procedure of Marvel and McElvain.[6] An azo dye, 2-nitro-5(?)-(6-nitrocarvacrylazo)-6-hydroxy-*p*-cymene was isolated from the reaction product; its occurrence is explained by the formation of 6-nitrocarvacrol, through a side reaction, which served as a coupler with the diazo compound. The reduction of 2-chloro-6-nitro-*p*-cymene with either tin or a mixture of tin and zinc in hydrochloric acid yielded 6-chlorocarvacrylamine.

Various derivatives of 6-chlorocarvacrylamine were studied. The amine produced crystalline salts with hydrochloric, hydrobromic, nitric, sulfuric, phenylsulfonic, *p*-tolylsulfonic, dichloroacetic, trichloroacetic, oxalic, 3,5-dinitrobenzoic, 2,4,6-trinitrobenzoic and picric acids. These salts are soluble in alcohol, insoluble in water, easily hydrolyzed, and stable in the dry state. The amine has been characterized by its acetyl, benzoyl, 3,5-dinitrobenzoyl, benzenesulfonyl, *p*-tolyl-

sulfonyl, *p*-bromosulfonyl, *m*-nitrobenzenesulfonyl and picryl derivatives all of which are easily prepared and purified and possess very sharp melting points. The picryl derivative has a melting point almost identical to that of the picrate but the two are easily distinguished by crystal form, solubility, color, stability to water, and mixed melting point. A substituted urea was made by condensing the amine hydrochloride with potassium cyanate. 2,2′-Diazoamino-6,6′-dichloro-*p*-cymene resulted from coupling the amine with itself in half-saturated sodium acetate.

The diazotized 6-chlorocarvacrylamine gave an azo dye with 2-naphthol and disazo dyes with phenol, resorcinol, phloroglucinol, and 1,8-dihydroxy-3,6-naphthalene disulfonic acid. *m*-Phenylenediamine, 1-naphthylamine, 2-naphthylamine, naphthionic acid and 1-amino-8-hydroxy-4-naphthalenesulfonic acid coupled easily to give dyes but these dyes resisted every attempt toward purification and no analyses were obtained on these dyes. Each of the dyestuffs was applied to wool, silk, cotton, and rayon giving varying shades of red, yellow, and brown to the fibers. The vegetable fibers were previously mordanted with tannic acid. The colors are very brilliant on animal fibers and are fast to light, washing, alkali, and perspiration.

The data of previous studies[2,3] are compared to those of this investigation in Table I.

6-Bromocarvacrylamine hydrochloride and 6-iodocarvacrylamine hydrochloride were prepared in two steps from 6-nitrocarvacrylamine, the former by a process similar to that used for the chloro analog and the latter by the method of Griess.[7] The intermediate compounds, 2-bromo-6-nitro-*p*-cymene and 2-iodo-6-nitro-*p*-cymene and the free bases of these amines have not been isolated and characterized.

(7) Griess, *Ann.*, **137**, 76 (1866).

Experimental Part

2-Chloro-6-nitro-*p*-cymene.—Precipitated cuprous chloride, prepared from 312 g. (1.25 moles) of hydrated copper sulfate, 87.5 g. (1.5 moles) of sodium chloride, 66.6 g. (0.64 mole) of sodium bisulfite, and 44 g. (1.1 moles) of sodium hydroxide, was washed several times by decantation and dissolved in 400 cc. of concd. hydrochloric acid in a stoppered flask. At 0°, 230.5 g. (1 mole) of 6-nitrocarvacrylamine hydrochloride was stirred for thirty minutes with 1200 cc. of water, 575 g. (6 moles) of concd. hydrochloric acid, and 74.5 g. (1.08 moles) of sodium nitrite. The excess nitrous acid was destroyed with urea. With vigorous stirring the cold diazo solution was added rapidly to the cuprous chloride solution which had been cooled previously to 0°. Stirring was continued for two hours at room temperature and for thirty minutes at 60°.

The oily layer was separated and distilled with superheated steam at 155–160°. About 10 liters of distillate was collected. The yellowish-red oil in the distillate was separated, stirred with an equal volume of concd. sulfuric acid at 0° for an hour, diluted and stirred with 1 kg. of cracked ice, separated, washed successively with water, dilute sodium hydroxide and water, taken up with ether and dried over anhydrous calcium chloride. After removal of the drier and ether the oil was distilled at reduced pressure. The fraction boiling at 132–133° at 2 mm. was collected. The distillate was a highly refractive, light yellow oil, n^{25} 1.5397, d^{25}_4 1.1834, soluble in ethanol, methanol, ether, acetone, carbon tetrachloride, benzene, petroleum ether and other organic solvents; yield 165.7 g.; 77.5%.

A more rapid isolation of the product was obtained by ether extraction in place of superheated steam distillation, followed by the same treatment as above but purification was easier when the steam distillation was used.

Anal. Calcd. for $C_{10}H_{12}O_2NCl$: Cl, 16.60. Found: Cl, 16.60, 16.49.

2-Nitro-5(?)-(6-nitrocarvacrylazo)-6-hydroxy-*p*-cymene.—A solid, insoluble in water and ether, was found in the isolation of 2-chloro-6-nitro-*p*-cymene as a residue in the steam distillation and as a flocculent precipitate at the interface in the ether extraction. It was purified by crystallization from acetone. The brilliant red, irregular platelets melted at 186–187°.

Anal. Calcd. for $C_{20}H_{24}O_5N_4$: N, 13.99. Found: 13.82, 13.84.

6-Chlorocarvacrylamine. (A) Hydrochloride.—To a 3-liter flask, under reflux condenser and heated on a steam-bath containing 107 g. (0.5 mole) of 2-chloro-6-nitro-*p*-cymene, 50 cc. of ethanol and 178 g. of mossy tin, was added with frequent shaking 280 cc. of concd. hydrochloric acid during a period of two hours. Refluxing and shaking was continued for two hours after the addition of the acid. The cooled reaction product was treated with an excess of sodium hydroxide, a cold saturated solution containing about 450 g. The oil was extracted with five 300-cc. portions of ether. A troublesome emulsion accompanied the extraction. The combined extracts were dried over solid sodium hydroxide, decanted from the drier, and saturated with dry hydrogen chloride. The precipitated salt weighed 100 g., was decomposed by water, stable and only slightly soluble in hydrochloric acid, and gave glistening white needles when crystallized from alcohol and hydrochloric acid; yield 91%; softens at 210–220°; m. p. 225–226° with decomposition.

Less troublesome emulsions were encountered in the ether extraction when the reduction was obtained by using a mixture of tin (10%) and zinc (90%). After completion of the reduction, the hot solution was decanted from any undissolved material and cooled. The crystals which formed were filtered and the filtrate was concentrated and cooled as long as it yielded more crystals. The above procedure of making alkaline and isolating the amine was repeated.

Anal. Calcd. for $C_{10}H_{15}NCl_2$: HCl, 16.57. Found: HCl, 16.66, 16.68.

(B) Free Base.—The hydrochloride suspended in 500 cc. of water was made alkaline with dilute sodium hydroxide. The oil was extracted with ether (five 100-cc. portions), dried over solid sodium hydroxide, decanted, ether removed and distilled at 1 mm.; b. p. 134–136°. The colorless amine became red when exposed to light and air, was soluble in common organic solvents, n^{20} 1.5604, and d^{20}_4 1.0977.

Anal. Calcd. for $C_{10}H_{14}NCl$: Cl, 19.32. Found: Cl, 19.38, 19.48.

Salts of 6-Chlorocarvacrylamine.—The following procedures gave good yields of pure salts: (A) To a dry ether solution containing the required amount of acid was added 0.005 mole of the amine in ether solution. The precipitated salt was filtered and washed with ether. (B) The amine and acid, 0.005 mole of each, were dissolved in a small amount of alcohol and heated on a steam-bath. Water was added until a slight turbidity was produced and the salt separated on cooling; it was recrystallized from alcohol and water. (C) The amine, 0.005 mole, was boiled with sufficient quantity of 5% solution of the acid to dissolve it. The hot charcoaled, filtered solution gave the salt in crystalline form when cooled. (D) The amine and acid, 0.005 mole of each, were dissolved in 10 cc. of benzene and heated to boiling on a steam-bath. The hot solution was diluted with 20 cc. of hot heptane and cooled in ice. The salt was washed in cold benzene and heptane mixture.

The data on the salts are found in Table II.

N-Acyl Derivatives of 6-Chlorocarvacrylamine.—To the amine, 0.005 mole, dissolved in pyridine, 0.006 mole, was added the acyl chloride, 0.006 mole. The mixture was stirred and placed on a steam-bath for ten to fifteen minutes. The reaction product was worked with cracked ice until it solidified. The solid was washed successively with water, dilute alkali, water, dilute acid and water and recrystallized from a suitable solvent. In each case a needle crystal resulted, white in color except in the presence of nitro groups where a straw color was observed. The data on the acyl derivatives are found in Table III.

TABLE III

Acyl derivative	Solvent	M. p., °C.	Cl Analyses, % Calcd.	Found
N-Acetyl	Heptane–pet. ether	117–118	15.72	15.68

N-3,5-Dinitroben-zoyl	Alc.–water (4:1)	197–198	9.39	9.40

Sulfonyl Derivatives of 6-Chlorocarvacrylamine.—The amine, 0.005 mole, dissolved in pyridine, 0.006 mole, was treated with the sulfonyl chloride, 0.006 mole, stirred and warmed on a steam-bath for ten to fifteen minutes. The solid was stirred with water and ice until it solidified, then filtered, washed, dissolved in 2% sodium hydroxide, stirred with charcoal, filtered, and acidified with hydrochloric acid. The filtered and washed precipitate was recrystallized in each case from alcohol and water mixture (2:1). The crystals were white in each case except in the presence of a nitro group where a yellow color was noted. The data on the sulfonyl derivatives are given in Table IV.

6-Chlorocarvacrylpicrylamine.—Picryl chloride, 0.75 g. (0.003 mole), and 1.10 g. (0.006 mole) of 6-chlorocarvacrylamine were mixed in a test-tube, heated at 100° for an hour and then for an hour at 145°. During the latter

period the reaction mixture solidified. The solid recrystallized from alcohol as reddish-orange spear-shaped crystals which melted at 150.5–151.5°.

Anal. Calcd. for $C_{16}H_{15}O_6N_4Cl$: Cl, 8.99. Found: Cl, 8.84.

2-Ureido-6-chloro-*p*-cymene.—In 5 cc. of water, 0.74 g. (0.004 mole) of 6-chlorocarvacrylamine was suspended and treated with 2.5 g. of potassium cyanate and 1.25 cc. of concd. hydrochloric acid. A pink flocculent precipitate soon appeared. The solution was left on a steam-bath for three hours after evaporation to dryness. The solid was washed several times with water. The product recrystallized from alcohol and water (3:2) and melted at 180–182° with decomposition; at 185–187° with decomposition if placed in a bath at 160° and heated.

Anal. Calcd. for $C_{11}H_{15}ON_2Cl$: Cl, 15.59. Found: Cl, 15.44.

2,2′-Diazoamino-6,6′-dichloro-*p*-cymene.—Two grams of 6-chlorocarvacrylamine hydrochloride (0.009 mole) in 20 cc. of water at 0° was treated with 0.318 g. (0.0046 mole) of sodium nitrite. After twenty minutes of stirring, an equal volume of cold saturated solution of sodium acetate was added. The reaction product stood for an hour at 0°, then was filtered, dried, and recrystallized from petroleum ether; m. p. 110°.

Anal. Calcd. for $C_{20}H_{25}N_3Cl_2$: Cl, 18.75; N. 11.11. Found: Cl, 18.47; N, 11.16.

Azo Dyes from 6-Chlorocarvacrylamine.—Diazotization of 1.1 g. (0.005 mole) 6-chlorocarvacrylamine hydrochloride was carried out in the usual manner and the excess nitrous acid was destroyed with urea. The diazo solution was added to the solution of the coupler dissolved in a slight excess of sodium hydroxide and stirred for ten to fifteen minutes. The dye was precipitated by making acid and was recrystallized from a suitable solvent. An azo dye was obtained with 2-naphthol whereas the other couplers gave diazo dyes. Data on the dyes are given in Table V.

6-Bromocarvacrylamine Hydrochloride.—Cuprous bromide was prepared by dissolving 62.4 g. (0.25 mole) copper sulfate and 35.6 g. (0.30 mole) potassium bromide in 300 cc. of boiling water. To this solution was added slowly with stirring 150 cc. of alkaline sodium sulfite prepared from 13.3 g. (0.128 mole) of sodium bisulfite and 8.8 g. (0.22 mole) of sodium hydroxide. The precipitated cuprous bromide was washed several times by decantation, dissolved in 100 cc. of 48% hydrobromic acid and 50 cc. of water, stoppered, and cooled to 0°.

According to the general method of diazotization, 38.8 g. (0.2 mole) of 6-nitrocarvacrylamine suspended in 600 cc. of water was treated with 68 cc. of 48% hydrobromic acid and 14.9 g. (0.216 mole) of sodium nitrite dissolved in 200 cc. of water. The diazo solution was rapidly poured into the cold cuprous bromide solution. A purplish-brown addition product separated. The mixture was stirred for two hours at room temperature and for thirty minutes at 50 to 60°.

The oil which separated was stirred with an equal volume of concd. sulfuric acid at 0° for an hour, diluted with an equal volume of cracked ice, separated, washed with water, dilute sodium hydroxide, and water, and dried over calcium chloride; 39 g. oil.

A portion of the crude 2-bromo-6-nitro-*p*-cymene, 12.8 g., was reduced with 18.4 g. of tin and 28 cc. of concd. hydrochloric acid. The reduction product was rendered strongly alkaline with sodium hydroxide and extracted with ether. The dried ether solution was saturated with dry hydrogen chloride. The precipitated salt gave 10 g. of white needles when recrystallized from alcohol and hydrochloric acid; m. p. 213–214° with decomposition; yield 57.5%.

Anal. Calcd. for $C_{10}H_{15}NClBr$: HCl, 13.79. Found: HCl, 13.77.

6-Iodocarvacrylamine Hydrochloride.—6-Nitrocarvacrylamine, 48.5 g. (0.25 mole) in 500 cc. of water at 0° was treated with 57 g. of concd. sulfuric acid and 18.6 g. (0.27 mole) of sodium nitrite in 100 cc. of water. The excess nitrous acid was destroyed with urea. To the diazo solution was added gradually with stirring 72.6 g. (0.44 mole) of potassium iodide in 150 cc. of solution at 0°. The mixture was stirred for an hour after reaching room temperature and then for an hour on a steam-bath. The oily layer was separated, stirred for an hour at 0° with an equal volume of cracked ice, washed with water, dilute alkali, and water, and dried over calcium chloride; 46.5 g. of oil.

Part of the crude 2-iodo-6-nitro-*p*-cymene, 14.8 g., was reduced with 18.4 g. of tin and 28 cc. of hydrochloric acid. The reaction product was made strongly alkaline with sodium hydroxide and extracted with ether. The dried ether solution was saturated with dry hydrogen chloride. The hydrochloride gave 11.5 g. of white needles when crystallized from alcohol and hydrochloric acid; m. p. 244–245° with decomposition; yield 46.5%.

Anal. Calcd. for $C_{10}H_{15}NClI$: HCl, 11.71. Found: HCl, 11.59, 11.49.

Summary

1. A direct method for the synthesis of 6-halogenated carvacrylamines from *p*-cymene in good yields has been accomplished.

2. 6-Chlorocarvacrylamine as previously described has been shown to be impure.

3. The position of substituents in 2-chloro-6-nitro-*p*-cymene, 6-chloro, 6-bromo, and 6-iodocarvacrylamines has been located by synthesis.

4. 6-Chlorocarvacrylamine has been characterized by twelve salts, three acyl and four sulfonyl derivatives, a secondary picrylamine, a substituted urea, 2,2′-diazoamino-6,6′-dichloro-*p*-cymene, one azo and four diazo dyes.

5. The dyes gave varying shades of yellow, red and brown when applied to wool, silk, cotton, and rayon; they were fast to washing, light, alkali, and perspiration.

Synthesis of Glycol Glucosides[1]

BY SULO KARJALA AND KARL PAUL LINK

During the last ten years the production and extensive use of the glycol solvents has created a need for comprehensive toxicological studies on these compounds. This Laboratory recently undertook the preparation of large quantities of diethylene glycol β-*d*-monoglucoside for pharmacological investigations.[2] The synthesis of glucosides of other members of the glycol solvent series was studied during the course of this work.

Prior to the time that the work reported in this communication was started, ethylene glycol β-*d*-monoglucoside prepared by Fischer and Fischer[3] was the only substance of this class that had been obtained in the crystalline state. Subsequently Vintilescu, Ionescu and Kizyk[4] reported the enzymatic synthesis of this glucoside by emulsin. Bourquelot, Bridel and Aubry[5] had previously reported the biochemical synthesis of sirupy propylene glycol glucoside by the same enzyme.

A short time after our work was started, Helferich and Hiltmann[6] reported the preparation of the monoglucosides of ethylene glycol monomethyl ether, trimethylene glycol, tetramethylene glycol and the *cis* and *trans* forms of cyclopentanediol, as well as the diglucosides of ethylene, trimethylene, pentamethylene and hexamethylene glycols. Some of the work reported by them already had been completed in this Laboratory, and reference is made in the experimental part to agreement in data obtained.

Experimental

β-*d*-Acetobromoglucose.—The following procedure gave a stable product in yields above those reported previously.[7,8]

To 60 g. of acetic anhydride in a 500-cc. round-bottomed flask, fitted with a rubber stopper bearing an inlet tube reaching to the bottom of the flask and with a calcium chloride tube outlet, was added 60 g. of glucose pentaacetate. The suspension was cooled in ice and dry hydrogen bromide was introduced through the inlet tube. After all the glucose acetate had gone into solution, the passage of hydrogen bromide was interrupted, and an additional 60-g. portion of the acetate was added. Passage of the gas was resumed until the second portion of acetate had gone into solution and the mixture was saturated. With the use of a conventional naphthalene generator,[9] about 350 g. of bromine is required. The reaction takes about five hours. After the solution had stood overnight at room temperature, it was evaporated to a sirup under reduced pressure. Crystallization occurred during the concentration or upon the addition of a small amount of anhydrous ether. The crystalline product was dried and recrystallized from anhydrous ether. The mother liquors were concentrated and worked up in the same way. The yield is 109 g. (86%); m. p. 88–89°. The product could be kept indefinitely in a desiccator over phosphorus pentoxide.

Ethylene Glycol β-*d*-Monoglucoside Tetraacetate.—To 40 g. of ethylene glycol were added 12 g. of acetobromoglucose and 14.4 g. of dry silver carbonate. The mixture

was shaken until no more carbon dioxide was evolved. Anhydrous benzene (75 cc.) was added and the mixture shaken overnight. The silver salts were removed, the two layers in the filtrate separated, and the glycol layer repeatedly extracted with anhydrous benzene. The benzene fractions were combined and concentrated[10] to a sirup which crystallized readily. Ten grams (87%) of the crude product, after recrystallization from water, gave 8 g. of the pure product; m. p. 105–106°, $[\alpha]^{23}D$ −26.3° (*c*, 3.5; H_2O).

Anal. Calcd. for $C_{16}H_{24}O_{11}$: C, 48.95; H, 6.17. Found: C, 49.15; H, 6.15.

Fischer and Fischer[3] reported a m. p. 101–103° cor., $[\alpha]D$ −26.23° in water (yield of 45%) and an uncrystallizable sirup which appeared to be an isomeric glucoside acetate. When we prepared the β-*d*-monoglucoside acetate following the original directions of Fischer and Fischer we again obtained a product melting at 105–106°. Helferich and Hiltmann[6] gave no constants on this compound.

Ethylene Glycol β-*d*-Monoglucoside.—Six grams of the above glucoside acetate was deacetylated by the method of Fischer and Fischer.[3] After standing for one month at 0°, the oily sirup was inoculated with a minute crystal of diethylene glycol β-*d*-monoglucoside (m. p. 116.5–118°). Crystallization occurred immediately. Upon recrystallization from absolute alcohol 2 g. of product was obtained; m. p. 117.5–118°, $[\alpha]^{22}D$ −28.5° (*c*, 3.4; H_2O). The melting point of a mixture with diethylene glycol *d*-monoglucoside was 102–106°.

Anal. Calcd. for $C_8H_{16}O_7$: C, 42.85; H, 7.19. Found: C, 42.73; H, 7.0.

Instead of 117.5–118°, Fischer and Fischer as well as Vintilescu, Ionescu and Kizyk[4] report a melting point of 137°. We were able to obtain this higher melting product by deacetylating a second portion of the glucoside acetate by the method of Zemplén and Pacsu.[11] The sirup crystallized readily, giving a product which after recrystallization from absolute alcohol melted at 136–137°. When a portion of the lower melting product was recrystallized using the higher melting form for inoculation, the crystals obtained melted at 136–137°. A mixture of the two products melted at 136–137°, with preliminary sintering at 123°.

The rotation of the higher melting form was $[\alpha]^{28}D$ −29.4° (*c*, 2.1; H_2O). Fischer and Fischer reported $[\alpha]^{16}D$ −30.20°, while Vintilescu, *et al.*, found $[\alpha]^{20}D$ −25.62°.

Ethylene Glycol bis-β-*d*-Glucoside Octaacetate.[12]—To 7 g. of ethylene glycol monoglucoside tetraacetate (m. p. 105–106°) in 100 cc. of anhydrous benzene was added acetobromoglucose (4 g.) and dry silver carbonate (5 g.). The mixture was shaken for twenty-four hours, filtered and the filtrate concentrated to a thick sirup. This sirup was heated to 60–70° with 350 cc. of water and filtered. The crystalline residue and the crystals obtained from the filtrate on cooling were recrystallized from absolute alcohol: yield, 3.8 g. (54%); m. p. 169–170° (cor.); $[\alpha]^{23}D$ −31.76° (*c*, 4.6; $CHCl_3$). Helferich and Hiltmann[6] report m. p. 170–171° (cor.), $[\alpha]D$ −31.80° ($CHCl_3$).

Diethylene Glycol β-*d*-Monoglucoside Tetraacetate.—This compound was prepared by the procedure used for ethylene glycol β-*d*-monoglucoside tetraacetate. The crude product (10 g., m. p. 81–84°) on recrystallization from a benzene–petroleum ether mixture gave 8 g. (63%) of the pure compound, m. p. 92–93° (cor.); $[\alpha]^{24}D$ −27.62° (*c*, 3.4; H_2O).

Anal. Calcd. for $C_{18}H_{28}O_{12}$: C, 49.52; H, 6.47. Found: C, 49.54; H, 6.58.

In order to prepare this compound in large quantities the following procedure was adopted. A solution of 100 g. of acetobromoglucose and 400 g. of diethylene glycol in 400 cc. of anhydrous dioxane was shaken for twenty-four hours at room temperature with 70 g. of dry silver carbonate. The silver salts were removed and the filtrate concentrated to remove the dioxane. The concentrate, after filtration through asbestos, was diluted with 400 cc. of water. This solution was extracted 6–8 times with thiophene-free benzene (1 liter). The combined benzene fractions were dried over sodium sulfate and concentrated until the crystallization of the glucoside acetate made distillation difficult. Enough petroleum ether (about 600 cc.) was added to throw out the glucoside acetate, and the mixture was allowed to stand overnight at 0° to ensure complete crystallization. The total yield from five such runs was 386 g., or an average of 77 g. to a run, representing a yield of 73%. The melting point of the crude product was 85–88°. This product was satisfactory for deacetylation.

Diethylene Glycol β-*d*-Monoglucoside.—Three grams of the above pure tetraacetate was dissolved in 50 cc. of absolute methanol and 2 cc. of 0.1 *N* sodium methoxide was added. The solution was refluxed for three minutes, cooled and concentrated to a sirup. A small amount of absolute alcohol was added, and the sirup warmed. Crystallization began immediately. After standing for twelve hours at 0°, 1.55 g. (84%) of the deacetylated product was obtained. Upon recrystallization from absolute alcohol, the product melted at 116.5–118°; $[\alpha]^{23}D$ −22.4° (water; *c*, 3.1).

Anal. Calcd. for $C_{10}H_{20}O_8$: C, 44.74; H, 7.52. Found: C, 44.81; H, 7.52.

For the deacetylation of large quantities of the glucoside tetraacetate the same procedure was used with 50 g. of the crude tetraacetate (m. p. 85–88°) in 200 cc. of absolute methanol and 5 cc. of 0.2 *N* sodium methoxide. By this procedure 386 g. of the tetraacetate gave 210 g. (89%) of the crude, slightly colored glucoside (m. p. 113–115°), which was recrystallized twice (carbon clarification) from two liters of absolute alcohol, yielding 202 g. of glucoside (m. p. 115–116.5°).

Diethylene Glycol bis-β-*d*-Glucoside Octaacetate.—Nineteen grams of diethylene glycol β-*d*-monoglucoside tetraacetate, 10 g. of silver carbonate and 12 g. of acetobromoglucose were shaken in 100 cc. of anhydrous dioxane for twenty-four hours, filtered, the precipitate washed with hot dioxane, and the filtrate concentrated to a thick sirup, which was heated in 400 cc. of water. The hot aqueous solution was decanted from the insoluble oil, which was washed with small portions of hot water and allowed to crystallize. On recrystallization from ab-

(10) All solvents were removed under a reduced pressure of 12 mm. unless otherwise stated.

(11) Zemplén and Pacsu, *Ber.*, **62**, 1613 (1929).

(12) Helferich and Hiltmann system of nomenclature[6] where "bis" connotes a *diglucoside*.

solute alcohol 7 g. (31%) of the product was obtained, m. p. 125.5–126.5°; $[\alpha]^{22}D$ −23.5° (*c*, 3.0; $CHCl_3$).

Anal. Calcd. for $C_{32}H_{46}O_{21}$: C, 50.12; H, 6.06. Found: C, 50.20; H, 6.07.

Deacetylation of Diethylene Glycol bis-β-*d*-Glucoside Octaacetate.—Three grams of the octaacetate, on deacetylation with sodium methoxide as described above, yielded an oil which could not be induced to crystallize. The oil was quite insoluble in cold absolute alcohol. An attempt was made to distil the product in a molecular still at 190° and 0.004 mm. pressure. The pressure changed from 0.004 mm. to 0.1 mm. during the distillation. Apparently cleavage of the glucoside occurred.

Propylene Glycol β-*d*-Monoglucoside Tetraacetate.—To 50 g. of freshly distilled racemic propylene glycol were added 12 g. of acetobromoglucose, 14.4 g. of silver carbonate and 50 cc. of anhydrous benzene. The mixture was shaken for twenty-four hours. After filtration and repeated extraction of the propylene glycol with benzene, the combined benzene extracts were concentrated to a sirup. A portion of the sirup, on scratching on a watch glass, crystallized, and the crystals were used to inoculate the main portion, which then slowly crystallized to give a mass of colorless crystals and a small amount of a red oil. The mass was treated with 100–150 cc. of water in which the red oil, which probably consisted of some diglucoside, was insoluble. The aqueous solution on evaporation to dryness gave a mass of colorless crystals which were taken up in cellosolve and treated with petroleum ether. When the solution was kept at 0°, an oil separated, but when it was allowed to stand for some time at 10–15°, a small amount of crystalline material, m. p. 67–72°, was obtained. Repeated recrystallization from cellosolve–petroleum ether or alcohol–petroleum ether mixture slowly raised the melting point until it finally remained constant at 99–101°. The yield was about 1 g. of pure material; $[\alpha]^{26}D$ −6.8° (*c*, 2.9; $CHCl_3$).

Anal. Calcd. for $C_{17}H_{26}O_{11}$: C, 50.24; H, 6.45. Found: C, 50.20; H, 6.49.

The intermediate fractions could be obtained crystalline upon evaporation to dryness. However, when the crystals were taken up in solvents, in an effort to separate the isomers by fractional crystallization, oily products were obtained.

Propylene Glycol β-*d*-Monoglycoside.—The deacetylation was carried out as above with sodium methoxide, 0.8 g. of the tetraacetate yielding 0.2 g. (43%) of product melting at 136–138°. The product was crystallized from absolute alcohol–ether; $[\alpha]^{22}D$ −25.5° (*c*, 2.0; H_2O).

Anal. Calcd. for $C_9H_{18}O_7$: C, 45.37; H, 7.62. Found: C, 45.47; H, 7.62.

A small portion of the glucoside gave a faint, but definitely positive, iodoform test which indicates that the glucosidic linkage is on the primary alcohol group of propylene glycol. Ethylene glycol β-*d*-monoglucoside, as would be expected, gave a negative test under the same conditions.

Triethylene Glycol β-*d*-Monoglucoside Tetraacetate.—To a solution of 100 g. of freshly distilled triethylene glycol and 12 g. of acetobromoglucose in 100 cc. of anhydrous benzene was added 14.4 g. of dry silver carbonate. After shaking for twenty-four hours the mixture was filtered, and the homogeneous filtrate was treated with 100 cc. of water. The aqueous solution was extracted repeatedly with benzene, the benzene solution dried over anhydrous sodium sulfate and concentrated. The resulting oil could not be induced to crystallize and was not investigated further.

Ethylene Glycol Monoethyl Ether β-*d*-Monoglucoside Tetraacetate.—A mixture of 25 g. of freshly distilled cellosolve, 6 g. of acetobromoglucose and 7.2 g. of silver carbonate was shaken until no more carbon dioxide was evolved. The reaction was very rapid, and a slight evolution of heat was observed. The mixture was filtered, the precipitate washed with hot cellosolve, and the filtrate concentrated at 45–50° to a colorless sirup, which soon crystallized. Upon recrystallization from cellosolve–water the product was isolated as long rods, yield 5 g. (82%); m. p. 65–67°; $[\alpha]^{23}D$ −19.5° ($CHCl_3$; *c*, 3.4).

Anal. Calcd. for $C_{18}H_{28}O_{11}$: C, 51.43; H, 6.72. Found: C, 51.25; H, 6.72.

Ethylene Glycol Monoethyl Ether β-*d*-Monoglucoside.—Five grams of the glucoside acetate was deacetylated with sodium methoxide. The free glucoside crystallized on evaporation of the methanol under reduced pressure and was recrystallized from absolute alcohol. The yield of the substance was 2.5 g. (83%); m. p. 139–140°; $[\alpha]^{23}D$ −26.0° (*c*, 3.1; H_2O).

Anal. Calcd. for $C_{10}H_{20}O_7$: C, 47.61; H, 7.99. Found: C, 47.5; H, 7.9.

Trimethylene Glycol β-*d*-Monoglucoside Tetraacetate.—This substance was prepared in 78% yield by the same method used for the preparation of ethylene glycol β-*d*-monoglucoside tetraacetate. Recrystallized from water, it melted at 97–98°; $[\alpha]^{26}D$ −17.3° (*c*, 4.1; $CHCl_3$). Helferich and Hiltmann[6] report a melting point of 97.5–98.5° (cor.) and $[\alpha]D$ −17.0° for this compound.

A small amount of water-insoluble material was isolated. Upon recrystallization from absolute alcohol, 0.5 g. of substance melting at 171–172° (uncor.) was obtained; $[\alpha]^{26}D$ −15.8° (*c*, 2.8; $CHCl_3$).

This substance is without doubt trimethylene glycol *bis*-β-*d*-glucoside octaacetate, for which Helferich and Hiltmann[6] report a melting point of 175–176.5° (cor.) and an $[\alpha]D$ of −16.9°.

Diethylene Glycol Monoethyl Ether β-*d*-Monoglucoside Tetraacetate.—The procedure was the same as that given for the triethylene glycol β-*d*-monoglucoside tetraacetate. A colorless sirup was obtained which could not be crystallized. The sirup was taken up in benzene which was then extracted two times with water. From the benzene solution an oil was obtained again. The aqueous extract, on evaporation to dryness, yielded crystals. On recrystallization from absolute alcohol–petroleum ether the product had m. p. 104–105.5°. This substance was identical with the monoglucoside acetate of ethylene glycol, m. p. 105–106°, a mixture of the two having m. p. 105–106°. Thus the original carbitol solution contained significant quantities of ethylene glycol as an impurity.

Distillation of the carbitol glucoside acetate in a molecular still at 160–180° and 0.004 mm. pressure gave a glassy film on the condenser. The film reverted to an uncrystallizable oil when brought to room temperature.

Deacetylation of the above Carbitol Glucoside Acetate.—A portion of the oil obtained above was deacetylated with a trace of sodium methoxide, yielding an uncrystallizable oil. Upon distillation in a molecular still at 180° and 0.004 mm. pressure a slight decrease in vacuum (to 0.01 mm.) was observed. The substance distilled, however, to give a glassy film similar to the one obtained above which reverted to an oil on warming to room temperature.

We are indebted to Dr. H. A. Campbell, Research Assistant in Biochemistry, for the micro carbon and hydrogen determinations. Our thanks are also due to Dr. P. N. Leech, Director of the Chemical Laboratory of the American Medical Association, Chicago, Illinois, and Dr. E. W. Schoeffel, chemist for the A. M. A. Chemical Laboratory, for the chemicals used in this study. Dr. Schoeffel also has checked some of the C–H determinations.

Summary

1. The properties of the monoglucosides, the monoglucoside tetraacetates, the diglucosides and the diglucoside octaacetates of ethylene and trimethylene glycol were checked with those appearing in the literature. Improvements in the methods of preparation of these glucosides are described.

2. The β-*d*-monoglucosides and the β-*d*-monoglucoside tetraacetates of diethylene glycol, propylene glycol and ethylene glycol monoethyl ether, and the β-diglucoside octaacetate of diethylene glycol have been prepared and the constants reported.

3. Triethylene glycol β-*d*-monoglucoside tetraacetate, the β-monoglucoside tetraacetate of diethylene glycol monoethyl ether and the free glucoside from the latter have been obtained as sirups.

4. A procedure is described for the large-scale preparation of diethylene glycol β-*d*-monoglucoside tetraacetate and diethylene glycol β-*d*-monoglucoside.

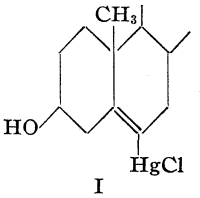
The Mercuration of Cholesterol

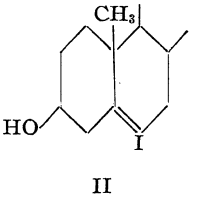
BY R. H. LEVIN AND M. A. SPIELMAN

Merz[1] mercurated cholesterol with mercuric acetate in hot glacial acetic acid, and after treating the product with sodium chloride he was able to isolate in poor yield a chloromercuricholesterol of unknown constitution. The chloromercuri derivative reacted smoothly with iodine to give an iodocholesterol which, because of the inertness of the halogen atom, resisted all efforts at structure proof. This paper presents a reinvestigation of the problem.

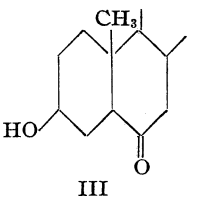
We have prepared chloromercuricholesterol and iodocholesterol with minor modifications of the Merz method. In agreement with him we have found iodocholesterol to be an exceedingly inert compound. Hydrolysis was, however, achieved with the aid of copper catalysis in a steel bomb at 225°. The product was a saturated hydroxy ketone identified as 6-ketocholestanol (III) by comparison with a synthetic specimen made by the usual methods.[2] It follows, therefore, that the compounds in question are 6-chloromercuricholesterol (I) and 6-iodocholesterol (II). The dibasic acid $C_{27}H_{43}O_4I$ from the sodium hypobromite oxidation of 6-iodocholesterol is without doubt 6-iodo-Diels' acid (IV).



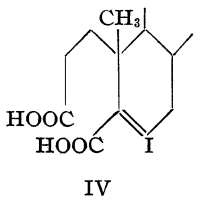
I



II



III



IV

No other products of mercuration could be isolated from the sirupy mercury-containing residues after isolation of the 6-chloromercuricholesterol. The large amounts of mercurous acetate formed indicate dehydrogenation, but no

ketones were present and spectroscopic examination revealed no absorption in the region characteristic of 7-dehydrocholesterol.[3]

Experimental Part[4]

6-Chloromercurichlesterol.—The method of Merz was used with essentially the same results. A product melting at 185–205° and giving no antimony trichloride color reaction was found satisfactory for the subsequent experiment. The yield was 27% of theoretical, or corrected for recovered cholesterol, 35%. The numerous crystallizations from acetone necessary to produce a white preparation melting at 200–205° reduced the yield to 17–20% of theoretical. The mother liquors were freed of mercury by hydrolysis with hydrochloric acid. The thick brown residue gave a purple color with antimony trichloride in chloroform. No pure product could be isolated from it other than cholesterol.

6-Iodocholesterol.—The Merz method was modified as follows. Twenty-five grams of crude chloromercurichlesterol was dissolved in 300 cc. of chloroform; the solution was filtered and 10 g. of iodine was added in portions with shaking. The mixture was allowed to stand six hours and was then filtered to remove the vermilion precipitate of mercuric iodochloride. Excess iodine was eliminated by adding 30 cc. of water and bubbling in sulfur dioxide for fifteen minutes. The solution was again filtered, 50 cc. of water was added and the chloroform was removed by distillation. The water was decanted and the residue was taken up in 500 cc. of hot absolute alcohol. The mixture was treated twice with norite and allowed to cool; 9.5 g. of 6-iodocholesterol separated, and concentration of the mother liquor yielded 4.5 g. more. Crystallization from glacial acetic acid gave colorless needles melting at 156–158°; yield 50%. When pure chloromercurichlesterol was used the yield was 75% of the theoretical.

Anal. Calcd. for $C_{27}H_{45}OI$: C, 63.2; H, 8.85. Found: C, 63.4; H, 9.06.

6-Iodocholesterol benzoate is a new compound prepared by benzoylation in pyridine at room temperature for thirty minutes. Crystallization from chloroform–ether, and from dioxane, gave colorless prisms; m. p. 214–215°.

Anal. Calcd. for $C_{34}H_{49}O_2I$: C, 66.2; H, 8.02. Found: C, 66.2; H, 8.30.

6-Ketocholestanol Benzoate.—Ten grams of 6-iodocholesterol was placed in a small steel bomb (80 cc. void) together with 6 g. of sodium bicarbonate, 20 cc. of water and 50 mg. of cupric chloride. The mixture was heated to 225° for nine hours with continuous shaking. The water was decanted after cooling and the residue was taken up in chloroform. The residue after evaporation of the chloroform was benzoylated in pyridine at room temperature with 4 cc. of benzoyl chloride. The product was crystallized from methanol–chloroform and from ethanol–ether. It melted at 171–172° in agreement with the figure given by Windaus[5]; yield 89%; $[\alpha]^{20}D$ +4.0 in chloroform.

Anal. Calcd. for $C_{34}H_{50}O_3$: C, 80.6; H, 10.0. Found: C, 80.9; H, 10.1.

6-Ketocholestanol was obtained by saponification of the benzoate. It formed needles, m. p. and mixed m. p. 143–144°.[5]

Anal. Calcd. for $C_{27}H_{46}O_2$: C, 80.5; H, 11.5. Found: C, 80.6; H, 11.8.

The 6-ketocholestanol was also characterized as the acetate, m. p. and mixed m. p. 129–130°; the formate, m. p. 104–105°; and the *p*-nitrophenylhydrazone, m. p. 194°. Melting points all agreed with literature values.[5]

6-Ketocholestanol 3,5-dinitrobenzoate is a new derivative made by benzoylation in cold pyridine during twenty-four hours. Repeated crystallizations from chloroform–methanol yielded colorless crystals melting at 226–228°.

Anal. Calcd. for $C_{37}H_{48}O_7N_2$: C, 68.4; H, 8.1. Found: C, 68.2; H, 8.2.

Summary

1. Mercuric acetate in acetic acid mercurates cholesterol at position 6.

2. The mercurated product has been converted by a series of reactions to 6-ketocholestanol.

Physiologically Active Amines. III. Secondary and Tertiary β-Phenylpropylamines and β-Phenylisopropylamines

BY E. H. WOODRUFF, JOHN P. LAMBOOY[1] AND WILLIAM E. BURT[2]

It is known[3,4] that the N-alkylation of analogs of phenethylamine has an effect on their physiological activity. The quantitative effect of this change in structure, as well as whether an increase or decrease of activity results, is variable, so that a prediction of expected properties is subject to doubt. In continuing the studies of amines it was desirable to determine the effect on the pressor and bronchodilator activity of the introduction of N-alkyl and N-aralkyl groups into the primary amines previously prepared in this Laboratory.[5,6] The synthesis of the secondary and tertiary amines described here was accomplished by one or the other of two methods.

Method I.—

$$C_6H_5CH(CH_3)CH_2NH_2 \longrightarrow C_6H_5CH(CH_3)CH_2N{=}CHC_6H_5$$

$$C_6H_5CH(CH_3)CH_2N{=}CHC_6H_5 + RI \longrightarrow C_6H_5CH(CH_3)CH_2\underset{\displaystyle I}{\overset{\displaystyle R}{\overset{|}{\underset{|}{N}}}}{=}CHC_6H_5$$

$$C_6H_5CH(CH_3)CH_2\underset{\displaystyle I}{\overset{\displaystyle R}{\overset{|}{\underset{|}{N}}}}{=}CHC_6H_5 + H_2O \longrightarrow C_6H_5(CH)CH_3NHR\cdot HI$$

The hydrolysis of the quaternary salt formed by the reaction of a benzalamine and an alkyl halide is that of Decker and Becker.[7,8,9] This method gave good results when R = CH_3 but variable and generally unsatisfactory results when used for the introduction of larger alkyl groups. The time required for the formation of the quaternary ammonium compound becomes progressively longer as the size of the alkyl group is increased. Decker and Becker[10] state that when a certain temperature or duration of heating is exceeded, by-products are obtained. This was evidently true where the hydrolysis of the ammonium compound failed to give products that could be isolated and identified and thereby limits the usefulness of the procedure.

Method II.—

$$C_6H_5CH(CH_3)CH_2NH_2 + RCHO \xrightarrow[\text{Raney Ni}]{H_2} C_6H_5CH(CH_3)CH_2NH(CH_2R)$$

$$C_6H_5CH(CH_3)CH_2NH(CH_2R) + RCHO \xrightarrow[\text{Raney Ni}]{H_2} C_6H_5CH(CH_3)CHN(CH_2R)_2$$

This is the reduction of a mixture of an amine and an aliphatic aldehyde without isolation of the intermediate reaction product.[11-18] This direct reduction procedure has been termed "reductive alkylation."

The reduction of the isolated Schiff base[19] is satisfactory when an aromatic aldehyde is used and the Schiff base readily isolated. When aliphatic aldehydes are used, Skita and Keil[11] and Emerson and Walters[17] prefer reductive alkylation. While platinum oxide catalyst is quite satisfactory for the reduction of the isolated Schiff base,[19] experiments by the authors as well as Emerson and Walters show it to be less satisfactory than Raney nickel when the reductive alkylation method is used. Skita, *et al.*,[12] on the other hand, found colloidal platinum superior to their nickel catalyst.

The procedure of Emerson and Walters, using Raney nickel and hydrogen, has been used for the reductive alkylation (II, R = H, CH_3, C_2H_5) of amines as indicated in the table of compounds. This catalyst was also successfully used to reduce the isolated benzal amine.

The only previous catalytic reductive alkylation experiments reported using formaldehyde (II, R = H) were with secondary amines.[15] Contrary

[a] All melting points taken on a thermometer standardized against a set of Bureau of Standards Anschütz thermometers. [b] Decker and Becker method. [c] Reductive alkylation. [d] Melting point. [e] Smith, *J. Chem. Soc.*, 2056 (1927), gives m. p. 87–88° for free amine and m. p. 189–190° for the hydrochloride. [f] Two forms of this hydrochloride were obtained. Simple crystallization was sufficient to make the change, though when the melting point would change could not be predicted. In fifteen consecutive crystallizations six crops were of the high melting form and nine were of the lower melting form. No further investigation is being made of this phenomenon.

to what might be expected from the work of Emerson and Walters it was not possible to isolate any secondary amine from the reaction product when formaldehyde was used as the alkylating agent. The products were identified as the N-dimethyl derivatives and were obtained in yields ranging from 51 to 85% of the theoretical. This result resembles that obtained when other than catalytic means of reduction are employed in the reductive alkylation of an amine with formaldehyde, such as the Eschweiler reaction,[20,21,22,23] and gives a convenient method for the preparation of N-dimethylamines from the corresponding primary amine. The use of this method to convert l-ephedrine to l-methylephedrine shows that the alcoholic hydroxyl is not disturbed in the reaction. Reductive alkylation with formaldehyde therefore offers a general one step method for the preparation of N-dimethylamines without affecting the aliphatic portion of the molecule.

With higher aldehydes (II, R = CH_3, C_2H_5) the monosubstitution products were isolated, the yield increasing as the alkyl groups became larger.[17,18,24]

This change in type of product, *e. g.*, from N-dimethyl to a mixture of the higher N-alkyl and N-dialkyl amines, also resembles results obtained by the

reduction of aldehydes in the presence of ammonia.[11]

Experimental difficulties with crystallization have retarded the reporting of more N-ethyl and N-propyl amines as well as the identification of the higher boiling N-diethyl and N-dipropyl amines.

Experimental

The preparation of the methoxy primary amines used in these syntheses has been described previously.[5,6]

Alkylation by the Method of Decker and Becker.[7,8,9]—The Schiff bases used were prepared by refluxing for thirty minutes equimolecular quantities of the amine and benzaldehyde dissolved in 95% ethyl alcohol. The solvent was removed and the product distilled *in vacuo*. The Schiff bases were obtained in yields of 95% and were mostly yellow oils with a few low melting solids. They were used without further purification or analysis.

Equimolecular proportions of a benzal amine (Schiff base) and the appropriate alkyl iodide were introduced into a thoroughly dried Carius tube. After sealing, the tube was heated at 100° by steam for five to twenty-four hours, the longer time being used for the higher halides. The reaction was considered complete when the whole contents of the tube upon cooling was a red to orange viscous oil or a partially crystalline mass. A layer of mobile liquid above the viscous mass showed the reaction to be incomplete. After opening, the contents of the tube were washed out with an alcohol, methyl alcohol for the methylated product and ethyl alcohol for the higher alkylated product, to which had been added one-eighth of its volume of water. The mixture was refluxed for thirty minutes, after which it was poured into an equal volume of water and boiled until the odor of benzaldehyde had disappeared. The solution was made weakly acid with acetic acid and extracted three times with ether. After basification with 30% sodium hydroxide the amine was extracted with ether, the ethereal solution dried with anhydrous magnesium sulfate, and after removal of the solvent the residue was distilled *in vacuo*. The hydrochlorides were prepared from an anhydrous ether solution by the addition of gaseous hydrogen chloride and were recrystallized from ether–alcohol mixtures.

Reductive Alkylation.—One-tenth mole of amine, 0.3 mole of the desired aldehyde, and 1.0 g. of anhydrous sodium acetate in 100 cc. of ethyl alcohol were reduced by 58 g. of Raney nickel and hydrogen (initial pressure 50 pounds (3 atm.)) in an Adams[25] reduction machine as described by Emerson and Walters.[17] When hydrogenation was complete the catalyst was removed by filtration[26] and the alcoholic solution of the amine evaporated to dryness. The amine is extracted from the sodium acetate by ether, the ethereal solution dried with anhydrous magnesium sulfate and the residual oil fractionated. The amine hydrochlorides were prepared and purified as in Method I. Amines of the type prepared here are not sufficiently volatile with steam for this to be a practicable method to effect any separation.

Solution formaldehyde U. S. P. XI was used as the source of formaldehyde. Acetaldehyde and propionaldehyde were materials of usual purity.

Reduction of Schiff Bases with Raney Nickel.—0.05 mole of benzal amine, 30 g. of Raney nickel and 100 cc. of ethyl alcohol were shaken in the Adams[25] reduction machine under an initial hydrogen pressure of 50 pounds (3 atm.). The theoretical amount of hydrogen was absorbed in about two hours. The catalyst was removed by filtration, the solvent distilled off and the residue distilled *in vacuo;* yield, 55–85%. When less catalyst is used the reduction proceeds more slowly. These results parallel those obtained with platinum oxide[19] as a catalyst. The hydrochlorides of the benzyl amines are less soluble in absolute alcohol than those of the N-alkyl amines.

The authors wish to thank Mr. C. H. Emerson for the microanalyses reported in this work.

Summary

For the purpose of pharmacological testing a group of N-alkyl, N-dimethyl, and N-benzylphenylpropyl and isopropylamines have been prepared.

The reductive dimethylation of primary amines by means of formaldehyde and Raney nickel has been described.

Chlorinations with Sulfuryl Chloride. III. (a) The Peroxide-Catalyzed Chlorination of Aliphatic Acids and Acid Chlorides. (b) The Photochemical Sulfonation of Aliphatic Acids

BY M. S. KHARASCH AND HERBERT C. BROWN[1]

In an earlier paper[2] it was shown that various types of hydrocarbons can be chlorinated rapidly and conveniently by sulfuryl chloride in the presence of a small quantity of an organic peroxide. It was suggested that the reaction depends upon the initiation by the peroxide of a chain reaction involving chlorine atoms.

We have extended the study of the action of sulfuryl chloride to other types of organic compounds. The present paper is devoted to the chlorination of aliphatic acids and acid chlorides and to a preliminary report of the photochemical sulfonation of aliphatic acids.

Chlorination of Acids and Acid Chlorides

In the dark and in the absence of catalysts sulfuryl chloride does not react with aliphatic acids or acid chlorides to any appreciable extent at temperatures as high as the boiling point of the reaction mixtures (70–90°). In the presence of a small quantity of peroxide, however, chlorination of acids and acid chlorides takes place readily. Acetic acid and acetyl chloride, however, are exceptions to this generalization.

The chlorination of acids and acid chlorides by this method has been carried out, for the most part, in accordance with the general procedure described in the first paper of this series.[2] A slight modification of this procedure, however, was found to be advisable. Except in the case of acetic acid, the chlorination of the carboxylic acids is a vigorous reaction, and it was found desirable to add a small quantity of a diluent. The acid chlorides react much less violently, and the addition of a diluent is unnecessary.

In the absence of added peroxides, acetic acid is not chlorinated to any extent by sulfuryl chloride. Upon heating of a mixture of the two compounds in the dark, the sulfuryl chloride under the catalytic influence of the acid is slowly dissociated into sulfur dioxide and chlorine, and the acetic acid can be recovered unchanged. In the presence of an added peroxide, chlorination occurs. The yield of chloroacetic acid, however, is poor compared to the almost quantitative yields which can be obtained in the chlorination of the higher homologs of acetic acid. Even under optimum conditions, the yield of chloroacetic acid is not greater than 50%[3] because of loss of sulfuryl chloride by dissociation.

Acetyl chloride differs even more from its higher homologs than does acetic acid: the compound cannot be chlorinated to any appreciable extent by the use of sulfuryl chloride and either lauroyl or benzoyl peroxide. This inactivity cannot be due to the low boiling point of acetyl chloride since addition of chlorobenzene to the reaction mixture (to raise the boiling point) has no effect, while addition of cyclohexane or toluene leads immediately to a vigorous reaction in which chlorination of the hydrocarbon occurs.

In marked contrast to the inactivity of acetic acid and acetyl chloride to the reagent, is the action of trimethylacetic acid and its acid chloride. These compounds, which are usually considered to be very unreactive toward substituting reagents, are chlorinated with remarkable ease by sulfuryl chloride in the presence of benzoyl peroxide. The beta chloro derivatives are formed.

Propionic acid and propionyl chloride are chlorinated readily by the reagent to yield both the alpha and the beta chloro isomers with the beta in excess.

The preferential chlorination of an aliphatic acid or acid chloride in the beta position is rather unusual in view of the emphasis usually placed upon the activity of the alpha position in these compounds. However, the study of the chlorination of *n*-butyric acid and isobutyric acid and the corresponding acid chlorides has established the fact that the above instance is no exception. In all the cases that we have investigated, *substitution takes place preferentially on a carbon atom which is some distance removed from the carboxyl group, with the result that the yields of beta or beta and gamma chlorinated derivatives which are obtained far exceed the amount of the alpha isomer.*

(1) Eli Lilly Fellow, 1938–1939.

(2) Kharasch and Brown, THIS JOURNAL, **61**, 2142 (1939).

(3) The yields are based on the sulfuryl chloride.

The relative yields of isomers obtained in these reactions are listed in Table I.

TABLE I

PRODUCTS OF THE CHLORINATION OF ALIPHATIC ACIDS AND ACID CHLORIDES BY SULFURYL CHLORIDE AND PEROXIDES

Compound chlorinated	Products
Propionic acid	45% α-chloropropionic acid
	55% β-chloropropionic acid
Propionyl chloride	40% α-chloropropionyl chloride
	60% β-chloropropionyl chloride
Isobutyric acid	15% α-chloroisobutyric acid
	85% β-chloroisobutyric acid
Isobutyryl chloride	20% α-chloroisobutyryl chloride
	80% β-chloroisobutyryl chloride
n-Butyric acid	10% α-chloro-*n*-butyric acid
	45% β-chloro-*n*-butyric acid
	45% γ-chloro-*n*-butyric acid
n-Butyryl chloride	15% α-chloro-*n*-butyryl chloride
	55% β-chloro-*n*-butyryl chloride
	30% γ-chloro-*n*-butyryl chloride

An examination of the effect of the ordinary chlorination catalysts upon mixtures of sulfuryl chloride and organic acids or acid chlorides yielded more conventional results. For example, the addition of iodine to a reaction mixture of propionyl chloride and sulfuryl chloride kept at 70° initiates a slow reaction. The alpha chloro derivative was the only product which was isolated.

Results similar to those obtained in the peroxide-catalyzed reaction have been reported in the *photochemical* chlorination of carefully purified acids and acid chlorides in the absence of halogen carriers.[4] On the other hand, the chlorination of aliphatic acids and acid chlorides with the aid of halogen carriers as catalysts yields only the alpha-substituted derivatives.[5]

Obviously different mechanisms must operate in reactions giving such divergent products. Our entire experience suggests that both the photochemical chlorination and the peroxide-catalyzed reaction with sulfuryl chloride (which, alike, favor substitution in positions of the carbon chain other than the alpha) proceed through chain mechanisms involving chlorine atoms; on the other hand, chlorination of acids and acid chlorides with the aid of halogen carriers (in which substitution takes place only in the alpha position) must involve the action of some other form of active chlorine[6] upon the organic compound.

If, as seems probable, the active agent in the peroxide-catalyzed reactions of sulfuryl chloride is the chlorine atom, the explanation for the fact that the alpha position is not substituted to a degree commensurate with that calculated on a statistical basis is to be sought in the deactivating effect of the carboxyl and the acid chloride groups on the carbon–hydrogen bonds at the alpha position.

This is substantiated by the facts that neither the carboxyl nor the acid chloride groups can inhibit the peroxide-catalyzed reaction of sulfuryl chloride with other substances,[7] and observations that the sensitivity of the carbon–hydrogen bond to attack by chlorine atoms can be markedly decreased by substituents on an adjacent carbon atom. Thus, (1) secondary hydrogen atoms are substituted more readily than primary, (2) substitution of a second chlorine atom upon a carbon atom already holding a halogen substituent is difficult, and (3) a second chlorine atom tends to substitute a point on the carbon chain as far removed from the first chlorine substituent as possible.

The inertness of acetyl chloride toward chlorine atoms (produced from sulfuryl chloride and a peroxide) is therefore interpreted on the basis of a combined effect of the relatively high energy of activation and dissociation of primary hydrogen–carbon bonds and the further deactivation of these bonds induced by the acid chloride group. This suggestion is further supported by the fact that methyl chloroform also does not undergo the peroxide-catalyzed reaction with sulfuryl chloride.

Sulfonation of Aliphatic Acids

As has been mentioned, aliphatic acids do not react with sulfuryl chloride in the absence of catalysts and light. If light is not excluded, however, reaction occurs, leading not to chlorination but to sulfonation of the acid. In this way we have been able to prepare β-sulfopropionic acid and a sulfobutyric acid from the action of sulfuryl chloride on the corresponding acids.

The direct sulfonation of aliphatic acids and acid chlorides in the past has been accomplished by the action of sulfur trioxide or chlorosulfonic

(4) Michael and Garner, *Ber.*, **34**, 4046 (1901).

(5) Markownikow, *Ann.*, **153**, 241–242 (1870); Wolffenstein and Rolle, *Ber.*, **41**, 735–736 (1908); Bass, U. S. Patent 2,010,685. In the case of the aliphatic acids of high molecular weight, such as stearic acid, it is reported that treatment with chlorine yields a mixed product; the rule that substitution takes place predominantly in the alpha position no longer holds.

(6) This problem will be taken up in detail in a forthcoming publication.

(7) Kharasch and Brown, THIS JOURNAL, **61**, 2148 (1939). Furthermore, the presence of an equimolar portion of acetyl chloride does not prevent the chlorination of either cyclohexane or toluene; the acetyl chloride acts only as an inert diluent.

acid upon the organic compound. In all cases, the product formed is reported to be the alpha sulfo derivative.

On the other hand, the photochemical sulfonation of aliphatic acids mentioned above does not lead to the alpha sulfo derivative. Indeed, a careful study of the product obtained from the action of sulfuryl chloride on propionic acid[8] indicates that the only sulfopropionic acid formed is the beta derivative. Thus, here again is an example of different mechanisms favoring different positions for substitution: attack of acids by reagents through what appears to be an ionic mechanism leads predominantly to alpha substitution, while attack through an atomic or free-radical mechanism favors beta substitution.

The generality of this sulfonation reaction of aliphatic acids was investigated, and it was found that while acetic acid does not react, *n*-butyric and isovaleric acids can be sulfonated by this means. The yields are somewhat poorer than that obtained with propionic acid. The position of the sulfonic acid group in these products was not established.

This reaction, photochemical sulfonation with sulfuryl chloride, appears to be catalyzed by the carboxyl group. This view is based upon the observation that aliphatic hydrocarbons can be sulfonated by sulfuryl chloride in the presence of acetic acid. The yields, however, are poor, indicating that the carboxylic acids are comparatively inefficient catalysts for this reaction. Since more efficient catalysts are now available,[9] the study of this catalytic activity of organic acids was not extended.

Experimental Part

Apparatus and Materials.—The types of reaction vessels and fractionating columns which were used in this work are described in an earlier article.[2] The acids used were either Eastman Kodak Co. or commercial chemicals with one exception, trimethylacetic acid.[10] The acid chlorides available commercially were not used: impurities present in these substances (volatile sulfur and phosphorus compounds) could be removed only with difficulty. Pure acid chlorides were prepared more conveniently by the action of benzoyl chloride upon the corresponding acids.[11]

Chlorination of Acetic Acid.—The following experiments are typical of the attempts made to chlorinate acetic acid with sulfuryl chloride.

The reaction mixture, consisting of 36.0 g. of anhydrous acetic acid[12] (0.6 mole) and 40.5 g. of sulfuryl chloride (0.3 mole), was refluxed in the dark for two hours, until evolution of gas ceased. Fractionation of the reaction mixture yielded better than 90% recovery of acetic acid (b. p. 117–119°). The formation of chloroacetic acid could not be demonstrated.

A similar reaction mixture of acetic acid and sulfuryl chloride was made up, and benzoyl peroxide (0.75 g., 0.003 mole) was added. Upon heating of this mixture a vigorous reaction occurred and was complete in fifty minutes. Fractionation of the product indicated a 30% yield of chloroacetic acid (b. p. 106–109° at 40 mm.).

An attempt was made to improve the yield by adding a diluent. The reaction mixture consisted of 36.0 g. of acetic acid, 40.5 g. of sulfuryl chloride, 0.75 g. of benzoyl peroxide, and 92.4 g. of carbon tetrachloride (0.6 mole). Refluxing of the reaction mixture initiated a slow reaction. At the end of three hours, and again at the end of six hours, 0.75-g. portions of benzoyl peroxide were added. At the end of nine hours, the reaction was but 70% complete (on basis of loss of weight). The chloroacetic acid isolated amounted to 50% of the calculated yield.

Acetyl Chloride.—Acetyl chloride could not be induced to undergo the peroxide-catalyzed reaction. Since the results are negative, the experiments need not be described in any detail. One reaction mixture, consisting of equimolar parts of sulfuryl chloride and acetyl chloride, was heated for twenty-four hours in the presence of 2 mole per cent. of benzoyl peroxide without effect. Addition of solvents (carbon tetrachloride, chlorobenzene) was unavailing. The inactivity cannot be due to any inhibiting properties of the molecule since acetyl chloride can be used as an inert solvent in the chlorination of toluene or cyclohexane.

Propionic Acid and Propionyl Chloride.—Propionic acid and propionyl chloride are chlorinated readily by the reagent. The isomeric chloropropionyl chlorides can be separated easily by fractionation. Since this method of analysis cannot be utilized for the separation of the isomeric chloropropionic acids without considerable difficulty, these isomers were separated by fractionation only after they had been transformed into the corresponding acid chlorides.

The reaction mixture consisted of 59.2 g. of propionic acid (0.8 mole), 54.0 g. of sulfuryl chloride (0.4 mole), and 61.6 g. of carbon tetrachloride (0.4 mole). Benzoyl peroxide (0.5 g., 0.002 mole) was added, and the mixture was heated gently under reflux in the dark. After one and one-half hours, no more gas was evolved, and the reaction was considered complete. An excess of thionyl chloride was added (190.4 g., 1.6 moles) and the heating continued for four hours more. The carbon tetrachloride, excess thionyl chloride and propionyl chloride were distilled at atmospheric pressure; the remainder was fractionated at 100 mm. The relative yields[13] of α-chloro-

(8) The sulfonation of this acid was studied most thoroughly because of the relatively high yields which can be obtained, and the ease of separation and identification of the two possible isomers.

(10) "Organic Syntheses," Coll. Vol. I, 1932, p. 510.

(11) Brown, THIS JOURNAL, **60**, 1325 (1938).

(12) The acetic acid was heated under reflux with 10% of its weight of acetic anhydride for twenty-four hours, and then carefully distilled through an efficient fractionating column.

(13) The total yield of monochloropropionyl chlorides before separation was 75%. In the preparations reported in this paper (with the exception of acetic acid) the yields of monochlorinated derivatives which were obtained varied between 70 and 90% of the calculated (based on chlorine). Losses were chiefly due to the formation of higher chlorinated compounds and loss of sulfuryl chloride through the condenser.

propionyl chloride (b. p. 51–54° at 100 mm., $n^{20}D$ 1.440) and β-chloropropionyl chloride (b. p. 81–84° at 100 mm., $n^{20}D$ 1.454) were as 45 to 55.

The identities of the products were confirmed by the preparation of the anilides: α-chloropropionanilide, m. p. 91–92°, and β-chloropropionanilide, m. p. 119–120°.

The chlorination of propionyl chloride is a much slower reaction which requires four to six hours for completion.

Isobutyric Acid and Isobutyryl Chloride.—The chlorinations of isobutyric acid and isobutyryl chloride were carried out in a manner similar to those already described. The product first was fractionated under reduced pressure and then refractionated at atmospheric pressure. The analysis and identification of the products was complicated by the fact that the values of the boiling points of the two isomeric chloroisobutyryl chlorides reported in the literature are in error. Michael and Garner[14] report the boiling points of α- and β-chloroisobutyryl chlorides to be 126–127° and 171–172°, respectively. The distillation of the reaction products from our preparations yielded two fractions, b. p. 117–118° ($n^{20}D$ 1.4369) and 151–152° ($n^{20}D$ 1.4542). The lower-boiling of these products was identified as α-chloroisobutyryl chloride by transformation into the acid, m. p. 28–30°, and the preparation of the anilide, m. p. 71–71.5°. The anilide of the higher-boiling fraction, which must be the β-chloro derivative, was prepared; the derivative crystallized from alcohol and water in long prismatic needles, m. p. 109.0–109.5°.

Anal. Calcd. for $C_{10}H_{12}ONCl$: N, 7.1; Cl, 17.98. Found: N, 7.2; Cl, 18.01.

***n*-Butyric Acid and *n*-Butyryl Chloride.**—Both *n*-butyric acid and *n*-butyryl chloride reacted with great ease. The chlorination of 150–200 g. of these compounds was complete in less than one hour. The isomeric chlorinated acids were isolated as the acid chlorides (after treatment with thionyl chloride) by fractionation under reduced pressure. At a pressure of 40 mm., the alpha derivative was collected at 45–50°, the beta ($n^{20}D$ 1.4525) at 65–67°, and the gamma ($n^{20}D$ 1.4631) at 83–85°. The identities of the isomers were confirmed by the preparation of the *p*-toluides.[15]

Trimethylacetic Acid and Chloride.—The β-chlorotrimethylacetic acid was separated from the reaction mixture by fractionation under reduced pressure; the acid was collected at 126–129° at 30 mm. It crystallized from low-boiling ligroin in the form of plates melting at 40–42°. The identity of the product was established by a chlorine determination and the neutralization equivalent.

Anal. Calcd. for $C_5H_9O_2Cl$: Cl, 26.07; neut. equiv., 136.5. Found: Cl, 25.88; neut. equiv., 136.

The amide crystallized from water in the form of plates, m. p. 108–109°.

Anal. Calcd. for $C_5H_{10}ONCl$: N, 10.34. Found: N, 10.42.

The β-chlorotrimethylacetyl chloride, formed by the chlorination of trimethylacetyl chloride, was also isolated from the reaction mixture by fractionation (b. p. 85–86° at 60 mm., $n^{20}D$ 1.4539). The amide was prepared and found to be identical with that obtained from the chlorinated acid.

(14) Michael and Garner, *Ber.*, **34**, 4054–4055 (1901).

(15) Wolffenstein and Rolle, *ibid.*, **41**, 736–737 (1908).

Chlorination of Propionyl Chloride (Effect of Halogen Carriers).—The reaction mixture was made up of 46.3 g. of propionyl chloride (0.5 mole) and 40.5 g. of sulfuryl chloride (0.3 mole). Iodine (0.5 g.) was added, and the mixture heated under reflux for twelve hours. The loss in weight of the reaction mixture was 80% of the calculated amount. Fractionation of the reaction mixture yielded 24.3 g. of material distilling in the range 103–110°. This material was treated with mercury to remove free iodine, and redistilled. The final yield was 22.0 g. of an acid chloride (b. p. 108–109°) which was identified as α-chloropropionyl chloride. The formation of the beta isomer could not be demonstrated.

Catalysts other than iodine were tested. Granulated animal charcoal causes complete dissociation of the sulfuryl chloride in five hours; however, less than 20% of chlorinated acid chloride was formed. Aluminum chloride, which is a very vigorous catalyst for the chlorination of aromatic nuclei with sulfuryl chloride, was unsatisfactory for this reaction. A mixture of iodine and carbon reduces the time required for the reaction to six hours and may therefore have some advantage over the use of iodine alone. In all cases the alpha isomer was the only chlorinated acid chloride which could be isolated.

Sulfonation of Propionic Acid.[16]—A mixture of 78.0 g. of propionic acid (1.0 mole) and 67.5 g. of sulfuryl chloride (0.5 mole) was heated gently under reflux for two hours. During the course of the reaction the flask was illuminated by a 300-watt lamp situated about 5 cm. from the reaction flask. After the reaction was complete, a mixture of ligroin (60–70°) and benzene was added, precipitating a white solid. The mixture was permitted to stand for twenty-four hours at room temperature to ensure complete precipitation. The supernatant liquid was then decanted, and the solid was washed several times with dry ligroin. Finally, the mixture was filtered on a Büchner funnel and the solid quickly transferred to a desiccator containing paraffin and phosphorus pentoxide. The weight of the dry crude product (m. p. 100–102°) was 28.3 g., a yield of 37%.

Its properties and reactions indicate that this substance must be β-sulfopropionic acid. The analysis and identification were rendered difficult by our inability to purify the product by recrystallization: the crude material was insoluble in ligroin, benzene and chloroform, and extremely soluble in water and alcohol to yield strongly acid solutions. The extreme hygroscopic nature of the substance added to the difficulties of analysis. A qualitative analysis showed the presence of sulfur and the absence of halogen.

Anal. Calcd. for $C_3H_6O_5S + {}^1/_2H_2O$ ($HO_3SC_2H_4COOH + {}^1/_2H_2O$): C, 22.09; S, 19.63; H, 4.3; neut. equiv., 81.5. Found: C, 22.11; S, 19.62; H, 4.7; neut. equiv., 80.6.

The water indicated in this analysis is probably not a definite quantity. It was noted that even very short exposures to the atmosphere rapidly increased the water content of the material.

The position of the sulfonic acid group was definitely established by a study of the solubility and composition of the barium salt. The barium salt of α-sulfopropionic

(16) These results are to be considered as a preliminary report; we are continuing the study of this reaction.

acid crystallizes from water with 1.5 moles of water and is soluble to the extent of 7 parts of salt per 100 parts of water. On the other hand, the barium salt of the β-isomer crystallizes with 5.0 moles of water and is less than one-tenth as soluble.

Ten grams of the dried sulfopropionic acid was dissolved in 300 cc. of hot water, and the solution was neutralized with crystalline barium hydroxide. The hot solution was filtered and permitted to cool to room temperature. The crystals which separated (prismatic plates) were collected on a filter and air dried. The filtrate was then concentrated to 100 cc. and the process was repeated. A total yield of 22.1 g. of the air-dried salt was obtained (first crop, 15.8 g.; second crop, 6.3 g.), representing slightly more than 90% of the yield theoretically possible.

Anal. Calcd. for $Ba(C_3H_4O_5S)\cdot 5H_2O$: H_2O, 23.73; Ba, 36.21. Found: H_2O, 23.57; Ba, 36.33.

In the course of the attempts to recrystallize the original product, it was found that treatment with thionyl chloride yielded a crystalline substance which has been tentatively identified as an anhydride of β-sulfopropionic acid.

Three grams of the crude sulfopropionic acid was heated under reflux for three hours with 20 g. of thionyl chloride. Ligroin was added, and the mixture was heated until the solid which at first had precipitated, redissolved. Upon cooling, a solid separated in the form of thin plates. This material was recrystallized from thionyl chloride and ligroin, and placed in a vacuum desiccator over paraffin and freshly fused potassium hydroxide. The substance melted sharply at 76–77°. It contained sulfur, but no chlorine. The neutralization equivalent was found to be 67.4, 68.3; the calculated value for the anhydride is 68.0.

Acids as Catalysts for Sulfonation of Hydrocarbons.[9]—Since the carboxyl group appears to be the active catalyst in this reaction, we studied the photochemical sulfonation of hydrocarbons in the presence of a carboxylic acid. Sulfonation occurs, but the yields are low. The following experiment is typical of the results obtained.

In a flask were placed 42.0 g. of cyclohexane (0.5 mole), 33.8 g. of sulfuryl chloride (0.25 mole) and 1.0 g. of acetic acid. The mixture was heated gently and illuminated for four hours. Upon fractionation, there was obtained 20 g. of cyclohexyl chloride (b. p. 65–70° at 60 mm.) and 2.2 g. of cyclohexane sulfonyl chloride (b. p. 125–135° at 12 mm.). The yield of sulfonyl chloride is but 5% of the calculated.

Summary

1. The action of sulfuryl chloride on acetic, propionic, *n*-butyric, isobutyric, and trimethylacetic acids and the corresponding acid chlorides under various conditions, has been investigated.

2. In the absence of catalysts and light sulfuryl chloride does not react with organic acids and acid chlorides.

3. In the presence of a small quantity of added peroxide, the higher aliphatic acids and acid chlorides react vigorously to form 70 to 90% yields of chlorinated derivatives. On the other hand, acetic acid reacts with difficulty, and acetyl chloride cannot be chlorinated in this way.

4. The yields of the various isomeric chloro derivatives indicate that the alpha position in the carbon chain is substituted with greater difficulty than the beta and gamma positions. That is, *the product consists chiefly of beta or beta and gamma chloro acids (or the corresponding acid chlorides)*. For example, the chlorination of *n*-butyryl chloride yields 15% α-, 55% β-, and 30% γ-chlorobutyryl chloride.

5. If halogen carriers, such as iodine, instead of peroxides are used to catalyze the reaction of sulfuryl chloride with acid chlorides, substitution takes place only at the alpha position. The mechanisms involved in the two reactions must be of two different types; it appears that the peroxide-catalyzed reaction is a chain reaction involving chlorine atoms, while the iodine-catalyzed chlorination is due to another form of active chlorine.

6. Sulfuryl chloride also undergoes a photochemically catalyzed reaction with the higher aliphatic acids to yield sulfonated acids. In this way, a 37% yield of β-sulfopropionic acid readily can be isolated. *n*-Butyric and isovaleric acids also have been sulfonated. Acetic acid does not react.

7. Acetic acid catalyzes the photochemical sulfonation of hydrocarbons with sulfuryl chloride. The yield is small.

8. In the course of this investigation, the following compounds have been prepared and characterized: β-chlorotrimethylacetic acid and the corresponding acid chloride and amide, and the anhydride of β-sulfopropionic acid.

The Viscosities of Arabogalactan Solutions

BY HARRY S. OWENS

Arabogalactan is a water-soluble polysaccharide present in the Eastern, Western and Siberian varieties of the larch. Trimble[1] in 1898 described a water-soluble material extracted from larch wood, but he reported no quantitative data concerning it. Schorger and Smith[2] investigated it further and called it ϵ-galactan, believing that the only monosaccharide residue present in the molecule was galactose. Wise and Peterson,[3] Wise and Unkauf,[4] Nikitin and Soloviev,[5] Barry[6] and Woodruff[7] have shown that arabogalactan contains both arabinose and galactose and that the proportion of sugar residues in the molecule is about one to six, respectively.[8]

As much as 17% of arabogalactan has been reported present in the heartwood of the Western larch,[2] yet little is known of its properties, functions in the tree, or its possible utilization. It seemed desirable to determine some of its physical properties because of this scarcity of information and also because the knowledge obtained could be applied to other problems under way in these Laboratories.

Viscosity measurements were chosen because they offer a means of obtaining some idea of the shape of large molecules in solution, and they may be used to determine the approximate molecular weight of such molecules.

Materials.—The arabogalactan was extracted from shavings taken from the butt of a Western larch tree. A system of counter-current extractions was used in which 400 g. of shavings was placed in a crock with sufficient water to saturate the fibers; then 4 liters of water was added. After four days the extract was poured on a fresh batch of water-soaked shavings while 4 liters of water was added to the extracted shavings. This process was repeated until the initial 4 liters of water had extracted 1600 g. of shavings. The concentrated extract was filtered through a filter bed of filter-aid and charcoal until clear and colorless, then poured into four volumes of 95% alcohol. After drying the precipitate, a white powder was obtained having an ash content of 0.06% and an anhydrogalactose content of 85% (87.7% of theoretical). The product was dissolved in water, and filtered through fritted glass membranes in order to remove filter paper fibers and particles of dust that could not be removed by filtrations through fine filter paper. It was reprecipitated with alcohol and dried at 105°, before using.

The ether, acetone, dioxane, acetic acid and chloroform were analytical reagent grade. The alcohol was 95% U. S. P., and the chloroform was U. S. P. grade. Isobutyl alcohol, ethylenediamine (69.8%), Butyl Carbitol, Cellosolve and monoethanolamine were commercial solvents supplied by the Carbide and Carbon Chemicals Corp. The amyl acetate was a commercial product supplied by Sharples Solvent Corp. Merck activated charcoal was used for all decolorizations. Pfanstiehl Chemical Co. C. P. *d*-lactose and *d*-galactose were used also.

Methods.—An Ostwald viscometer was used throughout this work. The measurements were made in a thermostat kept within 0.1° of the temperature desired.

Densities were determined with a specific gravity bottle of about 50 ml. capacity, and the weights were corrected to readings in vacuum.

Calibrated volumetric flasks were used in making up solutions, and precautions were taken to have the solutions made up to volume at the temperature to be used for measurements.

The tests for solubility of arabogalactan in various solvents were purely qualitative. One-tenth of a gram of the solid was weighed and shaken with 40 to 60 ml. of the solvent. If the solid did not dissolve, the supernatant liquid was decanted and evaporated to dryness and the residue weighed. The solvent acted upon the solid for twenty-four hours at room temperature with intermittent shaking.

Results.—The viscosity measurements made with arabogalactan solutions at 20, 40, and 60° are plotted in Fig. 1. It will be seen that the viscosities of the solutions are directly proportional to the concentration until about 6% is reached. Viscosities of solutions from 6–10% in concentration showed greater and greater deviations from linearity.

Results at 25° with arabogalactan, galactose and lactose solutions are shown in Fig. 2. The viscosity measurements made by Pulvermacher[9] with galactose and lactose are shown for comparison.

The density values for arabogalactan solutions at 25° have been converted to the reciprocals (specific volumes) and are plotted in Fig. 3.

(7) Woodruff, M.S. Thesis, University of Idaho, 1937, under the direction of Dr. E. C. Jahn, now at Syracuse University.

(8) Barry[6] disagrees with this ratio and the significance attached to it. On the basis of specific viscosity measurements of the propionyl and benzoyl derivatives of arabogalactan from various sources and because he was able to fractionate these derivatives, he concluded that arabogalactan is a mixture of araban and galactan.

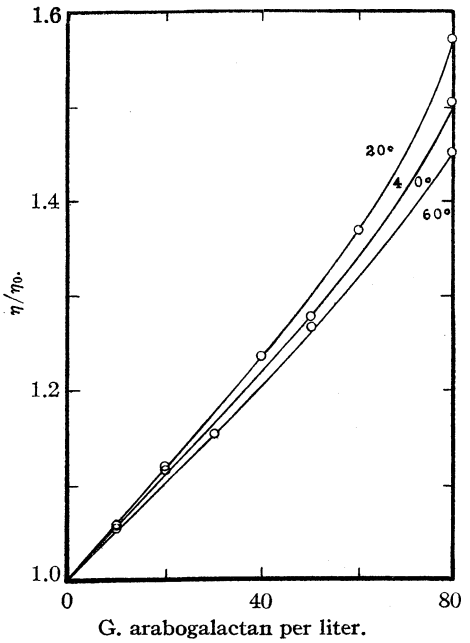

Fig. 1.—Effect of temperature on the relative viscosities of arabogalactan solutions.

By extrapolation to 100% arabogalactan a specific volume is obtained of 0.65 ml. per g.

The tests for solubility indicate that arabogalactan is so difficultly soluble in any of the solvents tried that viscosity measurements were limited to water systems. Arabogalactan was soluble to about a 0.2% solution in carbon tetrachloride,

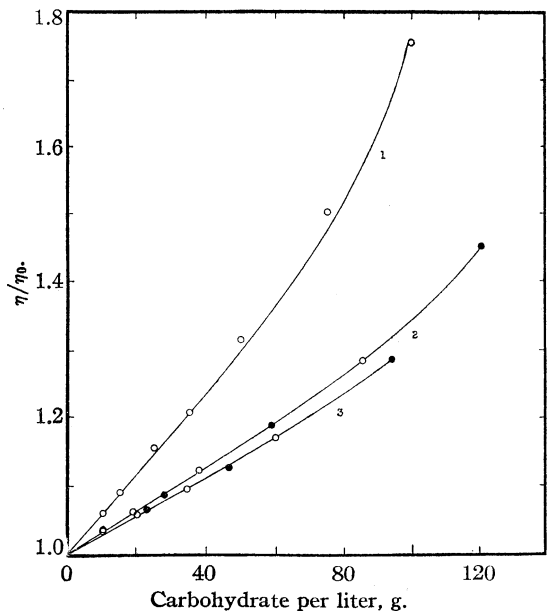

Fig. 2.—Comparison of the relative viscosities of arabogalactan (1), lactose (2), and galactose (3) at 25°; ● Pulvermacher's results.

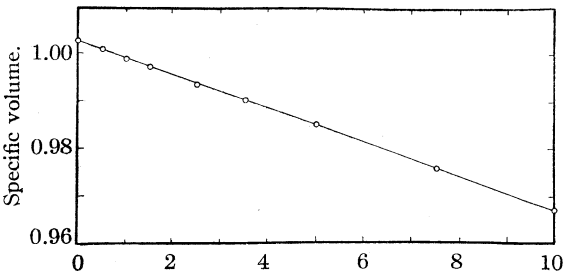

Fig. 3.—Specific volumes of arabogalactan solutions.

ethylenediamine (69.8%) Cellosolve and monoethanolamine. About a 0.1% solution could be formed in Butyl Carbitol. Arabogalactan was insoluble in the other solvents tried.

Discussion

There are several equations available which correlate viscosities and the percentage of the volume of a solution occupied by the dispersed substance. Einstein's[10] equation $\eta/\eta_0 = 1 + 2.5\ \phi$ where η is the viscosity of the solution, η_0 is the viscosity of the pure medium, and ϕ is the fraction of the volume occupied by the dispersed substance, is probably the most widely known. Hatschek's[11] equation $\eta/\eta_0 = 1 + 4.5\ \phi$ has received attention also. A purely empirical equation obtained by Kunitz[12]

$$\eta/\eta_0 = \frac{1 + 0.5\,\phi}{(1 - \phi)^4}$$

probably expresses the facts better than either of the theoretical equations.[13]

The viscosity data have been used in calculating values of ϕ by all three equations. The specific volume also has been calculated by dividing ϕ by the percentage concentration of the arabogalactan solution. The values calculated are shown in Table I.

TABLE I

RELATIVE VISCOSITIES AND PARTIAL VOLUMES OBTAINED FROM VARIOUS VISCOSITY EQUATIONS

		Kunitz		Einstein		Hatschek	
C, g./l.	η/η_0 at 25°	ϕ, %	V, ml./g.	ϕ, %	V, ml./g.	ϕ, %	V, ml./g.
20	1.118	2.50	1.25	4.72	2.36	2.62	1.31
40	1.235	4.68	1.17	9.38	2.35	5.21	1.30
60	1.372	6.90	1.15	14.88	2.48	8.25	1.37
80	1.538	9.20	1.15	21.50	2.69	11.95	1.49
100	1.758	12.00	1.20	30.20	3.02	16.80	1.68

The constancy of the values for the specific volume (V) of arabogalactan to a concentration

(10) Einstein, *Ann. Physik*, **19**, 289 (1906); **34**, 59 (1911).
(11) Hatschek, *Kolloid Z.*, **7**, 30 (1910).

(13) Gortner, "Outlines of Biochemistry," John Wiley and Sons, N. Y., 1938, p. 54.

of 60 g. per liter, regardless of the equation used, indicates that the molecule must be spherical. For the entire range of concentrations, the Kunitz equation shows greater constancy for the values of V.

Other evidence indicating a preference for the Kunitz equation comes from the density measurements. The specific volume obtained from those measurements is 0.65 ml. per g., and Fig. 1 indicates that the degree of solvation is low; consequently the lowest figures obtained for the specific volume by means of the viscosity equations should be more nearly correct. The values for V from the Kunitz equation are the lowest reported.

Whether or not the difference between the specific volumes obtained by the viscosity and the density methods represents the amount of water solvated by arabogalactan will require confirmation through measurements of the rate of diffusion of arabogalactan.

Staudinger[14] has devised equations expressing the relation of specific viscosity $\eta_{sp} = (\eta/\eta_0 - 1)$ and the molecular weight. One of these equations can be used for this work. It is $\eta_{sp} = K_m CM/B$ where K_m is a constant determined from viscosity measurements with substances of similar natures of known molecular weights; C is the concentration in g. per liter; B is the "base weight," the molecular weight of the simplest repeating unit in the molecule; M is the molecular weight of the complete molecule.

Galactose was used to determine the value of K_m which was found to be 2.7×10^{-3}. The simplest repeating unit in arabogalactan is $[C_5H_8O_4 \cdot (C_6H_{10}O_5)_6]$, which has a base weight of 1104. Substituting these values in the Staudinger formula yields an average molecular weight of 2300 for arabogalactan.

This value agrees very well with that of Nikitin and Soloviev,[5] who obtained 2208 by chemical methods after they had found that cryoscopic methods were not applicable. (Schorger and Smith[2] report a value of 3286 using cryoscopic methods.) The agreement between the values obtained by Nikitin and Soloviev and the author may or may not be significant. Viscosity measurements of this kind should be made in a medium which will not be solvated by the dissolved material. The search for a solvent having a lower dipole moment than water proved fruitless. However, the greatest source of error in these experiments is the application of the constant, K_m, determined with galactose having a molecular weight of 180. Staudinger and Daumiller[15] working with cellulose triacetates, Fordyce and Hibbert[16] with polyoxyethylene glycols and Kraemer and van Natta[17] with hydroxydecanoic acid derivatives have all shown that the constant, K_m, increases rapidly as the molecular weight of compounds of a homologous series decreases from a value of 2000. K_m is more nearly a true constant with compounds having a molecular weight above 2000. Values for K_m reported in the literature for various types of compounds vary from 0.2 to 2.3×10^{-3}; consequently one can conclude that the molecular weight of arabogalactan is at least 2208 and may be even higher.

Summary

1. The viscosities of arabogalactan solutions having concentrations of from 1–8% have been measured at 20, 25, 40, and 60°.

2. Arabogalactan was found to have a spherical shape when dissolved in water.

3. The molecular weight of arabogalactan is at least 2208, the simplest formula being $(C_5H_8O_4 \cdot (C_6H_{10}O_5)_6)_2$.

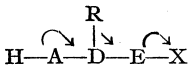
Elimination and Metathetical Reactions and the Electronic Theory of Rearrangements

BY CHARLES R. HAUSER

Various workers have attempted to formulate general mechanisms for elimination, metathetical and intramolecular rearrangement reactions, which are characteristic of many compounds containing an electronegative atom or group, X (such as halogen or hydroxyl). In 1928 Ingold and Shoppee[1] pointed out that the fundamental type of electronic change underlying a number of apparently diverse rearrangements is the same. They represented these changes according to the following scheme, in which A, D and E are atoms of carbon, nitrogen or oxygen



In 1932 Whitmore[2] formulated a more comprehensive and detailed theory for eliminations, metatheses and intramolecular rearrangements. The essential feature of the theory is that X is removed with a complete octet of electrons, leaving an atom with only a sextet of electrons. The positive fragment thus formed may add an anion, lose a proton or undergo rearrangement (involving the shift of an electron pair together with R attached) to form a new positive fragment which may undergo these changes.

While these generalizations account for the products (both "normal" and rearranged) that are formed in certain reactions effected by acidic reagents[3] or heavy metal salts,[4] it is now recognized that the thory requires modification. Evidence has been presented that at least in certain metatheses[5] and in a pinacol type of rearrangement[6] (in which a molecule of water is eliminated) an atom with an "open" sextet is probably not actually formed as an intermediate.

For the purpose of predicting products it is generally adequate to describe the general courses of reactions, rather than to give detailed mechanisms. The roles of reagents used to effect reactions should be taken into account, and, for convenience, the course may be represented in steps. The courses of eliminations, metatheses and intramolecular rearrangements effected by means of acids, acidic reagents or heavy metal salts (or in certain cases by heat alone) may be described by the generalizations outlined by Whitmore (with the modification that the steps may occur simultaneously). These reactions may be initiated (or facilitated) by an attack of the reagent on X,[7] which is removed with its bonding pair of electrons. The course of elimination of HX involves the removal of X, with or without rearrangement of the molecule, accompanied or followed by the loss of a proton. Metatheses in the presence of these reagents may involve the primary removal of X, or might follow the course outlined in the next paragraph.

Metathetical reactions with basic anions, for example, the alkaline hydrolysis of alkyl halides, may be considered to involve an attack by the anion on the face of the carbon tetrahedron which is opposite X, the addition of the basic anion and the release of X as an anion occurring simultaneously (and being accompanied by the Walden inversion).[8]

Elimination reactions in which HX is removed by bases, probably involve a primary attack on the hydrogen, even when it is attached to a carbon atom. It is obvious that when a base is used to remove HX from a distinct acid, for example, trichloroacetic acid (where X is CCl_3) or a bromoamide, the hydrogen is first withdrawn as a proton, and evidence has been presented by Ingold,[9] Olivier[10] and others[11] that in the elimination of HX from the adjacent atoms of alkyl halides[10] or certain other compounds, the reaction is initiated

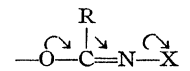
by an attack on the hydrogen atom. The remainder of this paper is devoted to the development of these ideas.

The Removal of HX from Organic Compounds by Means of Bases.—In this paper it is assumed as a working hypothesis that most organic compounds from which HX is removed by means of bases to form unsaturated products (or, in certain cases, cyclic products) function as acids, and that the primary acid–base reaction conditions subsequent changes that may occur. For convenience, the general course of these elimination reactions may be divided into three steps. First, the hydrogen is removed as a proton; second, X is released with a complete octet of electrons (*i. e.*, as an anion); and third, the molecule is stabilized. While intimate mechanisms may differ, most eliminations effected by bases may be considered to follow this general course.[12]

The first step is regarded as an acid–base reaction according to the modern conception of acids and bases. The extent to which this reaction may occur independently of subsequent changes should depend upon the acidic strength of the organic compound, the solvent, and the strength of base used. For a given base and solvent, the equilibrium of the acid–base reaction will of course be determined by the acidic strength of the organic compound. Two extreme types of reaction would be type I, in which the equilibrium of the acid–base reaction is far on the side of corresponding salt, and type II, in which the equilibrium of the acid–base reaction would be far on the side of the original acid and base. An example of type I is the reaction of alkali with a distinct acid, such as trichloroacetic acid, or even a bromoamide, and an example of type II is the reaction of this base with an extremely weak acid, such as an alkyl halide or a compound of the type RCH=NX. Although these types exhibit different kinetics, both may be classified according to the general course outlined above. It should be pointed out that in reactions of type I, steps (2) and (3) may occur simultaneously, while in reactions of type II, all three steps may be simultaneous and dependent on one another.

It has been shown that at least in certain cases reactions of type I exhibit monomolecular kinetics, the reaction measured presumably being the decomposition of the negative organic ion[13] of the salt which is formed by the removal of the proton. The rate of decomposition of the negative organic ion, even though rearrangement occurs, in general appears to be dependent upon the anionic stability (or the "negativity") of X and on the capacity for electron release of the remainder of the molecule. Thus, for example, in the decomposition[14] of negative organic ions of the type



the order of increasing rate (as well as the order of increasing anionic stability of X) when R is phenyl and X is varied is as follows: p-$CH_3OC_6H_4COO$ < HC_6H_4COO < m-FC_6H_4COO < m-$NO_2C_6H_4COO$; while the order of decreasing rate (as well as the order of decreasing capacity for electron release of R) when X is benzoate or bromine and R is varied is as follows: p-$CH_3OC_6H_4$ > HC_6H_4 > m-ClC_6H_4 > m-$NO_2C_6H_4$.

Most reactions of type II, at least when HX is removed from adjacent atoms, exhibit bimolecular kinetics, the rate of elimination of HX being dependent upon the "activity" of the hydrogen and the strength of base used. Thus, hydrogen bromide is removed by alkali two hundred times faster from ethylene dibromide than from ethylidene bromide,[10] and in the series of para substituted benzalchlorimines, $Y—C_6H_4CH=NCl$, the rates of elimination of hydrogen chloride by alcoholic alkali are directly related to the strengths of the corresponding carboxylic acids.[11]

Since the rates of elimination of HX from adjacent atoms of compounds of type II are related to the activities of the hydrogen, it might appear that the removal of the proton is the rate determining step of the reaction,[15] but it might also be possible for the rate determining step to be the release of X as an anion from the negative organic ion that would be formed by the removal of the proton. Since the equilibrium of the acid–base

(12) In certain cases in which the hydrogen is relatively unreactive, and X relatively easily released as an anion, it is possible that X might be removed first followed by the loss of the proton, even in the presence of a base. In this connection see *J. Chem. Soc., Ann. Repts.*, **35**, 226 (1938).

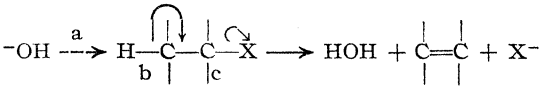
(13) The decomposition of the trichloroacetate ion exhibits monomolecular kinetics. The reaction gives carbon dioxide and presumably the ion $(CCl_3)^-$ which immediately takes up a proton from the solvent forming chloroform; Verhoek, THIS JOURNAL, **56**, 576 (1934).

(14) See Renfrow and Hauser, *ibid.*, **59**, 2308 (1937); Hauser and Renfrow, *ibid.*, **59**, 121 (1937); Bright and Hauser, *ibid.*, **61**, 618 (1939).

(15) The reactions of certain extremely weak acids (in which the acidic hydrogen is attached to carbon) with bases, are slow enough to measure; Conant and Wheland, *ibid.*, **54**, 1212 (1932).

reaction would be far on the side of the original base and extremely weak acid, the concentration of the negative organic ion should be dependent upon the concentrations of both the base and the acid. The fact that the rate is directly related to the activity of the hydrogen rather than the ease of release of X, as in reactions of type I, might be accounted for on the basis that the activating atom or group, for example, the para substituent of a benzalchlorimine, activates the hydrogen relatively more than it retards the release of chloride ion.

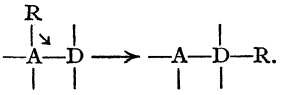
According to the generally accepted view of elimination of HX from the adjacent atoms of many compounds of the type II, the removal of the proton and the release of X are regarded as essentially simultaneous processes. A more detailed mechanism for the elimination of hydrogen halide from alkyl halides may be represented as follows



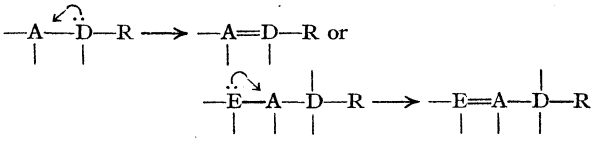
As bond a is being formed, bonds b and c are extended and finally broken simultaneously, the electron pair from bond b shifting at the same time to form the double bond. In this way a minimum of energy would probably be required for the elimination reaction.

Although the complete withdrawal of the proton may be accompanied by the simultaneous release of X as an anion, the alkyl halide may still be regarded as an acid in a broad sense; the elimination appears to involve a primary attack by the base on the "active" hydrogen atom, the shift of the electron pair and the release of X being dependent[16] upon this primary reaction. Regardless of the intimate mechanism involved, the base apparently conditions the reaction so that its course may be described by the steps outlined above.

The second step of the general course, involving the release of X with a complete octet of electrons, would leave an atom with only a sextet of electrons; this makes it possible for an electronic shift to occur within the molecule. If there is a free pair of electrons on an atom adjacent to the one from which X was released, this pair may shift to form a double (or triple) bond between the two atoms, thereby stabilizing the molecule; thus  . But if there is no free pair of electrons on atom A, the deficiency of atom D may be satisfied by a shift of an electron pair together with group R (or hydrogen) attached from atom A to atom D, thus



This rearrangement may involve inversion (Walden) of atom D. The migration of the electron pair (together with R) from atom A to atom D would leave atom A with only a sextet of electrons, a deficiency which may be satisfied by a shift of a free pair of electrons from atom D, or from another atom E, adjacent to atom A, to form a double (or triple) bond thus



From the foregoing discussion one should expect that when the proton is removed by a base, followed by the release of X (with a complete octet of electrons) from an *adjacent* atom, no rearrangement should occur, since the molecule can be stabilized merely by the shift of the free pair of electrons (left by the removal of the proton) to form a double or triple bond[17]; the shift of a free pair of electrons in this manner should take place more readily than a shift of an electron pair together with hydrogen or group R attached from one atom to another. On the other hand, if the proton and X are eliminated from the same atom or from a three atom system, rearrangement may be expected. It is noteworthy that although the removal of the proton cannot in itself bring about a rearrangement, the primary acid–base reaction plays an important role in determining whether or not rearrangement will occur.

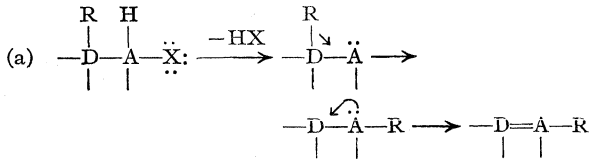
It may be considered that the manner in which the molecule is stabilized, the third step of the general course, depends upon the system from which HX is removed. This is based of course on obvious valency requirements and may be illustrated by the equations listed below, in which A, D and E represent atoms of carbon, nitrogen, or oxygen. Steps (1) and (2) are combined for

(16) The reaction appears to be dependent also on the polarizability of X, since the ease of elimination of hydrogen halide from alkyl iodides, bromides and chlorides decreases in this order. In this connection see Taylor, *J. Chem. Soc.*, 1962 (1937).

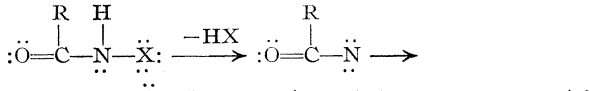
(17) See Hauser and Jordan, THIS JOURNAL, **57**, 2454 (1935).

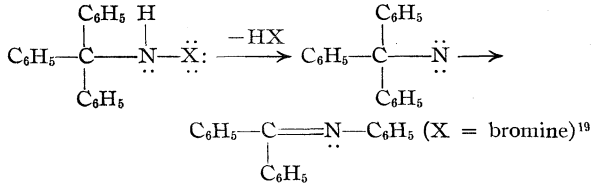
simplicity with step (3) shown separately, but this representation is to be regarded merely as a formal scheme which is an aid in predicting products. It should be noted, also, that as far as the prediction of products is concerned, there need be no distinction between reactions of types I and II.

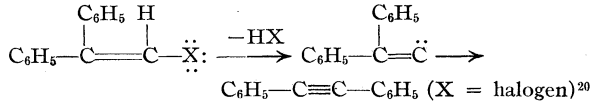
When HX is removed (by a base) from the same atom, the molecule may be stabilized by the formation of unsaturated products (a), by rearrangement, or (b) by dimerization.

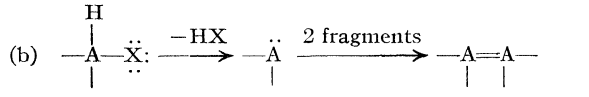


Examples:

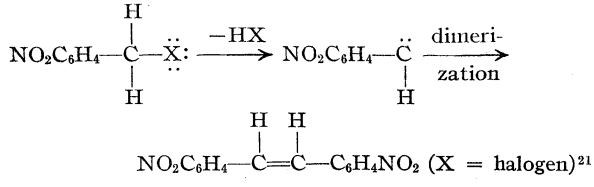




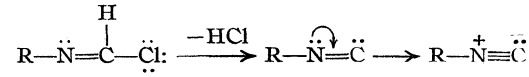




Example:

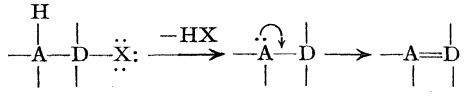


A special case arises when HX is removed from the same atom, adjacent to which there is an atom with a free pair of electrons. Then it is theoretically possible for the molecule to be stabilized, in accordance with the octet rule, merely by a shift of the free electron pair, without involving rearrangement of the molecule; in this case, however, one atom becomes positively, and the adjacent one negatively, charged. This might occur in the formation of isonitriles from primary amines, chloroform and alkali. According to the mechanism frequently assumed for this reaction the intermediate, RN=CHCl, is formed. This could eliminate HCl followed by the shift of the free electron pair on the nitrogen atom, thus:

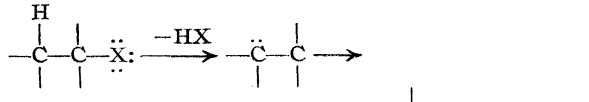


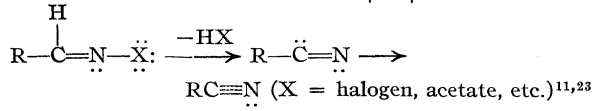
Recent evidence supports this structure for isonitriles. The fact that isonitriles when heated[22] rearrange to nitriles, indicates that the molecule can become more stable by the migration of R together with its electron pair to form the less polar nitrile.

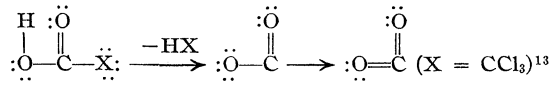
When HX is removed (by a base) from adjacent atoms, the molecule may be stabilized by the formation of unsaturated products without rearrangement; the stabilization involves merely the shift of the free pair of electrons, left by the removal of the proton, to form a double or triple bond; thus



Examples:







When HX is removed (by a base) from a three-atom system the molecule may be stabilized, (a)

(18) In the Hofmann and Lossen reactions HX may be considered to be removed from a one or a three-atom system (see ref. 14).

(19) Stieglitz and Vosburgh, *Ber.*, **46**, 2151 (1913).

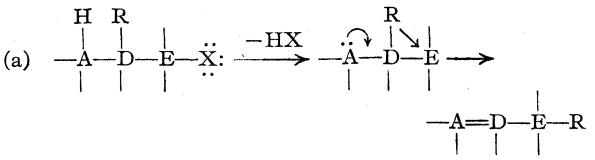
(20) Coleman and co-workers [THIS JOURNAL, **56**, 132 (1934); *ibid.*, **58**, 2310 (1936)] have found that with potassium amide in liquid ammonia diarylhaloethenes give good yields of tolanes.

(21) Ortho and para nitrobenzyl halides with alcoholic alkali give partly the corresponding dinitrostilbenes. See Michael, *ibid.*, **42**, 820 (1920). It should be noted that in these cases rearrangement is not possible.

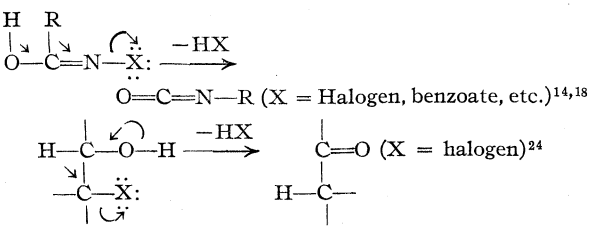
(22) See Hurd, "The Pyrolysis of Carbon Compounds," The Chemical Catalog Co., New York, N. Y., 1929, p. 603.

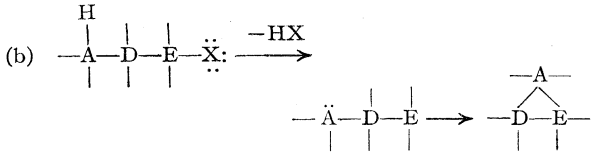
(23) The geometrical configuration of these compounds determines the ease with which the elements of HX will be eliminated, the *anti*-isomers eliminating HX much more readily than the *syn*-isomers (see especially ref. 17).

by the formation of unsaturated products involving rearrangement of the molecule, or (b) by cyclization

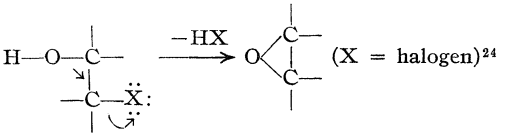


Examples:

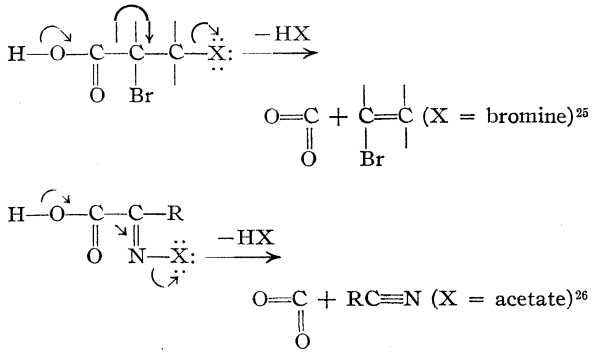


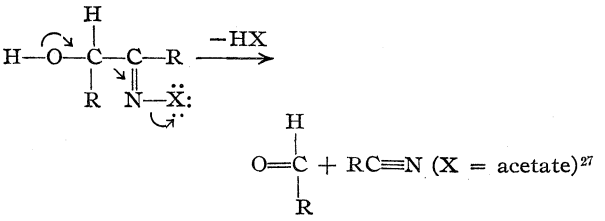


Example:

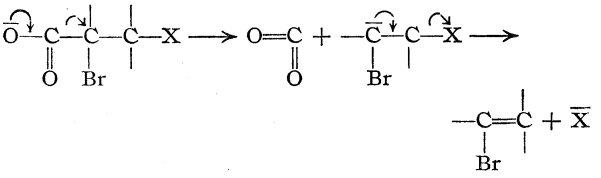


When HX is removed (by a base) from a four-atom system the molecule may be stabilized (a) by the formation of two unsaturated products without rearrangement, or (b) by cyclization. Examples in which two unsaturated products are formed without rearrangement may be represented as follows





These systems might be "double" two atom systems in which case the decomposition of the anion (formed by the removal of the proton) could be represented as follows:



When HX is removed (by a base) from five and six atom systems, the molecules are generally stabilized by cyclization. It should be pointed out that these reactions may or may not involve the primary removal of the hydrogen as a proton. The elimination of HX from acids, for example, γ-bromobutyric acid,[28] in the presence of alkali (where the acid–base reaction is of type I) obviously involves, first, the removal of the hydrogen as a proton to form the alkali salt, followed presumably by the release of bromide ion and cyclization to give γ-butyryl-lactone. But the elimination of HX from weaker acids, for example, 4-bromobutylamine, $BrCH_2CH_2$-$CH_2CH_2NH_2$, in the presence of alkali, apparently does not involve the primary removal of the hydrogen as a proton, since the reaction is not dependent upon the concentration of the base. In these cases the elimination of hydrogen halide is facilitated by the presence of the base apparently because it neutralizes the acid that is formed in the elimination, thereby preventing the reverse reaction (*e. g.*, opening of the ring). The mechanism for these eliminations has been discussed by Salomon.[29]

In the examples listed above and in others, the formation of unsaturated products involves rearrangement of the molecule (except in cases of dimerization) when HX is removed by a base from one or three atom systems, but no rearrangement when HX is removed by a base from two

(24) Apparently, on elimination of HX, *cis*-halohydrins undergo rearrangement, while *trans*-halohydrins cyclize giving ethylene oxide rings. See Suter and Lutz, THIS JOURNAL, **60**, 1360 (1938); Winstein and Lucas, *ibid.*, **61**, 1576 (1939); Bartlett, *ibid.*, **57**, 224 (1935).

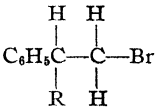
or four atom systems.[30] These facts support the general theory discussed in this paper.[31]

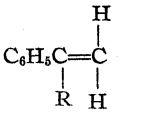
In most of the examples listed above, the organic compound can eliminate the elements of HX only from one particular system of atoms. There are many compounds, however, which might eliminate HX in two or more ways; for example, a compound of the type  might eliminate the elements of HX either from the same atom (accompanied by rearrangement or dimerization) or from adjacent atoms. In these cases it has frequently not been possible to determine with certainty which course is followed,[32] since the same unsaturated product could be formed by either course; thus, the elimination of HX from atom D, accompanied by a shift of the hydrogen (together with its electron pair) from atom A to atom D would give an unsaturated product identical with the one resulting from the elimination of HX from the adjacent atoms A and D.

Most recent workers have assumed that with alkyl halides of the type  , the hydrogen halide is removed by bases from adjacent atoms[33] without rearrangement of the molecule, and although there are statements in the literature to the contrary,[34] it now appears that at least the olefins formed from simple alkyl halides may be accounted for on this basis. Olivier[10] lists a number of alkyl halides and related compounds which, when treated with bases, give unsaturated products that could be formed without rearrangement. Chablay[35] has reported that isobutyl halides with sodamide in liquid ammonia give the expected isobutylene. Recently, Whitmore and co-workers have made a careful search for all products formed from certain alkyl halides and hot alcoholic alkali. They found[36] that *n*-butyl iodide gives butene-1 and *n*-butyl ethyl ether, while isoamyl iodide gives 3-methyl-butene-1 and isoamyl ethyl ether; no other olefins were obtained. The ethers were formed presumably by substitution reactions. Since the olefins may be accounted for on the basis that the elements of hydrogen iodide were eliminated from adjacent carbon atoms, they may be regarded as "unrearranged" products; however, it should be remembered that the same olefins would have resulted if the elements of hydrogen iodide were removed from the same carbon atom, and the elimination accompanied by the shift of a hydrogen from an adjacent carbon atom.

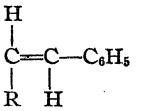
In contrast to the results discussed above, Amagat[37] has reported that certain phenylalkylethyl bromides when heated with sodamide in boiling xylene (b. p. 140°) give rearranged olefins. Under these conditions, bromides of type (I), in which R is methyl, ethyl or isopropyl



(I)



(II)



(III)

were reported to give almost exclusively olefin (III), the formation of which would obviously involve rearrangement of the molecule.

On repeating this experiment in this Laboratory[38] using potassium amide instead of sodamide, we have found that the bromide in which R is ethyl, although giving some of olefin (III), also gives approximately an equal amount of olefin (II). It has been found, furthermore, that when the reaction is carried out with potassium amide in liquid ammonia (b. p. −33°), the bro-

(30) Whether or not this is true in all cases remains of course to be determined by experiment. An apparent exception has been reported by Werner and Piguet, *Ber.*, **37**, 4295 (1904); Werner and Detscheff, *ibid.*, **38**, 69 (1905). These workers reported that β-benzoinoxime or β-benzilmonoxime when heated with benzenesulfonyl chloride and alkali give partly phenyl isocyanide, which is a rearrangement product. Evidence has been obtained in this Laboratory, however, that the rearrangement is effected merely by heat rather than by the action of the base. These results will be published shortly.

(31) Ingold and co-workers have shown that in the decomposition of quaternary ammonium compounds to form unsaturated products, the removal of HNR_3 from the same atom of the positive ion (α-hydrogen elimination) is accompanied by dimerization, and the removal of HNR_3 from a three-atom system (γ-hydrogen elimination) is accompanied by rearrangement; whereas the removal of HNR_3 from adjacent atoms (β-elimination) forms unsaturated compounds without dimerization or rearrangement. See Ingold and Rogers, *J. Chem. Soc.*, 722 (1935).

(32) It is of interest to note that the substitution of certain hydrogen atoms by deuterium might serve to give positive data concerning the course followed. This study is being carried out in this Laboratory.

(33) In this connection see Watson, *J. Chem. Soc., Ann. Repts.*, **35**, 226 (1938); also, see ref. 10.

(34) It has been stated, for example, that isobutyl halides with alcoholic alkali give both *n*-butylene and isobutylene; see Francis, "Notes on Organic Chemistry," Edward Arnold and Company, London, 1935, p. 182.

(36) Whitmore, Wittle and Flinn, reported at the Pittsburgh meeting of the American Chemical Society, September, 1936.

(37) Amagat, *Bull. soc. chim.*, **49**, 1410 (1931).

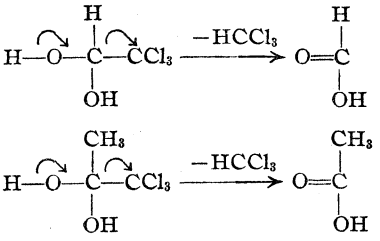
(38) These results were presented by Hauser, Bright and Renfrow before the division of organic chemistry at the Boston meeting of the American Chemical Society, September, 1939. These results will be published soon.

mide (in which R is methyl or ethyl) gives almost entirely olefin (II).[38] The formation of this olefin has been assumed to involve the elimination of hydrogen bromide from adjacent carbon atoms without rearrangement, but it is possible that hydrogen bromide was removed from the same carbon atom, accompanied by the shift of the hydrogen atom.

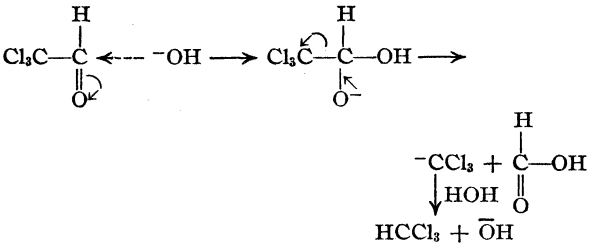
The formation of olefin (III) under the more drastic conditions (at 140°) might have involved the removal of hydrogen bromide from the same carbon atom, accompanied by the shift of the phenyl group or of R; or the reaction might have consisted of a thermal decomposition in which the base functioned merely to neutralize the hydrogen bromide eliminated.

It has been reported[39] that ethylchloroamine when warmed with alcoholic alkali and the mixture treated with excess hydrochloric acid, gives acetaldehyde, formaldehyde and methylamine. While the acetaldehyde could have been formed without rearrangement (by hydrolysis of acetaldehyde-imine which would be formed if the elements of hydrogen chloride were eliminated from adjacent atoms), the formation of formaldehyde and methylamine would necessarily involve a rearrangement of the molecule. These compounds may be accounted for on the basis that the elements of hydrogen chloride were removed from the same atom (nitrogen) and the elimination was accompanied by a shift of the methyl group to give formal-methylamine, which subsequently underwent hydrolysis; the acetaldehyde also could be accounted for on this basis, by assuming the shift of the hydrogen atom. Since the hydrogen attached to the nitrogen of the ethylchloroamine is much more active (acidic) than the hydrogen on the adjacent carbon atom, one might expect that the elements of HX would be removed from the same atom (nitrogen).

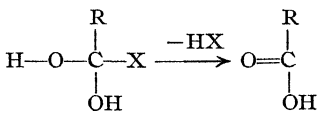
The reactions of bases with compounds containing the carbonyl (or similar) group require special consideration. Simple aldehydes and ketones are relatively stable toward alkali, but negatively substituted derivatives, for example, CCl_3CHO or CCl_3COCH_3, are readily cleaved by this reagent. Since these compounds form hydrates,[40] the reaction with aqueous alkali may be considered to involve the removal of HX, where X is CCl_3, from adjacent atoms of the hydrate; thus



The intermediate negative organic ion that would result if a proton were removed from the hydrate might also be formed by a direct attack of the hydroxyl ion on the carbonyl group of chloral; thus



Represented in this manner the haloform reaction becomes analogous to the hydrolysis of esters, amides, anhydrides, acid chlorides, etc. These compounds may be represented by the general formula $\begin{matrix} R-C=O \\ | \\ X \end{matrix}$ or $\begin{matrix} H-C=O, \\ | \\ X \end{matrix}$ where X is an electronegative atom or group, such as OC_2H_5, NH_2, OCOR, Cl, CCl_3, etc. In the presence of water these carbonyl compounds form hydrates (at least in low concentrations) which may eliminate the elements of HX from adjacent atoms



The hydrolysis of compounds of the type $\begin{matrix} R-C=O \\ | \\ X \end{matrix}$ by means of aqueous alkali apparently involves the intermediate formation of a negative organic ion,[41] which may be formed either by the removal of a proton from the hydrate or by a direct attack of the hydroxyl ion on the carbonyl group; thus

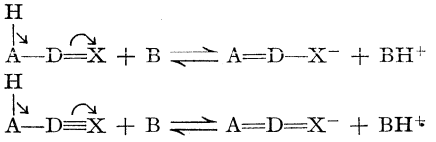
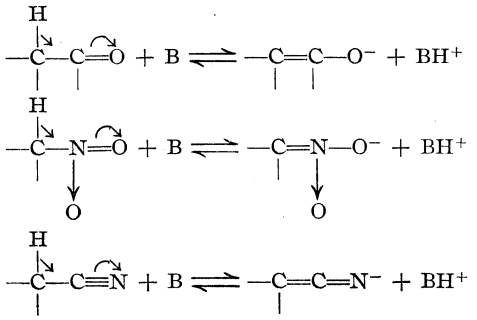
In the compounds considered thus far, X is linked by a single bond. In the elimination of the proton and of X as an anion from such compounds, the covalence of X is decreased one unit. It might be expected that certain compounds containing a relatively negative atom or group X joined by a double or triple bond, as for example, the oxygen in the carbonyl group or the nitrogen in the cyanide group, might give up a proton to a base and "partially" release X, in which the covalence of X likewise decreases one unit; the removal of the proton by a base (B) and the "partial" release of X from adjacent atoms may be illustrated as follows:

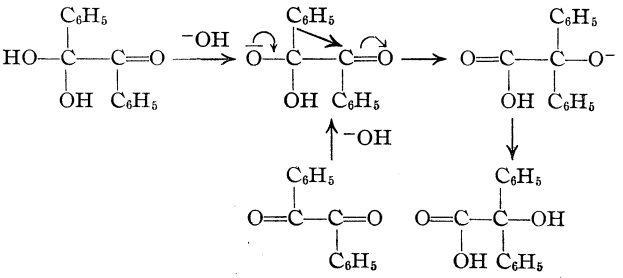


Examples:



Obviously, these are examples of enolizations of the well-known triad systems[42] in the presence of bases. It should be pointed out that the anions formed in these enolizations are resonance structures; consequently, these examples are not strictly analogous to the elimination reactions discussed in this paper.

In the enolizations in the presence of bases represented above there is a removal of the proton and "partial" removal of X from adjacent atoms; therefore, no rearrangement should be expected. Similar processes are known, however, in which there is a removal of a proton and a "partial" removal of X from a three-atom system, and in these cases rearrangement takes place. The benzil–benzilic acid rearrangement belongs to this type.[43] Westheimer[44] and Roberts and Urey[45] have presented evidence recently that this rearrangement in the presence of alkali involves the intermediate formation of a negative organic ion. This might be formed either by loss of a proton from the hydrate of benzil or by a direct attack of hydroxyl on benzil. The formation of the intermediate negative ion and its rearrangement to benzilic acid may be represented as follows



The ideas discussed in this paper are applicable to a number of other apparently diverse eliminations and rearrangements.

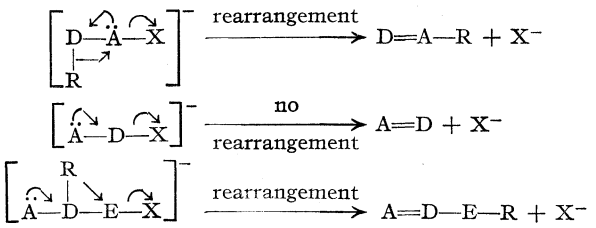
Finally, it should be pointed out that the fundamental change that takes place when the elements of HX are removed from organic compounds by means of bases to give unsaturated products may be considered to involve the decomposition of negative organic ions; the latter may exist for an appreciable time as, for example, in the reaction of a bromoamide with alkali, or may have only transient (or no "actual") existence, as in the reaction of an alkyl halide with this base. The negative organic ion is generally formed by the removal of a proton by the action of a base, but in certain cases may be formed by an attack of a basic ion (hydroxyl) on the carbonyl or similar group, as may occur, for example, in the benzil-benzilic acid rearrangement in the presence of alkali. The products formed on decomposition of the negative organic ions may be predicted readily from a consideration of the relative positions of X and the free pair of electrons carrying the negative charge, as illustrated by the following examples

(42) In this connection see, for example, Gilman, "Organic Chemistry," John Wiley and Sons, New York, N. Y., 1938, pp. 1705, 1707.

(43) For other examples, see especially ref. 1.

(44) Westheimer, THIS JOURNAL, **58**, 2209 (1936).

(45) Roberts and Urey, *ibid.*, **60**, 880 (1938).



These illustrations are of course essentially the same as those given above where it was considered that the products formed depended upon the system from which HX is removed and, as already pointed out, the molecule may be stabilized in certain cases by dimerization or cyclization instead of by rearrangement.

Conclusions and Summary

1. General theories are presented for the classification of eliminations, metatheses and rearrangements of compounds containing X, a relatively electronegative atom or group, such as halogen, hydroxyl, etc.

2. Eliminations, metatheses and intramolecular rearrangements effected by acids, acidic reagents and heavy metal salts (electron acceptors) are initiated by an attack of the reagent on X, which is removed with its bonding pair of electrons. The general courses of reaction are described by the generalizations outlined by Whitmore with the modification that the steps may occur simultaneously.

3. Eliminations effected by bases (proton acceptors) are initiated by an attack of the base on the hydrogen. Two extreme types of reactions are considered; in type I, the equilibrium of the primary acid–base reaction is far on the side of the resulting salt, while in type II, the equilibrium of the acid–base reaction is far on the side of the original acid (extremely weak). The general courses of reaction are described by the following steps: The hydrogen is removed as a proton; X is released with a complete octet of electrons; the molecule is stabilized. In reactions of type I, the second and third steps may be simultaneous processes, while in reactions of type II, all three steps may occur simultaneously. The manner in which the molecule is stabilized depends upon the system from which HX is removed. When HX is removed from the same atom or from a three-atom system, the molecule may be stabilized by rearrangement (or dimerization) giving unsaturated products, whereas when HX is removed from adjacent atoms or a four-atom system, ("double" two-atom system) the molecule may be stabilized by the formation of unsaturated products without rearrangement. When HX is removed from systems containing three or more atoms, the molecule may be stabilized by cyclization.

4. Metathetical (substitution) reactions involving basic anions, for example, the alkaline hydrolysis of alkyl halides, commonly occur side by side with eliminations. In these cases, the anion attacks the carbon at the face of the tetrahedron opposite the position of X, the addition of the anion and the release of X as an anion occurring simultaneously.

5. Certain compounds are considered in which it is possible for HX to be removed by bases in two ways; for example, alkyl halides of the type  , might eliminate the elements of HX either from the same carbon, accompanied by rearrangement or dimerization, or from the adjacent carbon atoms without rearrangement.

6. The reactions of certain carbonyl compounds and their hydrates with bases are discussed in the light of the generalizations presented above.

The Physical Chemistry of Secalin. Electrophoresis and Diffusion Constant Studies of the Prolamine of Rye[1]

BY A. C. ANDREWS[2]

Those proteins in the cereal grains which are soluble in 60–80% ethyl alcohol, classified as prolamines, have been found to possess properties that are nearly identical in many respects. The prolamine in the cereal rye (*Secale Cereale*) has been described repeatedly as being identical with the gliadin in wheat. It was this close similarity of properties of these two prolamines that prompted studies of the electrophoretic mobilities and diffusion constant of the rye prolamine, since corresponding properties of the prolamine in wheat are fairly well worked out. The literature on this rye protein is not extensive, and a separate name was not suggested for it until Gortner[3] gave it the name of "secalin." Previous to this it shared with the prolamine from wheat the name of "gliadin."

Experimental

Preparation of Secalin.—Fresh rye grain was ground by a commercial mill into a meal of moderate degree of fineness. About 2000 g. of this rye meal was then placed in a four-liter bottle and covered with enough 70% alcohol to assure an excess present after the meal became thoroughly soaked. This mixture was allowed to stand for forty-eight hours with frequent stirring, filtered by suction, and washed thoroughly with 70% alcohol. The alcohol extract, which was dark red in color, was then poured slowly with constant stirring into a large quantity of iced water containing potassium chloride. Secalin, being insoluble in aqueous solutions, was immediately precipitated and settled out on the bottom of the containing vessel. The yellowish brown, sticky mass of secalin was reprecipitated in like manner several times. About 30–70 g. of impure wet secalin was obtained from the 2000 g. of rye meal.

Purification of Secalin.—The procedure used in purifying secalin was a modification of the method used by Dill and Alsberg[4] in their purification of gliadin from wheat. The alcoholic solution of secalin was placed in a cold room for three days at a temperature of −10°. Because of the large change in solubility with temperature, much of the secalin precipitated upon standing at this temperature. The solid secalin was filtered off and the supernatant liquid was three times subjected for three hours to an acetone–dry-ice bath (about −35°), until all the secalin had been precipitated. In so doing, the coloring matter and fat accumulated in the supernatant liquid. Finally this purified secalin was dissolved in 70% alcohol and twice dialyzed against fresh solvent through cellophane membranes. All dialyses were carried out in tightly stoppered bottles in a refrigerator. The outer liquid from the first dialysis was colored a slight green, but that from the second dialysis remained colorless and was therefore used as solvent for diluting the dialyzed protein when more dilute solutions were required.

An attempt was made to purify secalin by a method similar to that sometimes used in the purification of zein from corn. This method involves the extraction of coloring matter and fatty impurities by repeated shaking out of the impure alcohol extract with an immiscible organic solvent. Great difficulties were encountered in attempting to purify secalin by this method, especially in the selection of the best organic solvent. In the preparation of zein, low boiling point petroleum ether is used; with secalin, this solvent invariably resulted in the precipitation of the dissolved protein. The extent to which this precipitation took place was variable, sometimes great quantities of the protein being precipitated merely by the addition of ether to the extract, without shaking. Other times the protein was precipitated during shaking, resulting in a semi-permanent emulsion. As the emulsion broke and the ether rose, the precipitated protein rose with it, from which it could be separated only with great difficulty. Protein so precipitated was but slowly redissolved, if at all, in 70% alcohol. It had a pure white color while still wet, but rapidly turned gray upon drying and exposure to air. In attempting to find an organic solvent for the extraction of fat and coloring matter, many were tried, and finally carbon tetrachloride was chosen because it had the least precipitating effect upon secalin in 70% alcohol. Even it would at times precipitate secalin, but upon long standing in contact with the alcohol the protein would partially redissolve. Concentrated solutions of this protein in 70% alcohol were reddish-brown in color, becoming light yellow upon addition of more alcohol.

Other organic liquids were used in attempting to find a suitable solvent for the impurities, of which acetone, tetrachloroethane, oleic acid, and dioxane were found to have a precipitating effect. Ethyl oleate, decahydronaphthalene, glycerol, and ethylene glycol showed no precipitating effect. The precipitating reaction produced by acetone was very marked.

The Diffusion Apparatus.—The apparatus used in the determination of the diffusion constant of secalin was similar to that used by Tiselius and Gross,[5] but the concentration gradients were measured by the refractometric

method developed by Lamm,[6] in which a transparent uniform scale is photographed through the diffusion cell. The refractive index gradient at the diffusion boundary produces a distorted image of the scale, in which the displacement of the scale lines is proportional to the concentration gradient, provided the refractive index is a linear function of the concentration. The arrangement of the apparatus was similar to that described by Lamm and Polson.[7] The diffusion cell was nearly identical to the one used and described in detail by them, and by Svedberg.[8] The internal diameter of the diffusing solution arm was 1 cm. The linear scale was a photographic reduction of a large scale to a length of 53 mm., consisting of 200 divisions, every tenth being numbered. The source of illumination was a sodium vapor lamp. The final line displacement caused by the blurring of the boundary was read by means of a Gaertner micro-comparator. These line displacements were then plotted against the undeviated scale, and the curve so obtained was used in calculation of the diffusion constant.

The Electrophoresis Apparatus.—The apparatus used in obtaining the electrophoretic mobility was similar to that in general use, which employs the moving boundary method and is described in detail by Tiselius.[9] It consisted of a "U" tube having an inside diameter of 1 cm., accurately ground and polished cylindrical inside each arm. The electrode vessels that made connection to the top of each arm of the "U" tube had a combined capacity of 450 cc. The protein solution made connection at the bottom of the "U" through a three-way stopcock, in which the boundary was formed and from which it was moved into position in the two arms of the "U." The apparatus was immersed in the same water-bath at 25° and the same optical system was used as in the diffusion constant determinations. The movements of the boundaries were followed by the refractometric method developed by Lamm. Silver–silver chloride electrodes were used with an electrolyte solution of magnesium chloride in 70% alcohol. Currents between 2–3 milliamperes were used and the value taken was the mean of the current strength at the beginning and end of a time interval.

The protein solutions were prepared from purified secalin in 70% alcohol in concentrations from 0.4 to 1%. The solvent used for the solutions in electrophoresis was 62.9% by weight of ethyl alcohol solution, made 0.02 molar with respect to sodium acetate. The buffers were then made by adding varying amounts of acetic acid to this sodium acetate–alcohol–water solvent, in concentrations from 0.0022 to 0.18 *M*. The resulting *p*H values of all solutions and solvents were determined by means of the glass electrode after dialysis. Dialysis was carried out similarly to that described previously, the protein solution being dialyzed against buffers of the same concentration as that used as solvent. The outer liquid from the last dialysis served as the solvent into which the protein moved during electrophoresis. All conductivity measurements on solutions and solvents were made in a conductivity cell of the type designed by Washburn, using a Leeds and Northrup Jones conductivity bridge at 25°.

Calculations.—The distance between the scale divisions of the developed photographic plates was read to a thousandth of a millimeter. The normal undeviated scale, photographed through the solvent was computed and used as a reference scale. The differences between corresponding scale divisions of the deviated and "deviated" scale, called "*Z*" values, were plotted against the deviated scale. The curve so produced should approach the normal Gaussian or probability curve for a homogeneous dispersed substance.

In the calculation of the diffusion constant the equation used was

$$Dt = \frac{A^2}{4\pi H_{max.}^2}\left(\frac{l-b}{l}\right)^2$$

Here D is the diffusion constant, t the time in seconds, A the area under the Gaussian curve, determined with a planimeter, $H_{max.}$ the maximum ordinate of the curve, l the optical distance from the scale to the objective lens, and b the optical distance from the center of the diffusion cell to the scale. Zero time was chosen as that time at which the boundary first became visible in the cylindrical portion of the tube. The diffusion constants are expressed as $D \times 10^7$ cm.^{2} per sec.

In the calculation of the electrophoretic mobility, the Gaussian curves were not nearly as symmetric as the diffusion curves, being more irregular and jagged in outline. In an electrophoresis experiment there would be one such Gaussian curve from each scale picture taken corresponding to each interval of time, the difference between the pictures being mainly that of a displacement of the maximum ordinate along the scale in a direction depending upon the direction and time of flow of the current. Accumulated percentages of the areas under each curve for each 0.5 cm. abscissa interval were then calculated and plotted against the deviated scale, giving a series of "*S*" curves, one for each picture. The differences in the "*S*" curves would be a shift along the millimeter scale abscissa by an amount corresponding to the direction of current flow, to the velocity of migration and to charge on the protein particle. The value of u(cm.^{2} sec.$^{-1}$ volt^{-1}) was then calculated by $u = qkd/it = d/Ft$, where $F = i/qk$. In this equation, q is the cross sectional area of the "U" tube, k, the conductivity of the solution, t, the time in seconds, i, the mean current during the interval between photographic exposures, and d, the magnitude of the displacement in cm. of the 50% point in the "*S*" curves.

Results

Diffusion Constant.—The general law of linear diffusion was stated first by Fick in 1855 in two mathematical laws that bear his name. Fick's second law, $\partial c/\partial t = D\partial^2 c/\partial x^2$, defining the linear diffusion constant, allows of experimental verification. This partial differential equation and the corresponding theory are completely re-

viewed in many places [Williams and Cady[10]] and has for our problem a solution

$$C = C_0/2 + \frac{C_0}{2\sqrt{\pi Dt}} \int_0^{\frac{x}{2\sqrt{Dt}}} e^{-(\alpha - x)^2/4Dt}\, d\alpha$$

Here the integral is of the form of the well-known probability integral and so can be evaluated from experimental results, provided it is assumed that the refractive index is exactly proportional to the concentration for all concentration ranges used. In Fig. 1 are shown four experimental typical curves obtained by plotting "Z" against the deviated scale. They are actually those obtained in diffusion experiment no. 4. The

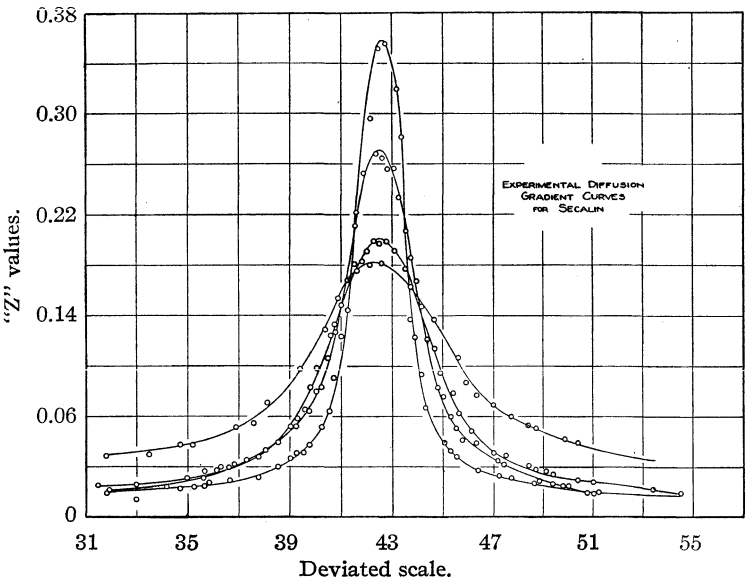

Fig. 1.—Experimental diffusion curves, showing the decrease in maximum ordinate with time as the boundary blurs.

curves are symmetrical about the maximum ordinate, and the experimental points lie nicely on the smooth curve. In Table I are given the constants obtained from all such curves. The areas under the curves of Fig. 1 show a maximum deviation from the average area of 3%. In Table I the results tabulated are those obtained for secalin from the two described methods of preparation. The first three experiments were made on a solution containing 1.035 g. of secalin per 100 cc. of solution and prepared by the use of an organic solvent; the other experiments used secalin obtained by the method of low temperatures in concentration of 0.695 g. per 100 cc. of solution. Secalin obtained by either method gave nearly identical diffusion constants.

(10) J. W. Williams and L. C. Cady, *Chem. Rev.*, **14**, 171 (1934).

The values of the diffusion constant decreased with the elapsed time of diffusion. Such a variation in diffusion constant with time seems to be inherent with the experimental method, probably explained in a large part by the mechanical inability to form a perfectly static boundary. Other investigators apparently have noticed this, because in nearly all cases the values are reported for those in which the elapsed time was sufficient for D to become fairly constant. In Table I the value of D for secalin decreases rapidly for the first 40,000 seconds and then in some cases becomes very nearly constant. Extrapolation of the diffusion constant–time curve to very large time intervals gives $D_{25} = 1.84 \times 10^{-7}$. An average of all such values for times 50,000 seconds or greater gives $D^{\text{av.}}{}_{25} = 1.91 \times 10^{-7}$. The curve obtained by the method of least squares for the combined values in experiments 1, 2, and 4 gives $D_{25} = (1.8 \pm 0.2) \times 10^{-7}$, when extrapolated to large time intervals. The value of the diffusion constant of secalin calculated to water solution at 25° by use of the equation $D^{H_2O}{}_{25} = D^{\text{alc.}}{}_{25}\, \eta^{\text{alc.}}{}_{25}/\eta^{H_2O}{}_{25}$, where $D^{H_2O}{}_{25}$ and $D^{\text{alc.}}{}_{25}$ are the diffusion constants in water and alcohol, and $\eta^{H_2O}{}_{25}$ and $\eta^{\text{alc.}}{}_{25}$ are their viscosities, gives $D^{H_2O}{}_{25} = 4.78 \times 10^{-7}$. For 20° the value is $D^{H_2O}{}_{20} = 4.3 \times 10^{-7}$.

This value of D for secalin compares favorably with the values of diffusion constants for gliadin, hordein, and zein. Williams and Watson[11] report the diffusion constants (20°) for three rather arbitrary fractions of zein as $D^{H_2O}{}_{20} = 3.0 \times 10^{-7}$, $D^{H_2O}{}_{20} = 4.0 \times 10^{-7}$, and $D^{H_2O}{}_{20} = 5.2 \times 10^{-7}$, in which the second fraction was present in the greatest amount. Lamm and Polson[7] report diffusion constants for three fractions of gliadin as $D^{H_2O}{}_{20} = 4.86 \times 10^{-7}$, $D^{H_2O}{}_{20} = 5.85 \times 10^{-7}$ and $D^{H_2O}{}_{20} = 6.72 \times 10^{-7}$. Quensel and Svedberg[12] report a diffusion constant for hordein from barley of 6.5×10^{-7}.

Sedimentation constants have been reported for zein by Williams and Watson of $s_{20} = 1.9 \times 10^{-13}$ for the predominant zein fraction, and

Krejci and Svedberg[13] give one for gliadin of 2.10×10^{-13}. Until secalin is actually centrifuged, its sedimentation constant can be assumed to lie between that of zein and gliadin, as does the diffusion constant. Then an approximate molecular weight can be calculated by the use of the formula $M = RTs/D(1 - Vd)$. Here M is the molecular weight of the sedimenting molecule, R, the gas constant, T, the absolute temperature, D, the diffusion constant, V, the partial specific volume of the protein, and d, the density of the solvent. The quantity V is taken as 0.722 (see Krejci and Svedberg[13]), and s is assumed to be 2.0×10^{-13}. Using these values for secalin gives an approximate molecular weight of 40,500. Lamm and Polson[7] calculated a value 27,500 for gliadin, while a value of 26,750 was reported by the use of the equilibrium centrifuge. Quensel and Svedberg[12] similarly calculated a molecular weight of 27,000 for hordein. Ultracentrifugal determinations with zein reported by Williams and Watson[11] give 40,000 for the molecular weight of this prolamine.

Electrophoresis.—The electrophoretic mobility of a protein particle varies with the *p*H of the solution, the ionic strength of the medium, etc. In general there is a certain *p*H for which the mobility becomes zero. This *p*H, which is called the isoelectric point, is definite for each protein as long as the ionic strength of the system is kept low and constant. The mobility of the particle increases as the *p*H is changed from the isoelectric point, but the direction of movement is opposite on the two sides of this point. Secalin shows its greatest mobility in the more acid solutions, and the mobility gradually decreases as the *p*H of the solutions increases, becoming zero at *p*H (in alcohol) of 6.67 ± 0.1. Further decrease in acidity produces a movement of protein particles again, but in a direction opposite to that of the original.

Two representative curves are plotted in Fig. 2, one for the change in mobility as current goes "up" on the right as one faces the "U" tube, and "down" as the current goes in the reverse direction. The mobilities are not exactly the same in both directions. The slope of the "up" curve is 1.30 and of the "down" curve is 1.47; thus the protein migrated about 11% faster in "up" direction than in "down." Zero mobility in the "up" direction is at a *p*H (alc.) of 6.74, and in the "down" direction of 6.60. The average of these two values gives an isoelectric point for the protein secalin at a *p*H (alc.) of 6.67. Practically all the experimental mobilities in Table II lie well within a range of ±0.1 of a *p*H unit from the curves of Fig. 2. Also practically any other straight line that reasonably could be drawn will have a zero mobility within ±0.1 *p*H unit of 6.67. The notation *p*H as used here for expressing hydrogen-ion concentration in alcohol–water solutions is defined in the same manner

as Haugaard and Johnson,[14] namely: "a water–alcohol mixture has the same hydrogen-ion activity as an aqueous solution when they both have the same potential difference against the hydrogen electrode."

In comparing this value of the isoelectric point with other investigators' results, it is necessary to convert all such data to an alcohol–water basis. Gortner[3] gives an isoelectric point for secalin at a *p*H of 5.43 (in water) obtained by methods of acid and base combining ratios. This value calculated to the alcohol basis by use of the tables of Haugaard and Johnson[14] gives an isoelectric point at a *p*H of 6.75, which is about the value obtained from these mobility experiments. Czonka, Murphy, and Jones[15] tabulated the results of isoelectric points obtained by a method similar to the critical precipitation method for a large number of proteins. The isoelectric point of secalin is given at a *p*H of 6.2, but no statement is made as to whether it was on the water or alcohol–water basis.

Gortner[3] gives isoelectric points for zein and gliadin at 6.29 and 7.11, respectively, calculated to the water–alcohol basis. Similarly, Williams and Watson give isoelectric points for their three fractions of zein, calculated to alcohol–water basis, at *p*H of 6.29, 7.16, and 6.95. Thus it would seem that the isoelectric points of the prolamines from the cereals so far studied lie within the same *p*H region.

Miscellaneous Experiments

Dielectric Constant and the Time of Relaxation.—A series of preliminary experiments was made in which the dielectric dispersion curve was determined for secalin over a frequency range of 24.2 kilocycles to 24.2 megacycles. The secalin used in these preliminary experiments was especially purified by electrodialysis at 10 milliamperes and 110 volts until the conductivity of the solution became equal to that of the solvent; the concentration of this solution was 0.204 g. of protein per 100 cc. of solution. The ratios of the dielectric constant change in the solution to that of solvent were plotted against the logarithms of their frequencies. The midpoints of the curves showing anomalous dispersion give as provisional values times of relaxation of $\tau_1 = 7.4 \times 10^{-7}$ sec., and $\tau_2 = 7.0 \times 10^{-8}$ sec., for the rotations about short and long axes. These figures, corrected to a process taking place in pure water at 25°, are 29×10^{-8} sec. and 2.7×10^{-8} sec., respectively. The ratio of major to minor axis from these times of relaxation is about ten to one for the secalin molecule. Details of similar experimental work and calculations for the protein zein are given in a recent article.[16]

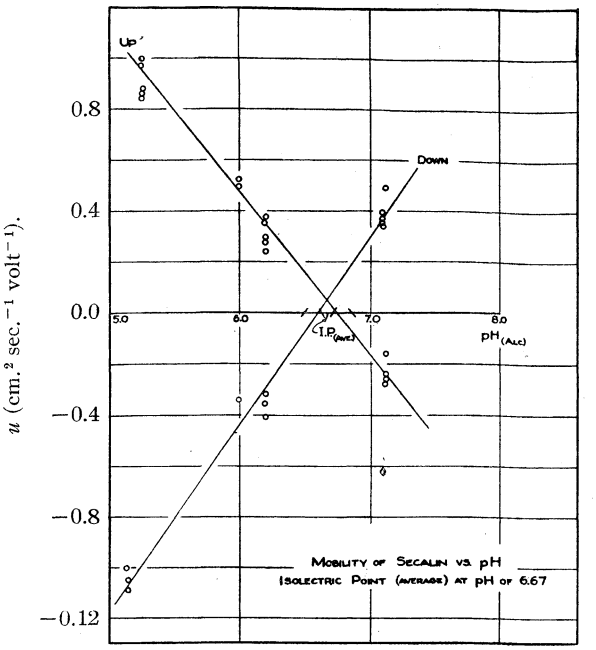

Fig. 2.—The effect of acidity upon the mobility of secalin in alcohol solution. The mobility becomes zero at *p*H of 6.67.

Optical Rotation and Refractive Index Increment.—The optical rotation for solutions containing 0.6950 and 0.5260 g. of secalin per 100 cc. of solution, respectively, gave specific rotations of −66.2 and −69.3° for an average of −67.7° at 25°. The refractive index increment ($\Delta\eta$ /g./100 cc.) was determined by the use of an immersion refractometer, giving an average refractive index increment of 1.51×10^{-3}.

The author wishes to express his thanks for the helpful advice of J. W. Williams throughout the course of this work. Grateful acknowledgment is also made to the Wisconsin Alumni Research Foundation for a scholarship which helped to make it possible to perform the work herein described.

Summary

The prolamine of rye grain was prepared and

purified by two different methods and certain of its physical constants were determined.

The diffusion constant calculated to the water basis at 25° was found to be 4.78×10^{-7} cm.^{2} per sec. (At 20°, $D = 4.3 \times 10^{-7}$ cm.^{2}/sec.)

A calculation by means of sedimentation methods, using this value of "D" and an estimated value of the sedimentation constant, gave a molecular weight for secalin of approximately 40,000. Thus the predominant constituent of secalin seems to belong in the egg albumin molecular weight class of molecules.

The ordinary isoelectric point for secalin as determined by electrophoretic mobilities was found to be at pH 6.67.

Fluorochloroethanes as Solvents for the Cryoscopic Determination of Molecular Weights

BY JACK BERNSTEIN AND WILLIAM T. MILLER

The purpose of this paper is to call attention to the suitability of fluoropentachloroethane, *sym*-difluorotetrachloroethane and *unsym*-difluorotetrachloroethane for use as solvents for the determination of molecular weights. These substances have large molecular freezing point depressions, are chemically inert and melt within convenient working ranges. Their solvent action is in general very good for non-associated substances. A representative list of qualitative solubilities of organic compounds in *sym*-difluorotetrachloroethane has been reported by Booth.[1]

Fluoropentachloroethane.—Fluoropentachloroethane was found to work particularly well as a molecular weight solvent using a semimicro procedure modeled after the Rast procedure as modified by Munster.[2] A sealed tube is necessary for the melting point determinations because of the high vapor pressure of this substance near its melting point. Small thin-walled "micro boiling point tubes" were used (4.5 × 60 mm.), and the fluoropentachloroethane was added by rolling it into small pellets which were dropped into the tube. In each case the ratio of the weight of the solute to the weight of the solvent was such as to give a depression of the freezing point between 9 and 15°.

From the observed values of the depression of the freezing point values of the freezing point constant k as calculated by the usual formula $k = \Delta TSM/s1000$ were obtained. The concentrations varied from 3–10%, and the values listed are the mean values of at least two determinations with an average deviation from the mean of about 0.1, except where otherwise indicated: benzyl bromide, 41.5; benzyl ether, 42.1; decachlorobutane, 42.6; *p*-dichlorobenzene, 42.1; 4,4′-difluorodiphenyl, 42.8; isoamyl acetate, 41.3; methyl benzoate, 41.1; naphthalene, 42.1; acetone, s/S = 0.0201, 0.0221, k = 31.5, 32.3; benzoic acid, s/S = 0.0230, 0.0483, 0.0682, k = 24.5, 22.0, 21.3; benzyl alcohol, s/S = 0.0485, 0.0691, k = 26.7, 23.6; *n*-butyl alcohol, s/S = 0.0304, 0.0512, k = 28.7, 23.5; butyraldehyde, s/S = 0.0149, 0.0220, 0.0226, 0.0379, k = 31.3, 33.5, 33.2, 27.7; α-naphthol, s/S = 0.0241, 0.0482, k = 38.3, 32.9; nitrobenzene, s/S = 0.0392, 0.0429, k = 35.8, 36.7, respectively.

Acetanilide, aniline and dimethylaniline were sparingly soluble in fluoropentachloroethane and hexachloroethane formed a crystalline solid phase of higher melting point. For the measurements in which there was complete solubility and no apparent association or compound formation, the average value of k was 42.0.

The fluoropentachloroethane used in this work was prepared by fluorinating pentachloroethane[3] and melted at 99.9° after purification by distillation. This substance also may be prepared readily from hexachloroethane and antimony trifluoride.[1,4]

***sym*- and *unsym*-Difluorotetrachloroethane.**—These compounds do not work well with the semimicro procedure because of the difficulty of observing crystallization in the small tubes. However, their large freezing point depressions and convenient melting temperatures may be utilized in the usual macro procedure,[5] and their use for precise cryoscopic measurements is indicated. The constant k for *sym*-difluorotetrachloroethane was determined as 37.7 and for *unsym*-difluorotetrachloroethane as 38.6, using naphthalene and *p*-dichlorobenzene.

Naphthalene, s/S = 0.00140, 0.00140, 0.00127, k = 37.1, 36.7, 37.4; *p*-dichlorobenzene, s/S = 0.00129, 0.00121, 0.00134, k = 38.1, 38.0, 38.8; naphthalene, s/S = 0.000660, 0.00113, k = 38.2, 37.9; *p*-dichlorobenzene, s/S = 0.000794, 0.000863, 0.000919, k = 38.2, 39.4, 39.3, respectively.

The *sym*-difluorotetrachloroethane was prepared by adding fluorine to tetrachloroethylene[3] and melted at 24.7°. It also may be prepared from hexachloroethane and antimony trifluoride.[1,4] No direct methods for the preparation of *unsym*-difluorotetrachloroethane have appeared in the literature although it has been character-

ized.[4] However, it was found possible to obtain this material directly from trifluorotrichloroethane ($CF_2ClCFCl_2$)[6] and aluminum chloride.[7]

Summary

Fluoropentachloroethane, *sym*-difluorotetrachloroethane and *unsym*-difluorotetrachloroethane were shown to be good cryoscopic solvents for non-associated substances. Their large molecular freezing point depressions, chemical inertness and convenient melting temperatures recommend their use.

Solubility and Molecular Rotation of Certain Tetra-, Penta- and Hexa-Substituted Benzenes

BY CHARLES P. SMYTH AND GEORGE L. LEWIS

In a discussion by Baker and Smyth[1] of the process of fusion, it has been pointed out that the gain of entropy by a solid through the setting in of molecular rotation in the crystal tends to raise the melting of the solid to a temperature much higher than that at which it presumably would have melted in the absence of such rotation. In view of the close relation between the processes of solution and fusion, it has seemed desirable to investigate the influence of molecular rotation in a solid upon its solubility. Recent dielectric constant measurements by White, Biggs and Morgan[2] have shown that the molecules of many penta- and hexa-substituted benzenes have rotational freedom in the plane of the benzene ring. Dr. Morgan has very kindly made a number of pure samples of these substances available to us for solubility and dipole moment measurements, the latter of which are discussed elsewhere.[3] In addition, the solubilities of hexamethylbenzene and hexachlorobenzene obtained from the Eastman Kodak Company have been measured. Benzene was used as a solvent which would dissolve adequate quantities of the least soluble of the substances investigated. It was purified in the usual manner.[4]

Experimental Method

The solubility measurements were carried out at four different temperatures in a thermostat. An excess of the substance, the solubility of which was to be measured, was added to the benzene in a test-tube mounted on a mechanical shaker in a water-bath and shaken at a temperature of about 48° until the solution was thought to be saturated, some of the solid still remaining undissolved. The temperature of the bath was then lowered to 41.88° where it was held fixed for at least forty-five minutes. The formation of new crystals was used as the criterion of saturation. Part of the saturated solution was withdrawn by means of a completely water-jacketed pipet, in which the temperature of the water was higher than that of the solution, and run into a weighing bottle. After this sample of solution had been weighed, the solvent was evaporated at about 40° in a current of warm, dry air, and the solute remaining as a residue in the bottle was weighed. The concentrations of the saturated solutions at three lower temperatures were successively determined in the same way, an ordinary pipet being used for temperatures below that of the room. The probable error in the solubilities thus determined was 2%.

Experimental Results

The solubilities expressed as the mole fraction N of solute in the saturated solution are listed in Table I for the four different temperatures at which they were determined. The substances are designated by letters in the first column, which are used in place of the long names of the substances in Table II and in Fig. 1. The solubilities may be examined with the aid of a slightly modified equation given by Hildebrand[5] $\log N = -\Delta E_f (T_m - T)/4.575\, T_m T$, in which ΔE_f is the latent heat of fusion of the solute and T_m its melting point on the absolute scale. According to this equation which represents the ideal solubility, the plotting of $\log N$ against $1/T$ should give a nearly straight line with slope $-\Delta E_f/4.575$ and upper limit with $N = 1$ at the melting point of the solute. As the latent heats of fusion of the substances under consideration here have not been determined, the ideal solubility curves cannot be drawn, but, in Fig. 1, the values of $\log N$ plotted against $1/T$ for each substance are

found to lie very close to a straight line drawn through the melting point at log $N = 0$. Several substances are omitted from Fig. 1 because their curves are very close to those shown and the curve for 3,4,5-trichloro-*o*-xylene is omitted because of the somewhat unsatisfactory character of the three values which were determined at different temperatures from the others. The slopes of similar curves plotted on a larger scale without reference to the melting points are used to calculate approximate values of the heats of fusion ΔE_f given in Table II, which, in turn, are used to calculate the entropies of fusion, $\Delta S_f = \Delta E_f/T_m$, given in Table II. The probable errors in these two quantities calculated from the slopes of the curves would appear to be about 5% but may more safely be set at 10%. Table II also lists the melting points t_m in °C. and the temperatures t_r determined by White, Biggs and Morgan below which rotation ceases or, more correctly speaking, at which rotation is so hampered that the imaginary part ϵ'' of the dielectric constant reaches a maximum for a frequency of 100 kc. A dash in this column indicates the absence of rotation in the solid. The dielectric constant of the solid would fail to give information as to the rotation of the symmetrical molecules of the first three substances listed and is not conclusive as to pentachlorobenzene. The last column gives the dipole moments found for the substances.[3]

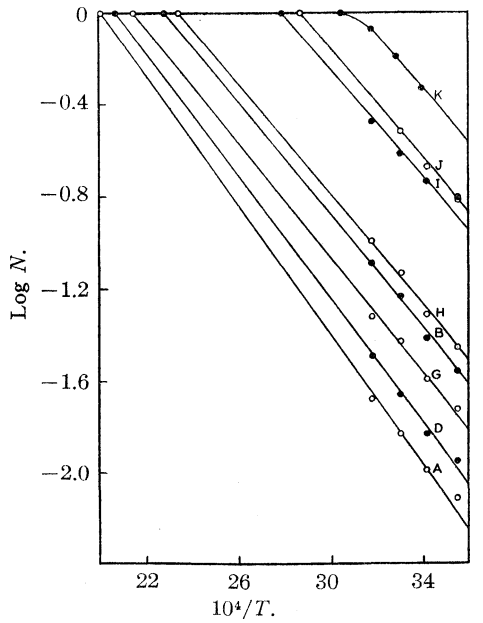

Fig. 1.—Solubilities of substituted benzenes in benzene.

Discussion of Results

Certain simple and expected relations are apparent in the data of Tables I and II and certain seeming anomalies occur. The hexamethylbenzene molecule with its hydrocarbon surface[6] is about four times as soluble in benzene as the hexachlorobenzene molecule with its less similar chlorine surface, and the melting point of the substance is correspondingly lower. Trichloromesitylene, sub-

(6) See Langmuir, "Third Colloid Symposium Monograph," The Chemical Catalog Company, Inc., New York, N. Y., 1925, p. 3.

stance C, is not half-way between hexachlorobenzene and hexamethylbenzene in solubility but is much closer to the former in solubility and melting point. The interchange of position of a chlorine and a methyl group to give the unsymmetrical 1,2,5-trimethyl-3,4,6-trichlorobenzene molecule with a considerable dipole moment has only a very small effect upon the solubility and melting point. Increase of the number of chlorines in the hexasubstituted molecule to four and five reduces the solubilities and raises the melting points a little so that they are hardly distinguishable from those of hexachlorobenzene, although tetrachloro-*o*-xylene possesses a particularly large dipole moment. The solubility curves for this substance and pentachlorotoluene are omitted from Fig. 1 because of their practical coincidence with that for hexachlorobenzene, A. Increase in the number of methyl groups in the hexa-substituted molecule increases the solubility until pentamethylchlorobenzene has a solubility about 25% greater than that of hexamethylbenzene together with a slightly lower melting point. These eight hexa-substituted benzenes may be grouped roughly as having relatively low solubilities and high melting points. Their dipole moments vary from 0 to 2.93 without having any apparent effect upon the solubility. The last five of them, D-H, have been found[2] to possess freedom of molecular rotation in the crystal and thus possess additional entropy in the solid, which raises their melting points according to the relation observed by Baker and Smyth[1] and lowers their solubilities. The first three substances, A–C, fit so well into this group that one would certainly expect their molecules also to possess freedom of rotation in the crystal. Also, it is difficult to see how the five somewhat less symmetrical hexa-substituted benzenes can rotate if these do not. However, Lonsdale[7] has interpreted careful X-ray analyses of hexamethyl- and hexachlorobenzene at room temperature on the basis of non-rotation of the molecules and Brockway and Robertson[8] have done the same with hexamethylbenzene. The results of White, Biggs and Morgan[2] indicate that molecular rotation should occur in hexachlorobenzene, but possibly only above the temperature employed in the X-ray investigation. The rotation of hexamethylbenzene might be expected to begin at a lower temperature and it seems possible that its transition at $-165°$, which produces a change in the slope of the specific heat–temperature curve and involves an entropy of transition of 2.28 e. u. per mole,[9] may mark the acquisition of rotational freedom in the plane of the ring. At any instant of time, most of the molecules would be executing rotational oscillation about potential energy minima which would occur at angular intervals of 60°. As location of the molecule in any one of these six minima would be indistinguishable from that in any other, it appears possible that the results of the X-ray analysis may correspond to that given by nearly stationary molecules in spite of the existence of rotational freedom. It appears possible, therefore, tentatively to regard the eight substances, which have been grouped because of low solubilities and high melting points, as possessing freedom of molecular rotation in the plane of the ring.

The dielectric constant results for pentachlorobenzene communicated to the authors by Dr. Morgan suggest a restricted rotation of the molecule somewhat like that in isopropyl bromide,[1] which apparently raises the melting point of the latter some 20 or 30°. The solubility and melting point of pentachlorobenzene are nearer to those of the non-rotating substances, although the melting point is somewhat raised as in the case of isopropyl bromide.

4,5-Dichloro-*o*-xylene and ethylpentachlorobenzene, which are definitely shown by their low dielectric constants[2] to possess practically no rotational freedom, have low melting points and high solubilities. The solubilities of pentachlorobenzene and 4,5-dichloro-*o*-xylene differ but slightly from each other, while the dipole moments are very different. Ethylpentachlorobenzene has a solubility more than twice as large as those of the other two and a dipole moment intermediate between theirs. 3,4,5-Trichloro-*o*-xylene has a solubility close to that of ethylpentachlorobenzene and a higher moment, 2.46. Its high solubility and fairly low melting point would lead one to expect non-rotation in the solid, but the dielectric constant determinations[2] show a rotational transition at 15–20°. This constitutes the only definitely established exception among these substances to the rule that molecular rotation in a solid tends to give the solid lower solubility than it would have in the absence of rotation, but the answer to the question of molecu-

(7) Lonsdale, *Proc. Roy. Soc.* (London), **A123**, 494 (1929); **A133**, 536 (1931).

(8) Brockway and Robertson, *J. Chem. Soc.*, 1324 (1939).

(9) Huffman, Parks and Daniels, THIS JOURNAL, **52**, 1547 (1930).

lar rotation is only tentatively indicated and not positively settled in the cases of three of the twelve substances.

It must be remembered that, at the temperature of a rotational transition, the solubility of the low-temperature form of a solid in equilibrium with the high-temperature form must be the same as that of the latter. The difference in slope of the solubility curves above and below the transition depends primarily upon the heat of transition. Although the substances under consideration here do not show sharp, reversible transitions, it is not unreasonable to suppose that solubilities measured not far from the temperatures at which molecular rotation ceases may well be either high or low as determined by factors other than molecular rotation, but, in a great majority of the cases here investigated, molecular rotation reduces the solubility.

The curves in Fig. 1 and those omitted from it show that the solubilities of these highly-substituted benzenes in benzene are close to the ideal. The curve for ethylpentachlorobenzene is the only one which does not pass through the melting point, partly, at least, because its points are so near the melting point that a slight adjustment in its slope cannot make it reach the melting point. A melting point only 10° lower, but still 10° higher than the apparently incorrect[2] value given in Beilstein, would fall on the line.

The entropies of fusion of all but the last two substances, J and K, in Table II lie between 10.8 and 12.9 units, differing from a mean value by no more than their possible errors. The last two substances, 4,5-dichloro-*o*-xylene and ethylpentachlorobenzene, which are the only two definitely proved to have no molecular rotation in the solid, have entropies of fusion four or five units higher, as they acquire degrees of rotational freedom on melting which most, at least, of the other substances have already acquired in the solid. The entropies of fusion of the rotating substances are higher than those found previously for substances with smaller molecules rotating in the solid, but are much lower than the value 22.1 found for the long molecule of cetyl alcohol,[10] which, because of molecular rotation around the long axis, is little more than half of that found for non-rotating hydrocarbons of about the same length. The values for the hexa-substituted benzenes with rotating molecules are close to those for the lighter molecules of the xylenes and dichlorobenzenes, which do not have freedom of molecular rotation in the solid. The value for hexamethylbenzene is lower than that calculated empirically by Huffman, Parks and Daniels[9] without allowance for rotation by about the amount which rotation might cause. In other words, the two substances, which have been definitely shown not to rotate, have reasonable values for their entropies of fusion, and the other substances in Table II have values lower by an amount which can arise from their possession of rotational freedom in the solid.

In conclusion, it may be said that, in the case of these similarly shaped molecules, the dipole moment of the molecule as a whole has no detectable effect upon the solubility of the substance in the non-polar solvent, benzene. The solubilities of these substituted benzenes are almost ideal and tend to be lower when the molecules possess freedom of rotation in the solid, although other factors occasionally predominate over this tendency. In view of the relations between molecular rotation and melting point and between melting point and solubility, an at least approximate relation between molecular rotation and solubility follows almost inevitably and from the same fundamental cause.

The writers wish to express their gratitude to Dr. S. O. Morgan of the Bell Telephone Laboratories for the loan of the substances upon which these measurements have been made as well as for information concerning them.

Summary

The solubilities in benzene of twelve tetra-, penta-, and hexa-chlorine and methyl substituted benzenes have been measured at four temperatures. The solubilities are approximately ideal and are independent of the dipole moments of the molecules. The heats and entropies of fusion have been calculated from the slopes of the solubility curves. In accordance with the relation previously observed between molecular rotation in the solid and melting point, the solubilities and entropies of fusion tend to be low and the melting points high when the molecules possess freedom of rotation in the solid.

The Reactivity of Atoms and Groups in Organic Compounds. XX. The Effect of Substituents on the Relative Reactivities of the Hydroxyl Group in Derivatives of Benzoic Acid

BY JAMES F. NORRIS AND ARTHUR E. BEARSE[1]

Some time ago a report was given of the study of the influence of substituents on the relative reactivities of the hydrogen atom of the carboxyl group in a number of derivatives of benzoic acid.[2] It appeared of interest to determine the relative reactivities of the hydroxyl group in the acids previously studied to discover the influence of the substituents on the carbon–oxygen bond. Comparisons between the effects on the two bonds linked to oxygen gave information in regard to the influence of substituents on reactivity through a chain of atoms; it also furnished evidence in regard to the theory of alternating strong and weak bonds put forward by Flürscheim.[3]

Among the acids studied were several which contained one or two substituents in the *ortho* position. These were studied with the expectation that the results would be helpful in a fuller understanding of the so-called "diortho effect."

The velocity constants of the reactions between the acids and thionyl chloride were determined: $RCOOH + SOCl_2 = RCOCl + HCl + SO_2$. The course of the reaction was followed by determining, from time to time, the pressure produced by the two gases as they were formed in a closed system of constant volume. Since thionyl chloride and the gases formed are corrosive, a new type of all-glass apparatus was designed; it is described in the experimental part of this paper. A large excess of thionyl chloride served as the solvent.

The results of the experiments are given in Table I.

TABLE I

Column I, substituents present in benzoic acid; Column II, average first order velocity constants at 25° of the reaction $RCOOH + SOCl_2 = RCOCl + HCl + SO_2$, time in minutes; Column III, relative values of the constants compared with benzoic acid taken as 1; Column IV, relative reactivities of the acidic hydrogen atoms, when known, benzoic acid taken as 1.

[a] Norris and Strain, ref. 2.

A comparison of the figures in Column III shows that the relative reactivities of the hydroxyl group in all the acids which contain CH_3, C_2H_5 or CH_3O groups are greater than the reactivity of the hydroxyl group in benzoic acid. The presence of two of these groups in the ortho positions greatly increases reactivity. It has been shown[4] that the acyl chlorides prepared from these diortho substituted acids react so rapidly with ethyl alcohol at 0° that the rates of the reaction could not be measured. The hydroxyl groups in the acids which contained Cl and NO_2 were less reactive than the hydroxyl group in benzoic acid. The presence of two of these substituents in the ortho positions greatly reduced reactivity. The acyl chlorides of these acids reacted so slowly at 0° with ethyl alcohol that the rates of the reactions could not be measured. These facts will be helpful in arriving at a satisfactory interpretation of steric hindrance. The effect on the reduction of reactivity of the hydroxyl group by Cl and NO_2 was greater in the meta than in the ortho position; the same conclusion was drawn from the relative reactivities of the acyl chloride with alcohol.

In the preparation of acyl chlorides from acids and thionyl chloride, a molecular quantity of pyridine has been used to assist the reaction.[5] L. F. Fieser and M. Fieser[6] prepared the acyl

chloride of a derivative of butyric acid by treating the latter, dissolved in ether, with thionyl chloride and a trace of pyridine. The effect of pyridine and its concentration on the rates at which certain of the acyl chlorides were formed was investigated to discover to what extent the substituent in the acid affected the rates. The effect of concentration of the catalyst was studied in the case of benzoic acid. When equal molecular quantities of the acid and of pyridine were used the rate of the reaction at 25° was 97 times that of the uncatalyzed reaction; with 12.5 moles of acid to 1 of pyridine the rate was 82 times; with 25 moles 64, and with 50 moles 36 times. It was evident that pyridine acted as a catalyst and not as a reagent to remove hydrogen chloride. This conclusion was strengthened by the fact that when 12.5 moles of benzoic acid was treated with a large excess of thionyl chloride and 1 mole of N,N-dimethylcyclohexylamine, the rate was increased 91 times and when an equivalent quantity of the hydrochloride of the amine was used the rate increased 67 times. Dimethylaniline in the same concentration increased the rate with benzoic acid only 14 times.

The reactions were carried out in the way used in the case of the uncatalyzed reactions. The results are given in Table II.

TABLE II

Column I, substituent in benzoic acid; Column II, first order velocity constant of catalyzed reaction at 25°; mole conc. of acid to pyridine 12.5 to 1, time in min.; Column III, ratio of constant of catalyzed reaction to constant of uncatalyzed reaction; Column IV, relative rates of catalyzed reactions with benzoic acid = 1; Column V, relative rates of uncatalyzed reactions, benzoic acid = 1.

I	II	III	IV	V
2-Nitro	0.35–0.30	1520	0.6	0.03
2-Chloro	.63	600	1.1	.16
2-Methyl	.66	89	1.2	1.1
Benzoic acid	.54– .55	82	1	1
3-Chloro	.048	77	0.09	0.09
2,6-Dichloro	.042	75	.08	.08
3-Methyl	.67	60	1.2	1.7
4-Methyl	.67	26	1.2	3.8
3-Nitro	.0011	..	0.002	..

The figures in Column III show the great effect of the catalyst in increasing the rate of the reaction between the acids and thionyl chloride. The effect was greatest in the case of the acids containing a substituent in the *ortho* position. From Column V it is seen that the two acids most affected were those that had low reactivity when measured by the uncatalyzed reaction. Columns IV and V show that the relative reactivities measured by the catalyzed and by the uncatalyzed reactions are not the same. The three methyl derivatives are more reactive than benzoic acid when measured in either way and the halogen and nitro derivatives, with the exception of the 2-chloro compound, are less reactive than benzoic acids.

The practical application of these results is evident, namely, the use of pyridine or dimethylcyclohexylamine as a catalyst in preparing acyl chlorides by means of thionyl chloride. Hans Meyer[7] who applied the reaction to a large number of acids, without a catalyst, reported that certain acids required heating the mixture for several hours. The acid chloride was obtained by removing the excess of thionyl chloride by distillation. In our experiment the catalyzed reaction was complete at 25° in the case of benzoic acid in about ten minutes; the 3-chloro acid required about one hour for complete reaction.

Details of Experiments

The Apparatus Used.—This is sketched in Fig. 1. The vessel in which the reaction took place (A, side view at left) had two arms, 8 cm. long and 3 cm. in diameter and a no. 20 ground glass joint. It was connected through the joint to a tube, attached to a shaking device, and flexible glass bends to the stopcock B. The apparatus up to the cock was placed in a thermostat at 25 ± 0.02°. A tube from B led to cock C and a closed spiral tube (18 turns 2.5 cm. in diameter) to which was sealed a small mirror. The tube and mirror were enclosed in a jacket which was connected with cocks as indicated and a manometer, having two arms, in which the pressure could be adjusted. When the pressure in the reaction vessel increased the spiral would cause the mirror to change its position. The position of the mirror was indicated by a beam of light reflected from it onto a screen. In order to determine the increased pressure in the partially evacuated apparatus, the pressure outside of the spiral was adjusted roughly by letting air in through the cocks, and a final adjustment was made by raising the vessel containing mercury attached to the manometer until the spot of light from the mirror returned to the original zero position. The pressure added to balance the inside pressure was measured on the manometer. This method of measuring the pressure of a corrosive gas was used successfully by Johnson[8] in measuring the vapor pressure of ammonium chloride at high temperatures and by workers in the Research Laboratory of Inorganic Chemistry of this Institute.

In using the apparatus the desired weight of the solid acid was introduced into the weighed reaction vessel A held so that one tube was vertical and the other horizontal. Through a short piece of glass tubing placed in the opening

(7) Hans Meyer, *Monatsh.*, **22**, 415, 477 (1901). See also McMaster and Ahmann, THIS JOURNAL, **50**, 145 (1928), and Clark and Ball, *Trans. Roy. Soc. Can.*, III, **27**, 97 (1933).

(8) Johnson, *Z. physik. Chem.*, **61**, 457 (1907).

was introduced a smaller tube carrying the acid. By tapping the tube the required amount of acid could be dropped into the vertical tube. The reaction vessel A was again weighed. The weight of acid introduced could be determined to 1 mg. The reaction vessel was connected with the rest of the apparatus by means of the ground glass joint which had been treated with "lubriseal," and water was added to the thermostat which was brought to approximately 25°. Enough of the water was then drawn off to permit the removal of the reaction vessel after it had been wiped dry. By means of a calibrated pipet exactly 10 cc. of thionyl chloride was added to the leg of the reaction vessel which did not contain the acid. The reaction vessel was again connected with the apparatus, care being taken to prevent the thionyl chloride from coming in contact with the acid. The water was returned to the thermostat and the shaker and water pumps connected at C and F were started. The system was evacuated until the pressure on the two sides of the spiral manometer was about 140 mm. This required about one and one-half minutes. The cocks C and E were then closed. Shaking was continued for ten minutes to allow the system to come to equilibrium; during this time the temperature of the thermostat was brought to 25 ± 0.02°. The shaker was stopped, the cock B was closed and the reactants were mixed by rotating the reaction vessel through 90 degrees. The time was recorded as zero time. The pressure was measured by adjusting the pressure in the outside of the spiral manometer so that the spot of light reflected from the mirror returned to the zero position. The cock B was opened and the shaker started.

Readings of pressure were made at intervals of time that depended on the rate at which the reactions were taking place. When a reading was made the cock B was closed and the shaker stopped. In order to avoid a possible leak in the apparatus, the two sides of the glass joint that connected the reaction vessel with the rest of the apparatus were held in position during the shaking by a wire around projections sealed to the two parts of the joint. Shaking was continuous during the first hour except when pressure readings were made; thereafter the shaker was run only for ten minutes preceding a reading. The adjustments in the outside pressure were made through the three-way cock F; air was either withdrawn by the pump or admitted through the cock.

Calculation of the Velocity Constants.—The constants were calculated from the formula

$$K = \frac{2.303}{t} \log \frac{P}{P - p}$$

in which P is the final pressure and p is the pressure at time t. By plotting the log terms against t a straight line was obtained up to a high percentage conversion in the case of most of the acids. The slope of the line is a measure of the constant. In certain cases the line did not cut the axis of time at zero and the time correction, determined in the usual way, was used in calculating the constant.

The method of calculation required the determination of the pressure when the reaction was complete (P). This value was determined in the case of benzoic acid and the acids more reactive than benzoic. It was found to be nearly constant since equivalent weights of the acids were used. In the case of the less reactive acids the experimental values found with benzoic acid were used for P.

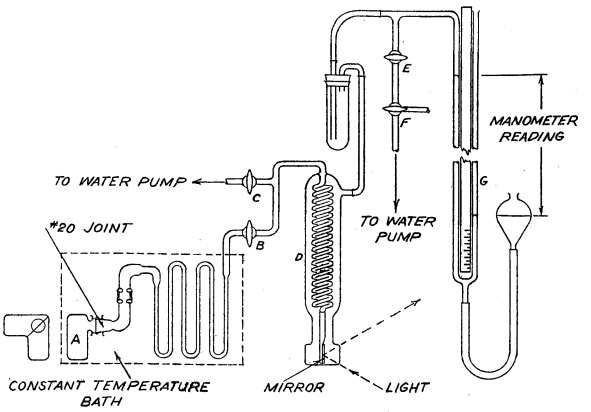

Fig. 1.—Apparatus for measuring pressure increase.

In the case of certain of the inactive acids the following formula was used as a check

$$K = \frac{2.303}{t_2 - t_1} \left(\log \frac{P}{P - P_2} - \log \frac{P}{P - P_1} \right)$$

Control experiments in which thionyl chloride without an acid was used showed that a pressure was developed slowly. This probably was due to the slow diffusion of the chloride into the parts of the apparatus outside the thermostat. In order to correct for this added pressure four runs were made; they agreed well and furnished average values to be used in calculating the real increase in pressure due to the reaction. The correction increased from 1 mm. to 10 mm. at the end of three hundred minutes. In the case of benzoic acid and the acids that were more reactive, the correction was a small percentage of the observed pressure; the constants were calculated from times less than one hundred and forty minutes. In the case of the very inactive acids the correction amounted to from 10 to 30 % of the observed reading.

The Reagents Used.—The acids were purified by crystallization until the melting points were constant and checked closely the best values in the literature. They were dried in an oven and finally in a vacuum desiccator over activated aluminum for at least twelve hours before use.

The 2,6-dichlorobenzoic acid was prepared from 2,6-dichlorotoluene by a convenient method which has not

been described. The method is given in detail because we were unsuccessful in preparing the acid by the direct oxidation of the toluene derivative with potassium permanganate.[9] Attempts to prepare the acid by oxidation of the toluene derivative with alkaline or acid permanganate, chromic acid and sulfuric acid in acetic acid, and potassium dichromate and sulfuric acid did not give satisfactory results.

Twenty grams of 2,6-dichlorotoluene was placed in a 300-cc. flask having two necks to which were attached a reflux condenser and a separatory funnel the end of which was just above the liquid. The flask was heated in an oil-bath at 170° and 19.8 g. of bromine was added slowly through the funnel at such a rate that no bromine escaped. When the reaction was complete and the flask was cold, the contents were transferred to a 1-liter flask fitted with a mercury seal stirrer, and a reflux condenser. A solution of 6 g. of sodium hydroxide in 500 cc. of water was added and the mixture heated to boiling with the stirrer running. Powdered potassium permanganate was added in small portions through the condenser and washed down with a little water. When the color disappeared more permanganate and small amounts of a solution of sodium hydroxide to keep the mixture alkaline were added. After 24.8 g. of the permanganate had been used during about two hours the color persisted. This was removed by alcohol and the mixture was distilled with steam; about 0.7 cc. of the chlorotoluene was recovered. The material in the flask was filtered and the solid washed with water. The filtrate was concentrated to about 150 cc. and enough hydrochloric acid added to precipitate the 2,6-dichlorobenzoic acid. The acid was digested with water, dried and crystallized from a mixture of equal volumes of benzene and ligroin. The yield of pure acid which melted at 143–144° was 57% of the theoretical amount calculated from the 2,6-dichlorotoluene used. A similar method could be applied probably to other hydrocarbon derivatives which resist ordinary oxidizing agents.

The method was based on information from the du Pont Company, that 2-chloro-6-nitrotoluene could be brominated readily in the side chain at 170°, whereas a higher temperature is required for chlorination and the resulting yield is very small.

In an attempt to prepare 2-chloro-6-nitrobenzoic acid from the corresponding aldehyde by means of the Cannizzaro reaction, it was found that the aldehyde group was removed and nearly the theoretical yield of *m*-chloronitrobenzene was obtained.

Purification of Thionyl Chloride.—The material used (Eastman Kodak Company, No. 246, b. p. 75–76°) was fractionally distilled in an all glass apparatus with a Davis column. The several fractions were used in test experiments with benzoic acid. The value of the velocity constant for the reaction varied from 0.0103 to 0.0131. It was evident that a small amount of impurity was present which increased the rate and could not be removed by fractionation. A portion of the original sample (50 cc.) was treated with 1 g. of benzoic acid and allowed to stand twelve hours. The excess of thionyl chloride was then distilled off, fractionated, and tested by determining the velocity constant of the reaction with benzoic acid. This was found to be less than before treatment. Four such treatments, followed by fractionation, caused a marked decrease in the constant. Four additional treatments caused only a slight decrease. Four more treatments changed the constant only within the experimental error of the process. All determinations were made with thionyl chloride that had been subjected to twelve treatments with benzoic acid and subsequent fractionation in which the first part of the distillate was rejected. Two separate preparations gave products which yielded constants that checked within less than 3%. The purification did not appreciably affect the boiling point of the thionyl chloride. The samples used boiled at 74.8–75.6° (751 mm.). The recorded boiling point is 75° (746 mm.).[10]

(9) Claus and Stanenhagen, *Ann.*, **269**, 224 (1892). Cohen and Dakin, *J. Chem. Soc.*, **79**, 1132 (1901), report failure with this method.

Summary

1. The relative reactivities of the acidic hydroxyl groups of a number of derivatives of benzoic acid have been determined by measuring the rates at which the acids react with thionyl chloride.

2. The results show that the acids which have the more reactive hydroxyl groups have the less reactive acidic hydrogen atoms.

3. Acids which have methyl, ethyl or methoxy groups in the two positions ortho to the carboxyl group have very reactive hydroxyl groups; the acids having chlorine or the nitro group in these positions have very inactive hydroxyl groups.

4. A study of the effect of pyridine and of N,N-dimethylcyclohexylamine on the rates of the reaction showed that the latter were greatly increased by the catalysts. The acids which contained the substituent in the ortho position were most affected; the rate with *o*-nitrobenzoic acid was increased 1520 times, *o*-chlorobenzoic acid 600 times, and *o*-methylbenzoic acid 87 times when the concentration of the catalyst was 1 mole to 12.5 moles of the acid.

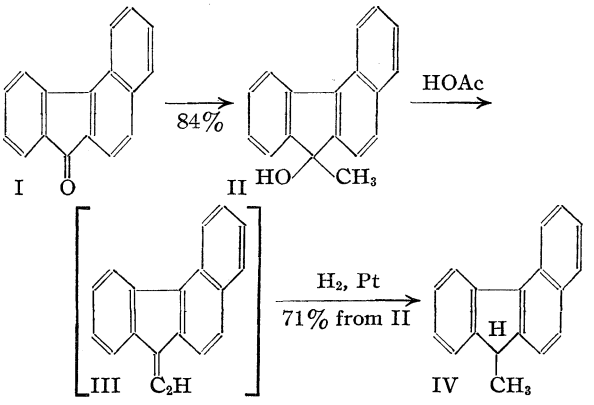
9-Methyl-3,4-benzfluorene

BY LOUIS F. FIESER AND LLOYD M. JOSHEL[1]

Because of the marked carcinogenic activity of 10-methyl-1,2-benzanthracene,[2] it seemed of interest to synthesize and test the somewhat analogous 9-methyl-3,4-benzfluorene (IV). 3,4-Benzfluorenone-9 (I) was prepared from 1-phenyl-2,3-naphthalic anhydride by the method of Schaarschmidt[3] but with the introduction of modifications which raised the over-all yield to 83%. Condensation of the ketone with methyl-



magnesium chloride gave the crystalline carbinol II in good yield, and it was found that this substance is readily dehydrated by short boiling in glacial acetic acid solution. On attempting to isolate the 9-methylene compound III only polymeric material was obtained, for the hydrocarbon appears to be a labile substance resembling 9-methylenefluorene (dibenzofulvene).[4] By heating the carbinol in acetic acid and shaking the resulting solution with hydrogen and Adams catalyst it was possible to obtain the desired hydrocarbon IV without difficulty.

Experimental Part[5]

3,4-Benz-9-fluorenone-1-carboxylic acid[3] was prepared by adding 100 g. of powdered aluminum chloride rapidly (less than five minutes) to a stirred suspension of 91.7 g. of 1-phenyl-2,3-naphthalic anhydride in 500 cc. of dry benzene, refluxing for two hours, and decomposing the cooled mixture with 200 cc. of 20% hydrochloric acid. The solvent was steam distilled and the scarlet red precipitate was washed with hot dilute hydrochloric acid and with hot water, affording 91 g. (99%) of material sintering at 293° and melting at 295–296°. Treatment of the anhydride with hydrogen fluoride at room temperature for twenty-four hours resulted in only partial conversion to the fluorenone derivative.

For decarboxylation to **3,4-benzfluorenone-9** the acid (20 g.) was heated with basic copper carbonate (0.5 g.) in a bath at 310–320°. As soon as the acid melted carbon dioxide was evolved vigorously and the reaction was over in about five minutes. The product was distilled at the pressure of the water pump and crystallized from acetone, giving 13.1 g. of the ketone in the form of orange prisms, m. p. 159–160.5°, and 1.0 g., m. p. 158–160° (84%).

9-Methyl-3,4-benzfluorenol-9 (II).—A solution of 5 g. of the ketone in benzene was treated with excess methylmagnesium chloride in ether and after refluxing for two hours the mixture was decomposed with 25% ammonium chloride solution. The organic layer was washed, dried, and evaporated and the product then crystallized from ether–ligroin in small, colorless needles, m. p. 116–118°; yield 4.5 g. (84%). This material was sufficiently pure for the subsequent steps. A sample recrystallized for analysis melted at 117.8–118.6°.

Anal. Calcd. for $C_{18}H_{14}O$: C, 87.77; H, 5.73. Found: C, 87.72; H, 6.01.

Dehydration.—A solution of the crude carbinol from 1 g. of ketone in 10 cc. of acetic acid was refluxed for one hour, diluted with water and extracted with benzene. Evaporation of the dried solution left an oily residue which when rubbed with alcohol gave an amorphous, almost colorless solid which sintered and darkened at about 200° and completely melted to a deep red liquid at 275–280°; yield 0.7 g. (71%). A similar polymer resulted on distillation of the crude carbinol with a crystal of iodine, followed by passage of a benzene solution of the distillate through a tower of alumina.

Anal. Calcd. for $(C_{18}H_{12})_x$: C, 94.70; H, 5.30. Found: C, 94.40; H, 5.59.

9-Methyl-3,4-benzfluorene (IV).—A solution of 0.60 g. of the carbinol in 25 cc. of acetic acid was refluxed for one hour, cooled, and at once transferred to a hydrogenation flask and shaken with 25 mg. of Adams catalyst and hydrogen. The absorption of one mole of gas was complete in twenty minutes. The product was collected and distilled in vacuum, and crystallization from benzene–ethanol afforded 0.4 g. (71%) of light yellow blades, m. p. 80–81° (a little polymeric material was removed by filtration of the solution). Recrystallization gave material melting constantly at 80.8–82.0°. The color was not removed by treatment with Norite or by passage through a tower of alumina.

Anal. Calcd. for $C_{18}H_{14}$: C, 93.87; H, 6.13. Found: C, 93.63; H, 6.27.

(1) Fellow of the Finney-Howell Research Foundation.

(2) For summary, see Fieser, *Am. J. Cancer*, **34**, 37 (1937).

(3) Schaarschmidt, *Ber.*, **48**, 1826 (1915); **49**, 1444 (1916); Schaarschmidt and Georgeocopol, *ibid.*, **51**, 1082 (1918).

(5) All melting points are corrected. Microanalyses by Lyon Southworth.

In a larger run using a more concentrated solution the yield was poorer and more polymer was encountered. In another experiment the preliminary refluxing was omitted and the solution of the carbinol in acetic acid was shaken with catalyst and hydrogen in a vessel equipped with a sealed-in steam coil. No polymer was formed, but the yield of saturated hydrocarbon was lower.

The **picrate** crystallized from ethanol as reddish-orange needles, m. p. 128–128.5°, with slight previous sintering.

Anal. Calcd. for $C_{24}H_{17}O_7N_3$: N, 9.15. Found: N, 8.72.

Summary

9-Methyl-3,4-benzfluorene has been synthesized for comparison with the actively carcinogenic 10-methyl-1,2-benzanthracene.

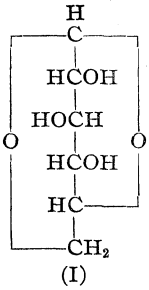
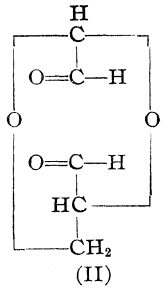
The Cleavage of the Carbon Chain of Levoglucosan by Oxidation with Periodic Acid[1]

BY ERNEST L. JACKSON AND C. S. HUDSON[1]

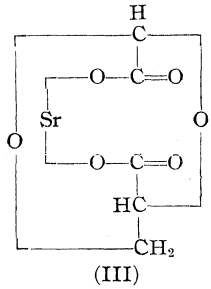
The structure of levoglucosan (I) has been established by methylation methods[2] and by its relationship to the structure of β-methylglucopyranoside.[3] A compound having this structure should be oxidized by periodic acid to produce the dialdehyde (II).



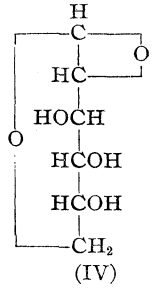
(I)
Levoglucosan



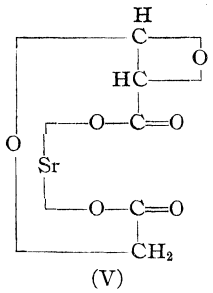
(II)
L′-Oxy-D-methylene-diglycolic aldehyde[4]



(III)
Strontium L′-oxy-D-methylene-diglycolate



(IV)



(V)

The oxidation of levoglucosan with periodic acid or sodium metaperiodate yields a sirupy product which is doubtless L′-oxy-D-methylene-diglycolic aldehyde (II). Oxidation of this product by bromine water kept neutral with strontium carbonate produces in good yield a crystalline strontium salt of a dibasic acid and, under the conditions employed, smaller amounts of strontium oxalate and strontium D-glycerate. The strontium salt of the dibasic acid was proved to be strontium L′-oxy-D-methylene-diglycolate (III) by oxidizing it with bromine water in the presence of strontium carbonate to produce strontium oxalate and strontium D-glycerate. The structure of the dialdehyde (II) follows from that of the strontium salt (III). The formation of strontium oxalate and strontium D-glycerate during the oxidation of the dialdehyde (II) to the strontium salt (III) with bromine water and strontium carbonate evidently is due to the oxidation of some strontium L′-oxy-D-methylene-diglycolate. These results prove levoglucosan to have structure (I); the beta configuration for carbon atom 1 is required by the accepted stereo configurations of the α- and β-forms of D-glucopyranose.[5]

Levoglucosan, upon oxidation by periodic acid or sodium metaperiodate, consumes two moles of the oxidant and produces one mole of formic acid.[6] These figures agree with formula (I). The same data could fit a compound having structure (IV), but (IV) is excluded since the corresponding strontium salt (V) could not yield strontium D-glycerate by oxidation with bromine water and strontium carbonate.

L′-Oxy-D-methylene-diglycolic acid, which is a cyclic acetal having as its two components glyoxylic and D-glyceric acids, could not be hydrolyzed by hot 2.5 *N* hydrochloric acid. This

acetal, like the chloraloses[7] and trichloroethylidene glycerol,[8] is exceptional in its stability in the presence of acids.

These oxidation reactions can be employed in the study of the structure of other sugar anhydrides. Strontium L′-oxy-D-methylene-diglycolate serves as a reference compound for the determination of the ring structure of any aldohexose anhydride, the two rings of which are of the α-1,5 and the β-1,6 type. An application of this method to the study of the structure of D-altrosan is shown in the following article.[9]

Experimental

Oxidation of Levoglucosan with Periodic Acid.—To 25 ml. of 0.542 *M* aqueous periodic acid solution (2.1 molecular equivalents) was added a solution of 1.0432 g. of pure levoglucosan in water. The solution, diluted with water to 50 ml. at 20° and kept in a 20–21° room, showed $[M]_D \times 10^{-2}$: −98.2 (4.3 min.); −92.5 (7.6 min.); −84.4 (13.8 min.); −71.9 (27.1 min.); −60.5 (50.7 min.); −48.4 (90.3 min.); −40.3 (145 min.); −33.6 (236 min.); −28.9 (357 min.); −19.5, constant (24 hrs.). The specific rotation of L′-oxy-D-methylene-diglycolic aldehyde, calculated from the final $[M]_D$ value of the oxidation solution, is −15.0°. After twenty-four hours an analysis of 5 ml. of the solution showed an excess of 0.14 molecular equivalent of periodic acid, the consumption of the oxidant thus being 1.96 molecular equivalents.

For the preparation of strontium L′-oxy-D-methylene-diglycolate, the oxidation of 10.4 g. of levoglucosan with 500 ml. of 0.271 *M* aqueous periodic acid solution was carried out as described above. Upon completion of the reaction, the solution was neutralized cautiously to phenolphthalein with hot strontium hydroxide solution. L′-Oxy-D-methylene-diglycolic aldehyde was isolated as a colorless sirup by the procedure described in a previous paper[4] for the methoxydiglycolic aldehydes from the methyl-pentopyranosides, with the exception that the solvent for extraction of L′-oxy-D-methylene-diglycolic aldehyde from the strontium salts was absolute methanol. To a solution of the dialdehyde in 2500 ml. of water were added 190 g. of strontium carbonate and 15 ml. of bromine. After the bromine had been dissolved, the mixture was kept in the dark at 25° for fifteen hours with frequent shaking during the first hour. Excess bromine was removed by aeration, and excess strontium carbonate was filtered off and washed with water. The solution, freed from bromine ions with silver carbonate and from excess silver with hydrogen sulfide, was concentrated *in vacuo* (bath, 50–55°) to 300 ml., filtered and the concentration continued to about 100 ml., when prismatic needles of strontium L′-oxy-D-methylene-diglycolate usually had started to separate. After the addition of 10–15% of ethanol, the mixture was left in the refrigerator to complete crystallization; yield[10] calculated as $C_5H_4O_6Sr$,[11] 7.2 g. (45%). The mother liquor contained strontium D-glycerate. The strontium L′-oxy-D-methylene-diglycolate, after one or two recrystallizations from water, was pure; it crystallizes from water at 20° or at refrigerator temperature as long prismatic needles of its pentahydrate; at 30° or above as small compact clusters of short needles of its monohydrate, which is less soluble in water than the pentahydrate. In preparing the solution of the strontium salt in water for crystallization, the less soluble monohydrate may be precipitated during the process of dissolving the pentahydrate, if a minimum amount of water and steam-bath temperature are employed. The procedure adopted, therefore, was to dissolve the strontium salt in a large excess of warm water, then concentrate the solution *in vacuo* (bath, 45–50°) to a relatively small volume and filter it quickly to remove any crystals that might be present. Thereafter, crystallization was allowed to proceed at a temperature selected to yield the desired hydrate of the strontium salt. For analysis and determination of the rotation of strontium L′-oxy-D-methylene-diglycolate, crystals of the pure pentahydrate were dried to constant weight at 100° *in vacuo*. The anhydrous strontium salt showed a specific rotation[12] of +37.5° in water (*c*, 0.45; *l*, 2). Upon exposure to the air at 20–25° the anhydrous salt soon showed an increase in weight in excess of the amount calculated for the water content of the monohydrate.

Anal. Calcd. for $C_5H_4O_6Sr$: C, 24.23; H, 1.63; Sr, 35.38. Found: C, 24.19, 23.99; H, 1.77, 1.49; Sr, 35.32, 35.16.

The monohydrate of strontium L′-oxy-D-methylene-diglycolate was prepared both by crystallization of the strontium salt from water, preferably at 45° which yields homogeneous crystals, and by efflorescence of the pentahydrate. Crystals of the pentahydrate, exposed to comparatively humid air at about 30°,[13] showed no appreciable change in composition during ten to fifteen days, but thereafter effloresced in the course of several weeks to produce the monohydrate. The monohydrate is characterized by its pronounced stability at high temperature. It lost weight only slowly at 145–150° *in vacuo*, but at 175° *in vacuo* was converted to an anhydrous strontium salt. The specific rotation in water of samples of the monohydrate obtained under three different conditions were: (from water at 30°) +36.9° (*c*, 0.38; *l*, 4); (from water at 45°) +36.8° (*c*, 0.39; *l*, 4); (from efflorescence) +36.4° (*c*, 0.47; *l*, 4).

Anal. Calcd. for $C_5H_4O_6Sr \cdot H_2O$: H_2O, 6.78; C, 22.60; H, 2.28; Sr, 32.98. Found: (from water at 45°) H_2O,

(10) The yield was only 25% in an experiment carried out under the same conditions, with the exception that the time for the oxidation of the dialdehyde was twenty-nine hours instead of fifteen hours.

(11) The water content of the crystals varies with the conditions of time, temperature and humidity under which they are dried. It was at first believed that the salt had crystallized as a trihydrate (*cf.* the accompanying article[9]), but a careful study has revealed with certainty only a mono and a pentahydrate.

(12) Except where otherwise stated, all rotations in this article are specific rotations at 20° for sodium light; *c* = g. per 100 ml. of solution; *l* = length in dm.

(13) Crystals of the pentahydrate, exposed to the air simultaneously at 20°, were stable as shown by the result of an analysis at the end of forty-five days. Calcd. for $C_5H_4O_6Sr \cdot 5H_2O$: H_2O, 26.67; Sr, 25.94. Found: H_2O, 26.71, 26.51; Sr, 25.80, 25.61.

6.77, 6.85; C, 22.45, 22.64; H, 2.28, 2.43; Sr, 32.85, 32.81; (from water at 30°) Sr, 32.85, 32.72; (from water at 95–100°) Sr, 32.84; (from efflorescence) Sr, 32.79, 32.95.

Strontium D-glycerate, which is produced during the oxidation of L′-oxy-D-methylene-diglycolic aldehyde with bromine water and strontium carbonate, was isolated as well-formed octahedral prisms of the dihydrate[14] by concentrating the filtrate from the crude strontium L′-oxy-D-methylene-diglycolate pentahydrate *in vacuo* to about 10 ml.; air-dried; yield of the crude dihydrate, 3 g. After purification by recrystallization from about three parts of water, the dihydrate melted at 136–137° (uncor.) and rotated +15.2° in water (*c*, 0.5; *l*, 2). The pure dihydrate is stable at 100° *in vacuo*, but at 125° *in vacuo* it loses approximately the weight calculated for two moles of combined water and becomes slightly colored. A specimen of calcium D-glycerate dihydrate, prepared from the strontium salt, rotated +15.5° in water (*c*, 0.6; *l*, 2) and melted at 142–143° (uncor.) alone or mixed with authentic calcium D-glycerate dihydrate.

Anal. Calcd. for $C_6H_{10}O_8Sr \cdot 2H_2O$: H_2O, 10.80; Sr, 26.26. Found: H_2O (dried at 125° *in vacuo*), 11.20, 11.30; Sr, 26.24, 26.08.

Oxalic acid was produced in the course of these oxidation reactions, as shown by the isolation of strontium oxalate from the excess strontium carbonate, which was recovered from the oxidation of L′-oxy-D-methylene-diglycolic aldehyde. A solution of the excess strontium carbonate in hydrochloric acid was boiled to expel carbon dioxide, cooled and neutralized with ammonium hydroxide solution. From the precipitate of strontium oxalate monohydrate (yield, 1.8 g.) was prepared oxalic acid dihydrate, which was characterized by usual methods.

L′-Oxy-D-methylene-diglycolic Acid.—The specific rotation of L′-oxy-D-methylene-diglycolic acid, obtained by liberating it from its pure anhydrous strontium salt in aqueous solution with an equivalent of hydrochloric acid, was +8.0° (*c*, 1.3; *l*, 2). The acid was isolated in crystalline condition, and was shown to be stable in hot aqueous solution. A solution of 2 g. of pure strontium L′-oxy-D-methylene-diglycolate in 80 ml. of hot water was cooled to 25°. After the addition of the calculated amount of *N* sulfuric acid solution and 90 ml. of absolute ethanol, the strontium sulfate was filtered off and the filtrate was concentrated *in vacuo* (bath, 50°) to a colorless sirup, which was made up to 50 ml. of solution in water. The rotation of this solution was unchanged by heating it in a stoppered flask on the steam-bath for five and one-half hours. The solution was then concentrated *in vacuo* to a sirup, which crystallized as needles during evacuation of the flask at room temperature to remove the last traces of solvent. The crystalline acid is readily soluble in acetone and in ether, but practically insoluble in petroleum ether. That the acid was unchanged by the heating of its aqueous solution and the subsequent operations was proved by neutralization of its solution in water with strontium hydroxide and isolation of strontium L′-oxy-D-methylene-diglycolate, which in the anhydrous condition rotated +37.5° in water (*c*, 0.4). Calcd. for $C_5H_4O_6Sr$: Sr, 35.38. Found: Sr, 35.28. The acid was not hydrolyzed by hot 2.5 *N* hydrochloric acid solution. To a suspension of 0.3 g. of pure strontium L′-oxy-D-methylene-diglycolate in water was added sufficient 5 *N* hydrochloric acid to balance the strontium ions and make the concentration of the hydrochloric acid approximately 2.5 *N* after the solution had been diluted with water to 25 ml. The rotation of this solution was unchanged by heating it in a stoppered flask on the steam-bath for four hours.

L′-Oxy-D-methylene-diglycolic aldehyde, likewise, seemed resistant to acid hydrolysis. A solution of the dialdehyde, prepared from 2.67 g. of levoglucosan as previously described, in 100 ml. of 0.1 *N* hydrochloric acid showed only a minor change in rotation when it was heated on the steam-bath for seven hours; the rotation, measured in a 1-dm. tube, changed from α_D −0.31° to α_D −0.24°; full hydrolysis to glyoxal and D-glyceric aldehyde would be expected to cause reversal of the sign of rotation.

Strontium D-Glycerate and Strontium Oxalate from the Oxidation of Strontium L′-Oxy-D-methylene-diglycolate.—Five grams of pure strontium L′-oxy-D-methylene-diglycolate, containing about 15% of combined water as indicated by its specific rotation of +31.9°, was dissolved in approximately 1500 ml. of water. After the addition of 90 g. of strontium carbonate and 7 ml. of bromine, the mixture was shaken until the bromine had dissolved and, thereafter, shaken occasionally while it was kept in the dark at room temperature. The rotation of the solution, measured in a 4-dm. tube, decreased during forty-two hours from α_D +0.39° to α_D +0.05°. Excess bromine was then removed by aeration, and excess strontium carbonate was filtered off and washed with water. The excess strontium carbonate was dissolved in hydrochloric acid, the solution was boiled to expel carbon dioxide and neutralized with ammonium hydroxide, which precipitated 1 g. (about 30% yield) of strontium oxalate monohydrate. Oxalic acid dihydrate, prepared from the strontium oxalate, was characterized by customary methods. The filtrate from the excess strontium carbonate, after being freed from bromine ions with silver carbonate and from excess silver with hydrogen sulfide, was concentrated *in vacuo* to 75 ml., filtered and the concentration continued to about 10 ml. The solution, which was somewhat acid, was neutralized to litmus paper with strontium hydroxide solution and then concentrated to a thin sirup to which ethanol was added to turbidity. After being seeded with crystals of strontium D-glycerate dihydrate, the solution yielded at room temperature 0.7 g. of crystals rotating +9.9° in water. From the mother liquor was obtained, by concentration and dilution with ethanol, 0.4 g. of crystals rotating +7.3° in water. The first crop gave by two recrystallizations from water about 0.1 g. of prisms, which resembled crystals of strontium D-glycerate dihydrate; air-dried; m. p. 131–132° (uncor.); rotation, +14.3° in water. Calcd. for $C_6H_{10}O_8Sr \cdot 2H_2O$: Sr, 26.26. Found: Sr, 26.70, 27.01. After another recrystallization from a mixture of water and ethanol, the crystals melted at 134–135° (uncor.) and showed no depression when mixed with authentic strontium D-glycerate dihydrate.

There were indications that another substance, as yet unidentified, may be formed in this oxidation reaction.

(14) *Cf.* Frankland and Appleyard, *J. Chem. Soc.*, **63**, 300 (1893).

The rotation of the crude product, which was a mixture not readily separable into its constituents with a small quantity of material, was considerably lower than that of both strontium D-glycerate and strontium L′-oxy-D-methylene-diglycolate. After several recrystallizations from mixtures of water and ethanol, crystals of doubtful purity containing 30.8% of strontium were isolated; specific rotation, +7.0° in water.

Oxidation of Levoglucosan with Sodium Metaperiodate.—A solution of 0.3488 g. of pure levoglucosan in water was mixed with 10 ml. of 0.453 *M* aqueous sodium metaperiodate solution (2.1 molecular equivalents). The solution, after being diluted with water to 25 ml. at 20° and kept in a 20° room for twenty hours, showed $[M]_D \times 10^{-2} = -19.1°$. The specific rotation of L′-oxy-D-methylene-diglycolic aldehyde, calculated from the final $[M]_D$ value of the oxidation solution, is −14.7°; this value is in good agreement with the specific rotation of −15.0° calculated from the end rotation of the periodic acid oxidation solution. After twenty hours an analysis of 5 ml. of the solution showed an excess of 0.11 molecular equivalent of sodium metaperiodate; the consumption of the oxidant was thus 1.99 molecular equivalents. The acidity of the reaction solution at the end of twenty hours corresponded to the production of 1.00 molecular equivalent of formic acid (5 ml., diluted with 300 ml. of water and neutralized to methyl red, required 4.30 ml. of 0.1 *N* sodium hydroxide; calcd. 4.30 ml.).

We express our thanks to Drs. A. E. Knauf and W. D. Maclay for a supply of levoglucosan and to Dr. W. T. Haskins for carrying out the microanalyses.

Summary

Levoglucosan yields, by oxidation with periodic acid or sodium metaperiodate, L′-oxy-D-methylene-diglycolic aldehyde, which is oxidized by bromine water kept neutral with strontium carbonate to produce, under specified conditions, crystalline strontium L′-oxy-D-methylene-diglycolate in 45% yield and smaller amounts of strontium oxalate and strontium D-glycerate. The structure of strontium L′-oxy-D-methylene-diglycolate was proved by its oxidation with bromine water in the presence of strontium carbonate to produce strontium oxalate and strontium D-glycerate. These results show the levoglucosan molecule to have two rings, one of which is of the pyranoid and the other of the septanoid type. This confirmation of the generally accepted ring structure of levoglucosan demonstrates the applicability of these oxidation reactions to the structural study of the sugar anhydrides.

L′-Oxy-D-methylene-diglycolic acid, which could not be hydrolyzed by hot 2.5 *N* hydrochloric acid, is one of the few acetals possessing such stability.

The Ring Structure of D-Altrosan[1]

BY NELSON K. RICHTMYER AND C. S. HUDSON

A few years ago we reported[2] that "crystalline D-altrose is converted by hot hydrochloric acid from $[\alpha]_D^{20}$ +34 to −98°; this is accompanied by partial loss of reducing power presumably due to the formation of an anhydro-D-altrose to the extent of 57% at equilibrium." Independently, Robertson and Griffith[3] found that the removal of the glycosidic methoxyl group from certain partially methylated α-methyl-altrosides by hydrolysis with 4–8% hydrochloric acid "leads to the production of an anhydro-derivative in equilibrium with a small amount of a reducing sugar." They cited also the case of the "methyl epiglucosamine" of Fischer, Bergmann and Schotte[4]; this substance, which is probably a 3-amino methylaltroside,[5] undergoes acid hydrolysis with the formation of an anhydro compound from the liberated sugar and consequent loss of reducing power.[6] Robertson and Griffith suggested that the anhydro-linkage in these compounds must involve position 4 or 6, since only these positions are available in the case of the 2,3-dimethylaltrose which forms an anhydride. The suggestion was confirmed later[7] by the fact that 4,6-dimethyl-α-methylaltroside is hydrolyzed in normal fashion to a reducing sugar without anhydride formation.

Hudson,[8] in 1938, presented conclusive evidence that sedoheptulosan, the anhydride which is formed spontaneously from sedoheptulose (D-altroheptulose) in acid solution, possesses the

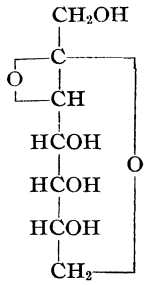
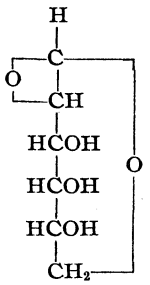
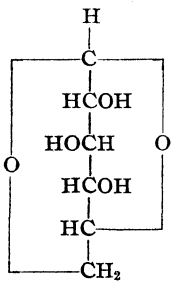
unusual combination of an ethylene oxide and a septanoid ring (I).



Sedoheptulosan
I



D-Altrosan (?)
II

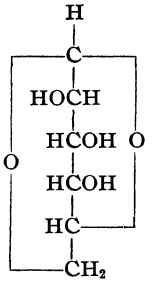


Levoglucosan
III

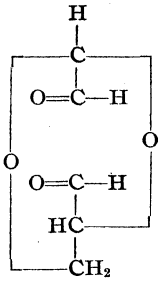
Because of the identical configurations of the asymmetric carbon atoms in sedoheptulose and D-altrose, and because of the ease with which these two sugars undergo anhydride formation in the presence of acids, it did not seem unreasonable to suggest that a similar structure II might be written for D-altrosan rather than a <1,5> <1,6> ring system like that which had been established previously for levoglucosan (III). It was emphasized, however, that formula II for D-altrosan rested solely upon the apparent analogy to sedoheptulosan (I), and that additional experimental data would be necessary to answer the question.

In a recent Communication[9] we announced the successful crystallization, after three years, of a sample of D-altrosan which had been prepared by removing the D-altrose component from the altrose–altrosan equilibrium mixture by oxidation with bromine water. With the additional crystalline material now available we are continuing our study of D-altrosan, and are reporting at this time a proof of its ring structure. To this end we have utilized the periodic acid method of oxidation developed by Jackson and Hudson,[10] especially as described in the preceding article.[11]

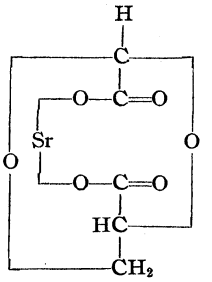
The oxidation of D-altrosan with periodic acid or with sodium metaperiodate has been shown to consume two equivalents of oxidizing agent, and to liberate one equivalent of formic acid. The resulting aldehyde upon further oxidation with bromine water produced a dibasic acid, readily isolated as a crystalline strontium salt of the composition $C_5H_4O_6Sr \cdot 5H_2O$. Of the many ring combinations possible for D-altrosan, $C_6H_{10}O_5$, only two could fulfill the requirements of reacting with two moles of periodic acid, with the elimination of one carbon atom as formic acid, and the subsequent formation of a dibasic acid containing the other five carbon atoms. These two possibilities are the <1,2> <1,6> formula II already suggested, and the <1,5> <1,6> formula IV analogous to that of levoglucosan (III).



D-Altrosan
IV



Dialdehyde
V



Strontium salt
VI

The actual decision between formulas II and IV for D-altrosan was relatively simple after the pioneer work reported in the preceding paper. Thus the rotation[12] $-14.7°$ for the dialdehyde V in the periodic acid solutions was in close agreement with the value recorded for L′-oxy-D-methylene-diglycolic aldehyde obtained from levoglucosan under comparable conditions. The crystalline strontium salt VI was found to agree in its rotation in water, its rotation in acid, in the conversion of the pentahydrate to the monohydrate (which is the stable form in air at room temperature), in its solubility in water, and by a determination of mixed solubilities,[13] with strontium L′-oxy-D-methylene-diglycolate from levoglucosan.

Since a compound with structure IV would be expected to produce the same dialdehyde V and the same strontium salt VI as are obtained from levoglucosan (III), whereas a compound with structure II could not, and since the proof of structure of the strontium salt from levoglucosan is in complete harmony with the structure III established previously for that compound, therefore D-altrosan must have the same ring system as levoglucosan, and accordingly may be designated[14] D-altrosan α<1,5>β<1,6>.

Experimental

D-Altrosan.—The reactions by which lactose is converted to D-altrosan have been described previously.[2,9] Briefly,

(9) Richtmyer and Hudson, THIS JOURNAL, **61**, 214 (1939).
(10) Jackson and Hudson, *ibid.*, **59**, 994 (1937).
(11) Jackson and Hudson, *ibid.*, **62**, 958 (1940).

(12) Throughout the article the rotations are specific rotations at 20° for sodium light; *c* designates concentration in grams per 100 cc. of solution.
(13) Montgomery and Hudson, THIS JOURNAL, **52**, 2105 (1930).
(14) The name altrosan (or altrose anhydride), rather than anhydroaltrose, is used to indicate anhydride formation involving the glycosidic hydroxyl group. This system of nomenclature is in accord with the proposal of M. Bergmann (*Ber.*, **58**, 2647, 2650 (1925); see also F. Micheel, "Chemie der Zucker und Polysaccharide," Akademische Verlagsgesellschaft m. b. H., Leipzig, 1939, p. 151).

lactose octaacetate was chlorinated and rearranged to acetochloroneolactose by the action of aluminum chloride and phosphorus pentachloride. The acetochloroneolactose[15] was hydrolyzed by six hours' boiling with water to hydrochloric and acetic acids, galactose and altrose; at the same time about 60% of the altrose was converted to altrosan. The acids were removed in the usual manner, the galactose by fermentation, the altrose by oxidation with bromine water and subsequent separation as calcium altronate, and the remaining altrosan was crystallized. From 1132 g. of acetochloroneolactose was obtained 75 g. of crystalline D-altrosan,[16] and from the mother liquors by acetylation was obtained 51 g. of crystalline 2,3,4-triacetyl-D-altrosan and 14 g. of altrose α-pentaacetate.[17]

Oxidation of D-Altrosan with Sodium Metaperiodate.—To 0.6173 g. of altrosan in 25 cc. of water was added 20 cc. of 0.419 *M* aqueous sodium periodate (2.2 equivalents of $NaIO_4$), and the solution left at 20° for forty-five hours. The volume was adjusted with water exactly to 50 cc. The specific rotation, calculated as the dialdehyde V, was −14.4° as compared with the value −14.7° obtained by Jackson and Hudson[11] for the dialdehyde formed in the same way from levoglucosan. The titration of an aliquot for excess periodate indicated the consumption of 1.97 equivalents of oxidizing agent. Titration of another aliquot with aqueous sodium hydroxide, using methyl red as indicator, showed the formation of 0.97 equivalent of acid, presumably formic acid.

Oxidation of D-Altrosan with Periodic Acid.—Since a preliminary experiment indicated that the reaction of altrosan with periodic acid proceeded almost instantaneously at 20°, with considerable evolution of heat, subsequent oxidations were carried out at a lower temperature. Thus, to 5.469 g. of D-altrosan, dissolved in 75 cc. of water and cooled in an ice-bath, were added six 25-cc. portions of 0.495 *M* aqueous periodic acid (2.2 equivalents of HIO_4) at ten-minute intervals. The solution was left overnight at 20°, and its volume adjusted to 250 cc. with water. The specific rotation, calculated as the dialdehyde V, was −14.5°, and in a second experiment −14.9°; these values are in good agreement with the rotation of −15.0° obtained by Jackson and Hudson from their similar oxidation of levoglucosan. The titration of an aliquot for excess periodic acid revealed that 1.96 equivalents of oxidizing agent had been consumed.

Isolation of the Dialdehyde V and Oxidation to the Strontium Salt VI.—The solutions from the oxidation of altrosan with periodic acid were combined, neutralized to phenolphthalein with strontium hydroxide, filtered, and the filtrate concentrated *in vacuo* to a small volume in the presence of 1 g. of strontium carbonate. The solution was filtered into a smaller flask and concentrated *in vacuo* practically to dryness. The dialdehyde was extracted readily with absolute methyl alcohol, and was left behind as a colorless sirup upon removal of the alcohol *in vacuo*. A concentrated aqueous solution of this sirup was estimated, from its rotation, to contain 4.95 g. of the dialdehyde, derived from 7.35 g. of D-altrosan.

For oxidation, the solution of dialdehyde was diluted with water to 1900 cc., and 145 g. of strontium carbonate and 7 cc. of bromine added. The mixture was shaken frequently during the first hour, then left fourteen hours more at room temperature (25°). Excess bromine, insoluble strontium salts and strontium bromide were removed by aeration, filtration and treatment with silver carbonate, respectively. The filtrate was freed from dissolved silver with hydrogen sulfide, and the solution concentrated *in vacuo*. The strontium salt which crystallized spontaneously during the distillation weighed 5.8 g. Twice recrystallized from water, and air-dried for two days, it had the composition of a pentahydrate.

Anal. Calcd. for $C_5H_4O_6Sr \cdot 5H_2O$: Sr, 25.94; H_2O, 26.67. Found: Sr, 25.94; H_2O, 25.91.

Identification of the Strontium Salt as Strontium L'-Oxy-D-methylene-diglycolate VI.—Inasmuch as the strontium salt derived from levoglucosan was found at first by Jackson and Hudson to crystallize apparently as a trihydrate, and the strontium salt from D-altrosan had crystallized as a pentahydrate, a careful comparison of the two substances was made. The pentahydrate rotated +28.1° in water, equivalent to +38.3° calculated as the anhydrous strontium salt (*c*, 0.45), as compared with +37.5° reported by Jackson and Hudson for their anhydrous strontium salt (*c*, 0.45). Dissolved in an excess of aqueous hydrochloric acid, the pentahydrate showed a rotation of +7.9° calculated as the free organic acid (*c*, 1.3), as compared with the rotation +8.0° for the L'-oxy-D-methylene-diglycolic acid (*c*, 1.5) liberated by Jackson and Hudson from their anhydrous strontium salt.

Further comparison was made directly between the strontium salt from D-altrosan and the strontium salt from levoglucosan prepared by the same procedure. Thus, the latter salt also was obtained as a pentahydrate by the concentration of its aqueous solution *in vacuo* with the bath temperature about 40°. This salt was filtered, washed with cold water, and a portion of it placed on a watch glass in a room kept at 20° ± 1°. Overnight the strontium salt lost its adsorbed moisture, then remained constant in weight for two days. A sample removed at that time showed it to be a pentahydrate.

Anal. Calcd. for $C_5H_4O_6Sr \cdot 5H_2O$: Sr, 25.94. Found: Sr, 25.92.

The remainder of this portion kept at 20° soon began to lose weight, slowly at first and then more rapidly as shown in Fig. 1, until a total of 3.85 molecular equivalents of water had been lost in thirty days. From another sample at 30°, the loss of water was complete in four days, and the final stage of the strontium salt monohydrate was reached.

Anal. Calcd. for $C_5H_4O_6Sr \cdot H_2O$: Sr, 32.98. Found: Sr, 32.79 (salt from levoglucosan), 32.82 (salt from D-altrosan, air-dried at 30° for twenty-four days).

The concluding proof of identity of the strontium salts from levoglucosan and D-altrosan was obtained through a study of their solubilities. In 5 cc. of aqueous solution,

(15) It is unnecessary to isolate the acetochloroneolactose except in preliminary experiments designed to ensure favorable yields. Instead, the mixture of acetochloro derivatives may be used, and the lactose component removed by the regular hydrolysis and fermentation operations.

(16) The rotation in water (*c*, 2.5) of a carefully purified sample of D-altrosan has been determined as −213.0 ± 0.6°, or slightly lower than the −215° reported in our preliminary Communication.

(17) These compounds and some of their transformation products will be described in a future publication.

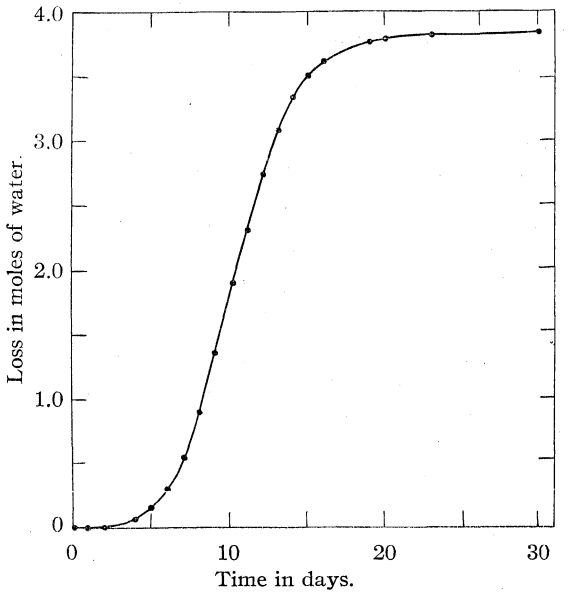


Fig. 1.—Conversion of strontium salt pentahydrate to monohydrate in air at 20°.

saturated by shaking five days at 20° with an excess of the solid strontium salt from levoglucosan, there was contained 40.6 mg. of the strontium salt monohydrate. In 5 cc. of a similar solution from D-altrosan there was 40.2 mg. To a portion of the solution saturated with the salt from levoglucosan then was added solid strontium salt from D-altrosan, and the mixture shaken five days at 20°; the filtered solution contained 40.2 mg. of the monohydrate in 5 cc. A similar value for the solubility, 40.6 mg. in 5 cc., was reached from supersaturation, by shaking the strontium salt from levoglucosan first at 30° (44.8 mg. soluble in 5 cc.), and then at 20°.

One of the authors (N. K. R.) desires to thank the Chemical Foundation of New York for a Research Associateship, and the American Academy of Arts and Sciences for a grant from the Cyrus M. Warren Fund. The authors also express their indebtedness to Dr. W. T. Haskins for carrying out the microanalyses, and to Dr. A. E. Knauf for the sample of levoglucosan which was oxidized.

Summary

The oxidation of D-altrosan with periodic acid, followed by bromine water and strontium carbonate, to the same strontium L′-oxy-D-methylenediglycolate which is obtained from levoglucosan, has shown that D-altrosan possesses the same ring system as levoglucosan, and accordingly is to be designated D-altrosan $\alpha<1,5>\beta<1,6>$.

Ketene Acetals. IV. Polymers of Ketene Diethylacetal[1]

BY PAUL R. JOHNSON,[2] HARRY M. BARNES[3] AND S. M. MCELVAIN

One of the first chemical properties of ketene acetal to be noticed was its readiness to polymerize. The polymer appeared as a thin, white deposit on the interior of the flasks and condensers in which ketene acetal had been distilled and also as a semi-solid gum which settled out of distilled samples of ketene acetal after a few days of standing. It soon was noted that distillation apparatus that had been cleaned with the ordinary chromic acid–sulfuric acid mixture before the distillation of ketene acetal acquired an excessive amount of the polymer on the inner glass surfaces. If, however, the interior of the apparatus were washed with an aqueous alkali solution after the use of the acid cleaning solution, and then rinsed and dried in the usual manner, the amount of polymer formed during the distillation of ketene acetal was scarcely noticeable. Similarly, dusting the interior of the containers in which ketene acetal was kept with sodium or potassium *t*-butoxide practically eliminated the polymerization of the acetal on standing.

Although acidified glass surfaces cause some polymerization of ketene acetal, this catalyst is not efficient enough to allow for the preparation of the polymer in quantity. In the first paper of this series[4] it was reported that heat caused polymerization of the acetal. It is now believed that the polymerization then noted was due to the acidity of the inner surface of the container in which the acetal was heated, since later experiments have shown that ketene acetal may be heated at 190–240° for six hours in *new* Pyrex tubes without any perceptible polymerization. Also, a sample of ketene acetal sealed in a new soft-glass container and kept in diffuse sunlight has remained clear and mobile after three years.

(4) Beyerstedt and McElvain, THIS JOURNAL, **58**, 529 (1936).

A search for other catalysts for this polymerization showed that benzoyl peroxide, which is such an efficient catalyst for the polymerization of many vinyl compounds, has no appreciable effect on ketene acetal, but that a number of metallic chlorides are very powerful catalysts for its polymerization. Barium, mercury and calcium chloride are least effective. In the order of increasing effectiveness as catalysts to transform ketene acetal into an immobile gel are the chlorides of nickel, cobalt, cadmium, zinc, iron, and aluminum. The cobalt and cadmium chlorides cause eventual polymerization to a white solid, but the cobalt polymer becomes discolored after twelve to twenty-four hours. The polymers obtained from nickel, zinc, iron, and aluminum are pasty products which rapidly turn brown or red. The most satisfactory polymer is that obtained with cadmium chloride, and all of the work which is now reported was done with this polymer.

The addition of a trace (6 mg. per 10 g. of acetal) of cadmium chloride to ketene acetal transforms it in a few hours, without any marked thermal effect, into a white, wax-like solid which contains about 45% of unpolymerized ketene acetal. The removal of the monomer by heating (100°) under reduced pressure (0.5 mm.) leaves the polymer as a perfectly dry, white powder. The carbon and hydrogen content of this polymer is practically the same as for ketene acetal; the ethoxyl value is slightly lower than that found for the monomer. The polymer is insoluble in all organic solvents, although ketene acetal and the aromatic hydrocarbons produce a noticeable swelling. The dry polymer is quite stable to heat, showing no evidence of decomposition at temperatures up to 200°. It is completely stable to alkali and is recovered without any apparent change after treatment with boiling 10% sodium hydroxide solution. The polymer is, however, very sensitive to acids. It slowly turns to a brownish-red powder when allowed to stand in the laboratory air for twenty-four hours. Dilute acids at room temperature convert it at once to a red oil which is insoluble in water. Refluxing the polymer with dilute acid converts it to a reddish-black oil which solidifies, on cooling, to a brittle glass. Both of these red polymers are alkali-soluble but are quite insoluble in other solvents. The difference between them appears to be in the extent to which ethoxyl groups have been removed by hydrolysis.

It seemed likely from previous work on unsymmetrically substituted ethylenes[5] that ketene acetal would polymerize in a "head to tail" manner. This supposition was supported by the properties of the red product obtained from the acid hydrolysis of the polymer. The color and alkali solubility of this product indicate a poly-1,3-diketone in an enolic, and hence highly conjugated, form. An unsuccessful attempt to obtain such a poly-1,3-diketone from poly-dichloroethylene has been reported.[6] This type of polyketone was undoubtedly obtained by Marvel and Denoon[5a] as the oxidation product of polyvinyl alcohol with dichromate. Although they did not isolate the polyketone they did obtain acetone from the alkaline hydrolysis of it.

The simplest representations of the white and red polymers from ketene acetal, on the basis of a "head to tail" union, are I and IV. In I and the

$$CH_3C(OEt)_2[-CH_2C(OEt)_2]_n-CH_2C(OEt)_3 \xrightarrow{H^+ + H_2O}$$

I

$$CH_3CO[-CH_2CO]_n-CH_2COOEt \longrightarrow$$

II

$$CH_3CO\left[-CH=\overset{\displaystyle OH}{\overset{|}{C}}-\right]_n-CH_2COOEt \longrightarrow$$

III

$$CH_3CO\left[-CH=\overset{\displaystyle OH}{\overset{|}{C}}-\right]_n-CH_3 + CO_2$$

IV

intermediate compounds, II and III, the ends of the chain are shown completed by the addition of a molecule of alcohol. It is seen that I has a saponifiable end-group, but attempts to estimate n by saponification equivalents were unsatisfactory. The values of the equivalents obtained ranged from 1600 to 3000 and this, together with the fact that the polymer remained insoluble in alcoholic alkali, indicated that adsorption of varying amounts of alkali on the polymer, rather than saponification, had occurred. However, the values obtained from the amount of carbon dioxide evolved during the acid hydrolysis of I to the polyketone (IV) were quite consistent and indicated a molecular weight of 2600–2700 for I. Such molecular weights show n in formula I to be 20–21. Since linear polymers in this range of polymerization are generally soluble in some of the organic solvents, the value of n as determined from the carbon dioxide evolved from the hydrolysis of I

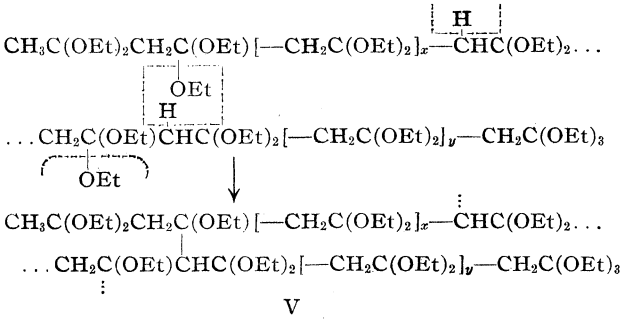
must be considered as a measure of the average length of unit chains that have undergone cross-linking. The nature of this cross-link has not been determined, but it is quite likely that it results from inter-unit loss of alcohol in some such manner as



V

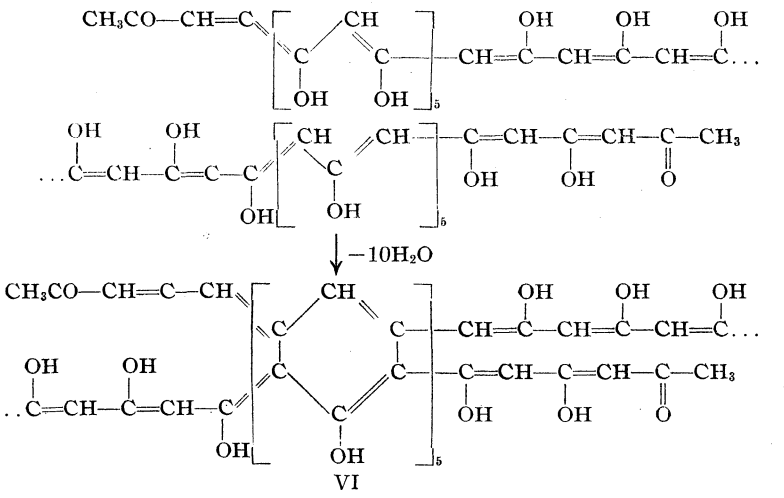
The amount of cross-linking per unit chain is not known but it cannot be very extensive because the ethoxyl content of the polymer (V) is very little lower than that of ketene acetal itself.

Approximate confirmation of the molecular weight of I as calculated from its yield of carbon dioxide was obtained from the other hydrolysis product, the red polymer. The carbon and hydrogen analyses of this polymer suggest an empirical formula of $C_{45}H_{38}O_{17}$, instead of $C_{45}H_{48}O_{22}$ which IV would have if n is 21. This indicates that the red polymer is composed of units of IV cross-linked by bonds resulting from the loss of an average of five molecules of water per unit of IV as in VI. It is unlikely that the end methyl groups in IV are involved in this cross-linkage. If this is the case, the red polymer would yield, on vigorous oxidation, two molecules of acetic acid for each unit of IV and for each molecule of carbon dioxide that had been obtained from the white polymer. On the basis of the empirical formula, $C_{45}H_{38}O_{17}$, 425 g. of the red polymer would be expected to produce 1 mole of acetic acid.

An alkaline solution of the red polymer was attacked rapidly by potassium permanganate and completely oxidized (to a permanent permanganate color) at 100°. On acidification 80% of the carbon of the polymer was evolved as carbon dioxide. Determinations of the acetic acid formed in a number of these oxidations gave values between 558 and 645 as the number of grams of polymer necessary to produce 1 mole of acetic acid. Considering the experimental errors involved in the determination, these results represent maximum values and are sufficiently close to the theoretical value of 425 to lend support to the molecular weight of I as determined by hydrolytic decarboxylation.

Attempts to obtain a neutral equivalent of the red polymer were unsuccessful. The usual colorimetric methods, of course, were not applicable and a potentiometric titration of an alkaline solution of the polymer using an antimony–antimony-oxide electrode gave a titration curve which showed no definite break except at the point of complete precipitation of the polymer.

The red polymer that was obtained by the hydrolysis and decarboxylation of I was very resistant to further hydrolysis. Heating in a bomb at 200° in 10% sulfuric acid for seven hours gave a trace of acetone and some acetic acid. When it was heated with 5% aqueous sodium hydroxide at 240° for twenty-two hours, acetone together with a considerable quantity of acetic acid was obtained. Acidification of the alkaline solution gave a reddish-black precipitate, the analysis of which showed an increase in the ratio of carbon to hydrogen and oxygen over that present in the original red polymer.



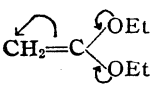
VI

The formation of acetone and acetic acid together with the higher ratio of carbon to hydrogen and oxygen in the polymer remaining after the drastic alkaline hydrolysis of VI suggest that this hydrolysis involves the cleavage of side chains from the cyclic nuclei of VI.

That the color of the red polymer is due to its high conjugation, which is most simply illustrated by the cross-linking of two chains of IV in VI, is shown by the fact that the color can be removed by hydrogenation. This hydrogenation was carried out on an alkaline solution of the polymer, with Raney nickel as the catalyst, at 225° and under 200 atmospheres of pressure. After an initial absorption of hydrogen the reduction stopped due to a coating of a tarry material on the catalyst. The red color of the solution remained but it was finally removed by separating the deactivated catalyst and continuing the reduction with fresh Raney nickel. Acidification of the resulting alkaline solution gave a tan-colored precipitate which amounted to about 12% of the weight of the red polymer taken for hydrogenation. From the filtrate ethyl alcohol and acetic acid could be distilled. Evaporation of the solution left a dark, viscous, alcohol-soluble oil which was not investigated further.

The results described above leave no doubt that, in the main, the ketene acetal polymers are built up by a "head to tail" linking of the monomer. This is further substantiated by the fact that nitric acid completely oxidizes the red polymer without leaving a trace of residue, a fact that shows there is no "head to head, tail to tail" linkage present, since this type of structure would be expected to leave succinic acid on such oxidation.

The mechanism by which ketene acetal undergoes polymerization is suggested by its structure. It is an unusual hetero-enoid system[7] in that two very effective hetero atoms, oxygen, are attached to the same unsaturated carbon atom. The anionoid center which is built up on the methylene carbon by the electromeric shifts from the hetero atoms, thus



is very powerful as is shown by the readiness with which ketene acetal adds compounds of the type of water, alcohol, acids, etc., which are capable of furnishing such a cationoid addendum as a proton. If the negative portion of the addendum (*e. g.*, :OH, :OEt, :Br, RCOO:, etc.) is sufficiently mobile it will add to the carbon atom that carries the hetero atoms. If, however, there is no mobile anion (as in the case of the acidified glass surfaces) or if the highly polarized methylene group of the acetal can coördinate with a metal, such as cadmium chloride, a chain reaction may be initiated and propagated in the following manner[8]:

Addition of the proton and the ethoxyl group from a molecule of alcohol to the ends of the polymer chain would release the catalyst from the methylene group and saturate the carbon atom at the other end of the chain.

The Dimer and Trimer of Ketene Diethylacetyl.—When ketene acetal was polymerized with a larger amount of catalyst (36 mg. per 10 g. of acetal) the reaction was very vigorous and the temperature rose sufficiently to cause refluxing of the acetal. The polymer so obtained was a soft gel from which a number of products were removed by distillation under diminished pressure. Up to 100° (0.5 mm.) a mixture of ketene acetal and ethyl orthoacetate, representing 8–15% of the weight of the starting material, distilled. Between 100–130° (0.5 mm.) a product, amounting to about 13% of the starting material and which proved to be a dimer of ketene acetal, came over. At 150–160° (0.5 mm.) another liquid product, amounting to about 20% of the original ketene acetal distilled; also a small amount of ethyl alcohol collected in a cold trap during the distillation of this higher boiling product. The residual polymer is a dry, light tan solid, the properties of which were quite similar to those of the white polymer described above.

The dimer of ketene acetal could not be obtained analytically pure. Although fractionation yielded a product with a constant boiling point and refractive index, the ethoxyl content was generally 2–3% lower than the theoretical value for VII. Work with this dimer was hampered by its tendency to lose alcohol on standing.[9] Freshly prepared samples showed molecular weights of 207–212 as determined by the freezing point of benzene (theoretical for VII, 232) and saponification equivalents of 217–239. Hydrolysis of the dimer by dilute acid yielded acetone and treatment with 95% alcohol containing a trace of hydrochloric acid, converted it, practically quantita-

(8) Only one chain of ketene acetal molecules is shown coördinated with cadmium chloride; obviously two such chains would be required to give the metal a complete octet of electrons.

(9) For example, one sample showed an ethoxyl content of 74.2% immediately after distillation, but a month later this sample contained only 63.0% ethoxyl.

tively, into acetoacetic ester. It absorbed bromine rapidly. All of these properties are readily explained by structure VII.[10]

XI

The fraction boiling at 150–160° (0.5 mm.) proved to be a mixture of the open chain trimer (VIII) and at least one other product. Fractionation failed to give a product with a constant refractive index although the product boiled over a rather narrow range. Ethoxyl determinations showed that successive fractions had approximately the same composition as ketene acetal. Cryoscopic methods and saponification equivalents gave widely varying values for the molecular weight. When a portion of this fraction was heated with 5% sulfuric acid, a small amount of a solid steam distilled. This product was shown to be 1,3,5-triethoxybenzene (IX). It seems likely that it was formed by the loss of alcohol from the cyclic trimer 1,1,3,3,5,5-hexaethoxycyclohexane (X) during the distillation of the trimer fraction, since alcohol appeared in the cold trap as this fraction was collected. The possibility that IX is formed by cyclization of the open chain trimer (VIII) was shown to be unlikely by the fact that fractions which were known to contain at least 50% of this trimer could not be converted to IX by heating for two hours at 180°.

When the trimer fraction was treated with 95% alcohol containing a trace of acid it was converted into ethyl γ-acetoacetoacetate (XI), which was characterized as the copper derivative and as the lactone of γ-acetoacetoacetic acid. An estimate of the amount of the trimer VIII that was present in the fraction was obtained by distillation under atmospheric pressure of the ethyl acetoacetoacetate formed from the trimer. Acetylacetone was formed by this distillation and the amount collected indicated that the trimer fraction was at least 50% of the open chain trimer VIII.

It should be mentioned that the dimer and trimer of ketene acetal are formed concurrently with the polymer and are not pyrolysis products of it. This is shown by the fact that the polymer prepared from a trace of cadmium chloride may be heated at 155° and under 0.5 mm. pressure for several hours without yielding any distillate. It is believed that the higher temperatures produced by the rapid polymerization of ketene acetal interrupt some of the reaction chains so that considerable amounts of the dimer and trimer are formed along with the polymer.

Substituted Ketene Acetals.—In contrast to the ease with which ketene acetal undergoes polymerization, the halogenated ketene acetals[11] do not polymerize. Samples of these compounds stored in ordinary glass bottles in diffuse daylight are, after eighteen months, clear and mobile. Neither the mono- or dichloro-ketene acetals nor the corresponding bromo compounds showed any tendency to polymerize with cadmium, cobalt or iron chloride. A sample of chloroketene acetal was heated with cadmium chloride at 110° for seventy hours without any apparent change. Another sample of this acetal, after heating for eighteen hours with benzoyl peroxide, still reacted as vigorously with water as did the original material. Boron trifluoride and the boron trifluoride–ether complex react with chloroketene acetal to produce a mobile red oil, but no material of a high polymer nature could be obtained by prolonged heating with this catalyst.

Experimental

Ketene Diethylacetal.—The ketene acetal used in this work was prepared by the action of potassium *t*-butoxide on bromoacetal[12] instead of iodoacetal which was used in the first paper[4] of this series. To 550 g. of *t*-butyl alcohol in a 1-liter round-bottom flask, with a small side tube and reflux condenser fitted with a calcium chloride tube, was added 39 g. (1 atom) of potassium. The alcohol was refluxed until all of the potassium had dissolved (about twelve hours). Then 198 g. (1 mole) of bromoacetal was added to the *t*-butyl alcohol solution and the resulting solution refluxed for about five hours. Without attempting to remove the precipitated potassium bromide, the reaction mixture was fractionated through an 18-in. (46-cm.) Vigreux column, equipped with a total-reflux, partial take-off distilling head and the *t*-butyl alcohol slowly distilled from an oil-bath at a reflux ratio of about 8:1.

(10) The possibility of this dimer being 1,1,3,3-tetraethoxycyclobutane was considered, but the marked unsaturation of the dimer and the apparent tendency of the cyclic trimer to lose alcohol seemed to support the open chain formula (VII).

(11) Beyerstedt and McElvain, THIS JOURNAL, **59**, 2266 (1937); Magnani and McElvain, *ibid.*, **60**, 2210 (1938).

(12) Filachione, *ibid.*, **61**, 1705 (1939).

When the alcohol ceased distilling at a bath temperature of 125° the pressure was lowered to 200 mm. and the remainder of the alcohol removed at 50–52°. A small amount of intermediate was followed by the distillation of ketene acetal at 83–85° (200 mm.). When an ebullition tube was used during the distillation nitrogen, rather than laboratory air, was drawn through it. The yield of ketene acetal amounted to 70 g. (60% of the theoretical).

Determination of Ethoxyl in Ketene Acetals.—In the past, attempts to apply the Viebock ethoxyl technique to ketene acetals have not been very successful. The results not only have been low, but have varied over a wide range. With ketene acetal and compounds derived from it satisfactory results were never obtained, while with the halogenated ketene acetals it was only by the most careful manipulation that acceptable analyses were made. The difficulty appeared to be due to the rapid hydrolysis of the acetals by the hydriodic acid and loss of ethyl alcohol before it was converted into ethyl iodide. The suggestions of Elek[13] improved the results somewhat but consistently accurate analyses could not be obtained even with these refinements in technique.

It was found necessary to redesign the apparatus so that any alcohol produced by the rapid hydrolysis of the sample could not escape from the reaction chamber without passing through boiling hydriodic acid. The apparatus that was found to give the best results is shown in Fig. 1. Flask A (25 ml.) was charged with 10 ml. of hydriodic acid (sp. g. 1.7), a few crystals of phenol, and about 40 mg. of red phosphorus; flask B (25 ml.) was charged with 2 ml. of hydriodic acid and 20 mg. of red phosphorus; a 5% cadmium sulfate–sodium thiosulfate solution was used in the scrubber C; in the absorption tube D was placed 10 ml. of a 10% solution of sodium acetate in acetic acid, to which 15–30 drops of bromine (approximately 20 drops for every 15 mg. of ethoxyl in the sample) had been added; in the tube E was placed 5 ml. of the acetate–acetic acid solution and about 5 drops of bromine. Before the start of the determination the acid in flask B was heated to gentle refluxing, and a slow stream of carbon dioxide allowed to pass through the system. The sample (15–30 mg.) was weighed into a small glass cup with ground in stopper and dropped into the reaction flask A at room temperature. The flask was reconnected to the apparatus as quickly as possible, and then slowly heated to gentle refluxing. Heating was continued for thirty minutes with a slow stream of carbon dioxide, and for fifteen to thirty minutes with a faster flow of the gas to carry the last traces of the ethyl iodide into the absorbent. The tubes D and E were then removed and their contents washed into an Erlenmeyer flask for the iodometric titration.

This apparatus has been found to give very satisfactory results with compounds related to ketene acetal. However, ketene acetal itself gave consistent values of 76.6% ethoxyl (77.6% is theoretical) regardless of the method of preparation of the compound or wide variations in technique of the determination.

Polyketene Diethyl Acetal.—To 83 g. of freshly distilled ketene acetal was added 50 mg. of powdered cadmium chloride and the polymerization allowed to proceed

(13) Elek, *Ind. Eng. Chem., Anal. Ed.*, **11**, 174 (1939).

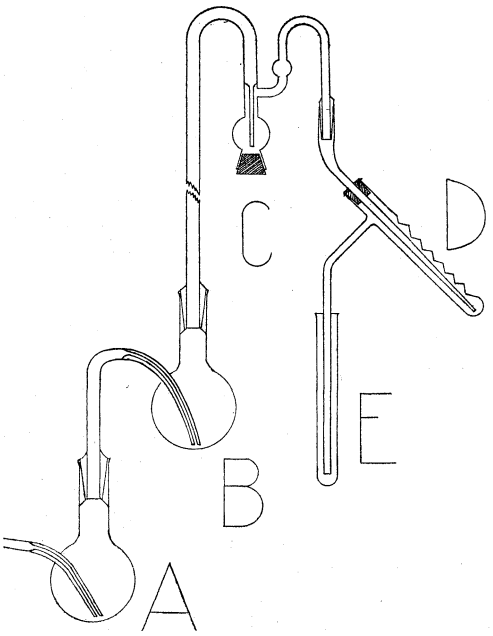

Fig. 1.

with occasional shaking. Several hours were required to reach the gel stage, after which the polymer was stirred to distribute the catalyst through the gel. After standing overnight the polymer was a waxy white solid. It was transferred to a distilling flask and heated in an oil-bath at 100° (0.5 mm.) for two hours. During this time 37 g. of ketene acetal collected in a carbon dioxide snow–acetone trap. The remaining polymer was a white powder

Anal. Calcd. for $(C_6H_{12}O_2)_x$: C, 62.02; H, 10.41; OC_2H_5, 77.6. Found: 62.19, 9.85, 76.3.

That the large recovery of ketene acetal is not due to depolymerization is shown by the fact that the monomer could be recovered from the polymer just as well by extraction in a soxhlet extractor with ether as by heating under diminished pressure. Also, heating the remaining polymer for one hour at 155° (0.5 mm.) gave no distillate, while heating at 210° (0.5 mm.) for one and one-half hours gave only a small amount of ethyl alcohol as a distillate.

When the dry polymer was heated at 250° (0.5 mm.) a fairly rapid decomposition took place and ethyl alcohol amounting to 27% of the weight of the original polymer was obtained as a distillate. The material remaining in the flask after this pyrolysis was an acetone-soluble, viscous, red tar.

The white ketene acetal polymer is insoluble in all of the common organic solvents including aniline, anisole, nitrobenzene, acetal and ketene acetal. The latter liquid and the aromatic hydrocarbons caused a noticeable swelling of the polymer. It is remarkably stable to alkali, remaining apparently unchanged after refluxing with a 10% aqueous solution of sodium hydroxide. It is, however, extremely sensitive to acids, being converted into a red oil immediately by aqueous acids. Refluxing with acid gives the red polymer described below.

Hydrolytic Decarboxylation of Polyketene Acetal.—A weighed sample of the polymer was placed in a 50-ml.

flask having a side arm and attached through a reflux condenser to a carbon dioxide absorption train. To the polymer was then added 25 ml. of a carbon dioxide-free 5% aqueous solution of sulfuric acid and the acid refluxed, with a stream of nitrogen passing through the system, until the ascarite tube in the absorption train attained constant weight. The unit weight of the polymer was calculated on the basis that one polymer unit would produce one molecule of carbon dioxide. Table I shows the data from two representative runs.

TABLE I

Sample, g.	CO_2, g.	Unit wt. of polymer calcd.
3.0464	0.0510	2628
3.1919	0.0515	2727

Hydrolysis of Polyketene Acetal. The Red Polymer.—Polyketene acetal (30 g.) was refluxed for half an hour in 50 ml. of 0.3 *N* sulfuric acid. The mixture was then cooled and the supernatant liquid poured from the viscous red precipitate. The precipitate was treated with 100 ml. of distilled water and the water refluxed for a few minutes, after which it was decanted into the original sulfuric acid solution. After cooling and solidifying the red polymer was ground to a fine powder, washed onto a filter and dried. The yield amounted to 8.9 g.

The aqueous acid solution, obtained by the two decantings, contained some of the red polymer in colloidal suspension. This solution was distilled until 100 ml. of distillate had been collected. The density of this distillate indicated that it contained about 24 g. of ethyl alcohol (theoretical for the amount of polyketene acetal used, 23.3 g.). The distillation of the alcohol caused the suspension of the red polymer to precipitate. By filtration an additional 1.1 g. of this product was obtained, which brought the total yield to 10 g. (theoretical, 11.4 g.).

Anal. Calcd. for $(-CH_2CO-)_x$: C, 57.2; H, 4.76. Found: C, 63.6; H, 4.49. Calcd. for $C_{45}H_{38}O_{17}$: C, 63.5; H, 4.47.

The red polymer is sufficiently soluble in alcohol and acetone to give a light red solution, but it is insoluble in ether, chloroform and benzene. It dissolves readily in dilute alkali to give a deep red, almost black solution from which it is not precipitated by saturation with carbon dioxide. Acidification of the alkaline solution precipitates the polymer as a gelatinous brownish-red precipitate. When heated to 60–70° the red polymer softens and changes to a viscous, dark red oil.

Oxidation of the Red Polymer.—A weighed sample of the solid red polymer was dissolved in 50 ml. of 0.1 *N* sodium hydroxide and carefully washed into a reaction flask which was connected through a reflux condenser to a carbon dioxide absorption train. The solution was heated to boiling and then a 1 *N* solution of potassium permanganate was added in portions from a buret until a permanganate color at 100° persisted for fifteen minutes. The oxidation required about ninety minutes. The mixture then was cooled and 50 ml. of 10% sulfuric acid added. The acidified solution was boiled to expel the carbon dioxide while the system was swept out with nitrogen. The acidified solution was centrifuged and the supernatant liquid decanted from the manganese dioxide which was washed with water and recentrifuged until the washings were neutral to litmus. The washings and original solution were combined and distilled until only 50 ml. remained. The distillate was titrated with standard alkali. Portions of water were added to the residue from the distillation and distilled out until negligible titration was obtained. Acetic acid was shown to be the acid present in the distillate by its Duclaux numbers and the melting point of its *p*-toluidide. Table II shows the results of two such oxidations.

TABLE II

Sample g.	1 *N* $KMnO_4$ used, ml.	CO_2, g.	Millimoles of acetic acid	Polymer per mole acetic acid, g.
0.6836	105	1.2898	1.2238	558
0.4442	68	0.8734	0.6879	645

A 2-g. sample of the white polyketene acetal was hydrolyzed by boiling with 50 ml. of 1% nitric acid. The alcohol formed was removed by distilling out one-half of the solution. The remainder of the solution which contained the red polymer was treated with 5 ml. of concentrated nitric acid and evaporated to dryness on a steam-bath. The black residue was treated with concentrated nitric acid until its color was destroyed. At this point no residue whatsoever remained.

Hydrolysis of the Red Polymer.—After heating the polymer in a sealed tube with 10% sulfuric acid at 200° for seven hours, 85% of it was recovered. The acid solution contained a trace of acetone and some acetic acid. Alkaline hydrolysis was much more satisfactory. A solution of 2 g. of the polymer in 60 ml. of 5% sodium hydroxide was placed in a steel bomb and heated at 240° for twenty-two hours. The hydrolysis solution then was washed into a distilling flask and about one-third of its volume distilled out. Acetone was determined quantitatively in this distillate as the 2,4-dinitrophenylhydrazone, and also by the procedure of Marasco.[14] The two procedures checked and showed the total yield of acetone from the hydrolysis to be 0.08 g.

Acidification of the reddish-black solution, remaining after the removal of the acetone, with dilute sulfuric acid precipitated 1.0 g. of a black substance which contained 73.9% of carbon and 4.6% of hydrogen. The acid solution was distilled, as described above, until all of the acetic acid had been removed. Titration with standard alkali showed that the distillate contained 0.35 g. of acetic acid. It was further identified as the *p*-toluidide.

Hydrogenation of the Red Polymer.—A solution of 11 g. of the red polymer in 100 ml. of 1% sodium hydroxide was refluxed for a short time over Raney nickel, which had been freed from the alcohol under which it was stored by several washings with distilled water. After cooling, the solution was decanted from the nickel and made up to 250 ml. with water that had been used to wash the nickel. This solution, together with 3 g. of washed Raney nickel, was placed in a bomb and shaken with hydrogen under 3500 lb. (233 atm.) pressure at 225° for five and one-half hours. During this time 26 (±2) moles of hydrogen were absorbed on the basis of a molecular weight of 850 (calcd. for $C_{45}H_{38}O_{17}$). The alkaline solution was still red in color

(14) Marasco, *Ind. Eng. Chem.*, **18**, 701 (1926).

and the catalyst was coated with about 1.2 g. of an acetone-soluble tar. This deactivated catalyst was replaced with fresh catalyst and the hydrogenation continued under the same conditions for another five hours. A small amount of additional hydrogen was absorbed, and the alkaline solution was no longer red, but was yellow with a green fluorescence. From this alkaline solution 0.8 g. of ethyl alcohol was distilled. Acidification of the remaining solution gave a precipitate of 1.4 g. of a tan-colored solid. This product was not investigated further. From the acidified solution 0.54 g. of acetic acid was removed by distillation. After removal of the acetic acid the solution was evaporated at 200 mm. and the residue extracted with alcohol. This alcoholic solution on evaporation left 0.8 g. of a dark, viscous oil.

The Dimer and Trimer of Ketene Acetal.—To 74 g. of freshly distilled ketene acetal was added 300 mg. of cadmium chloride. Polymerization was very rapid and the temperature of the reaction was sufficient to cause refluxing of the ketene acetal. In fifteen minutes after the addition of the catalyst the acetal became a moist solid. After standing overnight, the flask containing the polymer was attached, through a condenser, receiver and cold trap, to a vacuum pump and heated in an oil-bath under 0.5 mm. pressure. The fractions were collected at the bath temperature, in the amounts and in the places as shown in Table III.

TABLE III

Fraction	Bath temp., °C.	Wt., g.	Collected in
1	to 25°	2.4	Trap
2	102–108	3.65	Trap
3	102–108	4.35	Receiver
4	108–130	5.35	Receiver
5	152–159	1.80	Trap
6	152–159	15.00	Receiver

Fractions 1 and 2 were mixed and fractionated and shown to be a mixture of ketene acetal and ethyl orthoacetate. Fraction 3 was fractionated through an 8-in. (21-cm.) Stedman column and yielded 2.45 g. of material boiling at 61–62° (0.5 mm.). By a similar fractionation 2.75 g. of material of the same boiling point was obtained from fraction 4. This material contained the dimer of ketene acetal, the characterization of which is described below. Fraction 5 proved to be ethyl alcohol. Fraction 6, after the removal of a small amount of impure dimer and an intermediate fraction, yielded 12 g. of a product boiling at 91–92° (0.1 mm.) which is discussed below.

The fraction that boiled at 61° (0.5 mm.) showed an ethoxyl content of about 75% (the ethoxyl content of ketene acetal and its dimer (VII) is 77.6%); $n^{25}D$ 1.4258 for the first and last portions of the fractions; d^{25}_4, 0.9441; mol. wt. (freezing point of benzene), 207, 212; saponification equivalents varied from 217 to 239 (calcd. value for VII, 232). A sample of this fraction that had been opened from time to time was found, after a month, to have an ethoxyl content of 63%. This lower ethoxyl value may be due to intramolecular loss of alcohol or partial hydrolysis of an acetal group by moisture from the air. No attempt was made to ascertain which of these processes is responsible for the instability of the dimer fraction. Hydrolysis of a portion of this fraction with aqueous 5% sulfuric acid yielded acetone which was characterized as the 2,4-dinitrophenylhydrazone.

A 0.86-g. sample of this fraction was treated with 2 ml. of 95% alcohol containing a trace of hydrochloric acid and the resulting solution heated on a steam-bath under a reflux for ten minutes. The alcohol was removed under diminished pressure and the remaining acetoacetic ester (0.39 g.) was characterized as the semicarbazone, m. p., 129–130°.[15] The dimer does not add absolute alcohol. A 1.0-g. sample of it was allowed to stand with 2 ml. of absolute ethyl alcohol for forty-eight hours. After evaporation of the alcohol under diminished pressure and with a stream of dry nitrogen passing through the liquid, the remaining oil had the same refractive index and ethoxyl content as the starting material. Repetition of the experiment with a trace of hydrogen chloride in the alcohol led to the same results.

The fraction boiling at 91–92° (0.1 mm.), which was obtained from fraction 6 above, had an ethoxyl content of 76% (the ethoxyl content of ketene acetal and its trimer (VIII) is 77.6%). However, the refractive indices of the first and last portions of this fraction varied between 1.4414 and 1.4400. When 2.8 g. of this fraction was refluxed with 3% sulfuric acid for thirty minutes and the resulting mixture distilled, an oily substance, which crystallized on cooling in an ice-bath, came over with the aqueous distillate. After filtration and recrystallization from alcohol, the solid weighed 0.1 g., melted at 43.5°, and contained 64.2% ethoxyl. It was shown to be 1,3,5-triethoxybenzene (% ethoxy, 64.3) by comparison with an authentic specimen prepared by the method of Will and Albrecht.[16]

A 3.2-g. sample of the fraction boiling at 91–92° (0.1 mm.) was treated with 7 ml. of 95% alcohol containing a trace of hydrochloric acid. After standing overnight the excess alcohol was removed under diminished pressure and the remaining oil distilled. It boiled at 87–90° (0.4 mm.) and showed an ethoxyl content of 40.0%. A 0.3-g. portion of this distillate was boiled for a few minutes in 0.3 *N* sulfuric acid and then poured into a saturated solution of copper acetate. The copper derivative which formed immediately was filtered off and dried. It weighed 0.1 g. This blue derivative was suspended in boiling benzene for a few minutes, then filtered and dried. It melted at 183–184°[17] and contained 22.6% ethoxyl (calcd. for the copper derivative of γ-acetoacetoacetic ester, $Cu{\cdot}C_{16}H_{22}O_8$: 22.2%).

Six drops of the trimer fraction were added to 0.5 ml. of 70% sulfuric acid and the mixture warmed to 80° for five minutes. After standing without further heating, for an additional fifteen minutes, an equal volume of water was added. Cooling precipitated the lactone of γ-acetoacetoacetic acid which, after recrystallization from water, melted at 185–187°.[18]

A 1.95-g. portion of the trimer fraction boiling at 91–92° (0.1 mm.) was refluxed with 0.3 *N* sulfuric acid for twenty minutes. After cooling, the mixture was extracted with ether and the ether layer separated and dried. The ether

(18) Collie, *ibid.*, **59**, 609 (1891).

was removed by distillation and the remaining brown liquid heated with a free flame, under atmospheric pressure, until it distilled. Decomposition accompanied the distillation of a yellow oil which came over at 130–140°. The yield of this oil amounted to 0.25 g. and it was shown to be acetylacetone by its conversion to 1-(2,4-dinitrophenyl)-3,5-dimethylpyrazole, m. p. 121–122°, and the comparison of this derivative with an authentic specimen.[19] The 0.25 g. yield of this diketone indicates that the trimer fraction contained at least 50% of the straight chain trimer VIII.

The boiling point of the trimer fraction as well as its content of 1,3,5-triethoxybenzene remained unchanged after a sample of this fraction had been heated at 180° under atmospheric pressure for two hours.

Summary

1. Evidence is presented to show that ketene acetal is converted by cadmium chloride into a white polymer composed of chains having, on an average, 22–23 ketene acetal molecules joined in a head to tail manner. The insolubility of the polymer suggests cross-linking of these chains.

2. The white polymer is converted by acid hydrolysis into an alkali soluble red polymer composed of cross-linked poly-1,3-diketone units which exist in a highly conjugated, enolic form. Molecular weight estimation of this polymer from an end group corresponds fairly well with a similar estimation of the molecular weight of the white polymer.

3. Rapid polymerization of ketene acetal by larger amounts of cadmium chloride produces an open chain dimer and trimer together with 1,3,5-triethoxybenzene. The latter product probably is formed from the cyclic trimer, 1,1,3,3,5,5-hexaethoxycyclohexane.

4. Halogenated ketene acetals cannot be caused to polymerize.

5. An improved method for the preparation of ketene acetal from bromo-acetal is described.

6. The construction and operation of a new apparatus for the determination of the ethoxyl content of the types of acetals encountered in this work are described.

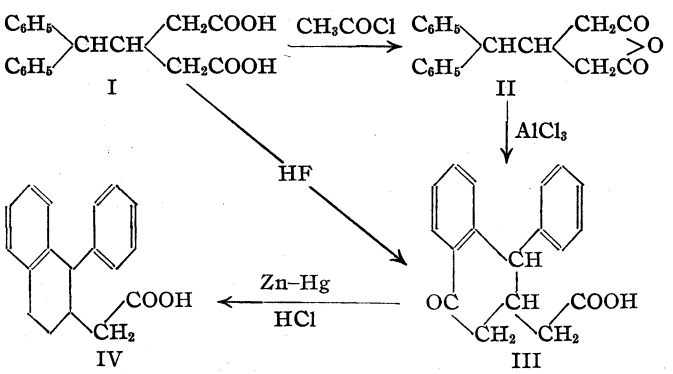
The Synthesis of 2-Methyl-3,4-benzphenanthrene

BY MELVIN S. NEWMAN[1] AND LLOYD M. JOSHEL[2]

Because of the interest in 3,4-benzophenanthrene as a structure possessed of carcinogenic activity, the previously reported synthesis[3] has been modified so that 2-substituted derivatives may be prepared. In this paper is described the synthesis of 2-methyl-3,4-benzphenanthrene[4] and 2-ethyl-3,4-benzphenanthrene.

In the earlier synthesis,[3] β-benzohydrylglutaric acid, I, after conversion to its acid chloride, was cyclized to 1,2,9,10,11,12-hexahydro-2,9-diketo-3,4-benzphenanthrene from which 2,9-disubstituted derivatives were prepared. The present modification consists in treating the anhydride, II, of β-benzohydrylglutaric acid with aluminum chloride whereby 1,2,3,4-tetrahydro-4-keto-1-phenyl-2-naphthaleneacetic acid, III, was isolated in 63% yield. The same keto-acid was obtained more easily in 89% yield by treatment of the acid, I, with anhydrous hydrogen fluoride.[5] By reduction III was converted into 1,2,3,4-tetrahydro-1-phenyl-2-naphthaleneacetic acid, IV.[4]



The remaining steps required for the synthesis of 2-methyl-3,4-benzphenanthrene and 2-ethyl-

3,4-benzphenanthrene are similar to those carried out by Hewett.[4]

In conclusion it seems of interest to point out that while 2-methyl-3,4-benzphenanthrene is a very potent carcinogenic agent when tested by painting on the skin,[6] it has proved to be only very slightly active when tested by the injection technique.[7] This finding serves to emphasize the differences in carcinogenic activity of hydrocarbons when estimated by the painting technique as compared to the injection technique. The present instance is one in which the compound is less active when tested by injection whereas in the case of 10-methyl-1,2-benzanthracene,[8] the activity measured by injection was greater than that measured by painting.[9] The following 3,4-benzphenanthrene derivatives have proved inactive when tested by injection[7]: 2,9-dimethyl-[3], 2,9-diethyl-[3], 6,7-dimethyl-[10] and 2-isopropyl-8-methyl-.[11]

Experimental[12]

β-Benzohydrylglutaric Acid, I.—After considerable experimentation the following procedure was found to yield the most consistent results. A solution of 50 g. of diphenylacetaldehyde in 150 cc. of ethyl cyanoacetate was treated with 5 cc. of diethylamine and allowed to stand in a stoppered flask for twelve hours at room temperature. The mixture was then heated for twelve hours on the steam-bath with the further addition of two 5-cc. portions of diethylamine. The resulting cloudy suspension was refluxed for sixty-two hours with a solution of 125 cc. each of water and concentrated sulfuric acid in 350 cc. of acetic acid. The organic acid fraction thus produced was isolated, decarboxylated by heating to 200°, and esterified with methanol and dry hydrogen chloride. A portion of the ester fraction, b. p. about 180° at 2 mm. was crystallized from aqueous methanol yielding colorless needles, m. p. 73.4–74.2°.

Anal. Calcd. for $C_{20}H_{22}O_4$: C, 73.60; H, 6.79. Found: C, 73.91; H, 6.90.

The remaining ester was saponified and 13.4 g. (17.6%) of acid, I, m. p. 172–175°, suitable for use in the next step, was obtained. The pure acid melted at 177.6–178.2°.[3]

1,2,3,4 - Tetrahydro - 4 - keto - 1 - phenyl - 2 - naphthaleneacetic Acid, III.—Twelve grams of the above acid was treated in a metal flask with 150 g. of anhydrous hydrogen fluoride[5] for nine hours at room temperature. The solution was poured on ice and the solids collected. The filtered carbonate extract of this material was acidified and the acid crystallized from benzene–ligroin to yield 9.3 g. of colorless needles, m. p. 115.4–116.2°, and 0.7 g., m. p. 113.0–114.5° (total 89%). The sample for analysis was crystallized from benzene and melted, after thorough heating *in vacuo*, at 115.4–116.2°.

Anal. Calcd. for $C_{18}H_{16}O_3$: C, 77.12; H, 5.75; neut. equiv., 280. Found: C, 77.43; H, 5.84; neut. equiv., 279.

The same acid was prepared in 63% yield from β-benzohydrylglutaric anhydride[3] using aluminum chloride in *sym*-tetrachloroethane solution.

1,2,9,10,11,12 - Hexahydro - 2 - keto - 3,4 - benzphenanthrene.—This compound was prepared either by Hewett's method[4] using *sym*-tetrachloroethane as solvent or by the use of anhydrous hydrogen fluoride,[5] the latter offering no advantage over the former.

1,2,3,4 - Tetrahydro - 1 - phenyl - 2 - naphthaleneacetic Acid, IV.—The keto acid, III, was converted in 74% yield into IV using Martin's modification of the Clemmensen reduction. Our purest sample melted at 140.2–140.8° (lit.[4] 138–139°).

2-Methyl-3,4-benzphenanthrene.—A solution of 1.9 g. of the above ketone in dry benzene was refluxed with an ether solution of methylmagnesium chloride for two and one-half hours. The crude alcohol was heated with 0.2 g. of palladium charcoal[13] for two hours at 290–320° (77% of the theoretical hydrogen collected). By crystallization of the picrate followed by chromatographic adsorption on alumina, there was isolated 1.11 g. (60%) of 2-methyl-3,4-benzphenanthrene, m. p. 69.6–71.0°. The hydrocarbon was recrystallized from benzene–methanol, separating as almost colorless needles, m. p. 70.4–71.0° (lit.[4] leaflets, m. p. 69.5–70.0°). The picrate formed bright orange-red needles, m. p. 141.8–143.2°, from benzene–alcohol.

Anal. Calcd. for $C_{25}H_{17}O_6N_3$: C, 65.93; H, 3.76; N, 9.23. Found: C, 66.11; H, 3.99; N, 9.35.

2-Ethyl-3,4-benzphenanthrene.—A benzene solution of 1.0 g. of 1,2,9,10,11,12-hexahydro-2-keto-3,4-benzphenanthrene was refluxed with an excess of ethylmagnesium bromide, the alcohol thus produced dehydrated by heating with a crystal of iodine, and the tetrahydro derivative aromaticized by heating with 0.26 g. of sulfur at 230° for forty minutes. The distilled crude hydrocarbon was treated with 1 g. of picric acid in benzene–alcohol. A total of 1.00 g. (51%) of picrate, m. p. 78.4–80.0°, was obtained. A portion recrystallized for analysis melted at 80.0–81.0°.

Anal. Calcd. for $C_{26}H_{19}O_7N_3$: C, 64.33; H, 3.95; N, 8.66. Found: C, 64.31; H, 3.78; N, 8.38.

By chromatographic adsorption on alumina, the hydrocarbon was obtained and distilled. Considerable difficulty in crystallization was encountered but by cooling a methanol solution with solid carbon dioxide, seed crystals were obtained. **2-Ethyl-3,4-benzphenanthrene** crystallized from alcohol in colorless needles, m. p. 50.4–51.2°, and had a blue–violet fluorescence in ultraviolet light.

Anal. Calcd. for $C_{20}H_{16}$: C, 93.71; H, 6.29. Found: C, 93.57; H, 6.16.

Summary

The preparation of 1,2,3,4-tetrahydro-4-keto-1-phenyl-2-naphthaleneacetic acid by ring closure of β-benzohydrylglutaric anhydride using aluminum chloride or by direct cyclization of β-benzohydrylglutaric acid using anhydrous hydrogen fluoride is described. The keto group of this keto acid was reduced by the Clemmensen method and the reduced acid cyclized to 1,2,9,10,-11,12-hexahydro-2-keto-3,4-benzphenanthrene. By reaction with the appropriate Grignard reagents followed by dehydration and dehydrogenation 2-methyl-3,4-benzphenanthrene and 2-ethyl-3,4-benzphenanthrene were prepared from the above hexahydroketone.

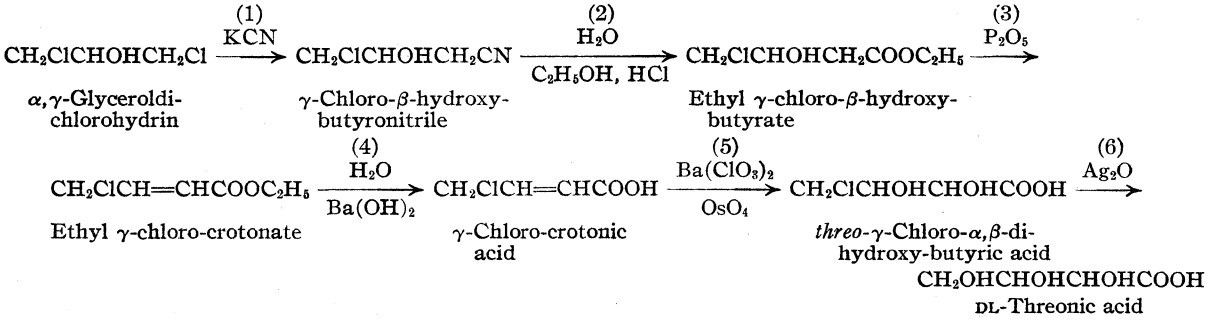
Improvements in the Preparation of DL-Threonic and DL-Erythronic Acids

BY J. W. E. GLATTFELD AND EDWARD RIETZ[1]

The reason for the interest in the two acids mentioned in the title of this article has been recorded several times.[2,3] Briefly, the acids are possible sources of the DL-aldotetroses. These are needed for a proposed study of the saccharinic acid rearrangement of the tetroses which it is hoped to make in these laboratories. Because of the availability of DL-erythronic lactone, definite progress has been made in devising a procedure for its transformation into DL-erythrose.[2] The difficulty of the preparation of DL-threonic acid, however, has prevented corresponding progress with this substance. The main object of the work reported below, therefore, was the simplification and improvement of the known procedure for the preparation of DL-threonic acid.[4] Incidentally, the method of preparation of DL-erythronic lactone was also much improved by the use of vinylacetic acid, an intermediate in the preparation of DL-threonic acid.

DL-Threonic Acid.—The only recorded synthesis of DL-threonic acid is that of Braun.[4b,c]



This process was carried out several times, but great difficulty was experienced at first in inducing the DL-threonic acid sirup to crystallize. The acid is converted into the lactone much more readily, apparently, than Braun's paper[4b] would indicate. To succeed in crystallizing the sirup obtained by concentration of a water solution of the acid, the evaporation must be discontinued before all of the water is removed, that is, while the residue is still a *thin* sirup. If the evaporation is continued at 40° and 2 mm. for four hours after nearly all of the water has been removed, as Braun recommends, the residue will be largely lactone and will not crystallize. That the acid is converted into lactone was demonstrated by the subjection of a sample of crystalline acid to distillation at 3 mm. The distillate, which titration indicated consisted of 87% lactone and 13% free acid, could not be induced to crystallize even when seeded with crystals of DL-threonic acid.

After having succeeded in producing crystalline acid by Braun's procedure, attention was turned

(1) This article is condensed from a dissertation presented by Edward Rietz in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the University of Chicago.

(4) Géza Braun, *ibid.*, **52**, (a) 3167, (b) 3176 (1930), (c) **54**, 1133 (1932).

to improvements in the process. These consisted in producing the intermediate, ethyl γ-chlorocrotonate in a 20% yield (calculated from allyl alcohol) by a much simpler method than that used by Braun. The steps involved in the new procedure are

$$CH_2{=}CHCH_2OH \xrightarrow[HCl]{(1)\ Cu_2(CN)_2} CH_2{=}CHCH_2CN \xrightarrow[HCl]{(2)\ H_2O} CH_2{=}CHCH_2COOH \xrightarrow[HCl]{(3)\ C_2H_5OH}$$

Allyl alcohol — Allyl cyanide (75%) — Vinylacetic acid (60%)

$$CH_2{=}CHCH_2COOC_2H_5 \xrightarrow{(4)\ Cl_2} CH_2ClCHClCH_2COOC_2H_5 \xrightarrow{(5)\ C_2H_5ONa} CH_2ClCH{=}CHCOOC_2H_5$$

Ethyl vinylacetate (70%) — Ethyl β,γ-dichlorobutyrate (not isolated) — Ethyl γ-chlorocrotonate (65%)

The feasibility of the procedure was first established by the preparation of the corresponding bromo derivative, which was obtained in 23.4% yield calculated from allyl alcohol. The ester was hydrolyzed to γ-bromocrotonic acid, which in turn was oxidized to *threo*-γ-bromo-α,β-dihydroxybutyric acid. The procedure for the preparation of the bromo ester was then successfully applied to the preparation of the corresponding chloro ester, which in turn was transformed by Braun's procedure (steps 4–6) into DL-threonic acid. This was obtained in 5.3% yield calculated from the allyl alcohol.

DL-Erythronic Acid.—The best source of DL-erythronic acid at present is the lactone of γ-hydroxy-isocrotonic acid, which is obtained by treatment of glycerolmonochlorohydrin with sodium cyanide, followed by hydrolysis of the nitrile so produced.[5] The amount of the unsaturated lactone formed varies greatly, the yield (average 23%) sometimes being as high as 30% and sometimes being almost negligible. It is oxidized to DL-erythronic acid, the lactone of which was obtained by Braun[6] in 75% yield. It was found that vinylacetic acid could be transformed into isocrotonolactone in 21% yield as follows

$$CH_2{=}CHCH_2COOH \xrightarrow[OsO_4]{(1)\ Ba(ClO_3)_2}$$

Vinylacetic acid

$$CH_2CHOHCH_2C{=}O \xrightarrow{(2)\ P_2O_5} CH_2CH{=}CHC{=}O$$

β-Hydroxybutyrolactone — Isocrotonolactone

Although the new procedure does not give the isocrotonolactone in larger yield than the old one at its best, it has definite advantages. It eliminates the uncertainty in the production of the lactone, is less time consuming, avoids the use of sodium cyanide, and permits the use of larger quantities in a run.

A few remarks concerning the oxidation of vinylacetic acid and the dehydration of β-hydroxybutyrolactone should be recorded. When the osmic acid was used in comparatively large amount, the reaction became violent. Furthermore, perfectly pure vinylacetic acid was found to be essential for good results. The pure acid obtained by extraction of the impurities from a solution of the sodium salt gave markedly better yields and required less catalyst than the acid purified by mere fractionation. The dehydration of β-hydroxybutyrolactone has been studied quite extensively in these laboratories. Glattfeld and Stack[7] observed that dehydration occurs (yield of unsaturated lactone 59%) when an absolute alcohol solution of the lactone containing a little sulfuric acid is heated for seventy-five hours in the presence of calcium sulfate. It was found that the use of more vigorous dehydrating agents shortened the time required for dehydration; phosphorus pentoxide was found to be the most satisfactory. By its use yields of the unsaturated lactone as high as 50% were obtained.

Experimental Part

I. Threonic Acid

Allyl Cyanide.—This was prepared in 75% yield (boiling range 115–120° at atmospheric pressure) by heating allyl alcohol and a slight excess of cuprous cyanide and concentrated hydrochloric acid under reflux according to the method of Brekpot.[8]

γ-Bromo-crotononitrile.—Although this material was found to be unsuitable for the preparation of threonic acid, the procedure by which it was prepared is described here because it is new to the literature and because the yield is much higher (55%) than that which the authors obtained by the older method of Lespieau and Brule.[9,10]

(5) Glattfeld, Leavell, Spieth and Hutton, THIS JOURNAL, **53**, 3164 (1931).

(9) Lespieau, *Bull. soc. chim.*, [3] **33**, 55 (1905).

(10) Brule, *ibid.*, [4] **5**, 1019 (1909).

One mole (67 g.) of allyl cyanide is dissolved in a mixture of 90 cc. of tertiary butyl alcohol and 450 cc. of medium boiling ligroin. One mole of bromine (160 g.) dissolved in 100 cc. of tertiary butyl alcohol is added dropwise to the vigorously-stirred solution of the nitrile. A mercury seal is used to prevent contact with atmospheric moisture. The temperature is maintained within the range 15–25°. The solution is allowed to stand for fifteen to thirty minutes to ensure complete absorption of the bromine. It is then cooled to 0° and a solution of 23 g. of sodium in the minimum amount of absolute ethyl alcohol necessary to effect solution is added dropwise to the vigorously-stirred solution. The solution is filtered (hood) and the solvent removed under reduced pressure at a maximum temperature of 45°. The residue is fractionated and the fraction boiling at 80–85° at 12 mm. is collected. This weighs 80 g. (55%).

Care is necessary in working with this material. It is a powerful vesicant and lachrymator.

Vinylacetic Acid.—This acid of boiling range 66–69° at 10 mm. was prepared in 60% yield by the hydrolysis of allyl cyanide according to the method of Falaise and Frognier.[11] During the distillation of this compound, a considerable amount of unchanged nitrile is recovered in a carbon dioxide–acetone cooled trap placed between the receiving flask and the pump. When this recovered nitrile is taken into account, the yield of vinylacetic acid approaches 75%.

Ethyl Vinylacetate.—The ester was prepared from vinylacetic acid, ethyl alcohol and hydrogen chloride according to the directions of Falaise and Frognier.[12] The yield of the fraction boiling at 119–124° at atmospheric pressure was 70%.

Ethyl γ-Bromo-crotonate.—The procedures for the preparation of this compound and of ethyl γ-chlorocrotonate are new to the literature and are therefore given in detail.

One fifth of a mole (23 g.) of ethyl vinylacetate is dissolved in 90 cc. of tertiary butyl alcohol, the solution is cooled to 15–25°, and a solution of one-fifth of a mole of bromine (32 g.) in 90 cc. of tertiary butyl alcohol is added dropwise to the well-stirred solution which is contained in a flask equipped with a mercury seal to prevent the access of atmospheric moisture. The solution is then allowed to stand for one-half hour to ensure complete absorption of the bromine, after which it is cooled to 0°. A solution of sodium ethoxide, prepared by the addition of sufficient absolute ethyl alcohol to effect solution of 4 g. of sodium, is added dropwise to the vigorously-stirred solution. The solution is filtered and the solvent removed under reduced pressure at a maximum temperature of 45°. The residue is fractionated and the fraction of boiling range 78–82° at 2 mm. is collected. A yield of 23 g. (60% is obtained. The over-all yield calculated on the basis of the allyl alcohol is 23.4% as compared with Braun's yield of 1.7% calculated on the basis of glycerol.

The material was hydrolyzed and the γ-bromo-crotonic acid was oxidized to *threo*-γ-bromo-α,β-dihydroxybutyric acid as described by Braun. Both compounds melted at the temperature noted by Braun. As the last-named acid is quite difficult to prepare, however, it is not a practical material for the preparation of threonic acid. It was found to be much easier to prepare threonic acid from ethyl γ-chlorocrotonate, the preparation of which is described in the next section.

Ethyl γ-Chloro-crotonate.—Three moles of ethyl vinylacetate (342 g.) is dissolved in 600 cc. of dry carbon tetrachloride, and dry chlorine is passed into the cool (10–20°) well-stirred solution. When the theoretical amount of chlorine (213 g.) has been absorbed (determined by increase in weight of the reaction mixture) the solution is allowed to stand at room temperature for one-half hour to ensure complete absorption of chlorine. The dichloro ester is unstable and loses hydrogen chloride. The mercury seal is not removed, therefore, while the mixture is attaining room temperature. The solution is then cooled to about −5° and a solution of 62 g. of sodium (90% of theory), dissolved in the quantity of absolute alcohol necessary to effect solution, is added dropwise to the vigorously-stirred solution. The temperature is maintained below 0° because of undesirable side reactions which occur at higher temperatures. After the ethoxide has been added, the sodium chloride which has precipitated is removed by filtration or by the use of the centrifuge. Filtration is frequently quite difficult, but the centrifuge has always given a satisfactory separation. The "centrifuging" is best accomplished by the use of four 250-cc. centrifuge tubes, emptying the contents, and repeating the operation until the solid material has been removed from the entire liquid. The solvent is removed under reduced pressure with the water pump, and the residue fractionated. The fraction of boiling range 72–80° at 10 mm. weighs 290 g. (65%).

Threonic Acid.—The procedure for the preparation of threonic acid from this point was essentially that of Braun. Ethyl γ-chloro-crotonate was hydrolyzed to γ-chlorocrotonic acid (78–80°, 60%) which in turn was oxidized to *threo*-γ-chloro-α,β-dihydroxybutyric acid (97–98°, 75%) by means of osmic acid-activated barium chlorate.

Forty-seven grams of *threo*-γ-chloro-α,β-dihydroxybutyric acid was treated according to Braun[4c] and yielded 23 g. of DL-threonic acid, m. p. 98°, 59% yield calculated from the *threo*-γ-chloro-α,β-dihydroxybutyric acid used.

II. Erythronic Acid

While the vinylacetic acid of boiling range 66–69° at 10 mm. is sufficiently pure for the threonic acid synthesis, a higher degree of purity is necessary for the preparation of erythronic acid. This substance was obtained by the procedure of Falaise and Frognier.[13] The pure acid was recovered from the salt in 90% yield and boiled at 71° at 13 mm.

β-Hydroxy-butyrolactone.—Thirty-five grams of pure vinylacetic acid is added to 90 cc. of water containing 25 g. of barium chlorate and 5 cc. of a 0.2% solution of osmium tetroxide. The temperature is kept below 35° by occasional cooling. After one day, an additional 5 cc. of 0.2% osmium tetroxide solution is added. At the end of the third day, the reaction mixture is subjected to distillation under reduced pressure at a maximum temperature of 50°. The lactone is extracted from the residue with absolute

(11) Falaise and Frognier, *Bull. soc. chim. Belg.*, **42**, 433 (1933).

(12) Falaise and Frognier, *ibid.*, p. 438.

(13) Falaise and Frognier, *ibid.*, p. 436.

alcohol, the solution is filtered free from inorganic material, and subjected to complete distillation under reduced pressure at 40°. The residue is fractionated. The fraction boiling between 135–160° at 2–5 mm. consists chiefly of the hydroxy-lactone. It weighs 14 g. (35%). Fractionation at reduced pressure yields the pure lactone which boils at 145–148° at 2–4 mm.

Preparation of Isocrotonolactone.—Seventy-one grams of phosphorus pentoxide is added, 10 to 20 g. at a time, to a solution of fifty grams of β-hydroxybutyrolactone in 200 cc. of dioxane. The mixture is allowed to stand for an hour (in one experiment the mixture stood overnight without ill effect). The dioxane solution is then decanted into a Claissen flask. The residue is extracted twice with absolute alcohol, the alcohol extracts being added to the dioxane solution. The solvent is removed under reduced pressure (10–15 mm. with water-bath at 70–80°), and the residue is distilled at 7 mm. The boiling range of 22 g. of material obtained in this way was 80–86° (53%).

Anal. Calcd. for $C_4H_4O_2$: H, 4.78; C, 57.1. Found: H, 5.16; C, 57.05.

The lactone was then transformed into DL-erythronic lactone by the procedure of Braun. From 78 g. of the unsaturated lactone of boiling range 82–86° at 7 mm. there was obtained 49 g. of crude DL-erythronic lactone, m. p. 88–90°; a yield of 45%.

Summary

1. New procedures which shorten the time of preparation and increase yields have been devised for the preparation of the following compounds: ethyl γ-bromo-crotonate, ethyl γ-chlorocrotonate, γ-bromo-crotononitrile, β-hydroxy-butyrolactone, and isocrotonolactone.

2. Braun's synthesis of DL-threonic acid has been greatly modified. The over-all yield by the new procedure is 5.3% (calculated from allyl alcohol) as against 2.2% (calculated from glycerol dichlorohydrin) by Braun's procedure.

3. The preparation of β-hydroxy-butyrolactone and isocrotonolactone from vinylacetic acid as reported in this article is a much more dependable process than the procedure in which these substances are made from glycerol monochlorohydrin.

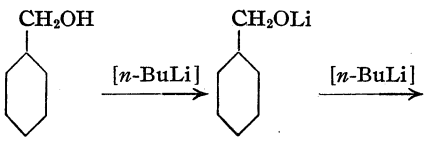
Metalation of Alcohols and Amines

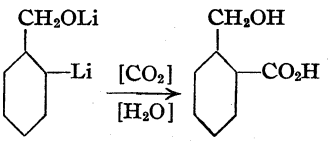
BY HENRY GILMAN, G. E. BROWN, F. J. WEBB AND S. M. SPATZ

Halogen-metal interconversion reactions have been noted in a great variety of reactions, and are of particular interest with polyfunctional compounds.[1] Hydrogen-metal interconversion reactions or metalations are also very common, but because they generally take place at a somewhat slower rate than halogen-metal interconversion reactions there is a greater opportunity for secondary reactions with polyfunctional compounds.

We are now reporting preliminary observations on the metalation of some selected simple alcohols and amines, and will report later on polyfunctional compounds having alcohol and amino groups. Metalation takes place with all the chief types of aromatic alcohols and amines: primary, secondary and tertiary. An illustration is the metalation of benzyl alcohol.



(1) Gilman, "Metalation and Related Interconversion Reactions," Eighth National Organic Chemistry Symposium, St. Louis, Dec. 30, 1939. See also recent papers in THIS JOURNAL on interconversion reactions with organometallic compounds.



In accordance with the general rules postulated for interconversions with organometallic compounds,[1] metalation occurs *ortho* to the group containing the hetero element. The only exception now known is the metalation of dibenzothiophene by phenylcalcium iodide, where metalation takes place in the 3- and not in the 4-position.[2,3]

Poly-metalation is to be expected with the more reactive organometallic compounds, and was observed earlier in the dibenzofuran series.[4] It may be stated that, in general, halogen-metal interconversions, hydrogen-metal interconversions as well as the numerous other interconver-

(3) Under generally drastic conditions of high temperature and pressure, Houben and co-workers [*Ber.*, **37**, 3978 (1904); **42**, 3729, 4488, 4815 (1909); **46**, 3833 (1913)] have obtained predominantly *para*-amino acids by interaction of carbon dioxide with the complexes derived from various secondary and tertiary amines with Grignard reagents. Under corresponding conditions they did not isolate acidic material from primary aromatic amines.

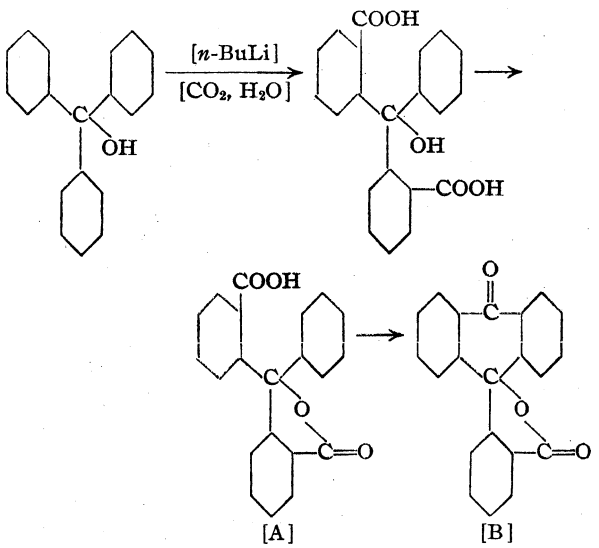
sions involving organometallic compounds can be correlated with the relative reactivities of organometallic compounds.[5] A case of dimetalation is reported now with triphenylcarbinol.



The acid isolated was the lactone of triphenylcarbinol-2,2′-dicarboxylic acid [A], which was characterized by dehydration to the oxanthrone [B]. It is of interest that this dimetalation took place with a quantity of *n*-butyllithium sufficient to react with but one of the three phenyl groups in triphenylcarbinol.

Metalation is probably one of the oldest reactions in organic chemistry. Davy[6] in 1837, incidental to attempts to obtain improved yields of his newly discovered potassium, fused potassium tartrate with carbon and obtained a highly reactive substance which yielded acetylene when treated with water. It is quite likely that an ethynylpotassium was formed as an intermediate. The halogen-metal interconversion reaction is also quite old, and an early reference is the work of Kalle on the reaction between benzenesulfonyl chloride and diethylzinc to yield zinc benzenesulfinate and ethyl chloride.[7]

Experimental Part

Benzyl Alcohol.—A solution of 10.8 g. (0.1 mole) of benzyl alcohol was added dropwise to a cold, stirred solution of approximately 0.2 mole of *n*-butyllithium in 400 cc. of ether. After refluxing for forty-two hours, the mixture was carbonated by pouring jet-wise on crushed carbon dioxide; acidified with iced dilute hydrochloric acid; and extracted with ether. Extraction of the ether layer with sodium bicarbonate solution, followed by acidification, yielded 1.5 g. of a yellow solid melting in the range 65–115°. This was evidently a mixture of phthalide[8] and *o*-carboxybenzyl alcohol[8] since heating with sodium hydroxide solution and then acidification gave 1.3 g. of *o*-carboxybenzyl alcohol, m. p. 120.5–121.5°, in a yield of 8.7%, or 21.5% based on the benzyl alcohol which had reacted.

Anal. Calcd. for $C_8H_8O_3$: neut. equiv., 152. Found: neut. equiv., 150.4.

On resolidification, the compound melted at 73–74°, showing the conversion to phthalide. Oxidation with alkaline permanganate gave phthalic acid which was identified by comparison with an authentic specimen.

From the neutral fraction there was recovered 6.5 g. or 60% of benzyl alcohol.

Benzyl Methyl Ether.—An orienting experiment showed that ethers of alcohols can also be metalated. A diethyl ether solution of 0.1 mole *n*-butyllithium and 12.2 g. (0.1 mole) of benzyl methyl ether was refluxed for twenty hours, then carbonated and worked up in a customary manner. The acid obtained, probably *o*-carboxybenzyl methyl ether, melted at 94–95° after recrystallization from petroleum ether (b. p., 60–68°).

Anal. Calcd. for $C_9H_{10}O_3$: neut. equiv., 166. Found: neut. equiv., 166.

Benzohydrol.—The usual initial vigorous reaction (due to replacement of active hydrogen by lithium) took place when 0.1 mole of *n*-butyllithium was filtered into an ether solution of 9.2 g. (0.05 mole) of benzohydrol. Ether was added to bring the total volume to 250 cc. The solution gradually turned brownish-red and after several hours became deep red. After refluxing for forty-six hours carbonation was effected by solid carbon dioxide. The yield of 2-phenylphthalide[9] (formed by lactonization of the *o*-carboxybenzohydrol) was 1.95 g. or 18.6%. This product melted at 114.5°, and was oxidized by alkaline potassium permanganate to *o*-benzoylbenzoic acid[9] (m. p., 126.5°).

Triphenylcarbinol.—The suspension resulting from mixing 13 g. (0.05 mole) of triphenylcarbinol with slightly more than 0.1 mole of *n*-butyllithium was stirred, and refluxed for forty-eight hours prior to carbonation. The alkaline extract of the hydrolyzate yielded 1.2 g. of a product melting at 187–215°. Recrystallizations from acetic acid raised the melting point to 240°.

Inasmuch as a first experiment with triphenylcarbinol gave no acid, the reaction was repeated using 0.5 g. of copper bronze as a catalyst. It was shown earlier that various catalysts can be used to retard and accelerate organometallic reactions.[10] The catalyst not only improved the yield (to 2.3 g.), but also gave a purer acid. It is now known that the interconversion reactions are affected not only by catalysts, but also by solvents, concentration of reactants, time and temperature. Apropos the first negative experiment with triphenylcarbinol, it should be recalled that the formation of organolithium

compounds is a little more erratic[11] than that of the corresponding Grignard reagents, and that one advantage to the use of carbonation in these preliminary studies is to get the extra check afforded by the odor of *n*-valeric acid formed by carbonation of the slight excess of *n*-butyllithium.

The acid melting at 240° was shown to be the lactone of triphenylcarbinol-2,2′-dicarboxylic acid,[12] and was characterized by conversion to 9-phenyl-9-hydroxanthr-10-one-2′-carboxylic acid lactone[12] melting at 234°. The yield of pure lactone-acid was 0.8 g. or 4.85%; or 52.5% if allowance be made for the recovery of 11.8 g. of triphenylcarbinol.

Aniline.—A mixture of 4.6 g. (0.05 mole) of aniline and slightly more than 0.15 mole of *n*-butyllithium was refluxed for fifty hours and then carbonated to yield 4.2% of anthranilic acid. Characterization was completed by diazotization and coupling with β-naphthol to the red 1-(*o*-carboxyphenylazo)-2-naphthol melting at 271°, using the method of mixed melting points with an authentic specimen.[13] There was recovered 2.9 g. of aniline, and the yield of anthranilic acid on the basis of aniline not recovered is 13.7%.

The larger than usual excess of *n*-butyllithium was used here to take care, if necessary, of the two active hydrogens attached to the nitrogen. It is quite likely that experiments now in progress will reveal the possibility of first replacing such hydrogens by metals other than lithium or by the use of organometallic compounds other than those of lithium.

Diphenylamine.—An ether solution of 13.5 g. (0.08 mole) of diphenylamine and 0.16 mole of *n*-butyllithium was stirred and refluxed for eighteen hours. Carbonation, followed by hydrolysis, yielded 1.85 g. or 10.9% of N-phenylanthranilic[14] acid melting at 182°. Recrystallization from a hot methanol–water mixture gave 1.45 g. or an 8.5% yield of the pure compound melting at 183.5°. The yield of N-phenylanthranilic acid based on the quantity of diphenylamine actually reacting was 30.3%.

In a second experiment the yield was somewhat improved by a longer period of refluxing. When the reactants were refluxed for twenty-four hours, the yield was 14.7%, or 38.2% based on the diphenylamine actually reacting.

N-*n*-Butylaniline.—Fifteen grams (0.1 mole) of freshly distilled N-*n*-butylaniline was heated for twenty hours with a slight excess over two equivalents of *n*-butyllithium in 275 cc. of ether. Subsequent to carbonation and hydrolysis, there was isolated a 2% yield of N-*n*-butylanthranilic acid.

N-*n*-Butylanthranilic Acid.—A solution prepared from 10 g. (0.073 mole) of anthranilic acid and 5 g. of potassium carbonate was refluxed for sixteen hours with 10 g. (0.073 mole) of *n*-butyl bromide. After cooling, the precipitate was dissolved in potassium hydroxide, and the oily material extracted with benzene. Neutralization of the alkaline layer precipitated the N-*n*-butylanthranilic acid which after crystallization from dilute methanol melted at 80–81° and weighed 6.4 g.

Anal. Calcd. for $C_{11}H_{15}O_2N$: N, 7.25. Found: N, 7.36.

A mixed melting point with the acid isolated from the metalation of N-*n*-butylaniline showed no depression.

Triphenylamine.—A reaction mixture of 12.25 g. (0.05 mole) of triphenylamine, 0.1 mole of *n*-butyllithium and 0.5 g. of copper bronze was stirred and refluxed for forty-five hours prior to carbonation. The yield of acidic material was 2.16 g. In addition, 9.6 g. or 78.5% of the triphenylamine was recovered. The mixture of acids has not as yet been resolved.

Piperidine.—An ether solution of 17 g. (0.2 mole) of piperidine and 0.42 mole of *n*-butyllithium was refluxed for twenty hours. On working up by customary procedures, subsequent to carbonation, there was obtained 21.6 g. or an 89% yield of piperidine hydrochloride in addition to a small quantity of an as yet unidentified oil. It is quite likely that more reactive organometallic compounds can effect such secondary reactions on piperidine as dehydrogenation[15] and cleavage.

Acknowledgment.—The authors are grateful to F. W. Moore and W. Harber for assistance.

Summary

It is shown that *n*-butyllithium metalates some typical primary, secondary and tertiary aromatic amines and some typical primary, secondary and tertiary aromatic alcohols.

Triphenylgallium[1]

BY HENRY GILMAN AND R. G. JONES

Trimethylgallium and triethylgallium have been examined in recent years,[2] but nothing is known of their behavior with a simple organic functional group like carbonyl. For purposes of comparison with other phenyl-metallic compounds, we have prepared triphenylgallium in adequate quantities from the expensive metal to permit examination of sufficient reactions to warrant broad correlations with related organometallic compounds. Triphenylgallium (m. p. 166°) is conveniently prepared in satisfactory yields (82%) by interaction of diphenylmercury with gallium.

The expected reaction with benzaldehyde was observed: namely, formation of benzohydrol. Inasmuch as H. D. Gooch[3] has shown that, in general, benzalacetophenone has a reactivity close to that of benzaldehyde and acetophenone, reaction was expected with the conjugated system in benzalacetophenone. 1,4-Addition did take place, and an 85% yield of β,β-diphenylpropiophenone resulted. There was no evidence of 1,2-addition, and this finding is in accordance with the generalization[4] that only extremely reactive RM compounds add 1,2; that moderately reactive RM compounds add 1,4; and that RM compounds of intermediate reactivity, like phenyllithium, add both 1,2 and 1,4.

Series of Relative Reactivities of Functional Groups.—On the basis of the series of relative reactivities of functional groups prepared by Entemann and Johnson[5] from their studies with phenylmagnesium bromide, benzonitrile is quite low in reactivity. Accordingly, it was not surprising to find that benzonitrile did not react with triphenylgallium under the selected conditions. Inasmuch as groups like the azo and anil linkages are of lesser activity than the nitrile group, reactions were not attempted with compounds like azobenzene and benzophenone-anil.

Again,[3] an inconsistency was observed with benzoyl chloride and benzophenone. Both of these compounds are of approximately equal reactivity with phenylmagnesium bromide. However, with triphenylgallium only benzoyl chloride and not benzophenone reacted under customary conditions. These results together with others[3,6] reported recently demonstrate rather conclusively that the order of reactivity of benzophenone and benzoyl halides with RM compounds that are less reactive than Grignard reagents is unlike the order established with phenylmagnesium bromide. Under unusual conditions, a liberal excess of triphenylgallium and extensive refluxing in xylene, reaction did take place with benzophenone, but the product isolated in 35% yield was triphenylmethane. Benzyl chloride and triphenylgallium gave undoubtedly diphenylmethane, for the oil resulting yielded benzophenone on oxidation.

Color Test.—The most surprising result was the absence of a color test[7] under usual conditions inasmuch as a color test has always been noted with those organometallic compounds sufficiently reactive to add to the carbonyl group in benzaldehyde and to the conjugated system in benzalacetophenone. Undoubtedly, the absence of a color test under customary conditions is associated in part with the pronounced tendency of gallium compounds to form coördinate linkages. For example, Dennis and Patnode[2a] have shown that the simple triethylgallium reacts violently with water, the etherate vigorously, and the ammine only very slowly. It is quite probable that the dimethylamino groups in the Michler ketone used in the color test may have tied up some of the triphenylgallium in the form of the less reactive ammine. Also, the carbonyl group in Michler ketone and in benzophenone may have participated in the formation of coördinate complexes. In any event, a color test was obtained by heating with an excess of triphenylgallium in benzene for about fifteen minutes. It is significant that the color tests were much weaker than those observed with triphenylthallium,[3] which is less prone to form coördinate linkages.

Relative Reactivities of Triphenylgallium and Triphenylthallium.—In preceding studies on the relative reactivities of organometallic compounds, the color test has been found most convenient. The necessity of using an excess of triphenylgallium for a color test precluded its use in a comparison with triphenylthallium. However, the relative reactivities of these two R_3M compounds was established by an indirect procedure involving benzaldehyde, which reacts with each of them. Under parallel conditions, a solution of known concentration of benzaldehyde was added separately to each of the R_3M compounds, and the periodic removal of samples on which tests were made for benzaldehyde showed that triphenylgallium is more reactive than triphenylthallium. The rate studies were carried out at room temperature to avoid the thermal conversion noted earlier[3] of triphenylthallium to the highly reactive phenylthallium.

The 79% yield of benzophenone based on interaction of one mole of triphenylgallium with three moles of benzoyl chloride shows that with some reactants all three phenyl groups are available. With triphenylthallium, only one R group enters into reaction and an invariable product is a diphenylthallium salt.

Experimental Part

Preparation of Triphenylgallium.—A mixture of 1 g. (0.0143 g. atom) of gallium metal and 5.45 g. (0.0153 mole) of diphenylmercury was heated in a Schlenk tube which had been thoroughly flushed out with nitrogen. Heating was effected at 130° in an oven, and after fifty hours the molten diphenylmercury had given place to a white crystalline mass. The tube was opened under nitrogen and 10 cc. of dry chloroform was added. After warming the chloroform to dissolve all of the solid, the solution was filtered and then subjected to distillation (under nitrogen) until crystals began to appear in the hot solution, about 4 cc. of which remained. The mass of shiny needle-like crystals which separated on cooling were filtered off on a sintered glass plate, and washed with petroleum ether (b. p. 65–68°). The product was redissolved in 3 cc. of hot chloroform, and the crystals which separated on cooling were again filtered, washed with petroleum ether, and dried under nitrogen. The triphenylgallium (1.85 g.) melted at 166°; the clear colorless melt quickly solidified on cooling and remelted at the same temperature.

Anal.[8] Calcd. for $C_{18}H_{15}Ga$: Ga, 23.18. Found: Ga, 23.27 and 23.38.

Better yields of triphenylgallium were obtained when the theoretically required quantities of gallium and diphenylmercury were used. Thus, from 1.92 g. (0.0275 g. atom) of gallium and 14.5 g. (0.0405 mole) of diphenylmercury, heated at 130° for seventy-five hours, 6.68 g. or an 82% yield was obtained of triphenylgallium which melted at 165–166° without recrystallization.

On short exposure, dry air appeared to have little effect on triphenylgallium. However, in the presence of any moisture the compound quickly decomposed, and one of the products was benzene. Complete solution of triphenylgallium in warm dilute sulfuric acid, incidental to analysis, required about twenty-four hours.

Benzaldehyde.—A solution of 0.83 g. (0.00277 mole) of triphenylgallium and 0.294 g. (0.00277 mole) of benzaldehyde in 20 cc. of benzene was refluxed for ten hours. After hydrolysis with 25 cc. of 2 *N* hydrochloric acid, the benzene layer was separated and washed with 40% sodium bisulfite solution. Removal of the benzene by distillation left an oil which crystallized on cooling to give a 70% yield of benzohydrol, melting at 65-66° after two crystallizations from petroleum ether (b. p. 60–68°). Identification was completed, as was done by all solids described in this paper, by the method of mixed melting points with an authentic specimen.

Benzalacetophenone.—A solution of 1.1 g. (0.00365 mole) of triphenylgallium and 0.76 g. (0.00365 mole) of benzalacetophenone in 20 cc. of benzene was refluxed for eight and one-half hours. Subsequent to hydrolysis by hydrochloric acid and then working up by customary procedures there was obtained 0.88 g. or an 85% yield of β,β-diphenylpropiophenone.

Benzoyl Chloride.—A solution of 1.44 g. (0.00478 mole) of triphenylgallium and 2.01 g. (0.0143 mole) of benzoyl chloride in 25 cc. of benzene was refluxed (under nitrogen, as usual) for eleven hours. The yield of benzophenone was 2.05 g. or 79%.

In another experiment, a mixture of 1.06 g. (0.0035 mole) of triphenylgallium suspended in 25 cc. of petroleum ether (b. p. 65–68°) containing 1.47 g. (0.0105 mole) of benzoyl chloride was heated for nine hours. The ketone was isolated in this case as benzophenone oxime, the yield of which was 1.4 g. or 68.4%.

It is interesting to note that generally satisfactory yields of ketones are obtainable from organometallic compounds of group III metals in their reactions with acid halides and acid anhydrides. This applies in a noteworthy extent to the organoaluminum halides. In most of these reactions of ketone formation, the acid anhydrides are superior to acid halides, both with RM compounds in group III and RM compounds like those of cadmium in group II.

Benzophenone.—After refluxing for twenty-four hours a solution of 1.00 g. (0.0033 mole) of triphenylgallium and 1.82 g. (0.01 mole) of benzophenone in 20 cc. of xylene, 94.5% of the benzophenone was recovered as the oxime, and no triphenylcarbinol was isolated. The experiment was repeated with xylene as the solvent, and also with benzene as the solvent. In the latter case, 95.5% of the benzophenone was recovered as the oxime.

An additional experiment was carried out with an excess of triphenylgallium. A solution of 1.51 g. (0.0050 mole) of triphenylgallium and 0.3 g. (0.00167 mole) of benzophenone in 15 cc. of xylene was refluxed for twenty-

(8) The analytical procedure was that used by Dennis and Bridgman, THIS JOURNAL, **40**, 1546 (1918).

four hours. A small quantity of white amorphous precipitate formed. After cooling, the reaction mixture was shaken with 25 cc. of dilute hydrochloric acid and 25 cc. of benzene. The aqueous layer was separated and the benzene–xylene layer was washed with dilute hydrochloric acid and then with water. The residue from the organic extract was subjected to steam distillation subsequent to removal of the solvents. The steam distillate yielded an oil which partially solidified on standing, and when crystallized from a mixture of 1 cc. of 95% ethanol and 1 cc. of petroleum ether (b. p. 60–68°) gave a 35% yield of triphenylmethane.[9]

Benzyl Chloride.—To a suspension of 1.36 g. (0.0045 mole) of triphenylgallium in 25 cc. unsaturate-free petroleum ether (b. p. 65–68°) contained in a conventional three-necked flask provided with a mechanical stirrer, was added slowly a solution of 1.71 g. (0.0135 mole) of benzyl chloride in 25 cc. of petroleum ether. There was no evidence of reaction until about one-third of the benzyl chloride solution had been added, when suddenly a large quantity of red, tarry precipitate appeared accompanied by some heat of reaction. Subsequent to hydrolysis, the oily residue remaining after removal of the organic solvents was oxidized by potassium dichromate and sulfuric acid to give 0.1 g. or a 9% yield of benzophenone, isolated and characterized as the oxime.

Color Test.—In preliminary tests, about 0.05 g. of solid triphenylgallium was added to about 1 cc. portions of benzene containing Michler ketone. Both saturated and 1% Michler ketone solutions were used. In every case the test was negative, even when the mixtures were heated at 70° out of contact with air or moisture for as long as two and one-half hours prior to hydrolysis.

A mixture of 0.57 g. (0.0019 mole) of solid triphenylgallium and 0.1 g. (0.00038 mole) of solid Michler ketone was placed in a flask containing nitrogen. Next 12.5 cc. of dry benzene was added, the time noted, and 1-cc. samples were removed periodically and tested by hydrolyzing and adding the acetic acid–iodine solution.[7] The test was negative after four hours at room temperature. The mixture was then heated on the water-bath at 65–75°, and after one hour a 1-cc. sample gave a good color test.

The experiment was repeated using 0.43 g. (0.00143 mole) of triphenylgallium, 0.13 g. (0.00048 mole) of Michler ketone and 16 cc. of benzene. The solution was heated immediately on the water-bath at 70°. A faint positive test was obtained in fifteen minutes; a better test in thirty minutes; and a good test in one hour. In all cases, the colors given in triphenylgallium tests were weaker than the color of a positive test for triphenylthallium.

Relative Reactivities of Triphenylgallium and Triphenylthallium.—In parallel experiments, a solution was prepared by mixing quickly benzaldehyde and R_3M compound in benzene, so that the initial concentration of benzaldehyde was 0.16 molar and that of R_3M was 0.20 molar. The solution was stirred constantly at room temperature, and at regular intervals 1-cc. samples were withdrawn and tested for benzaldehyde.[10] The end-point of the reaction was taken when three samples (removed within a period of ten minutes) no longer gave positive tests for benzaldehyde. The times in two experiments with triphenylgallium were eleven and fourteen hours; and the times in corresponding experiments with triphenylthallium were forty and fifty hours.

Summary

Triphenylgallium (m. p. 166°), prepared from gallium and diphenylmercury, reacts normally with benzaldehyde, benzalacetophenone and benzoyl chloride. Because of the probable formation of coördinate compounds with Michler ketone and benzophenone, there is no color test and no reaction with benzophenone under customary conditions. Extended heating with an excess of triphenylgallium gives a color test with Michler ketone, and benzophenone reacts to give triphenylmethane. Rate studies with benzaldehyde show triphenylgallium to be more reactive than triphenylthallium.

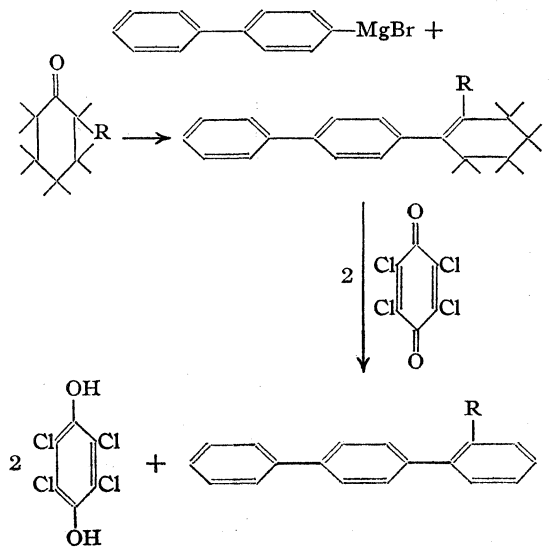
NOTES

Low Temperature Dehydrogenations. II

By Richard T. Arnold, Clair Collins and Wm. Zenk

In an introductory report[1] it was shown that several different types of hydroaromatic compounds can be dehydrogenated at comparatively low temperatures by making use of chloranil or other quinones with high oxidation potentials.

This method has now been extended to reactions leading to the preparation of unsymmetrical biphenyl, terphenyls, etc., according to the scheme



Of course, the synthesis of substituted cylohexenes in the first step here is limited to those molecules which do not have groupings present which will react rapidly with the Grignard reagent. However, these groups (—NO_2, etc.) are not affected in the dehydrogenation reaction with chloranil as they are when sulfur or selenium is used.

A convenient and cheap synthesis of chloranil has been described[2] and confirmed in this Laboratory. It makes use of the action of concentrated hydrochloric acid on benzoquinone in the presence of hydrogen peroxide (30%). This preparation practically eliminates the cost of these dehydrogenations, especially when it is realized that three-fourths of the hydroquinone which results can be recovered and converted quantitatively to the quinone by nitric acid.

(1) Arnold and Collins, This Journal, **61**, 140 (1939).
(2) M. Gallatti, *Ann. chim. applicata*, **22**, 602 (1932).

It has been demonstrated recently[3] that sulfur can be used to prepare certain unsymmetrical biphenyls in satisfactory yields, but in the terphenyl and phenylnaphthalene series the classical dehydrogenations are disappointing.[4,5] The procedure described in this paper gives very satisfactory yields (50–70%) in all of these cases.

Thermal rearrangements have been found to be commonplace in alkyl and arylnaphthalenes in the region of 300.[6] The use of low temperature dehydrogenation here is obvious.

Recently, the classical synthesis of terphenyls by the reaction between nitrosoamines and hydrocarbons has been extended to new cases and the conditions of the synthesis greatly improved.[7] While this method is very general, the yields reported are not comparable with those obtained in our investigations. The results obtained are summarized in Table I.

Table I

Compound	Product	Yield, %
1-*p*-Biphenylcyclohexene	Terphenyl	47
1-*p*-Biphenyl-2-methylcyclohexene	2-Methylterphenyl	72
1-α-Naphthylcyclohexene	α-Phenylnaphthalene	67
1-β-Naphthylcyclohexene	β-Phenylnaphthalene	72
1-*o*-Tolylcyclohexene	2-Methylbiphenyl	72

At present we are investigating the efficacy of chloranil as a dehydrogenating agent for straight chain hydrocarbons.

Experimental

1-*p*-Biphenyl-2-methylcyclohexene.—Ninety-five cubic centimeters of a Grignard solution (prepared from 100 g. of 4-bromobiphenyl, in 500 cc. of ether) was treated with 12 cc. of 2-methylcyclohexanone in an equal volume of benzene. The reaction mixture was decomposed with dilute sulfuric acid. Dehydration was accomplished by heating for one hour with 20% oxalic acid. The benzene layer was fractionated and the residue distilled in a sausage flask; yield 6.75 g.

2-Methylterphenyl.—A solution containing 3.58 g. of the above cyclohexene derivative, 7.3 g. of chloranil and 25 cc. of commercial xylene was refluxed for ten hours, cooled, and filtered, giving 4.55 g. of chloranilhydroquinone. The filtrate was diluted with an equal quantity of ether,

(7) France, Heilbron and Hey, *J. Chem. Soc.*, 1283 (1939).

washed with dilute alkali, dried, and fractionated. The residue was distilled in a small sausage flask and yielded 2.53 g. of the methylterphenyl which melted at 91–92° after recrystallization from methanol.[7]

Anal. Calcd. for $C_{19}H_{16}$: C, 93.34; H, 6.60. Found: C, 92.97; H, 6.58.

Terphenyl.—A sample (1.46 g.) of *p*-biphenylcyclohexene, 3.3 g. of chloranil and 18 cc. of dry xylene were refluxed and the reaction worked up as described in the preceding section; yield of terphenyl 0.63 g. The product melted at 210–211.5°. The identity of the substance was checked by preparing the nitro derivative; melting point 275°.[7]

α-Phenylnaphthalene.—Five grams of α-naphthylcyclohexene prepared as described in the literature[8] was refluxed with 11.8 g. of chloranil in 20 cc. of xylene for five hours. The reaction mixture was cooled, diluted with an equal volume of petroleum ether (30–60°) and filtered, yielding 8.4 g. of chloranil hydroquinone. The remainder was removed by basic extraction. The resulting fractionation yielded 3.33 g. of α-phenylnaphthalene. The structure was checked by the formation of its nitro derivative which melted at 129–130°. The literature reports 132°.[8]

β-Phenylnaphthalene.[5]—Following the same procedure as given above, β-naphthylcyclohexene was dehydrogenated to give β-phenylnaphthalene in a yield of 72%. The constitution of this molecule was proved by direct oxidation to β-phenyl 1,4-naphthoquinone; melting point 108–109°.[9]

2-Methylbiphenyl.—This substance was obtained by refluxing a solution containing 12 g. of *o*-tolylcyclohexene, 36 g. of chloranil, and 115 cc. of xylene. The yield of pure product obtained by fractionation was 8.5 g. (72.6%).[3]

Catalytic Action of 8-Hydroxyquinoline on the Oxidation of *p*-Phenylenediamine

BY FREDERICK BERNHEIM AND PHILIP HANDLER[1]

8-Hydroxyquinoline can, under certain conditions, catalyze the oxidation of cysteine to cystine.[2] It has now been shown that it has a catalytic effect on the oxidation of *p*-phenylenediamine and certain related substances. Figure 1 shows this effect on *p*-phenylenediamine recrystallized from water and from alcohol. The oxygen uptake was measured at 37° in the Warburg apparatus. Successive recrystallizations of the diamine have no effect on the catalysis, showing that the 8-hydroxyquinoline is not simply removing an antioxidant. Addition of metal ions such as the cupric, ferric and vanadate does not enhance the catalytic effect which is, therefore, probably not due to a metal-8-hydroxyquinoline complex. The catalysis is not affected by 0.02 *M* cyanide or pyrophosphate. It has an optimum *p*H at about 6.5 and the rate falls off rapidly in alkaline solutions. The oxidation product is deeply colored, which is characteristic of the polymer of the quinone diamine and which can be reduced by hydrosulfite. On isolation and hydrolysis with acid it gives free ammonia. From the oxygen uptake figures a small percentage of further oxidation products must be formed which have not been isolated.

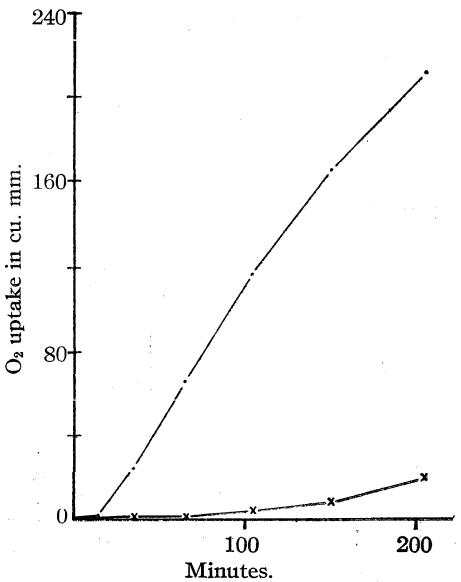

Fig. 1.—The oxygen uptake of 3.0 mg. of *p*-phenylenediamine in 2.0 cc. of water at *p*H 6.7: ×—×, control; ·—·, with 0.05 mg. of 8-hydroxyquinoline. The short latent period is characteristic.

8-Hydroxyquinoline has no effect on the oxidation of *o*-phenylenediamine, catechol or hydroquinone in acid or alkaline solutions. It has a comparatively small effect on the oxidation of *p*- and *o*-aminophenols in alkaline solutions (*p*H 7.8). 2-Hydroxyquinoline and certain other quinoline derivatives are without catalytic action.

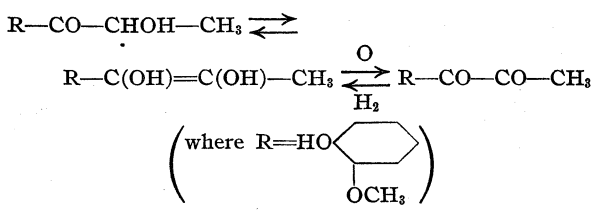
The Mechanism of Plant Respiration

BY HAROLD HIBBERT

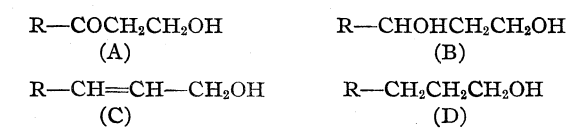
The discovery (see following note) in the ethanolysis products from spruce wood of methyl guaiacyl diketone alongside the previously re-

ported α-hydroxypropiovanillone[1] raises a question of considerable biochemical significance. The latter product, in its ene–diol form, is evidently the "donator" in a new oxidation–reduction system, the newly discovered diketone being the "acceptor."



Such a system with its presumptive accompanying dioxypropylene guaiacolase is thus closely related to the ene–diol catechol, –ascorbic acid and –dioxymaleic acid systems shown recently by Szent-Györgyi and co-workers[2] to form an integral part of the cycle of changes involved in plant (and presumably animal) respiration. The wide occurrence of this new oxidation–reduction system in various forms of higher plant life[1,3] and the fact that both methyl guaiacyl diketone and α-hydroxypropiovanillone apparently are derived from methyl glyoxal provide additional support for the author's theory of plant synthesis[4] in which this intermediate of carbohydrate metabolism appears to play such an extraordinarily important role.

In the suggested new system of plant respiration the roles of oxalacetic, malic, fumaric, and succinic acids are taken by (A), (B), (C) and (D), respectively

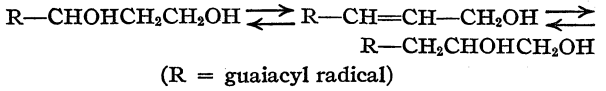


(R = guaiacyl radical)

Of these, coniferyl alcohol (C) is known to be a very widely distributed plant product.

It may also be pointed out that in this new conception the important biological system[5] known to function in intermediary metabolism

has its counterpart in that of

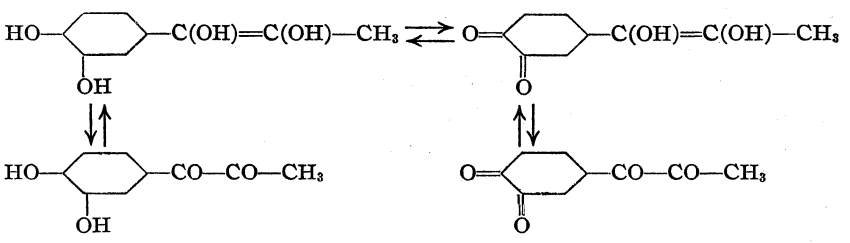


(R = guaiacyl radical)

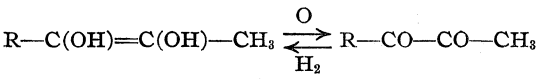
these last three products having a close biochemical relationship to the above ene–diol form.

Obviously the same considerations apply to the case of the corresponding syringyl compounds obtained in the ethanolysis of hard woods.[3]

Since in the early stages of plant growth the phenolic substances present are unmethoxylated, presumably the above new oxidation–reduction mechanism is represented there by a *di*-ene–diol system



in which not only the catechol ⇄ orthoquinone portion can function, but also the side chain grouping, as indicated by the changes



Such a combination is quite unique in cell oxidation systems and presumably is intimately related to the very much slower rate of reduction–oxidation changes involved in plant, as contrasted with animal, cell respiration.

It seems very probable that the above oxidation–reduction phenomena are intimately associated with (a) the very marked change in color taking place when chlorine and other oxidizing agents are brought into contact with unbleached pulps, and (b) the discoloration of newsprint and other papers in the presence of light and air.

Experiments with this new system on plant and animal tissues are to be undertaken and a full discussion of the subject is to appear in a forthcoming publication wherein the role of the ene–diol oxidation–reduction system as the almost certain forerunner of lignin synthesis is to be discussed comprehensively.

Structure of the Ethanolysis Products from Spruce and Maple Wood

BY LEO BRICKMAN, J. J. PYLE, W. L. HAWKINS AND HAROLD HIBBERT

A re-investigation of the "aldehyde fraction" obtained in the ethanolysis of maple and spruce wood[1] has shown that two of the constituents previously identified (incorrectly) as syringoyl- and vanilloyl-acetaldehydes are, in reality, 1,2-diketones, namely, the benzil derivatives, methyl-4-hydroxy-3,5-dimethoxyphenyl diketone (C_6H_3-(OH)$(OCH_3)_2$-CO-CO-CH_3) (A) and methyl guaiacyl diketone (C_6H_2(OH)(OCH_3)-CO-CO-CH_3) (B), respectively. Proof of this has been found in the synthesis of the benzils by oxidation of the corresponding benzoins, namely, α-hydroxypropiovanillone and α-hydroxypropiosyringone, by means of copper sulfate and pyridine. The monosemicarbazone of (A) melts at 213° and its disemicarbazone at 240°, while the mono-2,4-dinitrophenylhydrazone of (B) melts at 226–227° and its monosemicarbazone at 214–215°. No depression in melting point was found on admixture with the corresponding products isolated from the ethanolysis products.

The mistake in identity arose as a result of the aldehyde-like properties possessed by these 1,2-diketones.

A full account of the supporting chemical evidence is to be given in a forthcoming publication.

Purification of High Molecular Weight Fatty Esters

BY LORAN O. BUXTON AND ROLAND KAPP

In the course of our research it became necessary to prepare relatively large quantities of substantially acid-free high molecular weight fatty esters. We have found that the following process is more satisfactory for removing substantially all of the unreacted fatty acids than the usual methods.

The procedure most suitable is as follows. The unreacted alcohol is distilled from the esterification mass, and the residual mixture of free fatty acids, crude ester, and catalyst is dissolved in 2 to 5 parts by weight of a solvent such as ethylene dichloride to 1 part of ester. A convenient sample (10 to 20 g.) of the solvent solution of the crude ester is dissolved in an alcohol–ether mixture, and titrated with standard 0.5 *N* alcoholic potassium hydroxide. On the basis of this titration value an equivalent weight of concentrated aqueous potassium hydroxide, preferably of 38% strength, is added slowly with constant stirring to the solvent solution of the ester mixture. In a relatively short time the potassium soap of the unreacted fatty acids will rise to the surface as a flocculent aggregate, and any mineral acid present as catalyst will also precipitate out as the potassium salt. The solvent solution is filtered without suction, and the soap mass is washed with a small amount of fresh ethylene dichloride to remove traces of neutral ester, and the filtrate distilled. It is not necessary to dry the filtrate.

By this process we have been able to obtain quantitatively the yields of methyl and ethyl esters of lauric, oleic, linoleic, stearic and ricinoleic acids, from the original esterified mass prepared with the respective crude acids. The process also has been applied successfully to the preparation of relatively pure mono- and di-naphthenates of diethylene glycol. The esters obtained in this manner have acid values from 0.5 to 1.0 and can be purified further by vacuum distillation. Relatively large amounts of ester can be purified in this manner without the formation of troublesome emulsions and without the hazards hitherto inherent in the use of ether.

Lupine Studies. XVI.[1] The Isolation of Nonalupine from *Lupinus andersonii* Wats

BY JAMES FITTON COUCH

The isolation of nonalupine from *Lupinus sericeus* has been reported recently.[1] In that species this alkaloid is associated with spathulatine first isolated from *L. marianus*.[2] Nonalupine has now been isolated from *L. andersonii*, a perennial, Pacific States lupine, which has not previously been examined chemically. Spathulatine was not found in the last named species.

Experimental

Material.—The plant used in this investigation was collected by the writer on the south road, Crater Lake Mt.,

(1) Previous paper, No. XV, THIS JOURNAL, **62**, 554 (1940).
(2) J. F. Couch, *ibid.*, **46**, 2507 (1924).

Oregon, on August 24, 1930. At that time the plant was just beginning to bloom. The plants were dried and shipped to Washington, D. C. The whole plant with the exception of the roots was used.

Isolation of the Alkaloid.—The finely ground plant (7.415 kg.) was moistened with alcohol containing 75 g. of acetic acid and then extracted with alcohol. The alkaloid was recovered by the process previously described.[3]

The crude alkaloid weighed 130.4 g. or 1.76% of the plant material. It was negative to the modified Grant test for sparteine, practically insoluble in petroleum ether, slightly soluble in ethyl ether, and completely soluble in cold acetone. On standing the sirupy alkaloid solidified to a mass of crystals embedded in a thick sirup.

The mass was washed with cold ethyl acetate, which removed most of the sirup. The crystals were then recrystallized several times from hot ethyl acetate with the addition of a little norit and finally from methyl isobutyl ketone. The melting point was constant at 91–92° (cor.). Mixed with nonalupine from *L. sericeus* there was no alteration in the melting point. The substance was dried to constant weight for analysis.

Anal. Calcd. for $C_{15}H_{24}ON_2$: C, 72.50; H, 9.74; N, 11.28. Found: C, 72.37, 72.39; H, 9.55, 9.57; N, 11.28, 11.20.

The alkaloid was similar in all chemical and physical respects with nonalupine.

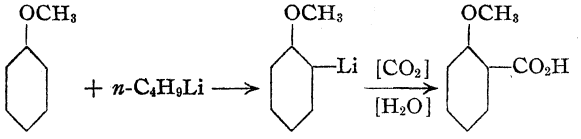
WASHINGTON, D. C. RECEIVED JANUARY 26, 1940

Lateral Metalation of Methyl Phenyl Sulfide

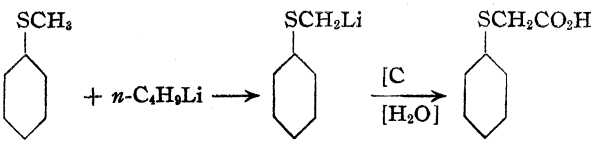
BY HENRY GILMAN AND F. J. WEBB

Metalation by organometallic compounds of a great variety of ethers invariably involves hydrogen situated *ortho* to the hetero element. Some of the types examined are: aryl alkyl ethers, diaryl ethers, and cyclic ethers like furan, benzofuran and dibenzofuran. The following reaction with anisole is typical.



The same general reaction takes place with the sulfur analogs of the diaryl ethers and the cyclic ethers mentioned, with but one exception. Metalation of dibenzofuran by a variety of organometallic compounds involves the 4-position (*ortho* to the hetero element); however, the exceptional case has been noted with the related heterocycle, dibenzothiophene. Although metalation of dibenzothiophene by organolithium and organopotassium compounds also involves the 4-position, metalation by phenylcalcium iodide introduces the metal in the 3-position, or *meta* to the hetero element.[1]

We now find that metalation of methyl phenyl sulfide proceeds quite unlike the related anisole, and instead of giving an *ortho* nuclear metalation product[2] yields exclusively a lateral metalation product.



There is a possibility that nuclear metalation may have occurred initially, and that the lithium then migrated to the methyl group. This remains to be established. In this connection, it is interesting to note that *o*-, *m*- and *p*-tolylsodiums rearrange laterally to benzylsodium.[3] The metalation of other sulfur and related types is being examined, together with some syntheses of these new reactive compounds such as the bridging of the 1- and 9-positions in dibenzofuran types by hetero elements and groups.

Experimental

A solution containing approximately 0.2 mole of *n*-butyllithium was divided into two equal parts. To one portion was added 12.4 g. (0.1 mole) of methyl phenyl sulfide in 30 cc. of ether; and to the other portion was added 10.8 g. (0.1 mole) of anisole in 30 cc. of ether. Each of the mixtures was stirred and refluxed for fifteen hours, and then carbonated by solid carbon dioxide. By means of the usual procedures, there was isolated from the reaction with methyl phenyl sulfide, 7.32 g. (43.5%) of phenylmercaptoacetic acid (m. p., 61–63°). This compound was identified by comparison with an authentic specimen prepared from thiophenol and chloroacetic acid in accordance with the directions of Gabriel.[4] In addition, there was recovered 3.7 g. or 29.8% of methyl phenyl sulfide, which raises the yield of phenylmercaptoacetic acid to 62% on the basis of methyl phenyl sulfide not recovered.

The reaction with anisole gave 4.92 g. or 32.4% of *o*-methoxybenzoic acid; 0.65 g. or 5.37% of 2,2′-dimethoxybenzophenone; and 1.9 g. or 17.6% of recovered anisole. All solids were identified by the method of mixed melting points.

From a check experiment with methyl phenyl sulfide there was obtained 5.9 g. or 35.2% of phenylmercaptoacetic acid (m. p. 61–63°) and 4.5 g. or 36.3% of recovered methyl phenyl sulfide.

IOWA STATE COLLEGE
AMES, IOWA RECEIVED FEBRUARY 26, 1940

Hydrogenation of Wood

BY H. P. GODARD, JOSEPH L. MCCARTHY AND HAROLD HIBBERT

Studies on hydrogenation of lignin and other plant materials at high pressures have now shown that maple and spruce wood meals readily undergo hydrogenation. The two latter products were first freed from resin, fats, etc., by the customary preliminary extraction treatment with alcohol–benzene, alcohol, and water in the order named, then dried, suspended in anhydrous dioxane, the copper–chromium oxide catalyst added and the mixture then subjected to the action of hydrogen at around 250 to 280° at a pressure of 5000–6000 pounds per square inch (333–400 atm.) for periods of twelve to sixteen hours.

The main products isolated were (a) 4-*n*-propylcyclohexanol-1, b. p. 92–95° (7 mm.), refractive index $n^{25}D$ 1.4633, and (b) 4-*n*-propylcyclohexanediol-1,2, b. p. 107–110° (1 mm.), refractive index $n^{25}D$ 1.4808; some higher boiling oils also were obtained. These substances undoubtedly originate from the lignin present in the wood, the combined yields of (a) and (b) in the preliminary work, when calculated on the total (Klason) lignin present originally, amounting to around 60 to 70% in the case of maple and about 35 to 40% in the case of the spruce meal. Similar results were obtained using wood meal previously extracted with cold 5% alkali, although in these cases the yields were somewhat lower.

Presumably other suspending media such as tetralin, decalin, cyclohexane, as well as the above solvents (a) and (b), can be used in place of dioxane, and these are being actively investigated.

It is of considerable interest that the accompanying carbohydrate–polysaccharide components also undergo simultaneous hydrogenation and hydrogenolysis as indicated by the large absorption of hydrogen (about 3.2 moles of hydrogen per 100 g. of wood meal). The nature of these reactions and of the resulting products are also under investigation.

The Effect of Chlorine Substitution on the Fungistatic Properties of Acetic and Propionic Acids

BY CHARLES HOFFMAN, T. R. SCHWEITZER AND GASTON DALBY

In a recent paper the fungistatic properties of β-iodopropionic acid were reported in connection with a study of a series of normal, branched-chain, and substituted fatty acids.[1] It was shown that β-iodopropionic acid had remarkable fungistatic properties which apparently depended to some extent on the nature of the iodine atom itself. The effect of substituents is also of interest from the point of view of the relationship of molecular structure to fungistatic power. Monochloroacetic, α-chloropropionic, and β-chloropropionic acids are readily available and their fungistatic curves illustrate the effect of the introduction of a single chlorine atom in all possible positions.

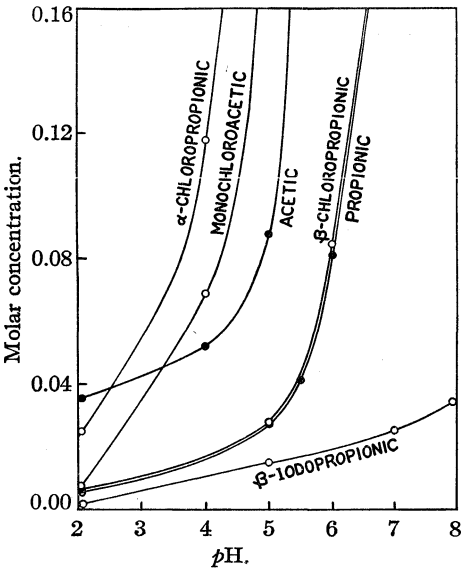

Fig. 1.—Molar concentrations of the indicated acids at various *p*H values necessary to inhibit mold for forty-eight hours at 37.5°.

The method used was as previously reported.[1] β-Chloropropionic acid has a curve practically identical with that of propionic acid itself and is markedly different from the β-iodopropionic acid curve which is indicated on the graph for comparison. The introduction of chlorine on the alpha carbon of propionic acid sharply decreases its fungistatic properties. Monochloroacetic acid is also much less effective than acetic acid except

(1) Hoffman, Schweitzer and Dalby, *Food Research*, 4, 539 (1939).

in the very high *p*H ranges. A chlorine atom on the carbon next to the carboxyl affects the fungistatic properties of the acid, whereas the same substituent on the beta carbon atom has no effect. Constitutional factors are therefore of considerable significance on the biological effect of fatty acids.

Langmuir[2] pointed out that halogen substitution had an appreciable effect on the dissociation constant of a fatty acid. The theory[3] is rather widely held that the biological activity of an acid is dependent on the dissociation constant; that is, the less ionized the acid, the more powerful its biological effect. The relative fungistatic properties of acetic and monochloroacetic, and of propionic and α-chloropropionic acids, when compared with their respective dissociation constants are in agreement with this theory. In the case of propionic and β-chloropropionic acids, however, the fungistatic properties are not so closely related to the dissociation constants. Propionic acid has a dissociation constant of 1.33×10^{-5}, and β-chloropropionic acid 8.59×10^{-5},[2] but the two acids have essentially identical fungistatic properties.

The Preparation of Aurin Tricarboxylic Acid*

BY DUNCAN A. HOLADAY

Recent work in this Laboratory required the use of pure aurin tricarboxylic acid. Several methods of preparing this compound were tried, including those of Scherrer and Smith,[1] Heisig and Lauer,[2] and Caro.[3] A product satisfactory for use in the determination of aluminum was obtained by each of these methods, but in no instance did the product contain more than 70% aurin tricarboxylic acid based on the air-dried material. The content of dye was determined by titration with titanium trichloride solution.[4]

In the course of the work it was observed that the material prepared by Caro's method would undergo a further reaction on treatment with a second portion of the oxidizing mixture (sodium nitrite–sulfuric acid solution). A study of this reaction developed the following modification of Caro's procedure which has several advantages over previously described preparations and yields a product of high purity. The methods of Heisig and Lauer, and of Scherrer and Smith, require that the temperature be kept below 5°. In the following procedure the reaction is not highly exothermic, and therefore no rigid temperature control is necessary. Caro recommends a purification with sodium bisulfite, which is difficult to perform and in the author's hands does not yield a pure product. In the modified procedure no purification of the reaction product is necessary except the removal of inorganic salts.

Experimental Part

Five grams of finely powdered sodium nitrite was added slowly and with vigorous stirring to 36 cc. of sulfuric acid, avoiding evolution of oxides of nitrogen. To this solution an intimate mixture of 10 g. of methylene-disalicylic acid[5] and 5 g. of salicylic acid was added in small portions with vigorous stirring. After addition of all of the solid material, the mixture was allowed to stand for an hour with occasional stirring. It was then poured into a solution of 5 g. of sodium nitrite in 36 cc. of sulfuric acid, stirred, and allowed to stand overnight. The reaction mixture was added slowly to one liter of cold water, allowed to stand for an hour, and filtered on a Büchner funnel. The precipitate was suspended in one liter of warm water (50°) and filtered. This suspension and filtration was repeated, the free water removed by drawing air through the funnel, and drying was completed in a vacuum oven at 70°. The yield of dry product was 10.5 g. It titrated 97% aurin tricarboxylic acid.

Type III Surface Tension Curves with Minimum in Dilute Solution in Pure Hydrocarbons

BY M. E. L. MCBAIN AND L. H. PERRY

Many properties of colloid systems in water are usually explained in terms of free ions, so that it becomes interesting to examine non-ionizing solvents to see in how far similar behavior is to be found where free ions are almost or quite lacking. One very striking property of many colloidal electrolytes in water is that in very dilute solution they lower the surface tension to about one-third that of water. The surface tension is then at a minimum and thereupon rises to a flat maximum in slightly less dilution. Some non-electrolytic detergents likewise similarly lower the surface

tension of water to an almost equal extent in very dilute solution, but it then remains constant on further concentration. The existence of these type III curves has been thoroughly established[1] and they are of special interest because the positive adsorption actually observed by a number of methods does not accord with the requirements of the Gibbs theorem as ordinarily applied to surface tension measurements.

Using hydrocarbons as solvents, we have found that type III curves with minima do actually occur in non-ionizing media. This is shown in Fig. 1 for pure lauryl sulfonic acid dissolved in

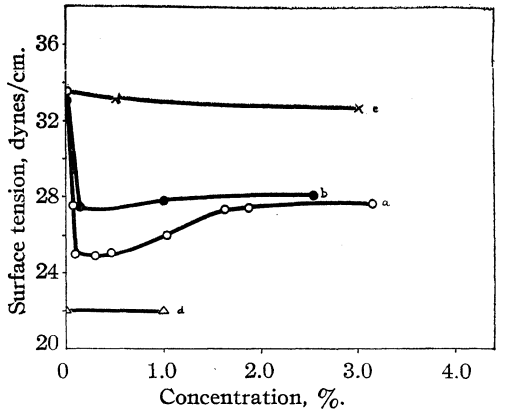

Fig. 1.—Surface tension curves in hydrocarbon solutions: Type III curves for lauryl sulfonic acid in (a) Nujol and (b) mineral oil; Type I curves for (d) lauryl sulfonic acid in *n*-heptane and (e) butyric acid in Nujol.

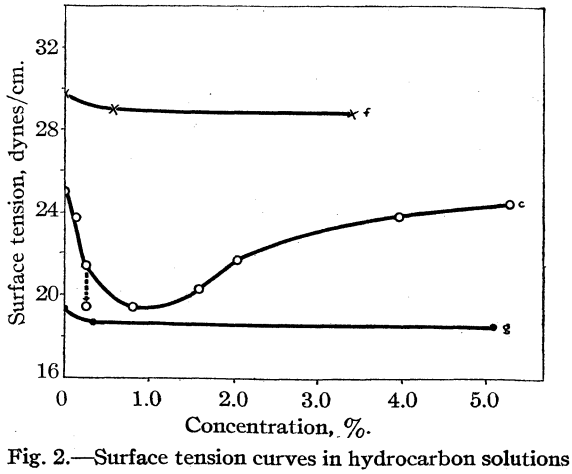

Fig. 2.—Surface tension curves in hydrocarbon solutions of lauryl sulfonic acid: Type I curves for (f) benzene and (g) iso-octane; Type III curve for (c) hydrogenated tetraisobutylene, showing with vertical dashed line the time effect in lowering of surface tension in very dilute solutions only.

(1) McBain and Mills, Reports on Progress in Physics, **5**, 30 (1939); McBain, Vinograd and Wilson, THIS JOURNAL, **62**, 244 (1940); McBain and Wood, *Proc. Roy. Soc.*, **174A**, in press (1940); McBain, Mills and Ford, THIS JOURNAL, **62** in press (1940).

(a) Nujol, (b) mineral oil, and, in Fig. 2, (c) hydrogenated tetraisobutylene. The results were obtained with the DuNoüy ring tensiometer at 27°, first sweeping the surface to remove contamination. These solutions unlike most of the others to be mentioned leave a film within the ring.

On the other hand, lauryl sulfonic acid in solvents such as iso-octane, xylene, benzene and heptane scarcely lowers the surface tension. For iso-octane the value 19.3 dynes/cm. falls steadily with concentration to 18.5 in 5% solution (type I curve). For benzene the value 29.7 of the pure solvent becomes 28.7 for 3.4%, and for *n*-heptane the value of 22.2 is not changed when 1% of acid is added. These results are summarized in Table I.

TABLE I

SOLUTIONS OF $C_{12}H_{25}SO_3H$ IN HYDROCARBONS SHOWING SURFACE TENSION OF SOLVENT, σ_0; OF 1% SOLUTION, σ_1; AT MINIMUM, $\sigma_{min.}$, IF ANY; AND TYPE OF SURFACE TENSION CURVE

Solvent	σ_0	σ_1	$\sigma_{min.}$	Type
Nujol	33.5	25.9	24.8 at 0.2%	III
Mineral oil	33.0	27.8	27.4 at 0.18%	III
Benzene	29.7	29.3	none	I
Xylene	27.8	27.3	none	I
Tetraisobutylene	25.3	22.5	22.3 at 0.15%	III
Hydrogenated tetraisobutylene	25.0	19.5	19.4 at 0.8%	III
Decane	23.7	22.3	none (?)	I, III (?)
Heptane	22.2	22.2	none	...
Iso-octane	19.5	19.2	none	I

It is interesting to compare a surface tension curve in Nujol and in the similar mineral oil with that in water,[1] where the surface tension at the minimum is the same in all three cases, though that of water is as high as 72 dynes. The first thought, that solvents whose own surface tension is already as low as this minimum could not be lowered, is negatived by the result in hydrogenated tetraisobutylene, where it drops from 25 dynes to 19.4. However, the two intervening solvents, benzene and xylene, are not similarly affected by lauryl sulfonic acid. They are lowered but slightly and yield no minimum, showing that surface tension of the solvent is no sufficient guide.[2] Decane appears to be on the borderline among saturated hydrocarbons.

Polar compounds are not enough. For example, nonyl glucoside and another excellent detergent, a polyethylene oxide derivative, scarcely

(2) Interesting contrasts between spreading behavior of hexane and benzene on mica surfaces have been reported by Bangham, Mosallam and Saweris, *Trans. Faraday Soc.*, **34**, 554 (1938); *Nature*, **140**, 237 (1937).

lower the surface tension of Nujol or hydrogenated tetraisobutylene. The measurements are hampered, however, by low solubility and a tendency to separate on cooling. In water, Woo's unpublished measurements show that they lower the surface tension from 72 to 31 dynes in extreme dilution, namely, 0.02 and 0.2% solutions, respectively, thereafter remaining constant up to 1% solution.

The sulfated sodium naphthenic or petroleum soaps supplied by the Sherwood Petroleum Company are oil-soluble, not water-soluble. They actually raise the surface tension of *n*-hexane from the value 20.2 to 20.4 or 20.5 for 10% solution and to 22.3 for 50% solution, thus giving a type II curve.

A number of especially interesting solutes of different types could not be tested on account of their insolubility, but a non-electrolytic detergent showed no appreciable lowering in Nujol although 14 and 24% solutions gave the small lowerings of 0.5 and 2.0 dynes. Butyric acid likewise is ineffective, the lowering being 0.5, 0.9 and 2.0 dynes for 1, 9 and 20% solutions, respectively. Lauric acid in 3% solution gave the distinctly greater lowering of 2 dynes. Triethanolamine oleate in 0.5 and 9% gave a lowering of 1 dyne and 2 dynes; thymotic acid in 1% solution 0.8 dynes; and stearic acid gave 1 dyne lowering for 0.7%. Calcium and zinc stearates have practically no effect.

It is evident that appreciable lowering and the production of a type III curve in these hydrocarbons require such a degree of polarity that the solute forms a strong electrolyte or colloidal electrolyte in water.

The only explanation to account for the minimum found in a type III curve is that put forward by McBain[3] based upon the electrical double layer. Now in the present non-ionizing solvents this would have to be a condensed Helmholtz double layer of the classical type instead of the partly diffuse type existing in water. However, the Helmholtz double layer is adequate for explaining lowering of surface or interfacial tension.

These novel observations evidently should suggest many other approaches and experiments to investigators in this field and are significant as a guide to other phenomena in hydrocarbon systems.

Alkanolamines. VIII. Reaction of Ethanolamines on *p*-Nitrobenzoic Acid

BY M. MELTSNER, DANIEL GREENFIELD AND HARRY ROSENZWEIG

In some of the previous papers of this series[1,2,3,4] it was shown that alkanolamines, but not their salts, may reduce an aromatic nitro group and that the unreduced and reduced compounds may form addition compounds with the alkanolamines. This is now confirmed by the following experiment on the action of ethanolamines on *p*-nitrobenzoic acid.

Experiment I.—One mole of ethanolamine and one mole of *p*-nitrobenzoic acid were heated at 100° for four hours. The brown solid residue, after extraction with ether and chloroform, was crystallized from alcohol. A white compound of m. p. 168° was obtained. An ether extraction of this substance from dilute hydrochloric acid yielded *p*-nitrobenzoic acid while the hydrochloric acid layer on evaporation gave a white solid, m. p. 82°, corresponding to ethanolamine hydrochloride. The white compound was therefore an addition product, $NO_2C_6H_4COOH\cdot NH_2CH_2CH_2OH$.

Similarly diethanolamine yielded $NO_2C_6H_4COOH\cdot NH(CH_2CH_2OH)_2$, m. p. 138°, and triethanolamine yielded $NO_2C_6H_4COOH\cdot N(CH_2CH_2OH)_3$, m. p. 116°.

Experiment II.—One mole of ethanolamine was refluxed with one mole of *p*-nitrobenzoic acid in an oil-bath for two hours. The reaction mixture was treated several times with cold water and filtered. The filtrate was evaporated to dryness on the water-bath and the residue extracted with alcohol. Evaporation of the alcohol gave a solid identified as *p*-aminobenzoic acid by its positive test for the amino group, its melting point (186°) and the melting point of the dinitrobenzoate (195°). The dry residue, insoluble in alcohol, was recrystallized from hot water and gave $NO_2C_6H_4COOH\cdot NH_2CH_2CH_2OH$.

The residue, insoluble in cold water, was extracted with chloroform to isolate some more *p*-aminobenzoic acid and then recrystallized from hot water. There was obtained in large amounts a pale yellow compound, m. p. 130°, which was identified as the addition product of two moles of ethanolamine and one mole of azoxybenzoic acid: N calcd., 13.72; found, 13.64. The compound can be reduced to yield *p*-aminobenzoic acid. Hydrolysis of the compound with alkali gave *p,p'*-azoxybenzoic acid which was identified by means of its ethyl ester. Hydrolysis of the compound with hydrochloric acid yielded monoethanolamine hydrochloride.

Experiment III.—Four moles of diethanolamine and one mole of *p*-nitrobenzoic acid were heated for two hours at 180°. The reaction mixture was washed with chloroform, extracted with hot water and filtered. On cooling, yellow crystals are obtained and identified as *p*-aminobenzoic acid.

The Oxidation–Reduction Potential of Vitamin K_1

BY BYRON RIEGEL, PERRIN G. SMITH[1] AND CARL E. SCHWEITZER

Because of the increasing physiological importance of oxidation–reduction systems, the oxidation–reduction potential of pure synthetic vitamin K_1 has been determined. Such potentials are also important for elucidating the structures of quinones and for this reason, at the suggestion of Professor L. F. Fieser, we first measured the potential of the vitamin in potent alfalfa concentrates. This value, 358 mv., in conjunction with the C-H analysis and the absorption spectrum first published by Dam, Karrer, *et al.*,[2] provided strong evidence that vitamin K_1 was a 2,3-dialkyl-1,4-naphthoquinone. This was evident from the values of Table I.

TABLE I

	E_0 in mv.
1,4-Naphthoquinone	484[a]
2-Methyl-1,4-naphthoquinone	408[a] 422[b]
2,3-Dimethyl-1,4-naphthoquinone	340[a]

[a] L. F. Fieser and M. Fieser, THIS JOURNAL, 57, 491 (1935).

[b] J. W. H. Lugg, A. K. Macbeth and F. L. Winzor, *J. Chem. Soc.*, 1457 (1936).

This information together with other known facts led to the prediction of the first specific structure[3] for vitamin K_1 which later proved to be correct.

Karrer and colleagues[4] have reported the oxidation–reduction potential $E_m = +5$ mv. for vitamin K_1. It is not absolutely clear, from their experimental data, how their value compares with other quinone potentials because they did not use the customary method. However, from a consideration of the pH of the solvent used it seems that their value of the oxidation–reduction potential E_0 is about 400 mv. This estimation does not take into account a possible junction potential.

In the fractionation of alfalfa extracts it was found that a stock solution of 3% vitamin K_1 concentration had the best keeping qualities and gave the most reliable potentials over a period of time. More highly refined concentrates showed considerable variation in both bioassay and potential upon storage. Because of these variations and the occasional presence of other substances which affected the oxidation–reduction curve it seemed advisable to delay publication until the determination could be made on the pure vitamin.

The length of time required to establish equilibrium (in some instances twenty-four hours for the complete titration) in the case of the refined concentrates made it necessary to employ a stable reference electrode. The Ag–AgCl electrode was found to be very suitable for this purpose since it is stable for at least several weeks.

The oxidation–reduction potential of pure vitamin K_1 was found to be 363 mv. at 20°.

Experimental

The preparation of the vitamin K active concentrates[5] from alfalfa has been described. The synthetic vitamin K_1 used in this work was prepared according to the method of Fieser.[6]

In the solvent used, 95% ethanol 0.2 N in hydrochloric acid and 0.2 N in lithium chloride, the positive potential of the Ag–AgCl electrode against the hydrogen electrode in the same solvent was approximately 200 mv. This value varies somewhat in different lots of the same solvent depending on the exact chloride ion concentration. However, it is necessary to determine the potential against the hydrogen electrode only once for any one lot of solvent. In the solvent used for the determination of the potential of the pure vitamin the Ag–AgCl electrode gave a value of +203 mv. against the hydrogen electrode. The solubility of the vitamin at room temperature was found to be about 5 mg. per ml. in the above solvent. This same solvent was used to prepare the very dilute solution of titanium trichloride used in the potentiometric titrations. Both platinized and bright platinum electrodes were used and gave the same results although the platinized electrodes seemed to reach equilibrium more rapidly.

Two independent determinations, checking within 1 mv., gave a potential of +160 mv. for the vitamin against the Ag–AgCl electrode. Thus the vitamin potential, E_0, against the hydrogen electrode is 363 mv. All measurements were made at 20°.

The Preparation of *unsym*-Difluorotetrachloroethane

BY WILLIAM T. MILLER

No very convenient methods for the preparation of *unsym*-difluorotetrachloroethane have appeared in the literature, although it has been synthesized by the chlorination of difluorotrichloroethane [$CHCl_2CF_2Cl$].[1] In this work, it was found possible to obtain the desired compound satisfactorily from trifluorotrichloroethane[2] [CF_2Cl-CCl_2F] and aluminum chloride. The simplicity of the experimental procedure and cheapness of the starting materials make the product readily available for the first time.

This reaction is not entirely a simple replacement of fluorine by chlorine as some gaseous products are formed[3] and too long heating leads to the formation of hexachloroethane. It was probably for this last reason that Henne and Newman[4] obtained little of the difluoro compound after refluxing trifluorotrichloroethane with aluminum chloride for forty-eight hours.

Experimental

Two hundred cc. of trifluorotrichloroethane[2] and 40 g. of finely powdered aluminum chloride were refluxed on a steam-bath for five hours. The surface of the aluminum chloride turned dark during this period. Distillation of the product through a 50 × 1 cm. column packed with glass helices yielded 51 g. of *unsym*-difluorotetrachloroethane, b. p. 90–91°, m. p. 40–41°, and a very small residue composed principally of hexachloroethane. The lower boiling material distilled almost entirely below 48° but was shown by freezing to contain appreciable amounts of CF_2ClCCl_3. Longer periods of reaction yielded increased quantities of hexachloroethane.

Some Addition Compounds of Phthaleins and Metallic Salts*

BY GEORG SACHS AND LILI RYFFEL-NEUMANN

K. H. Meyer and A. Hantzsch in 1907[1] described some compounds produced by addition of metallic salts to phenolphthalein, its lactoid dimethyl ether and its quinonoid dimethyl ether ester in non-aqueous solvents. No compound of this kind seems to have been prepared since except a zinc chloride addition compound of the hexamethyl ether of phloroglucin-phthalein.[2] It is surprising that these compounds are all colored, although the organic component might be colorless or even, as, *e. g.*, in the case of dimethoxyphenolphthalein, incapable of assuming a quinonoid structure.

By extending the Meyer and Hantzsch method to other phthaleins we found a number of definite types of addition compounds. As metallic salts we used stannic chloride and antimony pentachloride. Besides phenolphthalein and its dimethyl ether, the phthaleins we dealt with were 3,6-dimethylfluoran, fluorescein and the lactoid dimethyl ether of fluorescein. All addition compounds we obtained were colored. It may be pointed out that all phthaleins mentioned above give colored addition products with acids also and that there is a certain connection between those two series of addition compounds.

The substances were prepared by mixing the component solutions in the manner adopted by Meyer and Hantzsch, a deep tint indicating the formation of an addition compound. In several cases the metal chloride was added without solvent, or cooling was necessary. If the resulting substance did not separate by itself, it was precipitated by a second liquid.

The substances formed differed widely in their stability toward water. Those derived from dimethylfluoran were the most stable. Some of them were, because of their extreme sensitivity to moisture, obtainable only in a closed apparatus. A few substances were so unstable that they could not be weighed for testing and the analysis had to be limited to the determination of the proportion of some constituents. In such cases the addition of indifferent molecules of the solvent could not be controlled.

The compounds we prepared are collected in Table I. The compounds prepared by Meyer and Hantzsch from the same components are inserted and denoted by "M. and H."

The compound (4) mentioned by Meyer and Hantzsch could not be obtained. Instead compound (5) resulted, but, whereas Meyer and Hantzsch claim that the substance was formed slowly, (5) precipitated at once.

Except substance (9) which has a more complicated formula and substance (11) which is a salt

of the acid, $HSbCl_6$, all the compounds listed are included in four different classes: (A) $SnCl_4$·2P, substances (5), (12); (B) $SnCl_4$·P, substances (4), (7), (13); (C) $SnCl_4$·P·Solvent, substances (1), (2), (3), (8); (D) $SbCl_5$·P, substances (6), (10).

The chemical nature of the classes A, C and D seems to be clear. They are complex compounds of coördinated hexavalent tin or antimony, one molecule of the phthalein occupying a single coördination valence. The substances of class B may be interpreted by the hypothesis that the phthalein occupies two coördinated valences or they may be considered as bimolecular compounds with two coördination centers. They are mostly less deeply colored and are mainly formed if solvents lacking secondary valences are used.

GLASGOW, SCOTLAND RECEIVED SEPTEMBER 22, 1939

The Condensation of Phenol and Ethylene Oxide

BY RICHARD A. SMITH

The monophenyl ether of ethylene glycol was first prepared by the reaction between phenol and ethylene oxide in a sealed tube.[1] In this way, by heating at 180° for eight hours, we obtained an 85% yield based on the phenol.

More frequently, however, it has been prepared by the reaction of ethylene chlorohydrin with a phenol salt.[2] We find that using this latter method and refluxing the mixture for eight hours gives, after distillation through a 6-foot column and collection within 0.5°, 1.10 moles of phenoxy glycol (b. p. 165° at 80 mm.), or a 55% yield, from 2 moles of phenol. This same reaction, carried on in a sealed tube for eight hours, gives a 62.5% yield of the same purity.

We now find that by heating, without rocking, molar equivalents of phenol and ethylene oxide in an autoclave charged with hydrogen at tank pressure for four hours until the temperature reaches 200°, the pressure at that time being in excess of 2500 pounds per sq. in., and then allowing it to cool and redistilling the product in a vacuum, a yield of 94% of phenoxy glycol of the same purity is obtained.

The Physical Constants of Pentanol-3

BY FRANK C. WHITMORE AND J. D. SURMATIS

Pure pentanol-3 was required in large quantity for work in progress in this Laboratory. Since the physical constants for the carbinol reported in the literature[1] show wide disagreement, a study was made on the purity of material synthesized in the laboratory and that obtained from Sharples Solvents Corporation.

Propionaldehyde, b. p. 48.0° at 736 mm., $n^{20}D$ 1.3636, was prepared by dehydrogenation of *n*-propyl alcohol with a copper catalyst. It was treated in four 8-mole lots with ethylmagnesium chloride in anhydrous ethyl ether. The crude product obtained in 67% yield after distillation through a column of approximately 25 theoretical plates, was refractionated through a column, 2 × 260 cm. of the total condensation partial take-off type, having approximately 85 theoretical plates. From this distillation a yield of 90% of constant boiling and constant index material resulted. The boiling point was determined in a laboratory Cottrell apparatus, with a thermometer calibrated against one checked by the Bureau of Standards; the refractive index was determined by a Valentine refractometer: b. p. 114.4° at 740 mm., $n^{20}D$ 1.4104, d^{20}_4 0.8218.

Approximately 2800 g. of Sharples pentanol-3 was distilled through a column of approximately 16 theoretical plates, and then refractionated twice through the 85-plate column described above. Of the starting material 27% was obtained with the physical constants: b. p. 114.3–114.5° at 741.5 mm., $n^{20}D$ 1.4102–1.4104, d^{20}_4 0.8203.

COMMUNICATIONS TO THE EDITOR

THE TOTAL SYNTHESIS OF A NON-BENZENOID STEROID[1]

Sir:

We reported in the last paper[2] that a derivative of hexahydronaphthalene results from the addition of maleic anhydride to 2,5-dimethyl-1,5-hexadiene-3-yne. It has now been found that an analogous reaction occurs when the hydrocarbon I[3] is heated with one mole of maleic anhydride at 130° without solvent. The crystalline product, from ethyl acetate or benzene, has m. p. 249–251° (cor.) with decomposition, and is converted in low yield to 15,16-dihydro-17-cyclopenta[a]phenanthrene (III), m. p. 132–133° (cor.), by heating with palladium–charcoal. This hydrocarbon did not depress the m. p. of an authentic specimen[4] kindly furnished by Dr. Erich Mosettig. *Anal.*[5]

FURTHER COMPOUNDS HAVING ANTI-HEMORRHAGIC ACTIVITY

Sir:

In an investigation involving the synthesis and assay of a number of additional naphthoquinones and derived or related products, considerable data have been accumulated on the problem of correlating vitamin K activity and structure which will be presented after completion of adequate assays on the entire series of compounds synthesized in the two Laboratories. In the meantime we wish to report certain observations from the synthetic work and give some indication of the potencies of the new compounds.

The method developed by one of us for the synthesis of vitamin K_1 [Fieser, THIS JOURNAL, **61**, 2559, 3467 (1939)] has been found capable of wide application. By using 1,4-naphthohydroquinone as one component 2-geranyl, 2-farnesyl, and 2-phytyl-1,4-naphthoquinone have been synthesized in good yield. The phytyl compound [yellow oil, found: C, 82.82; H, 10.31] is the most active member of the series and gives a full response in the chick assay at 50 γ. Similarly the 3-farnesyl derivative of 2-methyl-1,4-naphthoquinone [found: C, 82.97; H, 8.98] is more potent than the 2-geranyl derivative but somewhat less active than vitamin K_1. The synthesis is also applicable in the benzohydroquinone series. 2,3,5-Trimethyl-6-phytyl-1,4-benzoquinone [yellow oil, found: C, 81.04; H, 11.00, hydroquinone diacetate, m. p. 56°] shows no vitamin K activity but it provides a new route to a vitamin E factor. By treatment with stannous chloride in acetic–hydrochloric acid the quinone was converted smoothly into α-tocopherol, identified through the allophanate, m. p. 175–176°, and *p*-nitrophenylurethan, m. p. 130°. Butadiene-toluquinone condenses with phytol under the usual conditions but at the reflux temperature, giving rise to 2-methyl-3-phytyl-5,8-dihydro-1,4-naphthoquinone [found: C, 82.27; H, 10.86], which is active at a level of 5–6 γ. By hydrogenating synthetic vitamin K_1 and purifying the products in the form of the solid hydroquinones, the β,γ-dihydride (active at 6 γ, hydroquinone diacetate, m. p. 57–58°) and $\beta,\gamma,5,6,7,8$-hexahydride (slight activity, diacetate derivative, m. p. 53°) have been obtained in analytically pure form. Both butadiene-toluquinone and 2-methyl-5,8-dihydro-1,4-naphthohydroquinone show marked activity, the latter at dosages as low as 8 γ.

A by-product of the vitamin K_1 synthesis, characterized as a ketonic substance of the formula $C_{31}H_{48}O_2$ [found: C, 82.38; H, 10.65; maxima at 253 and 300 mμ; 2,4-dinitrophenylhydrazone m. p. 107–108°], shows moderate vitamin K activity (50 γ). The Zerewitinoff determination indicates the presence of one active hydrogen and one carbonyl group. Aluminum isopropylate reduction gives a diol, probably $C_{31}H_{52}O_2$ [found: C, 81.52; H, 11.48], and pyrolysis of the by-product gives rise to small amounts of vitamin K_1. The isomeric naphthotocopherol [found: C, 82.30; H, 10.69; maxima at 246 and 320 mμ; *p*-nitrobenzoate, m. p. 84–85°] is active at a higher level (300 γ); on oxidation it yields a yellow hydroxyquinone [found: C, 79.19; H, 10.17].

THERMAL DECOMPOSITION OF ACETONE CATALYZED BY IODINE

Sir:

Several investigators[1] have shown that small amounts of iodine sensitize the thermal decomposition of various organic compounds. In the case of acetone, Bairstow and Hinshelwood[1a] have reported that the decomposition was not appreciably affected by the presence of iodine. However, Rice and Weiler[2] observed that the decomposition of acetone containing methyl iodide was appreciably faster than the rate for pure acetone. Moreover it was found that the addition of approximately 1% of ethyl iodide enormously increased the rate of decomposition of acetone at 526°.[3] When a small amount of ethyl iodide was allowed to decompose completely in the reaction vessel first and then the acetone added, a large increase in the rate also was observed. This

(3) Rice and Walters, unpublished results.

indicated that the iodine which was present in the decomposition products from ethyl iodide[4] was responsible for a large part of the promoting effect.

In the present investigation, we have found that small amounts of pure iodine actually do accelerate the decomposition of acetone in the neighborhood of 500°. The apparatus for this work is of the usual type and includes a Bodenstein valve and a click gage.

Temp., °C.	P_0, mm.	%, I_2	$(\Delta P/P_0)$ % 20–0 min.

493	207	1.55	29.5

(4) Ogg, THIS JOURNAL, **56**, 526 (1934).

From the Table it can be seen that addition of 2–3% of iodine causes the pressure change for the first twenty minutes of the reaction to increase by a factor of eight. The temperature at which Bairstow and Hinshelwood attempted the catalysis of acetone was not given, so that their failure to observe any catalysis may have been due to the fact that they were working in a different temperature range.

We are actively engaged in completing this investigation of acetone and intend to study other ketones such as diethyl and ethyl methyl ketones.

NEW BOOKS

May's Chemistry of Synthetic Drugs. By PERCY MAY, D.Sc. (Lond.), F.I.C., Consulting Chemist and Chartered Patent Agent, and G. MALCOLM DYSON, Ph.D., F.I.C., A.M.I. Chem.E., Chief Chemist, Genatosan Ltd. Fourth Edition, revised and rewritten. Longmans, Green and Company, Inc., 114 Fifth Avenue, New York, N. Y., 1939. xii + 370 pp. Illustrated. 14 × 22.5 cm. Price, $6.00.

During the past two decades there has been a steadily increasing demand for books which would adequately set forth in clear and concise fashion the salient facts dealing with the relations between the chemical constitution and physiological action of medicinal products and related substances. Despite this evident need there have been surprisingly few ventures into this field of scholarly activity.

May's "Chemistry of Synthetic Drugs," published some thirty years ago (the third edition appeared seventeen years ago), has deservedly had wide popularity. It has given readers an insight into the fundamental concepts of the field, without being handbook in nature. Indeed it was apparently never designed to serve in the role of a monograph which would point the way to new fields of research for the specialist. Rather it has been useful to young chemists who have desired a broad viewpoint of the field of medicinal products, without being compelled to delve into a maze of technical chemical and physiological information.

This, the fourth edition, has arisen from the joint efforts of Percy May and G. Malcolm Dyson. The general plan of the older editions has been followed, but a large amount of new material has been added. It has also been modernized by the inclusion of information on such subjects as hormones, vitamins, steroids, cardiac glucosides, and anthelmintics. Among the sections which have been enlarged are those dealing with hypnotics, mercurials, antiseptics, local anesthetics, analgesics, and alkaloids.

American readers, specialists in the field, will doubtless find cause for real criticism in the rather British and Continental flavor of the book, for it passes over lightly, or not at all, some of the fine developments which have come from the academic and industrial laboratories of this country. Nevertheless the authors have made a real contribution, and the book will unquestionably continue to play the important role which it has played since it was first written by Dr. May.

ARTHUR J. HILL

Plant Viruses and Virus Diseases. By F. C. BAWDEN, M. A., Virus Physiologist, Rothamsted Experimental Station. Chronica Botanica Company, P. O. Box 8, Leiden, Holland, and G. E. Stechert and Company, 31 East 10th Street, New York, N. Y., 1939. 272 pp. 37 figs. 16.5 × 25 cm. Price, Dutch guilders 7, or about $4.00.

Chemists have never been over-modest in their ideas as to the role of chemistry in the scheme of things. Bancroft, for example, has argued eloquently that all the natural sciences are mere provinces of the Chemical Empire. The developments of science in the past few years have certainly favored this *Weltanschauung*. Nevertheless, until very recently even chemists might have hesitated to designate as chemical a book on viruses, *i. e.*, living organisms defined as "obligate parasitic pathogens with at least one dimension less than 200 μ."

Today even this hesitation is unnecessary. Stanley's isolation in 1935 of the virus of the mosaic disease of tobacco as a crystalline protein established this virus as a definite though complicated chemical substance. This certainly makes a review of a book on viruses entirely appropriate for a journal of chemistry.

The contents of the present book justify this chemical allocation. After an introductory survey and chapters on the symptomatology of viruses, their transmission, strains and serological reactions, there follow chapters on their purification, size, optical properties, chemical nature, origin and multiplication. The occurrence of these viruses and the economic importance of the diseases which they produce are also set forth.

It appears from the careful and discriminating discussion in this book that the conclusions of Stanley as to the virus of the mosaic disease of tobacco have been confirmed by subsequent workers, although it has been shown not to be a globulin but a nucleoprotein. The viruses of several other similar diseases also have been isolated in crystalline form and their distinguishing properties ascertained.

The great question which interests every reader, as to whether these apparently inanimate crystalline proteins are alive or capable of living in a suitable environment, is not given a categorical answer. It is shown, however, that the uncertainty is not so much as to whether these viruses are proteins, but rather as to whether viruses are indeed alive. On the one hand, they are certainly small, discrete bodies which resemble bacteria in their behavior, are able to multiply with extreme rapidity in a favorable environment and retain their characteristics tenaciously throughout this multiplication. On the other hand, they have not as yet been successfully cultivated in the absence of living cells, and it may be that this is a decisive distinction which demonstrates them really to be inanimate. However, to the innocent bystander with the history of our knowledge of the enzymes in mind, this seems a somewhat frail barrier to serve as a last defence of vitalism.

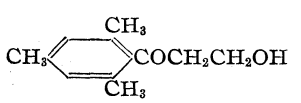
[CONTRIBUTION FROM THE NOYES CHEMICAL LABORATORY, UNIVERSITY OF ILLINOIS]

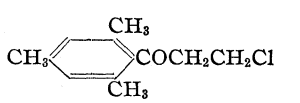
The Condensation of Paraformaldehyde with Acetomesitylene

BY REYNOLD C. FUSON AND C. H. MCKEEVER[1]

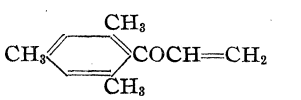
When acetomesitylene is condensed with paraformaldehyde in the presence of potassium carbonate and methanol the principal product is a liquid which was identified as the monomethylol derivative (I). Treatment with hydrochloric acid converted this compound into a substance which was thought to be the corresponding chloride (II).[2] However, subsequent work showed that these structures were open to question. The methylol derivative, made later by the action of formaldehyde on the bromomagnesium derivative of acetomesitylene,[3] proved to be different from that reported previously. The chloride was synthesized by adding hydrogen chloride to vinyl mesityl ketone (III).[4] The compound produced in this



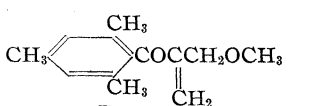
I



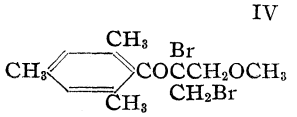
II



III



IV



V

manner was entirely different from that first reported. These observations made it necessary to reëxamine the product from acetomesitylene and paraformaldehyde.

By careful refractionation of this oil it was found that the main portion was a compound somewhat richer in carbon than the liquid which was described earlier. It proved to be *an unsaturated ether* having the structure represented by formula IV. The evidence for this structure is conclusive. The compound reacts with bromine to give a stable dibromide (V) from which it is regenerated by treatment with sodium iodide. Catalytic hydrogenation converts the unsaturated ether to isobutyromesitylene. Zeisel determinations show that one methoxyl group is present. Structure IV is the only one which will explain all of these facts.

The formation of the unsaturated ether (IV) by the action of paraformaldehyde on acetomesitylene might be explained by the following steps[5]

$$C_9H_{11}COCH_3 + CH_2O \longrightarrow C_9H_{11}COCH_2CH_2OH \quad (1)$$

$$C_9H_{11}COCH_2CH_2OH \longrightarrow C_9H_{11}COCH{=}CH_2 + H_2O \quad (2)$$

$$C_9H_{11}COCH{=}CH_2 + CH_3OH \longrightarrow C_9H_{11}COCH_2CH_2OCH_3 \quad (3)$$

$$C_9H_{11}COCH_2CH_2OCH_3\ (VI) + CH_2O \longrightarrow C_9H_{11}COCCH_2OCH_3\ (IV) \quad (4)$$
$$\qquad\qquad\qquad

companied by dehydration to the corresponding vinyl ketone (step 2). The addition of methanol to vinyl mesityl ketone (step 3) was found to take place in the presence of potassium carbonate. From the methoxypropiomesitylene (VI) so formed the unsaturated ether (IV) was obtained readily by treatment with paraformaldehyde (step 4). The unsaturated ether was made also by combining the last two steps, *i. e.*, by treating vinyl mesityl ketone with paraformaldehyde in the presence of methanol and potassium carbonate.

Experimental

Preparation of β-Mesitoylethyl Alcohol (I).—To 0.15 mole of the bromomagnesium enolate of acetomesitylene[3] in 300 cc. of absolute ether was added with stirring at 0° 0.3 mole of gaseous formaldehyde. The formaldehyde was produced by heating paraformaldehyde to 170–200° and was introduced into the reaction mixture through a large inlet tube. The mixture was stirred for ten hours at room temperature, then poured into 600 cc. of water which had been acidified with 30 cc. of concentrated hydrochloric acid. The ether layer was separated, washed three times with very dilute hydrochloric acid, twice with water and dried over calcium chloride. The ether was removed and the residue distilled *in vacuo*. There were obtained 6 g. of acetomesitylene, 14 g. of an almost colorless liquid boiling at 135–138° (4 mm.) and 3 g. of residue.

Ten grams of the liquid when redistilled yielded 5 g. of vinyl mesityl ketone, b. p. 95–96.5° (3 mm.), and 5 g. of β-mesitoylethyl alcohol, b. p. 121–123° (2 mm.); $n^{20}D$ 1.5340. The pure compound could not be distilled without appreciable loss, presumably due to dehydration.

Anal.[6] Calcd. for $C_{12}H_{16}O_2$: C, 74.94; H, 8.41. Found: C, 75.20; H, 8.37.

The low-boiling compound was proved to be vinyl mesityl ketone by a mixed melting point of the dibromo derivative with α,β-dibromopropiomesitylene. In one experiment, the crude β-mesitoylethyl alcohol decomposed completely when redistillation was attempted. Vinyl mesityl ketone was obtained in a yield of more than 90%.

Action of Concentrated Hydrochloric Acid on Mesitoylethyl Alcohol.—A mixture of 3 g. of the crude alcohol and 100 cc. of concentrated hydrochloric acid was stirred for forty-eight hours. The reaction mixture was poured into 500 cc. of water and extracted with ether. The ether extracts were washed several times with water, dried and the ether was removed by an air blast. The viscous yellow residue was cooled and induced to solidify by scratching the sides of the container. The chloride separated from low-boiling petroleum ether as colorless plates, m. p. 46–46.5°. The yield was 2.5 g. A mixed melting point with β-mesitoylethyl chloride (II)[4] showed no depression.

Preparation of 3-Methoxyisopropenyl Mesityl Ketone (IV).[2]—A mixture of 81 g. of acetomesitylene, 45 g. of paraformaldehyde, 5 g. of potassium carbonate and 200 cc. of methyl alcohol was shaken at room temperature for four days. The solution was poured into water, acidified with dilute hydrochloric acid and extracted with several small portions of benzene. The benzene extracts were washed thoroughly, the benzene was removed and the residue fractionally distilled at diminished pressure. The following fractions were obtained: (1) 16 g., b. p. 95–122° (4 mm.); (2) 56 g., b. p. 123–129° (4 mm.); (3) 6 g., b. p. 130–136° (4 mm.); (4) 20 g., residue. Fraction 2 was redistilled three times. The 3-methoxyisopropenyl mesityl ketone was a colorless oil, b. p. 110.5–111° (1.5 mm.); $n^{20}D$ 1.5208; d^{20}_{20} 1.0101.

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.02; H, 8.31; —OCH_3, 14.22. Found: C, 76.86, 76.76; H, 8.58, 8.50; —OCH_3, 13.85, 14.12.

Preparation of the Dibromo Derivative (V).—A solution of 5.8 g. of bromine in 15 cc. of carbon tetrachloride was added dropwise with stirring to a mixture of 7.8 g. of the ketone and 50 cc. of carbon tetrachloride. The reaction mixture was washed thoroughly with water, dried for one hour over calcium chloride, filtered and the carbon tetrachloride removed by an air blast. A small amount of low-boiling petroleum ether was added to the oil, the solution cooled to 0° and the walls of the vessel were scratched. The mixture solidified almost completely. The dibromide was recrystallized from low-boiling petroleum ether, then methyl alcohol, m. p. 50.5–51.2°; yield 11.5 g.

Anal. Calcd. for $C_{14}H_{18}O_2Br_2$: C, 44.47; H, 4.80. Found: C, 44.49; H, 4.84.

Reaction of Sodium Iodide with the Dibromide.—To 11 g. of the dibromide dissolved in 150 cc. of acetone was added a water solution of 13.5 g. of sodium iodide. The solution darkened immediately. It was allowed to stand overnight at room temperature, poured into 500 cc. of water to which had been added 10 g. of sodium thiosulfate, and extracted with ether. The ether extracts were washed with dilute sodium thiosulfate, then with water, the ether was removed and the residue distilled. There was obtained 4 g. (62% of the theoretical amount) of a liquid boiling at 118° (3 mm.). To remove a trace of iodine this liquid was dissolved in ether and the solution washed with dilute sodium thiosulfate solution. After the solvent was removed the residue was twice distilled, b. p. 114° (2 mm.); $n^{20}D$ 1.5211.

Anal. Calcd. for $C_{14}H_{18}O_2$: C, 77.02; H, 8.31. Found: C, 76.76; H, 8.42.

It could be reconverted to the dibromide.

Catalytic Reduction of 3-Methoxyisopropenyl Mesityl Ketone.—A mixture of 10.2 g. (0.046 mole) of the ketone, 150 cc. of methyl alcohol and 0.5 g. of Raney nickel was reduced under a pressure of two atmospheres. About 0.085 mole of hydrogen was absorbed. The mixture was filtered, poured into water and extracted with ether. The ether extracts were washed with water, dried and distilled. After the ether had been removed, there was obtained a very small amount of low-boiling material, 5 g. of colorless oil, b. p. 120–123° (10 mm.), 3 g. of light yellow oil, b. p. 116–125° (6 mm.) and a small amount of residue. The large fraction was redistilled, b. p. 120–121° (10 mm.);

(6) The analyses reported in this paper are microanalyses and were carried out by Mr. L. G. Fauble and Mr. W. H. Taylor.

$n^{20}D$ 1.5098. A second redistillation produced no change in the boiling point or refractive index. Isobutyromesitylene prepared from isobutyryl chloride and mesitylene by the Friedel–Crafts method boils at 120–121° (10 mm.) and has a refractive index $n^{20}D$ 1.5095. Nitration of this reduction product yielded a compound melting at 125–132°. After several recrystallizations from ethyl alcohol it crystallized in white plates, m. p. 135–138°. The mixed melting point with an authentic sample of dinitroisobutyromesitylene was 135–139°.

Preparation of β-Methoxypropiomesitylene (VI).—A solution of 10 g. of vinyl mesityl ketone, 100 cc. of methyl alcohol and 2 g. of potassium carbonate was shaken for thirty-six hours at room temperature. It was then poured into 300 cc. of water, acidified with dilute hydrochloric acid and extracted with ether. The ether extracts were washed and dried over calcium chloride. The ether was removed and the product distilled. There was obtained 7 g. (60% of the theoretical amount) of β-methoxypropiomesitylene, b. p. 117–117.5° (2.5 mm.); $n^{20}D$ 1.5110; d^{20}_{20} 1.0106, and 3.5 g. of residue.

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.69; H, 8.79. Found: C, 75.50; H, 8.86.

If fifteen drops of concentrated hydrochloric acid were used as the catalyst[7] and the reaction mixture refluxed for one hour, the yield of β-methoxypropiomesitylene was increased to 95%.

Bromination of β-Methoxypropiomesitylene.—To a solution of ten drops of the ketone and 3 cc. of carbon tetrachloride was added a 25% bromine–carbon tetrachloride solution until hydrogen bromide was evolved. The excess bromine and carbon tetrachloride were removed by an air blast. A small amount of low-boiling petroleum ether was added and the mixture cooled. It solidified almost completely. The solid recrystallized from methyl alcohol in the form of long white needles, m. p. 78–79.5°. A mixed melting point with α,β-dibromopropiomesitylene showed no depression.

Action of Paraformaldehyde on β-Methoxypropiomesitylene.—To 10 g. of the ketone was added 90 cc. of methyl alcohol, 3 g. of paraformaldehyde and 0.5 g. of potassium carbonate. The reaction mixture was shaken for four days. It was worked up as described above in the preparation of 3-methoxyisopropenyl mesityl ketone. There was obtained 7 g. of light yellow oil, b. p. 115–120° (2.5 mm.); $n^{20}D$ 1.5193, and 3 g. of residue. The oil was redistilled, b. p. 113.5–114° (2 mm.); $n^{20}D$ 1.5207. Bromination of this oil yielded a solid, m. p. 50–51°. The mixed melting point with the dibromo derivative of 3-methoxyisopropenyl mesityl ketone was 50–51°.

Reaction of Paraformaldehyde with Vinyl Mesityl Ketone.—A mixture of 17.4 g. of vinyl mesityl ketone, 6 g. of paraformaldehyde, 100 cc. of methyl alcohol and 2 g. of potassium carbonate was shaken at room temperature for four days. The reaction mixture was worked up as described in the preparation of 3-methoxyisopropenyl mesityl ketone. There was obtained by distillation 12.5 g. of liquid, b. p. 117.5–118.5 (2.5 mm.); $n^{20}D$ 1.5198, and from the residue 2.2 g. of white plates, m. p. 105–107°. A mixed melting point of this solid with a sample of 2,4-dimesitoyl-2,4-pentadiene[2] showed no depression.

A small portion of the liquid was brominated. The solid isolated from the reaction melted at 50–51° and proved to be identical with the bromination product of 3-methoxyisopropenyl mesityl ketone.

Summary

The monomethylol derivative of acetomesitylene ($C_9H_{11}COCH_2CH_2OH$) has been synthesized by condensing the bromomagnesium derivative of acetomesitylene with formaldehyde.

The corresponding chloride ($C_9H_{11}COCH_2CH_2Cl$) has been prepared by the action of hydrochloric acid on either the monomethylol derivative or vinyl mesityl ketone.

Attempts to prepare the methylol derivative by treating acetomesitylene with paraformaldehyde in the presence of potassium carbonate and methanol have been found to yield a complex ether, $C_9H_{11}COCCH_2OCH_3$ (with CH_2 double-bonded to the carbon).

A mechanism is presented for the formation of this ether.

The Action of Phosphorus Pentachloride on β-Phenylbenzalacetophenone

BY CHARLES R. CONARD*

When phosphorus pentachloride acts on acetone or other ketones of the type R_2CO, a ketochloride is formed

$$R_2CO + PCl_5 \longrightarrow R_2CCl_2 + POCl_3$$

Straus and others[1] tried this reagent on α,β-unsaturated ketones and found the resulting compounds to be very different from the ketochlorides of the saturated ketones. Straus[2] found, for example, that one of the halogen atoms is much more easily replaced than the other, and obtained the monochloromethoxyl derivatives of many of his unsaturated compounds by boiling their methyl alcohol solutions. He proved the structure of the unsaturated products by ozonization. Typical reactions may be represented as

$$C_6H_5CH{=}CH{-}CO{-}CH{=}CHC_6H_5 \xrightarrow{PCl_5} C_6H_5CHCl{-}CH{=}CCl{-}CH{=}CHC_6H_5$$

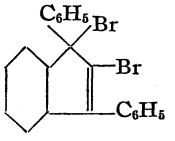
$$C_6H_5CH{=}CH{-}CO{-}C_6H_5 \xrightarrow{PCl_5} C_6H_5CHCl{-}CH{=}CCl{-}C_6H_5$$

$$C_6H_5CH(Cl){-}CH(Cl){-}C{=}C{-}C_6H_5 \xrightarrow{CH_3OH} C_6H_5CH(OCH_3){-}CH(Cl){-}C{=}C{-}C_6H_5$$

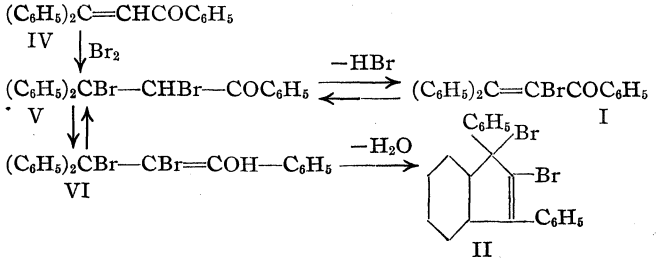
Although several α,β-unsaturated ketones react in this manner, it could not be assumed that β-phenylbenzalacetophenone would give a similar product, since the presence of a second phenyl group on the β-carbon atom may prevent a chlorine atom from attaching itself there. The surprising difference in the action of the β-phenyl derivative as compared to the benzalacetophenone itself is well illustrated by the work of Barre and Kohler,[3] who brominated β-phenylbenzalacetophenone and isolated both α-bromo-β-diphenylpropiophenone and 1,2-dibromo-1,3-diphenylindene. In the light of the above facts it appeared that the action of phosphorus pentachloride on the phenylated ketone would be of interest and this has been tried experimentally.

The β-phenylbenzalacetophenone was treated with phosphorus pentachloride in a manner very similar to that employed by Straus, and the product was handled at reduced temperature to avoid the hydrolysis of any chloro derivatives that might be formed. The product obtained was not a ketochloride; an ethoxy group was easily introduced by boiling in ethyl alcohol, yet the compounds did not correspond to the products isolated by Straus.

The product of the reaction is 1,2-dichloro-1,3-diphenylindene which reacts rapidly with ethyl alcohol to give 1-ethoxy-2-chloro-1,3-diphenylindene. Barre and Kohler have already shown that the halogen in the 1-position is unusually active since it is on a carbon joined to two benzene rings and a double bond.



The above results show that the phosphorus pentachloride is a chlorinating agent acting in a manner similar to the bromine used by Barre and Kohler. In their experiments, however, the conditions of the bromination and the method of handling the product could be used to control the nature of the substance isolated. They offer the following supposition concerning the nature of the reaction. "First the unsaturated ketone (IV)



would be expected to react with a molecule of bromine to form a dibromide (V). This dibromide (V) which contains a bromine atom linked to a carbon atom which also holds the two phenyl groups is very unstable and loses hydrogen bromide very easily. The loss of hydrogen bromide from the dibromide is reversible as is shown by the fact that the dibromoindene (II) is also ob-

* This work was done at the suggestion and under the direction of Professor E. P. Kohler (who died in 1938), and was accepted in partial fulfilment of the requirement for the degree of Ph.D. at Harvard University.

(3) Barre and Kohler, THIS JOURNAL, **50**, 2038 (1928).

tained from α-bromo-β-phenylbenzalacetophenone by the action of hydrogen bromide. Since hydrogen bromide is also a dehydrating agent, the formation of the indene derivative (II) from the enolic form (VI) of the dibromide (V) is easily explained under the conditions of the reaction."

Inasmuch as phosphorus pentachloride is an active dehydrating agent and at the same time produces hydrogen chloride, it would be expected that the loss of hydrogen chloride to form the monochloro ketone corresponding to their compound (I) would be prevented, and that the dehydrating action would favor the formation of an indene corresponding to (II). It, therefore, seems likely that the suppositions of Barre and Kohler are equally applicable to the action of phosphorus pentachloride on β-phenylbenzalacetophenone.

Experimental

Treatment of β-Phenylbenzalacetophenone with Phosphorus Pentachloride.—In attempts to isolate products corresponding to those found by Straus, several variations in the procedure were employed. Each time a reddish oil was produced from which no crystals were obtained.

Five grams of the ketone was dissolved in 50 cc. of dry benzene, 5.5–6 g. of phosphorus pentachloride added, the mixture allowed to reflux on the steam-bath for one hour, cooled and poured over cracked ice. The ice was removed as soon as the benzene had melted and the liquids were separated. The benzene layer was washed several times with cold water, dried over sodium sulfate or calcium chloride, and concentrated at room temperature to a thick reddish oil which must have contained 1,2-dichloro-1,3-diphenylindene.

A product having the same appearance and properties was obtained when 5 g. of ketone dissolved in benzene was treated with 4.5 g. of phosphorus pentachloride and the mixture, after standing at room temperature for four days, was poured over cracked ice, washed with water, washed with sodium bicarbonate solution, dried over calcium chloride, and concentrated.

Better yields of secondary products are obtained when the ketone is treated with 2.2 mols of phosphorus pentachloride, the flask being fitted with a reflux condenser carrying a tube for the removal of hydrogen chloride fumes. The mixture is boiled for one to two hours, after which it may be concentrated by evaporation, since most of the hydrogen chloride has already escaped.

Ozonization of 1,2-Dichloro-1,3-diphenylindene.—Since products similar to those found by Straus were possible, it was considered wise to ozonize the red oil (uncrystallized product) to see what evidence could be obtained. The concentrated residue from the phosphorus pentachloride treatment was taken up in carbon tetrachloride. The solution was ozonized for four hours using a slow stream of 6–8% ozone, and the ozonide decomposed by shaking with cold sodium bisulfite solution for several hours. The carbon tetrachloride was evaporated and the resulting mixture was extracted with ether. After evaporating the ether, the residue was steam distilled, the distillate extracted with ether, and the ether solution evaporated, leaving a product which proved to be benzophenone, doubtless coming from unchanged ketone.

The residue from the steam distillation was taken up in ether, dried over calcium chloride, and allowed to crystallize. After recrystallization from methyl alcohol, this melted at 145–146.5°. A mixed melting point with an authentic sample proved this substance to be *o*-dibenzoylbenzene.

Preparation of 1-Ethoxy-2-chloro-1,3-diphenylindene.—The concentrated benzene solution from the phosphorus pentachloride treatment is dissolved in ethyl alcohol and evaporated by boiling to one-third the original volume or less and enough ethyl alcohol added to bring the solution to the original volume, which may again be evaporated by boiling. This method of heating serves not only to cause a reaction with the ethyl alcohol but also to remove the benzene, in which the indene has a high solubility. A nicely crystalline product separates, which may be recrystallized from ethyl alcohol, m. p. 135.5–136°.

Anal. Calcd. for $C_{23}H_{19}OCl$: C, 79.6; H, 5.5; Cl, 10.2; OC_2H_5, 13.0. Found: C, 80.1, 79.3, 79.6; H, 5.4 (4.3), 5.7; Cl, 10.2, 10.0; OC_2H_5, 12.1, 12.7.

Ozonization of the 1-Ethoxy-2-chloro-1,3-diphenylindene.—One gram of the 1-ethoxy-2-chloro-1,3-diphenylindene dissolved in carbon tetrachloride was ozonized for four and a half hours. The ozonide was decomposed by shaking with a cold dilute (1%) solution of hydrogen peroxide and the carbon tetrachloride removed by evaporation. The apparatus was washed with alcohol and the washings were added to the main solution. The mixture was allowed to stand on the steam-bath for about eight hours, serving to remove the alcohol and ensuring the liberation of carbon dioxide from any α-ketocarboxylic acid, to give the ketone sought. The mixture was cooled, extracted with ether, the ether solution dried over calcium chloride and on standing overnight the *o*-dibenzoylbenzene had crystallized out. The product was recrystallized from methyl alcohol and a mixed melting point proved its identity.

Summary

1,2-Dichloro-1,3-diphenylindene has been prepared by the action of phosphorus pentachloride on β-phenylbenzalacetophenone, its identity shown by ozonization, and an ethoxy derivative prepared and ozonized.

The Formation of Sulfonium Compounds from Benzyl Iodide and Organic Disulfides

BY OTTO HAAS AND GREGG DOUGHERTY

Steinkopf and Müller[1] found that sulfonium salts were formed when alkyl disulfides are heated with alkyl halides. Since their experiments were carried out at 100° in sealed tubes for thirty hours, it seemed possible that the products resulted from rather profound decompositions. It was of interest therefore to study this reaction under mild conditions which would favor greater stability of the primary products, and possibly lead to a surer knowledge of the mechanism by which the products were formed.

Using mercuric iodide or ferric chloride as catalysts, it has now been found that benzyl iodide reacting on organic disulfides in acetone solution, forms the sulfonium salts of the monosulfides at room temperature. The compounds are isolated in the form of the addition complex with the salt used as a catalyst. (In this way the following have been prepared: tribenzylsulfonium iodide-mercuric iodide, dibenzylethylsulfonium iodide-mercuric iodide, dibenzylbutylsulfonium iodide-mercuric iodide, tribenzylsulfonium iodide-ferric chloride.) Unlike the results obtained by Hilditch and Smiles, who worked with ethyl iodide, diethyl disulfide and mercuric iodide, no disulfide sulfonium salts could be isolated.[2]

These reactions may be explained by a mechanism similar to that proposed by Steinkopf and Müller

$$R{-}S{-}S{-}R + HgI_2 + C_6H_5{-}CH_2{-}I \longrightarrow R{-}S{-}S{-}R{\cdot}HgI_2 \quad (1)$$
$$\qquad\qquad\qquad

the solution and this corresponds to 96.6% of the iodine originally added.

Summary

The reaction of benzyl iodide with three organic disulfides, in the presence of mercuric iodide or ferric chloride, has been studied.

Four sulfonium compounds, in the form of the addition complex with the metallic halide, were prepared. Two of these are new compounds.

A mechanism for the reaction has been proposed.

Reactions of Sulfur and Vapors of Organic Compounds at Different Temperatures[1]

BY GEO. D. PALMER, S. J. LLOYD, W. P. MCLURE, NORMAN LEMAISTRE, W. S. WARING AND L. W. BACHMAN

The preparation of a new series of sulfur dyes by a vapor method using benzene and other organic compounds in contact with molten sulfur at temperatures *above* 300° has been reported.[2] With similar apparatus, we are now able to report the preparation of two new classes of sulfur organic compounds prepared at temperatures *below* 300°.

Experimental

Preparation of New Sulfur Organic Compounds.—We find that the vapors of many organic substances, including benzene, toluene, aniline, phenol, etc., when passed through molten sulfur at 240–260° form resinous sulfur dyes (A) which are in some cases rubber-like after purification, whereas at 260–300° non-resinous sulfur organic compounds (B) which are not dyes result. These are brown to black powdery solids, insoluble in sodium sulfide and carbon bisulfide. Hydrogen sulfide is a by-product, much more being evolved in preparation of A than B. The yields of A are much better than those of B and are comparable to the yields of compounds prepared above 300° (C).[2]

Purification and Analyses.—Eighteen samples were purified with carbon bisulfide, acetone, benzene, and water for 525 hours in large-scale Soxhlet extractors. Analyses for sulfur were made at intervals until the percentage of sulfur in each substance became constant.

Discussion

All sulfur dyes prepared by this vapor method and producing intense colors contain 50 to 83% sulfur. A few aliphatic substances which have yielded small amounts of low-sulfur-content dyes have produced much less intense colors on cotton and rayon.

It appears that the higher the sulfur content of the dye, the less the sodium sulfide (in aqueous solution) required to dissolve it. It also appears that the higher the sulfur content, the more resinous is the material. The resinous property of the chlorobenzene product (A) is lost when it is dissolved in aqueous sodium sulfide, but is regained by precipitation with a mineral acid.

TABLE I

COMPOSITION OF PURIFIED SULFUR ORGANIC SUBSTANCES PREPARED BELOW 300°

Compd. reacting with sulfur	Opt. temp. for prepn., °C.	S, %	N, %	Cl, %
Benzene	260–300	30.95		
Aniline	260–300	30.96	9.63	
Chlorobenzene	240–260	83.44		1.08

TABLE II

PROPERTIES OF DYES PREPARED FROM CHLOROBENZENE AND SULFUR ABOVE AND BELOW 300°

Opt. temp., for prepn., °C.	Phys. form	Color of solid	Soly. in CS_2	Soly. in aq. Na_2S	Color on cot. and rayon
360–444.6	Powd.	Red	Insol.	Sl.	Red-brown
240–260	Res. matl.	Gray-black	Sl.	Fairly	Dark-brown

TABLE III

COMPOSITION OF PURIFIED SULFUR DYES PREPARED AT 360–444.6°

Sample	Compound reacting with sulfur	C, %	H, %	S, %	N, %	O, %
1	Benzene	34.54	0.92	62.46		
2	Toluene	36.17	0.93	62.68		
3	Phenol	34.95	1.97	55.15		7.93
4	Aniline	37.88	1.23	53.38	6.56	

Empirical formulas have been calculated for dyes 1 and 2 in Table III, and a constancy of $C_3H_1S_2$ is indicated. The grouping in these high sulfur content organic substances prepared from hydrocarbons and sulfur at 360–444.6 is apparently similar to the recurrent grouping in the formula of thiokol[3] in that in each case *one* hydro-

carbon group is attached to *four* sulfur atoms. Thus

$S_2C_2H_4S_2$ (Thiokol)
$S_2C_6H_2S_2$ (Sulfur dye from benzene)

Summary

1. By contacting vapors of organic compounds with molten sulfur *below* 300°, two new classes of sulfur organic compounds have been prepared, with hydrogen sulfide as a by-product.

2. Products prepared at 240–260° are resinous sulfur dyes, while products prepared at 260–300° are non-resinous and are not sulfur dyes.

3. High sulfur content is necessary in the sulfur dyes for the production of intense colors.

4. Additional ideas as to the structure of sulfur dyes prepared by vapor methods have been presented.

The Inversion of Sucrose

BY LAWRENCE J. HEIDT AND CLIFFORD B. PURVES

Recently we published data on the rates of hydrolysis of several fructosides including sucrose at 30 to 60° and calculated energies of activation, E, assuming that E did not vary with temperature. At the same time Leininger and Kilpatrick[1] found that in more concentrated solutions of sucrose E was smaller at 30 than at 0°, but that dE/dT approached zero as T increased. In addition, their data gave smaller values of E at 5.8 than at 0.5 N hydrochloric acid. Nevertheless, the rate constants obtained by extrapolating their data to our acid concentration of 0.01 N gave, within the limits of error, the same values of E and dE/dT between 25 and 35° as our previously published[2] values of $E = 25.75$ kcal. and $dE/dT = 0$ between 30 and 60°. They followed the inversion by noting the accompanying contraction of a fixed weight of solution. We used the copper reduction technique to measure the rate of formation of reducing sugars. The divergence of dE/dT from 0 obtained by the dilatometric method at temperatures lower than 25° led us to see whether this divergence could also be observed by the copper reduction technique when working in the same range of temperature and at the same concentrations of reactants used in reference 1. We were especially interested in this problem because conclusions like those we drew by comparing activation energies for the hydrolysis of fructosides[2] would be vitiated, of course, if the values of E were determined where dE/dT was not zero.

The reagents,[2] experimental procedure[2] and apparatus[3] have been described. Reactions at 10.00° took place in a thermostat kindly lent by Professor Scatchard. Especial care was taken to transfer each sample quickly from the reaction cell to just enough caustic soda solution at 0° so that the resulting solution was neutral to phenolphthalein. These neutral solutions were kept at 0° until analyzed.[2]

Corrections for the sucrose, sodium chloride, and concentrations of the reducing sugars present in the analyses were usually negligible. For example, 5 cc. of a 5% solution of sucrose formed cuprous oxide equivalent to 8 cc. of the 0.002 M sodium thiosulfate[4] and 1 cc. of a 23% solution of sodium chloride increased by 3.5% the cuprous oxide formed by the invert sugar. To reduce titration errors, the estimations of the reducing sugar in each sample withdrawn from the reaction cell were made at several concentrations scattered over the range covered in the calibrations.

Concentrations were referred to a liter of solution at the temperature the sucrose was inverted. Acid concentrations were obtained in each case by titrating with standard base weighed aliquots whose volumes at the temperature of the hydrolysis were carefully measured. Phenolphthalein was used as the indicator. The titrations agreed in every case with calculations based on the dilution of the standardized acid used to make up the sucrose solutions, so no measurable amount of acid was produced or consumed during the inversion.[5]

(1) Leininger and Kilpatrick, THIS JOURNAL, **60**, 2891 (1938).
(2) Heidt and Purves, *ibid.*, **60**, 1206 (1938).
(3) Heidt, *ibid.*, **61**, 3455 (1939).
(4) In the earlier work[2] this hypo was denoted as 0.002 N.
(5) These titrations, however, would not reveal slight decreases in the pH like those noted in the photosensitized reaction: Heidt, THIS JOURNAL, **61**, 3223 (1939).

The fraction of sucrose inverted was the same within 1%, whether calculated by the methods described by Mathews and Jackson[6] or by Guggenheim,[7] or from the concentration of invert sugar when inversion was complete.

The invert sugar found when inversion was complete agreed within 1% with the value obtained for the equivalent quantity, (360/342) × wt. of sucrose, of equal weights of glucose and fructose. The invert sugar, therefore, was not affected measurably by the hydrochloric acid present in our experiments. This is in accord with previous work.[6]

The logarithm of the concentration of sucrose remaining in an experiment was a linear function of time within the limits of error. The fraction of sucrose inverted per minute, given as the velocity constant k in Table I, was obtained, therefore, from the slope of the straight line through these points. Each line was obtained by the method of least squares with each point given a weight about equal to the average volume of the neutralized solutions used in the analysis. Reaction rates were followed until at least 60% of the sucrose had been inverted. In the earlier work,[2] k was obtained graphically.

The data are summarized in Table I.

In Fig. 1, lines A and C show the change in log k^* with $1/T$, and the B lines the change in log k^* with the concentration of HCl. The equations for these lines were calculated by the method of least squares and the quadratic mean errors in the constants of the equations were obtained in a way outlined elsewhere.[8] The probable error equals the quadratic mean error multiplied by 0.6745. The dots in Fig. 1 represent the common logarithm (log) of our average values of k^*.

The ordinates for the B lines are on the left side of the figure. The lower of these lines represents the data obtained at −0.01° by Leininger and Kilpatrick,[1] who found (1), log k^* = $\bar{4}$·1057 + 0.2394 [HCl]. The upper of the B lines represents our data at 0.00° which gave (2), log k^* = $\bar{4}$·1189 + 0.2495 [HCl]. The difference between the slopes of these lines is greater than the reproducibility of the velocity constants in either method.

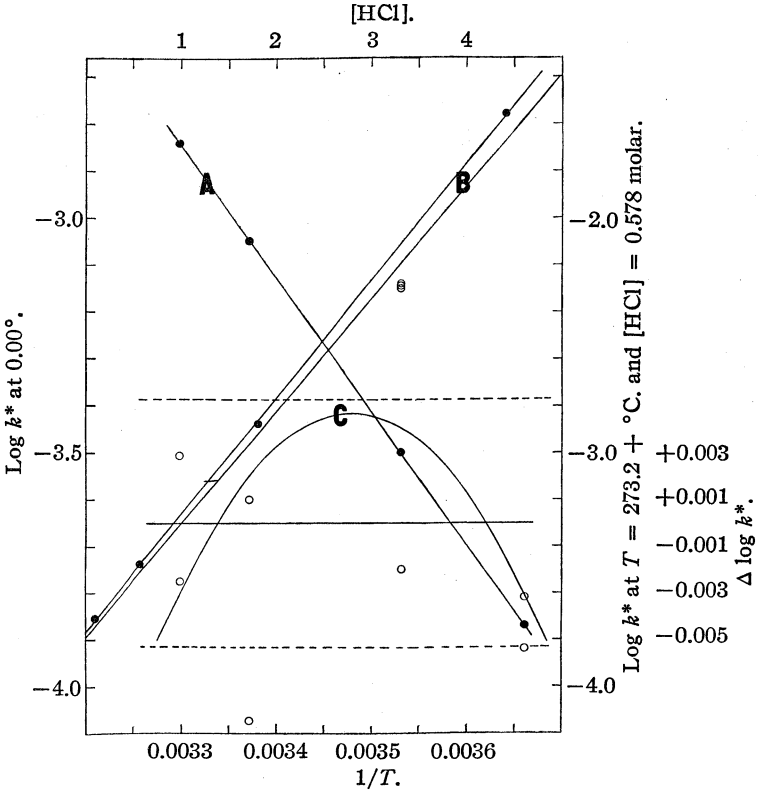

Fig. 1.

TABLE I

There was present initially about 2 g. of sucrose, weighed to 0.1 mg. per 100 cc. of solution. The fraction inverted per minute = k and k^* = k/[HCl].

Moles of HCl in a liter	10^4k	10^4k^*	°C.
4.41	74.1	16.8	0.00
4.41	73.1	16.6	.00
1.81	6.55	3.62	.00
1.81	6.63	3.67	.00
0.575	1.05	1.82	.00
.580	1.06	1.83	.00
.0965	0.136	1.40	.00
.0965	0.135	1.40	.00

(6) Mathews and Jackson, *Bur. Standards J. Research*, **11**, 619 (1933).

(7) Guggenheim, *Phil. Mag.*, **1**, 538 (1926).

(8) Whittaker and Robinson, "The Calculus of Observations," Chap. IX, D. Van Nostrand Co., New York, N. Y., 1924.

A manipulation tending to make our values of k^* high was the short time, about thirty seconds, that the solution undergoing hydrolysis was warmed slightly by the pipet, initially at 25°, while being transferred to the caustic soda solution. This produced a negligible effect upon k^* when $k < 0.0005$ at 0° so that it affected less than 1% any of the rate constants obtained at 0.58 N hydrochloric acid; however, it would account for part of the increasing divergence of the B lines as the concentration of hydrochloric acid was increased.

The possible errors in their refined dilatometric method have been discussed ably by Leininger and Kilpatrick.[1] Their data extended from 0.6 to 5.8 N hydrochloric acid where the logarithm of the activity of the acid also varies almost linearly with its concentration although deviating sharply from linearity in more dilute solutions. Nevertheless, they were careful to dot in the extension of their lines beyond their experimental values and thus correctly assumed that their linear plots could be extrapolated to give k^* down to [HCl] = 0. They thereby implied that k^* was not directly proportional to the activity of the hydrochloric acid, and their hypothesis is supported by our data at 0.1 N hydrochloric acid which, within the limits of error, falls on our linear plot instead of paralleling the activity of the hydrochloric acid.

Line A, whose ordinates are given on the right side of the figure, gives the linear dependence upon $1/T$ of our values of (3), $\log k^* = (17.0172 \pm 0.0678) - (5669 \pm 19.5)\ (1/T)$. The circles in the figure represent the deviations from line A of the individual values of $\log k^*$ included in the average values represented by the dots. The ordinates of these deviations, $\Delta \log k^*$, are on a scale obtained by magnifying one hundred times the scale of ordinates used for line A. An observation which did not deviate from line A would fall on the solid horizontal line in the figure, and one representing the probable deviation, 0.0053, would fall on either of the dotted horizontal lines. The second degree parabola representing the observed deviations is given by line C. The equation for this line plus that for line A is (4), $\log k^* = (14.1882 \pm 2.0960) - (4040 \pm 1208)\ (1/T) - (234057 \pm 173840)\ (1/T)^2$.

The quadratic mean error in the coefficient of $(1/T)^2$ in equation (4) is so large, according to the t test,[9] that the straight line given by equation (3) adequately represents our data.[10] The probable deviation in any experimental value of $\log k^*$ is 0.0053 from (3) and 0.0046 from (4) or 1.2% in k^*.

The energy of activation, in kcal., by equation (3) is 25.94. If equation (4) differed significantly from (3), E would be 26.35 at 0° and 25.55 at 30°. At the same concentrations of reactants, the average value of E from the measurements with a dilatometer[1] was 26.0 kcal. decreasing[11] from 26.6 at 0° to 25.4 at 30°.

When our concentrations are expressed as mole fractions, k^* is replaced by $k' = k^*\ (55.5062\ d - 1.0240\ N - 1.0517)$. The normality, N, of the acid is given in Table I, and d, the weight in grams of one ml. of solution at the temperature of inversion, was roughly 1.017 at 0.0°, 1.0122 at 10.0°, 1.0116 at 23.4° and 1.0085 at 30.0°. Our data now fit the equations (5), $\log k' = (18.7083 \pm 0.0626) - (5655 \pm 18)\ (1/T)$ and (6), $\log k' = (14.5375 \pm 2.0499) - (3251 \pm 1180)\ (1/T) - (346044 \pm 169935)\ (1/T)^2$. The probable deviation in any experimental value of $\log k'$ is 0.0049 from (5) and 0.0045 from (6). Also, from (6) E equals 26.5 kcal. at 0° and 25.35 at 30°, but again the quadratic mean error in the coefficient of $(1/T)^2$ is so large that the straight line adequately represents the data. Moreover, expressing concentrations as mole fractions instead of moles per liter of solution does not improve significantly the fit of our data to either a straight line or second degree parabola.

(9) R. D. Fisher, "Statistical Methods for Research Workers," Chapter V, Oliver and Boyd, London, 1936. The "Table of t" given near the end of this book lists a probability equal to 0.3 of getting by accident 234057 as the coefficient of $(1/T)^2$. This probability is much greater than the value of 0.05 given arbitrarily by this author as an upper limit for a significant result.

(10) Any systematic errors in the measurements *not* having the same percentage effect upon each value of k^* could vitiate this conclusion.

(11) The data of Leininger and Kilpatrick[1] (L. and K.) at 10, 15, 20, 25 and 30° and 1.120 to 1.124 N hydrochloric acid, and $\log k^*$ at 1.122 N acid and −0.01° calculated from their equation 4a give (7), $\log k^* = (16.9111 \pm 0.0856) - (5608 \pm 25)(1/T)$ and (8), $\log k^* = (11.7937 \pm 0.8956) - (2663 \pm 515)(1/T) - (423057 \pm 74000)(1/T)^2$. The probable deviation of $\log k^*$ is 0.0049 from (7) and 0.0017 from (8), and the probability is less than one in a hundred of obtaining accidentally the coefficient of $(1/T)^2$ given in (8) from which E equals 26.2 kcal. at 0° and 25.0 at 30°. These calculations, therefore, support the conclusion of L. and K. that their data give values of E changing with T. Moreover, when their concentrations are converted to mole fractions, values of $\log k'$ are obtained giving values of E also changing significantly with T. In addition, a comparison of the nearly equal probable deviations of the data from equations (3), (4) and (7) with that of $\log k^*$ from (8) reveals that unless $\log k^*$ can be determined to 0.4% or less over an interval of 30° changes in E with T as small as found by L. and K. are not significant. Moreover, corrections for the effect of the mutarotation of glucose upon the rates observed by L. and K. would straighten their plots of $\log k^*$ *vs.* $1/T$. It is quite possible that these and other corrections would change $\log k^*$ as much as 0.5% more at 0° than at 30° which would remove from their data any significant change in E with T for the inversion of sucrose.

Summary

Rates of inversion of sucrose measured by the reducing sugars produced were found to be slightly higher than the rates previously obtained by the dilatometric method at the same temperatures and concentrations of hydrochloric acid and sucrose.

The activation energy obtained is 25.9 kcal. and does not vary significantly with the temperature between 0 and 30°.

The logarithms of the velocity constants at 0° are a linear function of the concentration of hydrochloric acid between 0.1 and 4.4 *N*.

Thermal Data. XII. The Heats of Combustion of Urea and Guanidine Carbonate and their Standard Free Energies of Formation

BY HUGH M. HUFFMAN

In continuation of our program,[1] involving the study of the thermal properties of organic compounds of physiological interest, we have determined the heats of combustion of urea and of guanidine carbonate. These data have been used in conjunction with other data to calculate the standard free energies of formation of these compounds.

Experimental

Calorimetric Method.—The calorimetric method has been described in previous publications.[2] Since no important changes have been made, only the essential details will be given. All of the combustions were made in a Parr bomb having a volume of 0.380 liter and with an initial oxygen pressure of 30 atmospheres and with 1 ml. of water in the bomb.

The energy equivalent of the calorimetric system was controlled throughout the investigation by frequent calibration with Bureau of Standards benzoic acid standard sample 39e, having for its isothermal heat of combustion under standard conditions[3] and at 25° the value of $-\Delta U_B/m$ = 26,419[4] N.B.S. international joules. The conditions in our bomb are not quite standard, necessitating a correction of this value to 26,418 N.B.S. international joules.

A minor change was made in the calorimeter after the combustions on guanidine carbonate and hence a recalibration was required. The energy equivalent of the calorimetric system in the guanidine carbonate series was 3157.4 cal., mean of fifteen calibration experiments, with a standard deviation of 0.0016% and in the urea series 3157.0 cal., mean of seventeen calibration experiments, with a standard deviation[5] of 0.0021%. The results of all of our combustion experiments are expressed in terms of the defined conventional calorie which is derived from the N.B.S. international joule by dividing by 4.1833. The units and corrections are the same as those given in previous papers.[6] The molecular weights are based on the 1939 table of atomic weights. All of the thermal data are given for the isothermal process at 25° and for true mass.

Purification and Heats of Combustion

Urea.—Three combustion samples a, b and c were prepared from J. T. Baker C. P. urea by one and three crystallizations from redistilled water and by two crystallizations from purified methyl alcohol, respectively.

Guanidine Carbonate.—Material from Eastman Kodak Co. was dissolved in hot water and allowed to cool, it was then precipitated by the addition of about 2.5 volumes of purified ethyl alcohol. This process was repeated to give sample (a). Material from Hoffman–LaRoche was precipitated once as above to give sample (b).

Nitrogen determinations on the urea gave the theoretical results and the ash content was negligible. Titrations of the guanidine carbonate with dilute hydrochloric acid gave 99.7 and 99.8% of the theoretical. The ash content was about 0.03%.

The results of the combustions of these compounds are given in Table I. In the case of guanidine carbonate we have arbitrarily corrected the mass by subtracting from the observed mass the mass of ash found after each combustion. The uncertainties given in the table are the mean deviations from the mean.

In addition to the experimental values we have also calculated the quantities $-\Delta U_B$, $-\Delta U_R$, $-\Delta H_R$ and $-\Delta H_f^\circ$ which we have defined previously.[2b] To obtain the values of $-\Delta H_{f298}^\circ$ we have used for the heats of formation of water and carbon dioxide at 25° the value 68,318.1[7] and 94,030[8] calories, respectively.

Discussion

Urea has been burned by several workers (Berthelot 1890, Stohmann 1893, Krummacher 1904, Emery and Benedict 1911). It is not possible to make a careful comparison of our results

with those of the earlier workers because of insufficient data. We have made a rough recalculation of the data of Emery and Benedict[9] and find that their value of $-\Delta H_R$ is about 0.2% higher than that of this investigation. So far as we are aware there are no existing data for the combustion of guanidine carbonate.

The derived data are given in Table II. The uncertainties assigned to these data are calculated

from the standard deviations of the experimental data multiplied by two and combined with the uncertainties assigned to the various auxiliary data which were used. See reference (5) for details of these calculations. As far as we are aware there are no factors which would cause any absolute error in these determinations hence the assigned uncertainties may be taken as a measure of the absolute accuracy of these data.

(9) Emery and Benedict, *Am. J. Physiol.*, **28**, 311 (1911).

The Free Energies.—We have also calculated the free energies of these compounds using the entropy of urea as determined by Parks, Huffman and Barmore[10] and the value of Huffman, Ellis and Borsook[11] for guanidine carbonate. The values of the free energies and other necessary data are tabulated in Table III. To obtain ΔS

TABLE III

THERMAL DATA AT 298.1°K.

Urea	− 79.67	25.2	−108.9	− 47.21 ± 0.18[a]
Guanidine carbonate	−232.22	70.6	−331.7	−144.34 ± 0.45

[a] Estimated maximum uncertainty.

we have used for the entropies of C (graph), H_2, O_2 and N_2 the values 1.36,[12] 31.23,[13] 49.03[14] and 45.79[15] cal. degree^{-1} mole^{-1}, respectively. We have assigned uncertainties to the tabulated free energies but in this case this is only an estimate since we are unable to evaluate precisely the uncertainty in the entropies of the compounds. We do feel however that this is a very conservative estimate, especially in the case of urea.

Urea was used by Parks, Huffman and Barmore[10] to test the third law of thermodynamics.

(13) Giauque, *ibid.*, **52**, 4816 (1930).
(14) Giauque and Johnston, *ibid.*, **51**, 2300 (1929).
(15) Giauque and Clayton, *ibid.*, **55**, 4875 (1933).

In view of our new combustion data and also of the availability of more reliable free energy data for water and carbon dioxide it is interesting to again compare the free energy of urea as calculated from equilibrium data and from third law data.

The calculation from the equilibrium data may be summed up as follows

$$CO_2(g)+2NH_3(g) = H_2O(g)+CO(NH_2)_2(s);\ \Delta F_{298}=290^{16}$$
$$H_2O(g) = H_2 + 1/2O_2;\ \Delta F = 54{,}638^{7}$$
$$C(graph) + O_2 = CO_2(g);\ \Delta F = -94{,}239^{8}$$
$$N_2 + 3H_2 = 2NH_3;\ \Delta F = 7820^{17}$$
$$C(graph) + 2H_2 + N_2 + 1/2O_2 = CO(NH_2)_2(s);\ \Delta F = -47{,}131$$

This result is only 80 calories higher than the third law value and is less than the uncertainty in the $T\Delta S$ term due to the uncertainty in the entropy of urea.

(17) Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., Inc., New York, N. Y., 1923, p. 557.

In conclusion we wish to thank Dr. E. L. Ellis for the purification of the compounds used in this investigation.

Summary

1. The isothermal heats of combustion of urea and guanidine carbonate have been determined at 25°.

2. The free energies of urea and guanidine carbonate have been calculated.

3. A comparison of the free energy of urea from equilibrium data and third law data has been made.

The Crystal Structure of Sodium Formate, $NaHCO_2$[1]

BY W. H. ZACHARIASEN

The present investigation was undertaken primarily to obtain accurate values for the structure of the formate group.

Crystals of sodium formate, $NaHCO_2$, are reported[2] to have monoclinic-holohedral symmetry with crystallographic elements $a_1':a_2':a_3' = 0.9196:1:1.6512$, $\alpha_2' = 93°37'$. In this article another coördinate system, a_1, a_2, a_3, will be used. The correlation between the two sets of axes is $a_1 = a_1'$, $a_2 = a_2'$, $a_3 = {}^1/_2(-a_1' + a_3')$, and one finds readily $a_1:a_2:a_3 = 0.9196:1:0.9700$, $\alpha_2 = 121°51'$.

The crystals studied were obtained by recrystallization from aqueous solutions. Most of the specimens obtained proved to be twinned with (001) as the twinning plane. The single crystals were elongated in the direction a_3 and showed the faces (010), (110) and (001). The compound is somewhat hygroscopic.

A great many oscillation photographs, using CuKα radiation, were prepared. The directions [001], [100], [101] and [010] served as rotation axes. The crystals were shaped into approximate cylinders along the various rotation axes so that corrections for absorption readily could be applied.

(1) Some of the results of this investigation were published in an abstract which appeared in *Phys. Rev.*, **53**, 917 (1938).

(2) P. Groth, "Chemische Krystallographie," Vol. III, Leipzig, 1901.

The structure determination was based upon the reflections in the equator layer lines for which the intensity was set proportional to

$$|F_H|^2 \frac{1+\cos^2 2\theta}{\sin 2\theta} A$$

where A is the absorption factor.

The dimensions of the unit cell were found to be $a_1 = 6.19 \pm 0.01$ Å., $a_2 = 6.72 \pm 0.01$ Å., $a_3 = 6.49 \pm 0.01$ Å., with $\alpha_2 = 121°42' \pm 10'$. The reported density of 1.91–1.93 gives four molecules of sodium formate in the unit cell. No reflections appear for which $H_1 + H_2$ is odd, so the translation lattice is base centered. Furthermore, reflections H_1OH_3 are absent if H_3 is odd, showing that the symmetry plane is a glide-plane rather than a reflection plane. On the assumption that the reported point group is correct, the space group becomes $C2_1/n(C_{2h}^6)$.

In order to obtain a reasonable structure for the formate group, carbon and hydrogen atoms must lie on the twofold rotation axes. A Patterson analysis of the reflections H_1OH_3 proved conclusively that the sodium atoms also occupy positions on the twofold axes while the eight oxygen atoms are in a set of general positions of the space group. The distribution of the atoms is accordingly as follows: 4 Na in $\pm$ ($^1/_4$, u_1, $^1/_4$), 4 H in

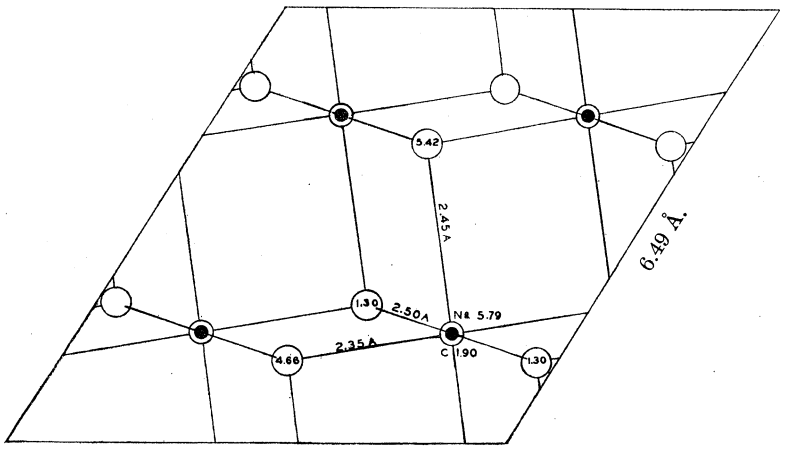

Fig. 1.—A projection of the structure on the (010) plane. Bonds between sodium and oxygen atoms are shown as connection lines. The length of the Na–O bonds and the heights of the atoms above the projection plane are indicated.

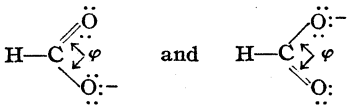
$\pm$ ($^1/_4$, u_2, $^1/_4$), 4 C in $\pm$ ($^1/_4$, u_3, $^1/_4$), 8 O in $\pm$ (x_1, x_2, x_3).

Approximate values for the parameters u_1, u_3, x_1, x_2, x_3 were found without difficulty (since the hydrogen atoms play a negligible part in the scattering, the parameter u_2 cannot be determined directly), while the accurate values were obtained from a series of Fourier projections. The results are: $u_1 = -0.139 \pm 0.001$; $u_3 = 0.283 \pm 0.002$; $x_1 = 0.043 \pm 0.002$; $x_2 = 0.194 \pm 0.002$; $x_3 = 0.185 \pm 0.002$. Setting $u_2 = 0.43$, one gets the reasonable value of 0.99 Å. for C–H separation in the formate group.

The agreement between observed and calculated structure factors is satisfactory, as shown in Table I. Figure 1 shows the projection of the crystal lattice on the (010) plane. As a consequence of the space group symmetry the two oxygen atoms are equivalent in the formate group, corresponding to complete resonance between the two structures



The bond angle φ is 124° and the C–O distance is

1.27 Å. For the dimer of formic acid the values $\varphi = 125°$ and C–O = 1.29 Å. were obtained from electron diffraction studies.[3]

Each sodium atom is linked to six oxygen atoms belonging to five different formate radicals. The sodium to oxygen distances are 2.35, 2.45 and 2.50 Å. with an average value of 2.44 Å., which is exactly equal to the distance predicted on the basis of ionic radii.[4] The atoms are arranged in layers parallel to the (001) plane as shown in Fig. 1; the separation of the layers is 2.76 Å. Four of the six oxygen atoms bonded to a given sodium atom lie in the same layer and the other two in the two adjacent layers. The bonds between different layers are thus few in number (only one bond per 10.4 sq. Å.) and excellent cleavage parallel to (001) results.

An inspection of Fig. 1 will show that there is a pseudo twofold screw axis normal to the plane (001), *i. e.*, normal to the layers. As a consequence it becomes possible to obtain satisfactory binding between two consecutive layers when one layer is turned through 180° and displaced parallel to itself. This fact is directly responsible for the formation of twinned crystals so common in this compound. Figure 2 illustrates the structure of such a twinned crystal.

The optical properties of sodium formate crystals are not known; but it becomes possible to make some predictions. The optical anisotropy must be ascribed almost entirely to the presence of the formate groups. These are all parallel in the crystal and they are highly anisotropic. Thus the crystals must exhibit strong birefringence. The normal to the plane of the formate group is the direction of smallest polarizability, while the direction of greatest polarizability is in the plane of the group parallel to the connection line between the two oxygen atoms. It may accordingly be stated that (010) is the plane of the optical axes, and that the vibration direction corresponding to the smallest refractive index makes an angle of about 13° with a_3 in the obtuse angle α_2.

(4) W. H. Zachariasen, *Z. Krist.*, **80**, 137 (1931).

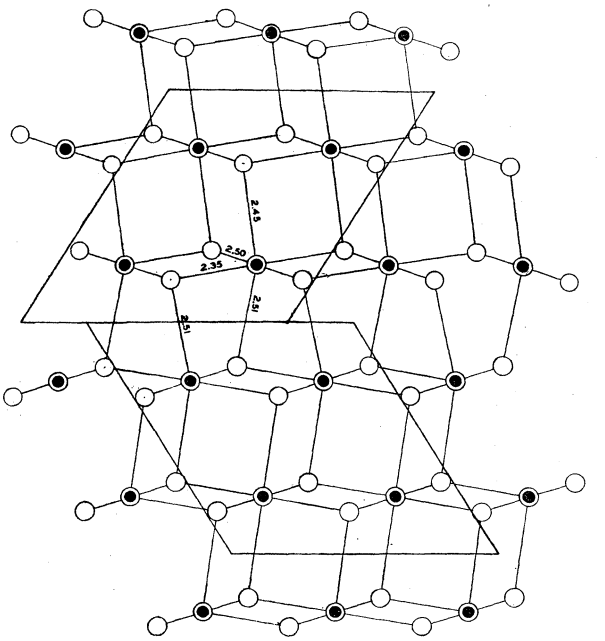

Fig. 2.—This illustrates the explanation of the observed twinning.

Summary

Crystals of sodium formate are monoclinic with four molecules of sodium formate per unit cell. The lattice dimensions are: $a_1 = 6.19 \pm 0.01$ Å., $a_2 = 6.72 \pm 0.01$ Å., $a_3 = 6.49 \pm 0.01$ Å., $\alpha_2 = 121°42' \pm 10'$. The space group is $C2/c(C_{2h}^6)$. Sodium, hydrogen and carbon atoms are on twofold rotation axes, oxygen atoms in general positions. The parameter values are:

	x_1	x_2	x_3
Na	1/4	−0.139 ± 0.001	1/4
C	1/4	.283 ± .002	1/4
H	1/4	.43	1/4
O	0.043 ± 0.002	.194 ± .002	0.185 ± 0.002

There is complete resonance between the two C–O bonds of the formate group. The C–O distance is 1.27 Å. and the bond angle is 124°. Sodium has six oxygen neighbors at an average distance of 2.44 Å.

The Coprecipitation of Barium Ion with Hydrous Aluminum, Chromic and Ferric Oxides in the Presence of Ammonium Ion

BY LEO LEHRMAN, JEROME BEEN AND MILTON MANES

It is well-known that in systematic qualitative analysis considerable amounts of barium are lost before its detection.[1] This loss vitally affects a quantitative analysis of this cation and must be taken into account in such a determination. The cause has been attributed by some to the following two factors, which result in the precipitation of barium compounds: (1) oxidation of sulfide ion to sulfate ion in both the hydrogen sulfide and ammonium sulfide groups; (2) absorption of carbon dioxide by the alkaline ammonium sulfide solution.[2] However, some preliminary experiments showed that in the ammonium sulfide group in the presence of ammonium salts, which is usually the case, neither of the above effects was involved. Yet the amount of barium recovered in the filtrate was less than in the original solution. In the ammonium sulfide group there are two kinds of precipitates, hydrous oxides and sulfides. Inasmuch as they might act differently, it was decided to study them separately.[3]

When a precipitate forms, several causes, *i. e.*, occlusion, mixed crystal formation, solid solution, surface adsorption, compound formation and postprecipitation, might account for the retention (coprecipitation) of soluble material.[4] One or more of these causes might account for the coprecipitation of barium ion by the hydrous oxides. Since they are either amorphous or consist of extremely minute crystals, it is quite likely that surface adsorption takes place. This is especially probable in an alkaline solution where the precipitates would be negatively charged and therefore favor the adsorption of cations.[5] Furthermore, it has been shown that ammonium ion has an effect on the coprecipitation of other cations with hydrous oxides.[6]

The purpose of our investigation was to determine what factors cause the loss of barium ion so that they might eventually be removed.

Experimental

For the metal ions, solutions of chlorides made from reagent grade material were used. All solutions were tested for sulfate ion and found to contain a negligible amount. All experiments were run in duplicate. If the results did not agree, the experiments were repeated.

Precipitation of Barium Due to Absorption of Carbon Dioxide by an Ammonia Solution in the Presence of Ammonium Chloride.—To 5 ml. of barium chloride solution, equivalent to 40 mg. of barium, was added 1 g. of ammonium chloride, 10 ml. of concentrated ammonia solution, the volume made up to 25 ml. with water and allowed to stand in an open flask. A similar solution was prepared and put in a stoppered flask. These two experiments were duplicated, only the amount of ammonium chloride was 4 g. After three hours all the solutions were perfectly clear. In the open flasks after one day, a small amount of precipitate was present in the solution containing 1 g. of ammonium chloride, while the other had a slight but visible one. The precipitation increased very slowly the longer (in days) the flasks remained open. In the stoppered flasks no precipitation occurred even after fourteen days. It is seen that a rather long period of time is necessary before enough carbon dioxide is absorbed to cause precipitation of barium carbonate in the presence of ammonium salts. This is much longer than the usual time for filtering and washing.

The Retention of Barium by Precipitated Hydrous Aluminum, Chromic and Ferric Oxides.—To 50 mg. of aluminum ion and 100 mg. of chromic and ferric ions, separately, were added 1 g. of ammonium chloride, varying amounts of barium ion from 8–40 mg. and 5 ml. of 0.02% gelatin solution.[7] The solutions were heated to boiling, 5 ml. of concentrated ammonia added, which is an adequate excess to ensure complete precipitation, and the final volumes made up to 25 ml. The solutions were filtered and the precipitates washed with distilled water until free of barium ion. The number of washings varied from 8 to 12 of 15 ml. each. Though the hydrous ferric

oxide required the most and the hydrous aluminum oxide the least, the former filtered and was washed much quicker. The filtrate and washings were evaporated to about 10 ml., filtered to remove small amounts of the precipitates that might have passed through and the filter paper washed until free of barium ion. The filtrate and washings were concentrated to about 10 ml., the barium precipitated as barium sulfate in special, calibrated tubes[8] and allowed to settle overnight. The amount of barium was determined first by measuring the height of the precipitate. This was compared with an equal height of barium sulfate in a similar tube, representing a known amount of barium, precipitated under the same conditions. Before using this rapid method, its accuracy was tested gravimetrically and found to give comparable results. It was noted that the height of the precipitated barium sulfate is a linear function of the amount of barium. Table I shows the results obtained.

TABLE I

THE RETENTION OF BARIUM ION BY HYDROUS ALUMINUM, CHROMIC AND FERRIC OXIDES

Fe^{+++}	32	9	23
Fe^{+++}	24	5	19
Fe^{+++}	16	3	13
Fe^{+++}	8	1.5	6.5

Figure 1 is the graph obtained by plotting the amount of barium found in the filtrate as abscissa and the amount retained (lost) by the different hydrous oxides as ordinates. It is a typical Freundlich isotherm, probably showing adsorption, inasmuch as the precipitations take place under fairly constant conditions, thus yielding an adsorbent of constant specific surface area (*i. e.*, surface per unit mass of adsorbent).

Effect of Aging the Hydrous Oxides on the Amount of Barium Ion Retained.—For this purpose, two sets of experiments were carried out using solutions containing 500 mg. of aluminum, chromic and ferric ions separately, 40 mg. of barium ion, 10 ml. of 0.02% gelatin solution and 1 g. of ammonium chloride. In the first set the procedure was the same as above. In the second set the solutions were allowed to age in stoppered flasks for six days before filtering, washing and determining the amount of barium in the filtrates and washings. These two sets of experiments were repeated with 4 g. of ammonium chloride. To obtain additional data on the effect of ammonium

Fe^{+++}	satd.	0	28	12

It is seen that aging decreases the amount of barium retained by hydrous ferric oxide while the opposite effect is shown with hydrous aluminum and chromic oxides. Increasing the amount of ammonium chloride reduces the loss of barium ion. This effect is slightly different for each hydrous oxide but practically the same whether they are aged or not.

Effect of Adding the Barium Ion, after the Formation of the Hydrous Oxides, on the Amount Lost.—Two sets of

experiments were performed. For the first set, solutions were made consisting of mixtures of equal amounts of aluminum and chromic ion, because of their similar action as shown in the previous experiments, varying from 15–250 mg. each, 40 mg. of barium ion, 10 ml. of 0.02% gelatin and 1 and 4 g. of ammonium chloride. The hydrous oxides were precipitated with ammonia as in the experiments above and the amount of barium in the filtrates and washings determined. In the second set the barium ion was added immediately after precipitation and then the amount in the filtrates and washings determined. For the purpose of noting the action of hydrous ferric oxide, the second set of experiments was repeated with 500 mg. of ferric ion. The results are shown in Table III.

TABLE III

EFFECT OF ADDING BARIUM ION, AFTER PRECIPITATION OF THE HYDROUS OXIDES, ON THE AMOUNT LOST

Mg. of metal	NH_4Cl, g.	Ba^{++}, when added	Ba^{++} in filtrate, mg.	Ba^{++} lost, mg.
500 Al^{+++} and Cr^{+++}	1	Before	19	21
500 Al^{+++} and Cr^{+++}	1	After	23	17
500 Al^{+++} and Cr^{+++}	4	Before	28	12
500 Al^{+++} and Cr^{+++}	4	After	30	10
200 Al^{+++} and Cr^{+++}	1	Before	21	19
200 Al^{+++} and Cr^{+++}	1	After	25	15
200 Al^{+++} and Cr^{+++}	4	Before	29	11
200 Al^{+++} and Cr^{+++}	4	After	30	10
50 Al^{+++} and Cr^{+++}	1	Before	35	5
50 Al^{+++} and Cr^{+++}	1	After	36	4
30 Al^{+++} and Cr^{+++}	1	Before	37	3
30 Al^{+++} and Cr^{+++}	1	After	37.5	2.5
500 Fe^{+++}	1	After	8	32
500 Fe^{+++}	4	After	14	26

In every case there is less barium ion retained (lost) if it is added after precipitation than if present in the original solution. However, it is seen that in similar experiments nearly as much barium ion is lost with 500 mg. of precipitate as with 200 mg. While adsorption is probably taking place, yet different amounts of adsorbent are being formed in the same volume (25 ml.). Thus it cannot be assumed that the conditions of the precipitation process are the same. Specific surface areas, therefore, might not be constant and the same conditions as to saturation would not result. Unfortunately the purpose of this work was to study the problem as it arises from the use of an accepted analytical method. Later, in the discussion, possible explanations will be given of these unusual results.

Combined Effect of Aging the Mixed Hydrous Aluminum and Chromic Oxides and the Addition of Barium Ion at Different Times on the Amount Retained.—Four sets of experiments were carried out. Solutions containing mixtures of 100 and 250 mg. each of aluminum and chromic ions, 10 ml. of 0.02% gelatin and 1 and 4 g. of ammonium chloride were prepared. In the first set 40 mg. of barium ion was added to the solutions, the hydrous oxides precipitated with concentrated ammonia as usual and the solutions allowed to age six days in stoppered flasks. Then the solutions were filtered, the precipitates washed free of barium ion, the filtrates and washings evaporated and the amount of barium ion determined. In the second set the procedure was repeated, only the 40 mg. of barium ion was added immediately after precipitation and then the solutions allowed to age six days in stoppered flasks. The third set duplicated the procedure except that the 40 mg. of barium ion was added after the hydrous oxides had aged for six days in stoppered flasks and then the solutions were filtered. In the last set the previous procedure was repeated with the addition of allowing the solutions to re-age two days in stoppered flasks after the 40 mg. of barium had been added. Table IV shows the results obtained.

TABLE IV

COMBINED EFFECT OF AGING THE HYDROUS OXIDES AND THE ADDITION OF BARIUM ION AT DIFFERENT TIMES ON THE AMOUNT RETAINED

A study of the results, especially when compared with those in previous tables, yields certain information. The same conclusion obtained from the data in Table III, *viz*,. less barium ion is lost if it is added after precipitation than if present in the original solution, also holds here. On comparing the results of this Table with similar experiments in Table III it is seen that aging the hydrous oxides in the presence of barium ion increases the amount retained (lost). Apparently, however, the loss from aging must be due to more than one factor as reaging results in a decrease of this loss. The anomalous behavior, *i. e.*, nearly the same loss of barium ion with 500 mg. of precipitate as with 200 mg., noted in connection with Table III, is also seen here.

Discussion

From the results of the first experiments it is evident that the loss of barium ion is not due to its precipitation as a carbonate, brought on by the absorption of carbon dioxide, contrary to Zolotukhin's assertion.[9] Yet, in later experiments, a definite amount of barium ion is lost where solutions containing precipitated hydrous oxides are kept in stoppered flasks. It is interesting to note in this connection that Curtman and Frankel, in determining the loss of barium ion due to the absorption of carbon dioxide by ammonia, said,

(9) Ref. 2b.

"Contrary to expectations, the loss in this operation was far greater than one might think."[10]

From the nature of the hydrous oxides and the fact that Fig. 1 is a typical Freundlich isotherm, the loss of barium ion is probably due to adsorption. In every experiment carried out, as the amount of ammonium salt present was increased, less barium was lost. Evidently ammonium ion replaces barium in the adsorption. This is in agreement with results reported by others.[6] This explains why Zolotukhin found that on washing the hydrous oxides with solutions of ammonium salts less barium ion was lost. In a saturated solution of ammonium salts some barium ion is still not recovered. This might be due to an incomplete replacement of barium by ammonium ion in the adsorption or else to occlusion of cations by the hydrous oxides as they are being formed. Increasing the amount of ammonium ion has a similar action, though different in extent, on the decrease of the loss of barium ion for each of the hydrous oxides. Yet in a saturated solution of ammonium ion, all three hydrous oxides, separately, adsorb about the same amount of barium ion. Important in analysis is the fact that while a high concentration of ammonium ion will decrease the adsorption of barium ion, it will not allow for its complete recovery. If the loss is due to surface adsorption, then it will be the same whether the barium ion is present before the hydrous oxides are precipitated or added immediately after. The results in Table III show there is a difference in the amount of barium ion lost depending on whether it is present before or after the precipitation. This indicates that besides surface adsorption some other effect must be occurring.

It already has been mentioned in connection with Tables III and IV that certain results appear to be anomalous. From Table I and Fig. 1 the surfaces of the precipitates of hydrous aluminum and chromic oxides are saturated when there is 14 mg. and 16 mg., respectively, or more barium ion in the filtrate. Besides there is a constant ratio of the amount of barium ion adsorbed to the amount of adsorbent when saturated. Therefore, in Table III, in similar experiments where 30, 50 and 200 mg. of mixed aluminum and chromic ion is precipitated in the presence of barium ion, the surfaces of the precipitates are saturated. Not only is there more than the criterion amount of barium ion in the filtrate, but there is a constant ratio of 1 mg. of barium ion retained to 10 mg. of mixed hydrous oxides. In the similar experiments where the barium ion was added after the precipitation, in order to eliminate occlusion, a slightly lower ratio, as is to be expected, of about 1:12 is obtained. But in the case of the experiments using 500 mg. of aluminum and chromic ion, the amount of barium ion retained is too low for saturation and therefore the amount in the filtrate is too high. It would seem, for some reason not apparent, that the surfaces of the precipitates in the latter are *not* saturated with barium ion. With a large amount of precipitate it might take a longer time before saturation is reached,[11] or internal surfaces do not come in contact with barium ion.[12]

If occlusion takes place while the precipitate is forming, then the amount of barium lost would be less if it is added after the hydrous oxides are formed. That this effect is present can be seen from the results in Table III. Furthermore, aging the precipitate should reduce the amount of barium occluded,[13] provided there is no post precipitation. If there is, then aging the precipitates would increase the amount of barium ion lost. Thus it is seen that while all three hydrous oxides cause loss of some barium ion by occlusion, there is postprecipitation with only hydrous aluminum and chromic oxides (see Table II). That the latter effect is appreciable is shown by the larger loss of barium ion on aging, which would tend to undo occlusion at the same time and therefore decrease the amount of barium ion lost. When hydrous aluminum and chromic oxides age, some change takes place which affects postprecipitation negatively. This is seen from the reaging experiments in Table IV where less barium ion is lost if it is added to aged hydrous oxides and then aged again. Some experiments were repeated in which the hydrous oxides were aged in the presence of barium ion for two days instead of six. The same results were obtained for the amount of barium ion lost, showing the postprecipitation was complete within two days.

Summary

1. The loss of barium ion when hydrous aluminum, chromic and ferric oxides are pre-

(10) Ref. 1, p. 728.

(13) Reference 4(c), page 881.

cipitated by ammonia in the presence of ammonium salts is not due to the formation of barium carbonate by absorption of carbon dioxide.

2. The loss of barium ion when hydrous aluminum, chromic and ferric oxides are precipitated by ammonia in the presence of ammonium salts is probably due partly to surface adsorption.

3. Ammonium ion replaces barium in the adsorption, yet all the barium ion is not recovered even in a saturated solution of ammonium salts.

4. All three hydrous oxides cause the loss during precipitation of some barium ion by occlusion.

5. Hydrous aluminum and chromic oxides also cause the loss of some barium ion by postprecipitation.

6. When large amounts of hydrous oxides are precipitated, the surfaces do not become saturated with barium ion.

Equilibrium in an Esterification Reaction with Perchloric Acid as Catalyst

BY H. M. TRIMBLE AND EARL L. RICHARDSON

Many workers have found that the equilibrium concentrations in reversible homogeneous reactions change when a catalyst is introduced, and that the degree of change varies with the concentration of the catalyst. Few, however, have investigated the phenomenon with other than small concentrations of the catalyst. This paper reports the results of a study of the reaction

$$CH_3COOH + C_2H_5OH \rightleftharpoons CH_3COOC_2H_5 + H_2O$$

in the presence of perchloric acid over a wide range of concentration. The efficiency of this substance in promoting simple esterification has not been examined previously, so far as the authors have been able to determine.

Experimental

Reagent grade perchloric acid, 70%, conforming to A. C. S. specifications was redistilled. It was diluted as needed to give aqueous solutions varying from 0.37 to 71.2% perchloric acid by weight which were used in making up the different reaction mixtures. Reagent grade glacial acetic acid was redistilled, saving the middle 75%. Repeated analyses showed it to be 99.8% pure. Ethyl alcohol was freed from aldehydes by treating it with silver oxide as described by Dunlap[1] and distilling. Its density was determined at 30° several times during the course of the work and found to remain constant at 0.80056 ± 0.00004. Reference to the tables by Osborne[2] shows that it contained 93.2% C_2H_5OH. The base used in all the titrations was approximately half normal sodium hydroxide. It contained a small excess of barium chloride, and it was protected at all times with soda lime tubes to ensure the absence of carbonate. It was standardized by means of reagent grade potassium hydrogen phthalate with phenolphthalein as indicator.

(1) Dunlap, THIS JOURNAL, **28**, 397 (1906).

(2) Osborne, *Bull. Bureau Standards*, **9**, 424–425 (1913).

The experiments were run at 30.00 ± 0.05°. The reaction vessels were 100- or 250-ml. bottles with well-fitting ground-glass stoppers. In experiments 1 to 7, 10-ml. portions of perchloric acid solution and 2-ml. portions each of acetic acid and ethyl alcohol, all measured at 30° by means of precision pipets, were taken in making up the reaction mixtures; in the other experiments half these quantities were used. The stoppers were sealed externally with paraffin wax and the bottles were immersed in the bath for three days or longer to allow the reaction to proceed to equilibrium. Titrations of the total acid present at equilibrium were carried out rapidly in the reaction vessels after adding ice water. Each experiment was run in triplicate, and repeated if the results failed to check satisfactorily. Portions of the perchloric acid solution used for each experiment were weighed and titrated at the same time as the mixture itself. The quantities of the organic substances delivered were checked by weighing, and found

[a] $K_{apparent}$ = moles EtOAc × moles H_2O/moles AcOH × moles EtOH.

to be constant to within ±0.1%. The alcohol contained 0.00360 mole of water per ml., and the water in the acetic acid was negligible. The essential data and results of the study are given in Table I. The graph shows the relation between the apparent equilibrium constant as calculated and the mole per cent. of perchloric acid present in the equilibrium mixtures. To save space the moles of ethyl alcohol and acetic acid at equilibrium have been omitted from the table. These values may be found for each experiment by subtracting the values of column 5 from 0.03190 for alcohol and 0.03456 for acetic acid in experiments 1 to 7, and from half these numbers for the others. These were the respective quantities of these substances introduced in making up the reaction mixtures.

A search of the literature indicates that perchloric acid will not oxidize any of the constituents of these mixtures, or react with alcohol to form an ester under the conditions of these experiments. This conclusion was borne out by suitable tests which were performed.

The relation of the apparent equilibrium constant to the mole per cent. of perchloric acid present is well expressed by the equation $K = 3.45 + 0.68\,M$ up to about $M = 11$. Calculation shows that the variation of this constant with concentration of the catalyst cannot be explained as due to combination of a part of the water with it to form a definite hydrate, as has been proposed by Jones and Lapworth.[3]

The Kinetics of Isotopic Exchange between Carbon Dioxide, Bicarbonate Ion, Carbonate Ion and Water[1]

BY G. ALEXANDER MILLS AND HAROLD C. UREY

Introduction

The important role of carbon dioxide in nature and in industry, as well as its intrinsically interesting properties, have made it the subject of intensive study.[2] These investigations have resulted in the belief that in aqueous solution less than 1% of the carbon dioxide present exists in combination with water. The rather strong metacarbonic acid so formed is highly ionized due to its small concentration. The first dissociation constant ordinarily determined is therefore not a true dissociation constant. Usually called the apparent dissociation constant it is nevertheless a real constant.

The differentiation between free and combined carbon dioxide has been possible through the circumstance, first noticed in 1912 by McBain,[3] that carbon dioxide does not react instantaneously with water. The effect of various reagents on the rate of reaction has been studied in detail.[4] The maximum amount of alkali instantaneously neutralized by a solution of carbon dioxide corresponds to the equilibrium amount of carbonic acid, ionized and un-ionized, if dissociation of carbonic acid is assumed to be very rapid. From conductivity data the ionized portion is known. The true first dissociation constant was therefore estimated to be 4×10^{-4}. The reaction also has

been followed by studying the rate of change of conductivity.[5]

Faurholt[6] in 1924 was first to recognize that the reaction process was determined by the *p*H of the solution. When the *p*H is less than 8 only simple hydration is important

$$CO_2 + H_2O \rightleftarrows H_2CO_3$$

When the *p*H is greater than 10 a bimolecular reaction predominates

$$CO_2 + OH^- \rightleftarrows HCO_3^-$$

Between these limits both determine the rate of reaction. By an ingenious method depending on the difference in rates of reaction between carbon dioxide and bicarbonate ion with amines Faurholt established approximately forward and backward reaction velocity constants for both reactions.

Measuring the rate of absorption and evolution of carbon dioxide by a buffered solution Brinkman, Margaria and Roughton[7] obtained data consistent with those of Faurholt. The use of two phases possibly introduces some uncertainty as to the interpretation of the results. However, the manometric measurements are much more precise. Stadie and O'Brien[8] have studied the reaction in physiological media. The catalyst, carbonic anhydrase, which occurs in blood, accelerates the reaction very considerably. Measuring the rate of reaction also by a "boat and manometer" method Roughton and Booth[9] have found an increase in the reaction rate in the presence of buffer solutions usually employed over that in pure water. They have incorporated their results in the form of a catalytic function and have evaluated this for several inorganic salts.

The rate of absorption of gaseous carbon dioxide by solutions is in part determined by the rate of chemical reaction. The effect of various substances on this rate was studied by Riou *et al.*[10] More recently a great deal of industrial work has been done using packed columns.[11]

The reaction between carbon dioxide and water results in an isotopic fractionation rather favorable for separation.[12] Experimental results[13] were lower than predicted, due, no doubt, to the slowness of the chemical reaction.

Method of Isotopic Exchange

The chemical identity of isotopes makes possible an investigation of reaction kinetics. The rate of establishment of isotopic equilibrium is measured in a system in a steady state except for the distribution of isotopes. This rate depends on the chemical reactions normally occurring. The chemical equilibrium ordinarily considered, which we may call *elementic* equilibrium, is concerned with the number of ions and molecules present. Isotopic equilibrium is concerned with the distribution of isotopes in the various ions and molecules. This latter equilibrium, except in the case of hydrogen and deuterium, results in a uniform distribution of isotopes in all compounds, since the constants for isotopic equilibrium are unity within a few per cent. The time necessary to reach isotopic equilibrium is greater than that necessary to reach ordinary equilibrium. This is true because in the former case each ion or molecule must come to equilibrium with all other ions and molecules. For example in the case of the oxygen exchange between carbon dioxide and water if the O^{18} content is not the same originally the hydration reaction must occur many times in order that there be isotopic equilibrium. Carbon dioxide dissolved in water will establish the half equilibrium concentration of carbonic acid in the order of one second. The half time necessary for oxygen exchange is about 1000 seconds.

A solution of carbon dioxide mixed with a solution of sodium bicarbonate will establish elementic equilibrium fairly quickly. If the C^{13} content of the carbon dioxide is not the same as that of the sodium bicarbonate there will be a comparatively slow change tending to establish a uniform distribution of the carbon isotopes. By drawing off samples of carbon dioxide from the solution at various times and making an isotopic analysis, the rate of change of C^{13} in the carbon dioxide can be measured. This can then be related to the rate of reaction of carbon dioxide with water.

Exchange occurs between the oxygen of carbon

dioxide, bicarbonate ion, carbonate ion and water. Carbon dioxide with an atom fraction of O^{18} different from ordinary may be dissolved rapidly in water. Samples of carbon dioxide extracted from portions of this solution at various times will have different O^{18} contents. The rate of oxygen exchange in solutions of carbonates and bicarbonates can be measured by studying the rate of change of O^{18} content in the carbon dioxide liberated at various times. All these results can be interpreted in terms of the kinetics of the reactions normally occurring.

The reversible hydration of carbon dioxide takes place quite rapidly. Investigation of the slower isotopic reactions is therefore of advantage. This is particularly true in the case of oxygen exchange. The correction for the effect of the back reaction is easily and quantitatively made and the effect of changing *p*H is eliminated. By studying the reaction in the liquid phase only, uncertainties due to rates of diffusion and solution are avoided.

Experimental

Preparation of Isotopic Material.—Employing a countercurrent method the reaction between carbon dioxide and bicarbonate ion has been used to obtain some concentration of C^{13}.[13] The carbonate solution so produced was first boiled with sodium hydroxide to drive off excess amines. Sulfuric acid liberated carbon dioxide which was then sublimed at liquid nitrogen temperatures. The C^{13} atom fraction of this carbon dioxide was 0.0140, the natural abundance being taken as 0.0106.

Water having an O^{18} atom fraction of 0.00500 compared to 0.00200 for ordinary has been produced by the fractional distillation of water.[14] This water was purified by refluxing and distilling from alkaline permanganate at least twice and once from chromic acid. The first and last portions were not used. Carbon dioxide with an O^{18} value greater than ordinary was prepared by shaking pure carbon dioxide with this water for at least ten hours.[15] Heavy oxygen sodium carbonate was prepared by dissolving pure sodium bicarbonate in the heavy oxygen water and allowing the solution to stand a week or more. The water was distilled off, the residue ground fine and heated at 300° for three hours.

Exchange Reactions with C^{13}.—A solution of carbon dioxide with a C^{13} content greater than ordinary was mixed rapidly with a solution of ordinary sodium bicarbonate. The temperature was maintained at 0.00 ± 0.03°. Liquid samples were withdrawn from time to time into evacuated vessels. The carbon dioxide first to come off was collected. It was assumed that this was representative of the carbon dioxide existing as such in solution. Carbon dioxide was obtained from the solution remaining by addition of acid. A rough estimation was thereby obtained of the combined carbon dioxide. The samples were analyzed on a Bleakney type mass spectrograph.[16] The error in analysis is about 1% of the C^{13} present. Typical results are given in Table I and in Fig. 1. α and β are the atom fractions of C^{13} in the carbon dioxide and bicarbonate ion, respectively.

TABLE I

Run 9; 0.00 ± 0.03°; $k_1[H_2O] = 0.0038$ sec.$^{-1}$; $[CO_2] = 0.021$ *M*; $[NaHCO_3] = 0.021$ *M*.

Time in sec.	β	α	$\log (\alpha - \alpha_\infty)$

70	.01176	.01326	−3.02
265	.01199	.01253	−3.63
∞	.01230	.01230	

Run 9-B; 25.00 ± 0.02°; $k_1[H_2O] = 0.021$ sec.$^{-1}$; $[CO_2] = 0.021$ *M*; $[NaHCO_3] = 0.021$ *M*.

Time in sec.	α	$\log (\alpha - \alpha_\infty)$
0	0.01352	−2.73
20	.01246	−3.09
58	.01171	
95	.01164	

For the *p*H range studied only simple hydration occurs. The possible reactions may be represented as

$$C^{13}O_2 + H_2O \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} H_2C^{13}O_3 \rightleftharpoons H^+ + HC^{13}O_3^-$$

$$C^{12}O_2 + H_2O \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} H_2C^{12}O_3 \rightleftharpoons H^+ + HC^{12}O_3^-$$

It is assumed that the ionization of carbonic acid is rapid. The rate of decrease of C^{13} in carbon dioxide is given by the expression

$$-d[C^{13}O_2]/dt = k_1[H_2O][C^{13}O_2] - k_{-1}[H_2C^{13}O_3]$$
$$-[CO_2]d\alpha/dt = k_1[H_2O][CO_2]\alpha - k_{-1}[H_2CO_3]\beta$$

However, since elementic equilibrium has been established quickly

$$k_1[H_2O][CO_2] = k_{-1}[H_2CO_3]$$

and so

$$-d\alpha/dt = k_1[H_2O](\alpha - \beta)$$

The amount of C^{13} is constant. Therefore, at any time

$$([CO_2] + [H_2CO_3] + [NaHCO_3])\alpha_\infty = \alpha[CO_2] + \beta([H_2CO_3] + [NaHCO_3])$$

$$-\frac{d\alpha}{dt} = k_1[H_2O]\left\{1 + \frac{[CO_2]}{[H_2CO_3] + [HCO_3^-]}\right\}(\alpha - \alpha_\infty)$$

The exchange reaction is of the first order, as is true in general.[17] The value of $k_1[H_2O]$ was obtained from the slope of the plot of $\log (\alpha - \alpha_\infty)$ against time, Fig. 1.

The precision is low because the reaction is so fast, being substantially complete in a few min-

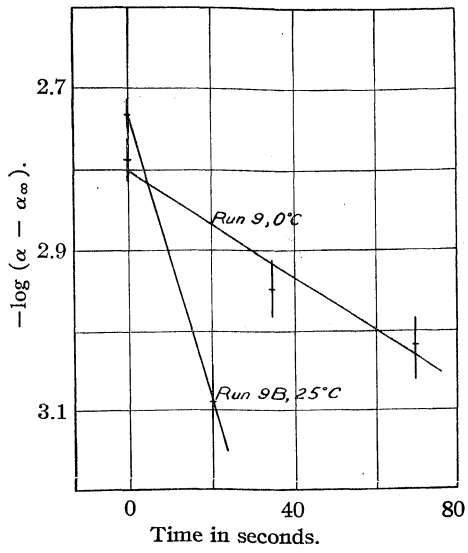

Fig. 1.

utes. Several seconds were necessary to take a sample. Also the low C^{13} atom fraction makes accurate analysis difficult. A number of experiments showed qualitatively the effect of added substances upon the reaction rate. Ethyl alcohol and basic solutions accelerated the rate while iron sol decreased it to some extent.

Exchange Reactions with O^{18}.—The rate of oxygen exchange between water and carbon dioxide depends upon the acidity of the solution.[18] The experiments made may be divided conveniently into three groups: (a) those in which the solution was acid enough so that substantially all the carbon dioxide remained in that state; (b) experiments in which the bicarbonate ion concentration was considerable; (c) reactions in basic solution where the carbonate ion was predominant. Carbon dioxide with an O^{18} content greater than ordinary was dissolved rapidly in water by shaking in a closed vessel. This solution was then placed in the reaction chamber, A, Fig. 2. From time to time a 10-cc. sample of this solution was withdrawn through the capillary manifold, B, into one of the evacuated bulbs, C. The carbon dioxide liberated was separated quickly from the water vapor by passage through an efficient trap, D, immersed in a dry-ice-bath. It was condensed in one of the sample tubes, E, by means of liquid nitrogen. The sample tube was sealed off and later analyzed for O^{18}. Frequent tests using a mass spectrograph showed that all but negligible amounts of water vapor were removed. The total time necessary to take a sample was ten seconds, though most of the carbon dioxide came off in the first part of this period. The liquid withdrawn from A was replaced with clean mercury from the reservoir, F, in order to prevent the formation of a gas phase above the liquid. Tests showed that the presence of mercury had no apparent effect on the reaction. When the time between samples was one minute or less, each sampling bulb was separately evacuated and equipped with an individual trap.

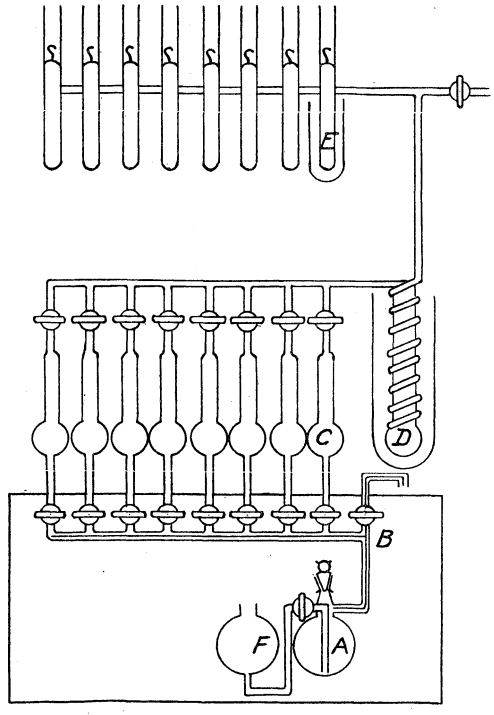

Fig. 2.

The rate of oxygen exchange between carbonate ion and water was studied. Sodium carbonate having an O^{18} content greater than ordinary was dissolved in ordinary water. Samples of this solution were withdrawn as before. In this case each sample bulb, C, contained 5 cc. of 0.3 *M* sulfuric acid. In a similar manner the oxygen exchange of various mixtures was studied. These were prepared by dissolving a known amount of heavy oxygen sodium carbonate in ordinary water and adding a known amount of standard acid, salt or phosphate buffer.

Details of typical experiments are shown in Tables II and III and in Fig. 3. α is the atom fraction of O^{18} in the liberated carbon dioxide. A summary of the results obtained in this way is given in Tables IV, V and VI.

Discussion of Experimental Results

For the *p*H range in which only hydration occurs the reactions possible may be represented as follows, assuming that the equilibrium between carbonic acid and its ions is rapid

$$CO^{16}O^{16} + H_2O^{16} \underset{}{\overset{k_1}{\rightleftharpoons}} H_2CO^{16}O^{16}O^{16}$$

$$CO^{16}O^{16} + H_2O^{18} \underset{}{\overset{k_{-1}}{\rightleftharpoons}} H_2CO^{16}O^{16}O^{18}$$

$$CO^{16}O^{18} + H_2O^{16} \rightleftharpoons H_2CO^{16}O^{16}O^{18}$$

$$CO^{16}O^{18} + H_2O^{18} \rightleftharpoons H_2CO^{16}O^{18}O^{18}$$

$$CO^{18}O^{18} + H_2O^{16} \rightleftharpoons H_2CO^{16}O^{18}O^{18}$$

$$CO^{18}O^{18} + H_2O^{18} \rightleftharpoons H_2CO^{18}O^{18}O^{18}$$

Then for the rate of change of O^{18} content in the carbon dioxide, carbonic acid and water

$$-\frac{dO^{18}(CO_2)}{dt} = k_1[CO^{16}O^{18}]\{[H_2O^{16}] + [H_2O^{18}]\} + 2k_1[CO^{18}O^{18}]\{[H_2O^{16}] + [H_2O^{18}]\} - {}^2/_3k_{-1}[H_2CO^{16}O^{16}O^{18}] - {}^4/_3k_{-1}[H_2CO^{16}O^{18}O^{18}] - 2k_{-1}[H_2CO^{18}O^{18}O^{18}]$$

$$-\frac{dO^{18}(H_2CO_3)}{dt} = k_{-1}[H_2CO^{16}O^{16}O^{18}] + 2k_{-1}[H_2CO^{16}O^{18}O^{18}] + 3k_{-1}[H_2CO^{18}O^{18}O^{18}] - k_1[H_2O^{16}]\{[CO^{16}O^{18}] + 2[CO^{18}O^{18}]\} - k_1[H_2O^{18}]\{[CO^{16}O^{16}] + 2[CO^{16}O^{18}] + 3[CO^{18}O^{18}]\}$$

$$-\frac{dO^{18}(H_2O)}{dt} = \frac{k_{-1}}{3}[H_2CO^{16}O^{16}O^{18}] + {}^2/_3k_{-1}[H_2CO^{16}O^{18}O^{18}] + k_{-1}[H_2CO^{18}O^{18}O^{18}] - k_1[H_2O^{18}]\{[CO^{16}O^{16}] + [CO^{16}O^{18}] + [CO^{18}O^{18}]\}$$

Let α, β and γ be the atom fractions of O^{18} in the carbon dioxide, water and carbonic acid, respectively. That is

$$\alpha = \frac{2[CO_2{}^{18}] + [CO^{16}O^{18}]}{2[CO_2]}$$

with similar expressions for β and γ. Substituting for the concentrations of the molecules present in terms of the atom fractions leads to the following equations. The same result is obtained if each molecule is assumed to be present in the proportion expected, if statistical equilibrium exists between all the isotopic varieties of each compound.

$$2[CO_2]\frac{d\alpha}{dt} = k_1[H_2O][CO_2]2(\gamma - \alpha)$$

$$3\{[H_2CO_3] + [HCO_3^-]\}\frac{d\gamma}{dt} = k_1[H_2O][CO_2](2\alpha + \beta - 3\gamma)$$

$$[H_2O]\frac{d\beta}{dt} = k_1[H_2O][CO_2][\gamma - \beta]$$

When $\{[H_2CO_3] + [HCO_3^-]\}$ is very small we may set $3\gamma = 2\alpha + \beta$. The O^{18} content of the carbonic acid is thus between that of the water and the carbon dioxide.

In solutions acid enough so that only carbon dioxide exists to any extent

$$-\frac{d\alpha}{dt} = \frac{k_1[H_2O]}{3}(\alpha - \beta)$$

The O^{18} content of the water remains effectively the same so that β may be taken as constant. The integrated expression is of the form

$$At + B + \log(\alpha - \beta) = 0$$

where $A = k_1[H_2O]\ 2.303/60$ and is the slope of the least square line determined experimentally and $k_1[H_2O]$ is in sec.$^{-1}$. The values of A and $k_1[H_2O]$ are given in Tables IV and V.

When considerable bicarbonate ion is present the rate of exchange is much slower, being proportional to the ratio $[CO_2] : \{[H_2CO_3] + [HCO_3^-]\}$. The three differential equations still represent the changes taking place. The solutions will be of the form

$$\alpha = a_1e^{-\lambda_1 t} + a_2e^{-\lambda_2 t} + a_3e^{-\lambda_3 t} \qquad (1)$$

with similar expressions for β and γ. It then turns out that

$$\lambda_1 = 0$$

$$\lambda_{2,3} = \frac{p + q \pm \sqrt{p^2 + q^2 + r^2 - 2pr - \frac{2qr}{3} + \frac{2pq}{3}}}{2}$$

where

$$p = k_1[H_2O],\ q = k_1\frac{[H_2O][CO_2]}{[H_2CO_3] + [HCO_3^-]} \text{ and } r = k_1[CO_2]$$

However, r is of the order of $^1/_{1000}$ of p or q and can be neglected. Using the boundary conditions, when

$$t = 0,\ \alpha = \beta = \alpha_0,\ \beta = \beta_0$$

and when

$$t = \infty,\quad \alpha = \beta = \gamma = \alpha_\infty$$

it turns out that the second term on the right in equation (1) for the atom fraction becomes unimportant soon after the reaction begins. During this time the O^{18} content of the carbonic acid and bicarbonate ion adjusts itself to a value less than that of the carbon dioxide. After this initial period

$$\alpha = \alpha_\infty + a_3e^{-\lambda_3 t}$$
$$\gamma = \alpha_\infty + c_3e^{-\lambda_3 t}$$

where

$$c_3\left[\frac{p}{p - \lambda_3} - \frac{p}{p - \lambda_2}\right] = (\alpha - \alpha_\infty)\left[1 - \frac{p}{p - \lambda_2}\right]$$

and

$$a_3 = \frac{p}{p - \lambda_3}c_3$$

The values of a_3 and c_3 are only a few per cent. different from unity, which they approach as the ratio $[CO_2] : [HCO_3^-]$ decreases. The value of $[H_2CO_3]$ is so small in these cases that it can be neglected.

Since the carbon dioxide liberated in the sample bulbs by sulfuric acid is representative of the carbon dioxide and sodium bicarbonate, we may represent its O^{18} fraction by

$$\delta = \frac{\alpha[CO_2] + \gamma[HCO_3^-]}{[CO_2] + [HCO_3^-]}$$

Making the proper substitutions

$$d \ln(\delta - \alpha_\infty)/dt = -\lambda_3$$

From the measured rate of the reaction obtained by evaluating A in the expression $At + B + \log(\delta - \alpha_\infty) = 0$, we obtain the value of the constant

$$p = k_1[H_2O]\text{sec.}^{-1} = A \times \frac{2.303}{60} \times \left\{ \frac{2}{1 + \frac{[CO_2]}{[HCO_3^-]} - \sqrt{1 + \frac{2}{3}\frac{[CO_2]}{[HCO_3^-]} + \left(\frac{[CO_2]}{[HCO_3^-]}\right)^2}} \right\}$$

The concentrations of $[CO_2]$ and $[HCO_3^-]$ were obtained from the weight of heavy oxygen sodium carbonate and the amounts of water and standard acid used. In an unsatisfactory attempt to determine the ratio $[CO_2] : [HCO_3^-]$ in another way the pH of the solution was determined at the reaction temperature by two opposing quinhydrone half cells. One contained the CO_2–HCO_3^- solution and the other a Sørensen phosphate buffer. The ratio $[CO_2] : [HCO_3^-]$ was calculated from the equation

$$\log \frac{[CO_2]}{[HCO_3^-]} = pK_a - p\text{H} + \log f_{HCO_3^-}$$

where $-0.5\sqrt{\mu}$ was substituted for $\log f_{HCO_3^-}$.[20] However, using standard solutions and carefully guarding against loss of carbon dioxide, e. m. f. values were obtained which yield pH values other than those calculated. A junction potential may account for this discrepancy. Keller[21] has reported a difference between the calculated pH and the observed pH for such solutions using a colorimetric method. At 40° the e. m. f. measurements were unsteady and the pH was determined using a Beaver colorimeter[22] with phenol red as indicator. The pK_a value was taken as 7.70 for these solutions whose ionic strength was about 0.05. The ratio $[CO_2] : [HCO_3^-]$ calculated from these measurements was in agreement with those obtained from weighings.

The values of A have been determined by the method of least squares from the experimental data and then $k_1[H_2O]$ evaluated. The results are given in Tables IV, V and VI.

Oxygen exchange between carbon dioxide and water takes place very slowly compared with the time necessary to establish elementic equilibrium. This is true because the carbon dioxide must come to equilibrium with all the water. When the solution was acid enough so that all the carbon dioxide remained as such in solution the values of the rate constant for the velocity of hydration have a constant value. The rate is not affected by addition of sodium chloride, sodium acetate or high concentrations of hydrochloric or acetic acid. In this range it appears that only simple hydration occurs. The results of this and other work are compared in Table VIII.

TABLE VIII

Reaction rate constants for the velocity of hydration of carbon dioxide $= k_1[H_2O]\text{sec.}^{-1}$. Those in parentheses were determined in buffer solutions. All values at 38° were obtained by extrapolation.

At 0° the rate of oxygen exchange is just that found by direct kinetic measurement for the rate of hydration of carbon dioxide. This agreement indicates that there is no rapid reversible reaction of carbon dioxide with water which could result in oxygen exchange as has been sometimes supposed. At 25° the value of the rate constant is considerably lower than that previously established. The fact that at elevated temperatures the reaction is so rapid that direct kinetic measurements are less precise probably accounts for this difference. The average energy of activation between 0 and 25° is 16,800 ± 400 calories.

The velocity constant for dehydration can be determined from a knowledge of the true dissociation constant of carbonic acid. Taking this as 4×10^{-4}, then at 0°

$$k_{-1} = \frac{[CO_2]}{[HCO_3^-]} k_1[H_2O] = \frac{K(\text{true})}{K(\text{apparent})} \times 0.0020 = 4 \text{ sec.}^{-1}$$

(20) Hastings and Sendroy, *J. Biol. Chem.*, **65**, 445 (1925); Stadie and Hawes, *ibid.*, **77**, 265 (1928).

(21) Keller, *Z. anal. Chem.*, **113**, 8 (1938).

(22) Beaver, *J. Optical Soc.*, **18**, 41 (1929).

When considerable amounts of bicarbonate ion are present, the rate of oxygen exchange is much slower, being dependent on the ratio $[CO_2]:[HCO_3^-]$. As is shown in Table IV, the value of $k_1[H_2O]$ remains constant until very small values of carbon dioxide concentration are reached. Then the inaccuracy in concentration satisfactorily accounts for the deviation. Actually as shown for run B-27 the ratio has varied some 200-fold while $k_1[H_2O]$ changes by only 50%. In Table V the rate constants in run C-1 and C-2 are low. It is thought that this is due to loss of carbon dioxide, a circumstance which occurs more easily at higher temperatures and which would explain the low values. A comparison of runs B-16 and B-20 shows that increasing the salt concentration considerably does not affect the rate. Therefore it seems that under these conditions the bicarbonate ion exchanges oxygen with water only through the reversible formation of carbon dioxide by simple hydration

$$CO_2 + H_2O \rightleftarrows H_2CO_3 \rightleftarrows H^+ + HCO_3^-$$

In the presence of $M/15$ phosphate buffer an increase of about 30% in the rate is observed. This is exactly in agreement with the recent data of Roughton and Booth,[9] who have found that the presence of the phosphate buffer, usually heretofore employed, accelerates the reaction to this extent.

Sodium carbonate exchanges all its oxygen slowly with water. It is not feasible to calculate a rate constant since the purity of the sodium carbonate so affects the concentration of carbon dioxide. However, even if one-fourth the sodium carbonate were sodium bicarbonate, it can be shown that the rate of exchange is 1000 times greater than can be accounted for by simple hydration. The rapidity apparently is due to the reaction of carbon dioxide with hydroxyl ion. When the solution has been made more basic by addition of sodium hydroxide, the exchange becomes very slow due to the extremely small amount of carbon dioxide present. The slow exchange of carbonate ion[18] has been studied also by Titani and Goto.[23,24] Our more precise analytical means allow observation of smaller changes.

(23) Titani, Morita and Goto, *Bull. Chem. Soc. Japan*, **13**, 329 (1938).

(24) Titani and Goto, *ibid.*, **14**, 77 (1939).

Oxygen exchange of other inorganic ions has been studied.[24,25] It has appeared that anhydride formation would in some cases account for exchange in acid solutions. Exchange with the sulfate ion is strongly catalyzed by hydroxyl ions.[26] No such effect was observed for carbonate ion.

Summary

The rate of carbon exchange between carbon dioxide and bicarbonate ion has been studied. Approximate rate constants were determined which are consistent with those established independently for the rate of hydration of carbon dioxide.

The rate of oxygen exchange between carbon dioxide, bicarbonate ion, carbonate ion and water has been investigated. The exchange between carbon dioxide and water is due to the reversible hydration only. The addition of salts or acids did not affect this rate. The rate constant at 0° agrees with that found recently by Roughton and Booth, being one-fourth lower than the previously accepted value which was established in the presence of buffer solutions. At higher temperatures the rate found is considerably less than that previously established. The average energy of activation between 0 and 25° is 16,800 ± 400 calories.

Oxygen exchange of bicarbonate ion occurs only through the reversible formation of carbon dioxide by simple hydration when the *p*H is less than 8. The rate is not affected by the addition of sodium or potassium chloride. In the presence of phosphate buffer the reaction is accelerated.

Carbonate ion slowly exchanges its oxygen with water. The rate is faster than for simple hydration of the carbon dioxide present. This increase is presumably due to the reaction of carbon dioxide with hydroxyl ion. A high concentration of hydroxyl ion retards the exchange, since then only very small concentrations of carbon dioxide are present.

The Strength of Carbonic Acid. The Rate of Reaction of Carbon Dioxide with Water and Hydroxyl Ion

BY A. R. OLSON AND P. V. YOULE*

A value of the order of 4×10^{-7} is accepted by most chemists as the first ionization constant of aqueous carbonic acid. If K_1 is defined as equal to

$$\frac{(H^+)(HCO_3^-)}{(\text{total } CO_2 \text{ in solution})}$$

this value is correct. For certain types of work such as those where bicarbonate ion or carbonic acid is used as a catalyst for reactions, it is necessary to distinguish between the total amount of carbon dioxide in solution and that fraction of it which is present as carbonic acid, a distinction emphasized by Brönsted.[1] In some of our unpublished work on the hydrolysis of β-butyrolactone, the catalytic character of bicarbonate ion indicated that carbonic acid was about ten times stronger than acetic acid, and so the literature was searched for information bearing on this point.

McBain[2] noted a slow neutralization of carbonic acid with phenolphthalein as indicator, an observation amplified by Vorländer and Strube[3] and by Thiel.[4] By colorimetric measurements Thiel, together with Strohecker, made a detailed study of the reactions involved, but, since much of this work was superseded in accuracy by Faurholt's, it is pertinent here to recall only one of Thiel's experiments. Thiel set the amount of carbonic acid present as equivalent to the amount of base neutralized by a given carbon dioxide solution in less than 0.4 second, which at 4° he found to be 0.67%, corresponding to a first dissociation constant of 5×10^{-4} (recalculated by Faurholt as 1.9×10^{-4}). The value 7.4×10^{-4} obtained by Lotte Pusch[5] through conductivity measurements was dismissed by Faurholt as doubtful.

Faurholt[6] determined the amount of carbonic acid present in carbon dioxide solutions by adding excess of dimethylamine to combine with the carbon dioxide in solution as carbamate so that the carbonic acid could be precipitated by barium chloride. By analyses at measured time intervals he followed the reaction of carbon dioxide with water

$$CO_2 + H_2O \xrightarrow{k_a} H_2CO_3 \qquad (1)$$

and with hydroxyl ion

$$CO_2 + OH^- \xrightarrow{k_b} HCO_3^- \qquad (2)$$

His value for k_a was checked by Stadie and O'Brien,[7] by Brinkman, Margaria and Roughton[8] using manometric and flow techniques, and by Urey and Mills[9] in a study of O^{18} exchange between carbon dioxide and water.

From Faurholt's results at 0 and 18° we calculate for reaction (1)

$$RT^2 \frac{\Delta \ln K}{\Delta t} = \Delta H = 0.7 \text{ kcal. per mole}$$

$$RT^2 \frac{\Delta \ln k_a}{\Delta t} = \Delta E = 19 \text{ kcal. per mole}$$

For the reaction with hydroxyl ion, the activation energy is from 10 to 13 kcal. per mole, according to the data used.

The velocity with which carbon dioxide adds to bases depends upon the strength of the base, as is shown by the following figures from Faurholt[10] for the reaction

$$CO_2 + R_2NH = R_2NCOOH$$

$$\frac{-d(CO_2)}{dt} = k(CO_2)(R_2NH)$$

Base	NH_3	$MeNH_2$	Me_2NH
k (18°, time in hours)	2.3×10^5	5×10^6	4×10^7

These figures also serve to justify Faurholt's method of analysis, which involved essentially a competition between two bases for the carbon dioxide.

Roughton and Booth[11] published approximate figures for the catalytic effect of bases on reaction (1). Their results conform roughly to a typical Brönsted diagram. Catalysis by bicarbonate ion corresponds to an acid strength for carbonic acid of about 5×10^{-5}, showing approximate agreement with our results.

Summary

The catalytic efficiency of HCO_3^- confirms the statements found in various published articles that the first ionization constant for carbonic acid is about 2×10^{-4}.

From the rates of the reaction $CO_2 + H_2O = H_2CO_3$ at various temperatures, the heat of activation is found to be 19 kcal./mole.

For the reaction $CO_2 + OH^- = HCO_3^-$ the heat of activation is found to be from 10 to 13 kcal./mole.

The Solubility of Cadmium and Zinc Oxalates in Salt Solutions

BY WARREN C. VOSBURGH AND J. FINK BECKMAN

In the determination of the ionization constants of cadmium and zinc oxalates by Clayton and Vosburgh[1] there were two sources of uncertainty. One was the value used for the second ionization constant of oxalic acid and the other the interpretation of the solubility data for cadmium oxalate in cadmium sulfate solutions. The redetermination of the second ionization constant of oxalic acid by Harned and Fallon[2] has made it advisable to recalculate some of the data of Clayton and Vosburgh,[1] and some new experiments have led to a better interpretation of the solubility data.

Materials.—Cadmium oxalate was prepared by precipitation as described by Clayton and Vosburgh.[1]

Potassium perchlorate was prepared from potassium hydroxide and perchloric acid. It was recrystallized three times and dried at 100°.

Cadmium perchlorate was prepared by addition of an excess of cadmium oxide to a known quantity of 60% perchloric acid solution. The solution was separated from the excess oxide and heated, whereupon some cadmium hydroxide precipitated. Filtration and dilution gave a stock solution with a *p*H of about 7 as measured by a glass electrode. The concentration determined by an electrolytic cadmium determination agreed with the concentration as calculated from the original quantity of perchloric acid. Dilution of the cadmium perchlorate solution caused a decrease in *p*H, the largest decrease observed being about one unit.

Potassium sulfate was recrystallized twice. Solutions of this and of potassium perchlorate were prepared by weight, and analysis was considered unnecessary.

Solubility Determinations.—Solutions of potassium and cadmium perchlorates and potassium sulfate were saturated with cadmium oxalate at 25 ± 0.02° (in an oil-bath) by stirring mechanically for at least two hours. Experiments showed that saturation could be attained in one hour. A large sample was drawn through a filter of Pyrex glass wool and portions of 200 ml. each were taken for analysis, without allowing the temperature to fall appreciably below 25°. The oxalate was titrated with 0.05 *N* permanganate solution by the use of a 5-ml. semi-micro buret. The permanganate solution was standardized frequently against sodium oxalate from the National Bureau of Standards under conditions similar to those used in the oxalate determinations. Experiments showed that the solvent salts did not interfere with the analyses. The results of the solubility determinations are given in Tables I–IV in the columns headed "total oxalate." It is believed that errors were within 1.5%.

The values reported for the solubility of cadmium oxalate in water by Clayton and Vosburgh[1] differ from the one in this paper by more than 1.5%, but it is believed that the latter is the more reliable and is accurate within the limit claimed.

Discussion

For the interpretation of the solubility data it is necessary to recalculate the solubility product of cadmium oxalate. Use of the value 5.18×10^{-5} for the second ionization constant of oxalic acid[2] and the experimental data of Clayton and Vosburgh[1] gives 1.44×10^{-8} for the activity solubility product.

By means of the solubility product and the activity coefficients of Kielland[3] the concentration of oxalate ion in the salt solutions was calculated. In potassium perchlorate and potassium sulfate solutions allowance was made for a small amount of autocomplex formation. For potassium perchlorate solutions the data in Table I were obtained.

TABLE I

SOLUBILITY OF CADMIUM OXALATE IN POTASSIUM PERCHLORATE SOLUTIONS

$KClO_4$ $m \times 10^3$	Total oxalate $m \times 10^3$	$\sqrt{\mu}$	$C_2O_4^-$ $m \times 10^3$	CdC_2O_4 un-ionized $m \times 10^3$
None	0.289	0.0232	0.133	0.154
5	.316	.0752	.163	.150

80	.475	.285	.303	.166

(1) Clayton and Vosburgh, THIS JOURNAL, **59**, 2414 (1937).

(2) Harned and Fallon, *ibid.*, **61**, 3111 (1939).

(3) Kielland, THIS JOURNAL, **59**, 1677 (1937).

The figures in the last column are the difference between the total oxalate and the concentration of oxalate ion plus twice the concentration of the complex ion $Cd(C_2O_4)_2^{=}$. The latter concentration was about 1% of the oxalate ion concentration, as will be shown later. The difference so calculated is assumed to represent undissociated cadmium oxalate and in Table I is as nearly constant as could be expected. The corresponding differences for the solutions of the other salts increased considerably with the concentration of the solvent salt. This is shown in Fig. 1, in which are represented also the data of Clayton and Vosburgh for cadmium sulfate solutions recalculated with the use of the new solubility product.

Clayton and Vosburgh assumed that the cadmium sulfate curve of Fig. 1 represented the solubility of undissociated cadmium oxalate in cadmium sulfate solutions. They also assumed that cadmium oxalate would behave similarly in other salt solutions. In view of the practically constant concentration of the undissociated oxalate in potassium perchlorate solutions, it now seems preferable to consider that small concentrations of electrolytes have no appreciable effect on the concentration of undissociated cadmium oxalate in saturated solutions.

The abnormal solubility in the cadmium perchlorate solutions cannot be ascribed to the perchlorate ion. Therefore it must be caused by the cadmium ion. The assumption of the existence of the ion $CdC_2O_4 \cdot Cd^{++}$ allows an explanation. This ion can be considered to be formed according to the equation

$$CdC_2O_4 + Cd^{++} \rightleftarrows CdC_2O_4 \cdot Cd^{++}$$

and its instability constant calculated by the equation

$$(CdC_2O_4)[Cd^{++}]/[CdC_2O_4 \cdot Cd^{++}] = K_1$$

in which parentheses indicate activity and square brackets concentration. The activity coefficients for the ions should cancel approximately.

The activity of undissociated cadmium oxalate was found by extrapolation of the curve for cadmium perchlorate in Fig. 1. This gives the value 1.44×10^{-4} m, as compared with 1.54×10^{-4} m, in Table I for the solubility in water. Since the extrapolated values for solutions of the two cadmium salts agreed well, 1.44×10^{-4} was accepted as the activity. The higher value for the potassium perchlorate and sulfate solutions involves a much larger correction for ionized cadmium oxalate, and appreciable hydrolysis may have taken place in these solutions and in water.

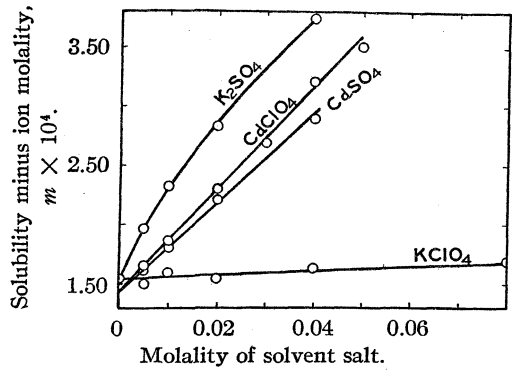

Fig. 1.—Variation of the solubility of cadmium oxalate with salt concentration. From the total solubility has been subtracted the concentration of the ionized cadmium oxalate as calculated from the solubility product.

The concentration of the ion $CdC_2O_4 \cdot Cd^{++}$ was taken as the difference between the total oxalate concentration and the sum of the oxalate ion and undissociated cadmium oxalate concentrations. The latter was assumed constant and equal to 1.44×10^{-4} m. Table II shows that K_1 is constant.

TABLE II

COMPOSITION OF CADMIUM PERCHLORATE SOLUTIONS SATURATED WITH CADMIUM OXALATE

$Cd(ClO_4)_2$ or Cd^{++} $m \times 10^3$	Total oxalate $m \times 10^3$	CdC_2O_4 $m \times 10^3$	$C_2O_4^{=}$ $m \times 10^3$	$CdC_2O_4 \cdot Cd^{++}$ $m \times 10^3$	K_1
5	0.173	0.144	0.008	0.021	0.034
10	.191	.144	.005	.042	.034
20	.234	.144	.004	.086	.034
30	.272	.144	.003	.125	.035
40	.323	.144	.003	.176	.033
50	.353	.144	.003	.206	.035

A similar calculation was made for cadmium sulfate solutions with the assumption that cadmium sulfate is only partially dissociated and the dissociation constant is 0.0050 as calculated by Davies.[4] The values for K_1 so calculated were not constant. If the concentration of the ion $CdC_2O_4 \cdot Cd^{++}$ is calculated by the use of the value 0.034 for K_1, an appreciable amount of the oxalate in the more concentrated cadmium sulfate solutions is left unaccounted for, as shown in the column headed "difference" in Table III. As a possible explanation for this difference the ion $CdC_2O_4 \cdot SO_4^{=}$ was assumed, and its equilibrium constant calculated by the expression

$$(CdC_2O_4)[SO_4^{=}]/[CdC_2O_4 \cdot SO_4^{=}] = K_2$$

(4) Davies, *J. Chem. Soc.*, 2093 (1938).

The results of this calculation, based on the experimental data of Clayton and Vosburgh, are given in Table III.

TABLE III

COMPOSITION OF CADMIUM SULFATE SOLUTIONS SATURATED WITH CADMIUM OXALATE

Total $CdSO_4$ $m \times 10^3$	Total oxalate $m \times 10^3$	Cd^{++} and $SO_4^{=}$ $m \times 10^3$	$CdC_2O_4 \cdot Cd^{++}$ $m \times 10^3$	Difference $m \times 10^3$	K_2
5	0.171	3.88	0.016	0.001	..
10	.188	7.12	.030	.006	0.17
20	.226	13.1	.056	.020	.09
40	.294	24.0	.102	.043	.08

For solutions of potassium sulfate it is necessary to assume the formation of both undissociated cadmium sulfate and the ion $CdC_2O_4 \cdot SO_4^{=}$. Because of the formation of cadmium sulfate, the oxalate ion molality is not equal to the cadmium ion molality. The values of K_2 for the ion $CdC_2O_4 \cdot SO_4^{=}$ agreed with those in Table III as well as could be expected. The data for potassium sulfate solutions are given in Table IV. The figures in the column headed "difference" were obtained by the subtraction of 1.54×10^{-4}, and the oxalate ion molality, and twice the concentration of the ion $Cd(C_2O_4)_2^{=}$ from the total oxalate molality. For the undissociated cadmium sulfate the molality 1.54×10^{-4} was used instead of 1.44×10^{-4} because the former is the extrapolated value in Fig. 1 for potassium sulfate and potassium perchlorate solutions. On account of the large activity of cadmium and oxalate ions, hydrolysis might be appreciable in these solutions and the larger figure would include a correction for this. The values for the "difference" in Table IV were taken as the molalities of the ion $CdC_2O_4 \cdot SO_4^{=}$.

TABLE IV

COMPOSITION OF POTASSIUM SULFATE SOLUTIONS SATURATED WITH CADMIUM OXALATE

K_2SO_4 $m \times 10^3$	Total oxalate $m \times 10^3$	$C_2O_4^{=}$ $m \times 10^3$	$Cd(C_2O_4)_2^{=}$ $m \times 10^3$	Difference $m \times 10^3$	K_2
5	0.390	0.230	0.002	0.002	...
10	.463	.285	.003	.018	0.079
20	.564	.368	.0035	.035	.082
40	.719	.481	.0045	.075	.076

It has been shown that the solubility of cadmium oxalate in dilute salt solutions can be explained on the assumption that the concentration of the undissociated portion is constant. This should apply to potassium oxalate solutions, and it is necessary to recalculate the data of Clayton and Vosburgh on the oxalatocadmiate ion. The results of such a recalculation are given in Table V. The concentration of the oxalatocadmiate ion, $Cd(C_2O_4)_2^{=}$, was taken as the difference between the total cadmium oxalate dissolved and the sum of the cadmium ion molality and the molality of undissociated cadmium oxalate. The instability constant was calculated by means of the equation.

$$(CdC_2O_4)[C_2O_4^{=}]/[Cd(C_2O_4)_2^{=}] = K_3$$

and the activity coefficients for the ions were assumed to cancel.

TABLE V

INSTABILITY CONSTANT OF THE OXALATOCADMIATE ION

Oxalate total $m \times 10^3$	CdC_2O_4 total $m \times 10^3$	$C_2O_4^{=}$ $m \times 10^3$	Cd^{++} $m \times 10^3$	$Cd(C_2O_4)_2^{=}$ $m \times 10^3$	K_3
5.76	0.194	5.53	0.007	0.043	0.019
9.49	.230	9.18	.005	.081	.016
24.56	.374	23.96	.004	.226	.015
27.00	.394	26.38	.003	.237	.016
28.66	.412	27.98	.003	.265	.015
48.6	.627	47.5	.003	.480	.014
97.5	1.077	95.5	.002	.931	.015

The ionization constant of cadmium oxalate at 25° can be calculated from the solubility product (1.44×10^{-8}) and the activity of the undissociated oxalate (1.44×10^{-4}), to be 1.00×10^{-4}. Money and Davies[5] found 1.3×10^{-4} at 18° by calculation from the conductivity data of Scholder.[6]

Recalculations for Zinc Oxalate.—Recalculation of the solubility product for zinc oxalate gives $K_{S.P.} = 1.28 \times 10^{-9}$. The solubility in water is 1.68×10^{-4} and if hydrolysis is neglected the concentration of undissociated oxalate is 1.29×10^{-4}. The ionization constant is 0.99×10^{-5} at 25° as compared with 1.3×10^{-5} at 18° calculated by Money and Davies.[5]

The effect of zinc sulfate on the solubility of zinc oxalate can be explained by the assumption of the ion $ZnC_2O_4 \cdot Zn^{++}$. In Table VI it is assumed that the concentration of this ion is equal to the total oxalate minus $1.29 \times 10^{-4}\ m$, with a further correction of $0.01 \times 10^{-4}\ m$ in two cases for

oxalate ion. The K_4 in the table is the instability constant of this ion calculated from the solubility data, with the assumption that zinc sulfate is incompletely dissociated and its ionization constant[4] is 0.0054.

Recalculation of the data on the oxalatozincate ion $Zn(C_2O_4)_2^=$ in the same manner as for the oxalatocadmiate ion gives the results in Table VII. To the data of Clayton and Vosburgh have been added some experimental data of Metler and Vosburgh[7] and some of Kunschert.[8] The first three values for K_5 from the data of Metler and Vosburgh are probably too high; the analysis for zinc gave somewhat low results and the error was probably largest in the most dilute solutions. It may be concluded that in the more dilute solutions the complex ion $Zn(C_2O_4)_2^=$ is formed, but all three sets of results are in agreement in showing that at a molality of between 0.05 and 0.1 the value of K_5 begins a rapid decrease. The significance of this is discussed by Clayton and Vosburgh.

Summary

The solubility of cadmium oxalate in solutions of potassium and cadmium perchlorates and potassium sulfate has been measured.

The increase in solubility with concentration in solutions of potassium and cadmium sulfates and cadmium perchlorate, and the constancy in potassium perchlorate solutions, can be explained if the existence of the ions $CdC_2O_4 \cdot Cd^{++}$ and $CdC_2O_4 \cdot SO_4^=$ is postulated and cadmium sulfate regarded as incompletely dissociated.

The solubility of zinc oxalate in zinc sulfate solutions can be explained similarly if the ion $ZnC_2O_4 \cdot Zn^{++}$ is postulated.

The instability constants of the ions $Cd(C_2O_4)_2^=$ and $Zn(C_2O_4)_2^=$ have been recalculated.

Ternary Systems. XXV. Solid Solutions of Some Picromerites at 25°

BY ARTHUR E. HILL,* GEORGE S. DURHAM** AND JOHN E. RICCI

In continuation of the project undertaken in this Laboratory, of collecting reliable equilibrium data on the distribution of isomorphous salts between liquid and conjugate solid solutions, a series of ternary systems consisting of water and a pair of double sulfates of the picromerite series, has been investigated, at the temperature of 25°. The purpose of these measurements is ultimately to relate if possible the distribution ratio of these salts between liquid and solid phases, with certain properties of the individual salts such as their aqueous solubilities. With the necessity in mind of having as nearly as possible ideal conditions for the interpretation of solution relationships, pairs of salts were chosen for this work which because of their very close similarity in formula and in other properties would be expected to form very nearly ideal solid solutions in their mixed crystals. Reports already have been published on a number of alum pairs,[1,2] as also on some picromerite systems.[3] The present report covers

* This paper is being published, following the death of Professor Hill, by his collaborators.

the experimental investigation of the equilibrium relations of six pairs of picromerites studied as ternary systems with water at 25°; the picromerites, or schoenites, are a series of isomorphous monoclinic hexahydrated double sulfates of univalent and divalent bases, of which Mohr salt, $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$, is a familiar example. In all the systems of the present study complete miscibility of the two picromerites in the solid state was found, at the temperature of the determinations.

The experimental procedure in these measurements is marked, as in the preceding papers of this series, by particular attention to the establishment of equilibrium both in respect to the solid–liquid relations and as to the equilibrium within the mixed crystals themselves, in order to leave no question as to the validity of the results for any possible theoretical interpretation. The procedure was therefore that already described, in which the solid solution equilibrium was approached, for every determination, from two opposite directions. Every complex was prepared in exact duplicate (Tubes A and B of the Tables). In Tube A one of the salts was dissolved completely in the water, and the second solid then added as the initial solid phase; this order was then reversed for Tube B of the same complex. If the two tubes give the same results for both liquid and solid compositions, equilibrium is proved. Although the attainment of this kind of solid solution equilibrium is in general very slow, it was found that by enclosing two glass marbles in each complex during the rotation, which by their motion kept the solid phase finely ground, a week was sufficient for the purpose.

The determinations involved the preparation, as described, of complexes of known composition, and analysis, at equilibrium, of both the liquid and the solid phases, the former after adequate filtration, the latter after centrifuging and air-drying; all the double salts of the systems studied are stable, as hexahydrates, exposed to ordinary air, so that this latter procedure involved no error except for the crystallization of salts from traces of residual mother liquor. In addition the algebraic extrapolation[4] of the tie-lines through the total compositions (complexes) and the compositions of the liquid solutions, was used as a check on the consistency and accuracy of the work, by comparing the extrapolated composition of the solid phase with the observed.

System I. Magnesium Ammonium Sulfate–Copper Ammonium Sulfate–Water, at 25°.—Both of the double salts forming the solid components of this system are congruently soluble at room temperature. While the magnesium salt is known to remain so up to the boiling point,[5] the copper salt has not been studied at temperatures above 61°[6,7]; nevertheless it can be prepared successfully by crystallization from boiling solution of the simple sulfates of copper and ammonium, followed by prolonged cooling and stirring.[3] This method was used for both the magnesium ammonium and the copper ammonium double sulfates for the present investigation. Their composition, checked by analyses both for the metal and for the ammonium radical, was found to agree with the theoretical formulas within experimental error. The ammonium was determined by distillation into standard acid and subsequent titration, with an accuracy of 1/500. The liquids and solids of the ternary system were analyzed by determination of magnesium and of copper. Magnesium was determined following the procedure given by Kolthoff and Furman,[8] by precipitation as ortho-hydroxyquinolate and titration of the precipitated quinolate with standard potassium bromate (Berg's method[9]), the end-point being fixed by spot-tests with potassium iodide–starch paper. In the presence of copper the magnesium was precipitated after addition of excess of potassium cyanide, which avoided the necessity of previous removal of the copper. This determination likewise had an accuracy of 1/500. Copper was determined electrolytically, the analysis being exact to 1/1000.

The solubilities of the two double salts of this system, here reported, were determined with very close agreement, from both under- and super-saturation, and are based on analysis for both of the positive radicals of each salt; the values found, 16.61% for the magnesium salt and 18.60% for the copper salt, are in close agreement with recent determinations appearing in the literature.[10,11]

The results for the ternary system are given in Table I, which includes the data for the remaining systems discussed below; the table is self-explanatory. The solubilities of the pure double salts have been omitted from this table and are collected, together with density measurements, in a subsequent table (II). The usual triangular diagrams for the graphical representation of the equilibria in the ternary systems are not shown; their appearance and the general disposition of the tie-lines involved are very similar to the diagrams for the related picromerite systems reported by Hill and Taylor.[3] The composition of the solid phase was checked by algebraic extrapolation of tie-lines passing through the compositions of original complex and of liquid solution, to the straight line joining the compositions of the two picro-

was only 0.30%. In connection with the magnitude of this deviation, it is to be noted that since the composition of the complex is usually quite near that of the resulting liquid solution, any analytical error in the composition of either will be multiplied by a factor of from ten to twenty in the extrapolation.

System II. Copper Potassium Sulfate–Nickel Potassium Sulfate–Water, at 25°.—The nickel potassium sulfate, being congruently soluble up to the boiling point,[12] was prepared in the manner described for the salts of System I. The copper potassium double sulfate was prepared from solutions of the simple sulfates at temperatures not above 55°, to avoid precipitation of basic salt.[7,13] The purity of the double salts was checked by analysis for copper and nickel, respectively. The analytical method for this ternary system involved the consecutive electrolytic determination of these metals, the nickel after deposition and removal of the copper. The analysis is judged to be accurate to 1/1000. The solubility of the copper potassium double sulfate, 10.35% from both under- and super-saturation, is in fair agreement with published results: 10.47 (Locke[10c]), 10.46 (Caven and Mitchell[7]), and 10.02 (Trevor[14]). That of the nickel potassium double salt, 6.33%, also both from under- and from super-saturation, may be compared with Locke's value, 6.43%.[10c]

Again complete miscibility is observed between the two solid picromerites at this temperature. The average

absolute deviation, in per cent. $CuK_2(SO_4)_2$, between the observed and the extrapolated compositions of the solid phase, was 0.49% for this system.

System III. Cobalt Potassium Sulfate–Copper Potassium Sulfate–Water, at 25°.—These salts were already known to form a complete series of solid solutions, the system having been studied at 0 and 7.8°, by Ploin.[15] The 25° isotherm was determined for the purpose of comparison with the other related systems. The cobalt potassium double sulfate, becoming incongruently soluble at 78° and ceasing to exist at 90°,[12] was prepared at temperatures not higher than 75°. Its purity was checked by determination of cobalt. The analytical method for the ternary system, involving the consecutive electrolytic determination of copper and cobalt, was accurate to 1/1000. The solubility here reported for the cobalt potassium double sulfate, 13.65% from both under- and supersaturation, differs widely from the older literature values, namely, 11.41% reported by Locke[10c] and 15.60% by Benrath.[12] The great difference is probably due to the difficulty of establishing true equilibrium between the various isomeric forms of hydrated cobaltic salts both in solution and in the crystalline state. The agreement between the two approaches to equilibrium both for the solubility of the cobalt potassium double sulfate itself and for the ternary complexes, does not, even in the present work, constitute absolute proof of the establishment of all the possible equilibria involved.

The average absolute deviation between extrapolated and observed percentage of $CoK_2(SO_4)_2$ in the solid phase, is very small (0.08%), indicating the high precision and the consistency, at any rate, of the various analytical steps involved.

System IV. Zinc Potassium Sulfate–Copper Potassium Sulfate–Water, at 25°.—This system also has been studied by Ploin, at 8°, showing similarly, at that temperature, complete miscibility of the two double salts.[15] The zinc potassium double sulfate was prepared at 85°, as it becomes incongruently soluble at 88° and above.[16] The purity of the salt so prepared was verified by analysis for zinc. The analytical procedure for the ternary system involved again the consecutive electrolytic deposition of copper followed by the deposition of the more active metal, in this case, zinc; the analysis was accurate to 1/1000. The solubility of the zinc potassium double sulfate, found to be 11.72% from both under- and super-saturation, was determined by direct evaporation to the anhydrous sulfates, a very accurate procedure. The result is in fair agreement with the value reported by Locke, 11.65%.[10c]

The analytical precision can be judged by the small average absolute deviation (0.08%) between extrapolated and observed compositions (as % $ZnK_2(SO_4)_2$) for the solid phase.

System V. Zinc Potassium Sulfate–Nickel Potassium Sulfate–Water, at 25°.—In this system the percentage of total solids was determined by evaporation, nickel was determined gravimetrically by precipitation with dimethylglyoxime, with an accuracy of 1/1000, and the zinc salt was then calculated by difference.

The average absolute deviation, in respect to per cent. of $ZnK_2(SO_4)_2$, between the extrapolated and observed compositions of the solid phase, was only 0.17%.

System VI. Copper Ammonium Sulfate–Copper Potassium Sulfate–Water, at 25°.—This system differs from the preceding five combinations in that here the univalent rather than the divalent cation of the picromerite is being varied. For the analysis the total copper was determined by electrolysis. The copper ammonium double salt was determined by distillation of ammonia, with an accuracy of 1/500, and the copper potassium double salt was then calculated by difference.

The deviation in this system between extrapolated and observed per cent. $Cu(NH_4)_2(SO_4)_2$ for the solid phase was 0.68%.

To permit the calculation of the molar solubilities of the various double salts involved, the densities of their pure saturated solutions at 25° were determined together with their weight per cent. solubility. These densities were determined with only moderate accuracy, by means of calibrated pipets fitted with proper filter paper to separate the liquid phase from excess of solid.

TABLE II

SOLUBILITIES OF SOME PICROMERITES AT 25°

Salt	Solubility, wt. % anhydrous salt	Density of saturated solution	Molar solubility
$Mg(NH_4)_2(SO_4)_2 \cdot 6H_2O$	16.61	1.090	0.7176
$Cu(NH_4)_2(SO_4)_2 \cdot 6H_2O$	18.60	1.160	.7399
$CuK_2(SO_4)_2 \cdot 6H_2O$	10.35	1.094	.3392
$NiK_2(SO_4)_2 \cdot 6H_2O$	6.33	1.056	.2032
$CoK_2(SO_4)_2 \cdot 6H_2O$	13.65	1.128	.4679
$ZnK_2(SO_4)_2 \cdot 6H_2O$	11.72	1.109	.3873
$Zn(NH_4)_2(SO_4)_2 \cdot 6H_2O$	12.24[3]	1.103	.4601
$Ni(NH_4)_2(SO_4)_2 \cdot 6H_2O$	7.09[3]	1.057	.2614

Distribution between Liquid Solution and Solid Solution.—The distribution of the picromerites here studied, between the equilibrium liquid and solid phases, may be considered from the point of view of Roozeboom's[17] classification of such binary solid solutions occurring in ternary systems of water and two salts. In order to interpret the above data in terms of this classification the concentrations have been recalculated into mole fractions of the two picromerites, disregarding water, in the two phases. The results, giving for each system the mole fraction of the more soluble picromerite (more soluble in molar units), are shown in Table III, and are plotted in Figs. 1 and 2, in which the curves I–VI represent, respectively, the six combinations studied; in the table and figures, the Y values represent the mole fraction of the more soluble picromerite in the liquid phase and X its mole fraction in the solid phase.

From the tabulation and the two figures, as also from a consideration of the disposition of the tie-lines in the triangular isothermal diagrams for the systems (not shown), it appears that these systems would all fall into Type I of Roozeboom's classification, systems in which there is complete miscibility between the two solid components and in which the proportion of one of these components is higher in the liquid than in the corresponding solid phase throughout the whole series of concentrations. We again note, as has been reported in connection with recent similar studies on a series of alum systems,[2] that the component present in greater concentration in the liquid than in the solid has the higher aqueous molar solubility. It must be observed of course at this point that the data are not sufficient to rule out the possibility that the curves of Figs. 1 and

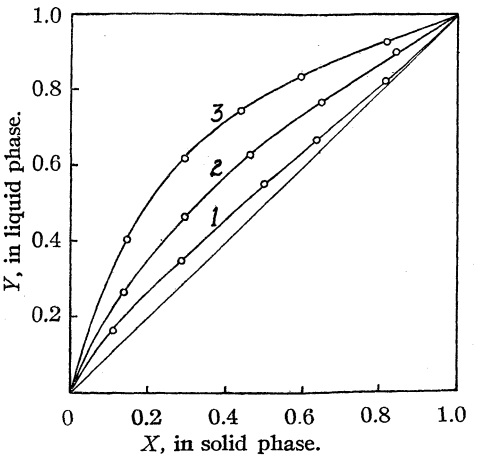

Fig. 1.—Distribution of picromerites between aqueous solution and solid solution at 25°: (1) $Mg(NH_4)_2(SO_4)_2$ in $Mg(NH_4)_2(SO_4)_2$–$Cu(NH_4)_2(SO_4)_2$; (2) $CuK_2(SO_4)_2$ in $CuK_2(SO_4)_2$–$NiK_2(SO_4)_2$; (3) $CoK_2(SO_4)_2$ in $CoK_2(SO_4)_2$–$CuK_2(SO_4)_2$.

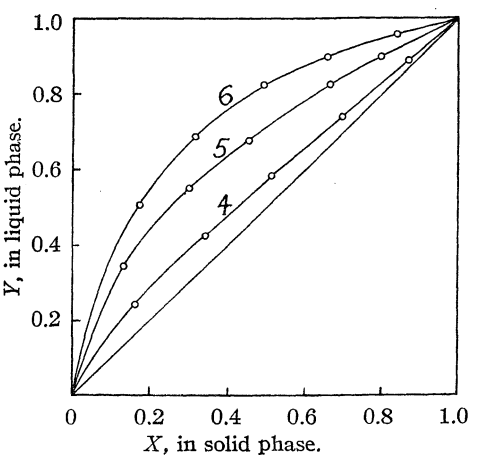

Fig. 2.—Distribution of picromerites between aqueous solution and solid solution at 25°: (4) $ZnK_2(SO_4)_2$ in $ZnK_2(SO_4)_2$–$CuK_2(SO_4)_2$; (5) $ZnK_2(SO_4)_2$ in $ZnK_2(SO_4)_2$–$NiK_2(SO_4)_2$; (6) $Cu(NH_4)_2(SO_4)_2$ in $Cu(NH_4)_2(SO_4)_2$–$CuK_2(SO_4)_2$.

2 may cross the diagonal near the extremities of the diagrams; in the case of the picromerites here reported, it appears, on the basis of further theoretical considerations not yet published, that this may actually be the case, and that these systems consequently would then fall into Type II of Roozeboom's classification, in which, starting from zero concentration of one component, the proportion of that component in the liquid phase (Y) is greater than its proportion in the solid phase (X) up to a certain point, then becoming smaller than X up to a mole fraction of one for the component. In continuation of the suggestion made in a previous article of this series, in

which the empirical equation $X = Y^m$ was advanced, these measurements, together with similar studies from this Laboratory, will be considered, in a subsequent publication, for the purpose of deriving some generalization relating the distribution ratio of these isomorphous salts between liquid and solid phases, to the molar solubilities of the individual salts in the pure solvent.

Summary

1. The following ternary systems have been studied at 25°

$Mg(NH_4)_2(SO_4)_2$–$Cu(NH_4)_2(SO_4)_2$–H_2O
$CuK_2(SO_4)_2$–$NiK_2(SO_4)_2$–H_2O
$CoK_2(SO_4)_2$–$CuK_2(SO_4)_2$–H_2O
$ZnK_2(SO_4)_2$–$CuK_2(SO_4)_2$–H_2O
$ZnK_2(SO_4)_2$–$NiK_2(SO_4)_2$–H_2O
$Cu(NH_4)_2(SO_4)_2$–$CuK_2(SO_4)_2$–H_2O

2. Continuous series of solid solutions were found in each case.

3. The results, considered from the point of view of Roozeboom's classifications of solid solutions, show all these systems to belong apparently to Type I of that classification.

Freezing Point and Solubility Data for the System Chlorine Monoxide–Water

BY C. H. SECOY AND G. H. CADY

It is known that chlorine monoxide dissolves in water to give hypochlorous acid but no previous study has been made of the possible existence of hydrates of this acid nor have highly concentrated solutions of the acid been prepared and studied. In this work freezing point and solubility data have been obtained for the system chlorine monoxide–water. The only pertinent data found in the literature were the freezing point of pure chlorine monoxide, reported by Goodeve[1] to be −116°, and the freezing points of very dilute solutions of hypochlorous acid.[2]

Experimental

Preparation of Chlorine Monoxide and Hypochlorous Acid.—Chlorine monoxide was prepared by passing a stream of dry chlorine mixed with air up through a column of yellow mercuric oxide.[3] A 35-mm. glass tube, one meter long, was filled with mercuric oxide with a sufficient quantity of porcelain chips added to prevent packing. The top of this tube was sealed to 8-mm. glass tubing leading to a 24 mm. × 30 cm. test-tube fitted with a stirrer and a thermocouple well. Other workers[3] have stated that the mercuric oxide previously should be heated to 400°, for a period of an hour or longer. This treatment, however, was not used since it has been found that it is neither necessary nor helpful.[4] The spent mercuric oxide was recovered by precipitation in the cold with sodium hydroxide, washed free of sodium hydroxide, and dried at 120°.[4] The air and chlorine were dried by bubbling through sulfuric acid and passed through a T-tube into the mercuric oxide. The rate of flow of the air was about twice that of the chlorine. The air prevented any noticeable heating effect from the reaction.

The chlorine monoxide was condensed by means of a dry-ice–alcohol cooling mixture, and hypochlorous acid of the desired concentration was then obtained by adding the required amount of water and stirring until equilibrium had been reached. Chlorine monoxide and strong hypochlorous acid were found to be stable over a period of a week if kept at a temperature below −20°. However, some free chlorine invariably was formed if the solution was allowed to stand for a few hours at a higher temperature.

Temperature Measurements.—Freezing point data were obtained by thermal analysis. Temperatures were measured by a copper–constantan thermocouple calibrated at the ice-point, the dry-ice point, and the boiling point of oxygen. The conversion table reported by Giauque, Buffington, and Schulze[5] was used after applying a constant factor, characteristic of the thermocouple used, to the e. m. f. readings. The use of this factor allowed points at the calibration temperatures to fall within 0.02° of Giauque's curve. The e. m. f. was measured with a Leeds and Northrup Type K potentiometer using a voltage-sensitive galvanometer. Readings were made to the nearest tenth of a microvolt and temperatures obtained were believed to be accurate to 0.1°. The warm junction of the thermocouple was kept at the temperature of melting ice.

Method of Analysis.—The method reported by Spinks[6] was used to determine both free chlorine and available chlorine in the form of chlorine monoxide and/or hypochlorous acid. The sample, from 0.2 to 0.5 g., was transferred by means of a pipet to a weighed flask containing a

solution of potassium iodide. The flask was then reweighed to determine the weight of the sample. The determination of the free chlorine served as a check on the possible decomposition of the hypochlorous acid, and no data were used from any sample which showed chlorine to be present.

The composition of the dihydrate, $HOCl \cdot 2H_2O$, was established by direct analysis of the crystals formed by partially freezing solutions of concentrations just above and just below 16.6 mole % chlorine monoxide. Both phases were analyzed after being separated quickly by filtration in a small centrifuge. The filter consisted of a piece of glass cloth fused to the end of a tube drawn and cut to just fit in a small test-tube which could be used in the centrifuge. After previously cooling the filter tube with dry-ice, the partly frozen slush was added to it and centrifuged for ten or fifteen seconds. The dry crystals were then transferred to a flask containing a solution of potassium iodide, weighed, and titrated. The data obtained are summarized in Tables I and II.

Solubility of Chlorine Monoxide in Water.—The two liquid phases were held at the temperature desired and stirred until equilibrium was established. After allowing any suspended oily drops of chlorine monoxide to settle from the water layer, a sample of the latter was taken for analysis. Measurements were not attempted at temperatures above 264°K., because of the high vapor pressure and the tendency for decomposition to occur at higher temperatures. Results are tabulated in Table III.

TABLE III

Solubility of Water in Chlorine Monoxide.—A 100-cc. flask containing phosphorus pentoxide was fitted with a glass cap, designated cap A, which slid down over the neck of the flask. The cap was made tight by fitting a short piece of rubber tubing over the neck of the flask and the cap. A second similar cap, designated cap B, was connected by a side arm to a potassium iodide absorption train. A glass tube extended through the top of cap B to the surface of the phosphorus pentoxide when the flask was in place. Saturation of the chlorine monoxide was obtained by adding sufficient water to form the double layer and stirring at constant temperature until equilibrium was reached. The samples were taken by means of a dipper constructed by blowing a small bulb in the end of a piece of 6 mm. glass tubing. A side opening was then blown just above the bulb and about 2 cm. from the end of the tube. In order to remove a sample not contaminated with the water layer, a piece of 10 mm. tubing was inserted into the solution, the water layer forced outside of this tube with compressed air, and the dipper used inside the tube.

After being weighed, with cap A in place, the flask was cooled with dry-ice and a sample of the chlorine monoxide saturated with water at the desired temperature was added. The flask was then attached to the absorption train by means of cap B, and, as the temperature rose, a slow current of air dried by phosphorus pentoxide was drawn through the system until all of the chlorine monoxide had evaporated. Cap A was then replaced and the flask weighed, the increase in weight giving the weight of water in the sample. The amount of chlorine monoxide in the sample was determined by titrating the liberated iodine. Results are given in Table IV.

TABLE IV

SOLUBILITY OF H_2O IN Cl_2O

270.0	3.4
236.8	2.9
194.6	1.8

The Freezing Point of Pure Chlorine Monoxide.—Cooling curves taken with a freshly prepared sample of chlorine monoxide, dried by passing the gas over phosphorus pentoxide, gave a freezing point of −120.6°. After adding water to the chlorine monoxide and stirring to secure saturation, the freezing point was found to be

−121.0°. Phosphorus pentoxide was then added directly to the liquid and again a freezing point of −120.6° was observed.

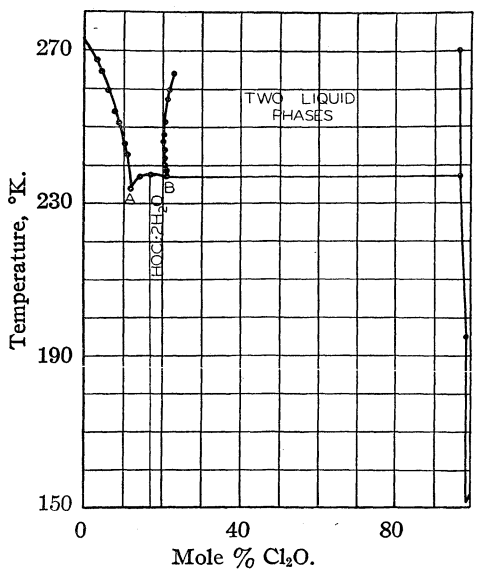

Fig. 1.—Temperature–concentration diagram for the system chlorine monoxide–water. Several experimentally determined points between A and B have been omitted on the graph (see Table I for data).

Due to the discrepancy between this result and the value of −116°, reported by Goodeve,[1] the thermocouple was recalibrated at the boiling point of oxygen. A fresh sample of chlorine monoxide, dried as before, was prepared. In order to free the chlorine monoxide from dissolved air and chlorine, approximately one-fourth of the sample was distilled off at about −75°. The freezing point then observed was −120.6°. After removing a second portion of the chlorine monoxide in the same manner, the same freezing point was obtained. Addition of water gave the same depression of 0.4°, as previously found.

The temperature–concentration diagram for the system is shown in Fig. 1. Point B, at 20.7 mole % chlorine monoxide and 236.8°K., is an invariant point representing equilibrium between two liquid phases, the solid phase and the gaseous phase. It is to be noted that solid HOCl is not obtained. A solution containing a sufficiently high concentration of chlorine monoxide to give the compound HOCl would separate into two liquid phases before freezing and give, as the solid phase, the hydrate, $HOCl \cdot 2H_2O$.

Summary

The freezing point–composition diagram for the system chlorine monoxide–water has been studied over the entire range, and solubilities of chlorine monoxide in water and of water in chlorine monoxide have been measured. Chlorine monoxide and water are a pair of partially miscible liquids. The solid phase formed from solutions of concentration greater than 11.7 mole % chlorine monoxide has the composition $HOCl \cdot 2H_2O$.

Photochemical Studies. XXX. The Fluorescence of Biacetyl. Some General Considerations Governing the Study of Fluorescence

BY F. C. HENRIQUES, JR., AND W. ALBERT NOYES, JR.

Recent studies of the fluorescence of acetone have shown that under some conditions a Stern-Volmer equation is at least approximately obeyed[1] but that if the intensity of the incident radiation is sufficiently high, noticeable increase of fluorescence with time is observed.[2] Moreover, the three intense bands of acetone fluorescence were shown to be identical with those of biacetyl. It also has been shown that the main portions of the fluorescences of acetaldehyde and of methyl ethyl ketone are identical with those of biacetyl and of acetone.[3] It seems probable, therefore, that the fluorescing molecule is the same in all of these cases and that it is probably biacetyl.

Several questions still remain unanswered concerning the so-called fluorescence of acetone, particularly those having to do with the mechanism whereby the biacetyl molecule is excited when acetone is the absorber. It has seemed advisable, therefore, to investigate the effect of certain variables on the fluorescence of biacetyl. The fluorescence of this molecule has been investigated

(1) Fisk and Noyes, *J. Chem. Phys.*, **2**, 654 (1934).

(2) Matheson and Noyes, THIS JOURNAL, **60**, 1857 (1938).

(3) Matheson and Zabor, *J. Chem. Phys.*, **7**, 536 (1939).

from several angles by Almy and his co-workers.[4,5,6,7] Their conclusions may be summarized briefly as follows: (a) the spectrum of the fluorescence is independent of the exciting wave length (3650, 4047, 4358 Å.); (b) little or no quenching by biacetyl is observed when the exciting wave length is 4358 Å., *i. e.*, as the pressure is increased, the intensity of the fluorescence is proportional to the absorbed intensity; (c) the fluorescence is quenched by oxygen and (strongly) by iodine; (d) the mean lifetime of the excited biacetyl molecules as determined by various methods is quite long, probably longer than 10^{-5} second; and (e) the quantum yield of fluorescence is quite low, being a maximum of about 0.03 fluorescence quantum per absorbed quantum at 3650 and 4358 Å.

In the present investigation a study of the effects of pressure, of temperature, of wave length, of intensity, and of added acetone on the fluorescence has been made. From this study certain seemingly valid conclusions can be drawn concerning the fate of the excited biacetyl molecules and the nature of upper electronic levels.

I. Some General Considerations Governing Fluorescence Studies

In a recent article[8] several aspects of problems relating to fluorescence have been treated. It was emphasized that with increase in pressure of the absorbing gas, there is a volume redistribution of absorbed intensity which may lead to spurious results unless the absorption coefficient is very low. That is, the measuring device will intercept a fraction of the fluorescent quanta emitted from a certain volume within the cell. If this fraction varies as the distribution of absorbed intensity throughout this volume change, no valid conclusions can be drawn concerning quenching. This problem will be examined briefly.

Referring to Fig. 1 we will assume that the fluorescence is being studied with the aid of a T-shaped cell, that the x-axis is horizontal, the y-axis vertical, and the z-axis perpendicular to the plane of the paper. For the sake of simplification a parallel beam of radiation, the intensity of which is uniform throughout a cross section perpendicular to the x-axis, is assumed. The radius of this cross section is y_1. I_0' is defined as the incident intensity at the center of the cell. It will be noted that this definition differs from that used later for I_0.

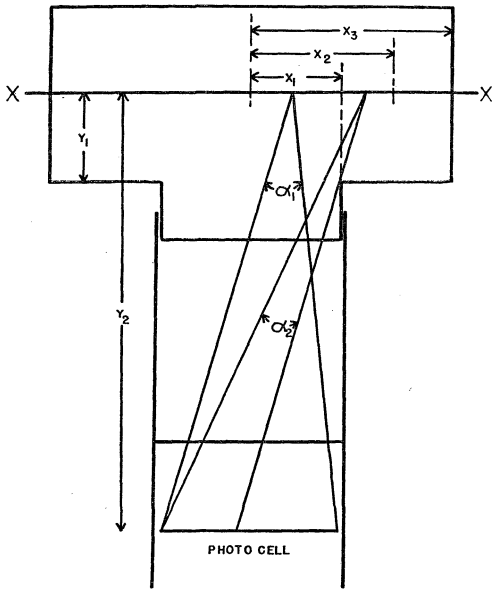

Fig. 1.

It is also evident that many complications are avoided if y_2, the distance from the axis of the main limb of the T to the light measuring device, is large compared to y_1, the radius of the tube making this limb. All radiation striking the walls is assumed to be absorbed.

Furthermore, the problem becomes very difficult to treat if the fluorescent intensity is not proportional to the absorbed intensity when all variables except the latter are kept constant. In the following paragraphs it is assumed that the intensity of the fluorescence from any volume element is proportional to the intensity absorbed when the pressure and the temperature are constant. The fluorescent radiation is assumed not to be absorbed by the gas, thus avoiding the serious complications due to radiation imprisonment.

It is obvious that the form of I_a, the intensity absorbed, must be

$$I_a = 2I_0' \frac{\int\int\int_0^{x_3} \Pi_{xyz}\, bP \cosh(bPx)\, dx\, dy\, dz}{\int\int\int_{-x_3}^{x_3} \Pi_{xyz} dx\, dy\, dz} \qquad (1)$$

where b is the absorption coefficient per unit distance along the x-axis and per unit pressure; P is the pressure. Π_{xyz} is the probability that

(4) Almy, Fuller and Kinzer, *Phys. Rev.*, **55**, 238 (1939).
(5) Almy and Fuller, *Trans. Illinois State Acad. Sci.*, **31**, 196 (1938).

(8) Noyes and Henriques, *ibid.*, **7**, 767 (1939).

fluorescent light from the volume element $dx\,dy\,dz$ will reach the light measuring device.

With the assumptions made above

$$\Pi_{xyz} = \text{const. } \Pi_x \qquad (2)$$

and hence I_a may be treated to a good first approximation as a function of x alone.

For $0 \leqq x \leqq x_1$

$$\Pi_x = \alpha_1/2\pi \qquad (3)$$

where to a good approximation

$$\alpha_1 = (2x_1/y_2)\left(1 - \frac{x_1^2 + x^2}{y}\right) \qquad (4)$$

For $x_1 \leqq x \leqq x_2 = x_1(y_1 + y_2)/(y_2 - y_1)$

$$\Pi_x = \alpha_2/2\pi \qquad (5)$$

where to a first order approximation

$$\alpha_2 = \frac{x_1(y_1 + y_2) - (y_2 - y_1)x}{y_1y_2}(1 - 2x_1^2/y_2^2) \qquad (6)$$

For $x_2 \leqq x \leqq x_3$

$$\Pi_x = 0 \qquad (7)$$

By integrating equation (1) after making the proper substitutions for Π_x one obtains

$$I_a = \frac{I_0'}{2\pi\int_0^{x_3}\Pi_x dx}\left[\frac{4x_1}{y_2^3}\left(x_1^2 + \frac{1}{b^2P^2}\right)\sinh x_1bP + \frac{y_2 - y_1}{y_1y_2bP}\left(1 - \frac{2x_1^2}{y_2^2}\right)\cosh x_2bP - \left(1 + \frac{2x_1^2}{(y_2 - y_1)y_2}\right)\cosh x_1bP\right] \qquad (8)$$

Unless the absorption coefficient is extremely high, all but the first two terms in the expansion of the hyperbolic functions may be neglected. Upon integration of $\int_0^{x_3}\Pi_x dx$ and substituting, one obtains

$$I_a = I_0'bP \qquad (9)$$

Equation (9) should be valid if the assumptions made above are obeyed and if the fraction of the incident radiation absorbed between $-x_2$ and $+x_2$ is not over about 0.4. For other cases the use of equation (8) would be necessary.

II. Experimental

The biacetyl (Eastman Kodak Co.) was repeatedly fractionally distilled at low pressures. The acetone (Merck reagent) was dried with calcium chloride and distilled in the dark.

Monochromatic radiation of wave length 3650 Å. was obtained from a General Electric Vapor Lamp Co. high pressure mercury arc (Uviarc UA30A2) combined with Corning Violet Ultra Glass and a cupric ammonium sulfate filter. For 3130 Å. a silvered surface and a solution of nickel and cobalt sulfates were used. For 2537 Å. the same solutions plus a filter of gaseous chlorine were used.

A T-shaped cell of the type previously used[3] was thermostated by a water jacket so that the temperature could be kept constant to 0.5°. The fluorescent radiation was intercepted by a quartz cesium–cesium oxide photocell with plane window, the current from which was amplified by a modified Barth[9] circuit, using an FP54 tube, the batteries being continuously charged with a trickle-charger. The radiation transmitted by the cell was intercepted by a potassium hydride cell with glass envelope, the current being read directly with a sensitive galvanometer.

The pressures were measured either directly on a manometer or by means of a McLeod gage of low sensitivity. When both biacetyl and acetone were used together, they were admitted to a large mixing chamber and condensed with liquid air. After vaporization sufficient time was allowed for complete mixing, and then a portion of the mixture was expanded into the cell.

In all instances the fluorescent radiation was partially limited to certain spectral regions by the use either of a Wratten 8 or a Wratten 25 filter. The fluorescence of biacetyl consists of three bands[2,5] with maxima at 5120, 5580 and 6100 Å. These filters transmit the following percentages of incident radiation at these wave lengths, respectively: Wratten 8, 73, 86, and 89%; Wratten 25, 0, 0, and 75%. Thus the use of the Wratten 25 filter permits a study of the 6100 Å. band alone. The Wratten 8 filter served mainly to eliminate scattered light.

III. Results

No visible fluorescence could be excited in pure biacetyl by the mercury lines at either 3130 or 2537 Å.

It does not seem useful to give all of the numerical data in detail. The absorption coefficient for biacetyl, using the 3650 Å. radiation obtained as described above, was first determined. Beer's law was found to be obeyed within experimental error. At 29° the transmitted light is given by the expression

$$I_{\text{trans.}} = I_0 \exp.\ (-0.00040dP) \qquad (10)$$

where d is the thickness in centimeters and P is the pressure in millimeters. I_0 is the intensity when the biacetyl is condensed with liquid air. Almy and his co-workers give a coefficient of 0.00042 without specifying the temperature.[4] At other temperatures (from 15 to 60°), the same law seems to be obeyed quite closely providing the change in density with temperature is taken into account. Thus if the pressure is expressed in millimeters, the coefficient may be written as $0.121/T$ where T is the absolute temperature.

Table I presents examples of data obtained at 29° through a Wratten 8 filter. For the first ten points the incident intensity was practically constant and the biacetyl pressure varied. The last

48.0	6.0	7.0	6.9	0.573	.0283

five points were obtained at constant pressure but with variable I_0.

The figures in the last column are based on the quantum efficiency for fluorescence of 0.029 obtained at relatively high pressures by Almy and his co-workers.[6] The factor 2.35 × 10^{-3} is empirically chosen to make the quantum efficiency have a maximum value of 0.029.

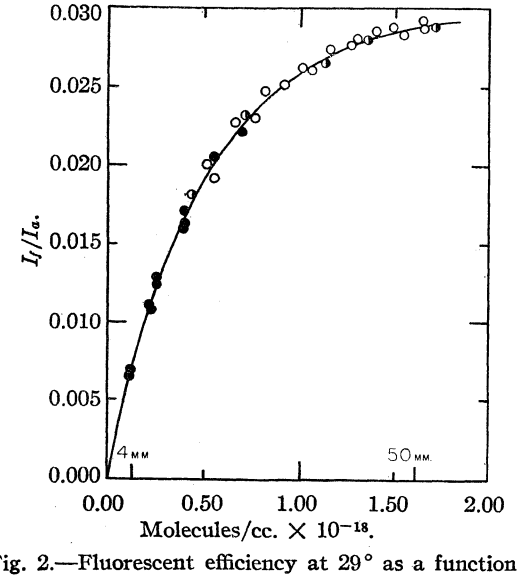

Fig. 2.—Fluorescent efficiency at 29° as a function of pressure of biacetyl: (1) ○, fluorescent radiation passed through a Wratten 8 filter. Incident light monochromated through use of Corning Violet Ultra glass and Cupric Ammonium Sulfate filter. (2) ●, fluorescence as in 1. Incident radiation monochromated by use of Violet Ultra glass alone. (3) ◑, fluorescence passed through Wratten 25 filter. Incident light as in 2. The curve is a graphical representation of equation (23).

Two conclusions relative to the data at 29° seem to be permitted from the data in Table I: (a) the fluorescence efficiency is not constant and independent of pressure but apparently decreases at low pressures; (b) at constant pressure the fluorescence efficiency is independent of the incident intensity even though the latter was varied nearly sevenfold.

The bulk of the data are summarized in Figs. 2 to 4 inclusive. In Fig. 2 it is seen that I_f/I_a increases with pressure at first rapidly and then more slowly, finally becoming practically constant. Moreover, by the use of color filters (Fig. 2) it is shown that there is no significant change of distribution of intensity among the wave lengths as a function of pressure. In Fig. 3 it is seen that I_f/I_a decreases with increase in temperature, although the general form of variation with pressure is maintained.

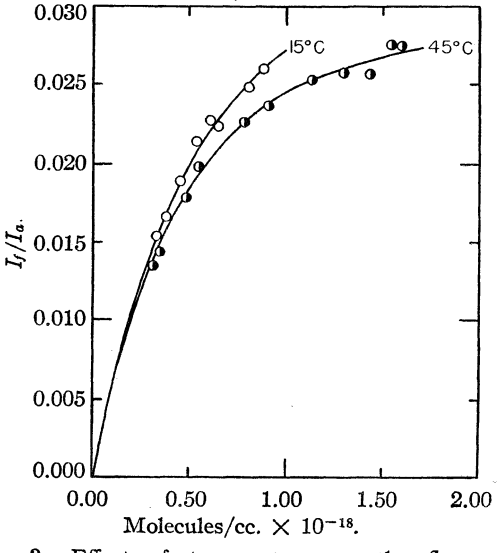

Fig. 3.—Effect of temperature on the fluorescent efficiency of biacetyl. Both curves are obtained from equation (23).

The data for Fig. 2 could not be carried to pressures higher than the vapor pressure of biacetyl. The curve might pass through a maximum if higher pressures could be attained. To afford a partial test of this point acetone was mixed with the biacetyl, the data being given in Fig. 4. Acetone was chosen because the fluorescence of this substance has been attributed to biacetyl and because resonance between the two molecules might be better than if some other foreign molecules

were used. Moreover, acetone is transparent at 3650 Å.

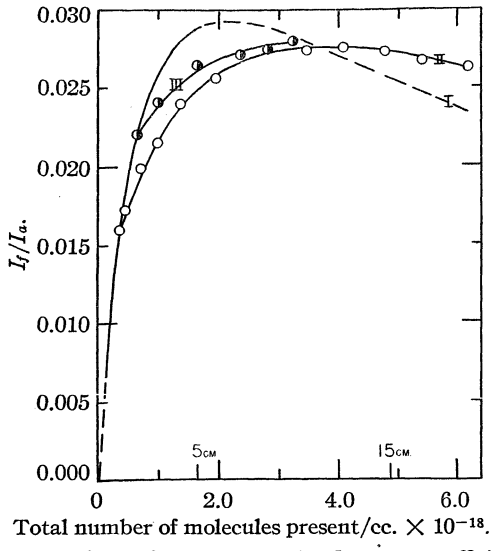

Fig. 4.—Effect of acetone on the fluorescent efficiency of biacetyl at 29°: I. No acetone was present. The broken lines are an extrapolation based on equation (24). II. Pressure of biacetyl is 11.5 mm. Pressure of acetone varies between 0 and 180 mm. III. Pressure of biacetyl is 20.0 mm. Pressure of acetone varies between 0 and 80 mm. Curves II and III are obtained from equation (22).

The addition of acetone to biacetyl increases the value of I_f/I_a but not quite to the same value that this ratio would have if the biacetyl were present alone at the same total pressure. With sufficient acetone the ratio passes through a maximum as it would probably also do if higher biacetyl pressures could have been used.

IV. Discussion

The trend of the I_f/I_a ratios with increasing pressure of biacetyl or with constant pressure of biacetyl and increasing pressure of added acetone indicates that collisions are effective, in some way, in enhancing the fluorescence. This is just the opposite of the effect one would expect from a Stern–Volmer mechanism where collisions are assumed to play only a deactivating role. This effect, whatever its cause, undoubtedly is accompanied by some collisional deactivation.

Various explanations of the data might be advanced, but most of them would rest on uncertain or completely illogical hypotheses. Thus there seems to be no *a priori* reason for believing that one vibration level of a stable upper state should have a much higher transition probability for fluorescence than other levels or at least than other adjacent levels. The spectrum of the fluorescence at various pressures and from various sources[2,3,4] indicates that transitions must occur solely or almost solely from one vibration level of the upper state, probably the lowest. Evidence presented above using color filters offers further substantiation of this point.

The most plausible explanation of the data is based on the following assumptions: (1) at 3650 Å. an upper state, B^0, is formed upon absorption which may either dissociate or undergo a transition to another state, B^1. This transition is reversible. (2) B^1 may dissociate, but the inclusion of this process is unnecessary for the explanation of the data. B^1 may, however, be transformed into a third state, B^2, by collisions. (3) B^2 may fluoresce, may be deactivated by collision, or may be converted back into B^1 by collision.

The mechanism may be stated in the equations

I_a	$B + h\nu = B^0$	(11)
$k_1(B^0)$	$B^0 =$ products	(12)
$k_2(B^0)$	$B^0 = B^1$	(13)
$k_3(B^1)$	$B^1 = B^0$	(14)
$k_4(B^1)(B)$	$B^1 + B = B^2 + B$	(15)
$k_5(B^1)(B)$	$B^1 + B = B + B$	(16)
$k_6(B^2)$	$B^2 = B + h\nu$	(17)
$k_7(B^2)(B)$	$B^2 + B = B + B$	(18)
$k_8(B^2)(B)$	$B^2 + B = B^1 + B$	(19)
$k_4'(B^1)(A)$	$B^1 + A = B^2 + A$	(20)
$k_7'(B^2)(A)$	$B^2 + A = B + A$	(21)

A represents a molecule of acetone. States B^0 and B^1 may fluoresce, but rates of fluorescent decay must be small compared to those of other reactions they undergo in this pressure range. This statement is strongly supported by the character of the spectrum. Other reactions involving acetone molecules can be shown to be unimportant. Equations (16), (18), and (21) could be replaced by other second order steps (for example, induced predissociation) which would lead to quenching.

The small amount of auto-quenching found by Almy and his co-workers[4,5,6,7] and also in this work indicates that k_5 must be small compared to k_4. The contribution of equation (19) will probably be small due to the Boltzmann factor.

With the usual assumptions regarding the steady state it is found that

$$I_a/I_f = 1/Q = \frac{k_1k_3}{k_2(k_4(B) + k_4'(A))} + \frac{(k_1 + k_2)}{k_2} + \frac{k_1k_3(k_7(B) + k_7'(A))}{k_2k_6(k_4(B) + k_4'(A))} + \frac{(k_1 + k_2)(k_7(B) + k_7'(A))}{k_2k_6} \quad (22)$$

While k_4 may vary slightly with temperature, the only constants which might be expected to vary appreciably with temperature are k_7 and k_7'.

In order to eliminate the arbitrary units used in measuring I_a and I_f, it is assumed that I_f/I_a at high pressures is 0.029 as found by Almy and co-workers.[6,7] The following empirical equation is found to fit the data between 15 and 60° for pure biacetyl

$$I_a/I_f = 15.2\cdot10^{18}/(\mathrm{B}) + 2.9 + 125\exp.(-1200/RT) + 24\cdot10^{-18}(\mathrm{B})\exp.(-1200/RT) \quad (23)$$

where (B) is in molecules per cubic centimeter. The smooth curves in Figs. 2 and 3 are obtained from equation (23) since (A) = 0.

By comparing the empirical constants of equation (23) with those in the theoretical equation (22) and converting to the more customary unit of moles per cubic centimeter we find

$$k_1/k_2 = 2 \quad (24)$$

$$k_4/k_3 = 8\cdot10^4 \text{ cc./mole} \quad (25)$$

$$k_7/k_6 = 5\cdot10^6 \exp.(-1200/RT) \text{ cc./mole} \quad (26)$$

Nothing definite can be said concerning the orders of magnitude of k_1 and k_2. Since k_1/k_2 should increase with frequency, the absence of fluorescence at 3130 and 2537 Å. is understandable. Also nothing can be said definitely concerning the magnitude of k_4 except that it might be expected to be about 10^{13}, a value found for most bimolecular reactions. If this value is assumed, k_3 is about 10^8, and the slow step in the fluorescence mechanism is equation (17). Almy and co-workers find the lifetime of the fluorescence to be about 10^{-3} second. If the responsibility for this long lifetime is placed on (17) (and this assumption cannot be further substantiated), k_6 is about 10^3. Then k_7 is found to be about $5\cdot10^9$ exp. $(-E/RT)$, leading to an effective cross section for quenching of 0.0025 Å.^{2} or to a transmission coefficient[8] of about 10^{-3}. Thus the small constant for quenching agrees with the results of Almy and co-workers at 4358 Å.

It should be pointed out that a normal rate of quenching would be obtained if k_6 were about 10^8. If the lifetime of B^2 is really as short as 10^{-8} second, the slow rate of decay of fluorescence will have to be explained by assuming that one of the states B^0 or B^1 (preferably B^1) is metastable with respect to all processes which tend to remove molecules from it.

Turning to the effect of adding acetone to the biacetyl, it is found that the results may be made to fit equation (22) if $k'_4 = 0.48\,k_4$ and $k'_7 = 0.53\,k_7$. Curves II and III in Fig. 4 are based on these values. Thus acetone is about half as effective as biacetyl either in quenching excited biacetyl to the ground state or in causing transitions from one excited state to another.

Summary

1. The proper use of the intensity of radiation absorbed for fluorescence experiments is discussed briefly.

2. Biacetyl emits no measurable fluorescence when irradiated by 3130 and 2537 Å.

3. The fluorescence of biacetyl as excited by radiation of wave length 3650 Å. has been studied as a function of pressure (4 to 50 mm.), temperature (15 to 60°), and intensity.

4. As the pressure of biacetyl increases, the quantum efficiency of fluorescence increases, indicating the apparent reverse of quenching. The fluorescence efficiency is independent of incident intensity.

5. The addition of acetone produces the same general effect of enhancing the fluorescence efficiency, although very high pressures of acetone lead to some apparent quenching.

6. The effect of temperature indicates an activation energy of about 1200 calories for the quenching process.

7. It is possible to explain the results by assuming that the state formed by absorption cannot fluoresce but is changed to other states which can fluoresce through the agency of collisions. At least three upper states seem to be involved.

The Preparation of Some Branched Chain Aliphatic Sulfonic Acids

BY SAVERIO ZUFFANTI

Introduction

Most of the work that has been done on the preparation of the anhydrous aliphatic sulfonic acids deals with the straight chain acids. Vivian and Reid[1] present data on the acids containing one to six carbon atoms in the chain, while Noller and Gordon[2] have prepared those containing nine to fourteen carbon atoms in the chain.

The present paper reports data on four branched chain aliphatic sulfonic acids: isopropyl, isobutyl, *t*-butyl and isoamyl. The method used for the preparation of these acids is different from any of those used by the above authors.

TABLE I

Alkyl halide	Used, g.	Satd. soln. of Na_2SO_3, cc.	Time of reflux, days	Yield of pure Na sulfonate, g.	% Eff.
Isopropyl bromide	118.0	250	2	129.1	92.2
Isobutyl bromide	75.6	250	4	65.8	74.6
Isoamyl bromide	36.6	250	1	40.4	95.7
t-Butyl bromide	54.9	250	7	36.4	56.8

TABLE II

	Na sulfonate used, g.	Decompn. time, hr.	Acid obtained, g.	Theo. yield, g.	% Eff.
Isopropyl	29.1	10	9.8	24.6	39.8
Isobutyl	18.7	7	9.2	16.1	57.2
Isoamyl	14.0	5	11.1	12.2	91.1
t-Butyl	20.24	14	7.2	17.5	40.1

Experimental

Preparation of the Sodium Salt of Isoamyl Sulfonic Acid.—36.6 grams of isoamyl bromide was refluxed with 250 cc. of a saturated water solution of C. P. sodium sulfite until the two layers disappeared (about one day). The resulting sodium isoamyl sulfonate was obtained from the solution by evaporating to dryness and purifying by repeated fractional crystallization from a 75% alcohol solution in water, until the salt obtained was practically free from bromide; yield 40.4 g. (95.7%).

Preparation of Anhydrous Isoamyl Sulfonic Acid.—14.01 grams of the dried (110°) and pulverized sodium salt was supended in approximately 250 cc. of absolute ether (distilled over sodium) and a current of dry hydrogen chloride introduced to decompose the sodium salt. The suspended salt changes in appearance from glossy flakes to a granular residue of sodium chloride that tends to settle quickly, thus affording a means of following the decomposition which, in this case, was complete in five hours. The residue was filtered off into a weighed sintered glass crucible and the weight of the dried residue indicated a practically quantitative decomposition. The filtrate was allowed to evaporate (at room temp.) in a vacuum desiccator, leaving a dark oily residue that was soluble in water. The last traces of hydrogen chloride and ether were removed in a drying pistol (under vacuum) using carbon tetrachloride vapors as a source of heat. The material was kept in the pistol for about four hours. In this manner the anhydrous isoamyl sulfonic acid was obtained (free from ether and chloride); yield 11.1 g. (91.0%).

Preparation of *m*-Toluidine Salts.—The *m*-toluidine salts were prepared by adding *m*-toluidine to an ether solution of the sulfonic acid. The precipitated salt was filtered off and purified by recrystallization from warm ether.

Determination of Melting Points.—The melting points of the sulfonic acids were determined by first freezing the acids in a bath of acetone and dry-ice and then allowing the bath to warm up to room temperature and noting the temperature of melting.

The tables summarize the data for the four acids reported.

The physical data obtained with these acids, together with the melting points of the *m*-toluidine salts are given in Table III.

TABLE III

IDENTIFICATION OF THE SULFONIC ACIDS

	B. p. °C.	B. p. Mm.	d^{25}_4	M. p., °C.	$n^{20}D$	% Purity by titration	S, % Calcd.	S, % Found	*m*-Toluidine salts M. p., °C.
Isopropyl	159	1.4	1.1877	−37	1.4332	99.7	25.81	25.19	109
Isobutyl	171	1.2	1.1910	−61	1.4364	99.4	23.19	22.86	123
Isoamyl	177	1.5	1.1292	− 5	1.4400	99.8	21.05	20.84	115
t-Butyl	173	1.5	1.2180	−76	1.4315	99.7	23.19	22.40	131

Summary

1. Isopropyl, isobutyl, isoamyl and *t*-butyl sulfonic acids have been prepared in the anhydrous state.

2. The boiling points, melting points, densities, indices of refraction, *m*-toluidine salts and sulfur determinations have been used to characterize the above acids.

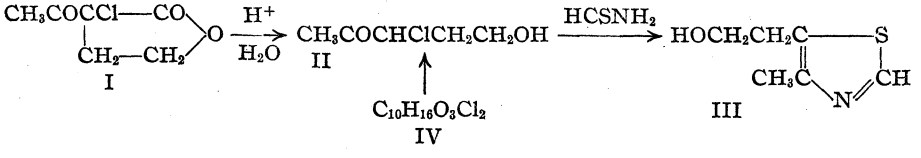
Derivatives of γ-Acetopropyl Alcohol[1]

BY JOSEPH R. STEVENS AND GUSTAV A. STEIN

While attempting to prepare pure chloroacetopropyl alcohol (II), following the Buchman[2] synthesis for 4-methyl-5-(β-hydroxyethyl)-thiazole, it was found that the principal product ultimately formed by the decarboxylation of chloroacetobutyrolactone (I) is an ether, $C_{10}H_{16}O_3Cl_2$ (IV), formed from two moles of the expected alcohol by the elimination of one mole of water.



As a result, an investigation was made to determine the structure and properties of this compound, to find out whether this ether formation is possible with γ-acetopropanol and its bromo derivative, and further to prepare chloroacetopropyl alcohol (II) and study its properties.

Discussion

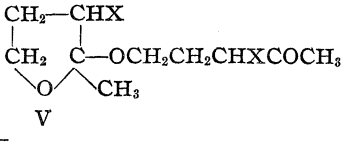
Although the ether is the principal product, chloroacetopropyl alcohol (II) is present in the reaction mixture and can be isolated from it. Chloroacetopropanol is found to be distillable at room temperature (molecular still); on mild heating, it is readily converted to its ether. By warming its *dilute* aqueous solution, the ether in turn is easily hydrolyzed to the alcohol, as demonstrated by the freezing point depression of the aqueous solution and by isolation. The ether with thioformamide hydrate yields 4-methyl-5-(β-hydroxyethyl)-thiazole (III), giving further evidence for the ease of cleavage of its ether linkage.

It is possible to distinguish between γ-chloroacetopropyl alcohol and its ether by means of their solubilities in ligroin; the former is not soluble whereas the latter is miscible. The crude reaction product (organic layer) obtained by decarboxylating chloroacetobutyrolactone (I) is miscible with ligroin, showing that the ether of chloroacetopropyl alcohol is not a secondary product formed during the purification (distillation) procedure.

Similar results are obtained in the preparation of bromoacetopropyl alcohol by bromination of γ-acetopropanol. In this case, the reaction mixture does not separate into two layers, suggesting that the product is chiefly bromoacetopropanol as it exists in the crude reaction mixture. However, when the extract is distilled at room temperature, only the ether $C_{10}H_{16}O_3Br_2$ is obtained. This ether is easily hydrolyzed to a dilute solution of bromoacetopropyl alcohol, but the extract of this solution yields only the ether. Apparently, the bromo alcohol is less stable in its free form than its chloro analog and reconverts spontaneously to its ether. From these facts one would expect the parent γ-acetopropyl alcohol to be the most stable member of this series, as was found to be the case.

γ-Acetopropyl alcohol is known in its free form and can be distilled at atmospheric pressure (b. p. 207–208°, 729 mm.). Lipp[3] observed partial dehydration of this alcohol on prolonged heating and under more severe conditions he was able to prepare an internal anhydride $(CH_3C{=}CH{-}CH_2CH_2)$ with O. In the course of this investigation, it was found that by slowly distilling γ-acetopropyl alcohol several times at 10 mm. pressure and fractionating the product, an ether between two moles of γ-acetopropanol is obtained. Small quantities of acids catalyze its formation. This substance behaves like an anhydride; it is quickly hydrolyzed with small quantities of water to γ-acetopropyl alcohol. When treated with semicarbazide in methanol, the semicarbazone of acetopropyl alcohol slowly forms.

Apparently these substances have the mixed ether structure (V) between the two recognized tautomeric forms[2] of γ-acetopropyl alcohol, the evidence for which follows

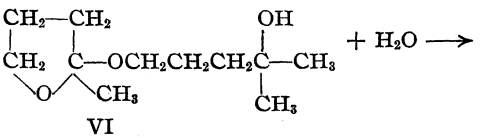


(1) This paper is No. XIX in the R. R. Williams Vitamin B1 Series (XVIII, Buchman and Richardson, THIS JOURNAL, **61**, 891–893 (1939).

(2) Buchman, *ibid.*, **58**, 1803–1805 (1936).

(3) Lipp, *Ber.*, **22**, 1196 (1889).

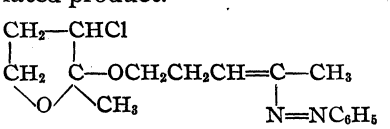
(1) The ether of acetopropyl alcohol shows no active hydrogen and one mole of Grignard reagent is consumed in a modified Zerewitinoff determination. When this reaction is carried out on a laboratory scale the reaction product is found to consist of a mixture of acetopropyl alcohol and 2-methylpentanediol-2,5, indicating the formation of an intermediate ketal (VI) which hydrolyzes



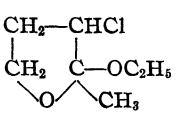
VI

$$CH_3COCH_2CH_2CH_2OH + (CH_3)_2COHCH_2CH_2CH_2OH$$

(2) The ether of chloroacetopropyl alcohol when treated with an excess of phenylhydrazine in an inert solvent gives a rapid precipitation of phenylhydrazine hydrochloride which stops when one mole has been formed, showing a marked difference between the activity of the two halogen atoms. The mother liquor yields a crystalline substance, $C_{16}H_{21}O_2N_2Cl$, corresponding to one mole each of the reactants, less a mole of water and a mole of hydrogen chloride. α-Bromoacetophenone reacts with phenylhydrazine[4] to give a similar product. By analogy chloroacetopropyl ether, if it contains a single —CO—CHCl— grouping, should yield the product (VII), which is in accordance with the composition of the isolated product.



VII



VIII

The Klingenfuss[5] ether (VIII), prepared by decarboxylating γ-chloroacetobutyrolactone in aqueous alcohol, does not react with phenylhydrazine under similar experimental conditions.

(3) Values obtained for the amount of iodine consumed in the iodoform reaction with the ether of chloroacetopropyl alcohol are about one-half as large as those for samples which have been previously heated in water in order to effect hydrolysis, indicating the presence of one free CH_3CO— group and another easily generated by hydrolysis.

The formation of the Klingenfuss ether may be considered as simple ketal formation from the cyclic tautomer of chloroacetopropanol. The presence of chloroacetopropyl alcohol during the reaction is demonstrated easily by the isolation of its ether as a principal product in the reaction mixture. In the preparation of the Klingenfuss compound (VIII), chloroacetobutyrolactone (I) may be replaced by the ether (IV).

The ether (VIII) is also easily hydrolyzed with water. When dissolved in water, in which it is soluble to a limited extent, the resulting solution gives no iodoform test. However, if the solution is brought to *p*H 3 or heated slightly and then cooled, complete hydrolysis occurs resulting in a solution which gives a strong iodoform reaction. When this solution is extracted with ether and the extract is distilled, the ether of chloroacetopropyl alcohol is obtained. From these results, it is apparent that chloroacetopropyl alcohol is the common intermediate in these reactions.

Experimental

Ether of γ-Chloro-γ-acetylpropanol.—Four hundred and ten grams of α-chloro-α-acetobutyrolactone (b. p. 74–75° at 1.5 mm.) was heated for about seven hours on the steam-bath with 410 cc. of water and 12 cc. of 38% hydrochloric acid until decarboxylation was complete.[6] On cooling, most of the ether separated as an oil, which was repeatedly extracted from the water layer with petroleum ether. After shaking the petroleum ether extracts with solid potassium carbonate, in order to render the product acid-free, the solvent was removed and the remaining oil was distilled. The cut (246 g.), b. p. 68–120° (1 mm.), on fractionation gave a product b. p. 111–112° (1 mm.); yield 200 g. (62%).

Anal. Calcd. for $C_{10}H_{16}O_3Cl_2$: C, 47.04; H, 6.32; Cl, 27.81; mol. wt., 255. Found: C, 47.13; H, 6.13; Cl, 28.07; mol. wt., 259 (dioxane).

This substance is a colorless and almost odorless liquid; it is difficultly soluble in water, easily soluble in organic solvents; d^{25} 1.2175; $n^{25}D$ 1.4748.

The ether (40 g.) when treated with thioformamide hydrate (38.5 g.) in isopropyl alcohol (17 cc.) gave 4-methyl-5-(β-hydroxyethyl)-thiazole (31.5 g.) boiling at 97.3–97.5° at 0.5 mm.; picrate m. p. (cor.) 164.5–165° (Buchnan 163°).

Anal. Calcd. for $C_{12}H_{12}O_8N_4S$: C, 38.69; H, 3.25. Found: C, 38.65; H, 3.10.

3-Chloro-3-acetylpropyl Alcohol.—When the low boiling fraction b. p. 68–75° (1 mm.) in a preparation such as that described above is collected separately and subjected to series of molecular distillations, 3×10^{-3} mm. at 20–24°, a product which is insoluble in ligroin can be isolated from the more volatile portion.

(4) Bodforss, *Ber.*, **52**, 1762, 1767 (1919); **72**, 468 (1939).

(5) Klingenfuss, U. S. Patent 2,123,653.

(6) In a private communication Dr. Buchman has suggested the use of weaker acid than that given in his original article. We have found these conditions satisfactory. Stronger acid gives more tarry products and a small amount of acetochloropropyl chloride, resulting in a contaminant in the final thiazole derivative. The principal reaction products are the same following both procedures. As judged by boiling point and chlorine analysis, Buchman apparently had fairly pure chloroacetopropyl ether which he reported as chloroacetopropyl alcohol.

Anal. Calcd. for $C_5H_9O_2Cl$: C, 43.95; H, 6.64; Cl, 25.97; mol. wt., 136.5. Found: C, 44.64; H, 6.29; Cl, 26.43; mol. wt., 146 (dioxane).

This substance is readily soluble in water. When it was redistilled at 1 mm., most of it distilled in the ether range up to 120°, with elimination of water, which was observed in a carbon dioxide trap.

Chloroacetopropyl Alcohol from its Ether by Hydrolysis.—The preparation of water solutions of this compound required warming. A minimum warming period at 60° of eighty minutes was found necessary. The solution then showed an inappreciable formation of chloride ion. The average of four determinations gave a freezing point lowering value of 1.57° per gram of added material per 10 cc. The apparent molecular weight is 119. Addition of 9 ($^1/_2$ mole of water) units to this figure, gives 128; mol. wt. chloroacetopropyl alcohol, 136.5.

Five grams of the ether was warmed at 60° for about six hours with 500 cc. of water. After allowing the mixture to stand overnight, all of the oily layer dissolved on shaking. The solution was extracted with ether, the ether solution dried and concentrated at 20°. The residual oil was distilled in a molecular still, at 27° (bath), press. 0.01 mm., d^{25} 1.210; $n^{25}D$ 1.4684.

Anal. Calcd. for $C_5H_9O_2Cl$: C, 43.95; H, 6.64. Found: C, 44.35; H, 6.48.

Ether of Bromoacetopropyl Alcohol.—Thirty-one grams of acetopropyl alcohol (b. p. 81–84° at 7 mm.) was dissolved in 150 cc. of water and 48 g. of bromine slowly added with stirring at 24–30° over a period of one and one-half hours. The aqueous layer was decanted from a small amount of oil, then treated with a little norit-charcoal. The resulting water-clear solution was extracted with ether; the ether extract after drying with sodium sulfate was concentrated at 20° under vacuum. About 55 g. of a colorless oil was obtained, part of which was distilled in a molecular still for analysis: boiling point 40° (bath) at 0.008 mm., d^{25} 1.592; $n^{25}D$ 1.4989.

Anal. Calcd. for $C_{10}H_{16}O_3Br_2$: C, 34.89; H, 4.69; mol. wt., 344. Found: C, 34.84; H, 4.56; mol. wt., 316 (dioxane).

A sample of this substance was dissolved in water and the freezing point was found to be 1.25° per g. of ether per 10 cc. of H_2O. The apparent molecular weight is 149, corrected for $^1/_2$ mole of water gives 158 as compared to 181 calculated for bromoacetopropanol. The test for Br^- ion was positive and the *p*H of the solution was 2.58. The hydrogen bromide concentration indicated by the *p*H gives rise to a 2% error in the determination.

Ether of γ-Acetopropyl Alcohol.—One hundred cc. of γ-acetopropyl alcohol, b. p. 81–84° (7 mm.), $n^{20}D$ 1.4372, containing one drop of concd. hydrochloric acid, was distilled several times. In each case the fraction of b. p. 105–115° (10 mm.) was collected. These combined cuts were fractionated and gave a product of b. p. 110–112° (10 mm.), d^{25} 0.9968; $n^{20}D$ 1.4435.

Anal. Calcd. for $C_{10}H_{18}O_3$: C, 64.59; H, 9.75; mol. wt., 186. Found: C, 64.28; H, 9.79; mol. wt., 182 (dioxane).

This substance dissolves readily in cold water; freezing point depression 1.98° per gram per 10 cc.; apparent molecular weight corrected for $^1/_2$ mole of water (+9) is 103; calculated for acetopropyl alcohol 102.

Two millimoles of semicarbazide hydrochloride was dissolved in 0.5 cc. of cold methanol, 2 millimoles of potassium acetate added and the potassium chloride centrifuged off. To the filtrate was added 1 millimole of ether of acetopropyl alcohol and the mixture allowed to stand at room temperature. The crystals that separated after a few hours had m. p. 157°. A mixed m. p. with the semicarbazone of γ-acetopropanol gave no depression.

2-Methyl-2-ethoxy-3-chlorotetrahydrofuran.—One hundred grams of chloroacetobutyrolactone, 120 g. of 80% ethyl alcohol and 36 g. of concd. sulfuric acid were stirred together and maintained at 40–50° until the evolution of carbon dioxide had ceased, which required about seven hours. After cooling, water and ether were added and the aqueous layer extracted several times with ether. The combined ether extracts were washed with a little cold water, neutralized with sodium carbonate solution and dried over calcium chloride. The ethereal solution was then distilled. The lower cuts, 50–70° at 13 mm., yielded on further fractionation about 30 g. of 2-methyl-2-ethoxy-3-chlorotetrahydrofuran (30%).

Anal. Calcd. for $C_7H_{13}O_2Cl$: C, 51.04; H, 7.97. Found: C, 51.22; H, 7.91.

The higher boiling cuts (70–120° at 1 mm.) gave about 28 g. of the pure ether of chloroacetopropyl alcohol.

Anal. Calcd. for $C_{10}H_{16}O_3Cl_2$: C, 47.04; H, 6.32. Found: C, 47.01; H, 6.12.

2-Methyl-2-ethoxy-3-chlorotetrahydrofuran from Ether of Chloroacetopropyl Alcohol.—To a cold mixture of 18 g. of sulfuric acid and 80 g. of 80% ethyl alcohol was slowly added 50 g. of chloroacetopropyl ether with cooling; the mixture was warmed at 40–50° for about seven hours and worked up as described above; yield 33 g.

Anal. Calcd. for $C_7H_{13}O_2Cl$: C, 51.04; H, 7.97. Found: C, 50.87; H, 7.77.

Ether of Chloroacetopropyl Alcohol from 2-Methyl-2-ethoxy-3-chlorotetrahydrofuran.—Twelve and one-half grams of 2-methyl-2-ethoxy-3-chlorotetrahydrofuran was shaken at room temperature with 100 cc. of water which was previously acidified with hydrochloric acid to a *p*H of 3. After a few minutes of shaking, all the oil had dissolved, and after thirty minutes the characteristic camphor-like odor of the compound had disappeared completely. At the end of one hour the solution was extracted several times with ether, etc.; the extracts yielded 5.4 g. of product, b. p. 111–112°.

Anal. Calcd. for $C_{10}H_{16}O_3Cl_2$: C, 47.04; H, 6.32. Found: C, 46.41; H, 6.36.

Reaction of Methylmagnesium Iodide on the Ether of γ-Acetopropanol.—A modified Zerewitinoff[7] analysis showed 0.24 equivalent of active hydrogen and 1.16 equivalents of reagent consumed.

Forty-three grams of the ether of γ-acetopropyl alcohol was treated with the Grignard reagent made from 66 g. of methyl iodide in the usual manner. After decomposition the aqueous layer was extracted exhaustively with ether.

(7) We are indebted to Dr. Richard Cramer of Harvard University for this determination.

The oil (39 g.) was found to be a mixture. A portion on treatment with semicarbazide gave the γ-acetopropyl alcohol semicarbazone, m. p. 157°, mixed m. p. no depression. This crude oil contained another substance in about equal amounts which was separated by extracting all of the acetopropyl alcohol with ligroin and distilling the residue; b. p. 77.5° (0.1 mm.), atmospheric pressure 218–219°. The recorded[8] boiling point of 2-methyl-2,5-dihydroxypentane is 218–219°. When heated with 10% sulfuric acid the characteristic camphor odor of 2,2-dimethyltetrahydrofuran[9] was observed.

Anal. Calcd. for $C_6H_{14}O_2$: C, 60.96; H, 11.95. Found: C, 61.07; H, 11.89.

Ether of Chloroacetopropanol and Phenylhydrazine.—A solution of 2.55 g. (0.01 mole) of the freshly distilled ether of chloroacetopropyl alcohol in about 80 cc. of absolute ethyl ether was chilled in ice; a cold solution of 2.16 g. (0.02 mole) of freshly distilled phenylhydrazine in about 20 cc. of absolute ether was added with shaking. After a few minutes the mixture became yellow and phenylhydrazine hydrochloride began to separate. After a few hours, all the phenylhydrazine hydrochloride had separated. This was filtered off, washed with ether and dried; yield 1.420 g. (0.98 mole) of phenylhydrazine hydrochloride, m. p. 240°; calcd. for 1 mole, 1.445 g. The reddish ether solution was washed with cold water until no chloride could be detected in the wash water; it was dried with calcium chloride and the ether was evaporated at room temperature, using high vacuum at the end of the concentration, in order to remove traces of ether. The remaining red viscous oil (about 3 g.) was dissolved in a minimum amount of isopropyl alcohol, and the solution chilled in a freezing mixture. The oil which separated soon crystallized. After centrifuging there remained a half oily, half crystalline mass which was recrystallized several times from warm isopropyl alcohol. The light yellow crystals thus obtained were dried in a high vacuum at room temperature; m. p. 85° (unsharp due to decomposition).

Anal. Calcd. for $C_{16}H_{21}O_2N_2Cl$: C, 62.21; H, 6.86; N, 9.07. Found: C, 62.20; H, 7.02; N, 9.19.

Titration Results with Iodine (Iodoform).—The samples for titration were dissolved in cold water (about 100 mg./100 cc.) with shaking. About 30 cc. of *N* potassium hydroxide was added, followed immediately with 70 cc. of 0.2 *N* iodine solution. The mixture was allowed to stand for fifteen minutes at room temperature. It was acidified with 40 cc. of 2.5 *N* hydrochloric acid and the free iodine titrated.

A. Ether of 3-Chloro-3-acetopropanol.—(1). Freshly prepared solution: iodine consumed 6.04 atoms; (2) after twelve hours, 7.7 atoms; (3) when the aqueous solution is heated for thirty-five minutes on a steam-bath, cooled, and treated with iodine, etc., 9.9 atoms were consumed.

The amount of iodoform which can be isolated from these mixtures is less than that calculated from the iodine consumed; apparently some of the iodination occurs on the 3 carbon atoms, complicating the reaction. The relative values are considered significant.

B. 2-Ethoxy-2-methyl-3-chlorotetrahydrofuran.—The cold aqueous solution shows no iodine consumed and no iodoform reaction. When it is heated at 100° for thirty-five minutes, cooled and assayed, 4.8 atoms of iodine are consumed. When the solution is kept at *p*H 3 for thirty minutes, neutralized and assayed, 5.3 atoms are consumed. A blank containing an equivalent of ethanol gave a negative result in this determination.

Acknowledgment.—The authors are grateful to Dr. Randolph T. Major, Dr. R. R. Williams, and Dr. E. R. Buchman for their many helpful suggestions. Mr. E. M. Chamberlin, Mr. M. Freiman and Mr. T. Perrine assisted with the experimental work. The physical measurements were made by Mr. W. A. Bastedo and the microanalyses by Mr. D. Hayman and Mr. W. Reiss.

Summary

γ-Acetopropanol is shown to be converted readily into its ether by repeated distillation. The ether readily is hydrolyzed back to the alcohol.

γ-Chloro and γ-bromoacetopropanols and their corresponding ethers are spontaneously interconvertible in water solution.

All three ethers contain one tetrahydrofuran ring, the other molecule of the propanol being in straight chain form.

2-Alkoxy-2-methyl-3-chlorotetrahydrofuran is similarly labile, being converted by mild hydrolysis to chloroacetopropanol and in turn to its ether. The reverse action proceeds in aqueous alcohol.

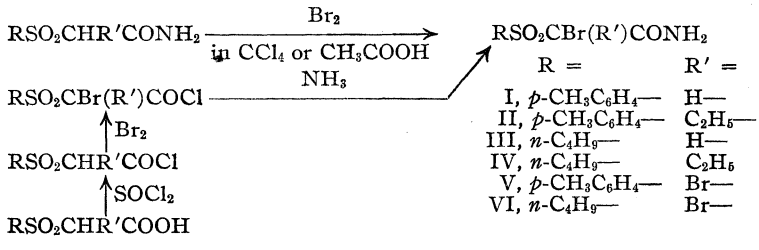
α-Bromo-α-sulfonylamides[1]

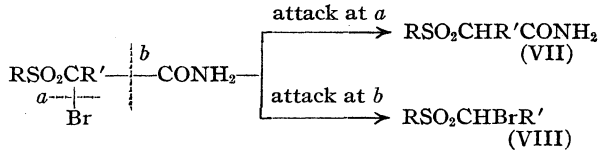
BY WILLIAM M. ZIEGLER[2] AND RALPH CONNOR

This study of α-bromo-α-sulfonylamides was undertaken for the purpose of comparing their reactions with those of the bromo derivatives of other active methylene compounds. While some reactions of the latter resemble the reactions of hypohalites ("positive halogen"[3]) rather than of halides, the ability of the sulfone group to produce this type of activation has heretofore received little attention.[4] No α-bromo-α-sulfonylamides appeared to have been prepared previously and it was first necessary to devise methods for their synthesis. Since the α-bromo-α-sulfonylamides were found to have properties identical with those of the compounds previously reported to be the isomeric N-bromoamides, the establishment of their structure constitutes a third phase of this report.

Preparation of α-Bromo-α-sulfonylamides.—Two of the α-bromo-α-sulfonylamides (I and IV) were prepared by converting α-sulfonyl acids to acid chlorides, bromination and treatment with ammonia. The method was laborious and the yields low. Much better results were obtained by treating α-sulfonylamides with bromine in moist[6] carbon tetrachloride and all of the α-sulfonylamides tested reacted readily under these conditions. Glacial acetic acid was satisfactory as a solvent for the preparation of I and III but the α-sulfonyl-*n*-butyramides were not brominated in this solvent.



Reactions of α-Bromo-α-sulfonylamides.—The reactions of these compounds were of two types. One resulted in the oxidation of the reagent and reduction of the α-bromoamide, showing the positive character of the halogen. The other type resulted in the cleavage of the —$CONH_2$ group. The predominant reaction depended both upon the reagent and upon the structure of the α-bromo-α-sulfonylamide. For example, sodium ethoxide gave the reduction product (VII) from IV but caused elimination of the —$CONH_2$ group from I to give the α-bromosulfone (VIII). Furthermore, II was not hydrolyzed under conditions which converted I to the α-bromosulfone[7] (VIII) and which resulted in attack at both the —Br and —$CONH_2$ groups of IV.



Two of the results reported in Table I are of especial importance. The liberation of two equivalents of iodine by the dibromo amides with potassium iodide in acid solution is contradictory to the report of Tröger and Hille that only one halogen atom of the dibromo amides underwent this reaction. It is also interesting to note that the time for complete reaction of the dibromo compounds with hydrazine was less than that for the corresponding monobromo compounds. It may therefore be inferred that this reaction is not stepwise and that the monobromo derivatives

(1) This communication is constructed from a thesis submitted by William M. Ziegler in partial fulfillment of the requirements for the degree of Doctor of Philosophy at the University of Pennsylvania in June, 1939.

(2) Harrison Fellow in Chemistry, 1938–1939.

(3) Waters, "Physical Aspects of Organic Chemistry," 2nd ed., George Routledge and Sons, London, 1937, p. 221.

(4) The results of Tröger and Hille[5] indicated that α-bromo-α-sulfonylamides do not contain positive halogen. Since our problem was begun, Samen [*Arkiv Kemi, Mineral. Geol.*, **12B**, No. 51 (1938); *Chem. Abs.*, **32**, 4520 (1938)] reported that triethylsulfonylmethyl bromide was reduced to triethylsulfonylmethane by treatment with hydrazine or hydriodic acid, and Mellander [*ibid.*, **12A**, No. 16, 32 (1937); *Chem. Abs.*, **31**, 5763 (1937)] found that α-bromo-α-sulfonyl acids were reduced by hydrazine.

(5) Tröger and Hille, *J. prakt. Chem.*, [2] **71**, 201 (1905).

(6) Water alone could not be used as a reaction medium, probably because of the insolubility of the α-sulfonylamides. Bromination occurred more slowly or not at all in dry carbon tetrachloride, suggesting that the reaction is similar to the basic catalysis in the bromination of ethyl acetoacetate [Pederson, *J. Phys. Chem.*, **38**, 601 (1934)]. However, aqueous sodium hypobromite was a less favorable reagent for halogenation of α-sulfonylamides than was bromine in moist carbon tetrachloride.

(7) The result of this hydrolysis was unexpected. According to Mossler [*Monatsh.*, **29**, 73 (1908)] α-bromoamides give aldehydes upon alkaline hydrolysis. A N-bromoamide would be expected to give an amine.[8]

are not intermediates in the reduction of the dibromo amides with hydrazine.

The reactions of the α-bromo-α-sulfonylamides with hydrazine, hydriodic acid, piperidine and mercaptides gave VII accompanied by nitrogen, iodine, piperidine hydrobromide and disulfide, respectively. Since similar results have been obtained with the bromo derivatives of active methylene compounds, it may be concluded that the sulfone group exerts upon halogen in the *alpha* position an effect similar to that of other labilizing groups.

Structure of the Bromoamides.—There seemed no reasonable doubt that the syntheses involving bromination of the acid chlorides would give α-bromo-α-sulfonylamides. However, I, prepared by this method, was identical with the product obtained by bromination of the α-sulfonylamide in glacial acetic acid by the procedure of Tröger and Hille[5] and reported by those workers to be a N-bromoamide (IX). Furthermore, IV prepared from the α-bromoacid chloride was identical with the products obtained by the method of Tröger and Hille and by bromination of the α-sulfonylamide in moist carbon tetrachloride. There seems to be little doubt, therefore, that the compounds assigned structures IX and X by Tröger and Hille are actually I and V.

$$p\text{-}CH_3C_6H_4SO_2CH_2CONHBr$$
IX

$$p\text{-}CH_3C_6H_4SO_2CHBrCONHBr$$
X

Attempts further to confirm the structures by synthesis of the isomeric N-bromoamides by bromination in the presence of alkali were unsuccessful because of the failure of the amides to react or the formation of dibromosulfones. The α-bromo-α-sulfonylamides did not react with nitrous acid and their conversion to α-bromo acids was therefore unsuccessful.

It should be pointed out that the arguments of Tröger and Hille for a N-bromo structure for these compounds were based largely upon the statement that the dibromoamides reacted with only one equivalent of iodide, a statement now shown to be incorrect. If further evidence for the attachment of bromine to carbon is necessary it may be gained from the following. (a) The compounds are stable toward boiling water.[8] (b) The difference in the ease of bromination of the acetamides and butyramides would not be expected to be so great if it depended upon the influence of an *alpha* ethyl group upon the reactivity of —$CONH_2$. (c) The conversion of I to an α-bromosulfone (VIII) by hydrolysis further establishes the position of the halogen.[9]

(8) Hofmann [*Ber.*, **15**, 411 (1882)] reported that N-bromoamides are decomposed by boiling water.

Experimental Part[10]

Reactions of α-Sulfonylamides[11] with Sodium Hypobromite.—To 21.4 g. of α-*p*-tolylsulfonylacetamide[12] was added 5.4 ml. (16 g.) of bromine, and the mixture shaken until about three-fourths of the amide had dissolved. The mixture was cooled in an ice-bath at −15° and a cold solution of 50% sodium hydroxide added dropwise with stirring until 10% more than the theoretical amount required to react with the bromine had been used. After standing in the ice-bath for one hour, cold water was added, the product removed by filtration and recrystallized from alcohol. The yield of *p*-tolylsulfonyldibromomethane, m. p. 116–117°,[9] was 2.9 g. (18% based on the bromine).

In another experiment 10.3 g. of α-*n*-butylsulfonyl-*n*-butyramide was mixed with 5.4 ml. (16 g.) of bromine and treated as described above. Unchanged starting material was the only product isolated.

Preparation of α-Bromoamides from Acid Chlorides

α-Bromo-α-*p*-tolylsulfonylacetamide (I).—To 21.4 g. of *p*-tolylsulfonylacetic acid[13] in 75 ml. of carbon tetrachloride, 13 g. of thionyl chloride in 25 ml. of carbon tetrachloride was added slowly. After refluxing for one hour and cooling, 6 ml. (18 g.) of bromine was added and the mixture then refluxed for ten hours, cooled, and poured into excess concentrated ammonia water at −15°. The lump that formed on stirring was removed and extracted several times with the same 200 ml. of water, cooling and removing the crystals between extractions. The crystals thus removed were recrystallized from water with the aid of charcoal. The yield was 2.40 g. (8%), m. p. 172–174°.

Anal. Calcd. for $C_9H_{10}O_3NSBr$: Br, 27.3. Found: Br, 27.2, 27.5.

α-Bromo-α-*n*-butylsulfonyl-*n*-butyramide (IV).—From 136.5 g. of ethyl α-bromo-*n*-butyrate and the mercaptide from 54.6 g. of *n*-butyl mercaptan under the conditions previously used for the preparation of the amides,[11] there was obtained 105 g. (74%) of crude ethyl α-*n*-butylthio-*n*-butyrate which was oxidized[11] in acetic acid–acetic anhydride mixture to the α-sulfonyl ester. The ester could not be crystallized and decomposed upon attempted dis-

(9) The formation of VIII might be considered possible from a N-bromoamide by hydrolysis of the latter to sodium hypobromite, followed by the action of the hypobromite upon the other hydrolysis products. This explanation of the hydrolysis result was eliminated by showing that none of the hydroylsis products were converted to VIII by sodium hypobromite.

(10) All melting points are corrected unless otherwise specified.

(11) The α-sulfonylamides were prepared by the methods described by d'Ouville and Connor, THIS JOURNAL, **60**, 33 (1938), and Pomerantz and Connor, *ibid.*, **61**, 3386 (1939).

(12) Similar results were obtained when sodium *p*-tolylsulfonylacetate was used but methyl *p*-tolyl sulfone did not react under these conditions.

(13) Gabriel, *Ber.*, **14**, 833 (1881).

tillation. The crude material was hydrolyzed with 400 ml. of 8% sodium hydroxide solution, acidified and extracted with ether. The acid obtained (93.6 g.) was converted to the acid chloride under the conditions described above, refluxed with bromine (71 g.) for twenty-five hours and treated with an excess of dry ammonia. The solvent was decanted, the residue extracted with alcohol and the alcohol solution treated with decolorizing charcoal. Removal of the solvent gave an oil which was crystallized with considerable difficulty. The solid was recrystallized several times from ether, seeding each time. The yield was 10.75 g. (6% based on the mercaptan), m. p. 56–57°. This was slightly less pure than the material obtained as described below.

Anal. Calcd. for $C_8H_{16}O_3NSBr$: Br, 27.9. Found: Br, 27.1, 27.2.

Preparation of α-Bromo-α-sulfonylamides from α-Sulfonylamides.—Five hundredths mole of the amide[11] was mixed with 100 ml. of carbon tetrachloride and 2.66 ml. (8 g.) of bromine added. With the acetamides the moisture present in unpurified carbon tetrachloride was adequate but the bromination of the butyramide was accomplished more readily by the addition of 2 ml. of water. After refluxing until the bromine color had disappeared, the solvent was removed quickly and the oil recrystallized. Slow removal of the solvent resulted in hydrolysis. A prolonged reaction period in the presence of excess water gave the dibromosulfonylmethane as shown below under the preparation of I.

α-Bromo-α-*p*-tolylsulfonylacetamide (I).—The mixture, without additional water, was refluxed for one hour and the solvent removed over a period of twenty minutes. The oil was dissolved in alcohol and allowed to crystallize. The solid was recrystallized from alcohol. From 10.7 g. of the amide there was obtained 6 g. (42%) of the product, m. p. 172–174°. The same product (51%) was obtained by the method of Tröger and Hille.[5] Neither sample lowered the melting point of the amide prepared from the α-bromo-α-sulfonyl acid chloride.

Anal. Calcd. for $C_9H_{10}O_3NSBr$: Br, 27.3; N, 4.80. Found: Br, 27.4, 27.6; N, 4.85, 4.80.

Ten and seven-tenths grams of α-*p*-tolylsulfonylacetamide in 100 ml. of carbon tetrachloride and 4 ml. of water was treated with 2.66 ml. (8 g.) of bromine and refluxed for one-half hour. The solution was then poured into a beaker and evaporated on a water-bath over a period of four hours. The sirup was dissolved in ether and filtered, the ether was then evaporated and the oil well chilled. After several hours chilling the paste that formed was mixed with enough very cold ether to dissolve the oily impurities and the material was filtered. The crystals were recrystallized from ligroin (b. p. 70–90°) and then from alcohol. The yield was 2.3 g. (28% based on the bromine) of product melting 116–117°, reported by Tröger and Hille[5] to be the melting point of *p*-tolylsulfonyldibromomethane.

α-Bromo-α-*p*-tolylsulfonyl-*n*-butyramide (II).—Two milliliters of water was added and the mixture refluxed for two and one-half hours. Half the solvent was removed and the material chilled. The product was recrystallized four times as follows: it was dissolved in a hot mixture of 75% carbon tetrachloride–25% ether, cooled and filtered. Then it was dissolved *immediately* in ether; failure to do so resulted in a product insoluble in ether. Just as solution was complete the product precipitated. It was removed by filtration and the process repeated. Twelve grams of amide gave 6.8 g. (43%) of product, m. p. 115–116°.

Anal. Calcd. for $C_{11}H_{14}O_3NSBr$: Br, 25.0; N, 4.38. Found: Br, 25.3, 25.0; N, 4.45, 4.44.

α-Bromo-α-*n*-butylsulfonylacetamide (III).—The mixture, without additional water, was heated for three-fourths hour and the solvent removed in twenty minutes. The oil was dissolved in alcohol, cooled and the product recrystallized once from benzene and twice from water. Nine grams of amide gave 5.75 g. (44%) of product, m. p. 130–131°. The procedure of Tröger and Hille[5] gave a 31% yield of the same material.

Anal. Calcd. for $C_6H_{12}O_3NSBr$: Br, 31.1; N, 5.45. Found: Br, 31.1, 31.0; N, 5.46, 5.50.

α-Bromo-α-*n*-butylsulfonyl-*n*-butyramide (IV).—The mixture with 2 ml. of water was refluxed for two hours and the solvent removed in twenty minutes. The oil was cooled and a seed crystal added. Seeding was also necessary in recrystallizing the product from ether. To obtain a seed crystal, a little of the oil was dissolved in ether and ligroin added to turbidity, then cleared with ether. The solution was allowed to stand open for three days, when the oil which first precipitated was crystallized. From 10.3 g. of the amide, 8.3 g. (58%) of product, m. p. 57–58°, was obtained. A mixed melting point with the product from the acid chloride was 56–58°.

Anal. Calcd. for $C_8H_{16}O_3NSBr$: Br, 27.9; N, 4.89. Found: Br, 27.7, 27.8; N, 4.74, 4.75.

α,α-Dibromo-α-*p*-tolylsulfonylacetamide (V).—The mixture without water but with 5.3 ml. of bromine was heated for two and one-half hours and the solvent removed in twenty minutes. The oil was taken up in alcohol and crystallized by cooling. It was then recrystallized from alcohol. The product from 10.7 g. of amide was 2.1 g. (11%), m. p. 134–135°.

Anal. Calcd. for $C_9H_9O_3NSBr_2$: Br, 43.1; N, 3.77. Found: Br, 43.3, 43.3; N, 3.65, 3.68.

α,α-Dibromo-α-*n*-butylsulfonylacetamide (VI).—This was obtained as a by-product in the preparation of III by the method of Tröger and Hille as mentioned above. The reaction mixture from 9 g. of α-*n*-butylsulfonylacetamide in 35 ml. of glacial acetic acid with 8 g. of bromine for one hour at room temperature was poured onto cracked ice and the III removed by filtration. The filtrate, after standing for three hours, gave a precipitate of VI which was recrystallized from dilute alcohol. The yield of VI was 1.8 g. (19%), m. p. 106–107°.

Anal. Calcd. for $C_6H_{11}O_3NSBr_2$: Br, 47.6; N, 4.17. Found: Br, 47.4, 47.6; N, 4.25.

Reactions of α-Bromo-α-sulfonylamides

With Sodium *n*-Butyl Mercaptide.—Four-tenths gram of sodium was dissolved in 30 ml. of absolute alcohol, and 1.7 ml. of *n*-butyl mercaptan added. This was cooled in a salt–ice-bath and a suspension prepared by dissolving 5.4 g. of II in 10 ml. of absolute alcohol and chilling, was added. The mixture was allowed to come to room temperature as the bath melted and then stand for five days.

The alcohol was evaporated to a small volume and the product poured onto chipped ice. The crystalline material was removed by filtration and recrystallized from water. The product was 2.45 g. (60%) of α-*p*-tolylsulfonyl-*n*-butyramide, m. p. 170–171°.

With Sodium *n*-Thiocresolate.—To 0.23 g. of sodium in 25 ml. of absolute alcohol was added 1.25 g. of *p*-thiocresol, then 2.85 g. (0.01 mole) of IV. The mixture was allowed to stand for five days and was then evaporated under reduced pressure until crystals separated. The residue was poured onto cracked ice, the product removed by filtration and recrystallized from alcohol. The product, 1 g. (80%), m. p. 45–46°, was ditolyldisulfide. Evaporation of the alcoholic and aqueous mother liquors gave, on recrystallization from water, 1.5 g. (73%) of α-*n*-butylsulfonyl-*n*-butyramide.[14]

This experiment was repeated using dioxane as a solvent and preparing the thiocresolate by the reaction of powdered sodium with *p*-thiocresol. There were isolated 0.75 g. (60%) of ditolyldisulfide, 0.72 g. (35%) of α-*n*-butylsulfonyl-*n*-butyramide and an oil from which nothing could be separated.

With Hydriodic Acid and with Hydrazine.—See Table I.

With Piperidine.—Six milliliters of piperidine dissolved in 10 ml. of dry dioxane was added to 6.25 g. of I dissolved in 40 ml. of dry dioxane and the mixture refluxed for seven hours. The crystalline precipitate was removed by filtration and washed with a little dioxane. The filtrate was evaporated to a smaller volume, removing both dioxane and piperidine, cooled and again filtered. The residue was washed with a little dioxane and added to the first one. The yield was 2.15 g. (60%) of piperidine hydrobromide,[15] m. p. 233–235°. Further evaporation of the filtrate resulted, on cooling and filtering, in a 2 g. (45%) yield of α-*p*-tolylsulfonylacetamide, m. p. 166–167°. Evaporation of this filtrate resulted in an oil from which nothing separated.

With Sodium Ethoxide.—To 50 ml. of absolute alcohol was added 0.23 g. of sodium. After the reaction was completed, the solution was cooled and 2.92 g. (0.01 mole) of I was added. The mixture was allowed to stand for two days at room temperature. Most of the alcohol was removed by distillation and a volume of water equal to the residue was added. On cooling and filtering 2.10 g. (84%) of *p*-tolylsulfonylmethyl bromide, m. p. 87–88°, was obtained. The identity of this compound was established by a mixed melting point with a sample prepared by a method to be described in a later paper.

To 25 ml. of absolute alcohol was added 0.23 g. of sodium. After the reaction was completed, the solution was cooled and 2.86 g. of IV was added. This was allowed to stand for four days, then most of the alcohol was evaporated, the residue poured into water and the mixture chilled. The resulting paste was recrystallized from alcohol and then water and gave 1.25 g. (61%) of α-*n*-butylsulfonyl-*n*-butyramide, m. p. 120–122°. The filtrates on evaporation gave a small quantity of oil.

(14) These reactions are comparable to the formation of di-*p*-tolyldisulfide and tribenzoylmethane from the sodium salt of *p*-thiocresol and tribenzoylmethyl chloride as reported by Kohler and Potter, THIS JOURNAL, **58**, 2168 (1936).

(15) Similar dehalogenations have been observed frequently; for example, Cope, *ibid.*, **54**, 1250 (1932).

TABLE I

REACTIONS OF α-BROMO-α-SULFONYLAMIDES

Amide	With HI,[a] % Br Calcd.	Found	With H_2NNH_2[b] N_2 (ml.) Calcd.	Found	Reaction time (hr.)	IX isolated %
I	27.4	28.2	44.8	45.0	5	82
II	25.0	24.3	39.5	39.0	4	87
III	31.1	32.2	47.5	46.5	2	80
IV	27.9	27.6	40.8	31.0	6	82
V	43.1	38.6	29.5[c]	30.0	1	83
VI	47.6	47.0	32.6[d]	33.0	1	47[d]

[a] Ten drops of 16 *N* sulfuric acid and 2 ml. of saturated potassium iodide solution were added to a solution of about 0.1 g. of the α-bromoamide in 15 ml. of glacial acetic acid. The flasks were stoppered and allowed to stand for thirty minutes with occasional shaking. The mixture was then titrated with 0.1 *N* sodium thiosulfate solution, using the disappearance of iodine color as an end-point and confirming by the addition of 0.5 ml. of 1% starch solution. Blanks were run in all experiments and, since they amounted to 10–15% of the total readings, the results reported are not considered to be quantitative. The data do show, however, that at least 90–95% of the total bromine in the compounds is able to oxidize hydriodic acid and that the observations of Tröger and Hille on the dibromo-*p*-tolylsulfonylacetamide were in error. [b] Except as otherwise indicated, about 1.00 g. of the α-sulfonyl-α-bromoamide was added to 15 ml. of water in a 50-cc. flask and a small tube containing 3.0 ml. of 10% hydrazine hydrate solution placed upright in the flask. This was then put in a water-bath at 75 ± 2°, allowed to come to this temperature, connected to a gas measuring apparatus, and the contents mixed. The mixture was kept at 75° and shaken occasionally until the evolution of nitrogen ceased. The contents of the flask were concentrated, chilled and the α-sulfonylamide removed by filtration, dried and weighed. [c] The sample weighed 0.45 g. [d] The sample weighed 0.50 g. The low recovery may be attributed to the difficulty of isolation of a rather small amount of a fairly soluble product.

With Nitrous Acid.[16]—To 5.4 g. of I dissolved in 50 ml. of alcohol–acetic acid (1:4) and kept cool, 2.6 cc. of *n*-butyl nitrite was added. The mixture was allowed to stand for twenty-four hours. Then hydrochloric acid was added and the mixture again allowed to stand for twenty-four hours; 80% of the bromoamide was recovered.

Addition of a solution of sodium nitrite to a solution of the bromoamide in acetic acid in the cold gave a 70% recovery. When the mixture was heated to 60° after one hour of standing the recovery was 85%.

Hydrolysis.—Two grams of I was sprinkled into 80 ml. of boiling 5% sodium hydroxide solution and the mixture boiled for two and one-half minutes. The material was chilled and filtered. The product was recrystallized from alcohol and yielded 0.78 g. (45%) of material melting at 89–90°. A mixed melting point with a sample of *p*-tolylsulfonylbromomethane (m. p. 90–91°) was 89–91°. This hydrolysis was carried out on the bromoamide pre-

(16) These experiments were carried out in an attempt to convert the amides to α-bromoacids as additional confirmation of their structure.

pared from the bromoacid chloride as well as that from the bromination of the amide in carbon tetrachloride. No trace of the α-sulfonyl acid was observed when the filtrate from the reaction mixture was acidified. Addition of silver nitrate solution gave silver bromide, indicating some hydrolysis of the halide.

Into 50 ml. of boiling 5% sodium hydroxide solution was sprinkled 2.86 g. of IV. The mixture was boiled about five minutes until only a faint test for ammonia was obtained. It was then chilled, acidified with nitric acid and extracted with ether. The aqueous portion gave a heavy precipitate with silver nitrate, indicating a large removal of bromine. The ether extracts were evaporated and gave a small quantity of oil that did not solidify at −15°. The amount of oil was less than 1 ml.

Two grams of II was sprinkled into 50 ml. of boiling 5% sodium hydroxide solution. The material formed opaque globules and only traces of ammonia were evolved. The mixture was refluxed for five minutes, chilled and filtered. The entire residue was unchanged amide.

Summary

Compounds reported to be N-bromo-α-sulfonylamides by Tröger and Hille have been shown to be α-bromo-α-sulfonylamides. The most satisfactory method of preparation of α-bromo-α-sulfonylamides was by direct bromination of α-sulfonylamides in moist carbon tetrachloride. Members of this series were also prepared by direct bromination of the amides in glacial acetic acid and by bromination of α-sulfonyl acid chlorides, followed by reaction with ammonia. The reactions of α-bromo-α-sulfonylamides showed that the sulfone group was similar to other labilizing groups in causing hypohalite characteristics in α-halo derivatives.

The Polyhydric Alcohol–Polybasic Acid Reaction. V. The Glyceryl Succinate and Glyceryl Maleate Polyesters

BY R. H. KIENLE AND F. E. PETKE

Although the glycol succinate reaction has been studied in some detail, no quantitative data have been published for the glyceryl succinate and the glyceryl maleate polymerization reactions. Glyceryl succinate was first prepared by Van Bemmelen.[1] It has been referred to frequently in resin literature[2] but the only published quantitative data on the polyester seem to be those of Hönel.[3] No such data appear to have been published for glyceryl maleate. In the present investigation, data are presented for the formation of these polyesters, succinic acid and succinic anhydride being used to prepare glyceryl succinate, and maleic anhydride to prepare glyceryl maleate.

The apparatus and technique used have already been fully described.[4] The purification and chemical constants of the glycerol employed similarly have been given. The maleic anhydride used was American Cyanamid Company chemically pure material, redistilled. The succinic acid and succinic anhydride were the chemically pure grade of Selden Division, American Cyanamid Company. The glycerol–succinic acid reaction was carried out at 190° in order that the data might be comparable with the recently published glyceryl phthalate (acid) investigation. The glycerol–maleic anhydride and glycerol–succinic anhydride reactions were carried out at 160°, since the reactions proceeded too rapidly at 190°.

Experimental Data

The detailed data obtained for the glycerol–maleic anhydride, glycerol–succinic anhydride, and glycerol–succinic acid reactions are listed in Figs. 1, 2 and 3, respectively.

Figure 4 gives the acid value–water evolved relationship for all three reactions. When the theoretical acid value–water evolved curves are inserted in this plot, assuming only interesterification has occurred, it is found, in the case of glyceryl maleate, that the water evolved experimentally was at all times greater than theory, while in the case of both the glyceryl succinate reactions, the water evolved was at all times less than the theoretical. The equation for determining this theoretical relationship is

$$A_t = \frac{56.1(V_f - V_t)}{18(W - V_t)}$$

where A_t is the acid value at time t, V_t the water evolved at time t, V_f the total water evolved at 100% esterification, and W the total weight of reactants used. This equation is the exact form of an approximate equation used in the previous papers of this series.

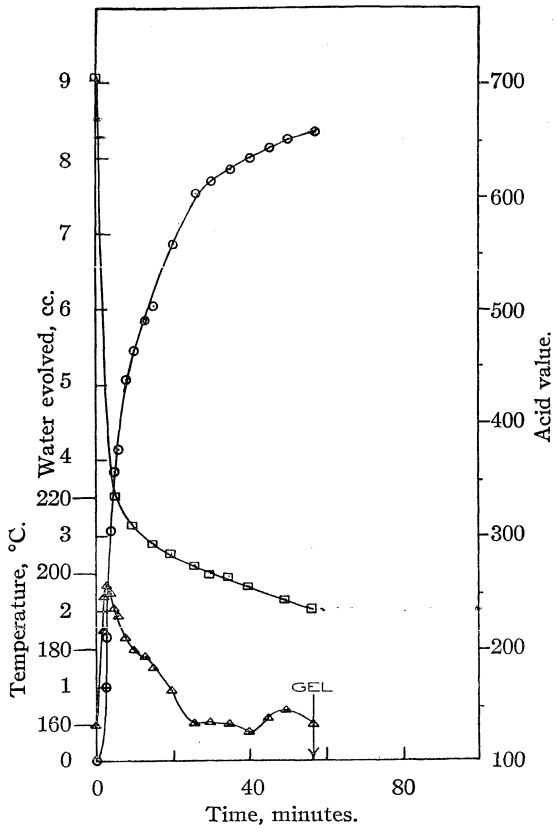

Fig. 1.—Reaction data. Glyceryl maleate: proportions, glycerol 69.0 g., maleic anhydride 110.3 g., temperature of mixing 160°, △, temperature, ⊡, acid value, ⊙, water evolved.

The log acid value–log time curves for the three reactions are shown in Fig. 5. It is interesting to note that the general shape of these curves is similar to the corresponding plots for glyceryl phthalate (anhydride) and glyceryl phthalate (acid). The changes of slope observed in the curves of the present investigation appear to occur at degrees of esterification corresponding to those previously noted for the glyceryl phthalates.

TABLE I

	Glyceryl maleate (anhydride)	Glyceryl succinate (acid)	Glyceryl succinate (anhydride)
Acid value	231	189	183.6

% Esterification	68.5	74.5	75.0
Average molecular weight	1050	1075	1085
Ultimate analysis C, %	46.9	46.7	46.7
Ultimate analysis H, %	4.6	5.2	5.4

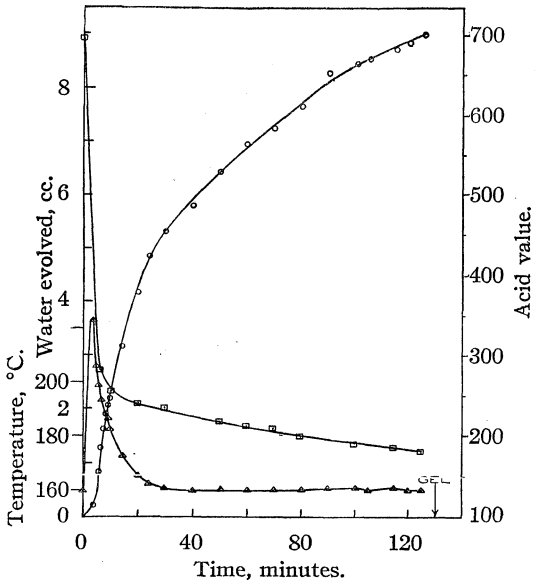

Fig. 2.—Reaction data. Glyceryl succinate (anhydride): proportions, glycerol 69.0 g., succinic anhydride 112.5 g., temperature of mixing 160°, △, temperature, ⊡, acid value, ⊙, water evolved.

Analytical Data.—Samples taken just prior to gelation in each reaction were found to be soft, rather flexible, very light amber colored resins.

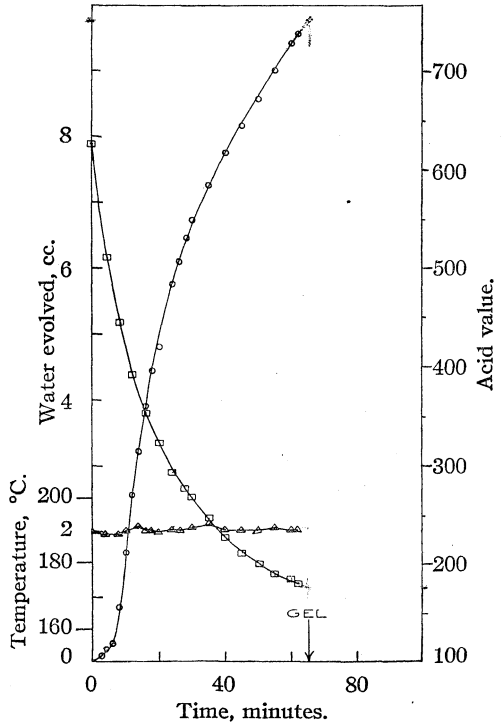

Fig. 3.—Reaction data. Glyceryl succinate (acid): proportions, glycerol 23.0 g., succinic acid 44.3 g., temperature of mixing 190°, △, temperature, ⊡, acid value, ⊙, water evolved.

The analytical data for these samples are given in Table I.

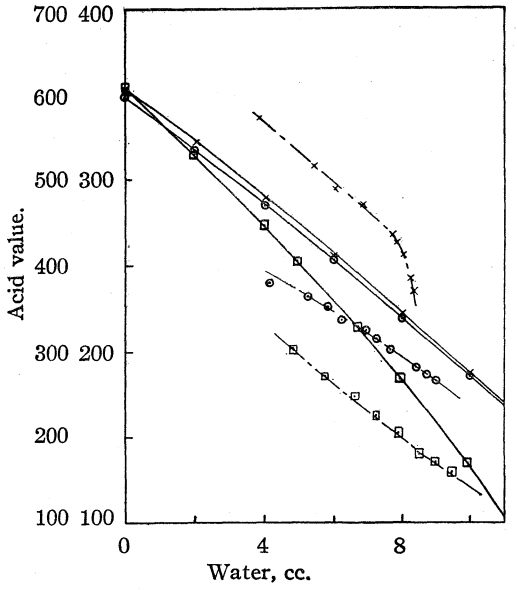

Fig. 4.—Acid value, water evolved relationship: ×, glycerol maleate, ⊙, glyceryl succinate (anhydride), ⊡, glyceryl succinate (acid), —— theory, - - - - experimental.

The infrared spectra from 1–15 μ for these resins have been measured[5] and are plotted in Fig. 6. The spectra show all the necessary linkages for polyester formation together with a suggestion of both conjugation and ring formation in the case of glyceryl maleate.

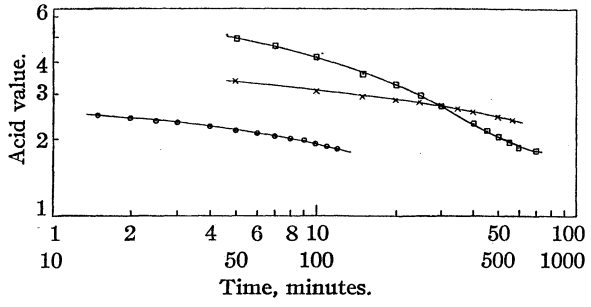

Fig. 5.—Log acid value–log time: ×, glyceryl maleate, T = 160°; glyceryl succinate anhydride, T = 160°; □, glyceryl succinate acid, T = 190°.

The spreading curves for these same polyester polymerides as monomolecular films on 0.001 N hydrochloric acid were determined and are given in Fig. 7. From these curves the areas per molecule were obtained by extrapolation and found to be 31.5 sq. Å. for glyceryl maleate and 80.5 sq. Å. for glyceryl succinate.

(5) Acknowledgment is made to Mr. R. R. Brattain for measuring these spectra.

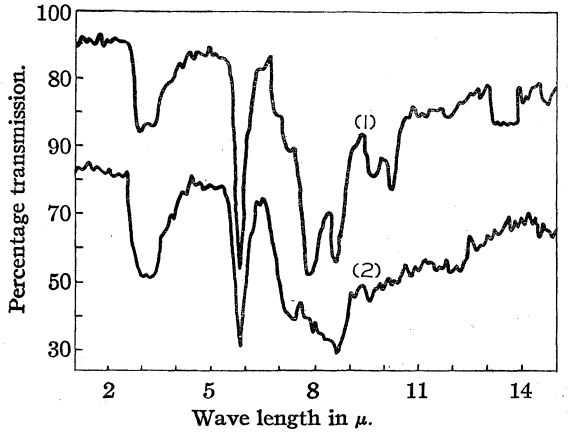

Fig. 6.—Infrared spectra: (1) glyceryl maleate, A. V. 231; (2) glyceryl succinate, A. V. 182.

In Table II there have been summarized pertinent data with respect to the sol–gel transition for the various polyester polymerides thus far reported. Also there have been included in this table the calculated acid values for the dimer and tetramer form of the several polyesters, assuming only interesterification had occurred. It is interesting to note that with the exception of glyceryl maleate, the acid value at which gelation occurs is between the two values.

TABLE II

Glyceryl polymeride	Mol. resin	React. temp., °C.	Time, to gel., min.	H_2O evolved, Va	A. V. at gelation (obsd.)	A. V. (calcd.) Dimer	Tetramer
Phthalate	1/4	160	160	7.99	120	139	117
Succinate	1/4	160	130	6.00	178	182	154
Maleate	1/4	160	57	5.44	230	187	157
Phthalate (acid)	1/3	190	164	10.80	120	139	117
Succinate (acid)	1/3	190	64	9.62	178	183	154

Discussion

In the glyceryl succinate reaction, when acid is used instead of anhydride, no initial temperature rise is observed and time is required to attain 50% esterification. From this point on to gelation, however, the reactions are fairly equivalent,

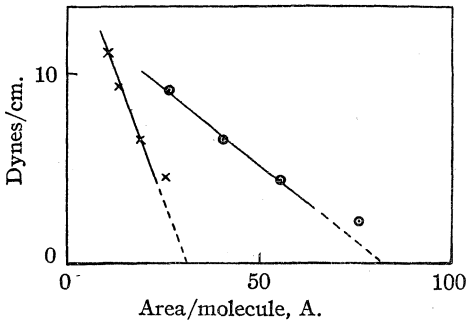

Fig. 7.—Monomolecular film data: T = 15–16°; 0.001 N HCl; ×, glyceryl maleate; ⊙, glyceryl succinate.

finally yielding polyesters with similar properties, as is evident from the analytical values shown in Table I. In the glyceryl succinate reaction, regardless of whether acid or anhydride is used, less water is evolved than is required theoretically. This seems to indicate that little more than interesterification is involved and that a portion of the water formed is retained by or dissolved in the polyesters.

The glyceryl maleate reaction is more complicated. From the beginning of the reaction to gelation more water is evolved than is predicted if only interesterification is assumed. The acid value of glyceryl maleate just prior to gelation is much higher than would be expected from the other polyesters examined. The formation of anhydrides and intraesterification, therefore, is required to explain the high acid value and the excess water evolved. Since the total evolved water in the glyceryl maleate is smaller than that resulting from the glyceryl succinate reaction, but the average molecular weights of the two resins at corresponding stages are practically equal, it would seem that addition polymerization also has occurred. The appearance of adsorption bands around 10.0 and 13.0 μ in the infrared spectrum of glyceryl maleate, common to ring compounds,[6] and the much lower spreading area of the glyceryl maleate polyester as compared with the glyceryl succinate polyester are further evidence in favor of the occurrence of addition polymerization.

In a previous paper[7] the importance of the average functionality of a highly functional polymeride with respect to when gelation will occur was discussed. In polyester polymerides, when stoichiometric proportions of reactants are used and optimum conditions of reaction are employed, it has been shown[4] that the average polymeric functionality with respect to the carboxyl groups can be calculated from the equation

$$MA_t = 56.1 \times 10^3 v$$

where v = the basicity of polyester, that is, the average polymeric functionality with respect to carboxyl groups. The calculated and observed values were found to agree very well. Gelation in all highly functional polymeric systems was shown to occur when the average polymeric functionality exceeded 3.0. In the case of glyceryl phthalate, gelation was found to result when v attained a value of 3.3 or just beyond the condition for potential gelation. At this point, not very large molecular weight polyesters are formed, but rather the mole percentage of tetramers or higher polymers has attained a low limited molar concentration sufficient to bring about a state of arrested motion. The glyceryl maleate and the glyceryl succinate data further support this concept. Thus, just before gelation, the average molecular weights are in the order of 1100–1200, while the average polymeric functionality at gelation for glyceryl maleate is approximately 4.3 and for glyceryl succinate is approximately 3.4.

Summary

1. The glyceryl succinate reaction has been investigated using both acid and anhydride. A difference was observed in the early portion of the acid reaction, but after 50% esterification had been reached, the two reactions were essentially similar. Less water was evolved than was required theoretically by interesterification. It has been suggested that part of the water formed was retained by the polyester.

2. The glyceryl maleate (anhydride) also has been studied. In this case more water was evolved than required by theory. This has been attributed to the formation of anhydrides and intraesterification along with interesterification. Data are presented indicating that addition polymerization also occurred.

3. Data for the various polymerides are summarized and gelation is explained in terms of low molecular weight polyester formation.

Viscosities of Linear Polyesters. An Exact Relationship between Viscosity and Chain Length

BY PAUL J. FLORY

Introduction

A number of different equations have been proposed for expressing viscosity as a function of molecular constitution.[1] The fact that nearly all of these contain the molecular weight, or the chain length, explicitly indicates general recognition of the existence of a close relationship between viscosity and the size of the molecule.

One of the best known viscosity–molecular constitution relationships, proposed by Dunstan,[1a] is

$$\log \eta = aM + b$$

where η is viscosity, M is molecular weight, a is a constant the same for all homologous series, and b is a constitutive factor characteristic of a particular series. Albert[1e] has shown that the viscosities of homologous esters deviate from Dunstan's equation within the brief molecular weight range 296–352. Members of an homologous series covering a wide range of molecular weights ordinarily are not available. Consequently, it has not been possible to determine with certainty the exact nature of the dependence of viscosity on molecular weight of homologous substances.

Although it is an easy matter to prepare synthetic linear polymers having average molecular weights varying over a wide range, precise molecular weight determination is usually difficult. Correlation of viscosities of molten polymers with their molecular weights does not seem to have been attempted. In fact, very few measurements of viscosities of molten synthetic polymers have been reported,[2] although much work has been devoted to viscosities of polymers in dilute solutions.

The linear polyesters are exceptionally well suited for investigation of viscosity–molecular weight relationships. These polymers can be prepared at any desired average molecular weight over a wide range and, when the preparation is carried out under properly defined conditions, their average molecular weights may be determined accurately by titration of the unreacted carboxyl end-group.

The present investigation has disclosed that the viscosities of molten linear polyesters can be represented with astonishing accuracy by the equation

$$\log \eta = A + C'M_w^{1/2} \qquad (1)$$

where M_w is the *weight average* molecular weight (*cf. seq.*) and A and C' are constants. Or

$$\log \eta = A + CZ_w^{1/2} \qquad (2)$$

where Z_w is the *weight average* chain length (*i. e.*, number of atoms in the chain skeleton) and C is a new constant. Not only does this relationship provide a simple means for determination of average molecular weight, but it also offers a new approach to the relationship between viscosity and chemical constitution.

Experimental Methods

Materials.—Since very small amounts of impurities could affect the experimental results appreciably, the purification of the materials used in this investigation will be described in detail.

Decamethylene glycol, which had been prepared by hydrogenation of diethyl sebacate, was obtained from the University of Illinois. It was stirred vigorously for two hours with boiling 5% aqueous caustic in order to saponify any unreduced ester, then washed with water until all alkalinity had been removed. The glycol was purified further by recrystallization. One batch was recrystallized three times from ethylene dichloride, the hot solution being stirred vigorously while cooling very slowly. Because of the low solubility of decamethylene glycol in ethylene dichloride at room temperature, a second batch was recrystallized twice from an ethylene dichloride–alcohol mixture containing 10% by volume of alcohol. The yield from each recrystallization was 85 to 90%. This glycol was finally recrystallized twice from pure ethylene dichloride. Each batch was dried in air, ground in a mortar to break up aggregates, and then heated at about 65° for two hours in vacuum in order to remove traces of solvent. Both samples gave "flat" cooling curves at the freezing point, 71.9°, with less than 0.05° decrease in temperature when 80% had solidified. On the basis of a freezing point constant calculated from an estimated heat

Souders, THIS JOURNAL, **60**, 154 (1938); (e) O. Albert, *Z. physik. Chem.*, **A182**, 421 (1938); (f) D. J. Lewis and A. R. Morgan, *J. Chem. Soc.*, 1341 (1939).

(2) H. I. Waterman and J. J. Leendertse, *Rec. trav. chim.*, **54**, 139 (1935), have reported the viscosities of a series of low molecular weight polymers of pentene-2 at several temperatures. E. Jenckel and K. Ueberreiter, *Z. physik. Chem.*, **A182**, 361 (1938), studied the viscosities of several polystyrenes near their softening temperatures. J. D. Ferry and G. S. Parkes, *Physics*, **6**, 356 (1935), determined the viscosity of a low molecular weight polyisobutylene at various temperatures.

of fusion (7000 cal./mole), a temperature drop of 0.05° at 80% solidification corresponds to about 0.03 mole % of impurities not soluble in the solid glycol. It must be admitted, however, that some of the most likely impurities (hydroxydecanoic acid, other glycols or possibly decyl alcohol) probably would enter the glycol crystal lattice to some extent. Experimental results obtained with the two batches of glycol are identical (*cf. seq.*).

Diethylene glycol, obtained from the Eastman Kodak Company, was fractionated carefully in a carborundum packed precision column. The boiling point, 129.5 to 130.0° at 10.5 mm., was practically constant throughout the entire distillation. A center cut was retained for use.

Adipic, sebacic, and succinic acids, obtained from the Eastman Kodak Company, were purified by recrystallizing twice from water. Each of these acids melted sharply; adipic acid at 150.6°, sebacic acid at 131.5°, and succinic acid at 187°. Their neutral equivalents were: adipic, 73.1, 73.2, 73.0, calcd. 73.06; sebacic, 101.0, 101.1, 101.3, calcd. 101.12; succinic, 59.0, 59.0, calcd. 59.04.

Viscometric Methods.—The viscometers used to measure viscosities of molten polyesters were similar in design to volumetric pipets. The capacity of the bulb and the diameter of the stem, extending about 4 cm. below the bulb, depended upon the viscosity range for which the viscometer was intended. A bulb volume of 1 cc. and an internal stem diameter of about 0.8 mm. was used for the range 0.1–3 poises. The viscometer designed for 20–300 poises had a 4-cc. bulb and 4-mm. stem.

By means of a three-way stopcock, to which the upper end of the viscometer was connected with rubber tubing, the viscometer could be connected either with nitrogen at a pressure slightly above atmospheric or with a reservoir of air at a pressure from 20 to 200 mm. less than that of the atmosphere. The difference between the atmospheric pressure and the pressure in the reservoir was registered on a mercury manometer. While the viscometer stem was immersed in the molten polymer, the surface of which was at atmospheric pressure, the stopcock was turned toward the reduced pressure reservoir. The time t required for filling the viscometer bulb was measured, after which the stopcock was immediately turned toward the nitrogen supply, causing the viscometer to empty slowly. The viscosity was calculated from

$$\eta = ctP \qquad (3)$$

where c is a constant and P is the pressure difference between the atmosphere and the reservoir, corrected for the effect of the mean difference in height between polymer in the viscometer and surrounding polymer.

The calibration constants c were determined by measuring the tP product for liquids of known viscosity. For this purpose mixtures of polymeric ethylene phthalate and *m*-cresol provided liquids having suitable viscosities. The rates of fall of accurately machined steel ball bearings ($^1/_8$" in diameter) through columns of these liquids one inch (2.5 cm.) in diameter were measured. The absolute viscosities of the liquids were then calculated from Stokes' law, supplemented with wall corrections as prescribed by Bacon.[3]

Independent standardizations using glycerol–water mixture, the viscosity of which was determined from the density using the tables published by Sheely,[4] yielded c values about 5% lower than those determined by the absolute method described above. This discrepancy is several times the experimental error, and no explanation of its source is suggested. The c's based on the absolute method have been used here. The viscosity measurements are believed to be accurate (relative to one another) within about ±2%, except at viscosities above 100 poises where the error may be about twice this. The possible 5% error in absolute values of the viscosities is of no consequence in any of the results included in this paper.

Above 10 poises it is necessary that the viscometers be allowed to empty very slowly (during five minutes or more) if an accurate subsequent measurement is to be made without cleaning the viscometer. Liquid adhering to the walls of the bulb decreases the effective volume, and hence the time t required for filling the bulb. Above 50 poises it is usually necessary to clean the viscometer between each reading if an error greater than 2% cannot be tolerated.

Several of the viscosities above 100 poises were measured using for viscometers straight glass tubes having 3 to 7 mm. inner diameters. Marks were etched at two points on the tube, usually at 2 and 12 cm., respectively, above the lower end. The time t (in sec.), required for filling the tube from the lower to the upper mark at a mean pressure difference P (in mm.), was recorded. The calibration constants c to be used in equation (3) were deduced from the mean cross sectional area of the tube with the aid of the equation (4) deduced from Poiseuille's law

$$c = 106\sigma/(h_2^2 - h_1^2) \qquad (4)$$

where σ is the cross sectional area in sq. cm., and h_1 and h_2 are the distances in cm. of the lower and upper marks, respectively, above the lower end of the tube. Comparison with results obtained with a viscometer of the type described previously confirmed the adequacy of this calibration method.

It should be pointed out that throughout the range investigated the viscous behavior of the polymers is Newtonian; that is, the rate of shear is proportional to the shearing stress. (The shearing stress is proportional to P divided by the length of the stem of the viscometer.) For example, a polymer having a viscosity of about 100 poises at 109° gave the same viscosity within ±2% over a five-fold variation of the shearing stress.

Methods of Polymerization.—Polymers were prepared by heating together precisely equivalent quantities of glycol and dibasic acid in a cylindrical Pyrex bulb sealed to the lower end of a 15-mm. vertical tube about 25 cm. long. Through a stopper in the upper end of this tube the viscometer was inserted. A gentle stream of nitrogen through the viscometer served to stir the mixture and to facilitate removal of water formed in the reaction. The effluent nitrogen and moisture passed through a 12-mm. side arm sealed to the vertical tube near its upper end. The side arm sloped upward for about 15 cm., and then led downward to a small trap for condensing moisture. Loss of a volatile reactant (glycol) was minimized by condensation in the side arm, followed by its return to the re-

(3) J. Bacon, *J. Frank. Inst.*, **221**, 251 (1936).

(4) M. L. Sheely, *Ind. Eng. Chem.*, **24**, 1060 (1932).

action mixture. Provision was made for reducing the pressure of the system by evacuation through the trap. The reaction bulb and several cm. of the vertical tube were heated by a vapor-bath (toluene, 109°; phenetole, 168°; *m*-cresol, 202°), which remained within 0.2° of constant temperature during any one experiment.

Experiments for the purpose of establishing viscosity–molecular weight relationships were carried out at 109° using as catalyst 0.10 to 0.20 equivalent % of *p*-toluenesulfonic acid (*i. e.*, from 1 to 2 mmol. of the catalyst per gram *equivalent* of dibasic acid). In order to assure rapid removal of water, the pressure was reduced to about 200 mm. After termination of an experiment conducted at this pressure and the above-mentioned temperature, the trap did not contain appreciable amounts of either glycol or acid.

At intervals during the course of the reaction the pressure was brought to atmospheric by introducing nitrogen simultaneously through the viscometer and through the trap. The viscosity was measured and a sample was removed immediately for analysis. The viscometer served as a pipet for removing samples. After having been weighed, samples having molecular weights below about 4000 were dissolved in chloroform; samples having higher molecular weights were dissolved in hot chloroform–chlorobenzene mixture. The solutions were cooled below 25° and titrated with 0.1 *N* alcoholic potassium hydroxide using phenolphthalein as indicator.[5] The end-point is very sharp in these solvents. The amounts of sample removed from the reaction bulb were sufficient to require from 4 to 10 cc. of the standard alkali. An accuracy within ±0.01 cc. was attained easily using a clean 10-cc. buret.

This polymerization method is especially well suited for the study of viscosity–molecular weight relationships. The low temperature, 109°, minimizes possible undesirable side reactions and loss of volatile reactants, which would vitiate molecular weight determination by titration (*cf. seq.*). The acid catalyst not only accelerates the reaction, but it also changes the kinetic order from third to second,[6] thus causing the molecular weight to increase approximately with the first power of the time. In the "uncatalyzed" third order reaction the molecular weight increases approximately with the square root of the time.

For studies of viscosity–temperature relationships, of viscosities of mixtures of polymers, and of density–temperature relationships, polymers containing catalyst obviously are not suitable because of the changes they will undergo during the course of the measurements. For such studies polymers were prepared by heating together equivalent amounts of glycol and dibasic acid at 202° without catalyst. Except that the pressure was not reduced during polymerization, the procedure described above was followed. Loss of glycol was considerable (about 1%) during the first few minutes, when much of the glycol had not yet reacted at either terminal OH. Molecular weights of polymers prepared by this method have been deduced from their viscosities using the viscosity–molecular weight relationship established on the basis of experiments carried out using an acid catalyst as described above. The neutral equivalent, determined by titration with alcoholic caustic, did not agree with the molecular weight calculated from the viscosity because OH and COOH groups were not present in equal number. On the basis of the discrepancy between the neutral equivalent and the molecular weight, the deficiency of glycol was calculated (see expression (11′)), and this amount was added to the polymer. After about an hour at 202°, the added glycol was completely assimilated by the polymer by means of ester interchange.

Determination of Densities.—The pycnometers used for determining densities of molten polyesters also resembled pipets. The bulb, having a capacity of about 4 cc., consisted of a section of 10-mm. glass tubing. The lower end of the bulb was sealed to a 1.5-cm. length of 5 mm. tubing which was drawn to an abrupt, thin-walled tip having an inside diameter somewhat less than 1 mm. The upper end of the bulb was sealed to a 4-cm. length of 0.5 mm. capillary tubing, which in turn was sealed to a 12-cm. length of 6-mm. tubing. A calibration mark was placed near the middle of the capillary section. The pycnometers were calibrated by weighing the water required to fill them from calibration mark to tip at 25°. The volume of the pycnometer at higher temperatures was corrected for the expansion of the Pyrex glass, using 0.96×10^{-5} per degree for its cubical expansion coefficient.[7]

After allowing sufficient time for polymer and pycnometer to reach the constant temperature of the vapor-bath, the molten polymer was drawn slowly into the pycnometer through the tip, filling it to the calibration mark. The difficulty with which viscous polymer flowed through the small capillary tubing facilitated adjustment to the mark. After permitting the pycnometer to remain briefly with its tip barely in contact with the polymer, it was removed quickly, and polymer on the outside of the tip was wiped away. Polymer in the capillary was frozen in order to prevent subsequent loss by drainage out of the tip. After careful cleaning of its exterior, the pycnometer and its contents were weighed at room temperature. The results are accurate within ±0.0001 g./cc.

Calculations.—Let a "segment" be defined as one glycol or one dibasic acid residue as contained within a polymer molecule. The extent of reaction p will represent the ratio of the number of ester groups to the number of ester plus unreacted carboxyl groups. When COOH and OH are present in equal numbers, $1 - p$ is the ratio of unreacted COOH groups (or OH groups) to the total number of segments, and the number of molecules must equal the number of unreacted carboxyls. Hence

$1 - p$ = (number of molecules)/(number of segments)

(5) Definite indication of degradation of high molecular weight polyesters containing catalyst which have been in contact with the atmosphere for a few days has been observed. Apparently, moisture absorbed from the air is capable, in the presence of catalyst, of hydrolyzing some of the ester linkages of the solid polyester. W. H. Carothers and J. A. Arvin, THIS JOURNAL, **51**, 2565 (1929), pointed out that polyesters absorb moisture readily. In the present investigation all samples were analyzed within two hours after removal, in order to avoid degradation prior to analysis.

(6) P. J. Flory, *ibid.*, **61**, 3334 (1939).

(7) This value is based on the linear expansion coefficient, 0.32×10^{-5} per degree, reported in the catalog of "Pyrex Laboratory Glassware" (1938), The Corning Glass Works, Corning, N. Y.

and the degree of polymerization DP, defined as the average number of segments per molecule, will be given by

$$DP = 1/(1 - p) \qquad (5)$$

Values of DP were calculated from titrations of samples containing p-toluenesulfonic acid as follows. Let

w = weight of sample in g.
t = titer in moles of potassium hydroxide
S = mean molecular weight of one segment
(S = half the molecular weight of —ORO—COR'CO—)
N_0 = number of moles of segments in the sample
γ = ratio of moles of p-toluenesulfonic acid monohydrate (mol. wt. = 190) to moles of segments
$w = SN_0 + (1 - p)18N_0 + 190\gamma N_0$
$t = (1 - p)N_0 + \gamma N_0$

Eliminating N_0 from these two equations and solving

$$1/(1 - p) = \frac{w - 18t}{(S + 190\gamma)t - \gamma w} \qquad (6)$$

According to (5) this expression is also equal to the degree of polymerization. The average molecular weight M_n is of course $S(DP) + 18$.

The average chain length, *i. e.*, the average number of atoms in the chain skeleton, has been taken to be

$$Z_n = zDP + 1 = z/(1 - p) + 1 \qquad (7)$$

where z is the mean number of chain atoms per segment. (For example, z for the decamethylene glycol–adipic acid polyester is 9.) The "1" has been included in (7) to represent the O atom of the terminal OH group.[8]

Discussion of Errors.—The predominant source of error in the results presented in this paper lies in the average molecular weight determination. The method given above assumes that no deleterious side reactions occur, that no appreciable quantities of impurities functionally capable of entering the reaction are present, and that the concentrations of unreacted OH and COOH groups are equal. In defense of the first of these assumptions, it can be pointed out that esterification is known to proceed without appreciable side reactions at moderate temperatures. The latter two assumptions depend upon the purity of the reactants and the quantities of reactants lost by volatilization (see above). The following discussion concerns the effects on the results of a deficiency of one reactant, and of certain impurities conceivably present.

(8) The interpretation of the results presented below would not require any modification if the "1" in (7) had been omitted. This equation must be regarded as a slightly arbitrary definition of Z_n.

Let $N_0'/2$ and $N_0''/2$ be the numbers of dibasic acid and of glycol segments, respectively, in the polymer. Let $r = N_0'/N_0''$. The extent of reaction p will be defined here as the ratio of ester groups to N_0', which equals the number of ester groups plus unreacted carboxyl groups. The total number of segments is given by

$$(N_0' + N_0'')/2 = N_0'(1 + r)/2r$$

The total number of ends of chains, *i. e.*, the total number of unreacted functional groups, is equal to

$$2N_0'(1 - p) + N_0'' - N_0' = 2N_0'(1 - p) + N_0'(1 - r)/r$$

Since each molecule has two ends

$$DP = \frac{\text{No. of segments}}{\text{(No. of ends)}/2} = \frac{1 + r}{2r(1 - p) + (1 - r)} \qquad (8)^9$$

When glycol and adipic acid segments are present in exactly equal numbers, $r = 1$, and (8) reduces to (5).

Reëxamination of the derivation of (6) shows that when r is not unity, the value of $1 - p$ derived from (6) will differ negligibly from $1 - p$ as defined here. The per cent. error in $1 - p$ calculated from (6) is approximately equal to the percentage difference between the weight of the polymer sample and the weight of another sample containing the same number of dibasic acid residues and having $r = 1$.

The error ΔDP introduced by calculation of DP from (5) when $r \neq 1$ is given by equation (5) minus equation (8).

$$\Delta DP = \frac{p(1 - r)}{(1 - p)(1 - r) + 2r(1 - p)^2} \qquad (9)$$

When p is near unity and $(1 - r)$ is small compared with $(1 - p)$, *i. e.*, when the excess of one segment is very small

$$\Delta DP \cong \frac{1 - r}{2(1 - p)^2} \cong (1 - r)(DP)^2/2 \qquad (10)$$

When glycol is present in excess $r < 1$ and ΔDP is positive; that is, the DP calculated from (5) is too large. When acid is present in excess, $r > 1$ and the calculated DP's are too small.

The approximate percentage error is

$$100(1 - r)DP/2 \qquad (11)$$

or

$$(\%\text{ excess of one segment}) \times DP/2 \qquad (11')$$

The approximate percentage errors in Z_n and in Z_w (the "weight average" chain length, *cf. seq.*),

(9) An equivalent equation has been derived by the author previously by a different method, THIS JOURNAL, **58**, 1877 (1936), equation (32). The above notation coincides with that introduced in the paper referred to.

since both are approximately proportional to DP over most of the range investigated, are also given by (11) or (11′). The approximate percentage error in $Z_w^{1/2}$, the abscissa in Figs. 2, 3, 4 and 5, is therefore

$$100(1 - r)DP/4 = 100(1 - r)Z_n/4z$$

It will be pointed out later that $Z_w \cong 2Z_n$, except at low values of Z_n. Hence, the % error in $Z_w^{1/2}$ is approximately

$$100(1 - r)Z_w/8z \qquad (12)$$

It follows that for a given value of $(1 - r)$ the *magnitude* of the abscissa error in the above-mentioned figures increases with the *cube* of the abscissa ($Z_w^{1/2}$) value. If, for example, in the polymerization of decamethylene glycol and adipic acid 0.10% excess of one reactant were present, the *magnitudes* of the errors in $Z_w^{1/2}$ at $Z_w^{1/2} = 10$, 20, 30 and 40 would be, respectively, 0.014, 0.11, 0.38 and 0.89. At $Z_w^{1/2} = 29$ the error would be about equal to the diameter of one of the experimental points in Fig. 3.

A similar analysis has been applied to the effects of a monofunctional impurity such as decyl alcohol, glycol and dibasic acid being present in equivalent amounts. The same equations, (8) to (12) inclusive, may be used if r is taken as the molar ratio of glycol to glycol plus the monofunctional reactant. Similarly, if a small amount of the glycol were replaced, mole for mole, by an hydroxy acid, these same equations could be used, taking r = (moles dibasic acid)/(moles dibasic acid plus hydroxy acid).

Results

Viscosity and Number Average Chain Length.—The present investigation was undertaken as a result of the accidental observation that the logarithm of the viscosity η of a linear polyester is approximately a linear function of the square root of the (number) average chain length. Experimental results are shown in Fig. 1 for the polyester formed from decamethylene glycol and sebacic acid. A straight line has been drawn through the points for comparison. Similar graphs of viscosities of the decamethylene glycol–adipic acid and diethylene glycol–adipic acid polyesters showed that in these cases also log η is approximately a linear function of the square root of the (number) average chain length Z_n. In all three cases, however, the experimental points seem to follow curves (concave toward the abscissa) which deviate slightly from straight lines (see Fig. 1).

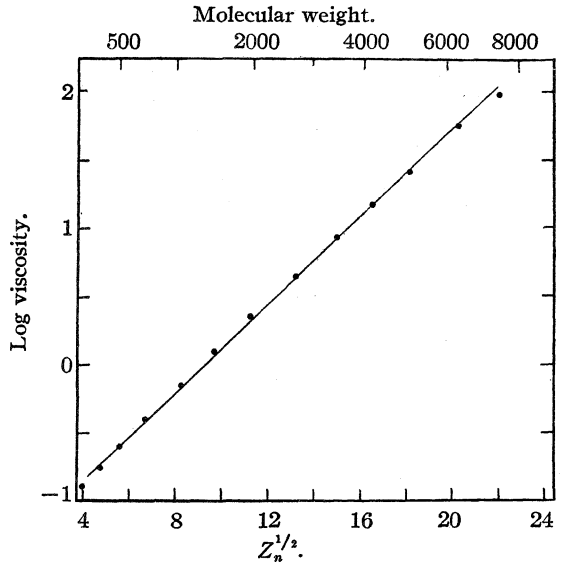

Fig. 1.—Decamethylene sebacate: log viscosity in poises at 109° *vs.* the square root of the *number average* chain length. Average molecular weights are included at the top of the figure.

Consideration of Various Averages.—When seeking a relationship between the viscosity and the average chain length of a synthetic polymer, such as a polyester, one must keep clearly in mind that these substances ordinarily are extremely inhomogeneous; some of the molecules of which they are composed are much smaller and some are much larger than the average. It would not seem improbable that the viscosity would depend upon the nature of the distribution of molecular species about the average molecular weight, as well as upon the average molecular weight itself.

Fortunately, the exact nature of the distribution of molecular species in linear polyesters is known from previous work. It has been shown[9] that the number of molecules possessing x segments is

$$N_x = N_0(1 - p)^2p^{x-1} \qquad (13)$$

where p is the extent of reaction as previously defined and N_0 is the total number of segments.[10] Let Z_x[11] refer to the chain length of the species of molecule possessing x segments. In accord with (7)

$$Z_x = zx + 1 \qquad (14)$$

or

$$Z_x \cong zx \qquad (14')$$

(10) Equation (13) rests entirely upon the postulate that reactivity of terminal functional groups does not depend on the chain length. This postulate has been confirmed by both experiment and theory.[6]

(11) Z_x must not be confused with Z_n. The latter is the number *average* chain length; the former is the chain length of an *individual* species.

The number of different average chain lengths which one could deduce for a mixture such as a polyester is unlimited. The common average molecular weight, obtained directly from end-group determinations, osmotic or cryoscopic measurements, is the *number* average.[12] The number average chain length is defined as

$$Z_n = \sum Z_x N_x / \sum N_x \qquad (15)$$

These summations, as well as those to follow, are all to be taken from $x = 1$ to ∞. Substituting (13) and (14) in this equation and evaluating the resulting summations leads to (7), which may be expressed approximately

$$Z_n \cong z/(1 - p) \qquad (7')$$

Another average, which is less familiar, is the *weight* average.[12] This is defined as

$$Z_w = \sum Z_x W_x / \sum W_x \qquad (16)$$

where W_x is the total weight of all molecules having chain length x. To a very slight approximation W_x is proportional to $Z_x N_x$. Hence

$$Z_w = \sum Z_x^2 N_x / \sum Z_x N_x$$

Substituting from (13) and (14′), we have

$$Z_w = z \sum x^2 p^{x-1} / \sum x p^{x-1} \qquad (17)$$

Upon evaluating the summations

$$Z_w = z(1 + p)/(1 - p) \qquad (18)$$

By comparison with (7′)

$$Z_n - {}^1/_2 Z_w = z/2 \qquad (19)$$

a useful formula for calculating Z_w from Z_n.

In similar fashion it can be shown that the root-mean-square chain length is

$$Z_{rms} = (1 + p)^{1/2}/(1 - p) \qquad (20)$$

i. e., it is the geometric mean of the weight and number averages.

From (7′), (18) and (20)

$$Z_n : Z_{rms} : Z_w :: 1 : (1 + p)^{1/2} : (1 + p) \qquad (21)$$

Except when the molecular weight is low, p is near unity. Hence this ratio is approximately $1 : \sqrt{2} : 2$. That is, for linear polyesters *these averages*, as well as many others which could be derived, *are approximately proportional to one another*. It follows, necessarily, that if log η is approximately linear with $Z_n^{1/2}$, it must also be approximately linear with the square root of other average chain lengths. The deviation from linearity will be slightly greater than, or for some averages perhaps less than, the deviation from linearity in the log η *vs.* $Z_n^{1/2}$ relationship (Fig. 1), since the various averages are only *approximately* proportional to one another.

Viscosity and Weight Average Chain Length.— Plots of log η *vs.* $Z_w^{1/2}$ are shown for four polymers, respectively, in Figs. 2, 3, 4 and 5. The complete set of data from one of the experiments with decamethylene adipate is presented in Table I. In all cases log η is more nearly linear with $Z_w^{1/2}$ than with $Z_n^{1/2}$. For decamethylene sebacate and decamethylene adipate there are no deviations from the straight line which are greater than the experimental error, except perhaps below $DP = 2$. In the latter case (Fig. 3) the relationship applies throughout the average molecular weight range 300–10,500, in which the viscosity increases *three thousand-fold*.

415	73.7	10500	664	1320	25.8	36.3	480

The results from three different experiments on decamethylene adipate are shown as solid circles (Expt. II), open circles (Expt. IV) and squares (Expt. V), respectively, in Fig. 3. In Expt. II the glycol had been purified according to the first procedure described above; in Expts. IV and V glycol purified by the second, and more rigorous, procedure (see above) was used. The amount of catalyst was 0.20 equivalent % in Expts. II and IV, and 0.10 equivalent % in Expt. V. The coincidence of the results from these experiments with the same straight line provides some assurance that the glycol was adequately pure. It also demonstrates that the presence of very small amounts of *p*-toluenesulfonic acid did not affect the viscosities appreciably.

Deviations at moderate molecular weights in the case of decamethylene succinate (Fig. 4) may

(12) The terms "number average" and "weight average" were introduced by E. O. Kraemer and W. D. Lansing, *J. Phys. Chem.*, **39**, 153 (1935), in order to differentiate the two averages defined by equations (15) and (17), respectively. Wherever the term "average" has been used in this paper without specifying which average, it is the number average which is referred to.

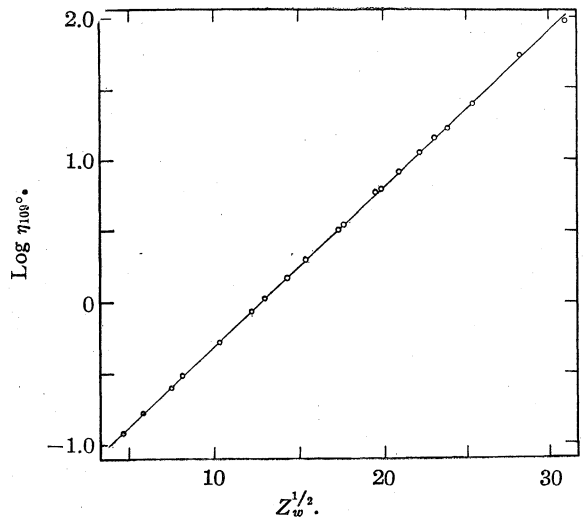

Fig. 2.—Decamethylene sebacate: log viscosity in poises at 109° *vs.* the square root of the *weight average* chain length.

be due to loss of succinic anhydride. The resulting deficiency in acid would make r (see equations (8) and (10)) become less than unity. Hence, the error in DP, and also in $Z_w^{1/2}$, would be positive, in agreement with the data. In an experiment in which the pressure was maintained somewhat lower than usual, the deviations were greater, and they became appreciable at an earlier stage of the polymerization.

In several experiments with decamethylene sebacate and with the adipate, at molecular weights of 8000 or greater, the $Z_w^{1/2}$ values suddenly

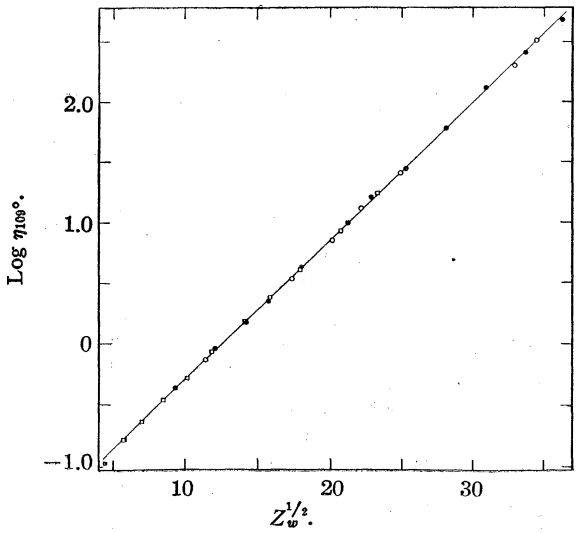

Fig. 3.—Decamethylene adipate: log viscosity in poises at 109° *vs.* the square root of the *weight average* chain length; □, 0.10 equiv. % of catalyst; ○ and ●, represent separate experiments with 0.20 equiv. % of catalyst.

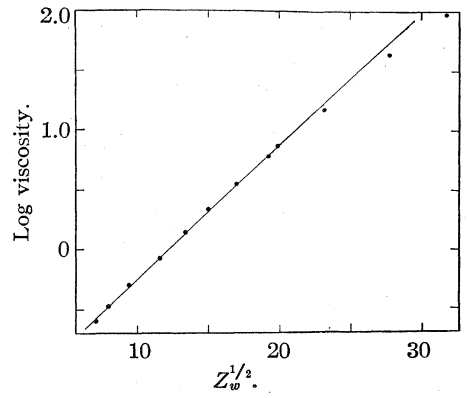

Fig. 4.—Decamethylene succinate: log viscosity in poises at 109° *vs.* the square root of the *weight average* chain length.

fell to the right of the straight lines in Figs. 2 and 3, respectively. This deviation, once it set in, always persisted at succeeding measurements, sometimes increasing in magnitude. In the experiments in which the deviation was pronounced, the pressure had been reduced below 100 mm. Perhaps these deviations are due, similarly, to volatilization of the less readily formed cyclic anhydrides of sebacic and adipic acid.

The experimental results for diethylene adipate (see Fig. 5, solid and half-filled circles) deviate considerably from the straight line at low chain lengths. In this particular case there is an appreciable change in density with chain length at low average molecular weights (*cf. seq.*). If in the low molecular weight region the viscosities

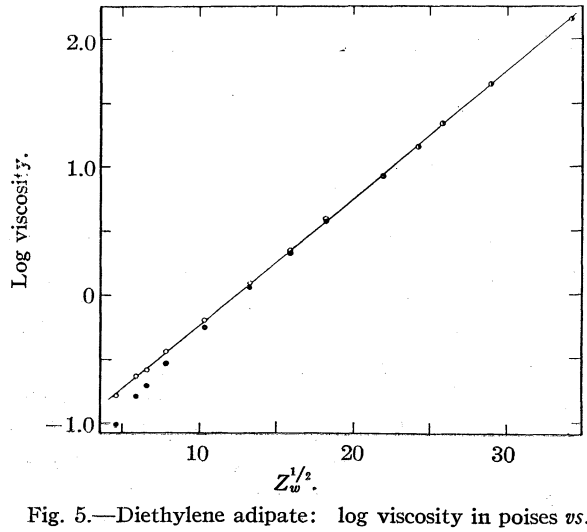

Fig. 5.—Diethylene adipate: log viscosity in poises *vs.* the square root of the *weight average* chain length; ● and ◑ represent experimental data at 109°; ○, viscosities corrected to constant density (1.1240 g./cc.); ◑, viscosities for which this correction would be negligible.

measured at constant temperature (109°) are converted to viscosities at constant *density, i. e.,* to the limiting density reached at higher chain lengths, a satisfactory linear plot (see open circles) is obtained throughout the range. The propriety of this adjustment will be discussed later.

The equations of the straight lines drawn in Figs. 2, 3, 4 and 5 are as follows

For decamethylene sebacate at 109°

$$\log_{10}\eta = -1.429 + 0.1108Z_w^{1/2} \qquad (2.2)$$

For decamethylene adipate at 109°

$$\log_{10}\eta = -1.435 + 0.1144Z_w^{1/2} \qquad (2.3)$$

For decamethylene succinate at 109°

$$\log_{10}\eta = -1.37 + 0.112Z_w^{1/2} \qquad (2.4)$$

The numerical quantities in (2.4) are less certain for reasons already discussed.

For diethylene adipate at constant density (1.1240 g./cc.)

$$\log_{10}\eta = -1.213 + 0.0992Z_w^{1/2} \qquad (2.5)$$

This equation is also satisfactory at constant temperature, 109°, at $Z_w > 100$; *i. e.,* at $M_n > 1700$.

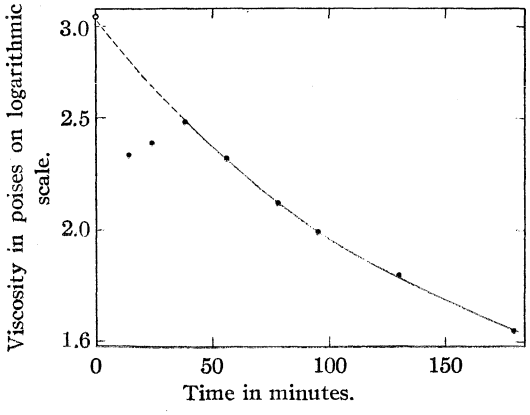

Fig. 6.—Viscosity at 109° of 19.7% mixture of series II (see Table II) as a function of time: ●, experimental points; ○, calculated initial viscosity.

The excellent linear relationships between log η and $Z_w^{1/2}$, obtained in several cases, do not prove that Z_w is necessarily the particular average to which log η should be related. Deviations when other averages are used are too small for a definite decision. Experiments with mixtures of polymers, which will be described next, have shown conclusively that the viscosity is primarily related to the *weight average* chain length.

Viscosities of Mixtures.—A low and a high molecular weight decamethylene adipate polymer were prepared at 202° without catalyst. The viscosities of various mixtures of these were measured at 109°. In spite of the stirring produced by the stream of nitrogen passing through the viscometer, dispersion of the two polymers into one another was very slow. From fifteen to thirty minutes were required before significant viscosities could be measured. Furthermore, the viscosity decreased continuously with time of heating at 109°. This decrease is believed to be due to ester interchange, which, though it does not affect Z_n, may change the distribution of various species, and in this way bring about a decrease in Z_w.[13]

The initial viscosities of the mixtures were determined by extrapolation of log η as a function of time to zero time, as shown in Fig. 6. The first two points in this figure are low due to incomplete mixing. Succeeding points fall on a smooth curve, which has been extrapolated to $t = 0$. Initial viscosities determined in this way for several mixtures of each of two pairs of decamethylene adipate polymers are given in the second column of Table II. A liberal estimate of the error involved in the extrapolation is included in parentheses.

The Z_w values for the individual polymers from which the mixtures were prepared (see 0 and 100% rows in Table II) were obtained from their viscosities by interpolation in Fig. 3. Their Z_n's were then calculated from Z_w's using equation (19). It should be noted that this method for determination of Z_n is equivalent to interpolation from the line (slightly curved) drawn through the experimental points when log η is plotted against $Z_n^{1/2}$.

TABLE II

VISCOSITIES OF MIXTURES OF DECAMETHYLENE ADIPATE POLYMERS

% by weight of higher molecular weight polymer	$\eta_{109°}$ observed	Z_n	Z_w	Calculated η's From number average	From weight average

(100)	164 (±3)	512	1014		

(13) The decrease in viscosity of a mixture with time of heating is being investigated further, and will be discussed in detail in a later paper.

Z_n's of mixtures have been obtained by number averaging the Z_n's of the components.

$$Z_n(\text{mixture}) = \frac{Z_{n,1}N_1 + Z_{n,2}N_2}{N_1 + N_2}$$

where the subscripts 1 and 2 refer to the component polymers, and N_1 and N_2 represent numbers of molecules of each polymer, respectively. Since $Z_{n,1}N_1$ and $Z_{n,2}N_2$ are proportional to the weight fractions w_1 and w_2, respectively

$$Z_n(\text{mixture}) = \frac{1}{w_1/Z_{n,1} + w_2/Z_{n,2}} \qquad (22)$$

Z_w's of the mixtures have been obtained by weight averaging Z_w's of components

$$Z_w(\text{mixture}) = w_1Z_{w,1} + w_2Z_{w,2} \qquad (23)$$

The viscosity "calculated" from the number average for a given mixture (column five) was obtained by taking the square root of Z_n for the mixture and interpolating to the corresponding η from the log η *vs.* $Z_n^{1/2}$ plot (not included here). Similarly, the viscosity "calculated" from the weight average (last column) was obtained from Z_w for the mixture using the log η *vs.* $Z_w^{1/2}$ plot (Fig. 3). The observed viscosities throughout the concentration range are in excellent agreement with those calculated on the weight average basis. The great disparity between the two calculated viscosities given in Table II is indicative of the sensitivity of the calculated viscosity to the method of averaging. Close agreement with a viscosity calculated on the basis of some other average could not be obtained, unless this average is always very nearly equal to the weight average. Not only is log η a linear function of $Z_w^{1/2}$ for a polyester having the "normal" distribution of various sized species obtained by ordinary polymerization, but log η is the *same linear function* of $Z_w^{1/2}$ for the wide variety of distributions obtained by mixing the low and high molecular weight polymers.

Viscosity–Temperature Relationships.—Viscosities of molten polyesters, prepared at 202° without catalyst, were measured at several temperatures from 202° to about 80°, which is a little above their melting points: 73° for decamethylene sebacate, 74° for decamethylene adipate, 69° for decamethylene succinate[14]; diethylene adipate polymers never could be induced to solidify even at the temperature of dry-ice. At the highest temperature, usually 202°, for which the viscosity is reported, the polymerization rate was appreciable. The first determination was therefore made at this temperature; successive viscosities were measured at intervals of several minutes, after which the polymer was cooled quickly to the next lower temperature (167°), where the rate of polymerization was much slower. The 202° viscosity was obtained by a slight extrapolation to the time when the temperature was lowered. Two viscosity determinations were carried out quickly at 167°, and the temperature was dropped to 138°. At this temperature and below, further polymerization was negligible during a reasonable length of time. After measuring the viscosity at the lowest temperature, the viscosity at 202° was determined again. After proper correction for the viscosity increase during the additional 202° heating period, the latter 202° viscosity agreed with the first.

TABLE III

VISCOSITY–TEMPERATURE DATA

34.3	11.95		
19.2	38.3		
0.2	280		

Typical data are given in Table III; all results are included in Figs. 7, 8 and 9, where log η is plotted against the reciprocal of the absolute temperature T. The average molecular weight is included with each curve. According to the well-known equation

$$\log \eta = A' + B/T \qquad (24)$$

the points in Figs. 7, 8 and 9 should follow straight lines. This is not the case except for a range of about 50° above the melting points of the decamethylene glycol polymers. The straight lines in Figs. 7 and 8 have been drawn through the points in this region. The convex downward curvature which occurs in all cases studied is characteristic of many long chain compounds[15]; *e. g.*, *n*-paraffin hydrocarbons, long chain esters, and alkyl halides. The slopes of the diethylene adipate curves became quite large at low temperatures; *i. e.*, the temperature coefficient of viscos-

(14) These are the melting points given by C. S. Fuller and C. J. Frosch, THIS JOURNAL, 61, 2575 (1939).

(15) See M. Souders, *ibid.*, 59, 1252 (1937).

ity becomes very great. This behavior is characteristic of substances supercooled to the "glassy" region below their melting points.[16]

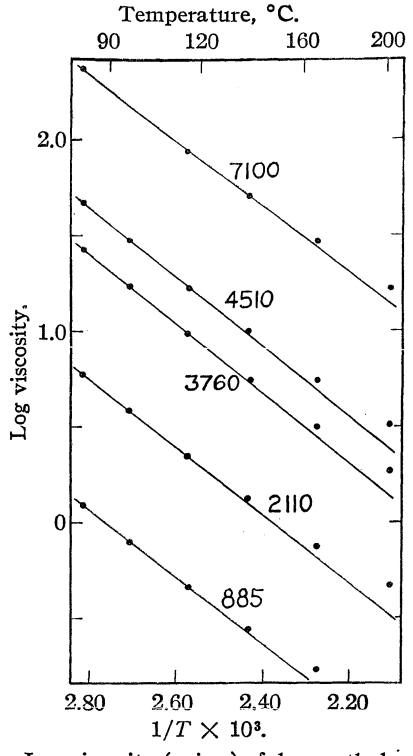

Fig. 7.—Log viscosity (poises) of decamethylene adipate polymers *vs.* reciprocal absolute temperature. Figures refer to average molecular weights of the five polymers.

The most important feature of these results is the slight dependence of the viscosity–temperature coefficient (d ln η/dT) on molecular weight. The slopes of the straight lines for decamethylene adipate (Fig. 7) are the same within 3%, which is within the experimental error. The slopes of the lines in Fig. 8 for the two decamethylene sebacate polymers are in similar agreement. The deviations from the straight lines at higher temperatures are slightly greater at low molecular weights. Careful examination shows that the curves for the three diethylene adipate polymers (Fig. 9) are parallel, except for very slight increases in slope toward higher molecular weights.

To the extent that the temperature coefficient of η is independent of molecular weight, equation (2) must be applicable at any temperature at which the polymer is molten. Furthermore, C in (2) must be independent of temperature. Within a

(16) See, for example, the results of G. S. Parks, L. E. Barton, M. E. Spaght and F. W. Richardson, *Physics*, **5**, 193 (1934), on the viscosity of supercooled glucose as a function of temperature.

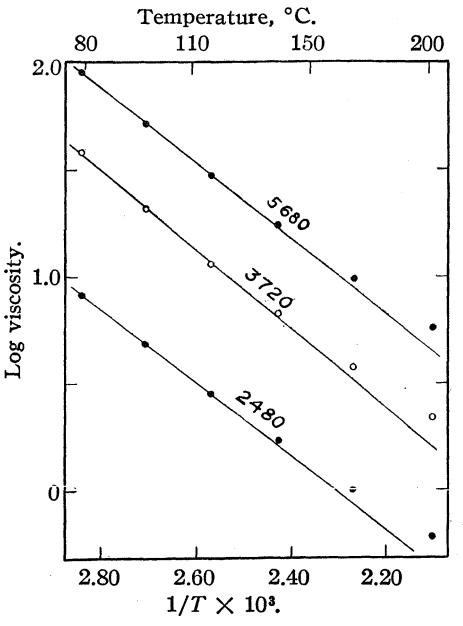

Fig. 8.—Log viscosity (poises) *vs.* reciprocal absolute temperature: ●, decamethylene sebacate; ○, decamethylene succinate; average molecular weights are included.

temperature interval in which equation (24) is applicable, (2) becomes

$$\log \eta = D + B/T + CZ_w^{1/2} \qquad (25)$$

where η is expressed as a function of chain length and temperature. (D is a new constant and B and C are the same constants used in previous equations.)

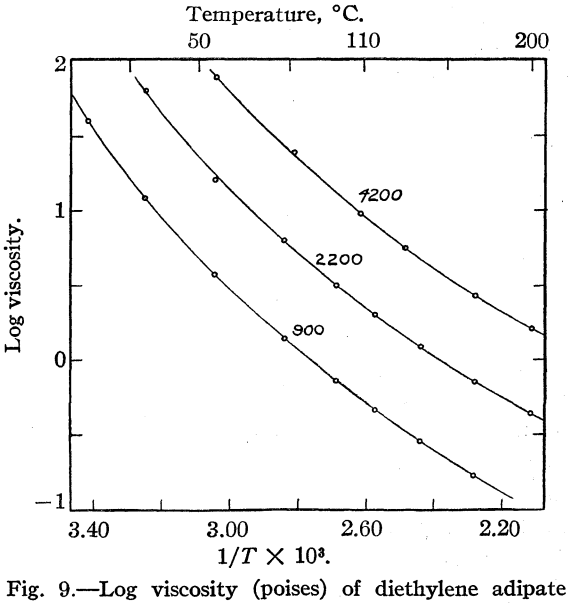

Fig. 9.—Log viscosity (poises) of diethylene adipate polymers *vs.* reciprocal absolute temperature; average molecular weights are included.

TABLE IV
MEAN SLOPES OF LOG η *vs.* $1/T$ (80 TO 120°)

Polymer	B	Activation energy for viscous flow in kcal.
Decamethylene sebacate	1760	8.05
Decamethylene adipate	1800	8.23
Decamethylene succinate	1870	8.55
Diethylene adipate	1840	8.40

Values of B for the temperature interval 80–120° are given in Table IV. Activation energies E for viscous flow, which are equal to $(2.3R)B$, are given in the third column of Table IV. This quantity has been interpreted as the energy required for the occurrence of the elementary process which is responsible for viscous flow. Eyring and Ewell[17] have pointed out the analogy of this elementary process to a chemical reaction, and have developed a theory of viscous and plastic flow on this basis. According to their concepts, E consists of two parts: the energy of formation of a hole in the liquid large enough for the entire molecule, or for that part of it which is displaced in the elementary process, to move into; and of the activation energy required for the displacement to occur when a hole is available. For simple molecules E is usually one-fourth to one-third of the heat of vaporization.[17b] Ewell[17c] has concluded, on the basis of the magnitudes of the activation energies E for viscous flow in rubber and other polymeric substances, that the hole in these cases must be only a fraction of the size of the entire molecule. Thus, the elementary process must consist either of a displacement of a small portion of the entire molecule, or of a displacement of the entire molecule through a comparatively small distance.

The activation energies for viscous flow in polyesters (Table IV) are not large; they are only two or three times those for simple esters. On the same basis as above, therefore, the elementary process in liquid polyesters must consist of a displacement which is not commensurate with the size of the molecule. Moreover, the present investigation has shown that *E does not depend upon molecular size*, since the slopes in Figs. 7, 8 and 9 are independent (or very nearly so) of average molecular weight. The conclusion that the elementary processes in low and high molecular weight polyesters are identical is virtually unavoidable.[18]

(17) (a) H. Eyring, *J. Chem. Phys.*, **4**, 283 (1936); (b) R. H. Ewell and H. Eyring, *ibid.*, **5**, 726 (1937); (c) R. H. Ewell, *J. App. Physics*, **9**, 252 (1938).

(18) Ewell and Eyring[17b] have calculated the size of the molecule (probably linear) in liquid sulfur above 190° from the viscosity–temperature coefficient, *i. e.*, from E. In view of the above results with polyesters, such a calculation is probably invalid.

Densities of Polyesters.—The importance of the free volume in relation to viscosity has been emphasized by Eyring and Ewell.[17] Van Wijk and Seeder[19] have shown that the viscosities of a number of simple non-polar molecules depend entirely upon the molar volume V throughout wide variations of both temperature and pressure. Their equation, derived from theory, is

$$\eta = \left(\frac{V}{V-b}\right)\varphi \qquad (26)$$

where b and φ are parameters dependent upon structure alone; b is the actual volume occupied by the molecules, and $V - b$ is the free volume. For other liquids they found that φ is dependent upon temperature to a small degree; in the case of configurational liquids (*e. g.*, water and alcohols) the variation of φ with temperature accounts for a considerable portion of the viscosity–temperature coefficient. In all cases, viscosity appears to vary inversely with the free volume.

These considerations provoked inquiry into the relation of the free volume to the viscosity of long chain substances. If the average actual volume of one chain atom (*i. e.*, b per chain atom) is considered to be constant, then the free volume per cc. must decrease linearly with the density when chain length or temperature is varied. Therefore, density data should offer some insight into the behavior of the free volume.

Densities of decamethylene adipate and diethylene adipate polymers were determined from time to time during polymerization at 109° in the presence of 0.1% *p*-toluenesulfonic acid catalyst. In Fig. 10 the densities are plotted as functions of the average chain lengths Z_n calculated from viscosities. The density of decamethylene adi-

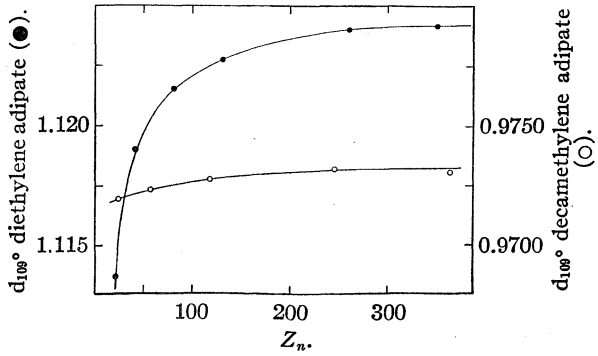

Fig. 10.—Densities (g./cc.) at 109.0° *vs. number average* chain length: ○, decamethylene adipate; ●, diethylene adipate.

(19) W. R. Van Wijk and W. A. Seeder, *Physica*, **4**, 1073 (1937); *ibid.*, **6**, 129 (1939).

pate, over the range investigated, increases by about 0.0013 density unit. This is no greater than the density change for a 2° temperature rise. Therefore, the free volume must be essentially independent of chain length, and the observed dependence of viscosity on chain length must be situated entirely in φ of (26). In other words, the observed empirical relationship (2) probably represents the direct dependence of viscosity on chain length, unobscured by effects of chain length on other properties of the liquid. If the free volume (per cc.) were not constant with increase in molecular weight, this simple relationship might not have been apparent.

The increase in density of diethylene adipate with chain length is much larger (see Fig. 10). It is tempting, because of the consequences, to attribute this change in density to a decrease in free volume. However, it should be pointed out first that the variation of d with Z_n can also be explained if it is assumed that the average molar volume V is given by

$$V = aZ_n + e \qquad (27)$$

where a is the mean volume occupied per chain atom and e is an end-group correction. For the average molecular weight, similarly

$$M_n = \alpha Z_n + \epsilon$$

where α is the mean molecular weight per chain atom of the structural unit, and ϵ is an end-group correction equal to $18 - \alpha$ (see definition of Z_n, equation (7)). Then

$$1/d = V/M_n = g + h/Z_n \qquad (28)$$

where d is density in g./cc., and

$$g = a/\alpha \qquad h = e/\alpha - \epsilon/\alpha d$$

Since the change in d is small, h as well as g may be considered constant. Then, if V is properly expressed by (27), the reciprocal of the density must be linear with $1/Z_n$ according to (28).

TABLE V

DENSITIES OF DIETHYLENE ADIPATE AT 109.0°

Z_n	d, g./cc.	$1/d$	$1/d$ calculated from (27)
21.2	1.1137	0.8979	0.8982
42.1	1.1190	.8936	.8936
81.5	1.1216	.8916	.8914
131	1.1228	.8906	.8906
261	1.1240	.8897	.8898
351	1.1241	.8896	.8896

A comparison of observed reciprocal densities with those calculated from (28), using $g = 0.8891$ and $h = 0.192$, is given in Table V. The agreement is probably within the experimental error. These values of g and h correspond to $a = 14.80$ cc. and $e = 4.43$ cc. ($\alpha = 16.63$ and $\epsilon = 1.38$ for diethylene adipate). The end-group correction, 4.43 cc., indicates that the volume occupied by the end-groups (—OH and —COOH) is greater by this amount than three times the mean volume per chain atom; *i. e.*, than $^3/_{13}$ of the volume occupied by the structural unit

$$—O—(CH_2)_2—O—(CH_2)_2—O—CO—(CH_2)_4COO—$$

Perhaps this is not unreasonable.

When the specific volumes ($1/d$) of n-paraffin hydrocarbons from C_{10} to C_{40} are plotted against $1/Z_n$, approximately a straight line is obtained, but the slope (h) leads to a volume of about 38 cc. for the two terminal H atoms. This value, which is more than twice the volume occupied by one $—CH_2—$ group, is unreasonable. The author is of the opinion that in this case the increase in density with chain length must be due, principally, to a decrease in free volume per chain atom. The agreement with (28) he regards as fortuitous.

Perhaps the density increase with chain length in the case of diethylene adipate is due likewise to a decrease in free volume, rather than to an excess volume of the end-groups. If this is true, and if (2) should be applied at constant free volume as was suggested above, then the viscosities in Fig. 5 should be corrected for the effect of the change in free volume with chain length. If it be assumed further that the effect of temperature on viscosity is entirely due to change in free volume with temperature, this correction may be introduced by converting each viscosity to the viscosity which would have been observed at the temperature at which the density equals the limiting density at large chain lengths. (Stated briefly, we assume that φ in (26) is entirely responsible for the dependence of η on chain length, and that φ is independent of temperature.)

From the viscosity–temperature coefficient (Table IV) of diethylene adipate we obtain for temperatures in the vicinity of 109°, approximately

$$\Delta \log \eta / \Delta T = 0.0125$$

From the change of density with temperature (Table VII)

$$\Delta d / \Delta T = -0.80 \times 10^{-3}$$

Combining, we obtain for the viscosity correction necessary to convert the viscosity to constant density

$$\Delta \log \eta = -15.6 \Delta d \qquad (29)$$

This simple equation is obviously valid only for small corrections.

TABLE VI

CORRECTION OF VISCOSITIES OF DIETHYLENE ADIPATE AT 109° TO VISCOSITIES AT CONSTANT DENSITY (1.1240)

Z_n	η 109° poises	$-\Delta d \times 10^4$ (from Fig. 10)	$\Delta \log \eta$ (calculated from (29))	η at d = 1.1240
14.3	0.098	150	0.223	0.164
21.1	.162	106	.165	.236
25.2	.198	80	.125	.263
33.7	.295	61	.095	.365
56.3	.563	39	.061	.647
90.6	1.16	22	.034	1.25
129	2.16	13	.020	2.26
168	3.88	8	.012	4.00

Open circles in Fig. 5 represent viscosities at the constant density, 1.1240, calculated from (29) taking $-\Delta d = 1.1240 - d$. The calculations are summarized in Table VI. The open circles fall on the same straight line with the points at higher chain lengths (half-filled circles) for which correction is negligible. Viscosities at 109° fall considerably below the straight line at small chain lengths. Thus, the interpretation presented above brings the data for low molecular weight diethylene adipate polymers into agreement with (2). The previously discussed possible explanation for the change of density with chain length of diethylene adipate cannot at present be excluded, however.

In this connection it should be mentioned that at constant temperature log η for n-paraffin hydrocarbons from C_{10} to C_{36} is definitely not linear with the square root of the number of carbon atoms ($Z_n = Z_w$ for these pure substances). With the aid of viscosity–temperature data and density–temperature data, viscosities of several n-paraffins in this range have been corrected to constant density. Log η at constant density is approximately linear with $Z^{1/2}$. The range is too brief for a definite conclusion, however. Perhaps further work will show that equation (2) is generally applicable to long chain substances at *constant free volume.*

TABLE VII

DENSITIES AND EXPANSION COEFFICIENTS OF POLYESTERS

Polyester	d at 109.0°[a] g./cc.	$-\frac{dd}{dT} \times 10^4$	Thermal expansion coeff. $= -\frac{d \ln d}{dT}$
Decamethylene sebacate	0.9378	6.6	7.0×10^{-4}
Decamethylene adipate	.9732	6.95	7.15×10^{-4}
Diethylene adipate	1.1247	8.05	7.15×10^{-4}

[a] These densities are the limiting ones for large chain lengths.

The densities of polyesters prepared without catalyst at 202° were measured at several temperatures from 80 to 167°. Within the experimental error the density is a linear function of temperature in this range. These data are listed in Table VII. The densities are a little greater and the expansion coefficients are somewhat smaller than those for analogous monomeric organic compounds.

Determination of Average Molecular Weights from Viscosities.—By means of equation (1), where $C' = C/\alpha^{1/2}$, weight average molecular weights may be calculated directly from viscosities of the polyesters. If the type of distribution is known, other averages may be computed from M_w. In particular, if the distribution is the "normal" one defined by (13) (*i. e.*, the distribution obtained by all ordinary methods of preparation), then upon taking $Z_n = M_n/\alpha$ and substituting (19) in (2)

$$M_n = (\log \eta - A)^2\alpha/2C^2 + \alpha z/2 \qquad (30)$$

by means of which the number average molecular weight can be calculated from the viscosity. Except for the small second term, log η is linear with M_n. For decamethylene adipate, for example, the viscosity being measured at 109°, equation (30) becomes

$$M_n = 603.6\ (\log \eta + 1.435)^2 + 71 \qquad (30.3)$$

Since C does not vary with temperature, molecular weights can be calculated from viscosities measured at other temperatures by converting A to the temperature of measurement, using the viscosity–temperature relationships presented above.

Equation (30) provides an unusually simple and precise method for determination of the average molecular weight of these polymers. It is true that its constants are deduced from viscosities of polymers the molecular weights of which have been determined by titration, which in itself is a simple molecular weight determination method. The titration method, however, is only applicable when purity of the reactants and precise stoichiometry of the reaction are assured, as the discussion of errors presented above makes clear. The viscosity method is not limited to such circumstances; it may be applied to polymers prepared from reactants which are not of exceptional purity, and which may not necessarily be present in exactly equivalent amounts.

It should be noted that since the molecular weight depends on the *logarithm* of η, it is not

necessary that η be determined very accurately. An error of 5% in η produces an error of only about 1.5% in M_n.

Summary

1. The viscosities (η) of molten linear polyesters having average molecular weights in the range 200 to over 10,000 have been measured. Log η has been found to be precisely a linear function of the square root of the weight average chain length throughout this range.

2. The viscosities of mixtures of two polyesters, one of them having a low and the other a high average molecular weight, agree with the same relationship, when the weight average chain length of the mixture is used therein. Thus, the relationship between viscosity and weight average chain length does not seem to depend on the type of distribution of species in the polymer.

3. The viscosity–temperature coefficient (d ln η/dT) is independent of the average molecular weight, and its magnitude is not many times greater than that found for similar monomeric substances. It has been concluded that the elementary process responsible for viscous flow must consist of displacement of only a small section of the chain, and that this elementary process is the same for polymers of all sizes.

4. The utility of the viscosity–chain length relationship as a simple and accurate means for determination of molecular weight has been discussed.

5. Densities and thermal expansion coefficients of polyesters have been measured.

6. An analysis of the errors incident to molecular weight determination by end-group titration has been presented.

Esters of Alginic Acid

BY H. J. LUCAS AND W. T. STEWART[1]

Since alginic acid is a polyuronide,[2] it would be expected to form two types of esters, *viz.*, alkyl esters and acyl esters, the former because of one carboxyl group per mannuronic residue, the latter because of one or two free hydroxyl groups per mannuronic residue. Of course, the terminal residue will have one additional hydroxyl group. If all of the carboxyl groups are free or are bound as in a salt or in an ester, there would then be two free hydroxyl groups per residue (except for the terminal ones), and dialkyl esters should be possible. However, if the carboxyl groups are bound in lactone formation, then only one hydroxyl group per residue would be free. Therefore the degree of esterification which can be attained presumably would depend, at least in part, upon the extent to which the mannuronic residues of the alginic acid molecule are in the acid or in the lactone form.

Alginic acid might be expected to undergo esterification and etherification of the hydroxyl groups, much as pectin does. The latter can be formylated, acetylated and nitrated without difficulty.[3,4] Methylation of pectin fragments or of pectin which has suffered partial degradation has been accomplished by heating the silver salt with methyl iodide under pressure,[5] by dimethyl sulfate[6] and by methyl iodide and thallium ethoxide.[7] Pectin acid has been exhaustively methylated.[8] Alkylation of the carboxyl group of alginic acid has been effected by heating with methanolic hydrogen chloride.[9,10]

Acetates of alginic acid have been prepared using acetic anhydride and aqueous hydriodic acid as the acetylating agent.[11] A dimethyl ether has been obtained from alginic acid methylglycoside methyl ester (from partially degraded alginic acid and methanolic hydrogen chloride) by the use of methyl iodide and thallium ethoxide.[10]

Experimental

Alginic Acid.—This was supplied by the Kelco Company, of San Diego, who manufactured it from *Macrocystis pyrifera* by a process involving digestion of the kelp with hot aqueous sodium carbonate, precipitation of calcium alginate by the addition of aqueous calcium chloride and conversion of this to alginic acid by means of hydrochloric acid.[12] Alginic acid is a wet fibrous product of about 12% solids. The dried product leaves about 2.5% ash on ignition. For the nitration water was extracted by agitating with several portions of ethyl alcohol which were poured off. The alcohol left finally was allowed to evaporate. The alginic acid remained as a rather compact mass, water content 15%. Another portion was dissolved in aqueous sodium carbonate. The acid was precipitated from the solution by the addition of dilute hydrochloric acid. After filtration through cloth, washing twice with water and then with aqueous methanol until free of chloride, washing well with alcohol, finally with ether, and drying over sulfuric acid, the alginic acid was left as a light, fluffy mass. The ash was reduced to 2.1%. This product was used in methylation as well as in some of the nitration experiments. The presence of methanol (25%) in the water prevented peptization of alginic acid and yet allowed removal of chloride.

Nitration.—This was accomplished with a mixture of nitric acid (d. 1.47) and concentrated sulfuric acid (d. 1.84). The mixture was kept cold during the mixing of the acids and placed in a refrigerator at 3 to 5°. The product was recovered by adding ice and water and centrifuging. Mineral acid was removed by shaking the residue with ice and water and centrifuging. This was done eight times. At first, two or three preparations were worked up by filtering the nitration mixture through a sintered glass funnel, followed by washing with water. Centrifuging was found to be more satisfactory and convenient, however. Next, the nitrated product was taken up in acetone and precipitated by the addition of ether. After this was done five times, the product was placed in a vacuum desiccator over calcium chloride. The dried weight is the one recorded in Table I.

[a] Reprecipitated alginic acid, alcohol and ether washed, dried over sulfuric acid to a light, fluffy product, ash, 2.1%. [b] Alginic acid, alcohol washed, dried to a compact mass, ash, 2.5%, H_2O, 15%. [c] As free acid. [d] As lactone. [e] Ash, 0.6%. [f] Ash, 0.5%.

(12) Thornley and Walsh, U. S. Patent 1,814,981 (July 14, 1931).

For analysis all samples were dried at 60° and 30 mm. over phosphorus pentoxide. Nitrogen was determined by the micro Dumas method. The analytical results are given in Table I.

Methylation.—Several attempts were made to methylate alginic acid with dimethyl sulfate and aqueous sodium hydroxide. It was found necessary to work at a temperature of 60° and to repeat the methylation twice with fresh reagents. An opalescent solution resulted. The product was recovered by acidifying with hydrochloric acid cold, centrifuging, and washing the precipitate four times with water, centrifuging each time. The product was dried by washing with ether, in which the methylated product was insoluble. Less than one methoxyl group per mannuronic residue was introduced. The methoxyl content of these and other preparations was determined by the method of Viebock and Schwappach[13] after drying at 60° and 30 mm. over phosphorus pentoxide (Table II).

TABLE II

METHYLATION OF ALGINIC ACID

Experiment		1	2	3	4
Alginic cpd.		Acid	Acid	Acid	Ag salt
Taken, g.		17.6	1.76	56.5	1.45
Reagent	Cpd.	Me_2SO_4 + NaOH	0.2 *M* CH_2N_2 in Et_2O		MeI
	g.	[a]	35.7[b]	2485	7.25
Methylated product (A)	g.	9.8	1.6	51	0.9
	MeO, %	9.78	18.2	22.4	2.44
Ammonolyzed product (B)	MeO, %	...	5.08	7.96[c]	..

	B	...	0.29	0.48	..

[a] Me_2SO_4, 75.6 g.; NaOH, 30%, 80 g. Three treatments at 60°. [b] For eight hours. [c] After forty-eight hours; MeO was 8.16% after twenty-four hours.

Best results were obtained with diazomethane. The alginic acid used in the methylations with diazomethane was the fluffy reprecipitated product. It was not freed of ether but was treated directly with diazomethane. Seven portions of 500 ml. (355 g.) of 0.2 *M* diazomethane in ether were added over a period of two hundred and forty hours to the acid (56.5 g. of the original dry acid). The final volume was 3.5 liters. The yellow color after addition of the first and second portions largely disappeared in a few hours, but after subsequent additions diminished but little on standing. The methylated alginic acid was recovered by drawing off most of the ether through a filter stick. The rest was removed by suction filtration under a rubber dam and by vacuum drying over concd. sulfuric acid.

Silver alginate was prepared by adding aqueous silver nitrate to aqueous ammonium alginate. The precipitate, after filtering and washing with methanol, was shaken with a solution of methyl iodide in methanol for ten hours, and the mixture allowed to stand in the dark, with occasional shaking, for two months. The product was recovered by first removing the liquid through filtration, then adding aqueous sodium cyanide to the solid and precipitating

(Table IV). The materials had been dried at 60° and 30 mm. over phosphorus pentoxide for twenty-four hours. The alginic acid, the nitrated alginic acid and the material methylated by means of dimethyl sulfate and sodium hydroxide were dissolved in aqueous sodium hydroxide, using just enough base to effect solution. The product obtained by the use of diazomethane was dispersed in water. Observations were limited to very dilute solutions, 0.3%, because at higher concentrations the Tyndall effect was so pronounced that satisfactory readings could not be made.

Titration.—The neutralization equivalent of nitrated alginic acid dried at 60° and 30 mm. over concd. sulfuric acid and solid caustic was determined by titrating a solution of the sample in acetone, obtained by shaking for about two hours, with standard base to a phenolphthalein end-point. The combined neutralization–saponification equivalent was obtained by heating the sample with an excess (10%) of aqueous standard base for four hours on a steam-bath, and back titrating. The equivalent weights are shown in Table V. The calculations were made thus:

Neutralization equivalent = $158 + (NO_3/C_6 \times 45)$

Combined neutralization–saponification equivalent = neut. equiv./$(1 + NO_3/C_6)$.

TABLE IV

Material	Description Table	No.	Solvent	Concn., %	Rotation α	$[\alpha]^{25}D$	$[M]^{25}D \times 10^{-3}$

Nitrated product	I	5	Aq. NaOH	.300	.34	−113	−22
Nitrated product	I	10	Aq. NaOH	.300	.33	−110	−22
Methylated product	II	1	Aq. NaOH	.300	.29	− 97	−16
Methylated product	II	3	H_2O	.300	.35	−117	−23
Methylated product	II	3	H_2O	.300	.35	−117	−23

the sodium salt of partially methylated alginic acid by the addition of ethyl alcohol to the cyanide solution. After centrifuging and washing the resulting gelatinous precipitate with small amounts of water, dilute hydrochloric acid was added. The gelatinous material was centrifuged, washed with a small amount of water, then with ether, and dried over concd. sulfuric acid at 30 mm.

Methylation of different specimens of nitrated alginic acid was carried out in three different ways as shown in Table III. The product from methanolic hydrogen chloride was precipitated by the addition of ether, thoroughly washed with ether and dried at 30 mm. over solid sodium hydroxide and concd. sulfuric acid. The aqueous solution from dimethyl sulfate treatment was acidified and the residue remaining after centrifuging was washed with 25% ethanol–water and dried at 30 mm. over sulfuric acid. The acetone solution from the treatment with silver oxide and methyl iodide was diluted with methanol, precipitated with ether and dried as above.

Ammonolysis.—Ammonolysis of methylated alginic acid was carried out by allowing the material to stand with concd. ammonium hydroxide for twenty-four hours. The resulting viscous liquid was acidified, the precipitated acid was washed several times with 50% ethanol–water, then with ether, and dried as usual. The recovery was approximately 60%. The methoxyl content was determined as before.[13] The results are shown in Table II. That the reaction was essentially complete is shown by the small drop in methoxyl content on a second twenty-four-hour treatment (8.16 to 7.96% OCH_3).

Other Derivatives.—Attempts to prepare products soluble in acetone by the action of benzoyl chloride, benzyl chloride and phenacyl bromide on sodium alginate were not successful.

Optical Rotations.—Optical rotations were observed on alginic acid, on two different specimens of nitrated alginic acid and on two specimens of methylated alginic acid

Discussion

The various specimens of nitrated alginic acids are much alike in properties. They dissolve in aqueous sodium carbonate, from which they are precipitated on acidification. They are readily soluble in acetone, methanol and ethanol, less readily in 1-propanol, dioxane and methyl iodide, and but slightly soluble in acetic anhydride and glacial acetic acid. They are insoluble in ethyl ether, isopropyl ether and chloroform. These last serve to precipitate the nitrated alginic acids from their solutions in other solvents.

The extent to which nitration took place varied from 0.49 to 1.18 nitrate groups per mannuronic unit, calculated as the lactone (Table I). Addi-

tional purification by dissolving once more in acetone and precipitating with ether left the material essentially unchanged, as shown in experiments 3 and 10, for the nitrogen content in the first case changed from 7.27 to 7.02 and in the second case from 6.94 to 7.21%. The best yield was obtained in experiment 4, where the time was shortened to one hour. The extent of nitration, however, was low. When the time was lengthened the yield was less, and in a general way was lower the longer the period of standing. On the other hand, the degree of nitration usually increased as the time was lengthened.

The recovery of a small amount (2%) of material from the first acetone–ether liquor (Expt. 8, Table I) indicates that precipitation of a nitrated alginic acid from its acetone solution by the addition of ether is essentially quantitative. The recovered material analyzed 8.05% N (1.26 NO_3 per C_6 unit).

Since the maximum number of nitrate groups in the main products was essentially 1 per C_6 residue, the assumption is justified that the alginic acid while undergoing nitration was essentially in the lactone form unless the second free hydroxyl group would not nitrate under these conditions, even in the presence of a good excess of the nitrating mixture. This must be regarded as a possibility in view of the fact that with diazomethane less than one hydroxyl group was methylated (Table II). However, lactonization of alginic acid presumably would be as likely as that of nitrated alginic acid which was shown by titration to be lactonized when dried. Alginic acid being nitrated may have been lactonized during drying, or when put into the nitrating mixture.

The recovery of a small amount of higher nitrated product from the acetone–ether mother liquor (Expt. 8) would seem to indicate that higher nitration products are formed to some extent.

The various specimens of methylated alginic acid are alike in that they peptize in water but in solutions containing 25% methanol or ethanol they do not peptize. They are alike also in that they are slightly soluble in methanol and in acetone, insoluble in ethyl ether and in chloroform. They differ in that the diazomethane preparations are less soluble and do not reduce Fehling solution. The product obtained by the action of methyl sulfate and hot sodium hydroxide reduced Fehling solution. Thus the drastic conditions involved in methylating with dimethyl sulfate bring about degradation of the alginic acid molecule whereas this is not the case with diazomethane.

Ammonolysis of alginic acid methylated by diazomethane showed that in the two cases approximately 74 and 66%, respectively, of the total methylation had taken place on carboxyl groups, and 26 and 34%, respectively, on alcoholic hydroxyl groups (Table II). It showed also that in the first case 84% and in the second case 92% of the carboxyl groups had been methylated. These results are based on the assumption that only the carbomethoxy groups react with ammonia.

Methylation of specimens of nitrated alginic acid did not change the ratio of nitrate groups per C_6 unit. There is thus no replacement of these groups by methoxyl under the conditions employed (Table III). The calculation of nitrate and methoxyl content in the methylated product is made on the basis that the extent of lactone ring opening is equivalent to the degree of methylation.

From the optical data equivalent rotations $[M]^{25}D$ were calculated on the assumption that the dried samples of alginic acid, of nitrated alginic acid and of the alginic acid methylated by means of dimethyl sulfate were lactonized. However, in the solutions of these as examined the materials were lactone free since they were in the form of salts. The equivalent rotation of the product methylated with diazomethane agrees well with the rotations of the sodium salts of alginic acid and of nitrated alginic acid. Thus in the substances which essentially were lactone free (the data of Table II indicate that 92% of the carboxyl groups were methylated) and which had not suffered degradation, the equivalent rotations were in agreement.

The low equivalent rotation for the methylated product resulting from dimethyl sulfate treatment can be ascribed to degradation, for this was the only material which reduced Fehling solution. The drop in rotation may be the result of isomeric changes in the terminal mannuronic residues of the smaller degraded molecules. At one end the configuration about C-1 might change and at the other end a furanose structure might change over to a pyranose structure.[14]

From the data in Table V it is evident that when thoroughly dried, specimens of nitrated alginic acid go over to the lactone form.

(14) Levene, Meyer and Kuna[8] believe that in pectic acid some of the galacturonic units have the furanose structure.

This research was made possible by a grant from the Kelco Company of San Diego, California.

Summary

Alginic acid is converted into a nitrated alginic acid when in contact with nitric–sulfuric acid mixture. The ratio of nitrate groups per mannuronic unit, which varies from 0.49 to 1.2, largely depends upon the excess of nitric acid taken and upon the time of standing.

The failure to obtain higher nitration products is believed to be due to lactonization of the mannuronic units as the result either of drying the acid or of its coming in contact with concd. sulfuric acid.

When nitrated alginic acid is thoroughly dried lactonization of the carboxyl groups takes place.

Methylation of alginic acid by means of dimethyl sulfate and aqueous sodium hydroxide at 60° is not satisfactory since less than one methyl group per mannuronic unit is introduced, and degradation takes place.

Diazomethane is satisfactory as a methylating agent in that little or no degradation takes place. While the carboxyl group is undergoing methylation some methylation takes place on the hydroxyl group.

Nitrated alginic acid can be partially methylated but there is no replacement of nitrate by methoxyl groups.

Some Fully Acetylated Sugar Acids and their Derivatives

BY GORDON B. ROBBINS AND F. W. UPSON

Interest in the fully acetylated aldonic acids has been stimulated by Major and Cook[1,2,3] through the preparation and application to synthesis of acid chlorides of these acids. A general method of preparing fully acetylated sugar acids has been reported by Hurd and Sowden,[4] who prepared fully acetylated *d*-gluconic, *d*-galactonic and *l*-arabonic acids by treating an acetic acid solution of the acetylated acid amide with nitrous anhydride. Direct acetylation of aldonic acid amides has been shown to be a simple and general method for preparing the fully acetylated amides.[5] Various acetylated amides which had been prepared by this method have been treated according to the method of Hurd and Sowden[4] to give new fully acetylated aldonic acids.

Direct acetylation of gluconic acid has been reported to be unsuccessful by Major and Cook.[3] We have found, however, that some aldonic acids can be acetylated directly. Several of these are described in the following investigation. In addition some other fully acetylated acids hitherto unknown were prepared by the method of Hurd and Sowden. Thus tetraacetyl-*d*-arabonic, pentaacetyl-*d*-gulonic, and hexaacetyl-*d*-α-glucoheptonic acids were prepared by this procedure. A modification of the method was employed in the preparation of pentaacetyl-*d*-talonic acid and pentaacetyl-*d*-mannonic acid monohydrate. These acids were prepared by treating the reaction mixture from the acetylation of the corresponding aldonic amide with nitrous anhydride.

It was impossible to prepare hexaacetyl-*d*-α-galaheptonic acid from the corresponding amide by this method. The acetylated amide proved too insoluble in any solvents at suitable temperatures.

The unusual stability of *d*-α-galaheptonic acid suggested the possibility of direct acetylation to give the fully acetylated acid. Direct acetylation yielded hexaacetyl-*d*-α-galaheptonic acid as was indicated by comparison of the product with the acetylated lactone, analysis of the product, and its conversion into the methyl ester. Direct acetylation of *d*-arabonic, *d*-galactonic, and *d*-talonic acids likewise yielded the corresponding fully acetylated acids which were identified by comparison with the product obtained from the acetylated amide. The yields were too low to be satisfactory for the preparation of the fully acetylated *d*-galactonic and *d*-talonic acids, but proved to be the most successful method for obtaining tetraacetyl-*d*-arabonic acid.

Attempts were made to prepare fully acetylated *d*-mannonic, *d*-gulonic and *d*-α-glucoheptonic acids

by treating the sodium salts of these acids with acetic acid–acetic anhydride mixtures, but the acetylated lactone was produced in each case.

Phenylhydrazides of the fully acetylated sugar acids were prepared by acetylation of the aldonic phenylhydrazide as Major and Cook[3] have done in preparing pentaacetyl-*d*-gluconic phenylhydrazide. Methyl esters were prepared by treating the fully acetylated acid with diazomethane.

d-Arabonamide and *d*-arabonic acid have been prepared in the course of this study and are reported for the first time. The acetylated *d*-arabonic and *d*-α-galaheptonic lactones are also reported.

Experimental

***d*-Arabonamide.**—*d*-Arabonic lactone was prepared by treating glucose with oxygen in 2 *N* potassium hydroxide according to the method of Spengler and Pfannenstiel.[6] The potassium salt was transformed to the calcium salt which was decomposed with oxalic acid to yield the lactone. The lactone was dissolved in liquid ammonia. The ammonia was allowed to evaporate, and the amide was heated at 60° *in vacuo* to remove the last of the ammonia. The amide was recrystallized several times from ethanol.

Fully Acetylated Aldonic Amides (Compounds 2–4).[7]—The aldonamide (7.5 g.) was acetylated with a solution of zinc chloride (4 g.) in 50 cc. of acetic anhydride at 0°. After the amide had dissolved, the mixture was stirred with ice water and neutralized with sodium bicarbonate. The product was obtained by extraction with chloroform and evaporation of the extract.

Compound 2 was recrystallized from absolute ethanol.

Compound 3 was prepared from *d*-talonamide.[8] It did not crystallize until the extract had stood *in vacuo* for a time. It was recrystallized twice from the butyl ethyl ether of ethylene glycol.

Compound 4 was prepared from *d*-α-galaheptonamide.[9] The product separated upon stirring with water. Filtration was substituted for chloroform extraction. The product was recrystallized twice from glacial acetic acid.

***d*-Arabonic Acid.**—The calcium salt was prepared by the method described in the preparation of *d*-arabonamide. It was converted to the sodium salt by treating the calcium salt with equivalent amounts of oxalic acid and sodium bicarbonate. The solution of sodium salt was concentrated to a sirup and treated with acetic acid according to the method of Brackenbury and Upson[10] for the preparation of *l*-arabonic acid. The acid was purified in the same manner as the *l*-form.

Fully Acetylated Aldonic Acids (Compounds 7–10).—The aldonamide was acetylated under the conditions described above. After acetylation was complete, the mixture was treated with nitrous anhydride at 8–10° until it remained yellowish-green. It was allowed to stand for four hours at room temperature. The mixture was diluted with 100 cc. of water, made alkaline with sodium bicarbonate, acidified with dilute hydrochloric acid, and warmed to 40°. The mixture was cooled and extracted with chloroform. The extract was evaporated to a sirup and crystallized from water. It was recrystallized twice from water.

Compounds 7 and 8 were best prepared by the above procedure.

Compounds 6–10 were prepared by a modification of the above procedure using a solution of the pure acetylated aldonamide in glacial acetic acid. This procedure was found to be the most satisfactory for compounds 9 and 10.

Compound 9 could not be crystallized. The sirupy extract was dissolved in ether and filtered from any unreacted amide. The ethereal filtrate was evaporated to a gum and dried in an Abderhalden drier for analysis and specific rotation.

Direct Acetylation of Aldonic Acids (Compounds 6 and 11).—The aldonic acid (10 g.) was treated with a solution of zinc chloride (4 g.) in 50 cc. of acetic anhydride at 0° for two or three days. The reaction mixture was stirred with ice water and extracted with chloroform. The extract was evaporated to a gum which crystallized.

In the preparation of compound 6, the product partially separated from the acetylation mixture and was filtered off before treatment with ice water. The product was recrystallized from toluene.

Compound 11 was recrystallized from water.

Acetylated Aldonic Lactones (Compounds 12 and 13).—The aldonic lactone (5 g.) was treated with 25 cc. of acetic anhydride at 0° and allowed to stand for a day. The mixture was stirred with ice water and extracted with chloroform. The extract was evaporated to a gum which crystallized on standing. The product was recrystallized from ethanol.

In the preparation of compound 12, zinc chloride (2 g.) was used as catalyst. The lactone was prepared as described under the preparation of the amide.

Compound 13 was prepared using concentrated sulfuric acid (1 cc.) as catalyst.

Fully Acetylated Aldonic Phenylhydrazides (Compounds 14–20).—The aldonic phenylhydrazide (7.5 g.) was treated with a solution of zinc chloride (4 g.) in 50 cc. of acetic anhydride at 0°. The mixture stood for a day at room temperature. It was stirred with ice water and extracted with chloroform.

Compounds 14, 15, 16, 17, 19 and 20 were obtained in crystalline form upon evaporation of the extract. The products were recrystallized by solution in ethanol and addition of ether.

Compound 18 failed to crystallize upon evaporation of the chloroform. The gum was dried in an Abderhalden drier for analysis and specific rotation.

Methyl Esters of Fully Acetylated Aldonic Acids (Compounds 21–27).—The fully acetylated aldonic acid was dissolved in a small amount of ethanol, cooled, and treated with the amount of an ethereal solution of diazomethane[11] which was necessary to produce a persistent yellow color. The solution was filtered and evaporated. The product

crystallized during evaporation, and was recrystallized from ethanol with the addition of a small amount of petroleum ether.

Compounds 21, 22, 23, 24, 26 and 27 were prepared by the above directions, while compound 25, which failed to crystallize, was obtained by drying the gum in an Abderhalden drier for analysis and specific rotation.

Summary

1. The amides and phenylhydrazides of several fully acetylated aldonic acids have been prepared by direct acetylation of the aldonic acid derivative.

2. Pentaacetyl-*d*-mannonic acid monohydrate, pentaacetyl-*d*-talonic acid, pentaacetyl-*d*-gulonic acid and hexaacetyl-*d*-α-glucoheptonic acid hemihydrate have been prepared by treating the corresponding acetylated amide with nitrous anhydride.

3. Direct acetylation of aldonic acids to the fully acetylated acids has been reported for the first time. Tetraacetyl-*d*-arabonic and hexaacetyl-*d*-α-galaheptonic acids have been prepared in good yield by this method.

4. Methyl esters of several fully acetylated aldonic acids have been prepared by treating a solution of the acid with a solution of diazomethane.

5. *d*-Arabonamide, *d*-arabonic acid, triacetyl-*d*-arabonic lactone, and pentaacetyl-*d*-α-galaheptonic lactone have been prepared.

LINCOLN, NEBRASKA RECEIVED JANUARY 29, 1940

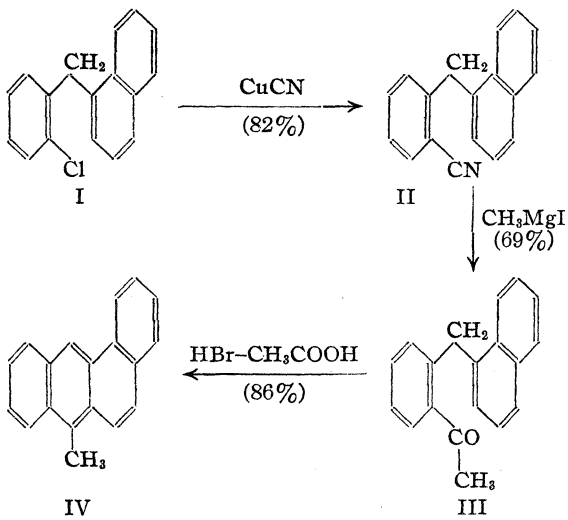
9-Methyl- and 10-Methyl-1,2-benzanthracene

BY CHARLES K. BRADSHER

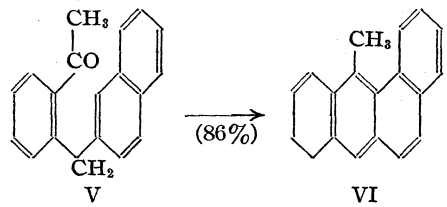
Recently[1] we have shown that *o*-benzylphenyl ketones may be cyclized to form 9-alkyl- and 9-arylanthracene hydrocarbons. The demonstrated[2] importance of *meso* substitution as a source of carcinogenic activity in derivatives of 1,2-benzanthracene made it of interest to attempt the application of the new reaction to this series.

Two carcinogenic hydrocarbons, 9-methyl- and 10-methyl-1,2-benzanthracene have now been prepared in this manner.



In the synthesis of the 10-methylbenzanthracene (IV), the crude carbinol produced by the action of α-naphthylmagnesium bromide on *o*-chlorobenzaldehyde was reduced with red phosphorus and iodine to give 1-(*o*-chlorobenzyl)-naphthalene (I). By action of cuprous cyanide, this was converted to a nitrile (II) which upon treatment with methylmagnesium iodide afforded *o*-(1-naphthylmethyl)-acetophenone (III). Cyclization to the hydrocarbon (IV) was effected in good yield by refluxing the ketone (III) for three days in a mixture of acetic and hydrobromic acids. The over-all yield of the pure hydrocarbon was 29%, calculated from the *o*-chlorobenzaldehyde taken.

The synthesis of 9-methyl-1,2-benzanthracene (VI) was accomplished similarly, starting from β-naphthylmagnesium bromide or iodide and *o*-chlorobenzaldehyde. Reduction of the carbinol, conversion to the nitrile and treatment with methylmagnesium iodide gave *o*-(2-naphthylmethyl)-acetophenone (V), which was cyclized easily to the expected hydrocarbon (VI).



Although the yield in the ring closure was exactly the same, the over-all yield was somewhat less than in the preparation of the isomer. It is interesting to note that only twenty-four hours were required for cyclization, undoubtedly due to the great reactivity of the *alpha* position in the naphthalene nucleus.[3] A parallel observation has been made in the case of the Elbs reaction.[4]

We feel that the new synthesis not only affords an eminently satisfactory route to 10-methyl-1,2-benzanthracene, but gives promise of providing a useful tool for the synthesis of new carcinogenic and antigenic compounds.

The author is indebted to Professor Louis F. Fieser, who has established the identity of the hydrocarbons prepared by comparing them with authentic specimens.

Experimental

1-(*o*-Chlorobenzyl)-naphthalene (I).—A Grignard reagent was prepared in dry ether from 45.5 g. of α-naphthyl bromide and 5.4 g. of magnesium. To this was added an ethereal solution containing 28.1 g. of *o*-chlorobenzaldehyde and the mixture allowed to stand overnight. The mixture was then decomposed with a 20% solution of ammonium chloride and the ethereal layer separated and concentrated on the steam-bath. The residue was dissolved in 500 cc. of acetic acid, and 10 g. of iodine, 10 g. of red phosphorus and 50 cc. of water added. This mixture was refluxed for twenty-seven hours and then the excess phosphorus was filtered off by suction. A quantity of ice was added to the filtrate and the mixture extracted with ether. The ethereal extract was freed of acetic acid and iodine by extraction with iced 10% sodium hy-

droxide solution, dried, concentrated and the residue distilled under reduced pressure. The product was a water-white liquid, b. p. 189–192° (2 mm.); yield 30.5 g. (60%).

Anal.[5] Calcd. for $C_{17}H_{13}Cl$: C, 80.76; H, 5.19. Found: C, 80.88; H, 5.12.

o-(1-Naphthylmethyl)-benzonitrile (II).—A mixture of 25.3 g. of the chloro compound (I) obtained above with 10.8 g. of cuprous cyanide and 10 cc. of pyridine was heated under an air condenser for thirty hours at 250–260°. It was then poured on a mixture of ice and sodium hydroxide and the mixture extracted with benzene. The benzene layer was filtered and then washed with dilute hydrochloric acid, water, and finally saturated sodium chloride solution. The benzene was then evaporated and the residue distilled under reduced pressure. The product was a viscous amber-colored oil, b. p. 216–217° (3 mm.), which solidified upon seeding. This material was pure enough for further reactions. A sample crystallized from ether–petroleum ether was obtained as stout prisms, m. p. 59–60°.

Anal. Calcd. for $C_{18}H_{13}N$: C, 88.85; H, 5.39. Found: C, 88.90; H, 5.46.

o-(1-Naphthylmethyl)-acetophenone (III).—A Grignard reagent was prepared from 28.4 g. of methyl iodide and 4.9 g. of magnesium. Most of the ether was distilled off and 12.2 g. of the nitrile (II) obtained above added in 150 cc. of dry benzene and the mixture refluxed overnight. After decomposition of the reaction mixture with ammonium chloride solution, the imine was extracted from the benzene layer with 2 *N* hydrochloric acid. To this acid extract, 50 cc. of concentrated hydrochloric acid was added and the mixture refluxed for one hour. The ketone thus liberated was taken up in ether. The ethereal extract was washed, dried and concentrated. The residue, distilled under reduced pressure, gave 8.9 g. (69%) of a viscous, nearly colorless liquid, b. p. 216–217° (3 mm.). This liquid was used for the cyclization experiments, but the ketone could be crystallized from ether–petroleum ether as colorless blades, m. p. 39–40°.

Anal. Calcd. for $C_{19}H_{16}O$: C, 87.66; H, 6.19. Found: C, 87.53; H, 6.29.

10-Methyl-1,2-benzanthracene (IV).—Two grams of the ketone (III) was refluxed for three days in a mixture containing 20 cc. of acetic acid and 20 cc. of 34% hydrobromic acid. At the end of this period, the hydrocarbon had crystallized from the boiling liquid. The mixture was cooled and the methylbenzanthracene collected. Once recrystallized from ethanol, it was obtained as yellow needles, m. p. 139–140° (cor.), and gave no depression of melting point when mixed with an authentic sample of 10-methyl-1,2-benzanthracene. The yield was 1.6 g. (86%), but a further quantity (0.19 g., m. p. 138–139°) could be obtained by concentration of the mother liquor.

Anal. Calcd. for $C_{19}H_{14}$: C, 94.18; H, 5.82. Found: C, 94.22; H, 5.96.

2-(o-Chlorobenzyl)-naphthalene.—A Grignard reagent was prepared in ether from 28.0 g. of β-iodonaphthalene and 2.7 g. of magnesium. An ether solution containing 14.4 g. of *o*-chlorobenzaldehyde was added and the mixture worked up as in the case of the isomer (I). The crude carbinol was reduced with red phosphorus and iodine, and the product distilled under reduced pressure. It was obtained as a nearly colorless oil, b. p. 203–204° (3 mm.); yield 7.9 g. (31%). This material was pure enough for further reaction, but could be separated from a small amount of high melting material (β,β'-dinaphthyl?) by addition of petroleum ether followed by cooling at 0° for twenty-four hours. The impurity crystallized and could be removed by filtration. Concentration of the filtrate followed by redistillation gave material of analytical purity.

Anal. Calcd. for $C_{17}H_{13}Cl$: C, 80.76; H, 5.19. Found: C, 80.89; H, 5.10.

In a single small scale experiment, starting from 9.1 g. of β-bromonaphthalene, the 2-naphthyl-(*o*-chlorophenyl)-methane was obtained in a yield of 3.5 g. (35%).

o-(2-Naphthylmethyl)-benzonitrile.—A mixture of 20.2 g. of 2-(*o*-chlorobenzyl)-naphthalene, 9.0 g. of cuprous cyanide and 10 cc. of pyridine was heated for thirty hours at 250–260° and then worked up as in the case of the isomer (II). The product, b. p. 223–226° (3 mm.), solidified immediately on cooling; yield 11.1 g. (57%). This material was used without further purification in the following reaction, but could be crystallized from methanol as colorless prisms, m. p. 84.5–85.5°.

Anal. Calcd. for $C_{18}H_{13}N$: C, 88.85; H, 5.39. Found: C, 88.87; H, 5.01.

o-(2-Naphthylmethyl)-acetophenone (V) was prepared from 9.75 g. of *o*-(2-naphthyl)-benzonitrile by the Grignard reaction in the same manner as that employed in the preparation of the isomer (III). Distilled under reduced pressure, it was obtained as a yellow, slightly fluorescent oil, b. p. 221° (3 mm.); yield 5.5 g. (52%).

Anal. Calcd. for $C_{19}H_{16}O$: C, 87.66; H, 6.19. Found: C, 87.82; H, 5.99.

9-Methyl-1,2-benzanthracene (VI).—Two grams of the ketone (V) obtained above was refluxed in a mixture of 20 cc. of acetic acid and 20 cc. of 34% hydrobromic acid. At the end of seventeen hours, the hydrocarbon solidified and after a total of twenty-four hours, refluxing was discontinued. Recrystallization of the material from methanol gave 1.6 g. (86%) of irregular, lemon-colored plates, m. p. 137.5–138.5° (cor.). This material gave no depression of melting point when mixed with an authentic specimen of 9-methyl-1,2-benzanthracene.

Anal. Calcd. for $C_{19}H_{14}$: C, 94.18; H, 5.82. Found: C, 94.00; H, 6.00.

Summary

Using a previously described method for the synthesis of *meso* substituted anthracene hydrocarbons, two carcinogenic compounds, 9-methyl- and 10-methyl-1,2-benzanthracene have been prepared.

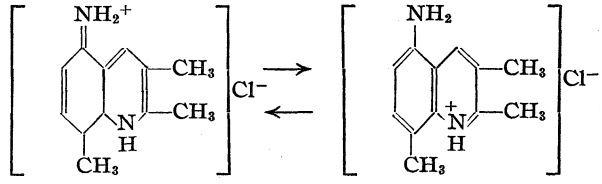
Petroleum Bases. I. Reactions of 2,3,8-Trimethylquinoline

BY ALFRED BURGER AND LUTHER R. MODLIN, JR.

Several polyalkyl pyridine and quinoline derivatives which are not easily accessible by synthetic approaches have become available recently by the separation of basic straight run and cracked petroleum fractions. Bailey and his co-workers[1] have published a long series of interesting articles dealing with the separation and the structure of individual nitrogen-containing constituents of these fractions. It seemed worth while to investigate whether some of the bases from kerosene containing the quinoline nucleus would lend themselves to the preparation of substances of pharmacological interest, since quinoline is the classical heterocyclic system encountered in a wide variety of medicinally important products.[2] One of the most readily available kerosene bases, 2,3,8-trimethylquinoline,[3] was chosen therefore as the starting material for our studies. This communication describes several reactions of this base leading to derivatives needed in the preparation of such substances which will be the subject of forthcoming publications from this Laboratory.

Nitration of 2,3,8-trimethylquinoline (I) with fuming nitric acid furnished 5-nitro-2,3,8-trimethylquinoline (II) in almost quantitative yield. Reduction of this nitro compound with stannous chloride led to the corresponding amine (III), while hydrogenation in neutral solvents in the presence of a platinum oxide catalyst not only reduced the nitro group, but also attacked the pyridine nucleus. When the reaction was interrupted after absorption of only three moles of hydrogen, the amino compound III could be isolated in yields of around 60%. Hydrogenation in the presence of Raney nickel recently recommended by Winterbottom[4] was abandoned when more than three moles of hydrogen was absorbed, and the unhydrogenated amine III could not be isolated from the reaction mixture.

The mono-hydrochloride of 2,3,8-trimethyl-5-aminoquinoline exhibits a deep brick-red color. When hydrochloric acid is added to the colored aqueous solution of this salt, the color disappears almost completely; when a sodium carbonate solution is added carefully to the resulting colorless acidic solution, the deep red color reappears, and vanishes only when the solution turns alkaline, and the base precipitates. The deep red color of the mono-hydrochloride may be explained by oscillation of the anion between the two nitrogen atoms; the salt may thus exist in resonating forms



A survey of some known 5- and 8-aminoquinoline derivatives revealed that a deepening of the color from diacidic toward monoacidic salts has been observed in several instances.[5] However, a similar change in color has been reported in the case of the salts of 6-aminolepidine.[6] In this case, a resonating system which would disappear upon addition of a second molecule of the acid cannot be held responsible for the deeper color of the monoacidic salts, because position-2 in the pyridine nucleus would be unable to hold a second hydrogen atom if the cyclic nitrogen atom assumed a positive charge.

5-Hydroxy-2,3,8-trimethylquinoline (IV), prepared from the amine III by diazotization, was converted into the methyl ether (V) by the action of diazomethane. The structure of 5-methoxy-2,3,8-trimethylquinoline was established by synthesis from 4-methoxy-2-aminotoluene and tiglic aldehyde.[7] The base obtained in this condensation, and its picrate, proved to be identical with V, and its picrate, respectively. This also establishes the position of the functional substituents in the related nitro (II), amino (III), and hydroxy (IV) derivatives. Attempts to prepare 5-nitro-2,3,8-trimethylquinoline (II) by condensation of 2-amino-4-nitrotoluene with tiglic aldehyde failed

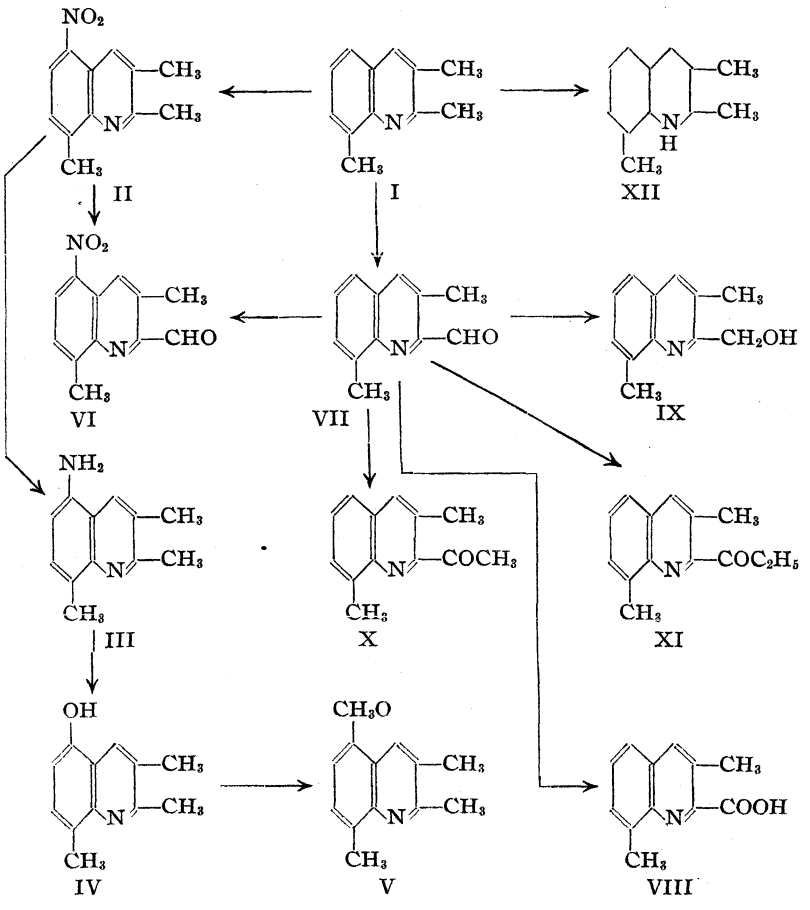
to yield well-defined products, probably because the nitro group of the starting material is reduced during the dehydrogenation of the intermediate dihydroquinoline derivative. Addition of arsenic acid[8] during the condensation caused extensive formation of resins and failed to improve the yield.



2,3,8-Trimethylquinoline exhibits the normal reactivity of quinaldine derivatives: for example, the 2-methyl group may be condensed with carbonyl compounds.[3] This methyl group is also the only one which is attacked by selenium dioxide. Oxidation of the base with this reagent, previously employed in similar cases,[9] proceeded very smoothly and furnished 3,8-dimethylquinoline-2-aldehyde (VII) in good yield. The position of the aldehyde group was confirmed by oxidizing the compound with silver oxide[10] to 3,8-dimethylquinoline-2-carboxylic acid (VIII).[3] Concentrated nitric acid did not oxidize the aldehyde group but caused quantitative mono-nitration of the compound. The nitro derivative thus obtained proved to be identical with 5-nitro-3,8-dimethylquinoline-2-aldehyde (VI) which had been prepared by oxidation of 5-nitro-2,3,8-trimethylquinoline (II) with selenium dioxide. Thus, the para-orienting influence of the 8-methyl group, and the ortho–para-orienting effect of the heterocyclic nucleus combine to determine the position of the entering nitro group, regardless of the type of substituent in position-2.

Catalytic reduction of 3,8-dimethylquinoline-2-aldehyde (VII) yielded 3,8-dimethylquinoline-2-methanol (IX) which contains a β-amino alcohol arrangement, —N=C—CH_2OH, and may be expected to exert some influence on blood pressure and peristalsis. We attempted to prepare the 5-amino derivative of the alcohol IX by catalytic reduction of the nitro aldehyde VI, but although the calculated amount of hydrogen was absorbed, no crystalline reaction product could be isolated. Reduction of VI to the corresponding amino aldehyde by various methods did not furnish well-defined products either.

3,8-Dimethylquinoline-2-aldehyde (VII) served as a convenient starting material in the preparation of α-quinolyl ketones. This class of compounds is not very easily accessible, and the reaction described here, namely, the action of diazoalkanes on a quinoline-2-aldehyde, may facilitate the approach to such substances. Diazomethane furnished a complex mixture containing moderate amounts of 3,8-dimethyl-2-quinolyl methyl ketone (X), while the main fraction consisted of high-boiling oils, perhaps polymers of the primary reaction products, namely, compounds of ethylene oxide character. Diazoethane gave a satisfactory yield of 3,8-dimethyl-2-quinolyl ethyl ketone (XI); both ketones were characterized by their oximes. The reaction of 3,8-dimethylquinoline-2-aldehyde with

diazoalkanes compares with that of some aromatic aldehydes, for example, piperonal,[11] which also reacts with diazomethane to yield ethylene oxide derivatives chiefly, while the corresponding aryl ethyl ketone is the main product of the reaction with diazoethane.

Taylor, Winckles and Marks[12] found that quinoline-2-aldoxime can form chelated metal compounds, and concluded that it must have the *cis* configuration. 3,8-Dimethylquinoline-2-aldoxime and its 5-nitro derivative also give color reactions and precipitates with a number of metallic ions. This would indicate that our aldoximes also are *syn*-oximes. The oximes of 3,8-dimethyl-2-acetylquinoline (X) and 3,8-dimethyl-2-propionylquinoline (XI), on the other hand, did not exhibit any reactions with metallic ions.

Hydrogenation of 2,3,8-trimethylquinoline in glacial acetic acid solution under ordinary pressure in the presence of a platinum oxide catalyst furnished 2,3,8-trimethyldecahydroquinoline (XII) in good yield. This compound may exist in a *cis*- and a *trans*-form. While the melting points of various fractions of the hydrochloride seem to indicate differences which may be attributed to a partial separation of the stereoisomers by fractional crystallization, a final evaluation of this separation must await future experimental results.

Acknowledgment.—The authors wish to thank Professor J. R. Bailey of the University of Texas, and the Union Oil Company of California for supplying the kerosene base used in this investigation.

Experimental

3,8-Dimethylquinoline-2-aldehyde (VII).—A solution of 5 g. of 2,3,8-trimethylquinoline and 3.5 g. of selenium dioxide in 40 ml. of ethanol was boiled under reflux for six hours, and the precipitated selenium was filtered from the hot solution. The filtrate was concentrated and 3.3 g. of the aldehyde was collected as straw-colored needles. The mother liquor was precipitated with water, the reddish solid was filtered, dissolved in 10 ml. of benzene, and the solution shaken with 30 ml. of a saturated solution of sodium bisulfite for one hour. The crystalline addition product was filtered, washed with ether, and decomposed with a dilute sodium carbonate solution. Another 1.2 g. of the aldehyde was obtained in this manner, the yield totalling 82%. The aldehyde was purified by distillation under 1 mm. pressure, and recrystallization from ethanol. It appeared as long colorless needles, m. p. 107–108°.

Anal.[13] Calcd. for $C_{12}H_{11}NO$: C, 77.80; H, 5.99. Found: C, 77.85; H, 6.18.

The oxime was prepared by the method of Bachmann and Boatner.[14] It crystallized from ethanol as almost colorless needles, m. p. 172–174°.

Anal. Calcd. for $C_{12}H_{12}N_2O$: C, 71.96; H, 6.04. Found: C, 71.87; H, 5.99.

The **semicarbazone** was prepared by heating equimolecular amounts of the aldehyde and semicarbazide hydrochloride in dilute ethanol solution for five minutes The alcohol was boiled off, the solution neutralized with sodium bicarbonate and allowed to cool. The semicarbazone crystallized in little colorless needles which, after recrystallization from dilute ethanol, sintered at 185°, m. p. 190–192° (dec.).

Anal. Calcd. for $C_{13}H_{14}N_4O$: N, 23.14. Found: N, 23.82.

3,8-Dimethylquinoline-2-methanol (IX).—A solution of 5.0 g. of 3,8-dimethylquinoline-2-aldehyde in 150 ml. of ethanol was hydrogenated in the presence of 0.2 g. of a platinum oxide catalyst. Absorption of one mole of hydrogen was completed in ten minutes. After filtration from the catalyst, the solvent was evaporated under reduced pressure at 40°, and the crystalline residue was dissolved in low-boiling petroleum ether. A small amount of a white insoluble material was removed by filtration, the solution was concentrated, and the carbinol crystallized as colorless prisms, m. p. 68–69°. The yield was 90%.

Anal. Calcd. for $C_{12}H_{13}NO$: C, 76.96; H, 7.00. Found: C, 76.95; H, 7.34.

The **hydrochloride** was prepared by the action of ethanolic hydrogen chloride on the base and recrystallized from ethanol. It consisted of colorless water soluble crystals which sintered at 160°, m. p. 176–185° (dec.). The aqueous solution turned yellow on standing, but the color could be removed by extraction into ether.

Anal. Calcd. for $C_{12}H_{14}ClNO$: N, 6.27. Found: N, 6.57.

The **acetyl derivative** was obtained by allowing the carbinol to stand with an excess of acetic anhydride in pyridine solution overnight, and working up the mixture in the usual manner. It was recrystallized from dilute ethanol and appeared as colorless needles, m. p. 62–63°.

Anal. Calcd. for $C_{14}H_{15}NO_2$: C, 73.32; H, 6.60. Found: C, 73.46; H, 6.36.

Oxidation of 3,8-Dimethylquinoline-2-aldehyde.—Two-tenths gram of the aldehyde and 0.08 g. of freshly prepared silver oxide in 10 ml. of ethanol was heated under reflux for three hours. Alkaline water was added, the coagulated silver precipitate was filtered, and the filtrate was concentrated to 10 ml. Acidification with acetic acid and scratching caused 3,8-dimethylquinoline-2-carboxylic acid (VIII) to crystallize in good yield. Crystallization from a few milliliters of water yielded colorless needles, m. p. 154–155°. The melting point reported by Bailey[3] is 157°.

3,8-Dimethyl-2-quinolyl Methyl Ketone (X).—A solution of 1 g. of 3,8-dimethylquinoline-2-aldehyde in 20 ml. of

ether and 4 ml. of methanol was treated with an ethereal solution of about 0.6 g. of diazomethane. Nitrogen began to evolve soon, and the solvent was evaporated after sixteen hours. The semi-oily residue was fractionated under 1 mm. pressure. A mostly crystalline fraction distilled first; the major fraction consisted of a brown oil of high boiling range. The crystalline fraction was recrystallized from dilute methanol and yielded 0.2 g. of yellowish needles, m. p. 90°.

Anal. Calcd. for $C_{13}H_{13}NO$: C, 78.35; H, 6.58. Found: C, 78.58; H, 6.66.

The **oxime,** prepared in ethanol–pyridine solution,[13] was crystallized from dilute methanol; colorless, m. p. 153–154°.

Anal. Calcd. for $C_{13}H_{14}N_2O$: C, 72.85; H, 6.59. Found: C, 72.80; H, 6.59.

3,8-Dimethyl-2-quinolyl Ethyl Ketone (XI).—Five-tenths gram of 3,8-dimethyiquinoline-2-aldehyde was dissolved in a solution of diazoethane (from 2 ml. of nitrosoethylurethan) in 30 ml. of ether. A vigorous reaction started soon and was completed by addition of 2 ml. of methanol. After standing overnight, the decolorized solution was evaporated, and the crystalline residue was recrystallized from slightly dilute methanol. The ketone appeared as colorless prisms, m. p. 80°. The yield was 52%.

Anal. Calcd. for $C_{14}H_{15}NO$: C, 78.83; H, 7.09. Found: C, 79.01; H, 7.10.

The **oxime** was obtained from dilute methanol as colorless crystals, m. p. 146–148°.

Anal. Calcd. for $C_{14}H_{16}N_2O$: C, 73.64; H, 7.07. Found: C, 73.49; H, 6.96.

5-Nitro-2,3,8-trimethylquinoline (II).—Twenty grams of 2,3,8-trimethylquinoline was added gradually to 200 ml. of fuming nitric acid (*d* 1.49). The solution became hot and was heated on a steam-bath for five hours. It was poured into 200 ml. of water, and the mixture was made alkaline with sodium hydroxide solution. Recrystallization from dilute ethanol rendered pale yellow needles, m. p. 124°, in a yield of 98%.

Anal. Calcd. for $C_{12}H_{12}N_2O_2$: C, 66.63; H, 5.60; N, 12.96. Found: C, 66.69; H, 5.60; N, 12.91.

5-Nitro-3,8-dimethylquinoline-2-aldehyde (VI).—(a) Thirteen and two-tenths grams of 3,8-dimethylquinoline-2-aldehyde was boiled under reflux with 132 ml. of fuming nitric acid (d. 1.49) for five hours, and the solution was poured into ammoniacal water. The nitro-aldehyde was crystallized from dilute ethanol and appeared as almost colorless felted needles, m. p. 165°. The compound contained one molecule of ethanol of crystallization. The yield was 85%.

Anal. Calcd. for $C_{12}H_{10}N_2O_3 \cdot C_2H_6O$: C, 60.84; H, 5.84. Found: C, 60.71; H, 5.63.

Ethanol of crystallization was lost when the compound was heated at 100° under 1 mm. pressure for one hour. The substance melted at 167°.

Anal. Calcd. for $C_{12}H_{10}N_2O_3$: C, 62.58; H, 4.38. Found: C, 62.39; H, 4.05.

(b) One half gram of 2,3,8-trimethyl-5-nitroquinoline was heated with 0.3 g. of selenium dioxide in 20 ml. of ethanol for fifty hours. After filtration from selenium, the solution was concentrated, and a brown oil precipitated which solidified on standing. After several crystallizations from ethanol–water the nitro-aldehyde was obtained in a yield of 38%; m. p. 164–165°. A mixture melting point with the substance obtained by procedure (a) showed no depression.

The **oxime** crystallized from dilute ethanol as a slightly yellow powder, m. p. 180–181°.

Anal. Calcd. for $C_{12}H_{11}N_3O_3$: C, 58.75; H, 4.52. Found: C, 58.64; H, 4.64.

The oximes of the aldehydes VI and VII undergo a number of reactions with metallic ions which are listed in Table I furnished by Dr. Lyle G. Overholser.

2,3,8-Trimethyl-5-aminoquinoline (III).—Two grams of 2,3,8-trimethyl-5-nitroquinoline was added to a solution of 8,5 g. of stannous chloride in 16 ml. of 17% hydrochloric acid, and the solution was heated on a steam-bath for three hours. A small amount of an orange-colored double salt separated out and was brought into solution by dilution with 25 ml. of water. The amino compound was precipitated by the addition of strong sodium hydroxide solution and was purified by sublimation at 100° under 0.1 mm. pressure. The yield was 97%. Recrystallization from dilute ethanol furnished yellow needles, m. p. 110–111°.

TABLE I

Metallic ion	3,8-Dimethylquinoline-2-aldoxime	3,8-Dimethyl-5-nitroquinoline-2-aldoxime
Ag^{+1}	Slight reduction on prolonged standing	Pale yellow color; pale yellow-greenish color in NH_4OH
Au^{+3}	Yellow color within one minute, yellow precipitate on standing	Pale yellow precipitate
Ce^{+4}	Yellow color, fades soon	
$Cu^{-}(NH_3)$	Green precipitate, soluble in strong NH_4OH	Slight precipitate in weak NH_4OH, no reaction in 1 *M* NH_4OH
Hg^{+2}		Slightly yellow precipitate
Ni	Pale green color in neutral solution, slight yellow-green precipitate in NH_4OH solution	Same reaction as with $Cu^{-}(NH_3)$
$OsCl_6^{-}$	Green color in HCl solution	Pale yellow precipitate in HCl, pale yellow color in KOH solution
Pd^{+2}	Stable green color	
Pt^{+4}	Pale yellow-green color in HCl solution	
S^{-}		Pale yellow color
Sn^{+2}		Orange-pink color in HCl solution

Anal. Calcd. for $C_{12}H_{14}N_2$: C, 77.36; H, 7.58. Found: C, 77.56; H, 7.45.

The **mono-hydrochloride,** prepared in ethereal solution, and recrystallized from ethanol, appeared as brick-red needles which sublimed at high temperatures without melting.

Anal. Calcd. for $C_{12}H_{15}ClN_2$: N, 12.59. Found: N, 12.13.

The **di-hydrochloride** was obtained as pale yellow crystals by treating the mono-hydrochloride with an excess of ethanolic hydrogen chloride. It loses hydrogen chloride slowly in the dry state, more rapidly in alcoholic solution, turning deep red.

Acetylation of the amine with acetic anhydride in pyridine solution yielded **2,3,8-trimethyl-5-acetaminoquinoline,** light colorless needles, m. p. 234–235°.

Anal. Calcd. for $C_{14}H_{16}N_2O$: C, 73.64; H, 7.07. Found: C, 73.73; H, 6.97.

2,3,8-Trimethyl-5-hydroxyquinoline (IV).—Five-tenths gram of 2,3,8-trimethyl-5-aminoquinoline, dissolved in 50 ml. of 5 *N* hydrochloric acid, was diazotized at 0° with a solution of 0.25 g. of sodium nitrite in 40 ml. of water. A small amount of urea was added, the solution heated to boiling, cooled, neutralized with sodium bicarbonate, and the phenolic base filtered. The yield was 76%. Sublimation at 125° and 0.1 mm. pressure yielded colorless rods, m. p. 219–219.5°.

Anal. Calcd. for $C_{12}H_{13}NO$: C, 76.96; H, 7.00. Found: C, 76.77; H, 6.81.

2,3,8-Trimethyl-5-methoxyquinoline (V).—(a) Methylation of the phenolic base IV with diazomethane in methanol–ether solution yielded the methoxy compound as colorless prisms, which were purified by sublimation at 75° and 0.01 mm. pressure, and recrystallization from dilute methanol; m. p. 80°.

Anal. Calcd. for $C_{13}H_{15}NO$: C, 77.56; H, 7.52. Found: C, 77.53; H, 7.31.

The **picrate** crystallized from methanol as short yellow prisms, m. p. 198–199°.

Anal. Calcd. for $C_{19}H_{18}N_4O_8$: C, 53.02; H, 4.22. Found: C, 53.19; H, 4.53.

(b) 2-Amino-4-methoxytoluene[15] was prepared by reduction of 2-nitro-4-methoxytoluene[16] with hydrogen in the presence of a platinum oxide catalyst in ethanol solution; the yield was 95%, m. p. 45°.

A solution of 4.2 g. (0.031 mole) of 2-amino-4-methoxytoluene and 3.5 ml. (0.031 mole) of tiglic aldehyde in 65 ml. of concentrated hydrochloric acid was heated on a steam-bath for two hours. The dark solution was diluted with water, and some unchanged methoxytoluidine was removed by diazotization and extraction of the resulting 2-hydroxy-4-methoxytoluene into ether. The solution was then made alkaline and 5-methoxy-2,3,8-trimethylquinoline was extracted into ether. It was purified by sublimation and crystallization and melted at 80°. The yield was 8%.

Anal. Calcd. for $C_{13}H_{15}NO$: C, 77.56; H, 7.52. Found: C, 77.64; H, 7.42.

The **picrate** melted at 197–199°.

Anal. Calcd. for $C_{19}H_{18}N_4O_8$: C, 53.02; H, 4.22. Found: C, 53.47; H, 4.34.

The mixture melting point of the 5-methoxytrimethylquinoline derivatives obtained (a) by degradation and (b) by synthesis, and that of their respective picrates, showed no depression.

2,3,8-Trimethyldecahydroquinoline (XII).—Five grams of 2,3,8-trimethylquinoline in 30 ml. of purified glacial acetic acid was hydrogenated in the presence of 0.4 g. of a platinum oxide catalyst. Another 0.3 g. of the catalyst had to be added to carry hydrogen absorption to completion. Five moles of hydrogen was absorbed in twenty-four hours. The catalyst was filtered, the solution was made alkaline, and the decahydro base was extracted into ether. It was fractionated under 10 mm. pressure, and the main fraction, a colorless oil of b. p. (10 mm.) 89–91°, was collected.

Anal. Calcd. for $C_{12}H_{23}N$: C, 79.48; H, 12.79. Found: C, 79.35; H, 12.39.

The **hydrochloride** was prepared in acetone–ether solution. It appeared as colorless crystals, m. p. 251–275° (dec.).

Anal. Calcd. for $C_{12}H_{24}ClN$: N, 6.44. Found: N, 6.53.

Summary

A number of reactions of the kerosene base, 2,3,8-trimethylquinoline, involving mainly positions 2 and 5 of the quinoline system, have been studied. The derivatives obtained in these reactions will serve as starting materials in the syntheses of compounds containing pharmacologically interesting groups.

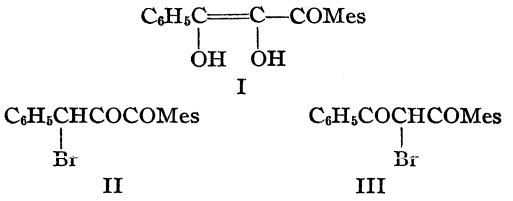
The Properties of Benzoylmesitoylmethane

BY R. P. BARNES, CHARLES I. PIERCE[1] AND CHAPPELLE C. COCHRANE[1]

In a previous paper[2] we reported the preparation and properties of an ene-diol (I), obtained from alpha-bromo benzylmesityl diketone (II). In this paper we are reporting the results of a similar investigation of the reactions of the isomeric bromobenzoylmesitoylmethane (III).

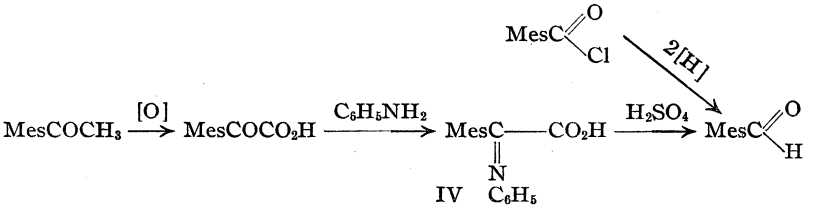


Benzoylmesitoylmethane is described by Kohler and co-workers as resulting from two series of reactions.[3,4] This substance is listed as a solid, melting at 79°, and being 100% enolic in alcoholic solution as indicated by Kurt Meyer titrations. Fuson and co-workers[5] describe mesitoylbenzoylmethane as a solid, melting at 74–77°.

In the light of the mechanism given for the formation of the enolic modification of *beta*-diketones,[6] it seemed likely that the two series of reactions as given by Kohler and his collaborators might lead to isomeric enols of benzoylmesitoylmethane. We have carried out these two series of reactions with slight modifications, exercising care to isolate the intermediates, and have found that there is only one stable enolic modification of benzoylmesitoylmethane, which is evidence that the mesityl group acts against enolization toward itself, which is in a sense hindrance to the existence of the 1,2-addition product resulting from the shift of hydrogen to the adjacent carbonyl.

Mesitylaldehyde (IV) was prepared by two methods: (1) the catalytic reduction[7] of mesitoyl chloride; and (2) the hydrolysis of the anil of mesitylglyoxylic acid obtained from the potassium permanganate oxidation of acetyl mesitylene.[8]

The preparation of the alpha-beta-unsaturated ketones (V) and (V[1]) and their corresponding dibromides (VI) and (VI[1]) was according to the methods of Kohler.[3,4] The dibromide (VI) was converted to the alpha-bromobenzalacetomesitylene (VII), by treatment with fused potassium acetate in glacial acetic acid solution. This compound was converted into the methyl ether of 1-phenyl-3-mesitylpropene-one-3-ol-1 (VIII), from which the enol, 1-phenyl-3-mesitylpropene-one-3-ol-1 (IX) was obtained by acid hydrolysis. The monobromo unsaturated compound (VII[1])



was obtained in poor yield by the potassium acetate–glacial acetic acid treatment of the parent dibromide (VI[1]). Both the mono-bromide (VII[1]) and the dibromide (VI[1]) were converted quantitatively into the methyl ether (VIII[1]) of 1-mesityl-3-phenyl-propene-one-3-ol-1 by treatment with sodium methylate. Acid hydrolysis of this methyl ether resulted in the enol (IX), 1-phenyl-3-mesitylpropene-one-3-ol-1.

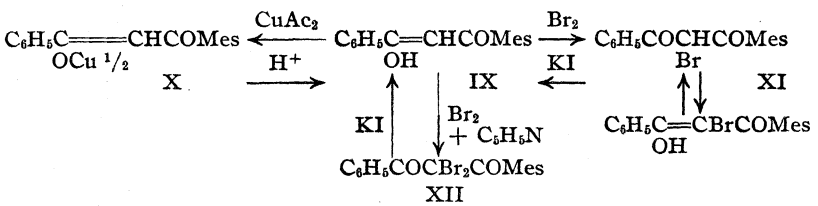
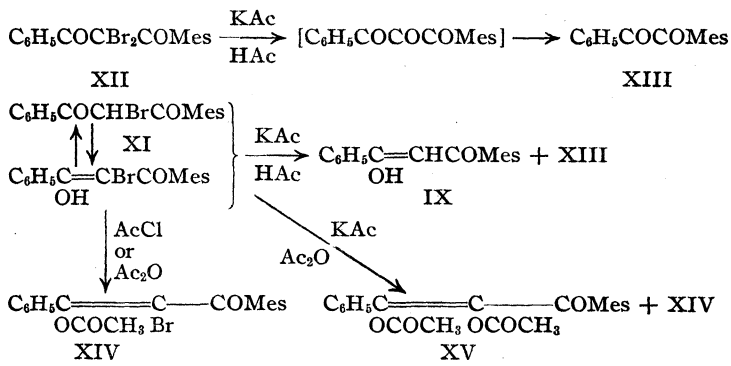
Enol (IX) gives a copper derivative (X) with copper acetate, from which the parent enol is regenerated.

This enol cannot be brominated completely to the monobromo compound by the direct addition of bromine to solutions of the enol, because the bromo compound is easily reduced by the hydrogen bromide formed. In solution in chloroform in the presence of a suspension of calcium carbonate, however, the enol is brominated quantitatively to the monobromo compound (XI), which is a colorless solid, enolic[9] to the extent of 24% in alcoholic solution. In acetic acid solution in the presence of pyridine, enol (IX) is brominated to the dibromo compound (XII).



The dibromo compound (XII) is converted to the diketone (XIII) on treatment with potassium acetate in glacial acetic acid. When the monobromo compound is treated similarly there results a mixture of the parent enol and the diketone (XIII). This is explained in terms of the equilibrium (KBr + HAc $\rightleftarrows$ KAc + HBr), the hydrogen bromide reducing the monobromo compound, and hydrolyzing any diacetate that might be formed, it being subsequently oxidized to the diketone.

The monobromo compound (XI) is acetylated[10] by both acetyl chloride and acetic anhydride to the acetate (XIV), which is not reduced by potassium iodide.



Since we could not obtain the carbinol acetate of benzoylmesitoylmethane by acetylation of the monobromo compound with potassium acetate and glacial acetic acid, we sought a solvent which would not furnish an active hydrogen. Thus the choice of acetic anhydride[10] which, in the presence of freshly fused potassium acetate, yields a mixture of the monobromo acetate (XIV) and the diacetate (XV) of mesitoylphenylacetyleneglycol.[2] The monobromo acetate (XIV), does not suffer further acetylation, since this reaction would necessarily involve a metathesis, and halogen atoms in the system, $\rangle C{=}C\overset{\diagup}{Br}$, which cannot relieve itself by rearrangement, do not take part in double decomposition reactions. Thus the acetylation process must involve two competitive reactions: first, direct esterification of the alpha-bromo ketone itself by splitting out potassium bromide resulting in the carbinol acetate which is subsequently esterified to the diacetate[10]; second, acetylation of the enolic modification of the alpha-bromo ketone, which is not further acetylated.

Further work is now in progress with 2,4,6-trimethylbenzyl phenyl diketone, the alpha diketone isomeric with mesitylbenzylglyoxal,[11] and with 2,4,6-trimethylbenzyl mesityl glyoxal.

Experimental

Preparation of Mesitylaldehyde.—(I) A solution of 90 g. of mesitoyl chloride in 270 g. of faultlessly dry xylene together with 20 g. of palladized barium sulfate was refluxed gently while a stream of dry oxygen-free hydrogen was passed through the solution. The process was continued until hydrogen chloride ceased to be evolved, about eighteen hours. The catalyst was filtered off and the filtrate distilled. The mesitylaldehyde came over at 96–98° (6 mm.). The yield was 60 g., which was 80%.

(II) A chilled mixture of 50 g. of acetylmesitylene and 200 cc. of water was treated dropwise with rapid stirring with a solution of 100 g. of potassium permanganate and 32 g. of potassium hydroxide in 3000 cc. of water. The manganese dioxide was filtered off and washed with water and the pale green solution was made strongly acid with concd. sulfuric acid and allowed to stand in the ice box overnight. A yellow oil consisting of a mixture of trimethylbenzoic, trimethylmandelic and mesitylglyoxylic acids separated out and crystallized. The mixed acids were filtered off and dried, weighing 31 g. The filtrate was extracted with ether, dried over anhydrous sodium sulfate and evaporated, yielding 19–20 g. Assuming the

(9) All titrations were done as by S. R. Cooper and R. P. Barnes, *Ind. Eng. Chem., Anal. Ed.*, **10**, 379 (1938).

(10) THIS JOURNAL, **62**, 894 (1940).

(11) R. P. Barnes, *ibid.*, **57**, 937 (1935).

total mixed acids to be mesitylglyoxylic acid, it was heated to boiling for thirty minutes with the calculated amount of aniline. The yellow solution was cooled, taken up in ether, and washed with dilute hydrochloric acid to remove the excess aniline. The ether was evaporated and the residual yellow oil warmed with 25 g. of concd. sulfuric acid. The dark red solution was allowed to cool and was taken up in the ether and washed with water to remove the excess sulfuric acid and aniline sulfate. Finally the trimethylbenzoic and trimethylmandelic acids were washed out with bicarbonate solution. The ethereal solution was dried over anhydrous sodium sulfate and distilled. The yield was 22.5–23.5 g. of mesitylaldehyde, boiling at 96–98° (6 mm.). This was 50% of the theoretical.

alpha-Bromobenzalacetomesitylene (VII).—To a solution of 234 g. of freshly fused potassium acetate in 500 cc. of hot glacial acetic acid was added 117 g. of dibromobenzalacetomesitylene. The mixture was refluxed for thirty minutes. The solution turned yellow and potassium bromide separated out. When cold the contents of the flask were poured into a large volume of water. A light brown oil separated out which upon stirring and cooling soon crystallized. The yield was 85–86 g. of crude material which was 91–92% of the theoretical. This solid was crystallized from the least amount of hot methyl alcohol, yielding 80–81 g. of lemon yellow solid, melting at 86°.

Anal. Calcd. for $C_{18}H_{17}OBr$: C, 65.6; H, 5.2. Found: C, 65.3; H, 5.1.

This monobromo compound reduces permanganate and decolorizes chloroform solutions of bromine. Phenylmagnesium bromide converts it into alpha-bromo-beta-phenylbenzylacetomesitylene.[12]

alpha-Bromo 2,4,6-Trimethylbenzalacetophenone (VII[1]).—A solution of 100 g. of fused potassium acetate and 50 g. of the dibromide in 250 cc. of glacial acetic acid was treated as indicated in the preparation of alpha-bromobenzalacetomesitylene. A yellow oil resulted from the water treatment. Extraction with ether, washing, drying and concentrating yielded 3.1 g. of pale yellow solid melting at 98° and mix-melting with the parent alpha-beta-unsaturated ketone at 98°. Further concentration produced a crystalline solid which when recrystallized from methyl alcohol amounted to 7.1 g., melted sharply at 95°, and mix-melted with the parent alpha-beta-unsaturated ketone at 73–85°.

Anal. Calcd. for $C_{18}H_{17}OBr$: C, 65.6; H, 5.2. Found: C, 65.7; H, 5.5.

It decolorizes permanganate and bromine solutions.

The Methyl Ether of 1-Mesityl-3-phenyl-propene-one-3-ol-1 (VIII[1]).—A solution of 1 g. of the monobromo unsaturated ketone in sodium methylate made from 0.1 g. of sodium in 1 g. of methyl alcohol was refluxed for one hour. On cooling, pale yellow needles separated. The mixture was poured into three times its volume of water. There was obtained 0.8 g. of material melting at 106–113°, which when recrystallized from methyl alcohol melted and mix-melted at 113° with a sample obtained by the treatment of the dibromo compound with sodium methylate.[4]

(12) E. P. Kohler, *Am. Chem. J.*, **38**, 555 (1907).

1-Phenyl-3-mesityl-propene-one-3-ol-1 (IX).—To the solution of 80.3 g. of alpha-bromobenzalacetomesitylene in the least amount of hot methyl alcohol was added slowly and carefully with shaking, a solution of 34 g. of potassium hydroxide in the least amount of hot methyl alcohol. The solution turned red and potassium bromide separated out. When cold it was poured into 300 cc. of cold water and acidified with dilute hydrochloric acid. The milky solution thus produced was extracted with ether, the ethereal extract washed with water and the ether distilled. The oily residue was dissolved in hot methyl alcohol from which, on cooling, a cream-colored solid separated. The yield was 53–55 g. of enol, melting at 76–77°. This crude yield was 79–81% of the theoretical. On recrystallizing from methyl alcohol, it melts sharply at 79°.

To a solution of 29.2 g. of the methyl ether of 1-mesityl-3-phenylpropene-one-3-ol-1 in 160 cc. of methyl alcohol was added 30 cc. of concd. hydrochloric acid, and the mixture refluxed for three hours. On cooling overnight, colorless plates separated out. This yield was 20.7 g. of crude product melting at 78°. Recrystallization from methyl alcohol gave beautiful plates, melting sharply at 79°, with no depression on mix-melting with the 79°-melting enol.

It is 100% enolic in methyl alcohol and less then 1% enolic in carbon tetrachloride.

Preparation of the Copper Derivative (X).—A saturated ether solution of 1 g. of the enol was shaken for several hours with an excess of saturated copper acetate solution. The resulting greenish-tan crystalline solid was filtered, washed and dried, and weighed 0.9 g. It melts with decomposition at 221°.

Anal. Calcd. for $C_{36}H_{34}O_4Cu$: Cu, 10.71. Found: Cu, 10.69.

When the copper derivative is shaken in chloroform solution with hydrochloric acid, the enol is regenerated.

Preparation of Bromo Benzoylmesitoylmethane (XI).—Fourteen grams of calcium carbonate was suspended in a solution of 10 g. of the enol in 30 cc. of chloroform. A solution of 6.1 g. of bromine in 10 cc. of chloroform was added slowly with rapid stirring. The bromine was absorbed rapidly without any evolution of hydrogen bromide. The mixture of calcium carbonate and calcium bromide was filtered off and the chloroform pumped off. A pale yellow viscous mass was left which crystallized upon standing in an evacuated desiccator over potassium hydroxide. Recrystallization from low-boiling petroleum ether yielded 6.2 g. of colorless prisms, melting at 64–66°.

Anal. Calcd. for $C_{18}H_{17}O_2Br$: C, 62.6; H, 4.9. Found: C, 62.9; H, 5.2.

Differential Kurt Meyer titrations show that this substance is 24% enolic. It gives a characteristic red color with alcoholic ferric chloride and is reduced to the parent enol by potassium iodide.

Five grams of the monobromo compound was dissolved in 25 cc. of glacial acetic acid and refluxed for one hour with 5 g. of freshly fused potassium acetate. It was poured into a large volume of cold water to distribute the acetic acid, whereupon a yellow oil separated out. This oil was crystallized from methyl alcohol, yielding 3 g. of the parent enol, and 0.5 g. of mesityl phenyl diketone, each identified by its melting point and mix-melting point.

Dibromo Benzoylmesitoylmethane (XII).—A solution of 20 g. of concd. sulfuric in 40 cc. of glacial acetic acid was added with cooling to a solution of 16 g. of pyridine in 40 cc. glacial acetic acid. To this mixture was added 26.8 g. of enol (IX) dissolved in 170 cc. of glacial acetic acid. Finally with cooling and vigorous shaking, 32 g. of bromine in 400 cc. of acetic acid was added. The bromine was taken up rapidly. The acetic acid was distilled under diminished pressure; the residual oil was poured into water and extracted with ether. The ethereal solution was washed with sodium bicarbonate solution and with water. The ether was evaporated and the resulting pale yellow oil crystallized from methyl alcohol yielding pale yellow crystals, melting at 101–106°. Recrystallization from low-boiling petroleum gave 16 g. of pale yellow crystals melting at 107–108°.

Anal. Calcd. for $C_{18}H_{16}O_2Br_2$: C, 50.9; H, 3.8; Br, 37.7. Found: C, 51.0; H, 3.9; Br, 37.8.

This dibromide upon treatment with glacial acetic acid and potassium acetate is converted into mesityl phenyl diketone, identified by comparison with an authentic sample.

The Acetate (XIV).—Five grams of the bromobenzoylmesitoylmethane was refluxed for one hour with an excess of acetyl chloride. The acetyl chloride was pumped off and the residue crystallized from methyl alcohol. A practically quantitative yield of colorless crystalline solid, melting at 96°, was obtained.

Anal. Calcd. for $C_{20}H_{19}O_3Br$: C, 62.0; H, 4.9. Found: C, 62.0; H, 5.2.

This substance is non-enolic and is hydrolyzed by acids to the parent bromo compound. It is not acetylated further by potassium acetate in acetic anhydride, nor is it reduced by potassium iodide in acid solution. The same compound is obtained when the bromobenzoylmesitoylmethane is treated with acetic anhydride.

The Action of Acetic Anhydride–Potassium Acetate on Bromobenzoylmesitoylmethane (XIV) and (XV).—To a hot mixture of 10 g. of freshly fused potassium acetate and 50 cc. of acetic anhydride were added 10 g. of the monobromo compound. This mixture was refluxed gently for forty-five minutes. The solution turned dark brown and potassium bromide separated out. When cold it was poured into a large volume of cold water and stirred vigorously until the acetic anhydride was decomposed. It was then taken up in ether, washed with sodium bicarbonate solution, and finally with water, dried and evaporated. The residue was dissolved in methyl alcohol, from which by fractional crystallization 5 g. of the bromo acetate, melting at 96°, and 1.0 g. of the diacetate, melting at 131°, were obtained. Both products were identified by their mixed-melting points with known samples.

Summary

In this paper we have reported the properties of the enolic modification of benzoylmesitoylmethane, which properties are influenced considerably by the presence of the mesityl nucleus, which seems not only to activate the *alpha* substituents but also to have a directing influence upon enolization.

Ring Closure of Acylic Ureides Resulting from the Elimination of Alcohol: A Study of the Esters of beta-Phenylalanine-N-acetic Acid and Related Compounds[1]

BY DOROTHY A. HAHN, MARGARET J. MCLEAN AND MARGARET M. ENDICOTT

Further study of the derivatives of β-phenylalanine-N-acetic acid has resulted in the synthesis of the isomer of C-5-benzylhydantoin-N-1-acetate, to which reference was made in an earlier report.[1a] It was then stated that although the formation of two isomeric hydantoin-acids was theoretically possible following the hydrolysis of the ureidic salt

(I) $H_2NCON\begin{matrix}CH_2COOK\\CH(CH_2C_6H_5)COOK\end{matrix}$

under the action of hydrochloric acid, ring closure actually had been observed to take place in one sense only.[2] Moreover, since the product[3]

(II) $HOOCCH_2\overline{NCONHCOCHCH_2C_6H_5}$

was precipitated instantly in yields averaging more than 90% of the theoretical, it seemed reasonable to conclude that the rates at which the two carboxyl groups were capable of reacting respectively with the hydrogen of the amide group in the ureide must differ greatly in magnitude. It appeared probable therefore that the formation of the isomer

(III) $HOOC(CH_2C_6H_5)CH\overline{NCONHCOCH_2}$

could not be expected under ordinary conditions. However, it was still possible that in the case of a compound having the configuration

(1) Original manuscript received November 7, 1939.

(1a) Hahn and Endicott, THIS JOURNAL, **60**, 1045 (1938).

(2) A similar observation has been reported by E. Ware, *ibid.*, **60**, 2653 (1938), who found that although two isomeric hydantoins were theoretically possible as a result of the cyclization of a hydantoic derivative of tyrosine-N-acetic acid, only one product could be isolated and identified, namely, $HOOCCH_2\overline{NCON(C_6H_5)COCHCH_2}$-$C_6H_4OH$.

(3) The configuration of this compound has been definitely established, Hahn and Endicott, *loc. cit.*, p. 1042.

(IV) $H_2NCON\langle^{CH_2COOR^4}_{CH(CH_2C_6H_5)COOK}$

ring closure, taking place in an alkaline medium and accompanied by the elimination of alcohol, might occur. This possibility has been realized and it can now be stated that cyclization of this type has been effected following the synthesis of certain derivatives of β-phenylalanine-N-acetic acid, a brief discussion of which follows.

The mono-alkyl esters of this unsymmetrical acid, together with the corresponding hydrochlorides, may be assumed to be capable of existing in two isomeric modifications, such as, for example

(a) $HCl\cdot NH\langle^{CH_2COOR}_{CH(CH_2C_6H_5)COOH}$ and

(b) $HCl\cdot NH\langle^{CH_2COOH}_{CH(CH_2C_6H_5)COOR}$

It has been found, however, that only *one* salt of this type can be isolated as a result of dissolving the imino acid in a hydrogen chloride solution of either methyl or ethyl alcohol. For reasons to be discussed later these products, which under very specific conditions were precipitated in almost pure condition and in yields averaging 70% of the theoretical, were assumed to possess the configurations

(V) $HCl\cdot NH\langle^{CH_2COOCH_3}_{CH(CH_2C_6H_5)COOH}$ and

(VI) $HCl\cdot NH\langle^{CH_2COOC_2H_5}_{CH(CH_2C_6H_5)COOH}$

The filtrate contained a mixture of the hydrochlorides of the free acid, its mono- and di-alkyl esters.[5]

Following their final purification, both salts were transformed (under loss of hydrogen chloride) into the corresponding free esters:

(VII) $^+NH_2\langle^{CH_2COOCH_3}_{CH(CH_2C_6H_5)COO^-}$ and

(VIII)[6] $^+NH_2\langle^{CH_2COOC_2H_5}_{CH(CH_2C_6H_5)COO^-}$

These compounds are almost insoluble in water, alcohol and other organic solvents but both dissolve readily in ammoniacal solutions of alcohol to form one and the same monamide

(IX) $^+NH_2\langle^{CH_2CONH_2}_{CH(CH_2C_6H_5)COO^-}$

From this it follows that both esters possess the same configuration.[7]

The formulas that have been assigned to the compounds V, VI, VII and VIII, irrespective of their close chemical interrelationships, depend upon the fact that under the action of aqueous potassium cyanate *all four* were transformed into acyclic ureides which in weakly alkaline media underwent ring closure to give one and the same final product, XI. In the case of the compound VII, for example, the course of this reaction may be indicated most simply as

(VII) $^+NH_2\langle^{CHCOOCH_3}_{CH(CH_2C_6H_5)COO^-} \longrightarrow$

(X) $H_2NCON\langle^{CH_2COOCH_3}_{CH(CH_2C_6H_5)COOK} \longrightarrow$

$KOOC(CH_2C_6H_5)CH\overline{NCONHCOCH_2}$ + CH_3OH[8]

(XI)

The presence in the reaction mixture of a compound having the configuration XI was assumed from the fact that addition of hydrochloric acid resulted in the formation of an hydantoin acid, which on analysis was found to be isomeric with II.[3] While the formula which has been assigned to this new compound III has not as yet been confirmed as the result of a second synthesis, it is supported by a consideration of the following facts. The acids II and III show a striking similarity in their physical and chemical properties. For example, a comparison of their absorption curves reveals a very close relationship, since both show selective absorption that is identical

(4) Whenever used, R may be understood to denote either a methyl or an ethyl group.

(5) That this filtrate contained no decomposition products was shown by the fact that when evaporated to dryness and the residue treated as described by Hahn and Endicott (*loc. cit.*, p. 1041, footnote 4), the free imino-acid was regenerated in amounts corresponding very closely to the theoretical. Reference will be made frequently to this as a general procedure for recovering the free imino-acid.

(6) It may be noted that in the case of imino-diacetic acid only a single compound of this type was isolated. This was referred to by Jongkees [*Rec. trav. chim.*, **27**, 297 (1908)] as an "ether-salt," $NH(CH_2COOC_2H_5)CH_2COOH$, in which the function of the acid neutralizes that of the secondary amine since the compound is almost neutral to turmeric. It seems curious that the corresponding methyl ester was never separated, but this may be due to the fact that, as in the case of the corresponding derivatives of beta-phenylalanine-N-acetic acid, it was more difficult to prepare. For example, while the hydrochloride V is extremely stable in aqueous solution, VI is partially hydrolyzed even at ordinary temperatures and when the dry salt was treated with boiling water, its solution was followed almost instantly by the precipitation of VIII.

(7) A comparison of the electrolytic dissociation constants of VII, VIII and IX has revealed, moreover, that all three behave like weak monobasic acids. These constants agree very closely and are of the order of 10^{-7} (McLean, unpublished work).

(8) Ring closures accompanied by the elimination of alcohol which resulted in the formation of both hydantoin and hydantoin-N-1-acetic acid, have been reported by J. R. Bailey, *Am. Chem. J.*, **28**, 393 (1902), and by Bailey and Snyder, THIS JOURNAL, **37**, 945 (1915).

up to 37000 cm.$^{-1}$. Differences are to be found only in the intensities of absorption characteristic of the phenyl group and these may be accounted for as due to differences in the relative positions of this group in the two molecules.[9] Both acids have been shown to be dibasic as a result of electrometric titrations,[10] although due to a weakly acidic hydrogen atom in the N-3-position, each yields respectively only a single stable mono-sodium salt. The corresponding methyl esters also have been prepared and found to be isomeric and not identical. It may be added that the acid III has been obtained in yields of 70% from each of the compounds designated as V, VI, VII and VIII and that the course of the reaction in the case of VII has been demonstrated by the fact that methyl C-5-benzylhydantoin-N-1-acetate,[11] which could be formed only as a result of ring closure of X under the action of hydrochloric acid, was actually isolated from the reaction mixture.

In conclusion it may be stated that only one dialkyl ester of β-phenylalanine-N-acetic acid has as yet been prepared and that this was separated in pure condition only in the form of its hydrochloride

(XII)[12] $HCl\cdot NH\begin{cases}CH_2COOCH_3\\CH(CH_2C_6H_5)COOCH_3\end{cases}$

It is interesting to note that when this salt was treated with potassium cyanate and the reaction product subsequently hydrolyzed, both of the hydantoin-acids II and III were again isolated.

Experimental

The β-phenylalanine-N-acetic acid used in these experiments was prepared by alkaline hydrolysis of ethyl N-3-methyl-C-5-benzylhydantoin-N-1-acetate[13] and was purified by recrystallization from boiling water.

The hydrochloride of the mono-methyl ester, V, $HCl\cdot NH(CH_2COOCH_3)CH(CH_2C_6H_5)COOH$, m. p. 185–186° (dec.), was obtained in yields averaging 70 to 75% by dissolving the free acid in methyl alcohol under the action of hydrogen chloride. For example, to a clear solution of 5 g. of the free acid in 15 cc. of absolute methyl alcohol one-third saturated with dry hydrogen chloride,[14] after standing thirty minutes at 0° and then forty-eight hours at room temperature, 50 cc. of absolute ether was added.[15] After two hours the resulting white crystals were washed with a mixture of alcohol and ether (1:10)[16] and dried; weight 4.43 g.; m. p. 183–186°. On recrystallization from boiling acetone they decomposed sharply at 185–186°.

Anal. Calcd. for $C_{12}H_{15}O_4N\cdot HCl$: C, 52.65; H, 5.87; N, 5.12; Cl, 12.96. Found: C, 52.90; H, 5.85; N, 5.09; Cl, 12.79.

The salt is soluble in cold absolute methyl alcohol (1 g. in less than 3 cc.) and in acetone (1 g. in 500 cc. boiling and in 1250 cc. at 20°) but insoluble in ether. It loses hydrochloric acid readily to form the free ester VII when treated with the calculated quantity of dilute alkali but is stable in aqueous[17] and alcohol solutions. It yields the corresponding salt of the imino acid when warmed with concentrated hydrochloric acid,[18] and sodium and potassium salts on alkaline hydrolysis.[18]

The hydrochloride of dimethyl-β-phenylalanine-N-acetate, XII, $HCl\cdot NH(CH_2COOCH_3)CH(CH_2C_6H_5)COOCH_3$, m. p. 144–145° (dec.), was obtained in 70% yields from the hydrochloride of the imino acid after five days[19] of alternate saturation of a concentrated absolute methyl alcohol solution (8.5 g. in 25 cc.) with dry hydrogen chloride at 0°, and refluxing over a steam-bath. The clear solution evaporated to dryness under air blast gave a red gum which when dissolved in boiling acetone deposited white crystals; weight 6.8 g.; m. p. 138–142°. Recrystallized from acetone they decomposed sharply at 144–145°.[20]

Anal. Calcd. for $C_{13}H_{17}O_4N\cdot HCl$: C, 54.26; H, 6.30; N, 4.87; Cl, 12.32. Found: C, 54.20; H, 6.23; N, 4.70; Cl, 12.33.

The salt is very soluble in cold absolute methyl alcohol and moderately in acetone (1 g. in 75 cc. boiling and in 190 cc. at 20°)[21] but insoluble in ether. It separates from alcohol solutions on addition of ether in long, silk-like,

(9) McLean, unpublished work.

(10) Their respective pK_1 and pK_2 dissociations are II, 2.81 and 8.96; III, 2.91 and 9.20. Compare Pickett and McLean, THIS JOURNAL, **61**, 423 (1939).

(11) The identity of this ester was confirmed by a mixed melting point with an analyzed specimen previously synthesized. Compare Hahn and Endicott, *loc. cit.*, p. 1044.

(12) The hydrochloride of the corresponding diethyl ester and the corresponding derivative of iminodiacetic acid could not be isolated, although Jongkees (*loc. cit.*, p. 296) finally obtained a small quantity of a crystalline compound to which he assigned the formula $HCl\cdot NH(CH_2COOC_2H_5)_2\cdot H_2O$.

(13) Hahn and Endicott, *loc. cit.*, 1042; also compare Hahn and Litzinger, *ibid.*, **54**, 4663 (1932), and Litzinger, *ibid.*, **56**, 676 (1934).

(14) Yields were lower and extremely variable when hydrogen chloride was passed directly into a suspension of the free acid in alcohol.

(15) Excess ether caused the precipitation of an oil.

(16) The filtrate on evaporation under air blast gave a gum from which hydrochlorides of the imino acid and of its mono- and dimethyl esters were separated, but which when warmed with dilute hydrochloric acid was completely transformed into the free imino acid.[5] A similar gum was obtained when an alcohol solution of the hydrochloride of the imino acid was evaporated to dryness.

(17) The salt is very soluble in cold water, from which it separates undecomposed but dilute solutions (10 g. in 100 cc.) after prolonged boiling (twelve hours) deposit a gum (0.3 g.) on cooling. This consists of a mixture of the free ester and its hydrochloride.

(18) Identification effected by comparison with analyzed specimens, Hahn and Endicott, *loc. cit.*, p. 1043.

(19) When action was stopped after four or five hours, a mixture was obtained from which less than 40% of the above salt could be separated. Compare Jongkees, *loc. cit.*, pp. 295–296.

(20) The same salt was obtained from oils or gums similar to those described in footnote 16. Separation was effected by dissolving the gum in water, and extracting with ether following additions of sodium bicarbonate. The ether solution when *perfectly dry* and saturated with hydrogen chloride, deposited the salt in form of a gum which on stirring changed into white crystals, m. p. 144–145°.

(21) Due to marked differences in their solubilities in acetone, mixtures consisting *exclusively* of the hydrochlorides of the mono- and di-methyl esters may be separated readily.

glistening white needles that form in rosettes. Warmed with dilute hydrochloric acid it gave the free acid.[5]

The hydrochloride of the mono-ethyl ester of β-phenylalanine-N-acetic acid, VI, $HCl\cdot NH(CH_2COOC_2H_5)CH(CH_2C_6H_5)COOH$, m. p. 170–172° (dec.), was obtained from the free acid in yields of 70–75%, when absolute ethyl alcohol was substituted for methyl in the corresponding experiment, V. The product, consisting of hard white crystals,[22] was recrystallized from boiling acetone.

Anal. Calcd. for $C_{13}H_{17}O_4N\cdot HCl$: C, 54.26; H, 6.30; N, 4.87; Cl, 12.32. Found: C, 54.50; H, 6.34; N, 4.84; Cl, 12.25.

The salt is very soluble in cold absolute ethyl alcohol but only slightly in acetone (1 g. in 300 cc. boiling and in 750 cc. at 20°) and insoluble in ether. It differs in its reactions from the corresponding methyl derivative only in that it loses its hydrochloric acid when dissolved in water.[23]

The free mono-methyl ester of β-phenylalanine-N-acetic acid, VII, $^+NH_2(CH_2COOCH_3)CH(CH_2C_6H_5)COO^-$, m. p. 208–210° (dec.), was obtained from the corresponding hydrochloride by adding at 0° an equivalent of (a) sodium methoxide to its methyl alcohol solution, or (b) potassium bicarbonate to an aqueous solution. The gelatinous precipitate, consisting of salt mixed with free ester which formed in both cases, was resolved into fine white crystals on stirring or warming. Thus when 0.34 g. of sodium in 25 cc. of absolute methyl alcohol was added to 4 g. of salt in 10 cc., crystals m. p. 201–203° and weight 3.1 g. were obtained. After extraction with cold water and recrystallization from methyl alcohol, these were dried in a high vacuum at 20°.

Anal. Calcd. for $C_{12}H_{15}O_4N$: C, 60.75; H, 6.36; N, 5.91. Found: C, 60.51; H, 6.61; N, 6.18.

This "ester-salt" is only slightly soluble in absolute methyl alcohol (1 g. in 180 cc. boiling and in 250 cc. at 20°) and water (1 g. in 70 cc. boiling and in 200 cc. at 20°) but dissolves freely in aqueous alkali or acid. When warmed with dilute hydrochloric acid it passed quantitatively into the free imino acid.[5]

The free mono-ethyl ester, VIII, $^+NH_2(CH_2COOC_2H_5)CH(CH_2C_6H_5)COO^-$, m. p. 206–208° (dec.), was obtained when the corresponding dry salt VI was treated with boiling water. A clear colorless solution was first formed, then a gelatinous precipitate which dissolved on heating and finally a white crystalline compound. The latter was pure and the change quantitative in cases where the heating was prolonged for an hour. After recrystallization from boiling water, it was dried in a high vacuum at 20°.

Anal. Calcd. for $C_{13}H_{17}O_4N$: C, 62.14; H, 6.82; N, 5.58. Found: C, 62.30; H, 6.93; N, 5.75.

The "ester-salt" is even less soluble than the corresponding methyl derivative in alcohol (1 g. in 650 cc. boiling) and water but dissolves freely in aqueous alkali and acid. Warmed with dilute hydrochloric acid it passed quantitatively into the free imino acid.[5]

The monamide, IX, $^+NH_2(CH_2CONH_2)CH(CH_2C_6H_5)COO^-$, m. p. 196–197° (dec.), was obtained by passing dry ammonia into an absolute alcohol suspension of either VII or VIII at 20° and concentrating the resulting clear solution. The product was mixed with considerable quantities of the original ester but could be separated by extraction with small quantities of cold water made faintly alkaline with ammonia. Recrystallized from the same solvent, it separated in long, white, silk-like needles which completely filled the space occupied by the solution.

Anal. Calcd. for $C_{11}H_{14}O_3N_2$: C, 59.44; H, 6.35; N, 12.61. Found: C, 59.28; H, 6.66; N, 12.71.

The amide is only slightly soluble in alcohol (1 g. in 200 cc. boiling and in 400 cc. at 20°), but is very soluble in cold water. For example 2 g. in 20 cc., concentrated to 10 cc. under air blast, gives a precipitate of only 1 g., partial hydrolysis being avoided only by the presence of a trace of ammonia. Warmed with dilute hydrochloric acid, the amide passed quantitatively into the imino acid.[5]

Hydantoin-N-1-benzylacetic acid, III, $HOOC(CH_2C_6H_5)CH\overset{\frown}{NCONHCOCH_2}$, m. p. 157–158°, was obtained from four compounds (the hydrochlorides V and VI and the esters, VII and VIII) by treating an aqueous alcohol solution or suspension of each with aqueous potassium cyanate slightly in excess of the amount equivalent to the dissociable hydrogen present.

In previewing the course of these reactions it was assumed that if, for example, the compound VII were used as the starting point, primary ionic exchanges (a) would result in the formation of the cyanate, $HOCN\cdot NH(CH_2COOCH_3)CH(CH_2C_6H_5)COOK$. The latter might then be expected to rearrange (b) into the acyclic ureide, $NH_2CON(CH_2COOCH_3)CH(CH_2C_6H_5)COOK$, X; after which ring closure (c) accompanied by the elimination of methyl alcohol and the formation of the hydantoin salt, $KOOC(CH_2C_6H_5)CH\overset{\frown}{NCONHCOCH_2}$, XI, might or might not occur. It appeared probable, moreover, that the progress made in each of these transformations could be ascertained by stopping the reaction at the end of different time intervals as a result of adding hydrochloric acid in amounts exactly equivalent to the potassium in the cyanate that had been used in the experiment. Under these conditions, for example, the compound VII would be completely regenerated if no change other than that indicated by (a) had taken place.[24] If, however, even partial rearrangement (b) had occurred, the liberation of the corresponding hydantoic acid almost certainly would be followed by ring closure accompanied by the elimination of water. In this case the product, methyl C-5-benzylhydantoin-N-1-acetate, could also be readily separated and identified.[11] Finally if the transformation indicated by (c) had taken place, a new hydantoin acid, III, isomeric with II, would be formed. Complications arising from alkaline hydrolysis having taken place during the time allowed for the transformations (a), (b) and (c) also were considered. In that event dipotassium derivatives of both the cyanate, and the corresponding ureide X would be formed, *i. e.* $HOCN\cdot NH(CH_2COOK)CH(CH_2C_6H_5)COOK$, and NH_2-

(22) The filtrate from these crystals gave a gum which was exactly analogous to that described under footnote 16.

(23) The ease with which the mineral acid may be lost has been noted in the case of the salt of the imino acid itself.[5] For other examples compare Stadnikoff, *Ber.*, **41**, 4365 (1908), and **44**, 41 (1911); also Hahn and White, THIS JOURNAL, **54**, 2054 (1932).

(24) This was found actually to be the case when the reaction was stopped at the end of fifteen minutes.

$CON(CH_2COOK)CH(CH_2C_6H_5)COOK$ (I).[1] Introduction of mineral acid would then result in the precipitation of two additional compounds, namely, the free imino acid and the hydantoin-acid II.

In practice the final product was a mixture of all five compounds. For example 4.0 g. of the salt V dissolved in 90 cc. of 80% methyl alcohol was treated with 1.37 g. of solid potassium cyanate and then warmed gently in order to dissolve the resulting precipitate (VII). After cooling to 0° the clear solution was stirred mechanically for one hour, left at room temperature for forty-five hours, concentrated to 20 cc. under air blast and finally treated with 15.7 cc. of 1.018 *N* hydrochloric acid. Extraction with chloroform and then with alcohol-free ether yielded 0.42 and 2.0 g., respectively, of the hydantoin acids II and III and 0.36 g. of the methyl ester of the former, leaving a residue of 0.13 g. of the free imino acid and 0.30 g. of its mono methyl ester. Table I shows the relative percentages of hydantoin derivatives obtained under other conditions.[25]

TABLE I

% Aq. CH_3OH	Reaction period preceding addition of HCl, hr.	% of various products resulting from ring closures III	II	Ester of II
80	1.5	33	Trace only	13.0
80	24	72	Trace only	12.0
65	1.5	40	3.4	11.1
50	1.5	26	26	6.0

In later experiments 80% alcohol was used and excess hydrochloric acid added at the end of twenty-four to forty-eight hours, when the mixture was heated to ensure the hydrolysis of any esters before extracting the acids II and III with chloroform. After evaporation of the chloroform, the mixture was separated by fractional recrystallization from boiling water when III, m. p. 157–158°, was obtained in yields of 70 to 75%.

Anal. Calcd. for $C_{12}H_{12}O_4N_2$: C, 58.06; H, 4.87; N, 11.29. Found: C, 58.02; H, 5.08; N, 11.36.

The hydantoin acid III is not only more soluble than its isomer in water (1 g. in 3 cc. boiling and in 70 cc. at 20°) but when recrystallized from dilute solutions, separates in characteristic rosettes of 30 or more thin, flat hexagonal prisms 2 × 5 mm. at the base but tapering to a sharp point, with a length of 10 to 15 mm.,[26] that can be separated mechanically. Both acids separate as oils from concentrated aqueous solutions, and are very soluble in chloroform but only slightly soluble in ether.

Sodium hydantoin-N-1-benzylacetate was obtained in two different modifications, (a) anhydrous, which began to decompose at 188° and was completely carbonized at 300°, and (b) an alcoholate, which first melted between 60° and 70° with loss of alcohol and then solidified again at 91°. When heated higher this white solid began to decompose at 188° and was completely carbonized at 300°. In both cases the hydantoin-acid III, dissolved in alcohol (3.0 g. in 30 cc.), was treated with aqueous sodium hydroxide (0.4 g. in 5 cc.) and in both cases the product separated in fine white crystals.

Anal. (a) Calcd. for $C_{12}H_{11}O_4N_2Na$: Na, 8.51. Found: Na, 8.71. (b) Calcd. for $C_{12}H_{11}O_4N_2Na \cdot C_2H_5OH$: Na, 7.27; C_2H_5OH, 14.50. Found: Na, 7.39; C_2H_5OH, 13.85.

Both modifications are very soluble in water, only slightly soluble in boiling ethyl alcohol (1.0 g. in 250 cc.) and insoluble in ether. That neither is identical with sodium C-5-benzylhydantoin-N-1-acetate[26] was demonstrated by mixed melting points. Aqueous solutions treated with hydrochloric acid passed quantitatively into the corresponding hydantoin-acid III.

Methyl hydantoin-N-1-benzylacetate, m. p. 105–106.5°, was obtained in 85% yields by passing dry hydrogen chloride into a solution of III in absolute methyl alcohol. The product was separated from traces of III in the usual manner and then recrystallized from boiling 50% alcohol, from which it separated in small, colorless, transparent cubes.

Anal. Calcd. for $C_{13}H_{14}O_4N_2$: C, 59.51; H, 5.30. Found: C, 59.61; H, 5.38.

The ester is extremely soluble in cold methyl alcohol and slightly soluble in boiling water. That it is isomeric and not identical with methyl C-5-benzylhydantoin-N-1-acetate[11] was demonstrated by means of a mixed melting point determination.

Summary

Another example of ring closure accompanied by the elimination of alcohol and the formation of an hydantoin is described, together with the preparation of several new derivatives of β-phenylalanine-N-acetic acid.

SOUTH HADLEY, MASS. RECEIVED MARCH 1, 1940

(25) The concentration of V was the same in all experiments, but the heat required for the solution of the ester VII was never satisfactorily controlled and this undoubtedly led to variations in percentage yields not otherwise explained. It may be added that while no appreciable differences were observed when V and VII were used as starting points, the substitution of VI and VIII appeared to result in a definite increase in the speed with which the reaction mixture approached a condition of equilibrium. However, the maximum yields of III from all four compounds were approximately 70% of the theoretical.

Hydrogenation of Quinone with Palladium and Platinum Catalysts

BY EDGAR F. ROSENBLATT

The hydrogenation of quinone has recently been studied by Otto Neunhoeffer and Willibald Pelz,[1] with the interesting result that hydrogenations with palladium catalysts are feasible also in a carbon monoxide atmosphere instead of the commonly used hydrogen. To compare it with hydrogen hydrogenations, they also studied[1] the hydrogenation of different quinones in a hydrogen atmosphere and found to their surprise that, in contrast to the results with carbon monoxide, palladium could not catalyze the reduction of quinone in a hydrogen atmosphere; from this experimental result they draw the conclusion that reversible systems cannot be hydrogenated with palladium and hydrogen. Such a conclusion conflicts with a publication by Donald T. Bonney and Wilbert J. Huff,[2] recommending the use of a solution of anthraquinone disulfonates and colloidal palladium for the absorption of hydrogen in gas analysis.

A clarification of this discrepancy seemed desirable, so the experiments described herein were undertaken. We may say at once that we have confirmed the experimental results of Neunhoeffer and Pelz, but only under their very special conditions, *i. e.*, in an aqueous hydrochloric acid solution. However, the general deduction that palladium is not a catalyst for reversible systems in a hydrogen atmosphere, is erroneous, as in aqueous as well as alcoholic solution the hydrogenation of quinone to hydroquinone proceeds with remarkable speed, *as long as no mineral acid is present.*

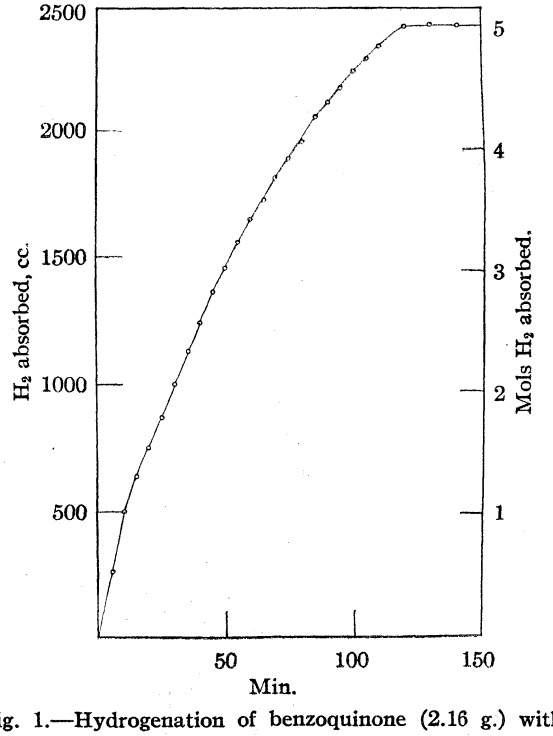

Fig. 1.—Hydrogenation of benzoquinone (2.16 g.) with platinum in HCl.

Our experiments are instructive also in another respect: though the platinum metals are quite generally recognized as excellent catalysts, due to their activity at low temperature and low pressure, there is considerable uncertainty regarding their relative activity, for instance that of palladium compared with platinum. From the following experiments, it can be seen that platinum, but not palladium, can catalyze the hydrogenation of quinone in a hydrochloric acid solution to cyclohexanol (as also found by Neunhoeffer and Pelz). However, in aqueous or alcoholic solution, the hydrogenation of quinone to hydroquinone takes place with either catalyst, and under these conditions the reaction with palladium charcoal is many times faster even than with platinum charcoal (see Fig. 3). Though it is not advisable to jump to hasty conclusions in such a complicated field as catalytic hydrogenation, it is suggestive that a similar result is obtained in many other instances, tending to show that palladium is a mild but extremely fast catalyst, while platinum is more powerful but slower.

Figure 1 shows the hydrogenation of 2.16 g. (0.02 mole) of quinone in 5% hydrochloric solution with the commercial platinum charcoal catalyst of Baker & Co., Inc. (1 g. charcoal was used containing 50 mg. Pt). The change of speed after the absorption of 1 mol of hydrogen is perceptible, especially if compared with normal hydrogenations, which run with undiminished speed almost to the reaction end. In one experiment, the hydrogenation was interrupted after the absorption of 1 mol of hydrogen, the catalyst filtered

(1) Neunhoeffer and Pelz, *Ber.*, **72**, 433 (1939).
(2) Bonney and Huff, *Ind. Eng. Chem., Anal. Ed.*, **9**, 157 (1937).

off and the filtrate evaporated; the residue was found to be hydroquinone, which therefore represents the first stage of the complete reaction leading to cyclohexanol.

Figure 2 shows how, in the absence of mineral acids, the hydrogenation of benzoquinone comes to a sudden stop after the hydroquinone stage has been reached. Curve 1 represents the hydrogenation of 2.16 g. of benzoquinone, with the same platinum catalyst as before, in acetic acid solution, curve 2 in ethyl alcohol. Curve 3 represents the hydrogenation in ethyl alcohol with the commercial palladium charcoal catalyst of Baker & Co., Inc. (1 g. charcoal containing 50 mg. Pd). Benzoquinone also can be hydrogenated with palladium in water, in which the quinone is not very soluble. This reduces the reaction speed considerably so that this hydrogenation curve lies between curves 1 and 2. The curve is not drawn as the reaction is not strictly comparable with the others.

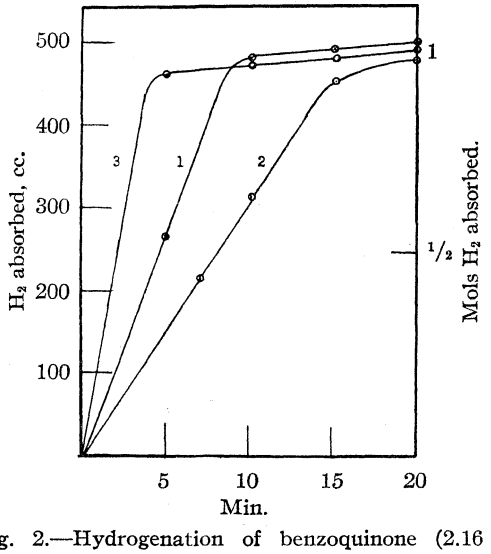

Fig. 2.—Hydrogenation of benzoquinone (2.16 g.): 1, Pt in acetic acid; 2, Pt in ethyl alcohol; 3, Pd in ethyl alcohol.

Figure 3 shows the greater speed of the reaction with a palladium catalyst; furthermore, it clearly indicates that there is no slowing down after the absorption of the 0.5 mol of hydrogen, *i. e.*, at the meriquinoid stage. In both cases 4 g. of benzoquinone was used, but in the case of platinum only a small part of the benzoquinone was hydrogenated when the experiment was interrupted.

A few experiments were made relating to the hydrogenation of other quinones, *i. e.*, *p*-toluquinone and anthraquinone in alcoholic solutions. The hydrogenation of *p*-toluquinone proceeds with practically the same speed as benzoquinone. The hydrogenation of anthraquinone is much slower due to the restricted solubility in ethyl alcohol. The reverse reaction, the dehydrogenation of hydroquinone to quinone, could be observed only in the case of anthrahydroquinone, which partially reoxidized before the palladium catalyst could be filtered off.

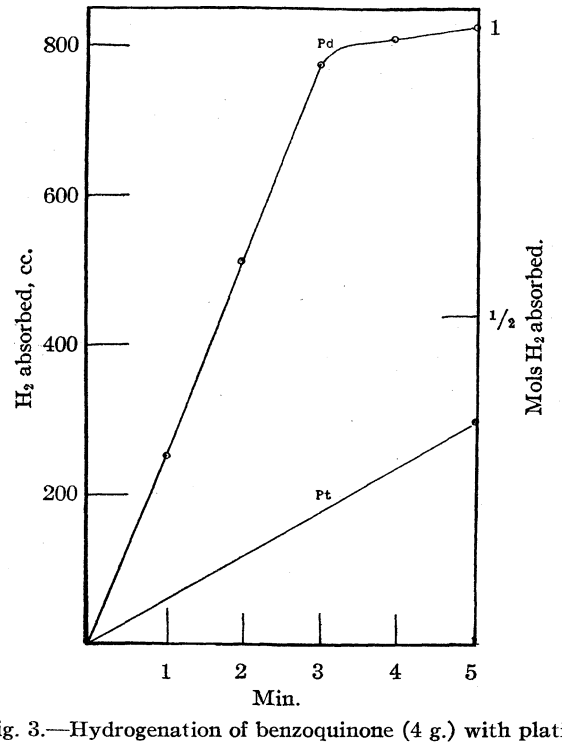

Fig. 3.—Hydrogenation of benzoquinone (4 g.) with platinum or palladium in methyl alcohol.

Experimental

All hydrogenations were done at room temperature and at atmospheric pressure. The reaction vessel was a thick-walled Pyrex Erlenmeyer flask of 1000-cc. content, which was placed in a shaking machine (275 oscillations per minute, the lateral stroke $1^1/_2$″ (3.7 cm.) long). The progress of the reaction could be followed by measuring the decrease in volume, due to the absorption of hydrogen. The results have not been corrected for barometer readings, temperature or humidity; since the last named factor is of the greatest relative importance, and is so difficult to evaluate accurately in the presence of different organic solvents, it seemed unnecessary to correct for pressure and temperature. Under our conditions the hydrogen absorption was around 24 liters per mole of hydrogen, instead of 22.4 liters. One hundred cc. of solvent was used in each experiment.

The catalyst was the commercial 5% platinum charcoal and 5% palladium charcoal (Baker & Co., Inc.), 1 g. of charcoal containing 50 mg. of platinum or palladium, re-

spectively, being used. The same catalyst was used throughout, as it could be filtered and dried at 100° after each experiment without impairing its activity.

Summary

The hydrogenation of various quinones in a hydrogen atmosphere in the presence of palladium catalysts produces hydroquinone with great speed, provided mineral acids are absent. The same reaction takes place with platinum charcoal, but more slowly. Platinum charcoal is active even in the presence of mineral acid, hydroquinone being only the first stage of the reaction which has cyclohexanol as the final product.

The Kinetics of Neutralization

BY MARTIN KILPATRICK

In a recent paper Lewis and Seaborg[1] have reported the study of the rate of fading of the blue trinitrotriphenylmethide ion in acid solutions. They interpret their results in terms of their classification of acids and bases as primary and secondary.[2,3]

Another kinetic interpretation of their results merits consideration. Considering the reaction to be catalyzed by acids we may write

$$B_S^- \underset{k_{-1}A^-}{\overset{k_1\,HA}{\rightleftharpoons}} B_P^- \qquad (1)$$

where B_S^- represents the blue ion, called the secondary base by Lewis, B_P^- the form called the primary base, HA any acid, and A^- its conjugate base. This reaction is followed by the reaction

$$B_P^- + HA \overset{k_2}{\rightleftharpoons} HB + A^- \qquad (2)$$

In other words, equation (1) is step (a) in the paper of Lewis and Seaborg (who do not, however, consider the acid–base catalytic nature of the reaction) and equation (2) represents the second step. In equation (1) B_S^- is transformed to B_P^- by the catalyst HA, the reverse process being catalyzed by the base A^-. Now if the reaction $B_P^- + HA$ is much faster than the reaction $B_S^- \rightarrow B_P^-$, and if $k_2C_{HA} \gg k_{-1}C_{A^-}$, the rate equation would be

$$-\frac{dC_{B_S^-}}{dt} = k_1C_{B_S^-}C_{HA} \qquad (3)$$

and the reaction would be of the second order in agreement with the experimental findings of Lewis and Seaborg. Lewis and Seaborg consider that a small concentration of B_P^- is maintained in equilibrium with B_S^- and that the rate-determining step is the reaction of the primary base B_P^- with the acid HA. They conclude that ". . . the measured heat of activation should be the same for the several acids and equal to the difference in energy between the primary and secondary forms of the base." In the present paper it is assumed that the change from B_S^- to B_P^- requires an acid catalyst and that B_P^- reacts rapidly with the acid if it is sufficiently strong.

The measured energies of activation for the stronger acids are found to average 9.1 kcal., and the energy of activation is calculated to be 8.9 for alcohol. The constancy of this value is not in contradiction to a catalytic mechanism. For example, in the mutarotation of glucose the measured energies of activation for such different catalysts as water, pyridine, acetate ion, and hydrogen ion were found to be 17.6, 19.1, 18.0, and 19.3 kcal., respectively.[4] In the enolization of acetoacetic ester[5] and in the iodination of acetone[6] the measured energies of activation for different catalysts are practically the same. From the data it is evident that the statement of Lewis and Seaborg "The constancy of the heat of activation over the great range from chloroacetic acid to alcohol can hardly be explained by the theory of an activated complex" is hardly in accord with the facts for reactions showing general acid and basic catalysis.

Turning now to the alcohol reaction, Lewis and Seaborg state "Alcohol is itself an acid, and although its acid strength is not high

enough to cause the fading of the blue color to occur to any great extent before equilibrium is established, it does, in the presence of stronger acids, play an important and sometimes preponderating part in the mechanism of the fading process. This is due to the relatively large number of alcohol molecules present. Side by side, therefore, with the reaction we have considered so far, is this reaction with the solvent...." The reaction scheme therefore includes a reaction of the primary base with alcohol. In the new interpretation the blue form is already in equilibrium with B_P^-, and as soon as the acid is added the species B_P^- is removed and the change of B_S^- to B_P^- is catalyzed by two acids, the acid added, which is present in small concentration, and the acid alcohol. That is

$$-dC_{B_S^-}/dt = k'C_{B_S^-}C_{C_2H_5OH} + k''C_{B_S^-}C_{HA} \quad (4)$$

The molar catalytic constant k'' will be greater than k' because of the greater strength of the acid but the "preponderating" part played by the alcohol is due to its high concentration. In addition, since the concentration of alcohol is constant, the observed velocity constant should no longer be truly of the second order for the weaker acids, and this is in agreement with the experimental results. If the greater part of the reaction is by way of the alcohol, the last term in (4) becomes unimportant, and the rate of reaction will no longer be sensitive to change in concentration of the acid HA. This is also in accord with the experimental results.

The velocity constants range from 30 for the strongest acid (monochloroacetic acid) to 0.09 for phenol, and this difference in velocity is explained by the statement "It appears as though increasing polarization of the acid, by its orienting effect, increases the probability that a given collision between the acid and primary base will be effective." In terms of the catalytic mechanism a different velocity constant for each catalyst is expected. From the concentration of B_P^- in equilibrium with B_S^-, and from the velocity constant for the reaction between the blue ion and chloroacetic acid, Lewis and Seaborg compute that the molar velocity constant for the reaction between the primary base and chloroacetic acid is 6×10^{10}, time being expressed in seconds. This would mean that there was a high probability of reaction at each collision. Lewis regards this calculation as erroneous. Now the experimental

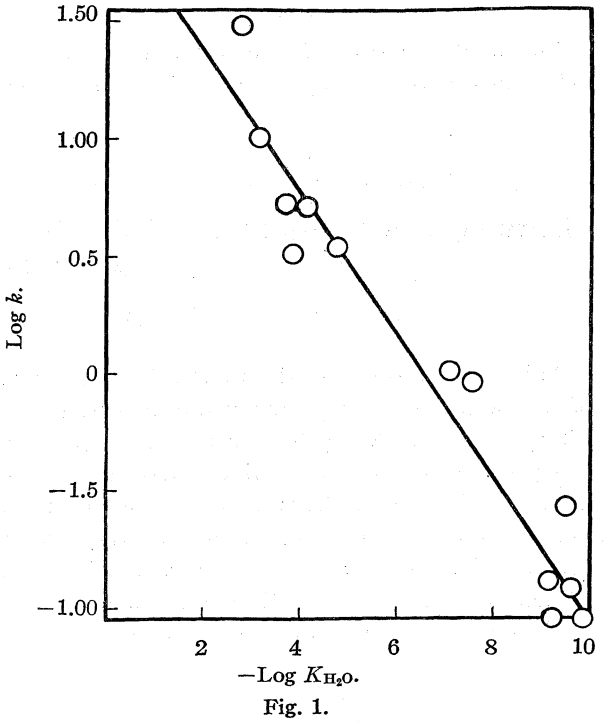

Fig. 1.

results for chloroacetic acid can be expressed by an equation of the Arrhenius type

$$\ln k = 27.5 - 10{,}200/RT \quad (5)$$

and the value 27.5 is in reasonable agreement with other acid–base catalyzed reactions. The corresponding values for the other catalysts range from 25.5 to 21.5. If the collision number were 10^{11} the value would be approximately 25.

The characteristic of all reactions showing general acid catalysis is the relation between the catalytic constant (k) and the acid strength constant (K)

$$k = GK^x \quad (6)$$

where G and x are constants for a series of catalysts of similar structure and charge type. For acids of different structure the relation is an approximate one. The following graph indicates that the relationship holds approximately in the present case. Lewis considers this relationship to be erroneous.[7] It should be pointed out that the velocity constants given in Table I of the paper by Lewis and Seaborg, and plotted here, include the alcohol reaction, so that the catalytic constants assigned to the weaker acids are somewhat too high.

(7) Lewis, *J. Franklin Inst.*, **226**, 293 (1938).

Summary

The neutralization of trinitrotriphenylmethide ion is interpreted as an acid-catalyzed reaction. The interpretation is in accord with the kinetic experiments.

Thermodynamic Properties of the Hexyl Alcohols. IV. 3-Methylpentanol-1 and 2-Methylpentanol-5

BY FRANK HOVORKA, HERMAN P. LANKELMA AND ISADORE SCHNEIDER[1]

This paper represents the fourth[2,3,4] of a series of investigations being carried out in this Laboratory concerned with the relation between physical properties and chemical constitution of the hexyl alcohols, and deals with the preparation, purification and determination of the vapor pressure, viscosity, density, surface tension and refractive index of 3-methylpentanol-1 and 2-methylpentanol-5 (4-methylpentanol-1).

Experimental

Preparation of Materials.—Both alcohols were prepared in a manner similar to that described by Dreger[5] for the preparation of hexanol-1. 3-Methylpentanol-1 was made by the Grignard reaction using secondary butyl bromide and ethylene oxide. Similarly, 2-methylpentanol-5 was prepared from isobutyl bromide and ethylene oxide.

Purification.—The alcohols were allowed to stand over "Drierite"[6] for a period of two months, filtered from the drying agent and fractionally distilled. The fractionating columns used have been described previously.[3]

The alcohols were considered pure when the boiling point range did not exceed 0.02°.

Apparatus.—A complete description of the apparatus and technique used for the determination of the physical constants can be found in the paper by Hovorka, Lankelma and Stanford.[3]

All the instruments used in the surface tension, density, and viscosity measurements were recalibrated before determinations were made.

Discussion of Results

Vapor Pressure.—The vapor pressure data are tabulated in Table I, column 5.

The summary of the values calculated from the vapor pressure data is given in Table II. The temperature variation of the vapor pressure was found to be given very closely by the Rankine equation, whose constants A, B and C are listed.

The values of the Trouton constant are considerably higher than the normal value of 21. These high values correspond with those found for the hexanols previously reported.[2,3,4]

Viscosity.—The viscosity data are tabulated in Table I, column 3. The viscosity *vs.* temperature curves for the two hexanols cross at 65° although the values from 65–150° do not vary by more than 0.6%. This peculiar behavior has been noticed previously. Like hexanol-1, reported by Hovorka, *et al.*, these two alcohols have a small temperature coefficient of viscosity.

Plots of Raman's equation[7] and Andrade's equation[8] yielded perfectly symmetrical curves instead of the required straight lines. The constants of the two equations and the deviations of the calculated from the observed viscosities are listed in Table III. It is very interesting to note here that of all the hexyl alcohols so far studied, hexanol-1 gives the least deviation from Andrade's equation, and that it is closely followed by 2-methylpentanol-5 and 3-methylpentanol-1.

Values of the degree of association have been calculated from the fluidity using a formula proposed by Bingham, *et al.*[9,10] The association factor as determined by the fluidity method is the ratio of the temperature required to give a certain fluidity to the temperature calculated from the "atomic temperature" constants. The values obtained are listed in Table IV. Calculation of the association factor for hexanol-1 gave values of 1.59, 1.48 and 1.41.

Bingham further calculates the degree of association by application of the formula, n =

TABLE II

SUMMARY OF VALUES CALCULATED FROM VAPOR PRESSURE DATA

$$\log P = A/T + B \log T + C$$

Substance		A	B	C	Deviation Maximum +	Deviation Average −
3-Methylpentanol-1	−4209.8	− 9.3605	37.3838	0.3	2.8	−0.43
2-Methylpentanol-5	−4778.8	−12.617	47.2894	.1	3.0	− .20

	Boiling point °C.[a]	Heat of vaporization[b]	Trouton's constant
3-Methylpentanol-1	152.44° ± 0.02	11,278	26.5
2-Methylpentanol-5	151.63° ± 0.02	11,124	26.2

[a] Boiling point values were obtained by interpolation from the vapor pressure curves.

[b] These values were calculated from the slope of the curve obtained by plotting log P against $1/T$.

$2.139 - 0.097\ N_c$, where N_c is the number of carbon atoms. This gives a value of 1.56 for the degree of association of the hexyl alcohols.

Refractive Index.—Using the values given by Eisenlohr[11] for the atomic refractive constants of carbon, hydrogen, and oxygen, the molecular refractive powers of 3-methylpentanol-1 and 2-methylpentanol-5 have been calculated. These values are compared with those calculated from the Lorenz–Lorentz equation in Table V.

(11) Eisenlohr, *Z. physik. Chem.*, **75**, 585 (1911).

TABLE III

CONSTANTS FOR RAMAN'S EQUATION $n = Ae^{B/T}$

	$A \times 10^6$	B	Maximum deviation +	Maximum deviation −
3-Methylpentanol-1	5.909	2675	5.8	7.4
2-Methylpentanol-5	6.759	2626	4.5	6.4

CONSTANTS FOR ANDRADE'S EQUATION $nv^{1/3} = Ae^{c/vT}$

	$A \times 10^6$	c	Maximum deviation +	Maximum deviation −
3-Methylpentanol-1	51.14	2503	6.9	10.5
2-Methylpentanol-5	56.13	2491	5.1	8.7

TABLE IV

CALCULATION OF ASSOCIATION FROM FLUIDITY

Rhes.	3-Methylpentanol-1 Calcd. temp., °A.	3-Methylpentanol-1 Obsd. temp., °A.	3-Methylpentanol-1 X	2-Methylpentanol-5 Obsd. temp., °A.	2-Methylpentanol-5 X
100	226.2	357.8	1.58	358.2	1.58
200	271.1	396.6	1.46	396.6	1.46
300	305.5	425.5	1.39	425.0	1.39

TABLE V

MOLECULAR REFRACTIVE POWER

	Lorenz–Lorentz equation	Summation of atomic constants
3-Methylpentanol-1	31.35	31.44
2-Methylpentanol-5	31.44	31.44

Surface Tension.—The surface tension data are listed in Table I, column 2.

The values of the Eötvös constant and the parachor were calculated over the entire temperature range and also are tabulated in Table I. The values listed are very similar to those calculated for the other hexanols. In all cases the values are those of associated substances.

The critical temperatures have been calculated from the Ramsay–Shields equation and are given in Table VI. A comparison of the surface tension of the two alcohols at equal distances from the critical point, so as to put the alcohols in corresponding states, showed that the values of the surface tension at one-third the critical temperature were identical, namely, 17.43 dynes. This may be ascribed to the fact that both alcohols seem to possess the same molecular aggregation at the higher temperatures.

TABLE VI

CRITICAL TEMPERATURES

Alcohol	T_c °C.	T_c °C.
3-Methylpentanol-1	403.9 (25–35)[a]	366.6 (145–150)
2-Methylpentanol-5	398.3 (25–35)	346.9 (145–150)

[a] The values in parentheses show the two temperatures used to calculate the critical temperature in question.

Summary

1. The preparation and purification of two hexyl alcohols, 3-methylpentanol-1 and 2-methylpentanol-5, have been described.

2. The surface tension, viscosity, density and vapor pressure have been determined over the temperature range from 5° to the boiling point. The refractive index has been determined from 15–45°.

3. The heat of vaporization, boiling point and the constants for Rankine's equation have been determined from the vapor pressure data. The vapor pressure values agreed very well with those calculated by the Rankine equation.

4. The viscosity values calculated from Raman's and Andrade's equation gave poor agreement with the experimental values. The two alcohols gave almost the same values for Andrade's constants and for degrees of association as obtained for hexanol-1.

5. The parachor, Eötvös constant and critical constants have been calculated from the surface tension data.

The Redistribution Reaction. V. R_4Pb Compounds

BY GEORGE CALINGAERT, HAROLD A. BEATTY AND HAROLD SOROOS

Previous papers in this series[1,2,3] have described the redistribution reaction for the interchange of organic radicals, and have shown that this reaction takes place quantitatively and leads to the formation of random equilibrium mixtures. The present paper covers the experimental data relating to the redistribution of tetraalkyllead and tetraaryllead compounds. In view of the novelty of the reaction, it was desired to explore the field as widely as possible before attempting a systematic or detailed study, and the data submitted here should be evaluated accordingly. The present tests were limited to an investigation of the generality of the reaction in the R_4Pb field, and to a preliminary study of how the reaction is affected by some experimental variables such as catalysts, catalyst concentration, solvents, temperature, and time. Later reports will cover more quantitative investigations of the most promising parts of the field explored.

With a few exceptions, the reactions were carried out in the same general manner, which consisted of taking the R_4Pb compound or mixture with the desired catalyst and in many cases with an inert solvent, maintaining this mixture at a given temperature for a certain length of time, removing the catalyst by extraction with water or with a suitable solvent or reagent, and finally analyzing the product by fractional distillation[2] or some other suitable method. In some of the cases, the analysis was carried out only far enough to indicate clearly that the reaction had taken place.

Systems Investigated.—The various R_4Pb systems tested are listed in Table I, and comprise thirteen different compounds containing six different alkyl and two different aryl radicals. With the exception of tests 12 and 14, the reaction conditions used were, as is described in the Experimental Part, essentially the same for each test, and these conditions were usually more than adequate to bring the reaction to completion. In each of the fourteen systems listed, the redistribution occurred and was judged to be complete or nearly so.

As far as the data indicate, all the alkyl radicals tested showed a reactivity of the same order of magnitude, with the exception of the tertiary butyl radical. Indeed, the redistribution of trimethyl-*t*-butyllead was accomplished only under drastic conditions, and it was accompanied by decomposition, which is presumably due to the instability of the poly-*t*-butyllead compounds formed. Judging from tests 13 and 14, it appears that the reactivity of the aryl radicals is of an order equal to, if not greater than, that of the alkyl radicals. The result of test 14 is of interest in showing that in the case of aryl groups the presence of a catalyst is not essential, and this recalls the interchange of phenyl and tolyl radicals previously observed in triarylbismuth compounds.[4]

As shown in Table II, the products of eight of these reactions, for which complete analyses were obtained, corresponded as well as could be expected to random equilibrium mixtures. More careful analyses would doubtless have shown even closer correspondence.[2] In the other six tests, complete analyses were not obtained, but the results (described in the Experimental Part) were nevertheless sufficient to show that redistribution had occurred.

In the three different systems used in tests 1, 2, and 3, which contain the same proportions of methyl to ethyl radicals, the product of each is in accord with the predicted composition, namely, 6.25 mole per cent. tetramethyllead, 25 mole per cent. trimethylethyllead, 37.5 mole per cent. dimethyldiethyllead, 25 mole per cent. methyltriethyllead, and 6.25 mole per cent. tetraethyllead; whereas the compound used in test 4 containing a different proportion of methyl to ethyl radicals gave a product containing the above five methyl-ethyl-lead compounds in close to the predicted proportions of 31.6, 42.2, 21.1, 4.7, and 0.4 mole per cent. respectively. The system used in test 10 contained equal proportions of the three different radicals, methyl, ethyl and *n*-propyl, and gave a product for which the analyses and distillation curve agree very well with the data calculated for the expected mixture of the fifteen

[a] Some decomposition occurred, with deposition of metallic lead. [b] The catalyst was not removed before distillation. [c] A moderate amount of side reaction occurred, with deposition of lead chloride.

greater stability of *n*-propyllead compounds. The distillation curves, which are illustrated in Fig. 2, clearly indicate that no isomerization takes place.

Catalysts.—The different catalysts for the redistribution reaction were tested with the system tetramethyllead–tetraethyllead. These catalysts are listed in Table IV, which also gives the concentrations and experimental conditions employed. It is believed that this list is by no means exhaustive. Bearing in mind that a large number of metallic halides have been shown to react with organo-metallic compounds to give organo-metallic halides[5] as, for example $Et_4Pb + AlCl_3 = Et_3PbCl + EtAlCl_2$, it will be noted that most of the catalysts either belong to the class of RMX compounds or will yield such compounds under the conditions of the reaction. For this reason, the list of catalysts probably could be enlarged quite readily by further tests. The different catalysts show a considerable variation in their activity, ranging from relatively weak catalysts such as the alkyllead halides and zirconium chloride, up to very

effective catalysts such as the methylaluminum chlorides. A general idea of the influence of the kind and amount of catalyst on the reaction velocity is obtainable from the data in Table V. For the system tetramethyllead–tetraethyllead, with or without solvents, no reaction was detected in the absence of a catalyst even after a long time at a high temperature. Of the catalysts, the trialkyllead halides increase in activity in the order: iodide, bromide, chloride; but they are at best relatively weak catalysts, concentrations of five to ten mole per cent. being required to bring about complete reaction in five hours at 80°. The aluminum chloride catalysts are effective at a concentration of 0.5 mole per cent., even in thirty minutes at room temperature. With smaller concentrations there was some indication that the reaction proceeded for a time at about the normal rate but then came to a halt, probably owing to the disappearance of the catalyst through decomposition reactions.

Temperature.—The effect of temperature on the reaction velocity is marked, as can be seen from the data for the trialkyllead halide catalysts in Table V, but no quantitative measurement of the effect has been made as yet. On the other hand, there is not the slightest indication of any effect of tem-

[a] About 50 ml. of an equimolecular mixture of Me_4Pb and Et_4Pb was used in all cases. [b] The course of the reaction was followed by vapor pressure measurements. [c] The product was distilled directly without first extracting the catalyst. [d] The acetone was distilled and the catalyst extracted, prior to distillation.

perature on the relative proportions of the R_4Pb compounds in the product of the completed reaction of a given system.

Solvents.—The presence of any of several chemically inert solvents does not appear to exert any pronounced effect on the reaction velocity, and certainly does not alter the relative proportions of the R_4Pb compounds in the completely-reacted product. The data in Table V indicate that, for the aluminum chloride catalyst, the presence of hexane may have a moderate retarding effect on the reaction velocity, but that a ten-fold increase in the amount of hexane has no further perceptible effect.

Experimental

Tetramethyllead and Tetraethyllead with Aluminum Chloride Catalyst.—Into a three-neck flask equipped with a reflux condenser and thermometer was added successively 0.5 g. of aluminum chloride and a mixture of 0.15 mole each of tetramethyl- and tetraethyllead, while maintaining an atmosphere of nitrogen within the system and cooling the flask in ice water. The mixture was kept at 80° for two hours. After cooling, an equal volume of water was added and after shaking the alkyllead layer was separated, filtered, and fractionated.[2] Redistribution was complete, as shown in Table II.

Other Alkyllead Systems.—The other alkyllead systems were run in a similar manner, except for variations in temperature, kind and amount of solvent, and concentration of the particular catalyst used, as shown in Tables I, IV, and V. When a solvent was used, the catalysts, with the exception of the methylaluminum chlorides, were added directly to the solution of the lead alkyls. The methylaluminum chloride catalysts were added by breaking small sealed glass capsules of the materials beneath the surface of the liquid lead alkyls, while maintaining an atmosphere of nitrogen in the system. In the experiment using boron trifluoride catalyst, the gas was bubbled into the solution of lead alkyls for one to two minutes prior to heating. In the two tests (Table V) in which acetone was used as the solvent, after the reaction the acetone was first distilled and the mixture of trialkyllead chloride catalysts extracted from the residue of lead alkyls with concentrated ammonia solution, prior to distillation of the product. In all other tests (Tables IV and V) where the trialkyllead halides were used for catalysts (with the exception of one test (Table V) where no solvent was used) the products of the reaction were distilled without first removing the catalyst.

In five tests listed in Table V, the course of the redistribution reaction was followed by a vapor pressure method which consisted of removing samples of the reaction mixture at regular time intervals, extracting the catalyst from the samples with water and filtering, and measuring the vapor pressure of the mixtures at 60°. The apparatus used for these measurements consisted of a bulb of about 200-ml. capacity, fitted with a mercury manometer and with a side arm for evacuating the system and introducing a measured amount of the sample. The apparatus was contained in a bath maintained thermostatically at 60 ± 0.01°. The vapor pressure of samples thus measured varied from 67 mm., indicating no redistribution, to 31 mm., indicating complete redistribution.

Trimethylisopropyllead and Dimethyldiisopropyllead with Aluminum Chloride Catalyst.—The product of the reaction of 0.3 mole of trimethylisopropyllead, 0.14 mole of dimethyldiisopropyllead and 1 g. of aluminum chloride, at 80° for five hours, on distillation gave the fractions listed in Table VI. The observed and calculated composition of the equilibrium mixture based on the lead analyses of the various fractions and the distillation curve (Fig. 2) are compared in Table II, test 7. The reaction, under the conditions used, was not entirely complete.

TABLE VI

DISTILLATION AND ANALYTICAL DATA FOR TEST NO. 7

Fraction	B. p. at 50 mm.,[a] °C.	Weight, g.	Lead analysis	Compounds present
1	→ 30		3.1935 g.	Me_4Pb + hexane[b]
2	49.5	9.4	76.57%	Me_4Pb + hexane[b]
3	93.0	56.0	70.22%	Me_4Pb + Me_3-*i*-PrPb
4	111.5	41.8	64.39%	Me_3-*i*-PrPb + Me_2-*i*-Pr_2Pb
5	122.0	8.6	60.37%	Me_2-*i*-Pr_2Pb + Me-*i*-Pr_3Pb
Residue[c]			0.401 g.	Me-*i*-Pr_3Pb + *i*-Pr_4Pb

[a] The actual boiling points were converted to 50 mm. by the aid of a nomogram.[2] [b] Solvent hexane used for extraction of aqueous layer. [c] The residue was washed from the still with carbon tetrachloride. Its R_4Pb content was estimated to be 80% *i*-Pr_4Pb.

Tetraethyllead and Tetra-*n*-propyllead with Aluminum Chloride Catalyst.—The product of the redistribution of 0.1 mole each of tetraethyl- and tetra-*n*-propyllead in the presence of 1 g. of aluminum chloride and 50 ml. of hexane at 80° for five hours showed complete redistribution on distillation. The distillation, however, was not of such precision as to warrant making an analysis of the products.

Diethyldi-*n*-propyllead with Aluminum Chloride Catalyst.—The product of the redistribution of 0.16 mole of diethyldi-*n*-propyllead in 38 ml. of hexane in the presence of 0.8 g. of aluminum chloride at 80° for five hours was judged to be complete although the distillation was not precise enough to make an analysis of the products.

Tetramethyllead, Tetraethyllead and Tetra-*n*-propyllead with Aluminum Chloride Catalyst.—In the system tetramethyl-, tetraethyl-, tetra-*n*-propyllead, it was not possible to separate all fifteen constituents by fractionation since the boiling points of the compounds containing the same number of carbon atoms are almost identical. The analysis was therefore limited to separation into the nine groups of compounds containing, respectively, from 4 to 12 carbon atoms, as shown in Table III. This was accomplished by making eight sharp distillation cuts, and determining by lead analysis the relative amounts of two consecutive groups of isomers in each cut. These compositions are indicated in Table VII, and the quantitative summation for each group of isomers is given in Table III.

Trimethyl-*t*-butyllead with Aluminum Chloride Catalyst.—The products from the redistribution of 0.08 mole of trimethyl-*t*-butyllead with 1 g. of aluminum chloride in 20 ml. of decalin at 100–130° for five hours were 7 g. of

TABLE VII

DISTILLATION AND ANALYTICAL DATA FOR TEST NO. 10

Fraction	B. p. at 50 mm.,[a] °C.	Number of carbon atoms in R_4Pb compounds present	Weight, g.	Pb analysis
1[b]	→ 33	4	..	1.99 g.
2[c]	78.5	4 + 5 + 6	35.5	71.09%
3	99.0	6 + 7	54.0	67.33%
4	114.7	7 + 8	66.0	64.20%
5	127.3	8 + 9	59.7	61.59%
6	132.5	9 + 10	20.3	60.07%
7	145.5	10 + 11	29.6	57.82%
Residue[d]		11 + 12	..	4.04 g.

[a] The actual boiling points were converted to 50 mm. by use of a nomogram.[2] [b] Contained some solvent hexane used for extraction of aqueous layer. [c] Estimated to contain 0.25 ml. of Me_4Pb. [d] The residue was washed from the still with carbon tetrachloride and its R_4Pb content was estimated to be 50% $EtPr_3Pb$.

metallic lead and 6 g. of tetramethyllead. The other lead alkyls were not isolated.

Tetramethyllead and Tetraphenyllead in Hexane with Aluminum Chloride Catalyst.—To a solution of 0.1 mole of tetraphenyllead and 0.2 mole of tetramethyllead in 75 ml. of hexane contained in a three-necked flask equipped with a reflux condenser and thermometer was added 1 g. of aluminum chloride. The mixture was maintained at 80° for seven hours, after which the flask was cooled and the catalyst extracted by shaking with water. After filtering the organic lead layer, two distillations yielded: tetramethyllead, 9 g., b. p. →77° (3 mm.); trimethylphenyllead, 31 g., b. p. 77–78° (3 mm.), $n^{20}D$ 1.5837 (*Anal.* Calcd. for $C_9H_{14}Pb$: Pb, 62.90. Found: Pb, 63.32); dimethyldiphenyllead, 25 g., b. p. 151–152° (2 mm.), $n^{20}D$ 1.6263 (*Anal.* Calcd. for $C_{14}H_{16}Pb$: Pb, 52.93. Found: Pb, 53.11); and a residue of 10 g., from which was obtained, by three recrystallizations from *n*-hexane, 3.5 g. of triphenylmethyllead, m. p., 62–63° (*Anal.* Calcd. for $C_{19}H_{18}Pb$: Pb, 45.69. Found: Pb, 45.65). A few crystals of tetraphenyllead, m. p. 226–228°, mixed m. p. 226–228°, also precipitated out of the equilibrium mixture prior to the distillation.

Tetraphenyllead and Tetra-*p*-tolyllead without Catalyst.—A mixture of 3 g. of tetraphenyllead and 3.3 g. of tetra-*p*-tolyllead in an air-jacketed test-tube equipped with a thermometer and stirrer was heated to melting in an oil-bath and allowed to cool slowly with stirring. Two successive cooling curves showed initial freezing points of 204.5 and 201.5°, respectively. After remelting and maintaining the mixture at 200° for three successive five-hour periods, the mixture showed initial freezing points of 177, 152.5 and 150°, respectively. Attempts to isolate the constituents by fractional crystallization and use of selective solvents were unsuccessful.

Summary

Data presented for the redistribution reaction in various R_4Pb systems show that the reaction is a general one for these compounds, and give an indication of the influence of some of the factors affecting the reaction such as the R groups, catalysts, catalyst concentration, solvents, temperature and time.

The Redistribution Reaction. VI. Alkyl Lead Halides

BY GEORGE CALINGAERT, HAROLD SOROOS AND HYMIN SHAPIRO

It was stated in the first paper of this series[1] that the interchange of alkyl groups in trialkyllead halides appears to be a general reaction for which no catalyst is required other than the alkyl lead halide itself.

The present paper covers the experimental data for this interchange of alkyl groups between two trialkyllead halides, between trialkyllead halides and tetraalkyllead compounds, and in a single mixed trialkyllead halide. The six systems tested, together with the experimental conditions employed, are listed in Table I. In each system the alkyl groups involved were methyl and ethyl. In the tests involving trialkyllead halides alone, only the chlorides were used; in the systems comprising tetraalkyllead with trialkyllead halide, both the chlorides and bromides were investigated. An experimental difficulty encountered in these reactions was the instability of the salts, particularly the bromides, which tend to disproportionate to lead alkyls, dialkyllead dihalides, and even alkyllead trihalides, and yield in addition the decomposition products of the last two, namely, hydrocarbons, alkyl halides, and lead halides. These secondary reactions were minimized by operating at a relatively low temperature and, in two cases, by converting the trialkyllead halides to the stable lead alkyls by means of an appropriate Grignard reagent immediately upon completion of the redistribution reaction.

TABLE I

REDISTRIBUTION OF ALKYLLEAD HALIDES

No.	Compounds	Moles	Solvent	Ml.	Temp., °C.	Hours	Notes
1	$Me_2EtPbCl$	0.38	Acetone	240	60	5	*a*
2	Me_3PbCl	.30	Acetone	300	60	5	*a*
	Et_3PbCl	.30					
3	Me_4Pb	.15	Hexane	50	76	5	*b*
	Et_3PbCl	.15					
4	Me_4Pb	.15	Hexane	50	76	5	*b, c*
	Et_3PbCl	.15					
5	Me_4Pb	.15	Hexane	50	76	5	*d*
	Et_3PbBr	.15					
6	Et_4Pb	.15	Hexane	50	80	5	*c, d*
	Me_3PbBr	.15					

[a] Complete analysis showed the product to be a random equilibrium mixture. [b] Analysis showed that both the R_3PbCl and R_4Pb in the product contained methyl and ethyl radicals in about equal proportions. [c] Added 2.5 mole per cent. of aluminum chloride catalyst to the lead compounds. [d] Analysis of R_4Pb in the product indicated a random equilibrium mixture; the R_3PbBr salts were not analyzed.

In the first two systems involving only trialkyllead chlorides, four compounds are predicted by theory and, correspondingly, by appropriate treatment with a suitable Grignard reagent, four lead alkyls were obtained which were readily separated by fractional distillation.[2]

In the systems containing tetraalkyllead, the theory predicts the formation of five lead alkyls and four trialkyllead halides. These were first separated by distillation into two groups, the liquid lead alkyls and the solid trialkyllead halides. The lead alkyls were subsequently fractionated. Although no attempt was made to separate the constituents present in the mixture of trialkyllead halides, the melting point as well as the lead and chlorine analysis of the mixture indicated the presence of both methyl and ethyl radicals. Whenever the analysis was carried to completion, the composition of the groups of compounds analyzed corresponded to the predicted random equilibrium, and these equilibrium compositions were independent of the identity of the starting materials.

Material balances for the halides could not be established as quantitatively as in the case of the catalytic redistribution of the lead alkyl systems,[3] first, because of a certain amount of decomposition of these salts, and, second, because their conversion to lead alkyls by the Grignard reaction was not quantitative.

The reactions appeared to take place readily and to reach completion in a relatively short time.[4] The compounds themselves act as catalysts, and the presence of an additional catalyst did not materially affect the rate of the reaction or alter the composition of the final product. Analytical data for the composition of three of the equilibrium mixtures are given in Tables II, III, and IV, and the distillation curves for two of the products are shown in Figs. 1 and 2.

TABLE II

PRODUCTS FROM THE REDISTRIBUTION OF $Me_2EtPbCl$

Compound	Identified as	Composition, mole per cent. Found	Calcd.[a] for $r^b = 2/3$
Me_3PbCl	Me_4Pb	30.0	29.6
$Me_2EtPbCl$	Me_3EtPb	47.2	44.5
$MeEt_2PbCl$	Me_2Et_2Pb	18.4	22.2
Et_3PbCl	$MeEt_3Pb$	4.4	3.7

[a] Calculated mole percentages are given[1] by: $Me_3PbCl = r^3$; $Me_2EtPbCl = 3r^2(1 - r)$; $MeEt_2PbCl = 3r(1 - r)^2$; $Et_3PbCl = (1 - r)^3$. [b] r is the mole fraction of methyl radicals in the starting compound.

TABLE III

PRODUCTS FROM THE REDISTRIBUTION OF Me_3PbCl WITH Et_3PbCl

Compound	Identified as	Composition, mole per cent. Found	Calculated for $r^a = 0.46$	Calculated for $r^b = 0.50$
Me_3PbCl	Me_4Pb	8.6	9.7	12.5
$Me_2EtPbCl$	Me_3EtPb	34.9	34.3	37.5
$MeEt_2PbCl$	Me_2Et_2Pb	41.5	40.3	37.5
Et_3PbCl	$MeEt_3Pb$	15.0	15.7	12.5

[a] r is the mole fraction of methyl radicals found in the product. [b] r is the mole fraction of methyl radicals present in the starting mixture.

TABLE IV

R_4Pb PRODUCTS FROM THE REDISTRIBUTION OF Me_4Pb WITH Et_3PbBr

Compound	Composition, mole per cent. Found	Calculated[a] for $r^b = 0.66$	Calculated[a] for $r^c = 0.57$
Me_4Pb	17.6	19.0	10.6
Me_3EtPb	44.0	39.1	31.9
Me_2Et_2Pb	22.6	30.2	36.0
$MeEt_3Pb$ + Et_4Pb	15.8	11.7	21.5

[a] Calculated mole percentages are given[1] by: $Me_4Pb = r^4$; $Me_3EtPb = 4r^3(1 - r)$; $Me_2Et_2Pb = 6r^2(1 - r)^2$; $MeEt_3Pb = 4r(1 - r)^3$; $Et_4Pb = (1 - r)^4$. [b] r is the mole fraction of methyl radicals found in the R_4Pb portion of the product. [c] r is the mole fraction of methyl radicals present in the starting mixture.

Conclusion.—The data show that the redistribution reaction of the trialkyllead halides takes place readily in the absence of any additional catalyst other than the halides themselves. This fact elucidates several reports of anomalous be-

havior which have appeared in the literature, but which have received very little consideration from either their authors or others. Previous work in this Laboratory[5] has shown that in the synthesis of certain $R_3R'Pb$ compounds from the reaction of R_3PbX compounds with Grignard reagents, some R_4Pb and $R_2R'_2Pb$ compounds are also formed. Grüttner and Krause[6] have emphasized that in the preparation of $R_2R'R''Pb$ compounds from $R_2R'PbX$, great care must be exercised to use the halides only when freshly prepared, as storage for any length of time, especially of the bromides, leads to low yields and an impure product. On the basis of the disclosures made in the present paper, it seems certain that these previous results were due to the spontaneous redistribution of the trialkyllead halides containing different alkyl groups, with the result that the final lead alkyl product contained, in addition to the expected compound, the three compounds corresponding to this redistribution.

Experimental

Redistribution of Dimethylethyllead Chloride.—The salt was prepared by passing dry hydrogen chloride into a hexane solution of trimethyllead. The precipitated salt was filtered, and freed of small amounts of lead chloride and dialkyllead dichlorides by dissolving the product in benzene, filtering, and reprecipitating the salt by dilution with hexane. The material was finally filtered, washed with hexane, and dried by evacuation.

Anal. Calcd. for $C_4H_{11}PbCl$: Pb, 68.66; Cl, 11.75. Found: Pb, 68.62; Cl, 11.76.

The redistribution of dimethylethyllead chloride and the subsequent conversion of the resulting random equilibrium mixture of trialkyllead chlorides to the corresponding tetraalkyllead compounds was accomplished in the following manner. A solution of 0.38 mole of dimethylethyllead chloride in 240 ml. of dry acetone was refluxed at 60° for five hours. After cooling and filtering from 0.6358 g. of precipitated lead chloride, the acetone was distilled, the last traces being removed at reduced pressure and condensed in a dry-ice trap. The residue was washed with cold hexane. Fractionation of the acetone distillate and hexane washings yielded 2.234 g. of lead alkyls. The residue was next dissolved in 300 ml. of dry benzene, filtered from 0.1849 g. of dialkyllead chlorides, precipitated by dilution with hexane at −70°, and filtered. An additional small amount of the salts obtained by evaporation of the filtrate was combined with the main body of the material. The mixture of trialkyllead chlorides was finally suspended in 200 ml. of dry ether and treated with an ether solution of 0.7 mole of methylmagnesium bromide. After decomposing the reaction mixture with water and separating the ether layer, fractionation of the product indicated an 83% yield of tetraalkyllead compounds in the proportions corresponding to a random equilibrium mixture of the trialkyllead chlorides, as shown in Table II and Fig. 1.

Redistribution of Trimethyl- with Triethyllead Chloride.—A solution of 0.3 mole each of trimethyl- and triethyllead chloride in 300 ml. of dry acetone was refluxed at 60° for five hours. After filtering from a minute amount of lead chloride, the acetone was evaporated and the residue dried by suction. The mixture of trialkyllead chlorides was converted to the corresponding tetraalkyllead compounds by treating the salts, suspended in 300 ml. of dry ether, with an ether solution of 0.9 mole of methylmagnesium bromide. After decomposing the excess Grignard reagent with water, and separating the ether layer, fractionation of the product gave an 88% yield of lead alkyls corresponding to the random redistribution of the trialkyllead chlorides shown in Table III. The distillation curve is shown in Fig. 2. The observed 46% methyl radicals in the product agrees with the 50% taken in the starting materials as well as is to be expected.

That the redistribution of the two trialkyllead chlorides was not brought about by any catalytic effect of the Grignard reagent was demonstrated by treating an ether suspension of 0.2 mole each of trimethyl- and triethyllead chloride with an ether solution of 0.6 mole of methylmag-

nesium bromide. After decomposing the excess Grignard reagent with water and separating the ether layer, fractionation of the product gave only two lead alkyls, namely, 0.18 mole of tetramethyllead and 0.123 mole of methyltriethyllead. The yield of lead alkyls was 76%.

Redistribution of Triethyllead Chloride with Tetramethyllead. (a) **With no Catalyst.**—A mixture of 0.15 mole each of triethyllead chloride and tetramethyllead in 50 ml. of hexane was refluxed at 77° for five hours. The mixture of liquid lead alkyls was distilled rapidly at reduced pressure (2–50 mm.) from the mixture of solid alkyllead chlorides. The residue was washed with hexane, dried on a porous plate (wt. 40 g.), and analyzed. *Anal.* Calcd. for $Me_{1.5}Et_{1.5}PbCl$: Pb, 67.10; Cl, 11.48. Found: Pb, 65.96; Cl, 11.83. A sample of the solids recrystallized from hexane decomposed at 95°; triethyllead chloride decomposes at 170°. Fractionation of the distillate of liquid lead alkyls gave 2.3 ml. of tetramethyllead, 7.7 ml. of trimethylethyllead, 4.6 ml. of dimethyldiethyllead, and 2–3 ml. of residue containing the higher lead alkyls. Although the data obtained in this and the experiments given below were not of such accuracy as to permit a complete analysis of the products of the reaction, the results were nevertheless sufficient to indicate conclusively that redistribution of the alkyl groups had occurred.

(b) **With Aluminum Chloride Catalyst.**—A mixture of 0.15 mole each of triethyllead chloride and tetramethyllead with 1 g. of aluminum chloride in 50 ml. of hexane, treated in the same manner as in (a), gave 40.8 g. of a mixture of solid alkyllead chlorides. *Anal.* Calcd. for $Me_{1.5}Et_{1.5}PbCl$: Pb, 67.10; Cl, 11.48. Found: Pb, 65.59; Cl, 11.68. A sample of the solid mixture recrystallized from hexane decomposed at 90°. Fractionation of the liquid lead alkyls gave 2.5 ml. of tetramethyllead, 6.9 ml. of trimethylethyllead, 3.1 ml. of dimethyldiethyllead, and 4–5 ml. of residue containing the higher lead alkyls.

Redistribution of Triethyllead Bromide with Tetramethyllead.—A mixture of 0.15 mole each of triethyllead bromide and tetramethyllead in 50 ml. of hexane was refluxed at 77° for five hours. The liquid portion of the product was filtered from the undissolved salts and the solids were washed with hexane. The lead alkyl filtrate and hexane washings were distilled rapidly at reduced pressure (2–50 mm.) from a small amount of dissolved salts. Fractionation of the distillate gave 3.8 ml. of tetramethyllead, 10.6 ml. of trimethylethyllead, 6.0 ml. of dimethyldiethyllead, and 4.6 ml. of a mixture of methyltriethyllead and tetraethyllead. The analysis of the product is given in Table IV.

The data show that considerable decomposition of the trialkyllead bromides took place, forming lead alkyls and lead bromide, since the total recovery of lead alkyls (0.161 mole) is greater than the input (0.15 mole).

Redistribution of Trimethyllead Bromide with Tetraethyllead.—The redistribution of 0.15 mole each of trimethyllead bromide and tetramethyllead with 1 g. of aluminum chloride at 80° for five hours, followed by filtration and vacuum distillation from the solid alkyllead bromide salts, and by fractionation of the liquid lead alkyls, gave 45.5 g. of lead alkyl distillate. The fractionation, although not adequate for accurate analysis, indicated a random equilibrium mixture, showing that the redistribution was probably complete.

Summary

Trialkyllead halides containing methyl and ethyl radicals undergo the redistribution reaction spontaneously and yield a random equilibrium mixture containing all four possible trialkyllead halides. Mixtures of trialkyllead halides and tetraalkyllead containing these two radicals yield the five possible lead alkyls as well as the four halides.

The Redistribution Reaction. VII. Alkyl Compounds of Mercury, Tin, Silicon and Zinc

BY GEORGE CALINGAERT, HAROLD SOROOS AND VINCENT HNIZDA

The first paper[1] of this series stated that the redistribution reaction takes place in a variety of metal alkyls and subsequent papers have described the reaction for R_4Pb compounds[2] and the trialkyllead halides.[3]

The present paper gives the experimental data relating to the interchange of alkyl groups in several other metal alkyls, namely, those of mercury, tin, silicon and zinc. The systems tested, together with the experimental conditions employed, are listed in Table I and comprise eleven compounds, four metals and three alkyl radicals. The results, except for zinc, were similar to those obtained for the lead compounds, the products being random equilibrium mixtures of all the possible metal alkyls for each metal and the two alkyl groups present.

Both methylethylmercury and an equimolecular mixture of dimethyl- and diethylmercury gave the same random equilibrium mixture of the three mercury alkyls, shown in Table II, when allowed to stand at room temperature in the presence of

the aluminum chloride catalyst. The analytical distillation curves[4] are shown in Fig. 1. The redistribution of dimethylmercury with diethylmercury and the subsequent isolation of methylethylmercury is of particular interest, since reports in the literature[5] suggest that methylethylmercury is too unstable to exist as such for any length of time.

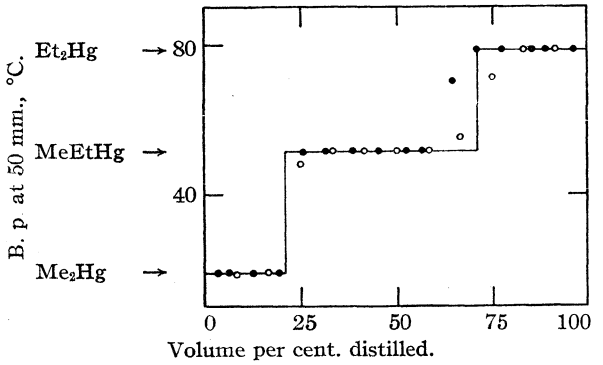

Fig. 1.—Distillation of reaction product from: ○, MeEtHg; ●, Me_2Hg + Et_2Hg; solid line calculated for random equilibrium in mixture having [Me] = 0.5.

Contrary to these reports, pure methylethylmercury appears to be a very stable compound, being unchanged on standing at room temperature for months, or on distillation at 127°, even after the addition of a small amount of iodine. Its isolation in a pure state can, therefore, be accomplished by fractional distillation of the random redistribution mixture of the three mercury alkyls obtained from the redistribution of a mixture of dimethylmercury with diethylmercury. In the light of the present study it now appears probable that Frankland's material contained catalytic amounts of alkylmercuric chloride which caused redistribution, and that the equilibrium was constantly displaced by the removal of dimethylmercury, thus resulting in the gradual disappearance of the methylethylmercury originally present.

(4) Calingaert, Beatty and Neal, THIS JOURNAL, **61**, 2755 (1939).

(5) Frankland, *Ann.*, **111**, 57 (1859), treated ethylmercuric chloride with dimethylzinc and stated that: "It is probable that mercuric ethomethide was formed in the above reaction; but subsequent distillations gradually transformed it, more or less perfectly, into a mixture of mercuric ethide and mercuric methide." Hilpert and Grüttner, *Ber.*, **48**, 906 (1915), state that RR'Hg compounds, sealed in glass and kept for a few weeks, decompose to R_2Hg and R'_2Hg; see also Kharasch and Marker, THIS JOURNAL, **48**, 3130 (1926).

TABLE II

MeEtHg	Found	28	47	25
	Calcd.	25	50	25

Random equilibrium mixtures containing the five possible metal alkyls were obtained from the redistribution reaction of tetramethyltin with tetraethyltin, and of tetraethylsilicon with tetrapropylsilicon. The analyses of the two products are given in Tables III and IV and the analytical distillations are shown in Figs. 2 and 3. The redistribution of tetraethylsilicon with tetrapropylsilicon was tested for convenience at the refluxing temperature of the mixture, and the possibility of reaction at a lower temperature was not investigated. These results for silicon recall the inter-

changes of radicals found at high temperatures (about 300°) by Dolgov and Volnov[6] in alkyl and alkyl–aryl $R_3R'Si$ compounds. These authors stated that the compounds rearranged according to the scheme $2R_3R'Si \rightarrow R_2R'_2Si + R_4Si$, and ascribed this to the greater stability of the symmetrical molecules. However, their analytical data are only sufficient for the identification of the new compounds so obtained, and are not adequate to determine the composition of the whole product or to demonstrate the existence of an equilibrium.

A mixture of dimethylzinc with diethylzinc did not undergo any redistribution at the boiling temperature (about 60°) in the presence of aluminum chloride or mixed methylaluminum chlorides as catalysts. The possibility that the reaction can be brought about at a higher temperature or under different operating conditions has not yet been tested.

Although only four metals and three alkyl radicals have been tested in the present study, it seems probable in the light of the results with lead[2] that the reaction will occur as well with other alkyl and aryl radicals of the present metals. It would at least with those metals which are known to form mixed compounds of the RR'M type. This supposition is borne out by the observation of Challenger and Ridgway,[7] who studied the transfer of aryl radicals in organo-metallic compounds, and stated that "a most interesting example of this type of reaction is afforded by the ready production of diphenyl-α-naphthylbismuth by the fusion of tri-α-naphthylbismuth and triphenylbismuth at 190°." Some amount of unchanged reactants was also found in the product, but the small quantities of materials and the methods of separation used obviously precluded an accurate analysis of the product, and no mention of phenyldi-α-naphthylbismuth is made. These authors also stated that "a preliminary experiment appeared to indicate that this reaction is reversible," without giving any experimental details. It would seem probable that this reaction is an example of redistribution and that a precise analysis would have shown a random equilibrium mixture of all four R_3Bi compounds.

Experimental

Dimethyl- with Diethylmercury.—A mixture of 0.11 mole each of dimethyl- and diethylmercury with 1.7 mole per cent. of aluminum chloride was allowed to stand in a stoppered flask at room temperature for eighteen hours. After extracting the catalyst by shaking with water, the distillation of the product, shown by the solid circles in Fig. 1, yielded the equilibrium mixture given in Table II.

Methylethylmercury.—The pure compound was obtained by fractional distillation of the random equilibrium mixture obtained from the redistribution of dimethylmercury with diethylmercury: b. p. 51.5 (50 mm.), d^{20} 2.71; $n^{20}D$ 1.5440. *Anal.* Calcd. for C_3H_8Hg: Hg, 81.98. Found: Hg, 81.24. The compound, after standing for seven months at room temperature, showed no evidence of spontaneous redistribution or decomposition to the symmetrical compounds, when redistilled at 50 mm. through a packed column in an atmosphere of nitrogen. Another sample distilled at atmospheric pressure (127.4° at 748 mm.) with no evidence of decomposition, even when the flask was almost dry. Repeating this high temperature distillation after the addition of a trace of iodine produced no change in boiling point or evidence of redistribution, although the iodine reacted immediately with the mercury compound.

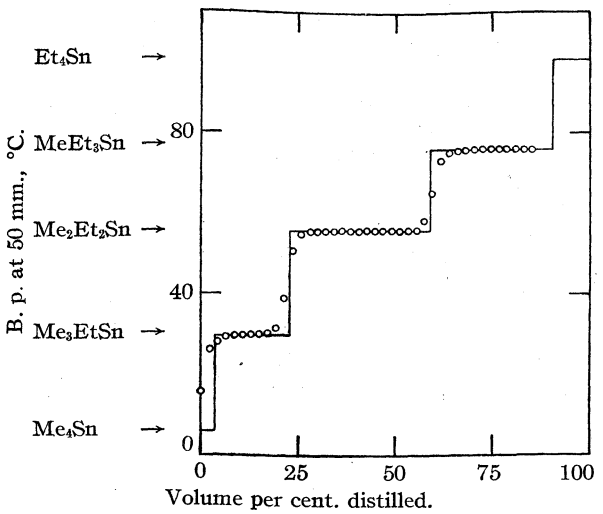

Fig. 2.—Distillation of the reaction product from $Me_4Sn + Et_4Sn$: solid line calculated for random equilibrium mixture having [Me] = 0.46.

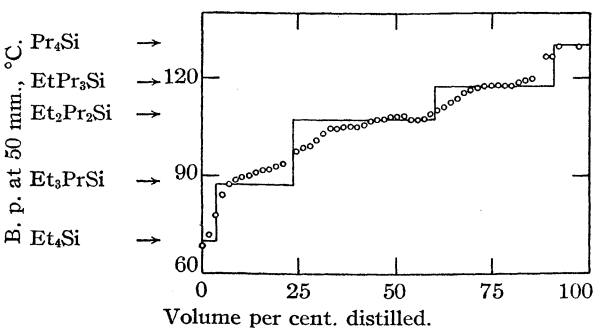

Fig. 3.—Distillation of the reaction product from Et_4Si and Pr_4Si: solid line calculated for random equilibrium mixture having [Et] = 0.464.

(7) Challenger and Ridgway, *J. Chem. Soc.*, **121**, 104 (1922).

The redistribution of the compound was effected by treating 0.07 mole with 3.5 mole per cent. of aluminum chloride at room temperature for sixty-six hours, followed by extraction of the catalyst with water. The analytical distillation of the product is shown by the open circles of Fig. 1, and its composition is given in Table II.

Tetramethyl- with Tetraethyltin.—The redistribution of a mixture of 0.15 mole each of the two tin alkyls with 2.5 mole per cent. of aluminum chloride was carried out in 50 ml. of pentane at the boiling point of the mixture, 60°, for five hours. The catalyst went into solution in the mixture and later there was formed about 1 ml. of heavy yellow oil, from which the product was decanted. After distilling off the solvent, there remained 61 g. of tin alkyls, whose analysis by distillation is given in Table III and Fig. 2.

Tetraethyl- with Tetrapropylsilicon.—The redistribution of a mixture of 0.14 mole of tetraethylsilicon and 0.15 mole of tetrapropylsilicon (48% ethyl radicals) with 2.5 mole per cent. of aluminum chloride was carried out at the boiling point of the mixture, 175–180°, for five hours. There was no visible reaction of the catalyst, which finally was extracted with water. The analytical distillation shown in Fig. 3, although not made carefully, showed that redistribution had occurred, and the estimated composition corresponded with the expected equilibrium mixture, as shown in Table IV.

Dimethyl- with Diethylzinc.—A mixture of 0.32 mole of dimethylzinc and 0.21 mole of diethylzinc, after refluxing for five hours in an atmosphere of nitrogen, was fractionated into the two original components without evidence of redistribution. After refluxing the same mixture at atmospheric pressure (temperature about 60°) for five hours in the presence of 1.4 mole per cent. of aluminum chloride, followed by vacuum distillation (20–50 mm.) from the catalyst, fractionation again gave only the symmetrical zinc alkyls. Repeating the experiment with the addition of 1.5 mole per cent. of a mixture of methylaluminum chlorides to the aluminum chloride still did not bring about redistribution.

The recovery of products in the above experiments was essentially quantitative, except for normal handling losses incurred during extraction of the catalyst, filtration, transfer, and distillation.

Summary

The alkyl compounds of mercury, tin and silicon readily undergo the redistribution reaction, yielding random equilibrium mixtures, while the zinc alkyls at 60° failed to react. Methylethylmercury was isolated and found to be stable on standing or distillation, in the absence of redistribution catalysts.

Studies in the Phenanthrene Series. XXIV. Phenolic Amino Alcohols and Naphthisoquinolines Derived from 9,10-Dihydrophenanthrene[1]

BY ALFRED H. STUART AND ERICH MOSETTIG

Ethanolamine and propanolamine derivatives of 9,10-dihydrophenanthrene prepared in our laboratory[2] have been found to exhibit a relatively high analgesic activity, which, unfortunately, was accompanied by convulsant and emetic effects of similar or even higher degree.[3] In the hope of finding compounds with a more favorable ratio of desirable and undesirable physiological effects, it was decided to synthesize analogous amino alcohols of the dihydrophenanthrene series, containing besides the alkamine side chain also a phenolic hydroxyl group.

The choice of positions into which the phenolic hydroxyl group can be introduced appears to be limited, and the same holds true for the introduction of a second substituent that can be used for building up alkamine side chains or other desirable groups. Thus, the phenolic hydroxyl group can be conveniently introduced only into position 2 of 9,10-dihydrophenanthrene.[4] Also acyl groups enter chiefly position 2, and position 7 if 2 is already occupied by a phenolic hydroxyl group.[2,4b] We have described recently a practicable method for the preparation of 2-hydroxy-7-acetyl-9,10-dihydrophenanthrene,[4b] and this compound, indeed, became the key substance for the various syntheses described in this communication. The 2-hydroxy-7-[2-(diethylamino)-1-hydroxyethyl]-9,10-dihydrophenanthrene (I) was prepared by bromination of the above-mentioned hydroxy ketone, replacement of the bromine by the di-

N-acetyl derivative VIIIa

ethylamino group, and subsequent reduction of the resulting amino ketone. Actually, the reactions were carried out on the respective O-acetyl derivatives, with saponification as the last step of the synthesis. Similarly, application of the Mannich amino ketone synthesis to 2-acetoxy-7-acetyl-9,10-dihydrophenanthrene gave 2-acetoxy-7-[3-(diethylamino)-1-oxopropyl]-9,10-dihydrophenanthrene, from which the amino alcohol II was obtained by catalytic reduction. In this procedure, aqueous formaldehyde[5] was employed, the advantage over the use of paraformaldehyde and isoamyl alcohol[6] being that unreacted starting material can be recovered readily.[7]

Encouraged by the favorable reports on the pharmacological effectiveness of an isoquinoline derivative,[8] which was obtained by closing a nitrogen-containing ring onto the phenanthrene nucleus, we decided to synthesize analogous compounds derived from 9,10-dihydrophenanthrene and 2-methoxy-9,10-dihydrophenanthrene. The starting materials in these syntheses were the aldehydes III and IV, which were prepared *via* the corresponding acids by the Rosenmund method.[9] The phenanthroic acids themselves were readily obtained from 2-acetyl- and 2-methoxy-7-acetyl-9,10-dihydrophenanthrene by oxidation with sodium hypochlorite. This detour to the aldehydes was chosen because thereby better results were achieved than by the application of the direct method, involving the action of metal chlorides and hydrogen cyanide on 9,10-dihydrophenanthrene.[4a] Attempts to prepare the hydroxy aldehyde corresponding to IV by modified Gattermann syntheses[10] were unsuccessful. We did not succeed in preparing the β-phenanthrylethylamines VII and VIII by electrolytic reduction of the corresponding nitrovinyl derivatives, a method that we had applied previously to the preparation of other β-phenanthrylamines.[8a] Eventually we were able to synthesize VII and VIII in yields of from 60 to 80% by the Curtius method, starting from β-[2-(9,10-dihydrophenanthryl)]-propionic acid (V) and β-[7-(2-methoxy-9,10-dihydrophenanthryl)]-propionic acid (VI). Acid V had been prepared by us previously.[4a] The analogous preparation of acid VI did not offer any difficulties.

Attempts to produce tetrahydroisoquinoline derivatives by cyclization of the formaldehyde

(6) *Cf.* van de Kamp and Mosettig, THIS JOURNAL, **58**, 1568 (1936).

(7) The possibility that the $-CH_2N(C_2H_5)_2$ group has entered a nuclear position activated by the acetoxy group, cannot be entirely excluded [*cf.* Auwers and Dombrowski, *Ann.*, **344**, 280 (1906)]. We had not enough material available to prove the structure of the amino ketone or the corresponding amino alcohol.

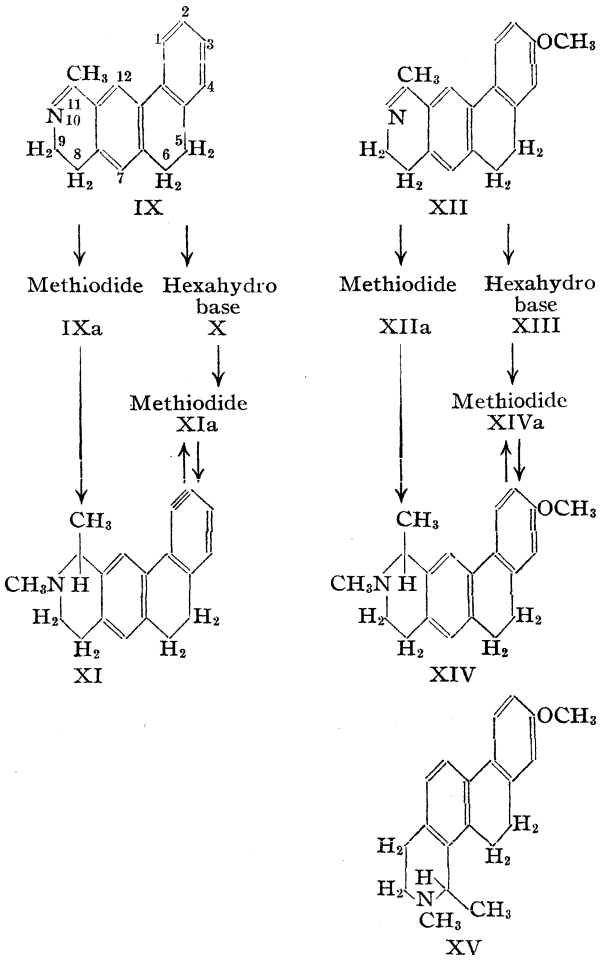
(9) See Mosettig and van de Kamp, *ibid.*, **55**, 2995 (1933).

(10) Adams and co-workers, *ibid.*, **45**, 2373 (1923); **46**, 1518 (1924); Hinkel and co-workers, *J. Chem. Soc.*, 2793 (1932); 184, 339 (1936).



condensation products of VII and VIII[11] were completely unsuccessful, variations in experimental conditions leading either to starting material or to amorphous, insoluble, and non-basic condensation products. No satisfactory method for the preparation of the desired isoquinoline derivatives in adequate amounts was devised. Ring closure was effected eventually by the Bischler–Napieralski reaction. After investigating a number of modifications of this method,[12] we found that the best results were obtained by cyclizing the N-acetyl derivatives, VIIa and VIIIa, to the dihydroisoquinoline derivatives IX and XII by the action of phosphorus oxychloride in boiling toluene, in an average yield of less than 30%. In order to transform IX and XII into the corresponding N-methyltetrahydroisoquinoline derivatives XI and XIV, two routes were followed in each series. (a) The methiodides IXa and XIIa respectively were reduced catalytically. (b) The bases IX and XII were reduced catalytically to X and XIII, respectively. The latter two were completely methylated, and the resulting methiodides XIa and XIVa were decomposed by heating in an oil-pump vacuum. In each series, identical end-products, XI and XIV, were obtained by either route.

Because of the large number of steps involved in the synthesis of XI and XIV, and, in particular, on account of the relatively poor yield in the Bischler–Napieralski reaction, we eventually did not have enough material available to attempt a structural proof of the bases XI and XIV. By analogy,[13] we assume structure XI to be correct, *i. e.*, the ring closure of VIIa to have taken place in position 3 of the phenanthrene nucleus. There are no precedents in the 9,10-dihydrophenanthrene series that would justify speculations whether the methoxyl group in the terminal nucleus had any influence on the direction of ring closure of compound VIIIa. Formula XIV, therefore, can be suggested only tentatively, and an alternative structural formula, XV, must also be taken into consideration.

Compounds I, II, and XIV have been submitted to pharmacological investigation. As yet only results obtained with I are available. The analgesic activity of I (10 mg./kg., cat) shows, according to Dr. Eddy, a twofold increase over that of its analog carrying no phenolic hydroxyl group, the 2-[2-(diethylamino)-1-hydroxyethyl]-9,10-dihydrophenanthrene. The former was also more toxic and more convulsant, but the difference in these respects was relatively less.

Experimental

2-Acetoxy-7-ω-bromoacetyl-9,10-dihydrophenanthrene.—A saturated solution of 2-acetoxy-7-acetyl-9,10-dihydrophenanthrene[4b] in absolute ethanol was mixed at 0° in a quartz flask with an ice-cold solution of one molecular equivalent of bromine in absolute ether, and the mixture was exposed to a mercury vapor-lamp for five minutes. The hydrogen bromide formed in the reaction was neutralized with potassium carbonate, and the solution was evaporated to dryness. The product crystallized from ethanol in small white needles that melted at 123–124°.

Anal. Calcd. for $C_{18}H_{15}BrO_3$: C, 60.18; H, 4.21. Found: C, 60.68; H, 3.81.

2-Acetoxy-7-[2-(diethylamino)-1-oxoethyl]-9,10-dihydrophenanthrene.—A mixture of the above bromo ketone

and diethylamine (5–6 molecular equivalents) in dry benzene was allowed to stand at room temperature for five hours. The amino ketone was isolated in the customary manner and purified through its perchlorate. It melted at 89–90°.

Anal. Calcd. for $C_{22}H_{25}NO_3$: N, 3.99. Found: N, 3.93.

The **perchlorate** was recrystallized from an ethanol–ether mixture. It melted at 165–166°.

Anal. Calcd. for $C_{22}H_{26}ClNO_7$: N, 3.10; Cl, 7.84. Found: N, 3.39; Cl, 7.68.

No crystalline hydrochloride could be obtained.

2-Acetoxy-7-[2-(diethylamino)-1-hydroxyethyl]-9,10-dihydrophenanthrene.—A mixture of 2 g. of the amino ketone perchlorate, 70 cc. of absolute alcohol, and 0.1 g. of platinum oxide absorbed the calculated amount of hydrogen within six hours. The perchlorate of the resulting amino alcohol and the base itself were oily. The **hydrochloride** was recrystallized from an alcohol–ether mixture and melted at 154–155°.

Anal. Calcd. for $C_{22}H_{28}ClNO_3$: N, 3.59; Cl, 9.09. Found: N, 3.55; Cl, 9.32.

2-Hydroxy-7-[2-(diethylamino)-1-hydroxyethyl]-9,10-dihydrophenanthrene (I).—The above acetoxy compound was saponified readily. The base itself could be obtained only as an oil. The hydrochloride was recrystallized from an alcohol–ether mixture and melted at 202–203°.

Anal. Calcd. for $C_{20}H_{26}ClNO_2$: N, 4.03; Cl, 10.19. Found: N, 4.05; Cl, 10.23.

2-Acetoxy-7-[3-(diethylamino)-1-oxopropyl]-9,10-dihydrophenanthrene.—A mixture of 3 g. of 2-acetoxy-7-acetyl-9,10-dihydrophenanthrene, 1.4 g. of diethylamine hydrochloride, and 1.1 cc. of 36% aqueous formaldehyde was stirred mechanically in a nitrogen atmosphere for ten minutes at room temperature, and for one hour at 100°, during which the formaldehyde lost by evaporation was replaced by occasional additions. The mixture was diluted with water, and unchanged starting material was extracted with ether (1.6 g., after crystallization from ethanol). The amino ketone was precipitated in the aqueous layer with ammonia and extracted with ether. The recrystallized **hydrochloride** weighed 1.5 g. and melted at 132–134° (yield, calcd. on the basis of reacting material, 75%).

Anal. Calcd. for $C_{23}H_{28}ClNO_3$: Cl, 8.82. Found: Cl, 9.32.

In subsequent runs, the relative amounts of reacting material varied somewhat, but the yield of amino ketone was constant. When the reaction was carried out by boiling a mixture of ketone, diethylamine hydrochloride, and paraformaldehyde in isoamyl alcohol, the yield of crystalline amino ketone hydrochloride was approximately the same, but starting material could be recovered only with difficulty.

2-Hydroxy-7-[3-(diethylamino)-1-hydroxy-*n*-propyl]-9,10-dihydrophenanthrene (II).—The above compound, when reduced catalytically, absorbed smoothly one molecular equivalent of hydrogen (PtO_2, absolute alcohol), but no crystalline base or salt of the resulting amino alcohol could be obtained. Therefore, the crude reduction product was saponified, whereby a crystalline phenolic amino alcohol of m. p. 178–185° was formed. It crystallized readily from ethyl acetate and melted, after drying in the desiccator, at 129–130°. The analytical data agree approximately with values for a base containing two moles of ethyl acetate

Anal. Calcd. for $C_{21}H_{27}NO_2 + 2C_4H_8O_2$: C, 69.42; H, 8.63. Found: C, 70.70; H, 8.34.

When this compound was dried at 100° in an oil-pump vacuum, its m. p. rose to 182–183°. Satisfactory analytical data were obtained only after the base was sublimed in an oil-pump vacuum. It then melted at 185–186°.

Anal. Calcd. for $C_{21}H_{27}NO_2$: C, 77.50; H, 8.36. Found: C, 77.41; H, 8.69.

The hydrochloride melted after recrystallization at 180–181°.

Anal. Calcd. for $C_{21}H_{28}ClNO_2$: C, 69.69; H, 7.80. Found: C, 69.61; H, 7.68.

By allowing the pyridine solution of the above hydrochloride and the calculated amount of benzoyl chloride to stand for five hours, we obtained a dibenzoyl derivative whose hydrochloride melted unsharply at 157–159° after two crystallizations from an alcohol–ether mixture.

Anal. Calcd. for $C_{35}H_{36}ClNO_4$: Cl, 6.22. Found: Cl, 6.58.

9,10-Dihydrophenanthroyl-2-chloride.—2-Acetyl-9,10-dihydrophenanthrene[2] was oxidized readily by 1.5% aqueous sodium hypochlorite solution. The dried crude acid was suspended in thionyl chloride and the mixture was boiled under reflux for four hours. The solution was evaporated in a vacuum, and left an oily residue, which was distilled twice in an oil-pump vacuum. The distillate solidified slowly (yield, 95%). The analytical sample was sublimed slowly, and appeared as long, colorless needles, m. p. 50–51°.

Anal. Calcd. for $C_{15}H_{11}ClO$: C, 74.23; H, 4.57; Cl, 14.61. Found: C, 73.91; H, 4.51; Cl, 14.49.

9,10-Dihydrophenanthrene-2-aldehyde (III).—The acid chloride[14] was converted into the aldehyde by the method of Rosenmund, using an aged palladium–barium sulfate catalyst and decalin as solvent.[9] The yield was 70% (identified as semicarbazone).

2-Methoxy-9,10-dihydrophenanthroyl-7-chloride.—This compound was prepared from the corresponding acid[4a] in the manner described above. The crude crystalline residue from evaporation of the reaction mixture was used for catalytic reduction. For analysis, a sample was sublimed twice in an oil-pump vacuum; white needles, m. p. 87–88°.

Anal. Calcd. for $C_{16}H_{13}ClO_2$: C, 70.46; H, 4.80. Found: C, 70.84; H, 5.29.

2-Methoxy-9,10-dihydrophenanthrene-7-aldehyde (IV).—The catalytic replacement of the chlorine by hydrogen proceeded smoothly, and the aldehyde was formed in a yield of 67% (calculated on the basis of acid). It was recrystallized from methanol and melted at 100°.

Anal. Calcd. for $C_{16}H_{14}O_2$; C, 80.65; H, 5.92. Found: C, 80.42; H, 6.22.

(14) The thionyl chloride used in the preparation of the acid chlorides was purified according to the directions of Fieser's "Experiments in Organic Chemistry," 1935.

2-(2-Nitrovinyl)-9,10-dihydrophenanthrene.—Aldehyde III (4.5 g.) was condensed[8a,15] with nitromethane (2.6 cc.) in ethanolic solution (300 cc.) in the presence of sodium hydroxide (2.8 g.). When the reaction mixture was poured into 10% hydrochloric acid, the product separated as a yellow oil, which slowly became crystalline. It crystallized from ethanol in bright yellow needles, m. p. 77°; yield, 75%.

Anal. Calcd. for $C_{16}H_{13}NO_2$: C, 76.48; H, 5.21. Found: C, 76.13; H, 5.43.

The electrolytic reduction according to Slotta and Szyszka,[16] employing 4.1 g. of the compound, 52 cc. of ethanol, 80 cc. of glacial acetic acid, and 12 cc. of concd. hydrochloric acid, proceeded rather rapidly, the yellow color having disappeared within two hours. A large amount of insoluble sludge was produced and the expected amine VII could be isolated in a yield of only 16%. Similar experiences were encountered in the electrolytic reduction of 2-methoxy-7-(2-nitrovinyl)-9,10-dihydrophenanthrene.

Hydrazide of β-[2-(9,10-Dihydrophenanthryl)]-propionic Acid.—The acid V was prepared according to Burger and Mosettig[4a] and converted to the methyl ester by diazomethane. The oily methyl ester was heated under reflux in a mixture of 2.4 parts (by volume) of absolute ethanol and 2.4 parts of 42% aqueous solution of hydrazine hydrate for forty-two hours. The white hydrazide separated from the cooled reaction mixture. It was recrystallized from water and melted at 134–135°; yield, 85%.

Anal. Calcd. for $C_{17}H_{18}N_2O$: C, 76.66; H, 6.81. Found: C, 76.17; H, 6.80.

2-(2-Aminoethyl)-9,10-dihydrophenanthrene (VII).—The Curtius reaction was carried out, following in part the technique of Mayer and Schnecko.[17] To a cooled suspension (0 to 3°) of 8.5 g. of hydrazide in 250 cc. of 0.5 *N* hydrochloric acid was added in several portions a solution of 6 g. of sodium nitrite in 25 cc. of water. The mixture was stirred for one hour after the last portion of nitrite had been added. The azide formed was extracted with ether, the ether solution was dried and mixed with 180 cc. of absolute ethanol. The ether was distilled off and the ethanolic solution was kept boiling under reflux for five hours. No attempt was made to isolate the urethan, but a solution of 74 g. of potassium hydroxide in 300 cc. of absolute alcohol was added and the whole was kept boiling for twenty hours. The reaction mixture was concentrated to a small volume, water added, and the oil taken up in ether. The dried ether solution left, after evaporation, the desired amine, which was distilled in an oil-pump vacuum. The distillate consisted of 5.4 g. of colorless oil. A crystalline hydrochloride was obtained and purified in the customary manner; m. p. 229–230°.

Anal. Calcd. for $C_{16}H_{18}ClN$: C, 73.97; H, 6.98; Cl, 13.65. Found: C, 73.50; H, 7.08; Cl, 13.36.

Acidification of the aqueous alkaline layer (from the extraction of the amine with ether) yielded 0.8 g. of nearly pure dihydrophenanthrylpropionic acid. Taking this into account, the yield of amine in the Curtius reaction was about 75%.

Formyl Derivative.—The formate of VII was precipitated by addition of formic acid to an ethereal solution of the base. Heated at 150° for one-half hour, the salt slowly melted down to a brown oil, which solidified on cooling. It was recrystallized from a mixture of benzene and petroleum ether, and melted at 91°; yield, 80%.

Anal. Calcd. for $C_{17}H_{17}NO$: C, 81.24; H, 6.82. Found: C, 80.82; H, 7.38.

Acetyl Derivative (VIIa).—A mixture of base VII with half of its weight of acetic acid was heated with stirring at 150° for one hour. After cooling, the mass solidified, and was recrystallized from a benzene–petroleum ether mixture; m. p. 112°, yield 85%.

Anal. Calcd. for $C_{18}H_{19}NO$: C, 81.47; H, 7.22. Found: C, 81.08; H, 7.12.

β-[7-(2-Methoxy-9,10-dihydrophenanthryl)]-acrylic Acid.—A mixture of 19 g. of the aldehyde IV, 24 g. of malonic acid, 2 cc. of piperidine, and 60 cc. of pyridine was heated on the steam-bath for seventy-five minutes, and then kept boiling for ten minutes in order to complete the reaction. The acrylic acid derivative was purified by crystallization from methyl ethyl ketone; m. p. 192–193°, yield, 87%.

Anal. Calcd. for $C_{18}H_{16}O_3$: C, 77.12; H, 5.75. Found: C, 76.53; H, 5.73.

β-[7-(2-Methoxy-9,10-dihydrophenanthryl)]-propionic Acid (VI).—This acid was obtained nearly quantitatively by reducing the unsaturated acid catalytically (absolute alcohol, platinum oxide catalyst). It was recrystallized from dilute ethanol, and melted at 177°.

Anal. Calcd. for $C_{18}H_{18}O_3$: C, 76.57; H, 6.43. Found: C, 76.00; H, 6.62.

The **methyl ester** was prepared with diazomethane, and was recrystallized from methanol; m. p. 61–62°.

Anal. Calcd. for $C_{19}H_{20}O_3$: C, 77.00; H, 6.80. Found: C, 76.05; H, 6.70.

Hydrazide.—A mixture of crude methyl ester (prepared from 20 g. of the methoxy dihydrophenanthrylpropionic acid), 55 cc. of 42% hydrazine hydrate, and 60 cc. of absolute ethanol was heated under reflux for forty-four hours. The hydrazide precipitated from the cooled solution, and was recrystallized from dilute ethanol; m. p. 155–156°, yield, 90% (calculated on acid).

Anal. Calcd. for $C_{18}H_{20}N_2O_2$: C, 72.95; H, 6.80. Found: C, 72.85; H, 6.50.

2-Methoxy-7-(2-aminoethyl)-9,10-dihydrophenanthrene (VIII).—Seven and five-tenths grams of the hydrazide was degraded in the manner described for the analog without the methoxyl group. The end-product was distilled in an oil-pump vacuum, yielding 3.8 g. of a pale yellow oil, which partly solidified. The hydrochloride melted over a wide range, beginning to sinter at 240°.

Anal. Calcd. for $C_{17}H_{20}ClNO$: C, 70.45; H, 6.96. Found: C, 70.33; H, 6.75.

The **acetyl derivative** (VIIIa) was prepared like its methoxy-free analog. After crystallization from a benzene–petroleum ether solution, it melted at 125–126°.

Ring Closure Experiments.—(a) According to the method of Decker and Becker. Numerous attempts were made to cyclize the formaldehyde condensation products of the amines VII and VIII. Condensation with formaldehyde took place readily with both, but no ring closure products could be obtained by heating the resulting products with hydrochloric acid. Variations in conditions of condensation extended from use of slightly more than one molecular equivalent of formaldehyde to use of a large excess of this reagent, and from five minutes to one hour of heating. The residues remaining after the removal of the excess of formaldehyde in each case were heated with 23% hydrochloric acid for times varying from five minutes to four hours. Under the mildest conditions, amine VII was isolated almost unchanged. When only one molecular equivalent of formaldehyde was used and the time of heating the condensation product did not exceed thirty minutes, small amounts of unchanged amine VII still remained. Under stronger conditions, and when using amine VIII under all conditions, only amorphous white products were obtained, which were insoluble in acids as well as in organic solvents.

(b) According to the method of Bischler–Napieralski. Attempts to bring about ring closure of the formyl derivatives of VII by the action of phosphorus pentoxide were unsuccessful. No reaction occurred in boiling benzene, while in xylene and in tetralin only tarry products were produced. In subsequent experiments the N-acetyl derivatives VIIa and VIIIa were used. Small amounts of IX were obtained by the action of phosphorus pentoxide on the acetyl derivative VIIa in boiling toluene or xylene. The use of phosphorus oxychloride as condensing agent in xylene gave similar results. The use of phosphorus oxychloride in boiling toluene appeared to be relatively most favorable.

11-Methyl-5,6,8,9-tetrahydronaphth[2,1-g]isoquinoline (IX).[18]—A typical reaction was carried out by boiling a solution of 1.6 g. of the N-acetyl derivative VIIa and 1.6 cc. of phosphorus oxychloride in 40 cc. of dry toluene for thirty-five minutes. After two minutes the solution became cloudy and oily material slowly began to separate. The isoquinoline derivative was isolated by extracting the reaction mixture repeatedly with small portions of 5 *N* hydrochloric acid. The base was liberated, extracted with ether, and reconverted to the hydrochloride. The salt melted at 230–232°.

Anal. Calcd. for $C_{18}H_{18}ClN$: Cl, 12.50. Found: Cl, 12.44.

Methiodide (IXa).—On addition of methyl iodide to an acetone solution of the base IX, the methiodide precipitated rapidly. It crystallized from absolute ethanol in long, pale yellow needles, m. p. 267–268°.

Anal. Calcd. for $C_{19}H_{20}IN$: I, 32.60. Found: I, 32.67.

(18) The nomenclature policy of *Chemical Abstracts* has been followed in numbering the naphthisoquinoline derivatives. Formula-pictures of IX, XI, XII, and XIV have been oriented accordingly. For the sake of emphasizing the direction of ring closure, formula XV (a naphth[1,2-*h*]isoquinoline derivative) has been oriented incorrectly (see also ref. 8a).

11-Methyl-5,6,8,9,10,11-hexahydronaphth[2,1-g]isoquinoline (X).—The hydrochloride of base IX, dissolved in absolute ethanol, absorbed readily one molecular equivalent of hydrogen when reduced catalytically (platinum oxide catalyst). The hydrochloride of the reduction product was recrystallized from an ethanol–ether mixture and melted at 239–241°.

Anal. Calcd. for $C_{18}H_{20}ClN$: C, 75.64; H, 7.05. Found: C, 75.06; H, 7.05.

Methiodide of 10,11-Dimethyl-5,6,8,9,10,11-hexahydronaphth(2,1-g)isoquinoline (XIa).—To a solution of 0.25 g. of base X in 3 cc. of acetone was added 0.15 g. of powdered potassium hydroxide and 0.4 cc. of methyl iodide. A white methiodide precipitated rapidly. It was filtered off, washed with water (0.3 g.) and recrystallized from absolute ethanol; m. p. 231°.

Anal. Calcd. for $C_{20}H_{24}IN$: I, 31.31. Found: I, 29.81.

10,11-Dimethyl-5,6,8,9,10,11-hexahydronaphth[2,1-g]-isoquinoline (XI).—(a) The methiodide IXa was reduced catalytically (absolute ethanol, platinum oxide). The oily base of the reduction product was liberated and distilled in an oil-pump vacuum. Its **hydrochloride** melted at 234–236°.

Anal. Calcd. for $C_{19}H_{22}ClN$: C, 76.11; H, 7.40; Cl, 11.83. Found: C, 75.39; H, 7.39; Cl, 11.80.

A sample of the base was dissolved in acetone, and methyl iodide was added. The white methiodide which precipitated immediately was identical (melting point, and mixture melting point) with the methiodide (XIa) that was obtained from 11-methyl-5,6,8,9,10,11-hexahydronaphth[2,1-g]isoquinoline (X), as described above.

(b) The methiodide XIa (from either source) decomposed smoothly when heated above 200° in an oil-pump vacuum. The oily base thus formed was redistilled and converted to the hydrochloride which melted at 232–235°. The mixture melting point with the hydrochloride of the base obtained in the catalytic reduction of methiodide IXa was 233–236°.

3-Methoxy-11-methyl-5,6,8,9-tetrahydronaphth[2,1-g]-isoquinoline-(?)(XII).—A solution of 2 g. of the acetyl derivative VIIIa and 2 cc. of phosphorus oxychloride in 50 cc. of dry toluene was boiled for thirty-five minutes. The reaction product was extracted with 5 *N* hydrochloric acid. The base was liberated and purified by crystallization of the hydrochloride (28%). The salt melted at 249–250°.

Anal. Calcd. for $C_{19}H_{20}ClNO$: Cl, 11.30. Found: Cl, 10.96.

Methiodide (XIIa).—This was precipitated from an acetone solution of the base by addition of methyl iodide. It was recrystallized from absolute ethanol, in which it is but slightly soluble; yellow, m. p. 287–288°.

Anal. Calcd. for $C_{20}H_{22}INO$: I, 30.27. Found: I, 30.43.

3-Methoxy-11-methyl-5,6,8,9,10,11-hexahydronaphth-[2,1-g]isoquinoline (XIII).—The hydrochloride of XII was hydrogenated rapidly in absolute ethanol solution (platinum oxide). The hydrochloride was precipitated with ether from the filtered solution, and melted at 261–263° after recrystallization from an ethanol–ether mixture.

Anal. Calcd. for $C_{19}H_{22}ClNO$: Cl, 11.23. Found: Cl, 11.73.

Methiodide of 3-Methoxy-10,11-dimethyl-5,6,8,9,10,11-hexahydronaphth[2,1-g]isoquinoline (XIVa).—The base from 0.2 g. of the above hydrochloride was dissolved in 3 cc. of acetone, and 0.3 cc. of methyl iodide and 0.1 g. of powdered potassium hydroxide were added. After one hour the white methiodide was filtered, and washed free of alkali with cold water. It was recrystallized from absolute ethanol; m. p. 256–258°.

Anal. Calcd. for $C_{21}H_{26}INO$: I, 29.15. Found: I, 29.47.

3-Methoxy-10,11-dimethyl-5,6,8,9,10,11-hexahydronaphth[2,1-g]isoquinoline (XIV).—(a) The methiodide XIIa (m. p. 287–288°) absorbed one mole of hydrogen rapidly when catalytically reduced. After removal of the catalyst, the ethanol solution was concentrated, and a white **hydriodide** was precipitated by addition of ether. It was recrystallized from ethanol, and melted at 236–238°.

Anal. Calcd. for $C_{20}H_{24}INO$: I, 30.12. Found: I, 29.75.

The **base** was liberated with ammonium hydroxide and slowly distilled at about 100° in an oil-pump vacuum; m. p. 97–98°.

Anal. Calcd. for $C_{20}H_{23}NO$: C, 81.87; H, 7.90. Found: C, 81.70; H, 7.72.

The **hydrochloride** was prepared and purified in the usual way, and melted at 200–202°.

Anal. Calcd. for $C_{20}H_{24}ClNO$: C, 72.82; H, 7.33. Found: C, 72.71; H, 7.53.

Addition of methyl iodide to an acetone solution of the base precipitated the quaternary methiodide, XIVa, identical (melting point, mixture melting point) with that obtained by the action of methyl iodide and potassium hydroxide on 3-methoxy-11-methyl-5,6,8,9,10,11-hexahydronaphth[2,1-g]isoquinoline (XIII).

(b) Base XIV was also obtained by heating the methiodide XIVa to 250° in an oil-pump vacuum. It was identified by melting point and mixture melting point.

Summary

The synthesis of two new phenolic amino alcohols, 2-hydroxy-7-[2-(diethylamino)-1-hydroxyethyl]-9,10-dihydrophenanthrene and 2-hydroxy-7-[3-(diethylamino)-1-hydroxy-*n*-propyl]-9,10-dihydrophenanthrene, is described.

The synthesis of two isoquinoline derivatives of the 9,10-dihydrophenanthrene series, 10,11-dimethyl-5,6,8,9,10,11-hexahydronaphth[2,1-g]isoquinoline and 3-methoxy-10,11-dimethyl-5,6,8,-9,10,11-hexahydronaphth[2,1-g]isoquinoline (?), is described.

The starting materials, 9,10-dihydrophenanthrene-2-aldehyde and 2-methoxy-9,10-dihydrophenanthrene-7-aldehyde, were obtained by the Rosenmund method from the corresponding phenanthroic acid chlorides, while the intermediate products, 2-(2-aminoethyl)-9,10-dihydrophenanthrene and 2-methoxy-7-(2-aminoethyl)-9,10-dihydrophenanthrene, were prepared by the Curtius reaction from the corresponding β-dihydrophenanthrylpropionic acids.

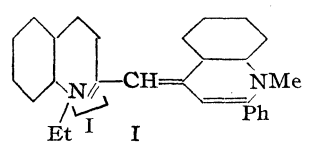
WASHINGTON, D. C. RECEIVED FEBRUARY 23, 1940

[JOINT CONTRIBUTION FROM THE KODAK RESEARCH LABORATORIES AND THE FRICK CHEMICAL LABORATORY, PRINCETON UNIVERSITY]

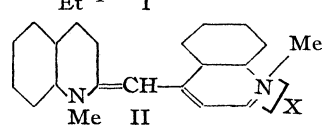
Color and Constitution. I. Halochromism of Anhydronium Bases Related to the Cyanine Dyes[1]

BY L. G. S. BROOKER, R. H. SPRAGUE, C. P. SMYTH AND G. L. LEWIS

In their work on the structure of the isocyanines, Kaufmann and Vonderwahl[2] brought forward evidence which they interpreted as indicating the static configuration I for 1-ethyl-1′-methyl-2′-phenyl-2,4′-cyanine iodide. They heated the dye in a high vacuum and obtained ethyl iodide and a base having the composition of a methylphenylquinolylidenequinaldine, and this was considered to prove that the iodine atom was attached to the nitrogen atom of the quinaldine nucleus.



I



II

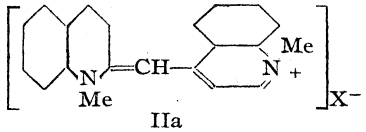
On the other hand, as a result of their experiments on the oxidation of 1,1′-dimethyl-2,4′-cyanine acetate, Mills and Wishart[3] felt that it was justifiable to accept II as the formula of this substance rather than the alternative structure in

(1) Communication No. 755 of the Kodak Research Laboratories. Presented in part before the Organic Section of the American Chemical Society at the September, 1937, meeting at Rochester, New York.

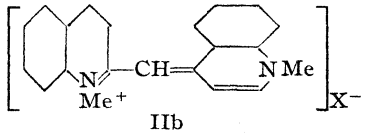
(2) Kaufmann and Vonderwahl, *Ber.*, **45**, 1407 (1912).

(3) Mills and Wishart, *J. Chem. Soc.*, **117**, 579 (1920).

which the nitrogen atom of the quinaldine nucleus is quaternary, but they recognized that the two forms might be virtually tautomeric. Since then, much evidence has been accumulated in favor of such tautomerism.[4] This conception has been amplified by the theory of resonance[5] according to which the molecule of a cyanine dye such as II is considered to be a resonance hybrid between two extreme states, the intense colors of the cyanines being attributed to such resonance. Thus, in the case of II, which is highly colored, we have the resonance scheme IIa ⟷ IIb.



IIa

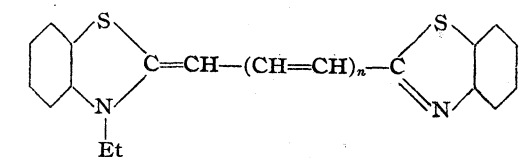


IIb

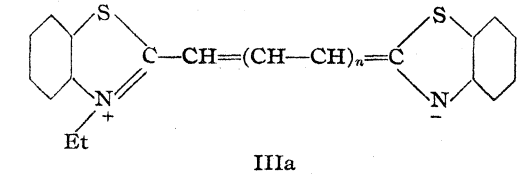
There can be no doubt that resonance of this type is very closely related to the occurrence of color in many organic compounds, and resonance structures have been assigned to practically all the principal dye types.[5] The subject has been particularly well worked out for dyes of the triphenylmethane series where it has been shown that so treating a dye that a possible mode of resonance is restricted results in the characteristic absorption of the dye being profoundly modified.[6]

In the present work, we have endeavored to throw further light on the nature of resonance in the cyanines by comparing the series of three symmetrical cyanines derived from benzothiazole (IV, n = 0, 1, 2) with the series of tertiary bases (III, n = 0, 1, 2) obtained from them by removal of the elements of ethyl halide by heating with diethylaniline according to the method of Schwarz.[7]

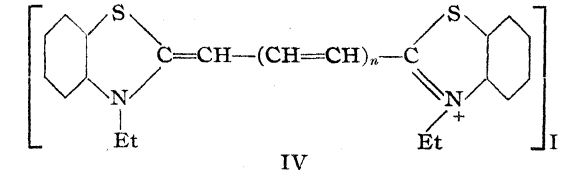
Of the three bases, that with the shortest chain (n = 0) was first prepared using another method by Mills,[8] who obtained it as a pale yellow



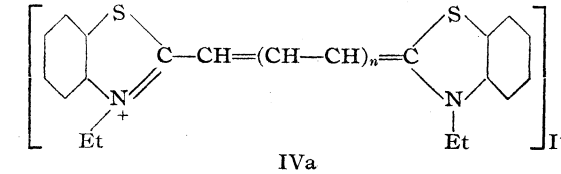
III



IIIa



IV



IVa

crystalline substance. Its methyl alcoholic solution has an extremely pale yellow color. The next higher vinylene homolog (n = 1) was made by Schwarz and Gevaert Photo-Producten, N. V.,[7] who describe it as slightly yellow colored and add that it absorbs only the short wave end of the visible spectrum without having a distinct maximum. We find, however, that its methyl alcoholic solution absorbs in the blue part of the spectrum and shows a well-defined maximum. The base with the longest chain (n = 2) has not hitherto been described. It forms lustrous reddish needles which dissolve in methyl alcohol to give a rather dull brownish-red solution.

In every case, a solution of one of these bases in methyl alcohol is markedly lighter in color than a solution of the cyanine with the same length of chain, the colors of the cyanines in solution being yellow (n = 0), bluish-red (n = 1) and blue (n = 2).

The absorptions of all six compounds in methyl alcohol are given in Fig. 1, and these curves reveal striking relationships. The positions of the absorption maxima are given in Table I, differences also being shown.

From Fig. 1 and Table I, it can be seen that in every case, a base (III) absorbs nearer the shorter waves than the cyanine with a chain of the same

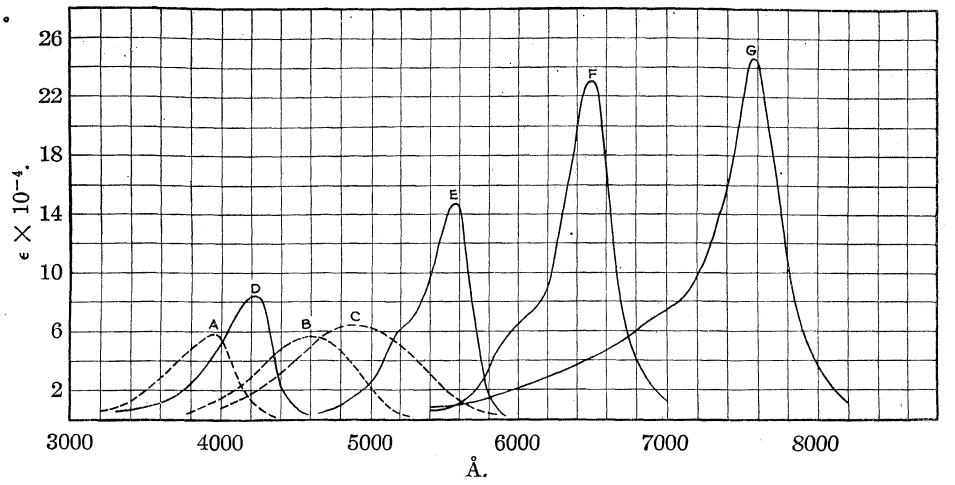

Fig. 1.—Absorption curves in methyl alcohol: A, B, C, = III, n = 0, 1, 2, respectively; D, E, F, G = IV, n = 0, 1, 2, 3, respectively.

TABLE I

Compound	Absorption max. Å.	Differences		Max. value of $\epsilon \times 10^{-4}$
III, n = 0	3960			5.85
III, n = 1	4580	> 620		5.65
III, n = 2	4900	> 320	270	6.4
IV, n = 0	4230		995	8.45
IV, n = 1	5575	> 1345	1600	14.8
IV, n = 2	6500	> 925		22.9
IV, n = 3	7580	> 1080		24.6

length. Furthermore, whereas it has been amply demonstrated that increasing the length of the polymethine chain joining the nuclei in a cyanine dye shifts the absorption toward the longer waves,[9] it can be seen that a similar relationship also holds in the series of tertiary bases. Here also lengthening the conjugated chain joining the nitrogen atoms shifts the absorption toward the red, but the amounts of the shifts are considerably smaller than with the cyanines. Whereas addition of a vinylene group to the cyanine IV, n = 0, produces a shift of 1345 Å., addition of vinylene to the base III, n = 0, produces a shift of only 620 Å., and addition of a further vinylene results in shifts of 925 and 320 Å. in the cyanine and base series, respectively. It follows that the difference in absorption between a cyanine and a base of the same chain length becomes greater with increasing length of the vinylene chain. There is only a difference of 270 Å. between base and cyanine in the series n = 0, this difference increasing to 995 Å. where n = 1 and to 1600 Å. where n = 2.

(9) *Cf.* in particular, (a) Fisher and Hamer, *Proc. Roy. Soc.* (London), **A154**, 703 (1936); (b) Beilenson, Fisher and Hamer, *ibid.*, **163**, 138 (1937).

In the cyanine series, the value of $\epsilon_{max.}$ increases continuously as the series is ascended, this being in agreement with the findings of Kuhn and Hausser[10] in series of polyene compounds that they examined. The difference between the values of $\epsilon_{max.}$ for IV, n = 1 and IV, n = 2 is, however, much greater than that between IV, n = 2 and IV, n = 3.

In the series of bases, the values of $\epsilon_{max.}$ are very close together, and the first member actually has a slightly higher value than the second, although the value for the third member is the highest of the three. However, these values are decidedly lower than those for the corresponding cyanines.

In the cyanine series, the two extreme resonance states IV and IVa are identical and have the same internal energy. The mobility of the linkages in the conjugated chain is therefore very great, and since there is a full ionic charge available for resonance, this reaches a high level of perfection. These conditions appear to give rise to absorption curves which rise, in the first few members, to a high value of $\epsilon_{max.}$, and which are widely separated with respect to wave length.

On the other hand, the bases III are not ionized structures, and no alternative formula for III can be written in which the sequence of single and double linkages of the conjugated chain between the nuclei is reversed and in which the nitrogen atoms are in the normal tri- or tetra-covalent states. However, there is a certain amount of probability for the alternative configuration IIIa.

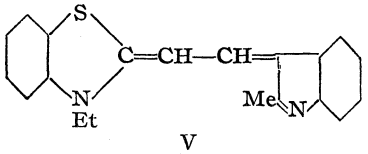
(10) Hausser, *Z. tech. Physik.* **15**, 10 (1934); note especially Fig. 20.

In particular, this gives an explanation of why addition of alkyl halide takes place solely at the right-hand benzothiazole nucleus. The negatively charged nitrogen atom is free to accept a proton or alkyl while the nitrogen of the left-hand nucleus will not do so because it is already quaternary. The resonance scheme III←→IIIa is, therefore, suggested for these bases which thus resemble the anhydronium bases of Robinson and coworkers.[11] Since III and IIIa are not identical, the actual state of the molecule will tend to approach the more stable of the two configurations, thereby becoming, in corresponding measure, less of a resonance hybrid. Resonance will therefore be more restricted in the bases than in the cyanines, and this accords with the observed lighter colors of the former.

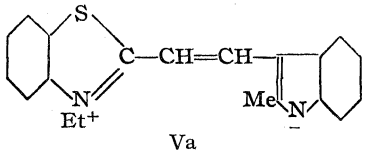
Of the two configurations III and IIIa, it seems probable that the former is the more stable, so that the actual state of the molecule will be closer to III than to IIIa. In the latter, the negatively charged nitrogen atom seems likely to be the least stable part (the quaternary nitrogen is a normal structure), and it would follow that if the negatively charged nitrogen could be rendered more stable, the whole configuration IIIa would become more stable. This would result in resonance being increased in the base which, in turn, would be accompanied by a deepening of color.

Now pyrroles and indoles with hydrogen attached to nitrogen will in general yield potassium derivatives and hence show a strong tendency to form negatively charged ions in which $>\overline{N}$ is stable.

We have accordingly prepared the base 3-[(3-ethyl-2(3)-benzothiazolylidene)-ethylidene]-2-methyl-indolenine (V) by condensing 2-methyl-3-indolealdehyde with 2-methylbenzothiazole ethiodide in acetic anhydride solution. This base dissolves in methyl alcohol to give a yellowish orange solution which is actually deeper in color

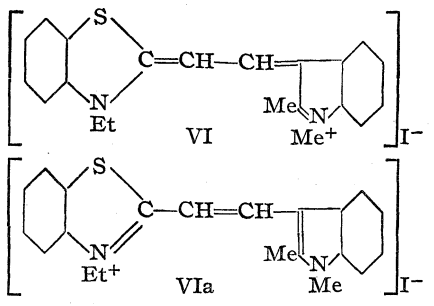


V



Va

(11) *Cf.* Freak and Robinson, *J. Chem. Soc.*, 2013 (1938).



than the solution of its methiodide VI made either by the addition of methyl iodide to V or by condensing 1,2-dimethyl-3-indolealdehyde with 2-methylbenzothiazole ethiodide. The absorption curves are shown in Fig. 2. The maximum

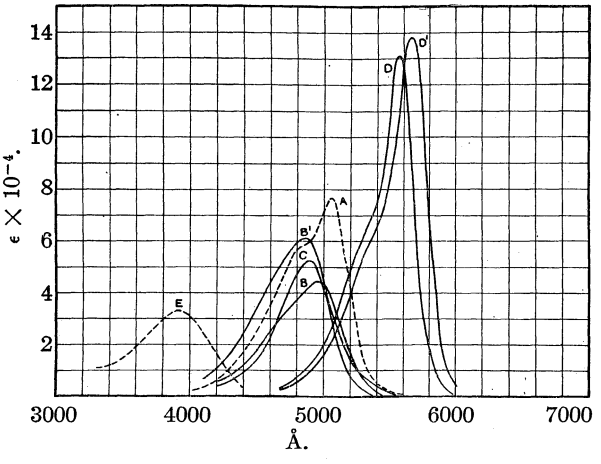


Fig. 2.—Absorption curves: A, 3-[(3-ethyl-2(3)-benzothiazolylidene)-ethylidene]-2-methyl-indolenine (V) in pyridine; B and B′, [3-ethyl-benzothiazole-(2)]-[1,2-dimethyl-indole-(3)]-di-methine-cyanine iodide (VI) in pyridine and nitromethane, respectively; C, bis-[1,2-dimethyl-indole-(3)]-methine-cyanine iodide (VIII) in nitromethane; D and D′, 3,3′-diethyl-thiacarbocyanine iodide in nitromethane and pyridine, respectively; E, 3-(β-2-benzothiazolyl-vinyl)-1,2-dimethyl-indole (IX) in pyridine.

absorption of V determined in pyridine is at 5060 Å., there being an inflection at shorter wave length and the maximum of VI in the same solvent is at 4970 Å. (Pyridine was chosen for the absorptions because in dilute methyl alcoholic solution there was a tendency on the part of V to develop a maximum at 4830 Å. corresponding to the acidified form. Addition of a few drops of piperidine deepened the color so that the maximum moved to 5070 Å., corresponding closely with the maximum developed in pyridine alone.)

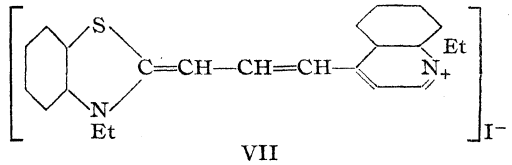
König[12] already has prepared several bases of the type of V, and he noted that they showed a "kind of reversed halochromism" in that they

(12) König, *J. prakt. Chem.*, [2] **85**, 514 (1912).

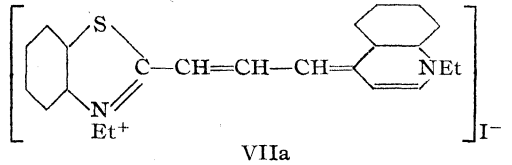
were deeper in color than their salts, but no explanation of this unusual state of affairs has so far appeared.

We now suggest that the known tendency of indole to yield an indolyl anion renders the configuration Va relatively more stable than the corresponding configuration IIIa and hence the actual state of the compound represented by the resonance scheme V ⟷ Va is closer to an intermediate position, *i. e.*, the base is more truly a resonance hybrid, than a base represented by III ⟷ IIIa. We consider, then, that V ⟷ Va represents a relatively high degree of resonance but, even so, it is remarkable that this base is deeper colored than its methiodide, in which a full ionic charge is available for resonance. The explanation of this apparent anomaly appears to lie in the fact that the methiodide VI, considered as an unsymmetrical cyanine, is exceptionally light in color.

Most of the unsymmetrical cyanines studied by Dr. Hamer and her colleagues[9b] have absorption maxima which agree fairly well with the calculated mean values of the related parent dyes, agreement being rather better in the carbocyanine than in the simple cyanine or dicarbocyanine series. This would seem to indicate that the internal energies of the two extreme resonance states of such unsymmetrical cyanines are very nearly the same. For example, the two extreme states in the case of 1′,3-diethylthia-4′-carbocyanine iodide (VII and VIIa) must have nearly



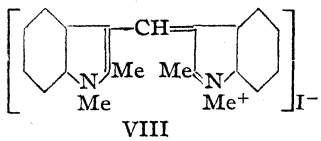
VII



VIIa

equal probability. This is understandable in view of the fact that although benzothiazole is considered to be somewhat less basic than quinoline, these bases are nevertheless comparable types, so that no very marked preference for the positive charge will be shown by either of the nitrogen atoms in dyes of this type, *i. e.*, VII will not be appreciably favored over VIIa or *vice versa*.

In the present case, the methiodide VI (or VIa) is a dimethine cyanine which may be considered as a cross between the two symmetrical dyes, *bis*-[1,2-dimethylindole-(3)]methine-cyanine iodide (VIII) and 3,3′-diethylthiacarbocyanine



VIII

iodide (IV, $n = 1$), but unlike the unsymmetrical cyanines hitherto described,[9b] the absorption of VI lies at markedly shorter wave length than the mean of the absorptions of the parent symmetrical dyes, and in fact, its absorption maximum in nitromethane actually lies at shorter wave length than that of the lighter of the parent dyes (VIII) (Fig. 2), and this constitutes the first recorded instance of an unsymmetrical cyanine absorbing in this way. (Nitromethane was chosen as solvent for the comparison because VIII was unstable in pyridine or in alcoholic solution.)

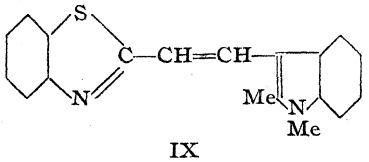
Since indoles are very weak bases and form salts with difficulty, it seems likely that of the two extreme resonance configurations VI and VIa, that in which the indole nitrogen is quaternary (VI) will be appreciably less stable than that in which the positive charge is associated with the more strongly basic benzothiazole nitrogen (VIa). Thus the actual state of the compound will tend to approach VIa in the resonance scheme VI ⟷ VIa with consequent diminution of resonance which will cause the color to be lightened.

The "reversed halochromism" of V may be attributed, therefore, to a combination of two related factors. The first is that the base is deeply colored because it resonates strongly according to the scheme V ⟷ Va, this being traceable to the stability of $\rangle\overset{+}{N}$ in the indole ring in Va. The second is that the methiodide is unusually light in color because in it resonance is inhibited due to the relative instability of one of the resonance configurations (VI) traceable in turn to the weak basicity of the indole nitrogen. The net result is that the base is more deeply colored than its methiodide.

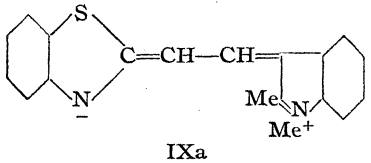
Since in some cases salt formation causes deepening of color and in others lightening of color, it is clear that it is theoretically possible for salt formation to bring about no color change at all. Actually, those instances appear to be more numerous in which a deepening of color occurs, and the term halochromism usually im-

plies this, but a lightening of color is no less significant from a theoretical standpoint.

That the mere presence of an indole nucleus in an anhydronium base does not give rise to unusually deep colors may be deduced from the following consideration. The base 3-(β-2-benzothiazolyl-vinyl)-1,2-dimethylindole (IX) was prepared by condensing 1,2-dimethyl-3-indolealdehyde with 2-methylbenzothiazole in the presence of hydrochloric acid and basifying the product.



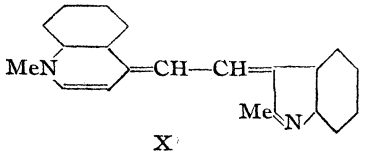
IX



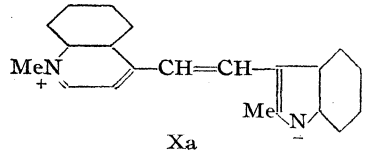
IXa

The second extreme resonance configuration of this substance, IXa, contains a negatively charged benzothiazole nitrogen which we have suggested is not as stable as the corresponding negatively charged nitrogen in Va, and also a quaternary indole nitrogen which we have argued above is also unstable. It will be concluded, therefore, that IXa is an especially unstable configuration and consequently the base will tend strongly to approach IX with corresponding loss of its resonance-hybrid character, and this will result in its having a relatively light color. This argument is supported by the facts, for IX is almost colorless in solution, its absorption maximum in pyridine being at 3920 Å. (Fig. 2, Curve E). Its structure was confirmed by the fact that it gave VI (or VIa) on treatment with ethyl iodide.

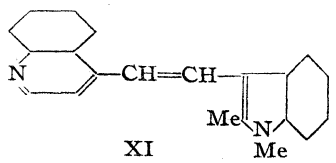
In a further set of comparisons, two isomeric bases were compared, 2-methyl-3-[(1-methyl-4(1)-quinolylidene)-ethylidene]-indolenine (X) and 1,2-dimethyl-3-(β-4-quinolyl-vinyl)-indole (XI).



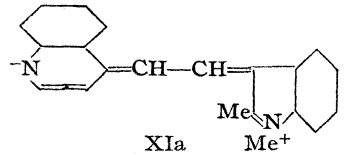
X



Xa



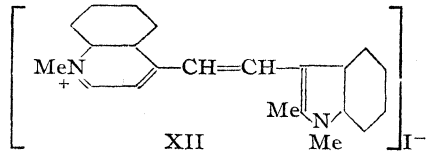
XI



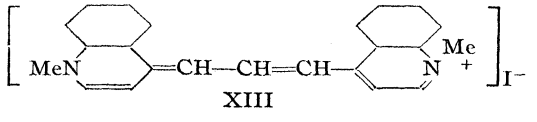
XIa

The first of these was prepared by condensing lepidine methiodide with 2-methyl-3-indolealdehyde in acetic anhydride solution and basifying the product, and the second by condensing lepidine with 1,2-dimethyl-3-indolealdehyde in the presence of hydrochloric acid and basifying the product. Of these bases, X is much the deeper colored of the two, its bluish purple pyridine solution having two absorption maxima of comparable strength at 5710 and 6160 Å., the former being somewhat the stronger (Fig. 3, A). On the other hand, XI gives only a pale yellow solution in pyridine which absorbs very weakly indeed with its maximum at 3940 Å. (Fig. 3, B), and these results can be correlated with the probability of much greater resonance mobility in X ⟷ Xa than in XI ⟷ XIa for precisely similar reasons to those advanced in the case of V and IX, respectively.

Both X and XI add methyl iodide readily to give the same methiodide XII, and this has $\lambda_{max.}$ at 5390 Å. in pyridine (Fig. 3, C) so that it is lighter in color than X but much deeper in color than XI. In this case XII may be regarded as



XII



XIII

the cross between the two symmetrical dyes VIII and 1,1′-dimethyl-4,4′-carbocyanine iodide XIII, and once again XII absorbs at markedly shorter wave length than the mean of the wave lengths of maximum absorption of these two,[13] for, it

(13) For this comparison, it was hoped to obtain the absorptions of all three substances in the same solvent. Curves D and C′ (Fig. 3) are those of VIII and XII in nitromethane but dilute solutions of XIII in this solvent proved to be extremely unstable, and

is suggested, a reason similar to that advanced in the case of VI.

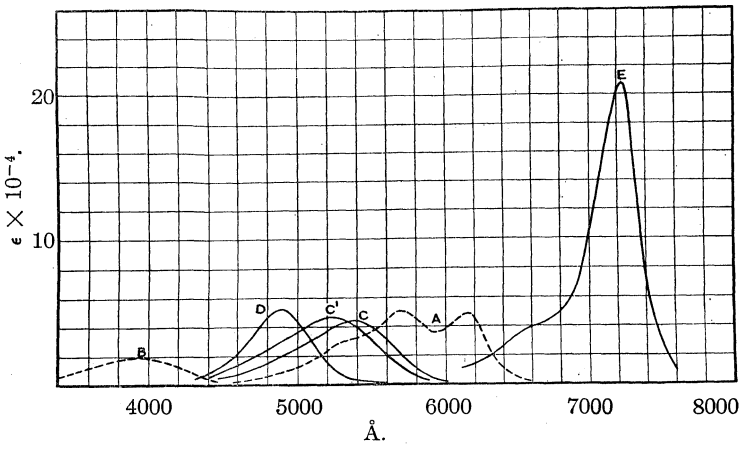


Fig. 3.—Absorption curves: A, 2-methyl-3-[(1-methyl-4(1)-quinolyl-idene)-ethylidene]-indolenine (X) in pyridine; B, 1,2-dimethyl-3-(β-4-quinolyl-vinyl)-indole (XI) in pyridine; C, [1,2-dimethylindole-(3)]-[1-methylquinoline-(4)]-dimethinecyanine iodide (XII) in pyridine, C′ in nitromethane; D, bis-[1,2-dimethylindole-(3)]-methinecyanine iodide (VIII) in nitromethane; E, 1,1′-dimethyl-4,4′-carbocyanine iodide (XIII) in pyridine.

Independent confirmation of the theories developed here to account for the colors of the anhydronium bases III (n = 1), V, IX, X and XI has been provided by a study of their dipole moments. If the suggested dipolar configurations were significant in defining the structures of these bases, then the dipole moments would be expected to be much higher than those calculated from the classical formulas. Further, since it has been argued that the dipolar configurations Va and Xa play more important parts in the resonance schemes V ⟷ Va and X ⟷ Xa than IXa and XIa do in the schemes IX ⟷ IXa and XI ⟷ XIa, it should follow that the dipole moments of the first pair of bases should be markedly higher than those of the latter. These expectations have been fully realized. Not only were the dipole moments of the bases in all cases markedly higher than those calculated from the classical formulas, but those of the deeply colored bases V ⟷ Va and X ⟷ Xa were much higher than those of the corresponding lighter colored bases IX ⟷ IXa and XI ⟷ XIa.

Curve E was determined in pyridine. In the three cases in this paper where absorptions have been determined in the two solvents (Fig. 2, B and B′, D and D′; Fig. 3, C and C′) nitromethane gives somewhat the lower value for $\lambda_{max.}$, so that by analogy, $\lambda_{max.}$ of XIII in nitromethane should lie at shorter wave length than that in pyridine. Even if an allowance of as much as 200 Å. is made for this effect, XII still absorbs at much shorter wave length than the mean of the absorptions of VIII and XIII. The value of $\lambda_{max.}$ for curve C′ (Fig. 3) is 5240 Å., and for E it is 7230 Å.

The dielectric constants of very dilute solutions of the bases in benzene were measured at a frequency of 520 kilocycles and a temperature of 25° with a heterodyne beat apparatus described elsewhere[14] and have been used, together with the densities measured with an Ostwald–Sprengel pycnometer, to calculate the dipole moments by the usual method.[15]

In Table II there are given the mole fraction c_2 of each substance in benzene solution, the dielectric constant D and density d of the solution, and the polarization P_2 of the substance calculated from these data. As the color of several of the solutions made impossible an accurate determination of refractive index, the molar refractions, MR_D, were calculated as the sums of the atomic refractions with due regard to constitutive influences. The uncertainties in these calculated values of MR_D given in the first column of Table II are small in comparison with the errors in the values of the polarization at infinite dilution, P_∞, obtained by extrapolation of the P_2 values. The probable errors in these P_∞ values are unusually large as the result of the high dilutions at which the measurements had to be made because of the low solubilities of the substances. The resulting experimental values of the moments given in the eighth column of Table II have probable errors of about 1% except in the case of X(Xa), where it is 5%.

The last column of Table II gives the values of the dipole moments μ calcd. which the molecules should have in the absence of resonance contributions from ionic structures other than those normally found in the bonds involved. These moment values are necessarily extremely approximate, having a probable error 0.5×10^{-18}. They are calculated[16] from bond moments and from the moments of groups obtained from molecular moments in the literature, rotation around single bonds being taken into account as far as possible.[17] Uncertainty as to rotation or orientation of large groups around single bonds and, in some cases, the question of *cis* or *trans*

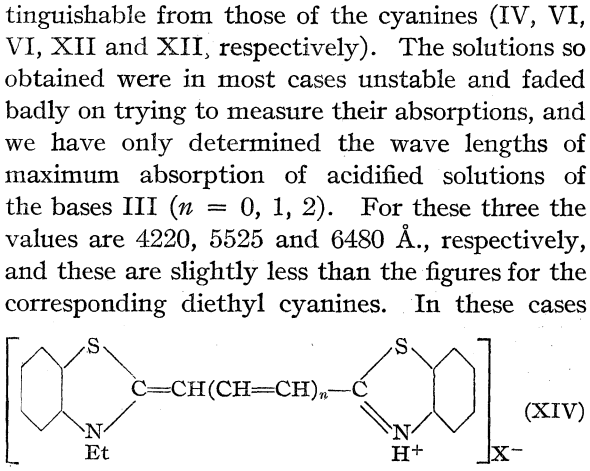
configurations contribute to the uncertainty of these calculated values. Moments calculated for dipolar structures are subject to far greater errors because of these uncertainties. The values estimated for these structures lie, for the most part, between 20 and 30 × 10^{-18}. As it seems probable that values thus calculated for such dipolar structures without knowledge of the reduction of the moments by induced shifts of charge are much too high,[16] they are omitted from Table II as misleading.

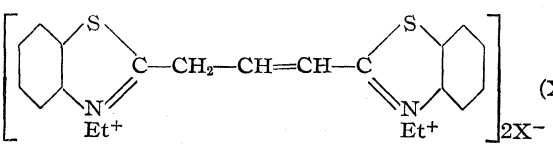
Addition of mineral acid to dilute alcoholic solutions of the anhydronium bases (III, V, IX, X and XI) gave colors which were visually indistinguishable from those of the cyanines (IV, VI, VI, XII and XII, respectively). The solutions so obtained were in most cases unstable and faded badly on trying to measure their absorptions, and we have only determined the wave lengths of maximum absorption of acidified solutions of the bases III (n = 0, 1, 2). For these three the values are 4220, 5525 and 6480 Å., respectively, and these are slightly less than the figures for the corresponding diethyl cyanines. In these cases



(XIV)

addition of a proton gives XIV and this can resonate in similar fashion to that postulated for IV.

Addition of excess of mineral acid to solutions of the cyanines or of the bases discharges the color completely, indicating destruction of the conjugated system as suggested in XV.



(XV)

Acknowledgment.—We wish to thank Mr. E. E. Richardson and Dr. L. A. Jones for the absorptions and Dr. L. T. Hallett for the analyses.

Experimental

2 - [(3 - Ethyl - 2(3) - benzothiazolylidene) - methylene] - benzothiazole (III, n = 0).—3,3'-Diethylthiacyanine iodide[18] (1.3 g.) was heated to refluxing with diethylaniline (100 cc.) for two hours. The mixture was then steam distilled and the residue extracted with 500 cc. methyl alcohol and the extract concentrated to 40 cc. The base separated and was purified by two recrystallizations from methyl alcohol (charcoal) (145 cc. per g.); yield 46%, m. p. 163–164° with darkening.

2 - [3 - (3 - Ethyl - 2(3) - benzothiazolylidene) - propenyl] - benzothiazole (III, n = 1).—3,3'-Diethylthiacarbocyanine iodide[19] (30 g.) was heated under dry carbon dioxide with diethylaniline (600 cc.) for two hours with mechanical

(19) Hamer, *ibid.*, 2796 (1927).

stirring, some of the solvent being slowly distilled off. After concentration *in vacuo* as far as possible 300 cc. of ether was added and the base separated on chilling, and was purified by recrystallization from absolute ethyl alcohol (30 cc. per g.); yield 65%. The base formed reddish-brown crystals with double green and blue reflex; m. p. 138–140° with some decomposition.

Anal. Calcd. for $C_{19}H_{16}N_2S_2$: C, 67.79; H, 4.80. Found: C, 67.62; H, 5.09.

2 - [5 - (3 - Ethyl - 2(3) - benzothiazolylidene) - 1,3-pentadienyl]-benzothiazole (III, $n = 2$).—3,3'-Diethylthiadicarbocyanine iodide[9a] (10 g.) was heated under dry carbon dioxide with diethylaniline (500 cc.) for one hour with mechanical stirring, some of the solvent (200 cc.) being slowly distilled off during the reaction. After filtration to remove a small residue of unchanged cyanine the liquid was concentrated *in vacuo* to 25 cc. The oily residue so obtained was extracted with 50 cc. hot methyl alcohol and separated as an oil from the extract on chilling. Crystals were obtained on stirring with cold acetone (15 cc.) and were purified by recrystallization from this solvent (50 cc. per g.); yield 4%; m. p. 161–162° with some decomposition.

Anal. Calcd. for $C_{21}H_{18}N_2S_2$: C, 69.55; H, 5.01. Found: C, 69.46; H, 5.15.

3 - [(3 - Ethyl - 2(3) - benzothiazolylidene) - ethylidene]-2-methyl-indolenine (V).—The hydriodide of this base was prepared by condensing 2-methylbenzothiazole ethiodide (5.75 g.; 1 mol) with 2-methyl-3-indolealdehyde (3 g., 1 mol) in acetic anhydride (30 cc.), refluxing for two minutes; yield 93%. After two recrystallizations from methyl alcohol (190 cc. per g.) the dye formed minute reddish-brown needles with a blue reflex and had m. p. 283–284°, dec.

Anal. Calcd. for $C_{20}H_{19}IN_2S$: I, 28.45. Found: I, 28.31.

The hydriodide (2 g., 1 mol) was stirred mechanically with a mixture of 50 cc. of 20% aqueous sodium hydroxide and 75 cc. of acetone at room temperature for one-half hour. The hydriodide slowly dissolved and crystals of the base separated. The aqueous layer was drawn off and more base was obtained by concentrating the acetone layer; yield 91%. After recrystallization from acetone (50 cc. per g.) the base formed beautiful reddish-brown prisms with a bright green reflex and had m. p. 286–288° dec.

Anal. Calcd. for $C_{20}H_{18}N_2S$: C, 75.43; H, 5.70. Found: C, 75.08; H, 5.84.

[3 - Ethyl - benzothiazole - (2)] - [1,2 - dimethyl - indole-(3)]-dimethine-cyanine Iodide (VI).—**(a).** 2-Methylbenzothiazole etho-*p*-toluenesulfonate[20] (3.5 g., 1 mol) and 1,2-dimethyl-3-indolealdehyde (1.73 g., 1 mol) were refluxed for five minutes in acetic anhydride (15 cc.). Dye separated on chilling; yield 91%. This was converted directly into the iodide using sodium iodide; yield 95% for the conversion. The dye separated in scarlet prisms from methyl alcohol (310 cc. per g.); m. p. 269–271°, dec.

Anal. Calcd. for $C_{21}H_{21}IN_2S$: I, 27.57. Found: I, 27.52.

(b) The dye was obtained in theoretical yield when the base V (1.6 g., 1 mol) was heated under reflux with methyl iodide (2.8 g., 4 mols) in nitrobenzene (25 cc.) for four hours. The base first dissolved and then the iodide separated rapidly, crystallization being subsequently promoted by adding ether. After recrystallization analysis gave I, 27.37.

(c) When the base IX (0.5 g., 1 mol) was refluxed with ethyl iodide (1.6 g., 6 mols) for six hours, the iodide separated slowly; yield 39%. After recrystallization analysis gave I, 27.34.

The identity of specimens obtained in a, b and c was established by m. p. and mixed m. p. determinations. The absorptions were also identical.

3-(β-2-Benzothiazolyl-vinyl)-1,2-dimethylindole (IX).—2-Methylbenzothiazole (3 g., 2 mols), 1,2-dimethyl-3-indolealdehyde (1.73 g., 1 mol) and concd. hydrochloric acid (2.3 g., 2 mols) were heated together at 100° for sixteen hours. The solid mass was dissolved in hot methyl alcohol (100 cc.), basified with triethylamine, chilled and the product filtered off; yield 50%. After recrystallization from methyl alcohol (46 cc. per g.) the canary yellow crystals had m. p. 150–151° with slight decomposition.

Anal. Calcd. for $C_{19}H_{16}N_2S$: C, 74.94; H, 5.30. Found: C, 74.68; H, 5.37.

bis-[1,2-Dimethylindole-(3)]-methine-cyanine Iodide (VIII).—1,2-Dimethylindole (2.9 g., 1 mol) and 1,2-dimethyl-3-indolealdehyde (3.46 g., 1 mol) were fused together and concentrated hydrochloric acid (2 cc., 1 mol) added. Much heat was generated and the mixture was stirred without further heating for five minutes. The product was dissolved in ethyl alcohol (15 cc.) and precipitated by adding excess of aqueous sodium iodide (6 g.). The dye was washed (water then ether) and was recrystallized from methyl alcohol (30 cc. per g.); yield 35%. The brown crystals had m. p. 221–222°, dec.

Anal. Calcd. for $C_{21}H_{21}IN_2$: I, 29.65. Found: I, 29.62.

2 - Methyl - 3 - [(1 - methyl - 4(1) - quinolylidene) - ethylidene]-indolenine (X).—The hydriodide of this base was prepared by condensing lepidine methiodide (14.3 g., 1 mol) with 2-methyl-3-indolealdehyde (8 g., 1 mol) by refluxing in acetic anhydride (50 cc.) for three minutes. Dye separated from the hot solution; yield 72%. After recrystallization from methyl alcohol (600 cc. per g.) the dye formed brownish coppery crystals with m. p. 319–320°, dec.

Anal. Calcd. for $C_{21}H_{19}IN_2$: I, 29.79. Found: I, 29.60.

The hydriodide was basified in similar fashion to V; yield quantitative. The base separated from acetone (330 cc. per g.) as dark blue needles m. p. 249–251° dec.

Anal. Calcd. for $C_{21}H_{18}N_2$: C, 84.50; H, 6.08; N, 9.40. Found: C, 83.91; H, 6.35; N, 9.21.

König[12] gives m. p. 240°. His analysis is that of $C_{21}H_{18}N_2 \cdot 2CHCl_3$.

1,2-Dimethyl-3-(β-4-quinolyl-vinyl)-indole (XI).—An excess of lepidine (3 g., 2 mols) was heated with 1,2-dimethyl-3-indolealdehyde (1.73 g., 1 mol) and concentrated hydrochloric acid (1.1 g., 1 mol) at 100° for sixteen hours. The hydrochloride of the base which resulted was purified by recrystallization from methyl alcohol (120 cc. per g.); yield 2 g. of red needles, and was suspended in cold methyl alcohol and basified by the addition of triethylamine. A

(20) Brooker and White, THIS JOURNAL, **57**, 550 (1935).

yellow solid separated and was recrystallized from methyl alcohol (160 cc. per g.); yield 43%. The yellow needles had m. p. 192–193° slight dec.

Anal. Calcd. for $C_{21}H_{18}N_2$: C, 84.50; H, 6.08; N, 9.40. Found: C, 83.84; H, 6.10; N, 9.29.

[1,2 - Dimethylindole - (3)] - [1 - methylquinoline-(4)]-dimethine-cyanine Iodide (XII).—(a) Lepidine methiodide (1.43 g., 1 mol) was condensed with 1,2-dimethyl-3-indolealdehyde (0.86 g., 1 mol) by refluxing in acetic anhydride (15 cc.) for three minutes. Dye separated from the hot mixture; yield 68%. After recrystallization from methyl alcohol (230 cc. per g.) the dye formed dull brownish crystals with m. p. 297–298° dec.; yield 59%.

Anal. Calcd. for $C_{22}H_{21}IN_2$: I, 28.83. Found: I, 28.82.

(b) The dye was obtained when the base X (0.5 g., 1 mol) was heated on a steam-bath to refluxing with methyl iodide (2 g., 8 mols) in nitrobenzene (10 cc.) for two hours; yield 88%. Found: I, 28.88 after recrystallization.

(c) XII was similarly obtained from XI; yield 81%. Found: I, 28.95 after recrystallization. The identity of the specimens from a, b and c was established by m. p. and mixed m. p. determinations and by absorptions.

Summary

A number of cyanine dyes have been compared with respect to absorption with the bases derived from them by removal of the elements of alkyl halide. In most cases the bases are lighter in color than the corresponding cyanines, but this is not invariably the case. These facts may be explained on the basis of the resonance theory. Certain of the arguments used have been confirmed by dipole moment determinations.

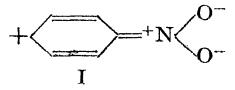
The Steric Inhibition of Resonance in Aromatic Nitro Compounds[1]

BY G. W. WHELAND AND A. A. DANISH[1a]

From a study of dipole moments, Birtles and Hampson have concluded[1b] that, in the aromatic nitro compounds, the resonance with quinoid structures of the type I[2] is sterically inhibited



I

when the nitro group lies between methyl groups in the two ortho positions. The work described in the present paper was undertaken in order to obtain chemical evidence bearing upon this hypothesis.[3]

The particular problem investigated was that presented by the striking effect of para nitro groups upon the acid strengths of the phenylmethanes. While triphenylmethane has been assigned[4] a pK value greater than 33, its trinitro derivative, 4,4′,4″-trinitrotriphenylmethane (hereafter called simply trinitrotriphenylmethane) is sufficiently acidic for its salts to be stable in aqueous alcohol.[5] It seems probable that resonance of the sort considered is at any rate partially responsible for this greater acidity of the trinitro derivative, since the quinoid structures increase the positive electrostatic potential at the position of the ionizable hydrogen atom, and since, moreover, the negative ion can be stabilized by resonance with these quinoid structures to a greater extent than the undissociated molecule.

If the above reasoning is correct, and if the contention of Birtles and Hampson is justified, it follows that 3,3′,3″,5,5′,5″-hexamethyl-4,4′,4″-trinitrotriphenylmethane (hereafter called simply trinitrotrixylylmethane) should be appreciably less acidic than trinitrotriphenylmethane. The former compound was, accordingly, prepared, and its acid strength was investigated in a manner analogous to that employed by Conant and Wheland[6] and by McEwen.[4] The sodium salts of both trinitrotriphenylmethane and trinitrotrixylylmethane are characterized by intense purple colors, and, consequently, the position of the equilibrium between either methane and its salt can be estimated colorimetrically. Since

(3) Since the present research was started, several papers have appeared dealing with the steric inhibition of resonance from the chemical point of view. These have provided strong support for the existence of such an effect in various types of compounds, but apparently little work of this sort has been done with nitro compounds. See for example, W. G. Brown, A. H. Widiger and N. J. Letang, THIS JOURNAL, **61**, 2597 (1939); G. Baddeley, *Nature*, **144**, 444 (1939).

only qualitative results were desired, no attempt was made to put the experiments upon a quantitative basis or to determine the values of the dissociation constants. It was considered sufficient to establish the relative stabilities of the two salts in a series of weakly acidic solvents.

The results of the experiments can be summarized as follows. The sodium salt of trinitrotrixylylmethane is stable in acetophenone and aniline, and in cyclohexylamine containing up to about 15% of methyl alcohol or 30% of ethyl alcohol; it is solvolyzed completely in methyl alcohol, ethyl alcohol and water–dioxane mixtures. The sodium salt of trinitrotriphenylmethane, on the other hand, is stable in all of the solvents named but is decomposed by phenol. Thus, it is evident that trinitrotrixylylmethane is a weaker acid than trinitrotriphenylmethane by several pK units. This conclusion is consistent with, and lends support to, the theory of Birtles and Hampson. However, since the observed difference in acidity is apparently not very great, the evidence is insufficient to establish the theory beyond question.[7] The problem is being investigated further.

Experimental. I

All melting points given below are uncorrected.

3,3′,3″,5,5′,5″-Hexamethyl Triphenylmethyl Chloride.—*sym*-Bromoxylene[8] was transformed into the Grignard reagent and treated with ethyl chlorocarbonate in the usual way. The resulting trixylylcarbinol was not purified but was transformed directly into the corresponding trixylylmethyl chloride by the action of dry hydrogen chloride in absolute ether.[9] The yield of crude chloride was 46%, based upon the amount of bromoxylene used. A small portion, after crystallization from high-boiling ligroin saturated with dry hydrogen chloride, formed colorless needles melting at 210°.

Anal. Calcd. for $C_{25}H_{27}Cl$: Cl, 9.77. Found: Cl, 9.83.

3, 3′, 3″, 5, 5′, 5″ - Hexamethyltriphenylmethane.—The crude trixylylmethyl chloride was reduced[10] with zinc dust in acetic acid solution under an atmosphere of carbon dioxide, and the resulting trixylylmethane was purified by crystallization from alcohol and water. The yield was 72% of the theoretical, based upon the amount of crude chloride used. The pure methane was colorless and melted at 108°.

Anal. Calcd. for $C_{25}H_{28}$: C, 91.41; H, 8.59; mol. wt., 328.2. Found: C, 91.52; H, 8.43; mol. wt. (camphor), 310.

3,3′,3″,5,5′,5″ - Hexamethyl - 4,4′,4″ - trinitro - triphenylmethane.[11]—The trixylylmethane prepared as above was nitrated with fuming nitric acid in a mixture of acetic acid and acetic anhydride in accordance with the method given by Powell and Johnson[12] for the nitration of mesitylene. After the completion of the reaction, the mixture was poured into an excess of ice water. The product, which then precipitated, was separated from the aqueous solution and washed free of acid. After one crystallization from glacial acetic acid and two from alcohol, the trinitrotrixylylmethane melted at 247°. The yield was only 16% of the theoretical. An attempt to obtain further material by adding water to the mother liquor from the original crystallization provided only a reddish oil, which changed to a resinous solid after a few hours of standing, and the composition of which could not be determined.

Anal. Calcd. for $C_{25}H_{25}N_3O_6$: N, 9.07; mol. wt., 463. Found: N, 9.06; mol. wt. (camphor), 465.

3,3′,3″,5,5′,5″ - Hexamethyl - 4,4′,4″ - triaminotriphenylmethane by Reduction of the Nitro Compound.—The trinitrotrixylylmethane was reduced with zinc dust in boiling glacial acetic acid.[13] The product, obtained in 64% yield after crystallization from dioxane and water, had no definite melting point. It darkened at 190° and decomposed completely at 275–280°.

Anal. Calcd. for $C_{25}H_{31}N_3$: N, 11.25. Found: N, 11.11.

3,3′,3″,5,5′,5″ - Hexamethyl - 4,4′,4″ - triaminotriphenylmethane by the Method of Giacalone.[14]—This preparation, which was undertaken in order to obtain material for comparison with that prepared as above, proceeded in two steps. First, 2,2′,2″,6,6′,6″-hexamethyltrianilidomethane was made by condensation of 2-amino-*m*-xylene with ethyl orthoformate, and then this was rearranged to the triaminotrixylylmethane. The reactions went much less readily than those reported by Giacalone, and more vigorous conditions were necessary.

(a) Forty-five grams of the xylidine and 30 g. of the ortho ester were refluxed together for twenty-four hours. From the resulting mixture, there was obtained 7 g. of the trianilido compound, melting at 179° (from benzene).

Anal. Calcd. for $C_{25}H_{31}N_3$: N, 11.25. Found: N, 11.26.

(b) One and one-half grams of the above trianilido compound, 3 g. of 2-amino-*m*-xylene, and 3 g. of 2-amino-*m*-xylene hydrochloride were heated together in an oil-bath at 170–175° for forty-eight hours and then at 140° for an additional fifty-three hours. The resulting mixture was steam distilled until no more volatile matter came over. From the residue in the flask was obtained 0.052 g. of the triaminotrixylylmethane. No unreacted starting material could be recovered, since extensive decomposition had occurred. In two preliminary runs, in which the heating was continued for only twenty-five and forty-two hours, respectively, the starting materials were recovered

(7) The correction for the direct inductive effect of the methyl groups is probably not significant, because the effect of the analogously situated methyl group in *m*-cresol upon the acidity of the substance appears to be quite small; *cf.* D. R. Boyd, *J. Chem. Soc.*, **107**, 1538 (1915).

unchanged, but no rearrangement product was obtained. The triaminotrixylylmethane, after crystallization from dioxane, darkened at 190° and decomposed completely at 275–280°.

Anal. Calcd. for $C_{25}H_{31}N_3$: N, 11.25. Found: N, 11.04.

Comparison of the Samples of 3,3′,3″,5,5′,5″-Hexamethyl-4,4′,4″-triaminotriphenylmethane from the Two Sources.—The two samples of triaminotrixylylmethane, prepared, respectively, by the reduction of the corresponding trinitro compound and by the method of Giacalone, exhibited the same behavior on melting, as did also a mixture of the two. This evidence of their identity was not conclusive, however, since the substances had merely decomposition points and not true melting points. A crystallographic comparison was accordingly made,[15] and this showed the two to be identical.

The fact that the same substance was obtained by the two methods establishes its structure; the preparation from the trinitro compound shows that it is a derivative of 3,3′,3″,5,5′,5″-hexamethyltriphenylmethane, and the preparation from 2-amino-*m*-xylene shows that each amino group lies between two methyl groups in one of the benzene rings. Thus, the substance can only be 3,3′,3″,5,5′-5″-hexamethyltriphenylmethane. The proof of the structure of the corresponding trinitro compound now follows at once.

II

The solvents used in the following tests were purified as stated.

Water: distilled water was used.

Methyl and ethyl alcohols: the commercial absolute alcohols were distilled over magnesium methoxide and ethoxide, respectively.

Acetophenone, aniline, cyclohexylamine, and dioxane: the Eastman Kodak Co. products were distilled and fractions boiling over a 1° range were retained. The dioxane was kept over sodium.

Some difficulty was encountered at the outset in devising an experimental procedure for the comparison of acid strengths, and many of the preliminary results were neither reproducible nor consistent. The procedures described below, however, were entirely satisfactory. All the tests were made as rapidly as possible, since the colors were discharged in a few minutes as a result of oxidation by the air.

Water as Solvent.—To approximately 1 mg. of trinitrotriphenylmethane dissolved in 1/4 g. of dioxane was added slowly 10 cc. of a 1 *N* solution of sodium hydroxide in water. The intense bluish-purple color of the salt appeared immediately with the first few drops of the aqueous solution. The color became fainter and more reddish as the remainder of the base was added, but it was still distinctly perceptible even after dilution of the solution with a further 10 cc. of water. The fading of the color presumably was due to the decreasing solubility of the methane, which precipitated from the solution.

When this experiment was carried out with trinitrotrixylylmethane, the color of the corresponding salt was not perceptible at any time.

Methyl or Ethyl Alcohol as Solvent.—When trinitrotriphenylmethane was added to a methyl alcoholic solution of sodium methoxide, or to an ethyl alcoholic solution of sodium ethoxide, the intense purple color of the salt was formed immediately. The concentrations used were not critical. If the solutions were diluted with water, the color persisted as long as an appreciable quantity of the methane remained dissolved, but if an excess of phenol were added, the color was discharged immediately.

Approximately 1 mg. of trinitrotrixylylmethane was dissolved in 5 g. of the alcohol in question, and a solution of the corresponding sodium alkoxide was prepared from 0.5 g. of sodium and 10 g. of the alcohol. When 1 cc. of each of these two solutions were mixed, no color appeared in either the methyl or the ethyl alcoholic solution. Cyclohexylamine was now added slowly. The color of the salt became just perceptible after the addition of about 10 cc. of cyclohexylamine to the methyl alcoholic solution, or of about 4 cc. to the ethyl alcoholic solution.

Cyclohexylamine as Solvent.—A dilute solution of sodium cyclohexylamide in cyclohexylamine was prepared by the action of sodium upon a large excess of the amine in the presence of naphthalene.[16] The concentration of the amide solution was not critical. When about 1 mg. of either trinitrotriphenylmethane or trinitrotrixylylmethane was added to 2–4 cc. of the solution, the intense purple color of the corresponding salt developed immediately.

Acetophenone or Aniline as Solvent.—A small amount of the solution of sodium cyclohexylamide in cyclohexylamine, prepared as above, was added to a larger quantity of acetophenone or aniline. The addition of about 1 mg. of either of the two methanes to 2–4 cc. of the resulting solution again produced immediately the color of the salt. The color was not discharged on the addition of further quantities of acetophenone or aniline, as the case might be, although it did become less intense as a result of dilution.

The authors wish to express their appreciation to Mr. Kurt Eder for making the elementary analyses reported in this paper, to Mr. George Monk, Jr., for carrying out the crystallographic comparison, and to Mr. R. D. Kleene for helping with some of the preliminary experiments upon the trinitrotrixylylmethane.

Summary

In order to obtain evidence bearing upon the hypothesis of Birtles and Hampson that methyl groups in the two ortho positions can inhibit the resonance of a nitro group with an aromatic ring, 3,3′,3″,5,5′,5″-hexamethyl - 4,4′4″ - trinitrotri - phenylmethane has been prepared and its acid strength compared with that of the corresponding trinitrotriphenylmethane. It was found, in agreement with the hypothesis of Birtles and Hampson, that the former substance is somewhat less acidic than the latter.

Apparent and Partial Molal Volumes of Sodium Chloride and Hydrochloric Acid in Mixed Solutions[1]

BY HENRY E. WIRTH[2]

In a previous paper[3] it was shown that the partial molal volumes of potassium chloride, potassium bromide and potassium sulfate in sodium chloride solutions depend on the total volume ionic strength. The slopes of the partial molal volume–square root of concentration curves for these salts in aqueous solutions are near the values predicted by the Debye–Hückel theory.[4] A few electrolytes (*i. e.*, hydrochloric acid, lithium chloride and nitric acid) give slopes that are less than the theoretical value.[5] The effect of hydrochloric acid on the partial molal volumes of sodium chloride, and the effect of sodium chloride on the partial molal volumes of hydrochloric acid have therefore been investigated.

Methods.—In general the same apparatus and methods were employed. Pyrex tubes were substituted for the silver plated containers previously used as the latter were attacked by acid solutions.

C. P. grade chemicals were used without attempt at further purification.

The partial molal volumes of sodium chloride were determined in water and in approximately 0.04, 0.16, 0.36, 1.0, 2.18 and 4.23 *N* hydrochloric acid solutions. Enough hydrochloric acid solution for each series was prepared and the concentration determined by base titration as described below for the stock acid solution. As a check the concentrations were also calculated from the determined densities. Weighed amounts of sodium chloride were added to weighed portions of the acid solution to give the solutions used in the density determinations.

The partial molal volumes of hydrochloric acid were determined in water and in approximately 0.04, 0.16, 0.36, 1.0 and 2.25 *N* sodium chloride solutions. To meet the requirement that the ratio of moles of water to moles of sodium chloride remain constant throughout a given series, weighed stock acid solution was added to a weighed amount of water and to this solution was added an amount of sodium chloride calculated from the total water present.

The stock acid solution was analyzed by adding a weighed excess of approximately 0.25 *N* carbonate-free base to a sample and titrating the excess with approximately 0.01 *N* acid in a carbon dioxide-free atmosphere. Phenolphthalein was used as the indicator. The base was standardized against potassium acid phthalate. The average of six analyses was 0.21975 g. of hydrochloric acid per g. of solution (average deviation 0.00005). The average of five determinations using the weight Volhard method for chloride was 0.21960 (average deviation 0.00002).

Results[6]

The experimental values of the density for the solutions studied are presented in Tables I, II and III. Each series of results was represented by an equation of the form

$$-F_3 = a + b(\mu_v^{1/2} - C_2^{0\,1/2}) + c(\mu_v^{1/2} - C_2^{0\,1/2})^2 \quad (1)$$

The values for the constants a, b and c are given in Table IV. The apparent and partial molal volumes were calculated from this equation using the methods previously employed.[3] Values of the apparent and partial molal volumes are given in Tables I, II and III for the actual concentrations studied. Tables V[1] and VI[1] present values of $\overline{V}_3$ for various even concentrations.

It is possible to compare the values of the apparent molal volumes of the solutes in aqueous solutions with values which have previously appeared in the literature. In Fig. 1 values of Φ_3 for sodium chloride at 25° as determined in the present study are compared with those reported by Kruis.[7] The apparent molal volume at infinite dilution ($\overline{V}_3^0$) found by Kruis is 16.60$_5$ as compared with 16.67$_0$. This difference arises in

(6) The symbols used have the following significance:

d_1, d_2, d_3 = Density of water, of solution containing one solute and of solution containg two solutes, resp.

M_1, M_2, M_3 = Molecular weight of water, of first solute and of second solute, resp.

n_1, n_2, n_3 = Moles of water, moles of first solute and moles of second solute, resp. In a given series the ratio n_1/n_2 was maintained constant while n_3 varied.

C_2, C_3 = Volume concentration of first and second solute, resp., expressed as moles per liter of solution.

V = Volume of solution containing $n_1 + n_2 + n_3$ moles.

$\overline{V}_1 = \partial V/\partial n_1$, $\overline{V}_2 = \partial V/\partial n_2$, $\overline{V}_3 = \partial V/\partial n_3$. Partial molal volumes of water, of first solute and of second solute, resp.

$\overline{V}_1^0$ = Molal volume of pure water.

$\overline{V}_3^0$ = Partial molal volume of second solute when $C_3 = 0$, $C_2 = C_2^0$.

Φ_3 = $[V - (n_1\overline{V}_1^0 + n_2\Phi_2)]/n_3$. Apparent molal volume of second solute, where Φ_2 is the apparent molal volume of the first solute in a solution containing n_1 moles of solvent and n_2 moles of solute only.

F_3 = $1000(d_2 - d_3)/C_3$.

μ_V = $\omega_2C_2 + \omega_3C_3$. Volume ionic strength, where ω is one-half the summation of the number of ions times the square of the valence of the ion.

the extrapolation to infinite dilution and does not represent a great variation in reported densities. Densities calculated from the equation in Table IV agree with those reported by Jones and Christian[8] with an average deviation of 0.0008% which is within the experimental error of their results. $\overline{V}_3^0$ calculated from the equation given by Jones and Christian is 16.62_1.

For comparison values of the apparent molal volumes at 18.55° as determined by Kohlrausch and Hallwachs[9] are also given in Fig. 1. The results of Prang[10] for concentrations below 0.015 N are in essential agreement and indicate that the value found by Kohlrausch and Hallwachs in the most dilute solution is probably in error.

The apparent molal volumes of hydrochloric acid in aqueous solutions are compared with the values determined by Hedestrand as reported by Geffcken[11] in Fig. 1. These are apparently the only values in the literature for the concentrations and temperature studied here. Hedestrand's value for $\overline{V}_3^0$ is 18.20 as compared with 18.07. The equation of Åkerlöf and Teare[12] derived from data at much higher concentrations and at other temperatures yields a value of 17.98_0 for $\overline{V}_3^0$ at 25°. Values of the apparent molal volumes at 17.15° as reported by Kohlrausch and Hallwachs[9] are also plotted in Fig. 1.

The partial molal volumes of sodium chloride are much less in the acid solutions than in solutions of the same volume ionic strength containing sodium chloride alone (Fig. 2). In the five cases ($\mu_v^{1/2}$ = 0.4, 0.6, 0.8, 1.0 and 1.2) where it is pos-

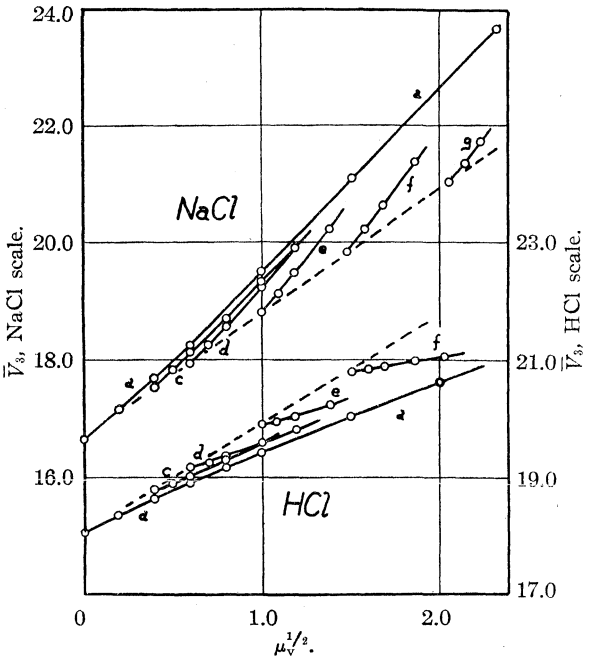

Fig. 2.—Partial molal volumes of sodium chloride in water (a), and in 0.16 *N* (c), 0.36 *N* (d), 0.99 *N* (e), 2.18 *N* (f) and 4.23 *N* (g) hydrochloric acid solutions (upper curves). Partial molal volumes of hydrochloric acid in water (a), and in 0.16 *N* (c), 0.36 *N* (d), 0.98 *N* (e) and 2.25 *N* (f) sodium chloride solutions (lower curves) (25°).

sible to make a comparison it was found that at constant total volume ionic strength the decrease in the partial molal volume is very accurately a linear function of the concentration of the acid (Fig. 3).

The partial molal volumes of hydrochloric acid are greater in solutions containing sodium chloride than in solutions of the same volume ionic strength containing acid alone (Fig. 2). Although there are two exceptions (the highest concentrations studied in 0.04 and 0.16 *N* sodium chloride solutions) it appears that at constant total volume ionic strength the increase in the partial molal volumes of hydrochloric acid is a linear function of the concentration of sodium chloride (Fig. 3).

In both cases presented in Fig. 2 it is possible to draw straight lines through the limiting values of the partial molal volumes ($\overline{V}_3^0$). All possible values of $\overline{V}_3$ are included between this line and the curve for $\overline{V}_3$ in aqueous solution. The slopes of the limiting lines are 1.81 for hydrochloric acid and 2.06 for sodium chloride. These values may be compared with a slope of 1.28 for hydrochloric acid and a slope of 3.12 for sodium chloride in water solutions at a concentration of 1 *N*.

The independent determination of the partial molal volumes of the two solutes in the mixed solutions makes possible the calculation of the partial molal volumes of water in most of the solutions studied.

In solutions containing only one solute, $\overline{V}_1$ can be calculated from the relation

$$\overline{V}_1 = \frac{(1000 - C_3\overline{V}_3)\,M_1}{1000d_3 - C_3M_3} \qquad (2)$$

For two solutes, $\overline{V}_1 = (1000 - C_2\overline{V}_2 - C_3\overline{V}_3)/n_1$. But since $n_1 = C_2K$ for all solutions of a given series and $K = (1000\ d_2 - C_2^0M_2)/C_2^0M_1$, the equation used in calculation becomes

$$\overline{V}_1 = \frac{(1000 - C_2\overline{V}_2 - C_3\overline{V}_3)\,M_1C_2^0}{C_2(1000d_2 - C_2^0M_2)} \qquad (3)$$

Values of $\overline{V}_3$ for even volume ionic strengths were taken directly from Table V[1] or VI,[1] while values of $\overline{V}_2$ were interpolated from Table VI[1] or V,[1] respectively. The calculated values of $\overline{V}_1$ are given in Tables VII[1] and VIII[1] and in Fig. 4.

In aqueous solutions $\overline{V}_1$ is decreased less by hydrochloric acid than by sodium chloride, and in mixed solutions the values are intermediate between those for the single solutes.

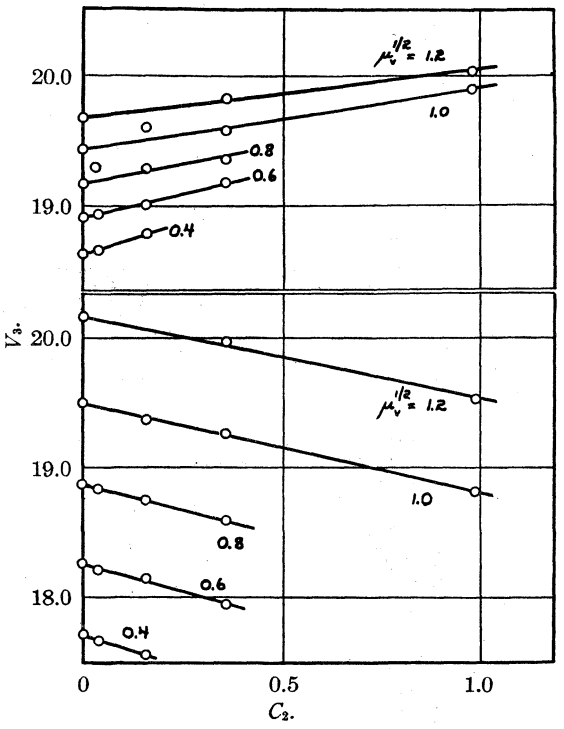

Fig. 3.—Partial molal volumes of hydrochloric acid *vs.* concentration of sodium chloride at constant total volume ionic strengths (upper graph), and partial molal volumes of sodium chloride *vs.* concentration of hydrochloric acid at constant total volume ionic strengths (lower graph) (25°).

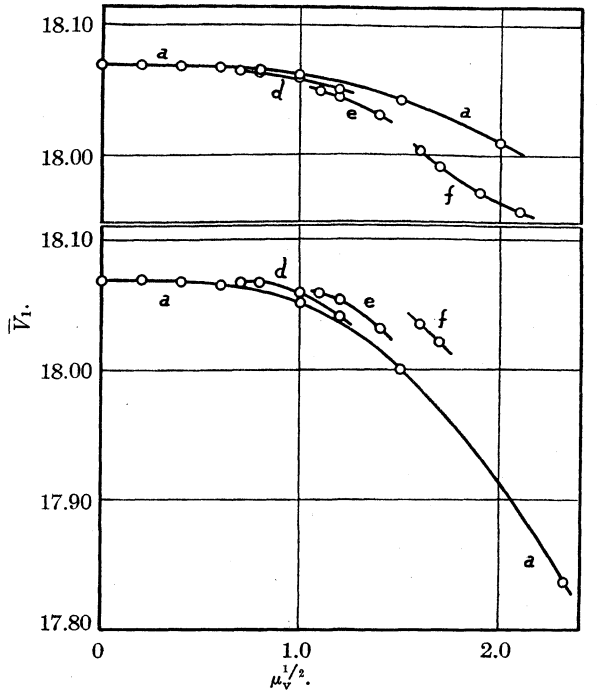

Fig. 4.—Partial molal volumes of water in hydrochloric acid solutions (a), and in hydrochloric acid solutions 0.36 *N* (d), 0.98 *N* (e) and 2.25 *N* (f) in sodium chloride (upper graph). Partial molal volumes of water in sodium chloride solutions (a), and in sodium chloride solutions 0.36 *N* (d), 0.99 *N* (e) and 2.18 *N* (f) in hydrochloric acid (lower graph) (25°).

Discussion

The slope of the apparent molal volume–square root of concentration curve for hydrochloric acid in water is less than for any highly ionized, uni-univalent electrolyte with the possible exception of nitric acid.[12,13,14] While the results obtained here do not exclude the possibility of $\partial\Phi/\partial C^{1/2}$ attaining the theoretical limiting value, this would require an abrupt change at concentrations below 0.04 *N*.

Since $\partial\Phi/\partial C^{1/2}$ is apparently least for substances containing hydrogen or lithium ions, the effect may be related to ion size. The second approximation derived by Redlich and Rosenfeld[4] from the Debye–Hückel expression involving ionic radii predicts however that $\partial\Phi/\partial C^{1/2}$ will be increased as the ionic size is decreased. The breakdown of the Debye–Hückel theory in other cases where small ions are involved has been attributed to ion association.[15]

The relationship between $\partial\Phi/\partial C^{1/2}$ and the partial molal volume of the solvent is of significance. For a single solute, the relations $(1000 - n_1\overline{V}_1^0)/C_3 = \Phi_3 = \overline{V}_3^0 + k_1C_3^{1/2}$, $\overline{V}_3 = \overline{V}_3^0 + kC_3^{1/2}$, and $k_1 = {}^2/_3k$(Geffcken[11]) can be combined with the equation $V = 1000 = n_1\overline{V}_1 + C_3\overline{V}_3$ to give the expression

$$\overline{V}_1 = \frac{\overline{V}_1^0(1000 - C_3\overline{V}_3^0 - kC_3^{3/2})}{1000 - C_3\overline{V}_3 - {}^2/_3kC_3^{3/2}} \qquad (4)$$

This equation holds with considerable accuracy at least up to concentrations of 1 *N* and shows that the partial molal volume of the solvent at a given concentration is determined by $\partial\Phi/\partial C^{1/2}$ $(= k)$, or *vice versa*.

Since $\partial\Phi/\partial C^{1/2}$ for moderately concentrated solutions cannot now be predicted accurately from theory, it may be convenient to take the view of Stewart[16] and others that the change in structure of water through decrease in coördination number in the presence of ions is the controlling factor.[17]

(13) D. O. Masson, *Phil. Mag.*, [7] **8**, 218 (1929).

(14) G. Åkerlöf and G. Kegeles, THIS JOURNAL, **61**, 1027 (1939).

(15) H. Falkenhagen, "Electrolytes," translated by R. P. Bell, Oxford University Press, New York, N. Y., 1934, p. 257.

(16) G. W. Stewart, *J. Chem. Phys.*, **7**, 869 (1939).

(17) This should be done without discarding the Debye–Hückel theory, since this theory correctly predicts the choice of variable ($C^{1/2}$ or $\mu_v^{1/2}$), the order of magnitude of $\partial\Phi/\partial C^{1/2}$, and the effect of valence on $\partial\Phi/\partial C^{1/2}$.

From this standpoint, the low value for $\partial\Phi/\partial C^{1/2}$ for hydrochloric acid is due to the ease with which the hydrogen ion fits into the existing structure of water, and only the chloride ion is effective in changing that structure.

The observed increase in the partial molal volume of hydrochloric acid at constant total volume ionic strength when the hydrogen ion is replaced by sodium ion must be due to the greater effect of the sodium ion on the water structure. The fact that the increase is a linear function of the amount of sodium ion added is in harmony with this view. The decrease in the partial molal volume of sodium chloride on replacing the sodium ion with hydrogen ion is explained in the same manner.

Summary

The apparent and partial molal volumes of sodium chloride and hydrochloric acid have been determined in water and in mixed solutions.

The partial molal volumes of sodium chloride are decreased at constant total volume ionic strength by the addition of hydrochloric acid. The decrease is a linear function of the acid concentration.

The partial molal volumes of hydrochloric acid are increased at constant total concentration by the addition of sodium chloride. The increase is a linear function of the sodium chloride concentration.

The partial molal volumes of water have been determined in the mixed solutions. At a given concentration they are largest in solutions of pure hydrochloric acid and least in pure sodium chloride solutions.

The observed behavior may be interpreted in terms of changes in the structure of water caused by ions in solution.

An X-Ray Investigation of the System Cr_2O_3–NiO[1]

BY L. THOMASSEN

The present work has for its purpose to investigate the phases that are present in the above system. This equilibrium diagram is of considerable practical interest since the scale formed on the common electric resistance wires of nominal composition 80% Ni 20% Cr mainly consists of these oxides.

An earlier investigation[1a] has shown that the compound $NiO{\cdot}Cr_2O_3$ is formed when mixtures of this composition are heated with a mineralizer such as potassium chloride. This compound crystallizes in the widely distributed spinel type of structure.[2] Regarding the rest of the system, no information seems to be available. Similar systems with ferric oxide as the trivalent metal oxide have been investigated.[3]

Experimental Procedure

Most of the samples were made by mixing the oxides in the proper proportions, grinding them intimately and heating them with potassium chloride in platinum crucibles at 1000° for one to two hours. An electric furnace with automatic temperature control was used for the heating. After fusion, the crucibles were taken out and allowed to cool rapidly in the air. Unless changes take place very rapidly, the material as investigated would represent equilibrium conditions at 1000°.

The chromic oxide used was obtained by heating C. P. ammonium chromate to 900°. Upon heating a sample to 1000° for ten hours, a loss of 0.2% was obtained. According to Wretblad[4] there is no danger of forming CrO_2 when heating Cr_2O_3 to 1000° in oxygen and there should be still less chance of forming such a compound in air.

The nickel oxide was obtained by heating C. P. nickel nitrate, cobalt free, to 400°. The oxide obtained analyzed 77.3% Ni instead of 78.5% theoretically. Both the weight loss of the chromic oxide and this deviation from the theoretical composition were taken into account when making up mixtures to be fused.

After fusion the samples were washed carefully to remove all the potassium chloride present. Invariably, the first wash water was yellow, showing that some chromic oxide was oxidized to chromate.

Boric oxide was also tried as a mineralizer but with the straight $NiO{\cdot}Cr_2O_3$ composition, a number of extra lines appeared on the X-ray diagram. This observation confirmed the doubts expressed by Holgersson[1a] regarding the advisability in using boric oxide in this synthesis.

(4) Wretblad, *Z. anorg. allgem. Chem.*, **189**, 329 (1930).

The method of grinding and pressing together the oxides in the proportions to form spinel and heating them at 1000° for two hours did not produce complete combination since both the nickel and chromium oxide lines were present besides the spinel lines.

Some of the samples used were produced by co-precipitation of nickel carbonate and chromium hydroxide with sodium carbonate. Proper proportions were taken out of solutions of known contents of $NiCl_2$ and Cr_2Cl_6, precipitated out of hot diluted solutions, filtered, washed carefully, dried and ignited, keeping the samples at 1000° for ten hours.

The porportions used may be seen from Table I. The samples with an asterisk are those prepared by co-precipitation. The sample of straight spinel composition was analyzed for nickel and gave 33.0% NiO instead of theoretically 32.6%.

The phases present were identified by X-ray diffraction patterns, using filtered chromium radiation. The X-rays were produced by a modified Siegbahn–Hadding tube with a plated chromium target. The samples were made up by mixing the powders with Duco Household Cement and rolling them out into rods of about $^3/_{10}$ mm. diameter. For lattice parameter determinations C. P. sodium chloride was mixed with the sample to provide a variable correction factor. The lattice constant of sodium chloride was taken to be 5.626 Å.[5]

Computations of lattice parameters are not given in this work since the lattice constants of the substances investigated are all known, and the precision determinations did not differ much from those in the literature. For more detailed information on the method of computation, see for instance L. Thomassen, *Z. physik. Chem.*, **135**, 388 (1928); *ibid.*, **B2**, 340 (1929).

Discussion of Results

The results obtained are shown in Table I. It will be seen that the only compound in the system is the spinel. A separate experiment shows that this compound remains cubic when cooled slowly from 1000° in the electric furnace. It also will be noticed that chromic oxide on one side of the spinel composition and nickel oxide on the other side appear when present in small excess over the 1:1 ratio. This means that if solid solubility exists, the amounts dissolved are small at the temperature of formation.

In order to investigate whether solid solubility could be detected in lattice dimensions, diffraction diagrams of the samples 0.95 $NiO{\cdot}Cr_2O_3$, $NiO{\cdot}Cr_2O_3$ and 1.1 $NiO{\cdot}Cr_2O_3$ were made, using sodium chloride as reference substance. Within experimental error, the measurements gave the same results, namely, 8.282, 8.282 and 8.284 Å., respectively, with an error of ±0.003 Å. This compares to the lattice constant given by Holgersson[1a] of 8.30 Å., also using sodium chloride as a reference substance. Since the lines were comparatively broad, no precision back reflection pictures were taken.

TABLE I

Mols of NiO per Mol Cr_2O_3	Phases present
0.25	Cr_2O_3
* .25	Cr_2O_3 + spinel
* .30	Cr_2O_3 + spinel
.375	Cr_2O_3 + increasing amount of spinel on increasing NiO
.50	
.75	
.87	
.95	
1.0	Spinel only
1.1	NiO + decreasing amount of spinel on increasing NiO
1.25	
1.50	
1.75	
2.0	
4.0	
8.0	
*20	
*50	
*100	NiO

From the table it will be seen that the samples with high chromic oxide content give conflicting results regarding phases present, depending on whether they are produced by co-precipitation or by fusion. The meaning of this observation is not clear and this question of the solubility of nickel oxide in chromium oxide will be treated in another paper.

Among the samples with high nickel oxide content, the one with 100 mols of nickel oxide is the only one which does not show spinel lines. By the technique used in this investigation the diffraction method will not detect phases present below one to three per cent. The one mol spinel which would be formed would hardly register in a diffraction diagram when diluted with 99 mols of NiO. Taking into account that the spinel lines were hardly discernible when present in the double concentration and in amounts which are at the threshold of detection, it seems probable that the solubility of Cr_2O_3 in NiO is very small.

As is well known, the nickel oxide crystallizes in the sodium chloride type of structure, and several investigators have found a lattice constant $a = 4.17$ Å.[6,7] The present investigation also gave $a = 4.170 \pm 0.003$Å.

(6) G. Lunde, *Z. anorg. allgem. Chem.*, **163**, 345 (1927).

(7) S. B. Hendricks, M. E. Jefferson and J. F. Schultz, *Z. Krist.*, **73**, 376 (1930).

It is a pleasure to acknowledge the assistance of Mr. George Manning who made up most of the preparations and also took some of the X-ray diagrams.

Summary

1. In the equilibrium diagram Cr_2O_3–NiO the spinel $NiO \cdot Cr_2O_3$ is the only compound present.

2. At 1000° the solubility of nickel and chromium oxide in the spinel is small.

3. Nickel oxide does not dissolve chromium oxide.

The Acid Catalyzed Esterification of Aliphatic Acids

BY HILTON A. SMITH

In two previous papers the effect of the alkyl chain of an aliphatic organic acid on its velocity of esterification in methanol was discussed. The first[1] dealt with normal acids only, and the second included simple methyl substituted acids.[2] The present paper reports a study of the velocity of esterification of certain other branched-chain aliphatic acids, together with a discussion of the general effect of alkyl substitution on reaction velocity.

Experimental

Methanol was obtained in a pure dry state, as in previously reported work, by careful fractionation of 99.5% methyl alcohol using a 5-foot (1.5-meter) spiral column. The material used distilled at a constant head temperature.

Trimethylacetic acid and **diethylacetic acid** were obtained by fractionation of the Eastman Kodak Co. acids in a 5-ft. (1.5-meter) Vigreux type column. The former analyzed 99.5% by titration with standard base and melted at 35.4°. The latter analyzed 99.9%.

β-Methylvaleric acid[3] was prepared by the malonic ester synthesis from diethyl malonate, *s*-butyl bromide and sodium ethylate. Ethyl *s*-butylmalonate was prepared by the method indicated in "Organic Syntheses" for its normal isomer,[4] and this ester converted to β-methylvaleric acid by hydrolysis and decarboxylation. The crude acid was purified by fractionation in a 5-ft. Vigreux type column. The sample used for esterification purposes distilled at constant head temperature (±0.05°) and analyzed 100.0% by titration with standard base.

Dipropylacetic acid, dibutylacetic acid, and **di-isobutylacetic acid** were prepared in a manner similar to that used for β-methylvaleric acid. The di-alkyl substituted ethyl malonates were prepared by introducing two alkyl groups into the ester using sodium ethylate and the necessary alkyl iodide. The substituted malonic ester was hydrolyzed and decarboxylated, and the crude acids purified by reduced pressure distillation in a 5-ft. Vigreux column. Each of the samples used in the esterification studies analyzed at least 99.6% by titration with standard base.

The method employed to obtain the rate constants for the hydrion-catalyzed esterification of these acids was similar to that previously described[1] with the exception that the glass-stoppered bottles were replaced by small Pyrex vials the openings of which were fitted with a glass plug. A rubber sleeve around the opening and the plug prevented possible loss of solvent by evaporation. This was necessary because of the slowness of the runs, some of them lasting for several weeks.

Experimental Results and Calculations

The rate constants were calculated from Goldschmidt's equation

$$k = \frac{(r + a) \ln [a/(a - x)] - x}{(\text{catalyst})rt}$$

where a is the original concentration of organic acid, x is the concentration of ester formed after time t, and the catalyst is hydrogen chloride. The values of the constant r used were those obtained in earlier work for normal aliphatic acids.[1]

The values of the reaction velocity constant, k, were quite constant for reactions run at the lower temperatures. This is illustrated in Table I for the esterification of trimethylacetic acid at 20°.

TABLE I

curred with di-isobutylacetic acid at 50°, this being the slowest high temperature run. The results of such a run are presented in Table II.

TABLE II

ESTERIFICATION OF CH_3OH AND DI-ISOBUTYLACETIC ACID AT 50°

$a = 0.500$, (HCl) = 0.005

t, min.	$(a - x)$	k (liters × moles^{-1} × sec.$^{-1}$) k (simple)	k (correct)
407	0.436	0.00121	0.00123
1130	.370	.00103	.00108
1842	.323	.000970	.00104
3376	.255	.000882	.00099
5415	.193	.000834	.00100
7130	.159	.000794	.00100
11297	.106	.000726	.00103

Inspection of column three of this table shows the extent of the falling off of the reaction velocity constant. The value of r at this temperature is 0.42. The falling off of the rate constants might be prevented by changing the value of r for the slow reactions, but this is not permissible since r is theoretically defined by the equation

$$r = \frac{(CH_3OH_2^+)(H_2O)}{(H_3O^+)}$$

and at any given temperature should be the same for all acids.

Hinshelwood[5] already has demonstrated that, at elevated temperatures, the reaction of methanol with hydrogen chloride is appreciable. For the purpose of correcting the rate constants for reaction of the catalyst with the solvent, the rate of reaction of a 0.005 N solution of hydrogen chloride in methanol was studied. The solution was placed in a thermostat in one of the reaction vials, and the disappearance of the acid followed by titration with dilute (0.00229 N) base. Figure 1 gives the results obtained at 30, 40 and 50°. It demonstrates the fact that, while this reaction is negligible in the study of esterification of normal or simple substituted aliphatic acids (80% reaction in a few hours), it must be taken into account for the slower reactions under consideration here.

The rate of reaction of hydrogen chloride with methanol as shown in Fig. 1 is somewhat faster than that found by Hinshelwood.[5] The reason for this difference is not apparent, but may be due to the different concentrations used.

Unfortunately it is impossible to make an absolute correction for the reaction of the catalyst with solvent since one cannot predict the effect of the

(5) Hinshelwood, *J. Chem. Soc.*, 599 (1935).

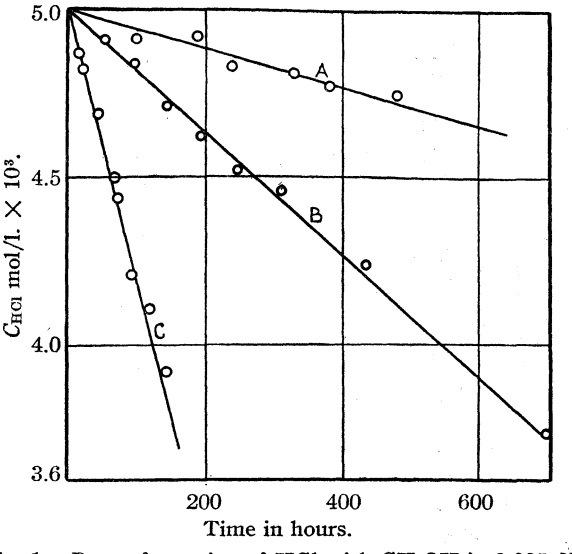

Fig. 1.—Rate of reaction of HCl with CH_3OH in 0.005 N solution: A, $T = 30°$; B, $T = 40°$; C, $T = 50°$.

acid and ester present on its rate. The corrected values of k in column 4 of Table II were calculated by substituting in equation (1) not the original concentration of hydrogen chloride for (catalyst) but rather the concentration present at time t, thus assuming the reaction of hydrogen chloride and methanol in the reaction mixture to proceed at the same rate as that found for the pure solutions. This correction results in reasonably constant values of the reaction velocity constants. Such a correction was applied for studies involving diethyl-, dipropyl-, dibutyl-, and di-isobutylacetic acids at temperatures of 30, 40, and 50°. With the exception of di-isobutylacetic acid at 50°, these corrections are not more than some 10% at as much as 80% reaction, and are usually considerably less.

The values of the specific reaction rate constants for esterification of the acids studied are given in Table III. They represent averages of the individual values of k over the range covered by 20 to 80% reaction. The ± deviations are generally of the order of 2–3%.

Figure 2 shows the plot of log k against inverse temperature for the acids studied. The activation energy for each acid is given in the last column of Table III. These were calculated from the slopes of the lines in the figure, and were checked by the method of least squares.

Discussion

The effect of the length of an alkyl chain of an aliphatic acid on its esterification velocity

[a] For trimethylacetic acid at 50°, a = 0.486, (HCl) = 0.00486. [b] For β-methylvaleric acid at 20°, (HCl) = 0.00386.

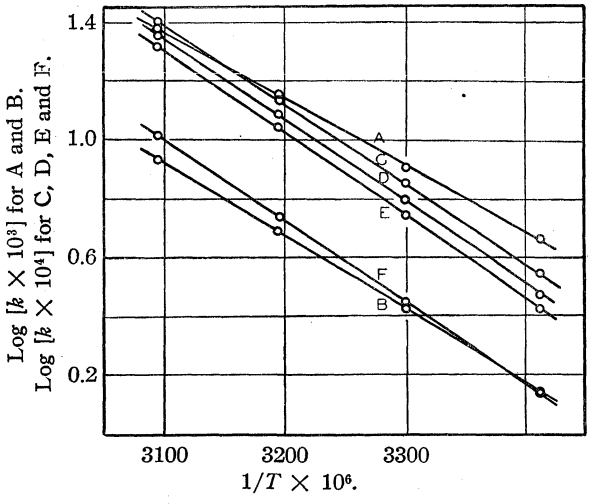

Fig. 2.—Temperature coefficients of hydrogen ion catalyzed esterification of substituted alkyl acids in methanol: A, β-methylvaleric acid; B, trimethylacetic acid; C, diethylacetic acid; D, dipropylacetic acid; E, dibutylacetic acid; F, di-isobutylacetic acid.

already has been discussed.[1,6] It was demonstrated that the velocity constants decreased from formic to butyric acids, and thereafter remained constant with increasing chain length. It was also demonstrated that the activation energy was constant throughout the series. It is now possible to consider the results of lengthening two chains simultaneously. Table IV gives a summary of the pertinent data.

TABLE IV

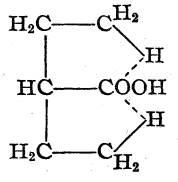
Acid	$k_{20°}$	E
Acetic[1]	0.0440	10,000
Isobutyric[2]	.0147	9,800
Diethylacetic	.000351	12,400
Dipropylacetic	.000297	12,400
Dibutylacetic	.000267	12,900

The results shown in this table are quite parallel with those found when the length of a single chain is increased. In each case a relatively small drop in the reaction velocity constant occurs on the first methyl substitution, a much larger one on an ethyl substitution, and little change occurs as the chain length is subsequently increased. For the disubstituted acids, some falling off does occur beyond diethylacetic acid, but this change is insignificant when compared to previous changes. In contrast to the normal acids, the change from dimethylacetic to diethylacetic acid is accompanied by a large change in activation energy.

The results of increasing the chain length of a normal aliphatic acid on its velocity of esterification were explained by postulating ring formation in butyric and higher acids. Similar rings have been postulated by Palomaa and co-workers in

(6) Smith and McReynolds, THIS JOURNAL, 61, 1963 (1939).

their studies of the ether-type linkage.[7] The results for disubstituted acids which are presented here are not readily explainable either by inductive effect[8] or by the mechanical model studies of Fairclough and Hinshelwood.[9] They are, however, readily explainable by the ring theory. The postulated ring structure of diethylacetic acid is



A similar structure might be expected even were no chelation to occur, since from stereochemical considerations alone the zig-zag structure usually assigned to a hydrocarbon chain is improbable for both chains of this acid. The slow esterification of diethylacetic acid is in accord with the explanation already advanced[6] for its high dissociation constant.[10] The fact that only minor changes in esterification rate are found when the alkyl chains are lengthened to form dipropyl and dibutylacetic acids is also expected from the ring theory.

The slow esterification of β-methylvaleric acid was predicted from previous results with impure isocaproic acid.[2] These predictions are now confirmed. The rate of esterification of this acid ($k_{20°} = 0.00463$) compared with that of isovaleric acid ($k_{20°} = 0.00488$) gives further evidence that substitution in the γ position ordinarily has little effect.

The results with di-isobutylacetic acid are interesting since k for this acid is considerably lower than those for diethyl, dipropyl and dibutylacetic acids. In the single chain series, the corresponding compound, isocaproic acid, esterified at the same rate as the corresponding normal acids. The slower rate for di-isobutylacetic acid is in line with the fact that some falling off of the esterification rate does occur when the chains in the di-substituted acids are longer than those in diethylacetic acid, and with the fact that β-methylvaleric acid esterifies a little slower than isovaleric acid.

(7) *Cf.* Palomaa and Siitonen, *Ber.*, **69B**, 1338 (1936).

(8) *Cf.* Evans, Gordon and Watson, *J. Chem. Soc.*, 1439 (1938); see also Smith and Levenson, THIS JOURNAL, **61**, 1172 (1939).

(9) Fairclough and Hinshelwood, *J. Chem. Soc.*, 593 (1939).

(10) Dippy, *ibid*, 1222 (1938). In this connection the attention of the author has been called to the fact that direct credit was not given to Dippy for the form of Fig. 3 in the publication of Smith and McReynolds.[6] A similar figure was presented by Dippy.

Complete data are now available for discussing the effect of substitution of methyl groups in the α position of acetic acid. This material is summarized in Table V.

TABLE V

Acid	$k_{20°}$	E
Acetic[1]	0.0440	10,000
Propionic[1]	.0400	9,800
Isobutyric[2]	.0147	9,800
Trimethylacetic	.00140	11,400

From this table it is evident that successive methyl substitution in the α position of acetic acid causes a decrease in the velocity of esterification of the acid, the decrease per methyl group becoming greater with increased substitution. This is in accord with the idea of geometrical steric hindrance. The activation energy is changed only when the third methyl group is introduced, in which case a considerable increase occurs. The high activation energy for trimethylacetic acid corresponds with the results of Hinshelwood and Legard[11] for the catalyzed esterification of this acid in ethanol. The increase in activation energy accompanying considerable substitution already has been discussed.[6]

In general, the results of the esterification studies with alkyl substituted acetic acids may be summed up as follows.

Substitution must ordinarily take place in the α or β position from the carboxyl group if the reaction velocity is to be affected, and substitution in either of these positions has approximately the same net effect. The so-called "ethyl effect" is the result of simultaneous substitution in the α and β positions.

One substituent in these positions has little effect on the esterification velocity and none on the activation energy, *e. g.*, propionic acid.

Two substituents have a considerably greater effect on the reaction velocity, but none on the activation energy, *e. g.*, isobutyric acid, butyric and higher normal acids.

Three substituents have a still greater effect on the esterification velocity, and result in a somewhat increased value of E, *e. g.*, methylethylacetic acid, isovaleric acid, β-methylvaleric acid, and trimethylacetic acid.

Four substituents have a large effect on the reaction velocity, and result in a greatly increased activation energy, *e. g.*, diethylacetic acid, dipropylacetic acid, etc.

(11) Hinshelwood and Legard, *ibid*, 1588 (1935).

Acids which have more than four substituents in the α or β positions should be practically unesterifiable under ordinary conditions.[12]

Finally, if considerable substitution in the α or β positions has already been made, substitution in the γ position may have some effect on esterification rate.

It has been demonstrated already that the effect of lengthening the alkyl chain of the acid portion of ethyl esters on the rate of saponification of these esters is the same as that observed in esterification.[8] In a subsequent paper it will be shown that the general effect of α and β substitution is the same for these two processes.

(12) *Cf.* Braun and Fischer, *Ber.*, **66B**, 101 (1933).

Summary

The kinetics of the hydrogen ion catalyzed esterification of the following organic acids have been studied: β-methylvaleric acid, trimethylacetic acid, diethylacetic acid, dipropylacetic acid, dibutylacetic acid and di-isobutylacetic acid.

The velocity of esterification of β-methylvaleric acid is similar to that of isovaleric acid. Trimethylacetic acid esterifies slowly, and has a greater activation energy than normal acids. The other four acids esterify very slowly, and have a considerably increased activation energy.

The general results of esterification studies of alkyl substituted acetic acids have been discussed

Some Unusual Hydrates of Quaternary Ammonium Salts

BY D. L. FOWLER, W. V. LOEBENSTEIN, D. B. PALL AND CHARLES A. KRAUS

Introduction

In concentrating a solution of tetra-*n*-butylammonium hydroxide for the purpose of preparing as nearly anhydrous a product as possible, it was observed that crystals appeared at room temperature in comparatively dilute solutions and that the entire mass solidified at this temperature while a large quantity of water was still present. On investigating this phenomenon further, it was found that tetra-*n*-butylammonium hydroxide forms a hydrate, containing 31 molecules of water, which melts at 30.2°. On examining solutions of tetra-*n*-butylammonium fluoride, a similar hydrate was found containing 18 molecules of water and melting at 37°. Somewhat later, tetramethyl-, tetra-*n*-propyl-, tetra-*n*-amyl- and tetraisoamylammonium hydroxides were investigated. It was found that only tetraisoamylammonium hydroxide forms a high hydrate. More recently, a considerable number of quaternary ammonium salts has been investigated in a preliminary fashion in order to determine whether they form hydrates and approximately of what composition. All the tetra-*n*-butylammonium salts having a high solubility in water were found to form hydrates, as did also tetraisoamylammonium formate, the one tetraisoamylammonium salt investigated. No salts of ions other than tetra-*n*-butylammonium and tetraisoamylammonium have been found that form high hydrates.[1]

Experimental

Method.—In determining the composition of these salt hydrates, a weighed sample of solution, which had previously been analyzed, was introduced into a suitable cell which was either cylindrical or of Erlenmeyer form and which was provided with a stopcock. The weight of the cell was known so that the composition of the solution could be obtained at any time by weighing the cell and its contents. The cell was attached to a vacuum system which was provided with a mercury manometer; an oil manometer, which had a higher sensitivity than the mercury manometer; a flask, containing water; a small pipet, graduated to 0.1 cubic centimeter; and a closed, drying tube for absorbing water vapor as desired. In most cases, the cell was attached to the apparatus by means of a short length of pressure tubing so that the contents of the cell could be shaken conveniently in determining melting points or in adjusting for pressure equilibrium. The entire apparatus was carefully exhausted so as to remove the permanent gases.

Most of the salts were prepared by titrating acids with solutions of the desired quaternary bases. The bases were prepared from the corresponding iodides by means of silver oxide. In preparing these bases, it is very essential to guard against carbon dioxide. All solutions must be made up with carbon dioxide-free water and the apparatus must

(1) The experimental work in connection with tetra-*n*-butylammonium hydroxide and fluoride was carried out by D. L. Fowler; that of the other hydroxides by W. V. Loebenstein; that of the remaining salts by David B. Pall. Since it is not planned to continue the investigation of these hydrates at this time, the results are presented as far as they have been obtained.

be filled with carbon dioxide-free air or nitrogen. Traces of carbon dioxide are immediately absorbed by the bases to form carbonates, thus introducing an additional component which renders a study of the desired phase relations impossible.

In determining the precise composition of the hydrates, several methods were employed, depending upon the nature of the hydrate. In some cases, the initial melting point and the point of disappearance of the last crystal were observed as the temperature was slowly raised, while in others the vapor pressure curve was followed and the break point observed in passing from one phase system to another. In still other cases, the melting point curves were determined.

Tetra-*n*-butylammonium Hydroxide, $(C_4H_9)_4NOH \cdot 31H_2O$.—A quantity of tetra-*n*-butylammonium hydroxide was prepared as described under careful exclusion of carbon dioxide. Several samples of the solution were taken for analysis and the remainder was introduced into the cell and attached to the vacuum system. Melting temperatures were determined until a maximum was reached at 30.2° where the mass melted homogeneously. The weight of the cell and homogeneously melting solid was taken and the results computed as follows: weight hydrated base, 2.7681; anhydrous base, 0.8780; moles anhydrous base, 0.003386; moles water, 0.1050; moles base/moles water, 1/31.01.

$(C_4H_9)_4NOH \cdot 4H_2O$.—On withdrawing water from the hydrate described above, the entire mass liquefied and on continued withdrawal of water, a new solid phase separated. This phase had a sharp melting point at 26°. Its composition was determined as follows: wt. hydrated base, 1.1225; anhydrous base, 0.8780; moles anhydrous base, 0.003386; moles water, 0.01358; moles base/moles water, 1/4.01.

$(C_4H_9)_4NOH \cdot 2H_2O$.—On dehydration of the tetrahydrate, another solid appeared which approximated the dihydrate in composition. However, the base is not stable when this hydrate is subjected to the action of a vacuum pump. With the sample used in the preceding experiments, most of the material was lost in the course of pumping, and upon opening the tube the presence of tributylamine was detectable. Accordingly, another sample was prepared and when no perceptible liquid was left in the solid mass, the tube was weighed. The results follow: wt. hydrated base, 1.6301; anhydrous base, 1.4200; moles anhydrous base, 0.00549; moles water, 0.01167; moles anhydrous base/moles water, 1/2.12.

Tetra-*n*-butylammonium Fluoride, $(C_4H_9)_4NF \cdot {}_{18}H_2O$.—A quantity of tetra-*n*-butylammonium fluoride was prepared by titrating a solution of the hydroxide with hydrofluoric acid. After taking samples of the solution for analysis, the remainder was introduced into the cell and the composition of the hydrate determined as in the case of the hydroxide. The homogeneously melting hydrate had a melting point of 37°. The tube was weighed and the composition of the hydrate determined as follows: wt. hydrated fluoride, 8.9582; anhydrous fluoride, 3.9832; moles anhydrous fluoride, 0.01526; moles water, 0.2764; moles fluoride/moles water, 1/18.11. On further dehydration of the octadecahydrate, the whole mass liquefied and there was no evidence of the formation of any other hydrate on continued dehydration down to the pure salt.

Tetraisoamylammonium, Hydroxide, $(C_5H_{11})_4NOH \cdot 32H_2O$.—A solution of this hydroxide was prepared as described above and introduced into a cell of the Erlenmeyer form. The advantage of a container of this type is that the thickness of the liquid layer is small and the surface large and it is, therefore, easier to establish equilibrium than in the case of a narrower tube with a greater depth of liquid. To determine the composition of the hydrate in this case, pressures were observed somewhat above and somewhat below the point at which the entire mass in the tube appeared to be solid, the water content of the cell being determined after each observation. Water was then withdrawn or introduced and the range between the upper and lower pressures gradually narrowed until it approximated the composition of the hydrate. The pressures observed at 20° in millimeters of oil and the mean composition of the system in moles of water per mole of base follow:

Moles of water/base	38.5*	44.3	31.4*	34	32.9
p, mm. of oil	277	274	<228	267	264
Moles of water/base	31.4	32.3*	31.99*	32.01*	
p, mm. of oil	218	266	217	>259	

The pressure readings on the oil manometer may be converted to millimeters of mercury by multiplying by the factor 0.0633.

Not all the pressures as read are precise equilibrium values but observations in any one case were continued long enough to ensure that the pressures corresponded either to the equilibrium of higher or of lower pressure. The upper pressure, which is in the neighborhood of 265 mm., is the vapor pressure of the more dilute solution in equilibrium with the base hydrate, while the lower pressure of approximately 218 mm. is the pressure of the more concentrated solution in equilibrium with the same base hydrate (at 25°). The composition of all the starred values was directly determined by weighing the cell and is, therefore, accurate. The other values were determined by taking account of the amount of water introduced or removed and although sufficiently accurate for the purpose, they are not as precise as the starred values. The data for the last two values are given: wt. of hydrated base, 5.8587, 5.8602; anhydrous base, 2.0717; moles water/moles base, 31.99, 32.01. The hydrate melts homogeneously at 31°.

$(C_5H_{11})_4NOH \cdot 4H_2O$.—On dehydrating the hydrate described above, the entire mass liquefied and upon further dehydration, crystals appeared which were evidently the tetrahydrate and which melted at 57.5°. They were not entirely stable at room temperature under the action of the pump. Assuming that the base decomposes to tertiary amine, olefin and water[2] and that the tertiary amine remains behind when the hydrate decomposes, the composition of the hydrate may be determined by titrating the strong base and weighing the cell and its contents. The correction due to decomposition was of the order of 10%. Following are the results for a typical determination: mmoles. base original sample, 6.659; mmoles. base after

(2) Meyer and Jacobson, "Lehrbuch der organischen Chemie," Vol. I, part 1, Leipzig, 1907, p. 378.

decomposition, by titration, 6.124; mmoles. base decomposed, 0.4568; wt. final product (hydrate and amine), 2.4571; wt. of amine (equivalent to 0.4568 mmoles.), 0.1038; wt. hydrated base, 2.3533; wt. anhydrous base (6.124 mmoles.), 1.9254; wt. water, 0.4279; mmoles. water, 23.75; moles base/moles water, 1/3.88.

Tetra-*n*-amylammonium Hydroxide, $(C_5H_{11})_4NOH \cdot 4H_2O$. —With this base there was found no evidence of the existence of a high hydrate. A solid ultimately was formed whose composition approximated that of the tetrahydrate and which proved unstable under the action of the pump. Making corrections for the amount of the base decomposed, and assuming that the free amine resulting was not lost, the following results were obtained: mmoles. original base, 8.273; mmoles. after decomposition, 7.676; mmoles. of water in final hydrate, 29.5; moles base/moles water, 1/3.9.

Tetramethylammonium Hydroxide, $(CH_3)_4NOH \cdot 5H_2O$. —On concentrating a solution of this base, the first hydrate that appeared was the already known pentahydrate.[3] The results follow: wt. anhydrous base, 0.6402; hydrated base, 1.2590; hydrate water, 0.6188; moles base/moles water, 1/4.9.

Tetra-*n*-propylammonium Hydroxide.—Although the existence of a heptahydrate of this base is reported in the literature,[4] all attempts to obtain a crystalline product with this base failed. In one case, the liquid having a composition closely approximating that of the heptahydrate was left at sub-zero temperature overnight without the appearance of crystals. On further concentrating the solution, the product decomposed rather suddenly at room temperature.

Ethyltri-*n*-butylammonium Hydroxide.—The behavior of a solution of this base resembled that of tetra-*n*-propylammonium hydroxide on concentration. No crystals could be obtained and when the concentration of the solution approximated that of three moles of water per mole of base, decomposition occurred.

Tetra-*n*-butylammonium Oxalate, $[(C_4H_9)_4N]_2C_2O_4 \cdot 38H_2O$.—The salt was prepared by metathesis of silver oxalate and tetrabutylammonium iodide. It was purified by recrystallizing three times from water at 0°. The composition of the hydrate was determined by the vapor pressure method; three determinations gave the following values for the number of moles of water per mole of salt: 37.5, 37.6, 37.9. The hydrate melted between 20 and 25°.

Tetra-*n*-butylammonium Formate, $(C_4H_9)_4NCHO_2 \cdot 33H_2O$.—This salt has a very flat melting point curve with a maximum near 12.5° and 33 moles of water. The composition was also checked by the vapor pressure method which yielded the same value but the difference between the upper and the lower vapor pressures was extremely small.

Tetra-*n*-butylammonium Bromide, $(C_4H_9)_4NBr \cdot 26H_2O$. —The salt was prepared by digesting tetra-*n*-butylammonium iodide with an excess of silver bromide in aqueous solution. After evaporating the solution, the salt was recrystallized from ethyl acetate, melting point 113°. The melting point curve of solutions of this salt is much less flat than that of the formate and has a maximum at 14.5° at a composition corresponding to 26 molecules of water.

(3) Walker and Johnston, *J. Chem. Soc.*, **87**, 958 (1905).
(4) Crichton, *ibid.*, **91**, 1796 (1907).

Other Hydrated Salts.—Rough determinations were made with some other salts. Tetraisoamylammonium formate yielded a product melting at 15–20° with a composition in the neighborhood of 50 moles of water per mole of salt. Tetra-*n*-butylammonium acetate yielded a hydrate melting at 10–15° and containing 60 molecules of water. Tetra-*n*-butylammonium propionate yielded a hydrate melting at 17° and containing 50 molecules of water. Tetra-*n*-butylammonium benzoate yielded a hydrate melting at 3.5° and containing approximately 35 molecules of water. Tetra-*n*-butylammonium nitrate yielded a hydrate melting at 5.8° and containing 27 molecules of water. Tetra-*n*-butylammonium chloride yielded a hydrate melting at 15° and containing 30 molecules of water. Tetra-*n*-butylammonium sulfate and tetra-*n*-butylammonium chromate both yielded hydrates but their approximate composition was not determined.

Tetra-*n*-butylammonium thiocyanate, picrate and cyanide were found to be difficultly soluble in water and yielded no hydrates. Tetra-*n*-propylammonium formate, tetra-*n*-amylammonium formate, tetra-*n*-amylammonium acetate, methyltri-*n*-butylammonium formate and propyltri-*n*-butylammonium formate yielded no hydrates. Tetra-*n*-propylammonium fluoride deposited a solid from fairly concentrated aqueous solution, apparently in anhydrous form.

Summary

The highly soluble salts of tetra-*n*-butylammonium and tetraisoamylammonium ions quite generally form hydrates containing above 15 molecules of water and having relatively high melting points. The following hydrates have been accurately determined: $(n\text{-}C_4H_9)_4NOH \cdot 31H_2O$, m. p. 30.2°; $(n\text{-}C_4H_9)_4NF \cdot 18H_2O$, m. p. 37°; $(i\text{-}C_5H_{11})_4NOH \cdot 32H_2O$, m. p. 31°; $[(n\text{-}C_4H_9)_4N]_2C_2O_4 \cdot 38H_2O$, m. p. 20–25°; $(n\text{-}C_4H_9)_4NCHO_2 \cdot 33H_2O$, m. p. 12.5°; $(n\text{-}C_4H_9)_4NBr \cdot 26H_2O$, m. p. 14.5°.

Other salts yielding high hydrates whose composition and melting points have been less accurately determined are the following: $(i\text{-}C_5H_{11})_4NCO_2 \cdot 50H_2O$, m. p. 15–20°; $(n\text{-}C_4H_9)_4NCH_3CO_2 \cdot 60H_2O$, m. p. 10–15°; $(n\text{-}C_4H_9)_4NC_2H_5CO_2 \cdot 50H_2O$, m. p. 17°; $(n\text{-}C_4H_9)_4NC_6H_5CO_2 \cdot 35H_2O$, m. p. 3.5°; $(n\text{-}C_4H_9)_4NNO_3 \cdot 27H_2O$, m. p. 5.8°; $(n\text{-}C_4H_9)_4NCl \cdot 30H_2O$, m. p. 15°. Tetra-*n*-butylammonium sulfate and tetra-*n*-butylammonium chromate both yield high hydrates but their approximate composition was not determined.

Higher hydrates could not be found in the case of tetramethylammonium hydroxide, tetra-*n*-propylammonium hydroxide, tetra-*n*-amylammonium hydroxide and ethyltri-*n*-butylammonium hydroxide.

Quaternary Ammonium Salts with Anions Containing Triphenylboron

BY D. LEIGH FOWLER* AND CHARLES A. KRAUS

Introduction

In solvents other than liquid ammonia, it is difficult to obtain negative ions with more than one organic group attached to the central atom. Nevertheless, salts of such ions are highly desirable for study in determining the influence of constitutional factors on the properties of electrolytes. Hawes found that sodium and potassium amides react with triphenylboronammine in liquid ammonia to form salts in which the NH_2^- ion is joined to boron by a coördinated linkage.[1] He measured the conductance of these salts in liquid ammonia[2] and found that the ammidotriphenylboron ion has a very low mobility and that its salts are exceptionally highly dissociated, the sodium salt having a dissociation constant of 150×10^{-4}. In solvents other than ammonia, it is necessary that the electrolytes have a high degree of stability, which is not the case with the ammidotriphenylboron salts. It seemed probable, however, that other small ions, particularly the fluoride and the hydroxyl ions, would coördinate with triphenylboron and that the resulting salts would be stable. It is well known that the lower alkyl boranes are absorbed by sodium or potassium hydroxide.

The general procedure in preparing the desired salts was to treat the quaternary ammonium fluoride or hydroxide with triphenylboronammine in alcohol solution. The ammonia is replaced by the fluoride or the hydroxyl ion and the salts are recovered from the solvent by crystallization.

Experimental

Tetramethylammonium Triphenylborofluoride, $(CH_3)_4NF \cdot B(C_6H_5)_3$.—The triphenylboronammine used was a stock sample which had been prepared in this Laboratory. Its preparation has been described by Hawes.[1] Tetramethylammonium hydroxide was prepared from the bromide by means of freshly precipitated silver oxide and the resulting base was titrated with hydrogen fluoride after separating from the solid material. The fluoride is very soluble in water but it may be obtained in anhydrous form by concentrating the aqueous solution and thereafter gradually heating to 115° while exhausting the system with a pump. The solid which is formed under these conditions reaches constant weight and is evidently anhydrous since a small sample of the salt was found to decompose at 180° in accordance with the earlier observations of Lawson and Collie.[3]

Equivalent quantities of tetramethylammonium fluoride and triphenylboronammine are introduced into alcohol, in which both are soluble, and the solution is refluxed for several hours during which time ammonia is evolved and crystals are formed. After cooling, the crystals are separated from the supernatant liquid and recrystallized from alcohol; melting point 175–177°.

The compound was analyzed for boron by the method of Booth.[4] The sample was warmed with a few cubic centimeters of concentrated sulfuric acid in a distilling flask. Thereafter, approximately 50 cc. of carefully dried methyl alcohol was added and the mixture was warmed for a few minutes to permit the reaction between the alcohol and the boric acid to complete itself. Thereafter, successive fractions of about 10 cc. of the methyl alcohol were distilled through a fractionating column into a suitable receiver until no further boron was carried over. Two or three fractions were generally sufficient. The boron was determined after hydrolysis of the methyl borate by titration with sodium hydroxide in the presence of mannitol. Sample, 0.2192, 0.1870; cc. 0.04413 *N* sodium hydroxide, 14.86, 12.62; % B found, 3.237, 3.222; calcd. for $C_{22}H_{27}BNF$, 3.229. The fluorine content of the compound was determined by the method of Allen and Furman[5] in which triphenyltin chloride is used as the precipitant. In order to break the fluorine–boron linkage, the compound was first hydrolyzed with sodium hydroxide solution, in which process it dissolved completely. However, when the solution was neutralized with hydrochloric acid, a precipitate appeared which was removed by filtration. The neutralized solution was then treated with triphenyltin chloride according to the directions of Allen and Furman. Sample, 0.3144, 0.3037; triphenyltin fluoride, 0.3445, 0.3398; % F found, 5.645, 5.764; calcd. for $C_{22}H_{27}BNF$, 5.671.

Tetrabutylammonium Triphenylborofluoride, $(C_4H_9)_4NF \cdot B(C_6H_5)_3$.—Tetrabutylammonium fluoride was prepared from tetrabutylammonium iodide in the same manner as was tetramethylammonium fluoride from the corresponding bromide. The anhydrous salt, together with triphenylboronammine, was dissolved in alcohol where reaction took place readily with the formation of crystals of the desired compound. After separating, these were recrystallized from ethyl alcohol and were found to melt at 161–162°. The compound was found to be stable in air.

Analyses were carried out as in the case of the tetramethylammonium compound. B: sample, 0.1932, 0.2101; cc. 0.04413 *N* sodium hydroxide, 8.68, 9.76; % B found,

2.145, 2.218; calcd. for $C_{34}H_{51}BNF$, 2.150. F: sample, 0.3133, 0.3171; triphenyltin fluoride, 0.2275, 0.2285; % F found, 3.741, 3.712; calcd. for $C_{34}H_{51}BNF$, 3.776.

Tetramethylammonium Triphenylborohydroxide Monoalcoholate, $(CH_3)_4NOH\cdot B(C_6H_5)_3\cdot C_2H_5OH$.—Tetramethylammonium hydroxide was prepared by treating an aqueous solution of tetramethylammonium bromide with moist silver oxide. After separating from the silver bromide and excess silver oxide, the solution was concentrated. The residual water was removed by pumping through a phosphorus pentoxide tube while at the same time placing the tube containing the base in a bath whose temperature was gradually raised to 100°. A small sample of the final product was found to decompose at 125–130°, which corresponds to the range given by Walker and Johnston[6] for the monohydrate. All attempts to remove the last molecule of water were unsuccessful. It should be stated that all operations described above were carried out under strict exclusion of carbon dioxide. The reaction between the monohydrate of tetramethylammonium hydroxide and triphenylboronammine was carried out in ethyl alcohol, as in the case of the fluoride. The product formed immediately on warming the solution. After separating from the alcohol, it was recrystallized from the same solvent. When heated to 230°, it puffed up slightly but did not melt until the temperature reached 359–360°, where it decomposed upon melting. This compound was not analyzed directly but was quantitatively converted to the corresponding monohydrate which was analyzed as will be described in the following section.

Tetramethylammonium Triphenylborohydroxide Monohydrate, $(CH_3)_4NOH\cdot B(C_6H_5)_3\cdot H_2O$.—When the alcoholate described in the preceding paragraph was treated with water for a few minutes and immediately pumped dry, a substance resulted which melted at 185–187°. When this, in turn, was dissolved in absolute alcohol and dried, the compound again melted at 360°. Evidently the alcoholate and the hydrate may be converted one to the other by treatment with the appropriate solvent. That the conversion is quantitative is shown by the following figures: wt. original alcoholate, 0.0937, 0.0910; wt. hydrate, 0.0870, 0.0845; observed loss in wt., 0.0067, 0.0065; calcd. loss, 0.0069, 0.0067. Wt. original hydrate, 0.2504; wt. alcoholate, 0.2705; observed gain in wt., 0.0201; calcd. gain, 0.0200.

Samples of the hydrated compound were analyzed for boron as described above. The results were: sample, 0.1915, 0.2182; cc. sodium hydroxide (0.04413 *N*), 12.30, (0.0657 *N*), 9.32; % B found, 3.067, 3.036; calcd. for $C_{22}H_{30}BNO_2$, 3.082.

In order to determine the amount of the base present in the compound, a known quantity of dilute hydrochloric acid, slightly in excess of that required to neutralize the base, was added to the salt and the resulting solution was refluxed for a couple of hours. At the end of this process, the salt had broken down and dissolved completely in the hot acid solution. Upon cooling, some solid precipitated, which was filtered off, after which the solution was titrated with standard alkali. Sample, 0.2501, 0.3279; cc. hydrochloric acid (0.0577 *N*), 12.38, (0.1084 *N*), 8.84; % OH found, 4.858, 4.970; calcd. for $C_{22}H_{30}BNO_2$, 4.845.

(6) Walker and Johnston, *J. Chem. Soc.*, **87**, 958 (1905).

Tetrabutylammonium Triphenylborohydroxide, $(C_4H_9)_4NOH\cdot B(C_6H_5)_3$.—This compound was prepared by two methods; the first was similar to that used in the case of the tetramethylammonium salts. This method, however, is disadvantageous because of the difficulty experienced in dehydrating tetrabutylammonium hydroxide. Accordingly, the base was prepared in absolute alcohol solution by allowing equivalent quantities of tetra-*n*-butylammonium chloride and potassium hydroxide to react. After the potassium chloride had been separated by filtration, an equivalent amount of the triphenylboronammine was added. The product, after recrystallization from alcohol, was found to melt at 143.5–145.5°. This compound, like those previously described, was perfectly stable in the atmosphere.

Analyses were carried out as in the case of the tetramethylammonium salt. B: sample, 0.1980, 0.1476; cc. 0.04413 *N* sodium hydroxide, 9.01, 6.88; % B found, 2.173, 2.226; calcd. for $C_{24}H_{52}BNO$, 2.159. Base: sample, 0.2205, 0.2916; cc. 0.0577 *N* hydrochloric acid, 7.49, 10.05; % OH found, 3.333, 3.382; calcd. for $C_{34}H_{52}BNO$, 3.393.

Some Other Salts.—In general, it is only the small ions, such as NH_2^-, OH^- and F^-, which form stable complexes with triphenylboron. Neither tetramethylammonium chloride nor tetramethylammonium bromide forms complexes with triphenylboron. Alcohol solutions of these salts brought together with amminotriphenylboron show no reaction and the original materials are recovered from solution unchanged.

Potassium cyanide reacts with amminotriphenylboron in alcohol solution. On addition of petroleum ether, hair-like crystals are precipitated which decompose in the neighborhood of 300°. They react vigorously with water. Sodium phenolate shows little reaction with amminotriphenylboron in liquid ammonia solution. Most of the reactants are recoverable. Sodium benzhydrolate reacts with amminotriphenylboron in liquid ammonia. The white solid which results upon evaporation of the solvent oxidizes slowly in air and is unstable in organic solvents at higher temperatures. Sodium triphenylcarbinolate reacts with amminotriphenylboron in liquid ammonia. The product may be recrystallized from benzene and it seems to be stable in air and in organic solvents at ordinary temperatures. The potassium salt exhibits similar properties. Sodium phenylacetylate reacts with amminotriphenylboron in liquid ammonia with the formation of a white solid which shows low stability when dissolved in organic solvents under ordinary conditions; the solutions develop color.

Summary

On treating amminotriphenylboron with quaternary ammonium hydroxides or fluorides, complex ions are formed in which the hydroxyl or the fluoride ion is coördinated with triphenylboron. The salts are stable in air. The following salts have been prepared: $(CH_3)_4NF\cdot B(C_6H_5)_3$, $(n\text{-}C_4H_9)_4NF\cdot B(C_6H_5)_3$, $(CH_3)_4NOH\cdot B(C_6H_5)_3\cdot C_2H_5OH$, $(CH_3)_4NOH\cdot B(C_6H_5)_3\cdot H_2O$, $(n\text{-}C_4H_9)_4NOH\cdot B(C_6H_5)_3$.

Alkylation of Benzene with Alcohols, Boron Fluoride and Assistants[1]

BY N. F. TOUSSAINT AND G. F. HENNION

Introduction

The alkylation of benzene with monohydric alcohols has received relatively little attention. The reactions proceed only in the presence of strong dehydrating agents such as zinc chloride,[2] sulfuric acid,[3] aluminum chloride,[4] and boron fluoride.[5]

Disadvantages of the reported procedures are a frequent need for autoclave or sealed tube methods and/or excessive amounts of condensing agent; products are often impure and yields unsatisfactory. Furthermore, these methods have not been applied to the higher alcohols now available from the hydrogenolysis of fats.

Because long-chain alkylbenzenes have possible utility in the field of detergents and wetting agents the authors have reinvestigated alcohol–benzene reactions with boron fluoride.[5] It was desired particularly to apply the method to various primary alcohols and to improve yields of monoalkyl products. It was soon observed that boron fluoride is assisted remarkably in these reactions by various acidic dehydrating agents as phosphorus pentoxide, sulfuric acid and benzenesulfonic acid. The effect of these secondary condensing agents is particularly marked with the primary alcohols. Data for a number of experiments are given in Table I.

Alkylation apparently occurs without carbon skeleton rearrangement. However, only secondary and tertiary alkyl benzenes have been made in this manner. While the reaction mechanism is in doubt, the products are those which would be formed by dehydration of the alcohol to olefin and addition of benzene according to Markownikoff's rule. The dialkyl derivatives are the para compounds.[5] Methylation and ethylation were unsuccessful.

Physical properties for the compounds are given in Table II. Analyses for octyl- and dodecylbenzene are given in Table III.

Procedure

Reagents.—Boron fluoride was purchased from the Harshaw Chemical Co. *n*-Octyl and *n*-dodecyl alcohols were furnished by the du Pont Co. Other alcohols were from Eastman Kodak Co. Benzenesulfonic acid was prepared as previously described.[6]

***s*-Butylbenzene (Expt. 10).**—Two moles (156 g.) of benzene and 0.5 mole (37 g.) of *n*-butyl alcohol were placed in a one-liter three-necked flask equipped with a reflux condenser and motor-driven mercury-sealed stirrer. The solution was cooled in a bath of cold water and boron fluoride admitted, with stirring, until 0.5 mole (34 g.) had been absorbed. Then 0.125 mole (17.7 g.) of phosphorus pentoxide was added quickly. The mixture was warmed *slowly*, with stirring, to reflux temperature and soon became homogeneous. On continued heating the solution became turbid and stratified into two layers when agitation was discontinued. Further heating caused gradual diminution in the volume of the lower layer. After heating for three hours the layers were separated and the upper one washed, neutralized, dried and fractionally distilled. There was obtained 50 g. (74.5%) of *s*-butylbenzene and 3 g. (6.3%) of *p*-di-*s*-butylbenzene.

***s*-Amylbenzene (Expt. 32).**—Sulfuric acid (25 g., 94% acid) was added to a solution of *n*-amyl alcohol (44 g., 0.5 mole) in benzene (312 g., 4.0 moles) previously saturated with boron fluoride (34 g., 0.50 mole). After heating for five and one-half hours the upper layer was separated and treated as above. Distillation gave 59.2 g. (80%) of *s*-amylbenzene.

Miscellaneous.—All experiments with phosphorus pentoxide gave homogeneous solutions after brief heating. Upon further reaction these separated into two layers, except in cases where dodecyl alcohol was used. Dodecylbenzene was distilled, *in vacuo*, from the crude reaction mixture, then washed, dried and redistilled.

In the sulfuric acid experiments with *n*-butyl alcohol (Expts. 25–29) three layers appeared after heating. The lowest layer was removed in each case and water added to the remaining layers. The hydrocarbon was then removed and treated in the conventional manner.

A condition of temporary homogeneity was observed only in experiments with phosphorus pentoxide. With sulfuric acid and benzenesulfonic acid separate phases persisted throughout the reaction periods.

Frequently dodecylbenzene gave troublesome emulsions when first washed with water. The emulsions were broken by addition of ether.

In the experiments with benzenesulfonic acid it was

found possible to recover boron fluoride, as the dihydrate, from the acid layers by addition of the calculated amount of water and distillation.[6] Boron fluoride was thus recovered as $BF_3 \cdot 2H_2O$, b. p. 91° at 25 mm., from Expt. 35 in 95% yield.

Further work is in progress.

Summary

1. Certain acidic dehydrating agents assist boron fluoride as a condensing agent in the alkylation of benzene with primary alcohols.

2. Data are given for thirty-eight experiments, showing the influence of conditions upon yields of products.

3. Normal and secondary alcohols give secondary alkylbenzenes. Iso and tertiary butyl alcohol gave *t*-butylbenzene. Dialkylation proceeds mainly para.

4. Alcohols as high as dodecyl have been used successfully.

The Chlorination and the Structure of Acetylketene

BY CHARLES D. HURD AND J. L. ABERNETHY

The recent paper[1] by Boese on "diketene" mentions that this substance "rapidly absorbs chlorine at low temperatures to yield γ-chloroacetoacetyl chloride" and states that it is "stable only at low temperatures and cannot be purified by distillation." Since no details were listed, this note is submitted in view of our similar work on the same compound.

Chlorine was passed into an ice-cold, vigorously-stirred solution of 7 cc. of acetylketene in 20 cc. of carbon tetrachloride until there was a 6-g. increase in weight. The mixture was slightly yellow in color. Distillation of the solvent with a steam-bath left an orange-colored residue of chloroacetoacetyl chloride, $ClCH_2COCH_2COCl$, which was vacuum distilled. Extensive decomposition occurred, but 1.5 cc. of the acid chloride was obtained at 93–96° (8 mm.), or 117–119° (17 mm.). The distillate was orange colored and fumed in moist air. A black tar remained in the distilling flask. These physical constants were obtained for the chloroacetoacetyl chloride: d^{20}_4 1.4397; $n^{20}D$ 1.4860; mol. rotation, calcd. 30.77, found 30.89.

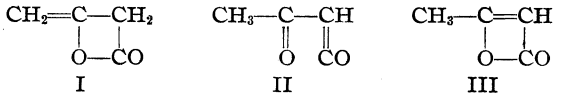
Anal. Calcd. for $C_4H_4O_2Cl_2$: Cl, 45.7. Found: Cl, 45.2, 45.1.

Chloroacetoacetyl chloride was converted to ethyl chloroacetoacetate, $ClCH_2COCH_2COOC_2H_5$, as follows. Five cc. of acetylketene in 30 cc. of carbon tetrachloride was treated with chlorine until 4.5 g. had been absorbed. Then, without distillation, the solution was poured slowly into an excess of absolute alcohol at 0°. On distillation, 6 cc. of the ethyl ester was collected at 117–119° (17 mm.). This ester has been made in other ways by several investigators.[2]

Chloroacetoacetanilide, $ClCH_2COCH_2CONHC_6H_5$, was obtained by mixing pure chloroacetoacetyl chloride with an equivalent amount of aniline in benzene. The aniline hydrochloride was removed by washing with water. Then the benzene was distilled off and the resulting anilide was crystallized from ether. The melting point was 140–141°.

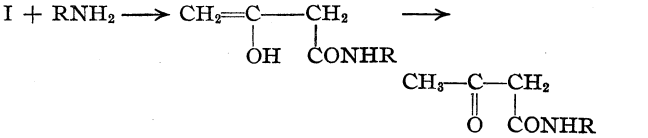
Anal. Calcd. for $C_{10}H_{10}O_2NCl$: N, 6.61. Found: N, 6.75, 6.71.

Boese adopts vinylaceto-β-lactone (I) as a preferred structure for ketene dimer. With



I II III

(I) addition reactions with alcohols or amines may be explained by assuming reaction at the lactone position, followed by tautomerization



Hydrogenation to butyro-β-lactone must involve addition at the double bond. Neither of these reactions are critical for purposes of structure

(1) Boese, *Ind. Eng. Chem.*, **32**, 20 (1940).

(2) Lespieau, *Compt. rend.*, **138**, 422 (1904); Picha, Doht and Weisl, *Monatsh.*, **27**, 1247 (1906); Schlotterbeck, *Ber.*, **42**, 2570 (1909); Alexandrow, *ibid.*, **46**, 1022 (1913).

proof because they may be explained also from acetylketene (II) or its resonance isomer crotono-β-lactone (III).

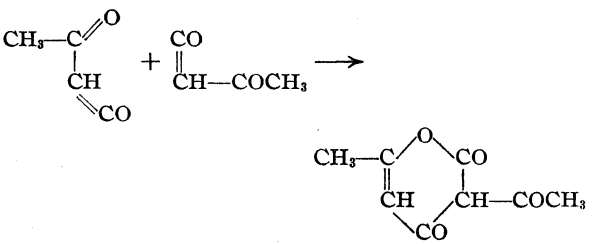
When the dimer is halogenated, chlorine presumably adds to the double bond. If structure II is selected then a subsequent rearrangement is involved to explain the formation of chloroacetoacetyl chloride which is actually produced. Since ethyl acetobromoacetate, $CH_3COCHBrCOOC_2H_5$, is known[3] to rearrange to ethyl bromoacetoacetate, $CH_2BrCOCH_2COOC_2H_5$, such a rearrangement for the corresponding acid chloride also seems plausible. Indeed it may be assumed that the COCl or COBr groups promote a more rapid rearrangement than the $COOC_2H_5$ group.

Formula I, in the halogenation reaction, also calls for rearrangement because  would represent the initial addition product at the double bond. Less readjustment is necessary than with II, however, because chlorine alone is involved, instead of hydrogen and chlorine. This seems to be the strongest evidence in favor of I. Unfortunately for its case, halogenation evidence is unreliable so frequently that one hesitates to trust it unless it is supported by other and better evidence.

An example in point is furfuryl chloride. By rules of metathesis, one would expect it to yield furylacetonitrile in its reaction with sodium cyanide. Instead, the substance obtained[4] is 5-methyl-2-furonitrile. Again, isobutylene and chlorine[5] yield chiefly methallyl chloride instead of isobutylene dichloride. Many other instances of irregularity with halogens might be cited.

The recently determined[6] value for the parachor of ketene dimer is more favorable to the equilibrium mixture of II $\rightleftarrows$ III than to I, II or III taken individually. The observed parachor at 25° is 188.0. The calculated parachors for I, II and III, respectively, are 182.4, 197.2, and 182.4.

Polymerization of ketene dimer to dehydroacetic acid (ketene tetramer) is far more simply explained from II than from I. From II, it is but an addition of the Diels–Alder type



From I, it is necessary to assume an initial condensation of the Claisen type, followed by several tautomeric shifts, and finally ring-closure.

One of the most powerful tools for structural proof is ozonolysis. By this approach, compound I should give rise to malonic acid, II to pyruvic aldehyde or acetic acid, III to pyruvic aldehyde or acetic acid. In the actual ozonolysis,[7] ketene dimer gave rise to pyruvic aldehyde and acetic acid. Malonic acid was sought for but not found.

This accumulation of critical evidence favors II and III as the correct structure for ketene dimer, and discredits formula I.

Summary

Evidence is reviewed for the structure of ketene dimer. An equilibrium mixture of the resonance isomers acetylketene and crotono-β-lactone best fits the evidence. Vinylaceto-β-lactone, which has been proposed recently, fails to explain the behavior on ozonolysis. Also, this structure does not satisfy the parachor, nor does it lend itself to a simple explanation of the polymerization to dehydroacetic acid.

Chlorine and acetylketene give rise to chloroacetoacetyl chloride. The latter reacts with alcohol and aniline to yield the ester and anilide, respectively.

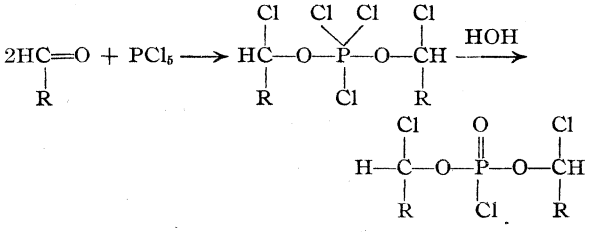
The Action of Phosphorus Pentachloride upon *aldehydo*-Galactose Pentaacetate. The 1,1-Dichloride of *aldehydo*-Galactose Pentaacetate

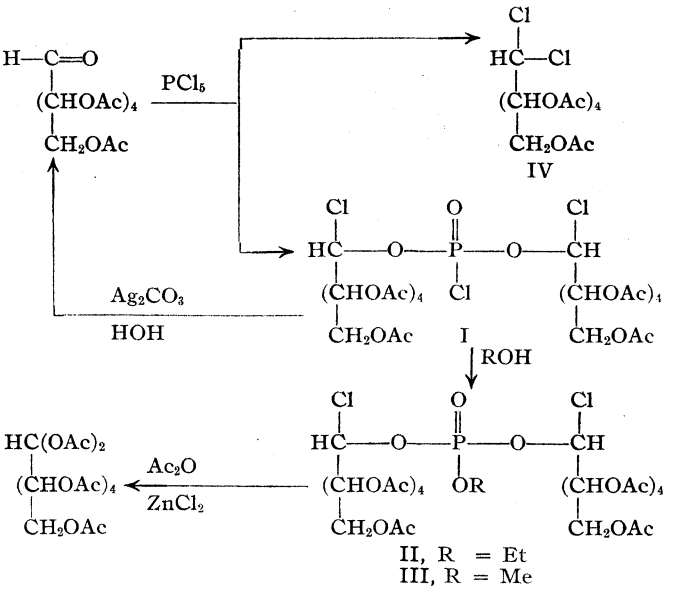
BY M. L. WOLFROM AND D. I. WEISBLAT

The action of phosphorus pentachloride upon aldehydes to produce the 1,1-dichlorides[1] is a well-known reaction. We were interested in its extension to an *aldehydo*-sugar acetate and were successful in obtaining a crystalline product in the galactose structure. The product, 1,1-dichloro-*aldehydo*-*d*-galactose pentaacetate (IV) is the first substance of this type in the sugar series. It is a very stable substance and reduces Fehling solution only on prolonged boiling. It does not reduce neutral copper acetate solution on boiling. We have found that the reduction of neutral copper acetate solution is a general property of *aldehydo*-sugar acetates and also of the very reactive acetyl chloride carbonyl addition compound of *aldehydo*-galactose pentaacetate.[2] The behavior of a number of significant sugar structures toward this reagent is tabulated in Table I. We believe that this lack of reduction toward neutral copper acetate confirms our assigned structure for substance IV.

If the reaction of phosphorus pentachloride with *aldehydo*-galactose pentaacetate is carried out in ether solution, an insoluble reaction product separates which is assigned structure I. This may be considered as a carbonyl addition compound of phosphorus pentachloride with two moles of the aldehyde in which two of the chlorine atoms attached to phosphorus have been hydrolyzed.



The structure of substance I, designated di-(1-chloro-*aldehydo*-*d*-galactose pentaacetate) chlorophosphate, is made probable by its analysis, its hydrolysis with water and silver carbonate to *aldehydo*-galactose pentaacetate and by the fact that it contains one reactive chlorine extremely readily replaceable by an alkoxyl group. On recrystallization from ethanol, I yields the substance II, designated di-(1-chloro-*aldehydo*-*d*-galactose pentaacetate) ethyl phosphate. II exhibits the predicted molecular weight and on acetylation with acetic anhydride and zinc chloride, yields *aldehydo*-galactose heptaacetate. The



compound III, analogous to II but containing a methoxyl group, also was synthesized.

It is probable that the substance I represents a general structure for the initial reaction stages of aldehydes with phosphorus pentachloride. In the cyclic sugar structures, Freudenberg and Braun[3] have reported a crystalline reaction product of 2,3,6-trimethylglucose with phosphorus pentachloride which on analysis proved to be $(C_6H_8O_3(OCH_3)_3)_2PCl_3$. Helferich and du Mont[4] have obtained a crystalline tri-(β-*d*-glucopyranose tetraacetate)-6-phosphate by the reaction of phosphorus oxychloride with β-*d*-glucose 1,2,3,4-tetraacetate.

Experimental

Di-(1-chloro-*aldehydo*-*d*-galactose pentaacetate) Chlorophosphate (I).—*aldehydo*-*d*-Galactose pentaacetate[5] (10 g.,

TABLE I

REDUCTION OF *d*-GALACTOSE DERIVATIVES BY COPPER ACETATE[a]

Substance	Time at b. p., sec.[b]	Reduction
d-Galactose	0	+
β-*d*-Galactopyranose pentaacetate	120	−
α-*d*-Galactopyranose pentaacetate	120	−
aldehydo-*d*-Galactose pentaacetate	15	+
aldehydo-*d*-Galactose isopropyl hemiacetal	45	+
d-Galactose heptaacetate	50	+
1-Chloro-*d*-galactose hexaacetate	60	+
1-Methoxy-*d*-galactose hexaacetate	90	+
1-Chloro-1-ethoxy-*d*-galactose pentaacetate	30	+
d-Galactopyranose tetraacetate	90	+
1,1-Dichloro-*aldehydo*-*d*-galactose pentaacetate[c]	120	−
Di-(1-chloro-*aldehydo*-*d*-galactose pentaacetate) chlorophosphate[c]	120	−

[a] One mole equivalent of 0.05 g. *d*-galactose in 5 cc. of saturated aqueous cupric acetate solution. [b] In the case of a positive reduction, the time of boiling recorded is that at which visible reduction was initiated. *d*-Galactose gave a visible reduction before the boiling point was attained. [c] No reduction also on addition of ethanol.

1 mol) and powdered phosphorus pentachloride (5 g., 0.9 mol) were suspended in 200 cc. of anhydrous ether and refluxed for twelve hours in an all-glass apparatus equipped with a drying tube. The product began to separate from the reaction mixture within the first hour of reflux. At the end of this period of refluxing an equal volume of petroleum ether (b. p. 65–110°) was added and the mixture kept overnight at icebox temperature. The product was removed by filtration and washed three to four times with ether–petroleum ether (1:1); yield 4.5–6 g., m. p. 145–155°. The product was immediately recrystallized from about 80 parts of hot ethyl acetate; yield 3.5 g., m. p. 190° (dec.), spec. rot. −20° (26°; *c*, 2.2; $CHCl_3$).[6]

The substance was very soluble in chloroform, moderately so in acetone and practically insoluble in ether, petroleum ether and cold water. It showed no reduction toward copper acetate (see Table I) but slowly reduced boiling Fehling solution. It gave a positive Schiff test very slowly on standing. The material is very unstable unless of maximum purity, in which condition a sample in a desiccator over soda lime has shown no decomposition over a period of one year.

The substance was also formed by shaking the reaction mixture at room temperature over a period of several days. No appreciable difference was noted on starting with the aldehydrol form of *aldehydo*-*d*-galactose pentaacetate.

By working up the mother liquor material from the ethyl acetate recrystallizations by means of alcohol–water, a very small amount of 1,1-dichloro-*aldehydo*-*d*-galactose pentaacetate (see below) could be obtained in very high purity. No conditions could be found for converting compound I into the dichloride (IV).

Anal. Calcd. for $C_{32}H_{42}O_{23}Cl_3P$: Cl, 11.41; P, 3.32; saponification value (15 equivalents), 16.1 cc. 0.1 *N* NaOH per 100 mg. Found: Cl, 11.3; P, 3.34; saponification value (Kunz and Hudson procedure[7]), 16.0 cc.

Hydrolysis of Di-(1-chloro-*aldehydo*-*d*-galactose pentaacetate) Chlorophosphate (I) to *aldehydo*-*d*-Galactose Pentaacetate.—I (2 g.) was suspended in 100 cc. of toluene and 4 g. of freshly prepared silver carbonate and 0.5 cc. of water added. The mixture was refluxed for twenty-one hours with vigorous mechanical stirring. The silver salts were then removed by filtration and crystalline material was obtained by solvent removal under reduced pressure. The crystalline material was recrystallized from absolute ethanol and 0.3 g. of pure *aldehydo*-*d*-galactose pentaacetate ethyl hemiacetal was obtained which was identified by melting point (133–135°), mixed melting point and optical behavior in chloroform solution.[8]

Di-(1-chloro-*aldehydo*-*d*-galactose pentaacetate) Ethyl Phosphate (II).—When di-(1-chloro-*aldehydo*-*d*-galactose pentaacetate) chlorophosphate (I) was recrystallized from 75 parts of boiling absolute ethanol, hydrogen chloride was evolved and on cooling, filtering, and concentrating the mother liquors, a practically quantitative yield of the di-(1-chloro-*aldehydo*-*d*-galactose pentaacetate) ethyl phosphate (II) was obtained; m. p. 156–158°, spec. rot. −24° (21°; *c*, 1.3; $CHCl_3$).

The product was similar to substance I in solubility and behavior toward copper acetate, Fehling solution and the Schiff reagent.

Anal. Calcd. for $C_{32}H_{44}O_{23}(OC_2H_5)Cl_2P$: Cl, 7.53; P, 3.29; OC_2H_5, 4.79; saponification value (15 equivalents), 15.9 cc. of 0.1 *N* NaOH per 100 mg.; mol. wt., 941.6. Found: Cl, 7.60; P, 3.30; OC_2H_5, 5.0; saponification value,[7] 15.9 cc.; mol. wt. (Rast), 950.

Conversion of Di-(1-chloro-*aldehydo*-*d*-galactose pentaacetate) Ethyl Phosphate (II) to *aldehydo*-*d*-Galactose Heptaacetate.—II (1 g.) was dissolved in a solution of 0.3 g. of freshly fused zinc chloride in 10 cc. of acetic anhydride and the solution heated for one hour at 98°. The black solution was poured on a mixture of sodium bicarbonate and crushed ice. This mixture was extracted with chloroform and the extract washed with an aqueous solution of sodium bicarbonate and finally with water. The dark sirup obtained on solvent removal of the dried (decolorizing charcoal) extract was dissolved in benzene and petroleum ether added to incipient opalescence. After standing overnight at icebox temperature the supernatant liquid was removed by decantation and the separated sirup was crystallized from 50% ethanol; yield 0.32 g., m. p. 95°. Pure material was obtained on recrystallization from ethanol and from methanol; yield 0.10 g., m. p. 100–102° (mixed m. p. unchanged), spec. rot. +10° (20°; *c*, 2, abs. EtOH). Micheel and co-workers[9] report for *aldehydo*-*d*-galactose heptaacetate m. p. 103°, spec. rot. +10° (EtOH).

Di-(1-chloro-*aldehydo*-*d*-galactose Pentaacetate) Methyl Phosphate (III).—This substance was prepared according

(6) All specific rotations are recorded to the D-line of sodium light; 26° is the temperature; *c* is the concentration in grams per 100 cc. of solution.

(7) A. Kunz and C. S. Hudson, THIS JOURNAL, **48**, 1982 (1926).

(8) M. L. Wolfrom, *ibid.*, **53**, 2275 (1931).

(9) F. Micheel, H. Ruhkopf and F. Suckfüll, *Ber.*, **68**, 1523 (1935).

to the procedure described for the corresponding ethyl compound (II) except that 150 parts of methanol was used in place of the ethanol. A good yield was obtained; m. p. 187–188° (dec.), spec. rot. −19° (30°; *c*, 4.2; $CHCl_3$). The substance crystallized in rod-shaped prisms and showed solubilities and behavior similar to II.

Anal. Calcd. for $C_{32}H_{44}O_{23}(OCH_3)Cl_2P$: OCH_3, 3.35. Found: OCH_3, 3.97.

1,1-Dichloro-*aldehydo-d*-galactose Pentaacetate (IV).—*aldehydo-d*-Galactose pentaacetate (10 g., 1 mol) was dissolved in 100 cc. of pure benzene, 15 g. of Drierite (anhydrous calcium sulfate) added and the whole refluxed in an all-glass apparatus equipped with a drying tube. Powdered phosphorus pentachloride (6.8 g., 1.3 mol) was introduced quickly and the reflux maintained for twelve hours, whereupon the pale yellow solution was filtered and the filtrate washed with ice water and with an aqueous solution of sodium bicarbonate until halogen free (eight to twelve washings). Solvent removal from the dried (decolorizing charcoal) solution left 3 to 5 g. of a pale yellow sirup. This sirup was dissolved in the minimum quantity of hot ethanol and was crystallized on the addition of an equal volume of water. Pure material was obtained on further recrystallization from 80% ethanol; yield 0.8–1.6 g. of m. p. 148–150°; spec. rot. +11° (20°; *c*, 3.2; $CHCl_3$).

The substance was soluble in the common solvents except petroleum ether and cold water. It showed no reduction toward copper acetate (see Table I) and reduced Fehling solution only on long boiling. It gave a positive Schiff test very slowly on standing.

It was found that a reflux period less than specified above (twelve hours) yielded compound I while a longer period yielded only sirups which could not be crystallized and which readily decomposed.

Anal. Calcd. for $C_6H_7O_5(CH_3CO)_5Cl_2$: C, 43.2; H, 4.98; Cl, 15.9. Found: C, 43.3; H, 5.07; Cl, 15.6.

We are indebted to Mr. John Walker (W. P. A. Project 18062) for assistance rendered in the analytical determinations. We also acknowledge the general assistance of Mr. Irving Auerbach (N. Y. A. Project O. S. U. 167).

Summary

1. The action of phosphorus pentachloride upon *aldehydo-d*-galactose pentaacetate in dry benzene produces a crystalline substance (IV) which is shown to be 1,1-dichloro-*aldehydo-d*-galactose pentaacetate.

2. The action of phosphorus pentachloride upon *aldehydo-d*-galactose pentaacetate in ether leads to the isolation of a crystalline substance (I) designated di-(1-chloro-*aldehydo-d*-galactose pentaacetate) chlorophosphate.

3. From I is obtained di-(1-chloro-*aldehydo-d*-galactose pentaacetate) ethyl (and methyl) phosphate, II, and III.

4. The structure assigned to I is made probable by its hydrolysis to *aldehydo-d*-galactose pentaacetate and by its reaction with ethanol to form II, from which *aldehydo-d*-galactose heptaacetate is obtained on acetylation.

Crystalline Phenylurethans (Carbanilates) of Sugar Glycosides

BY M. L. WOLFROM AND D. E. PLETCHER

A well-established procedure in organic chemistry is the characterization of carbinols as N-aryl urethans prepared by the reaction of N-aryl isocyanates with the carbinol. Maquenne and Goodwin[1] investigated the extension of this reaction, using phenyl isocyanate, to a number of unsubstituted sugars but obtained only amorphous powders. Jolles and Botrini,[2] likewise employing phenyl isocyanate, obtained as amorphous powders the phenylurethans or carbanilates of several naturally occurring glycosides. Crystalline fully substituted carbanilates of some of the sugar alcohols have been reported.[1,3]

We have now been successful in obtaining in crystalline form the carbanilates of four of the methyl glycosides of the sugars, in which derivatives all of the free hydroxyls have been brought into reaction. These substances melt with decomposition at high temperatures and exhibit correspondingly low solubilities. Under certain conditions they show a pronounced tendency to separate as gels and are in general rather difficult to manipulate.

These polyurethans or polycarbanilates were not sufficiently soluble in chloroform for satisfactory polarizations. Rotations are recorded in acetone solution for all except β-methyl-*d*-glucoside tetracarbanilate, for which pyridine was found to be the only suitable polarization sol-

(1) L. Maquenne and W. Goodwin, *Bull. soc. chim.*, [3] **31**, 430 (1904).

(2) E. Jolles and M. Botrini, *Gazz. chim. ital.*, **65**, 1217 (1935).

(3) H. Tessmer, *Ber.*, **18**, 968 (1885).

vent. It is of interest to note that the tetracarbanilate of α-methyl-*d*-mannoside (+ 79°, water) exhibits a specific rotation in acetone solution of eighteen degrees to the left. Such a reversal of rotation had been noted by Jolles and Botrini[2] for the amorphous tetracarbanilates of arbutin and esculin in pyridine solution.

Crystalline carbanilates and thionocarbanilates on carbon one of glucose and other sugars have been synthesized through the Fischer[4] procedure of treating acetobromosugars with silver cyanate or silver thiocyanate and subsequent treatment with an alcohol.[5]

When the work herein reported was practically completed, we were pleased to note the publication of Salmon and Powell.[6] These workers found that phenyl isocyanate formed readily crystallizable, easily purified, derivatives with two partially substituted glucose structures in which only one or two hydroxyl groups remained free and which failed to form crystalline acetates or tosylates (*p*-toluenesulfonates). In fact, they were able to crystallize 5,6-dimethyl-monoacetoneglucose only by seeding with crystals obtained by the hydrolysis of the corresponding urethan (carbanilate). The sodium methylate hydrolysis procedure of Salmon and Powell was applied to one of our derivatives and the parent glycoside was regenerated. We did not find any of the N,N-diphenylallophanate derivatives mentioned by these workers when pyridine was used as a reaction catalyst.

It would appear that the carbanilates (phenylurethans) are worthy of further consideration by investigators in the carbohydrate field, especially when derivatives are desired of structures containing only one or two free hydroxyl groups.

Experimental

β-Methyl-*d*-glucoside Tetracarbanilate.—β-Methyl-*d*-glucoside (5.0 g., 1 mol, previously dried over phosphorus pentoxide in a vacuum desiccator) was dissolved by heating in 30 cc. of dry pyridine in an apparatus equipped with a reflux condenser and a drying tube. To the solution, cooled to room temperature, was added 12.5 cc. (4.5 mols) of phenyl isocyanate. A reaction was immediately initiated with the liberation of considerable heat. The solution was refluxed for three hours and on cooling a crystalline product separated which was removed by filtration and washed with cold pyridine and finally with ether or petroleum ether; yield 4.5 g., m. p. 223–225°[7] (dec.), preliminary softening at 220°. Pure material could be obtained on recrystallization from pyridine, acetone or ethyl acetate; m. p. 225° (dec.), mixed m. p. with diphenyl urea (m. p. 235°), 210–211°, spec. rot. +13° (23°; *c*, 0.7; pyridine).[8]

The substance crystallized in long, fine needles. It was slightly soluble hot in acetone, chloroform, alcohol, ethyl acetate and pyridine. It was practically insoluble in water, ether and petroleum ether. It was not sufficiently soluble in acetone or chloroform for a satisfactory polarization.

Anal. Calcd. for $C_{35}H_{34}O_{10}N_4$: C, 62.67; H, 5.07; N, 8.35. Found: C, 62.68; H, 5.21; N, 8.38.

β-Methyl-*d*-xyloside Tricarbanilate.—β-Methyl-*d*-xyloside (5 g.) was treated exactly as described for the synthesis of β-methyl-*d*-glucoside tetracarbanilate and the crystalline reaction product was isolated in the same manner; yield 2.5 g., m. p. 233–235° (dec.). Pure material could be obtained on recrystallization from pyridine or alcohol–acetone (1:1); m. p. 234° (dec.), spec. rot. −23° (22°; *c*, 1; acetone).

The substance crystallized in long, fine needles and exhibited solubilities similar to those of the corresponding β-glucoside derivative except that it was more acetone-soluble.

Anal. Calcd. for $C_{27}H_{27}O_8N_3$: C, 62.19; H, 5.18; N, 8.06. Found: C, 62.00; H, 5.10; N, 8.24.

α-Methyl-*d*-glucoside Tetracarbanilate.—α-Methyl-*d*-glucoside (5 g.) was treated as described for the synthesis of the corresponding β-glucoside derivative except that the reaction product did not separate on cooling. The pyridine was then removed under reduced pressure and the amorphous residue washed repeatedly with warm ether; yield 11.5 g. The product was dissolved in a hot mixture of two parts of ethanol and one part of acetone, most of the acetone was then removed by boiling and to the residual hot ethanol solution water was added to incipient turbidity. The product crystallized on standing at room temperature and was removed by filtration. A second crop of approximately the same purity was obtained on mother liquor concentration; total yield 8 g., m. p. 210–214° (dec.). Pure material was obtained by repeating the above process several times; m. p. 227° (dec.), spec. rot. +73° (23°; *c*, 3; acetone).

The substance crystallized in long, fine needles and was somewhat more soluble in organic solvents than the corresponding β-glucoside derivative.

Anal. Calcd. for $C_{35}H_{34}O_{10}N_4$: C, 62.67; H, 5.07; N, 8.35. Found: C, 62.63; H, 5.10; N, 8.38.

α-Methyl-*d*-mannoside Tetracarbanilate.—α-Methyl-*d*-mannoside (5 g.) was treated with phenyl isocyanate as described for the β-methyl-glucoside but was isolated and crystallized by the procedure described for the α-methyl-glucoside derivative. The substance also could be recrystallized from absolute ethanol or isopropyl alcohol by the addition of water to the hot solution until incipient turbidity was produced; yield 3.4 g. of m. p. 189–190° (dec.); spec. rot. −18° (20°; *c*, 3; acetone).

The substance crystallized in long, fine needles and was

somewhat more soluble in organic solvents than the corresponding β-glucoside derivative.

The α-methyl mannoside was regenerated from this tetracarbanilate according to the procedure of Salmon and Powell[6] and was identified by melting point and mixed melting point.

Anal. Calcd. for $C_{35}H_{34}O_{10}N_4$: C, 62.67; H, 5.07; N, 8.35. Found: C, 62.60; H, 5.05; N, 8.29.

We are indebted to Mr. John Walker (W. P. A. Project 18062) and to Mr. H. S. Clark for all analytical determinations. We also acknowledge the assistance and counsel of Dr. John C. Sowden.

Summary

1. The tetracarbanilates of α-methyl-*d*-mannoside, α-methyl-*d*-glucoside, β-methyl-*d*-glucoside and the tricarbanilate of β-methyl-*d*-xyloside have been synthesized in crystalline condition.

aldehydo-Maltose Octaacetate

BY M. L. WOLFROM AND M. KONIGSBERG

The crystalline octaacetate of maltose diethyl mercaptal was reported[1] from this Laboratory some time ago. At the time, efforts to demercaptalate this substance yielded no crystalline product but the application of certain recent improvements[2] in the demercaptalation procedure has yielded the *aldehydo*-maltose octaacetate in crystalline form. A preliminary report[2] to this effect has been made and the details will now be communicated. The substance gives a positive Schiff aldehyde test and readily forms a crystalline oxime without loss of acetyl.

aldehydo-Maltose octaacetate exhibits no detectable mutarotation in ethanol solution but crystallizes as a compound with one mole of ethanol. This ethanol compound shows no detectable mutarotation in chloroform or ethanol solution and thus differs from the ethanol addition compounds of the *aldehydo*-acetates of galactose,[3] fucose[4] and mannose,[2] which have been demonstrated clearly to be true carbonyl addition compounds or ethyl hemiacetals. Table I indicates that the molecular rotations of *aldehydo*-maltose octaacetate and its ethanol compound are identical within the limits of experimental error. The ethanol compound is thus apparently not an ethyl hemiacetal but is a secondary valence compound with one mole of ethanol of crystallization. An alternative view would be that a change in the configuration of carbon one in this open chain derivative of maltose has little effect upon the rotation of the compound as a whole. This viewpoint receives some support in that the diethyl mercaptal of maltose octaacetate has practically the same rotation (specific, +88°; molecular, +69,000) in chloroform as the *aldehydo*-acetate. The fact that these maltose derivatives are α-glucosides might lead to the lactol carbon of the glucosidic portion making the controlling contribution to the rotation.

aldehydo-Maltose octaacetate is the first crystalline *aldehydo*-acetate in the disaccharide series.

TABLE I

ROTATIONS OF *aldehydo*-MALTOSE OCTAACETATE AND ITS ETHANOL COMPOUND

	$[\alpha]^{21}D$, $CHCl_3$ (alcohol free)	Mol. rotn.	$[\alpha]^{25}D$, EtOH	Mol. rotn.
aldehydo-Maltose octaacetate	+93.5°	+63,000	+96°	+65,000
The monoethyl alcoholate	+85	+62,000	+90	+65,000

Experimental

***aldehydo*-Maltose Octaacetate.**—Maltose diethyl mercaptal octaacetate[1] (20 g.) was dissolved in 300 cc. of acetone and added to a mixture of 60 g. of mercuric chloride, 70 g. of cadmium carbonate, and 7 cc. of water in 500 cc. of acetone. This mixture was stirred vigorously and refluxed for eight hours. The cold solution was filtered into a flask containing 75 g. of cadmium carbonate and the filtrate was concentrated under reduced pressure (35–40°) in the presence of the cadmium carbonate. The residue was extracted with warm chloroform (alcohol free) and the extract washed free of halogen, treated with decolorizing charcoal, dried over calcium chloride and concentrated to a thick sirup under reduced pressure. The sirup was dissolved in ether, one-fourth its volume of low boiling petroleum ether added, and cooled. The crystalline product was filtered and washed with cold ether; 8.5 g., m. p. 112–113°. A second crop was obtained from the mother liquors; 4.9 g. or 13.4 g. (78%) total, m. p. 105–113°. Pure material was obtained on two recrystallizations from absolute ether; m. p. 116–117°, spec. rot.

+93.5° (22°; *c*, 5; abs. $CHCl_3$),[5] spec. rot. +96° (25°; *c*, 1; EtOH; no mutarotation).

The compound crystallized as elongated prisms and was very soluble in chloroform and acetone and was moderately soluble in ether, alcohol and boiling water. It reduced Fehling solution on warming and reduced a neutral solution of copper acetate. In aqueous solution at room temperature it quickly restored the color to Schiff reagent.

Anal. Calcd. for $C_{12}H_{14}O_{11}(CH_3CO)_8$: C, 49.56; H, 5.64; CH_3CO, 11.8 cc. 0.1 *N* NaOH per 100 mg. Found: C, 49.49; H, 5.63; CH_3CO, 11.8 cc.

***aldehydo*-Maltose Octaacetate Monoethyl Alcoholate.**—This substance was obtained on recrystallization of *aldehydo*-maltose octaacetate from absolute ethanol or on working up the demercaptalation reaction with absolute ethanol in place of ether and petroleum ether. Pure material was obtained on several recrystallizations from absolute ethanol; m. p. 66–67°, spec. rot. +85° (21°; *c*, 5; abs. $CHCl_3$; no mutarotation), spec. rot. +90° (25°; *c*, 1; abs. EtOH; no mutarotation).

The substance was not very stable and slowly decomposed on long standing, with the liberation of alcohol and acetic acid. The product crystallized as long, lustrous needles and was very soluble in chloroform and acetone, moderately so in alcohol and warm ether, and was practically insoluble in water and ligroin. It reduced Fehling solution.

Anal. Calcd. for $C_{12}H_{14}O_{11}(CH_3CO)_8(C_2H_5OH)$: C, 49.7; H, 6.12; OC_2H_5, 6.22; CH_3CO, 11.0 cc. 0.1 *N* NaOH per 100 mg. Found: C, 49.5; H, 6.14; OC_2H_5, 6.16; CH_3CO, 11.0 cc.

***aldehydo*-Maltose Oxime Octaacetate.**—*aldehydo*-Maltose octaacetate (4 g.) was dissolved in 400 cc. of boiling water, filtered and a solid mixture of 0.9 g. of hydroxylamine hydrochloride and 1.8 g. of potassium acetate was added to the filtrate. A crystalline product separated on cooling; yield 1.5 g., m. p. 89–92°, spec. rot. +100° ($CHCl_3$). Pure material was obtained on two recrystallizations from water; yield 0.7 g., m. p. 93–94°, spec. rot. +107° (24°; *c*, 3; U. S. P. $CHCl_3$), spec. rot. +100° (24°; *c*, 3; EtOH). Recrystallization of the product from ether or aqueous alcohol did not alter the constants.

The product crystallized as fine rectangular rods and was soluble in chloroform, acetone, alcohol, ether and boiling water. It was insoluble in the hydrocarbon solvents.

Anal. Calcd. for $C_{12}H_{15}O_{11}N(CH_3CO)_8$: N, 2.02; CH_3CO, 11.5 cc. 0.1 *N* NaOH per 100 mg. Found: N, 2.00; CH_3CO,[6] 11.5 cc.

(5) All rotations are recorded to the D-line of sodium light, 22° is the temperature, *c* is the concentration in g. per 100 cc. soln.

We are indebted to Mr. John Walker (W. P. A. Project 18062) for assistance rendered in the analytical determinations. We also acknowledge assistance rendered by Mr. F. B. Moody.

Summary

1. The synthesis of the first crystalline *aldehydo*-acetate in the disaccharide series, *aldehydo*-maltose octaacetate, is reported.

2. *aldehydo*-Maltose octaacetate forms a crystalline oxime and a crystalline compound containing one mole of ethanol.

3. *aldehydo*-Maltose octaacetate shows no detectable mutarotation in ethanol solution and its ethanol compound shows no detectable mutarotation in chloroform or ethanol solution.

Disproportionation in Aryloxymalonic Acid Syntheses

BY JOSEPH B. NIEDERL AND ROSLYN T. ROTH[1]

In the course of the studies of substituted phenylmalonic acids[2,3] studies of various phenoxymalonic acids were undertaken as well. Mono- and di-phenoxymalonic acids, with and without substituents in the phenyl or the malonyl radical, were prepared.

In the preparation of the mono-phenoxymalonic acids from the diethyl mono-bromomalonate by the Williamson synthesis, a "disproportionation" phenomenon was encountered. Thus it was found that the di-phenoxy compounds result in about equal quantities with the monophenoxy products despite the use of equimolar quantities of sodium phenolate and diethyl mono-bromomalonate. On the other hand, no such disproportionation took place when the diethyl mono-chloromalonate was used instead of the bromo compound.

Although the mono- and diphenoxy-malonic acid esters had been prepared previously by Conrad and Brueckner[4] and the mono- and di-*p*-

(1) The material presented in this paper is taken from Part III of the thesis presented by Roslyn T. Roth to the Faculty of the Graduate School of New York University in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

(4) M. Conrad and C. A. Brueckner, *Ber.*, **24**, 2993 (1891).

nitrophenoxy malonic acid esters and acids by C. A. Bischoff[5] from the respective mono- and di-bromomalonic acid esters, neither one had reported the simultaneous formation of mono- and di-phenoxy derivatives from the mono-bromo ester. Formation of di-substituted malonic acid esters from equimolecular reactants of the mono-sodium salt of methyl malonate, or ethyl acetoacetate and mono-bromomalonic acid ester, while mono-substituted malonic acid derivatives were formed using the corresponding mono-chloromalonic acid ester, have previously been reported.[6,7]

While it is simple enough to state the formation of the mono phenoxymalonic acid esters from the respective sodium phenolates and the diethyl mono-bromomalonate (reaction A), interpretation of the disproportionation process (reaction B) is certainly more complicated and might be expressed in its simplest form as follows.

Reaction A

$$ROOC_2CH\boxed{Br + Na}OC_6H_4R \longrightarrow NaBr + (ROOC)_2CH\cdot O\cdot C_6H_4R$$

Reaction B

$$2(ROOC)_2CHBr + 2NaOC_6H_4R \longrightarrow 2NaBr + (ROOC)_2C(OC_6H_4R)_2 + (ROOC)_2CH_2$$

In the course of this investigation there were prepared the ethyl esters of the mono- (Ia) and the di-phenoxymalonic acids, the mono- (IIa) and di-*m*-cresoxymalonic acids (IIIa), the mono- and di-*p*-nitrophenoxy-malonic acids and the *p*-nitrophenoxy-methylmalonic acid (IVa), then several of the free acids (I, II, III, IV) and some of the amides (Ib, IIb). The various mono- as well as di-phenoxymalonic acid esters were subjected to rearrangement processes according to J. B. Niederl[8] and E. Wallis.[9] These attempts proved to be negative inasmuch as no carbon-arylated malonic acid could be obtained, the respective phenoxyacetic acids resulting from the mono derivatives. Of particular interest in this respect is the *p*-nitrophenoxy-methyl-malonic acid (IV) and ester (IVa), on account of its being a tertiary alkyl phenyl ether and yet being unable to undergo any rearrangement.

Experimental

Diethyl Aryloxymalonates.—These esters were prepared by refluxing until neutral 0.125 mole of diethyl mono-chloromalonate and the respective sodium phenolate, or cresylate, in absolute alcohol. The mixture was then poured into water and extracted with ether. The ether extract was fractionally distilled under reduced pressure. In this manner were prepared: diethyl phenoxymalonate (Ia) (yield 60%, the crystals were crystallized from methyl alcohol), and diethyl *m*-cresoxymalonate (IIa) (yield 60%). The diethyl di-*m*-cresoxymalonate (IIIa) was prepared by the method of M. Conrad and C. A. Brueckner[4] (yield 50%): the diethyl *p*-nitrophenoxy-methylmalonate was prepared according to the method of C. A. Bischoff[5] using xylene as the solvent (yield, 50–60%; the crystals were recrystallized from methyl alcohol).

Mono-aryloxymalonic Acids.—The individual free acids were prepared by hydrolyzing the respective esters with 5% alcoholic potassium hydroxide solution. The potassium salts which usually precipitated out were redissolved in water and the free acids were precipitated out of these solutions by subsequent acidification. Purification of the acids was effected by dissolving the acids in ether, extracting the ether solution with 5% aqueous sodium carbonate solution, precipitating the acids from the carbonate solution and re-extracting with ether. Upon concentration of the ether extracts at room temperature, the acids crystallized out on standing. The phenoxy and *m*-cresoxymalonic acids (I, II) were recrystallized from toluene, the *p*-nitrophenoxy-methylmalonic acid (IV) from a mixture of ether and petroleum ether. The free acids were hygroscopic. Upon heating and also on prolonged standing the acids lost carbon dioxide and were converted into the respective aryloxyacetic acids.

Di-aryloxymalonic Acids.—These acids also were prepared by hydrolysis of the corresponding esters. Usually only a short period of refluxing was required for the saponification of the ester. The di-*m*-cresoxymalonic acid (III) precipitated out on acidification in a partially hydrated state. The acid was recrystallized from hot water in the form of a tri-hydrate (III_1). On further heating or on long standing it lost water, forming the anhydrous acid (III). The anhydrous acid also was obtained from the ether solution of the acid or by precipitation by petroleum ether from the solution of the acid in benzene.

The di-aryloxymalonic acids upon heating underwent decomposition yielding the respective phenol, carbon dioxide, water and a non-volatile resin.

Mono-aryloxymalonic Acid Amides.—One gram of the aryloxymalonic acid ester (Ia, IIa) was shaken with 10 cc. of concentrated aqueous ammonium hydroxide solution for five minutes. The amide crystallized out in about 80% yield and was recrystallized from 30% alcohol (Ib, IIb).

Disproportionation.—The reactions between the sodium salts of the respective phenols (phenol, *m*-cresol, *p*-nitrophenol) and diethyl mono-bromomalonate (b. p. 125–127° (15 mm.)) were carried out with and without solvents. The solvents were ethyl alcohol (85%, 95% and absolute) and xylene. The mixtures were refluxed until they reacted neutral to litmus paper. They were then poured into water and the resulting aqueous mixtures were extracted with ether. The ether extract was separated and subjected to fractional distillation *in vacuo* (phenol and *m*-cresol). The fraction boiling above 140° (4 mm.) (a)

***p*-Nitrophenoxymethylmalonic acid**										
IV Acid	142 (dec.)	$C_{10}H_9NO_7$	47.04	46.88	3.57	3.39	5.49	5.52	128	128
(a) Ethyl ester	50–51	$C_{14}H_{17}NO_7$	54.07	53.95	5.47	5.59	4.50	4.59		

and 150° (4 mm.) (b) were reserved for examination. In the case of the *p*-nitrophenol (c) the esters crystallized out of the reaction mixture upon dilution with water when alcohol was used as the solvent; otherwise the solvent (xylene) had to be distilled off first.

(a) **Mono- and Di-phenoxymalonic Acids.**—The weighed esters as obtained above were first hydrolyzed with 20% aqueous potassium hydroxide solution and the solution acidified afterward. The di-phenoxymalonic acid (m. p. 173°) (the acetal) precipitated out and was weighed, while the monophenoxymalonic acid (I) (the ether) remained in solution. The second method for the determination of the proportion of mono- (ether) to the di-phenoxymalonic acid (acetal) involved treatment of the weighed ester mixture with concd. aqueous ammonium hydroxide solution. Only the mono acid (the ether) yielded an amide (Ib) which alone crystallized out and was then weighed.

The proportion of ether to acetal was two to three in absolute alcohol, xylene and no solvent. In 95 and 85% alcohols it changed to a one to one and a three to two ratio.

(b) **Mono- and Di-*m*-cresoxymalonic Acids.**—The proportion of mono- (ether) to the di-acid (acetal) was ascertained by determining the saponification equivalent of a weighed amount of the distillate. The second method involved determination of the refractive index of the ester mixture and comparing the value obtained with those of standard mixtures of the two components. Diethyl mono-*m*-cresoxymalonate: n^{23}°D 1.4895; sapon. equiv., 133. Diethyl di-*m*-cresoxymalonate: n^{22}°D 1.5221; sapon. equiv., 186. The proportion of ether to acetal was three to one using 95% alcohol as solvent.

(c) **Mono and Di-*p*-nitrophenoxymalonic Acid.**—The crude ester mixture was recrystallized from methyl alcohol. The melting point range of the mixture was then compared with those of a series of standard mixtures of the two components, which were prepared according to C. A. Bischoff[5] using diethyl mono-chloromalonate (b. p. 118–119° (16 mm.)) for the ether and diethyl di-bromomalonate (b. p. 140–143° (18 mm.)) for the acetal. The two esters were also separated by fractional crystallization from methyl alcohol in which solvent the ether compound is much more soluble than the acetal. Diethyl mono-*p*-nitrophenoxymalonate: m. p. 86°; diethyl di-*p*-nitrophenoxymalonate: m. p. 144°. The proportion of ether to acetal was two to three in absolute and 95% alcohol, three to two in 85% alcohol and one to one in xylene and without a solvent.

Summary

1. A disproportionation phenomenon involving abnormal aryloxylation has been described.

2. Various mono- and di-aryloxymalonic acids, their esters and amides have been prepared and their behavior on heating as well as under conditions which normally would lead to carbon arylation has been studied.

WASHINGTON SQUARE COLLEGE
NEW YORK, N. Y. RECEIVED JANUARY 31, 1940

[CONTRIBUTION FROM THE CHEMICAL LABORATORIES OF NEW YORK UNIVERSITY]

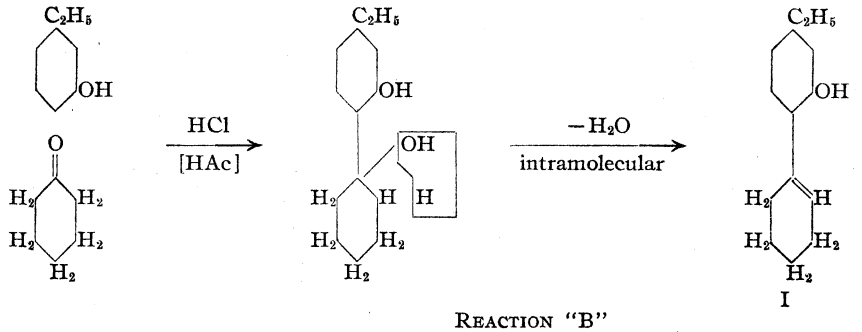
Flavans

BY JOSEPH B. NIEDERL AND ALBERT ZIERING

The condensation of cyclohexanone and *m*-ethylphenol to a cyclohexenylphenol (I)[1] takes place in glacial acetic acid, hydrogen chloride being used as the catalyst. It has now been found that, if the reaction is run without a solvent, the product is entirely different. The new compound is saturated and has twice the molecular weight of the cyclohexenylphenol (I). It has been assigned structure II, 2′-hydroxy-4′,7-diethyl-2,3-tetra-4,4-pentamethylene-flavan.

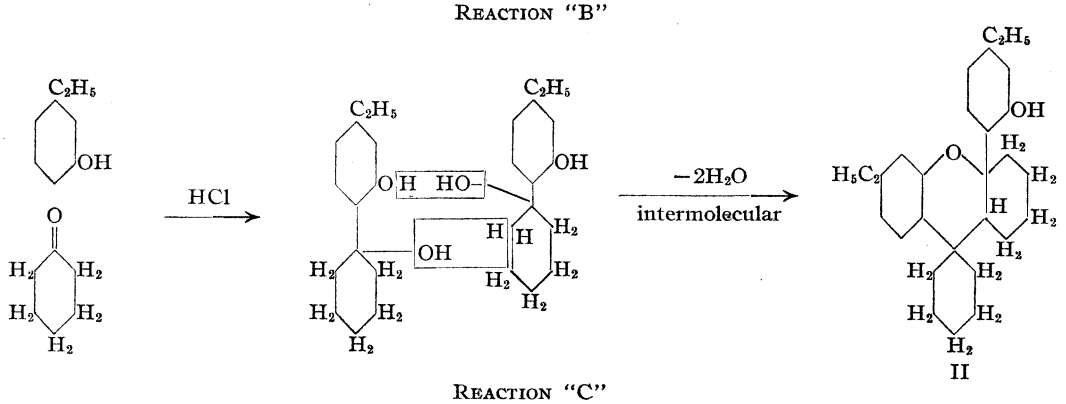
That this structure is correct was shown by an independent synthesis. *m*-Ethylphenol condensed with cyclohexylidenecyclohexanone gave the same flavan (II). Thus the probable mechanisms of these condensations can be represented as follows:

REACTION "A"



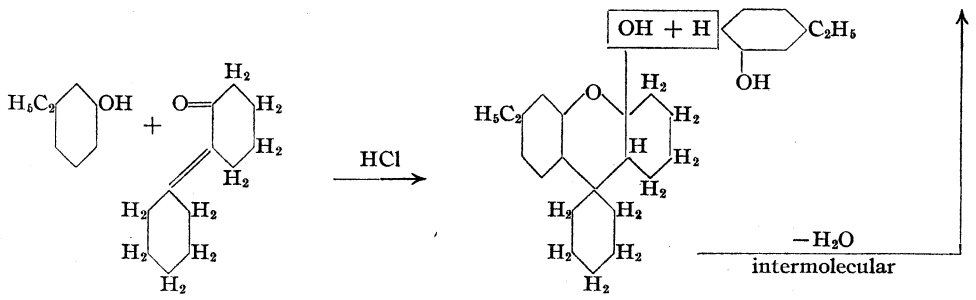
I

REACTION "B"



II

REACTION "C"



This reaction scheme would first of all suggest condensation of the cyclohexanone in the ortho position to the phenolic hydroxyl group, an assumption which is now well substantiated by spirochroman formation of the *m*-ethylphenol[2] and by coumaran formation of the same phenol when condensed with the alpha methylcyclohexanone.[1] That the cyclohexenyl radical is in the ortho position in the condensation product obtained in reaction "A" can be further inferred by the fact that its aryloxyacetic acid derivative,

(1) J. B. Niederl and co-workers, THIS JOURNAL, **61**, 1785 (1939).

(2) J. B. Niederl and co-workers, *ibid.*, **62**, 324 (1940).

despite being unsaturated, upon bromination gives a saturated monobromo derivative, while under the same condition the isomeric *o*-ethylphenol compound yields a dibromo derivative,[1] a fact which suggests cyclization in the former, yielding the respective coumaran compound (6-ethyl-2-carboxy-3,3-(2′-bromo)-pentamethylene-coumaran).

Thus in the last analysis the difference between condensation "A," involving the formation of the unsaturated phenol, and condensation "B" is that in the first case dehydration of the intermediate "phenol-hydrin" takes place "intramolecularly," whereas the second case, which involves the loss of two molecules of water from two molecules of the "phenol-hydrin," points to "intermolecular" dehydration.[3]

Experimental

Condensation Methods

Cyclohexanone and *m*-Ethylphenol.—One mol of *m*-ethylphenol was added to 1 mol of cyclohexanone in a 3-necked flask into which was inserted a thermometer, reflux condenser, and a gas inlet tube reaching to the bottom of the flask. A stream of dry hydrogen chloride gas was passed into the mixture for six hours. The temperature rose to 50° and was kept at that level for one hour. The flask was stoppered and set aside for five days, after which time crystals had formed. The mixture was filtered through a fritted glass filter, the crystals washed with benzene and recrystallized repeatedly from alcohol until colorless crystals were obtained; yield, 15% (five days condensation time).

Cyclohexylidene-cyclohexanone and *m*-Ethylphenol.—Eighteen grams, 0.1 mol, of cyclohexylidene-cyclohexanone (b. p. 143–146° at 15 mm.) prepared according to C. Mannich[4] was added to 24.6 g. (0.20 mol) of *m*-ethylphenol in a 3-necked flask equipped with a thermometer, reflux condenser, and a gas inlet tube. Hydrogen chloride gas was passed in for six hours, at the end of which time the flask was stoppered and let stand for a week. The crystals were washed with benzene and crystallized from alcohol; yield, 9% (one week condensation time).

2′ - Hydroxy - 4′,7 - diethyl - 2,3 - tetra - 4,4 - pentamethylene-flavan.—Soluble in organic solvents, but insoluble in Claisen solution; diazotization reactions positive. M. p., 195–196° (uncor.).

Anal. Calcd. for $C_{28}H_{36}O_2$: C, 83.17; H, 8.91; mol. wt., 404. Found: C, 82.77; H, 8.92; mol. wt., 404, 409.

Derivatives

Di-bromo Derivative.—One-half gram of the flavan compound was dissolved in 30 cc. of carbon tetrachloride and 0.4 g. of bromine in 10 cc. of the same solvent added drop by drop. The solvent was evaporated at room temperature and the crystals were recrystallized from alcohol; m. p. 180–181° (uncor.).

Anal. Calcd. for $C_{28}H_{34}O_2Br_2$: C, 59.78; H, 6.05; Br, 28.43. Found: C, 59.45; H, 6.25; Br, 28.47.

Benzoate.—One-half gram of the flavan was dissolved in 7 cc. of pyridine and 0.5 cc. of benzoyl chloride added. After the mixture had refluxed for one hour, it was poured with stirring into 20 cc. of water. The precipitate formed was taken up in ether and the solution washed with 3 cc. of 5% sodium carbonate solution and then with 5 cc. of water. After drying over calcium chloride and filtering, the ether was allowed to evaporate and colorless crystals of the benzoate remained; m. p. 169–170° (uncor.).

Anal. Calcd. for $C_{35}H_{40}O_3$: C, 82.68; H, 7.87. Found: C, 82.81; H, 8.18.

3,5-Dinitrobenzoate.—The procedure employed was the same as for the benzoate except that 3,5-dinitrobenzoyl chloride was used. The pale yellow crystals were recrystallized from alcohol; m. p. 176° (uncor.).

Anal. Calcd. for $C_{35}H_{38}O_7N_2$: C, 70.23; H, 6.35. Found: C, 70.20; H, 6.01.

Acetate.—One-half gram of the flavan was added to 20 cc. of acetic anhydride and the mixture refluxed for three hours. On pouring the cooled solution into water an oil separated which on standing solidified. The acetate was recrystallized from alcohol; m. p. 118–119° (uncor.).

Anal. Calcd. for $C_{30}H_{38}O_3$: C, 80.72; H, 8.52. Found: C, 80.90; H, 8.28.

Summary

Formation of a "flavan" type of crystalline condensation product from a cyclic ketone and a meta alkylated phenol was observed. The structure of the compound was proved by its synthesis from a cyclic alkylidene ketone and the same phenol. This as well as previous investigations seem to indicate that in condensations with ketones meta alkylated phenols appear to undergo alkylation in the *ortho* position to the phenolic hydroxyl group.

The Dehydration of *cis*- and *trans*-2-Phenylcyclohexanols

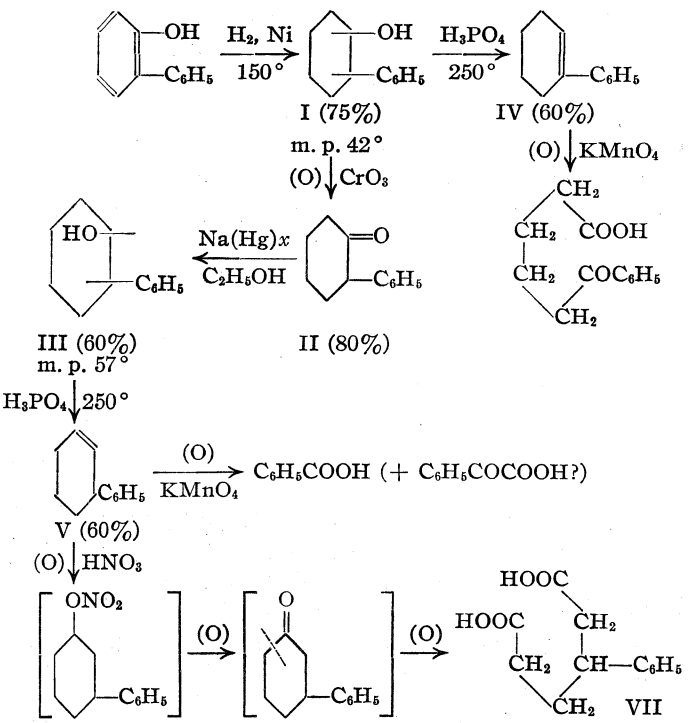
BY CHARLES C. PRICE AND JOSEPH V. KARABINOS

An investigation of the dehydration of *cis*- and *trans*-2-phenylcyclohexanols has been undertaken in order to obtain further evidence concerning the *trans*-elimination of water in such reactions. Vavon and Barbier[1] have observed that *cis*-2-alkylcyclohexanols are more easily dehydrated thermally or chemically than their *trans*-isomers, indicating that hydroxyl and hydrogen are more readily removed as water when they are in the *trans*-positions. They did not, however, determine the nature of the olefin formed in each case; it was with this purpose in view that the dehydration of the 2-phenylcyclohexanols has been investigated.

Only one of these two alcohols previously has beeen characterized and identified. From the catalytic reduction of *o*-phenylphenol with a nickel catalyst at temperatures above 200°, von Braun, Gruber and Kirschbaum[2] obtained a mixture of phenylcyclohexanol, cyclohexylcyclohexanol, cyclohexylbenzene and bicyclohexyl. The two alcohols were separated by oxidation to the ketones and subsequent reduction by sodium and alcohol; the 2-phenylcyclohexanol melted at 54–55°. Bedos[3] treated cyclohexene oxide with phenylmagnesium bromide and obtained a poor yield of a liquid which he suggested was a stereoisomer of the alcohol above, although it gave the same phenylurethan and phthalate. Cook, Lawrence and Hewitt,[4] however, pointed out that Bedos' alcohol may be contaminated by products of ring contraction. Using phenyllithium they obtained excellent yields of the alcohol, melting at 56–57° and identical with that reported by von Braun, Gruber and Kirschbaum.[2]

By the hydrogenation of *o*-phenylphenol with Raney nickel catalyst at 150° we have obtained an excellent yield of 2-phenylcyclohexanol melting at 41–42°. Since the compound crystallized only on standing for several days, the "viscous liquid" described by Ranedo and Leon[5] from a similar hydrogenation using platinum black in the cold may have been a slightly less pure sample of this isomer. The fact that this low-melting isomer has the *cis*-configuration is indicated by its method of preparation.[6]

Oxidation of the new low-melting *cis*-2-phenylcyclohexanol (I) with chromic acid yielded 2-phenylcyclohexanone (II) which was reduced to the high-melting isomer (III) by sodium amalgam and ethanol.



Dehydration of these two phenylcyclohexanols with phosphoric acid or anhydride gave chiefly 1-phenylcyclohexene (IV) from the *cis*-isomer (I) and 3-phenylcyclohexene (V) from the *trans* (III), another example of the well-known fact

(1) Vavon and Barbier (*Bull. soc. chim.*, [4] **49**, 567 (1931)) and Hückel and Neunhoeffer (*Ann.*, **477**, 135 (1930)) found that *cis*-2-cyclohexylcyclohexanol was dehydrated readily to Δ^1-cyclohexylcyclohexene while the *trans*-isomer was dehydrated with difficulty to give this same olefin contaminated by a small amount of an isomer which they suggested was Δ^1-hexahydrobenzylcyclopentene. A similar study with *trans*-2-methylcyclohexanol[3] gave no evidence for such a ring contraction, but the formation of both Δ^1- and Δ^2-methylcyclohexenes was demonstrated.

(2) Von Braun, Gruber and Kirschbaum, *Ber.*, **55**, 3668 (1922).

(4) Cook, Lawrence and Hewitt, *J. Chem. Soc.*, 71 (1936).

(5) Ranedo and Leon, *Añales soc. espan. fis. quim.*, **22**, 222 (1924).

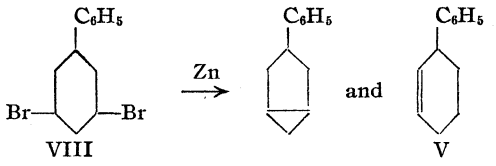
(6) See, *e. g.*, Vavon, *Bull. soc. chim.*, **41**, 1401 (1925); Bourguel, *Compt. rend.*, **180**, 1753 (1925); **187**, 383 (1928); Aronstein and Holleman, *Ber.*, **22**, 1181 (1899); Ott, *ibid.*, **61**, 2124 (1928).

that elimination to form a multiple link takes place most readily when the elements lost are *trans* to each other.[7]

In each case a small amount of the isomeric cycloölefin was obtained (Table I). In the second case (III) this could not have been due to isomerization after dehydration since the olefin (V) was unaffected when refluxed with phosphoric acid. The formation of a mixture must therefore be due either to the fact that some of the alcohol was isomerized before dehydration occurred or else *cis*- and *trans*-elimination must be competitive reactions; the first possibility seems the more likely.

The results differ somewhat from those with *trans*-2-methylcyclohexanol,[8] which gave nearly equivalent amounts of the two possible isomeric olefins. The *cis*-isomer of this compound has not yet been studied.

Of the two olefins above only 1-phenylcyclohexene (IV) has been reported previously in the literature.[9] Uspenski,[10] however, found that the treatment of 3,5-dibromo-1-phenylcyclohexane (VIII) with zinc yielded an olefin as well as the expected bicyclo compound. This olefin is identical in physical properties with the 3-phenylcyclohexene (V) above and is also similar in that no satisfactory products were obtained by permanganate oxidation (Uspenski obtained benzoic acid; we obtained benzoic, and possibly benzoylformic, acids).



VIII V

Oxidation of 3-phenylcyclohexene with dilute nitric acid gave a good yield of β-phenyladipic acid (VII). The formation of this acid was rather surprising; evidently the nitric acid attacks the double bond first by addition as indicated above.

Experimental

***cis*-2-Phenylcyclohexanol (I).**—*o*-Phenylphenol[11] was treated with hydrogen and Adams platinum catalyst in alcohol at 3–4 atmospheres at temperatures up to 70° but no hydrogen was absorbed.[5] When 680 g. of *o*-phenylphenol in 400 cc. of alcohol was treated with hydrogen at 135 atmospheres and 140–150° in the presence of Raney nickel until the theoretical amount of hydrogen had been absorbed, the product washed with 5% sodium hydroxide and distilled, 480 g. (75%) of *cis*-2-phenylcyclohexanol was obtained as a colorless, viscous oil, crystallizing after standing several days, b. p. 140–141° (16 mm.), m. p. 41–42°.[12]

Anal. Calcd. for $C_{12}H_{16}O$: C, 81.77; H, 9.14. Found: C, 81.44; H, 9.42.

Acidification of the alkaline extract above yielded 40 g. of starting material.

The **phenylurethan** was recrystallized readily from petroleum ether, m. p. 127.5–128°.

Anal. Calcd. for $C_{19}H_{21}O_2N$: N, 4.75. Found: N, 4.77.

Mixed with the phenylurethan from the *trans*-isomer (m. p. 136–137°) the melting point was 110–125°.

2-Phenylcyclohexanone (II).—The oxidation of the *cis*-cyclohexanol (I) was carried out by a modification of the method used by Cook, Lawrence and Hewitt.[4] To a solution of 31 g. of I in 50 cc. of glacial acetic acid, 14 g. of chromic oxide in 50 cc. of 80% acetic acid was added dropwise with vigorous stirring so that the temperature did not rise above 50°. After standing at room temperature for twenty-four hours, the mixture was poured into 250 cc. of water and extracted with one 200-cc. and two 100-cc. portions of benzene. The combined extracts were washed with sodium bicarbonate and with water, dried and distilled. The yield of 2-phenylcyclohexanone (II) was 25 g. (80%); b. p. 155–160° (16 mm.); m. p. 52.5–54.5°. The pure ketone melts at 63°[2,13]; the product reported by Cook, Lawrence and Hewitt[4] melted at 50–53°. The low-melting products are undoubtedly contaminated by a small amount of the unoxidized alcohol. The **semicarbazone** melted at 189–190°.[2,13]

***trans*-2-Phenylcyclohexanol (III).**—The ketone (II, 25 g.) was reduced by shaking with 433 g. of sodium amalgam (10 g. of sodium) in 175 cc. of alcohol for several hours. The mixture was partially evaporated, diluted with water and extracted with ether. The ether was washed, dried and distilled, yield, 15 g. (60%) of III, b. p. 152–155° (16 mm.), m. p. 52–54°. Recrystallized from petroleum ether, it melted at 56–57°.[2,4]

The **phenylurethan** had a melting point of 136–137°, in agreement with reports by other investigators.[2,3,4]

Dehydration.—Dehydration of the two alcohols was accomplished by refluxing with an equal weight of sirupy phosphoric acid for four hours. Ether and water were added and the ether washed, dried and distilled under diminished pressure. The composition of the fractions boiling from 115–130° (16 mm.) was determined by refractive index. These results are summarized in Table I. The physical constants of the purest samples of the two olefins are recorded in Table II.

One dehydration using phosphoric anhydride gave results very similar to those with phosphoric acid. The

1-Phenyl-[9]	128	16	1.569 (14°)	.9939	
3-Phenyl-[a]	115-117	16	1.5530	.9800	51.62
3(?)-Phenyl-[10]	101	9.5	1.5528	.9801	51.60

[a] *Anal.* Calcd. for $C_{12}H_{14}$: C, 91.08; H, 8.92. Found: C, 90.81; H, 9.32.

dehydration mixture was heated so that the product would distil at 16 mm. This crude olefin was washed, dried and redistilled as above.

3-Phenylcyclohexene (V, 1 g., $n^{20}D$ 1.5528) and 1 g. of phosphoric acid were refluxed for four hours and 75% of the hydrocarbon was recovered unchanged ($n^{20}D$ 1.5529), indicating that the dehydration conditions are not sufficient to cause isomerization of the double bond, in spite of the fact that in this case the isomer should be more stable due to conjugation. This conjugation, incidentally, leads to a slight exaltation in the molecular refraction for the 1-phenylcyclohexene (Table II).

Oxidation of 1-Phenylcyclohexene (IV).—Five grams of (IV) and 10 g. of potassium permanganate were stirred for twenty-four hours, initially at 0° but gradually warming to room temperature. Filtration and acidification gave an acid which was recrystallized from water as plates, 2 g., m. p. 75–76°. This corresponds to δ-benzoylvaleric acid (VI), the expected product. Its semicarbazone melted at 183–185°.[4,14]

Oxidation of 3-Phenylcyclohexene (V).—This hydrocarbon (4.75 g.) was refluxed with 100 cc. of 5% nitric acid for six days with the addition of a total of 7 cc. of concentrated nitric acid at intervals. On cooling, 3 g. of solid acid was obtained. Recrystallization from water gave β-phenyladipic acid (VII), m. p. 147–148°.[15] The permanganate (20.7 g.) oxidation of this olefin (4.5 g.) was not very satisfactory. Only benzoic acid precipitated on acidifying the filtrate. Semicarbazide gave a semicarbazone melting at 178–180° (the mixture with the semicarbazone of benzoylvaleric acid melted below 110°), which was hydrolyzed to an acid melting at 64–65° (benzoylformic acid is reported as melting at 66°).[16]

Summary

cis-2-Phenylcyclohexanol has been prepared in 75% yield by hydrogenation of *o*-phenylphenol.

Oxidation of this alcohol with chromic acid is an easy and economical method for the preparation of 2-phenylcyclohexanone.

cis-2-Phenylcyclohexanol and the *trans*-isomer yield chiefly 1- and 3-phenylcyclohexene, respectively, on dehydration, products corresponding to the *trans*-elimination of the elements of water in each case.

URBANA, ILLINOIS RECEIVED FEBRUARY 14, 1940

(14) Von Auwers and Treppmann, *Ber.*, **48**, 1217 (1915), report a melting point of 77–78° for the acid and 187° for the semicarbazone.

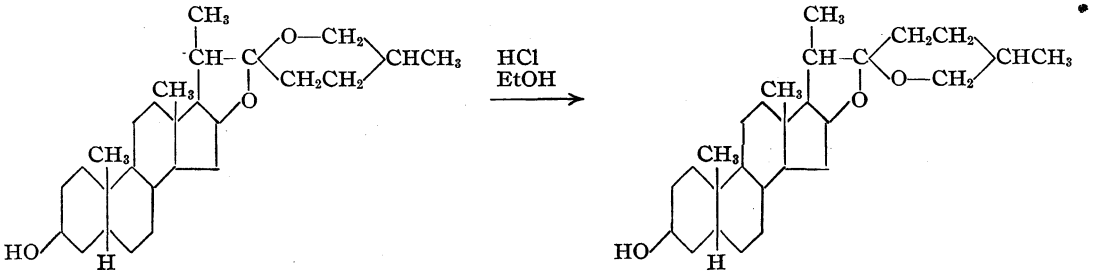
Sterols. XCVIII. Conversion of Isosarsasapogenin (Smilagenin) to Tigogenin

BY RUSSELL E. MARKER, EWALD ROHRMANN AND ELDON M. JONES

There has been considerable evidence presented recently indicating that sarsasapogenin differs from tigogenin not only in its configuration at C-5 but also in the configuration of the side chain,[1] the most significant evidence in this connection being the conversion of sarsasapogenin (I) to neotigogenin (III).[1,2] The fact that this transformation yielded neotigogenin rather than tigogenin suggested that the side chain of tigogenin possibly has the configuration of isosarsasapogenin[3,4] rather than of sarsasapogenin.



I. Sarsasapogenin

II. Isosarsasapogenin (Smilagenin)

III. Neotigogenin

IV. Tigogenin

We have now completely substantiated these predictions by effecting the conversion of isosarsasapogenin (II) to tigogenin (IV) by the procedure used for the conversion of sarsasapogenin to neotigogenin.[1] Isosarsasapogenone, prepared by the isomerization of sarsasapogenone with ethanolic hydrochloric acid, was converted to dibromo-isosarsasapogenone which upon treatment with pyridine yielded bromodehydro-$\Delta^{4,5}$-isosarsasapogenone. Reduction of this product with sodium and ethanol yielded tigogenin.

(1) Marker and Rohrmann, THIS JOURNAL, **62**, 647 (1940).
(2) Goodson and Noller, *ibid.*, **61**, 2420 (1939).
(3) Marker and Rohrmann, *ibid.*, **61**, 846 (1939).
(4) Marker and Rohrmann, *ibid.*, **62**, 898 (1940).

As might be anticipated, neotigogenin upon treatment with aqueous ethanolic hydrochloric acid readily passes into tigogenin.

Experimental Part

Dibromo-isosarsasapogenone.—To a solution of 21 g. of isosarsasapogenone, m. p. 186–188°, in 1 liter of acetic acid containing 2 cc. of 48% hydrobromic acid was added 101.5 cc. of 1.05 *N* bromine in acetic acid over a period of fifteen minutes with stirring at 20°. Much hydrogen bromide came off and the solution turned a deep violet color. Water was added and the precipitate filtered, dried and recrystallized from acetone containing 10% ethyl acetate to give white crystals, m. p. 184–188° dec.; yield 14 g.

Anal. Calcd. for $C_{27}H_{40}O_3Br_2$: C, 56.7; H, 7.1. Found: C, 57.1; H, 7.2.

Bromo-dehydro-$\Delta^{4,5}$-isosarsasapogenone.—A solution of 14 g. of dibromo-isosarsasapogenone in 140 cc. of dry pyridine was refluxed for eight hours. The solution was cooled and the precipitated material collected, washed well with ether and water, and dried. It melted with decomposition at 245–246° and was probably a pyridinium salt.

Anal. Calcd. for $C_{32}H_{45}O_3NBr$: C, 59.0; H, 7.0. Found: C, 58.7; H, 6.5.

The filtrate from the above was dissolved in ether and the pyridine removed by shaking with dilute sulfuric acid.

The ether solution was treated with Norit and the product crystallized from ether to give a product with m. p. 200–205°, dec.; yield 4.2 g.

Anal. Calcd. for $C_{27}H_{39}O_3Br$: C, 66.0; H, 8.0. Found: C, 65.8; H, 8.1.

Reduction of Bromo-dehydro-$\Delta^{4,5}$-isosarsasapogenone with Sodium and Ethanol.—To a boiling solution of 4 g. of bromo-dehydro-$\Delta^{4,5}$-isosarsasapogenone in 400 cc. of absolute ethanol was added 20 g. of sodium in small pieces over a period of one hour. Water was added and the precipitated solid taken up in ether, washed well with water and the ether evaporated. The residue was dissolved in a small amount of ethanol and to this was added a solution of 8 g. of digitonin in 400 cc. of 80% ethanol. After standing overnight the digitonide was collected, washed and dried; yield 6.2 g. This was decomposed with pyridine in the usual manner. The product was treated with Norit in methanol and crystallized from ether and methanol to give white crystals, m. p. 202–204°. A mixture with neotigogenin, m. p. 198–200°, melted at 174–185°. A mixture with sarsasapogenin, m. p. 199–201°, melted at 165–174°.

Anal. Calcd. for $C_{27}H_{44}O_3$: C, 77.8; H, 10.6. Found: C, 77.8; H, 10.5.

With boiling acetic anhydride the product gave an acetate which crystallized from methanol as white plates, m. p. 202–204°. When mixed with tigogenin acetate, m. p. 203–204° it gave no depression in melting point.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.9; H, 10.1. Found: C, 75.6; H, 9.9.

Isomerization of Neotigogenin into Tigogenin.—A solution of 100 mg. of neotigogenin in 20 cc. of ethanol and 2 cc. of concentrated hydrochloric acid was refluxed for eighty hours. Water was added and the product was crystallized from methanol–acetate, methanol and ethanol to give a product, m. p. 202–204°. When mixed with tigogenin, m. p. 204–206°, it melted at 203–206°. When mixed with neotigogenin of m. p. 199–201°, it melted at 180–186°.

Anal. Calcd. for $C_{27}H_{44}O_3$: C, 77.8; H, 10.6. Found: C, 77.7; H, 10.6.

When refluxed with acetic anhydride it gave an acetate which when crystallized from methanol melted at 202–204°. When mixed with tigogenin acetate, m. p. 203–205°, it melted at 203–205°.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.9; H, 10.1. Found: C, 75.8; H, 10.1.

We wish to thank Parke, Davis and Company for their generous help and assistance in the various phases of this work.

Summary

Isosarsasapogenin has been converted to tigogenin, indicating that the tigogenin side chain is of the "iso- configuration."

Neotigogenin upon isomerization with hydrochloric acid is converted into tigogenin.

Divalent Nitrogen. I. The Rate of Dissociation of Tetraphenylhydrazine[1]

BY C. K. CAIN[2] AND F. Y. WISELOGLE

The successive substitution of the hydrogen atoms of ethane by phenyl groups weakens the ethane carbon–carbon linkage to such an extent that hexaphenylethane in solution undergoes rapid dissociation into free radicals at 0°. This marked decrease in the bond strength has been attributed in part to stabilization of the resulting triphenylmethyl radicals through resonance of the odd electrons in the aromatic nuclei, resonance which is not possible in hexaphenylethane.[3]

If stabilization of triarylmethyl radicals through increased resonance is responsible for dissociation in hexaarylethanes,[4] then it seems reasonable to predict that substitution by aryl groups of the hydrogen atoms of any simple dimeric molecule would weaken the central bond of the compound. An accumulation of aryl groups could lead to compounds which would dissociate at moderate temperatures to give relatively stable radicals. Indeed Wieland has attributed many of the reactions of tetraarylhydrazines, $R_2N\text{-}NR_2$, to preliminary dissociation into free radicals, R_2N-, in which the nitrogen atom is divalent.[5] We have now undertaken a study of substituted hydrazines in order to determine the energetics of this dissociation process and thereby to determine the effect on the strength of the N-N bond of substituting various groups for hydrogen atoms. In this paper we report measurements of the rate of dissociation of tetraphenylhydrazine and from these data a calculation of the activation energy for the formation of diphenylnitrogen radicals.

(2) E. I. du Pont de Nemours and Co. Fellow, 1938–1939.

(3) Pauling and Wheland, *J. Chem. Phys.*, **1**, 367 (1933).

(4) Recently the importance of resonance as a factor in promoting dissociation of polyarylethanes has been questioned. See, for example, Marvel, Mueller and Ginsberg, THIS JOURNAL, **61**, 2008 (1939). That resonance plays some part in stabilizing the radicals, however, is not disputed.

(5) Wieland, "Die Hydrazine," Ferdinand Enke, Stuttgart, 1913, pp. 71–78.

Properties and Reactions of Tetraphenylhydrazine.—Tetraphenylhydrazine, prepared from diphenylamine by oxidation, is a colorless crystalline product melting with decomposition at 165–170° to a greenish-brown liquid. Solutions give the same color when heated to approximately 70°; at this temperature tetraphenylhydrazine rapidly undergoes disproportionation (Equation 1).[6]

$$2(C_6H_5)_2N{-}N(C_6H_5)_2 \longrightarrow \text{(9-phenylcarbazole)} + 2(C_6H_5)_2NH \quad (1)$$

Solutions of tetraphenylhydrazine absorb nitric oxide at 100° to give quantitative yields of N-nitrosodiphenylamine, a product which is also obtained by the action of nitrous acid on diphenylamine (Equation 2).[6] The formation of N-nitrosodiphenylamine

$$(C_6H_5)_2N{-}N(C_6H_5)_2 + 2NO \rightleftharpoons 2(C_6H_5)_2N{-}NO + 2(C_6H_5)_2NH + 2HONO \quad (2)$$

from nitric oxide is a reversible reaction since at 130° the nitric oxide is evolved in yields up to 95% of the theoretical. Although tetraphenylhydrazine does not react with gaseous oxygen, a reagent for trivalent carbon radicals, further evidence for dissociation was reported in the reaction with triphenylmethyl to give a coupling product of the two radicals (Equation 3)[6]

$$(C_6H_5)_2N{-}N(C_6H_5)_2 + 2(C_6H_5)_3C{-} \xrightarrow{100°} 2(C_6H_5)_3C{-}N(C_6H_5)_2 \quad (3)$$

Rate of Dissociation of Tetraphenylhydrazine.—In order to measure the rate of dissociation of tetraphenylhydrazine it was necessary to find a reagent which would react rapidly and irreversibly with the free diphenylnitrogen radicals but at a negligible rate with the undissociated tetraphenylhydrazine. The rate of the over-all reaction would thus be limited to that of the slowest step and therefore a measure of the rate of the dissociation process. Ziegler, Orth and Weber used nitric oxide successfully to measure the rate of dissociation of hexaphenylethane at temperatures from −20° to +10°[7]; if the partial pressure of nitric oxide was greater than about 0.2 atmosphere the rate of absorption was independent of the pressure and identical with the rate of reaction of hexaphenylethane with iodine or oxygen, proof that the rate-controlling step in each case was the dissociation process. Accordingly, we first selected the reaction of tetraphenylhydrazine with nitric oxide to determine whether the rate-controlling step in this case was the dissociation process.

Experimental

The gas absorptions were carried out in an air thermostat of inside dimensions 16″ × 19″ × 30″ (64 × 79 × 120 cm.) provided with rapid air circulation and containing a bimetallic thermoregulator capable of maintaining temperatures from 50 to 120° constant to within ±0.05°. Temperature control was achieved by using two electrical heating units of which one, carrying 75 to 500 watts, was manually operated to give the approximate temperature and the other, carrying 50 to 200 watts, was operated by the thermoregulator. The temperatures were read on a short stem thermometer graduated to 0.2° and calibrated against a thermometer certified by the Bureau of Standards.

A 200-cc. round-bottomed flask provided with an interchangeable ground glass joint was fastened by a spring clamp to an oscillating shaking mechanism. The thermometer was fastened to the thermostat so that the bulb was a few cm. from the center of the flask. The flask was connected by means of heavy rubber and glass capillary tubing through a T-stopcock to the top of a 100-cc. gas buret (Fig. 1). The buret communicated with a parallel glass leveling tube open at the top and leading through a stopcock into a reservoir of diethyl phthalate which was used as the retaining liquid. The glass leveling tube was connected to the buret by means of a rubber stopper which was protected from the retaining liquid by a layer of mercury. The diethyl phthalate was forced up into the buret and leveling tube by applying air pressure to the reservoir and temporarily opening the stopcock. When the level of liquid was the same in the buret and leveling tube the pressure within the system was equal to that outside. By varying the air pressure on the reservoir and by manipulating the stopcock this condition was maintained throughout each run. This design allowed the use of a light organic liquid sensitive to pressure changes within the system but avoided any direct contact between the organic liquid and rubber. The tedious manipulation of a leveling bulb also was eliminated.

***o*-Dichlorobenzene** was used as the solvent for the reaction. Preliminary experiments indicated that *o*-dichlorobenzene did not react with nitric oxide at any of the temperatures used in the rate studies. The technical product containing 5% of the para isomer was fractionated and the portion distilling at 180–181° (760 mm.) was retained.

Tetraphenylhydrazine was prepared according to the general directions in Gattermann.[8] Mechanical stirring was used during the addition of the potassium permanganate and the product was recrystallized from benzene and

(8) Gattermann, "Laboratory Methods of Organic Chemistry," The Macmillan Co., New York, N. Y., 1937, p. 355.

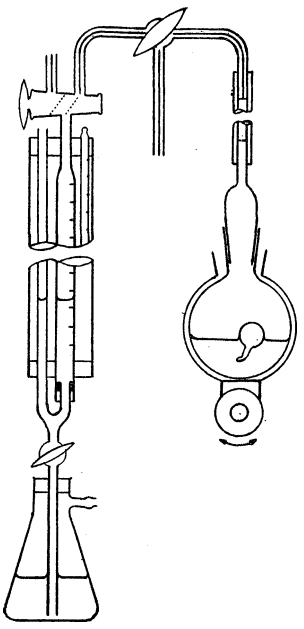

Fig. 1.—Apparatus for measuring rate of absorption of gas at constant pressure.

alcohol. The color on the surface of the crystals was removed by washing the filtered product on the funnel with cold ether. The recorded melting point (144°) is not significant. If the melting point tube was plunged into a preheated bath at this temperature there was a lag of about thirty seconds before the solid suddenly melted. This time lag was reduced at higher temperatures until at 165–170° essentially instantaneous melting took place. The product was dried at 50° under reduced pressure and was used at once for the rate measurements since the solid slowly acquired a green color on standing.

Nitric oxide was prepared by the action of diluted sulfuric acid (1/1) on a solution of sodium nitrite, the nitrogen dioxide being removed by washing the gases with 10% sodium hydroxide solution. The nitric oxide was stored in a gasometer over 1% sodium hydroxide solution, and was dried before use by passage through a tube containing soda-lime. Synthetic mixtures of known volumes of nitric oxide and nitrogen were prepared and stored in gasometers.

In a typical run the flask containing 25 cc. of solvent and a few glass beads was placed in the thermostat at the desired temperature. In order to remove any oxygen dissolved in the solvent the flask was repeatedly evacuated and filled with nitrogen. In the meantime approximately 0.34 g. of tetraphenylhydrazine was introduced into a previously weighed thin-walled glass bulb. The bulb was weighed, then evacuated, filled with nitrogen and sealed. After the flask and solvent had attained the temperature of the thermostat the sample was carefully introduced. Any air which entered the system at this time was removed by evacuation and displacement by nitrogen. The nitrogen was immediately displaced by nitric oxide of known partial pressure and the gas buret was filled with nitric oxide at a pressure of one atmosphere. The T-stopcock was turned to shut off the nitric oxide supply and to open the system to the buret.

As soon as the buret reading remained constant for two minutes while the flask was gently shaken, an indication of thermal equilibration, the bulb was broken by increasing the speed and eccentricity of shaking to that maintained throughout the run. The initial buret reading was taken the instant the bulb broke and was usually 0.3 cc. greater than the reading immediately before breaking. The increase in volume undoubtedly arose from the pressure built up within the bulb at the elevated temperature. Absorption of gas began immediately and buret readings were taken at regular, convenient time intervals.

The theoretical absorption was calculated from the equation

$$V = 370.8w(t + 273)/P$$

where w is the weight of the sample, t the temperature of the gas buret and P is the corrected barometric pressure in mm. The coefficient 370.8 is the value of $2 \times 760R/M$, where R is the gas constant, 82.07, M the molecular weight of tetraphenylhydrazine, 336.2, and the factor 2 arises from the absorption of two moles of nitric oxide by one mole of tetraphenylhydrazine.

In Table I, columns 1, 2 and 3, are recorded typical data obtained in a representative experiment.

Results and Discussion

Nature of the Reaction.—In Fig. 2 are plotted the time rates of absorption of nitric oxide at 95.15° by 0.04 molar solutions of tetraphenylhydrazine in *o*-dichlorobenzene at various nitric oxide pressures. From an inspection of the

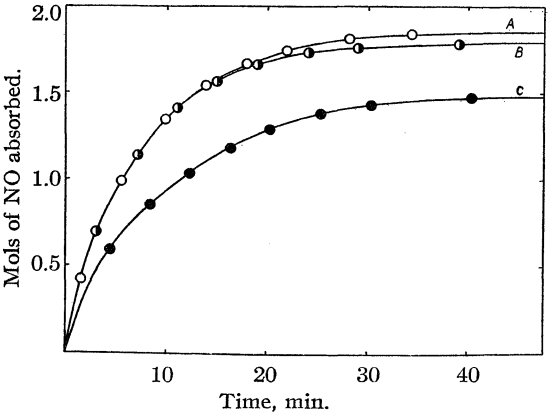

Fig. 2.—Rate of absorption of nitric oxide by solutions of tetraphenylhydrazine in *o*-dichlorobenzene at 95.15°: Curve A, pNO = 1.0 atm.; curve B, pNO = 0.2 atm.; curve C, pNO = 0.1 atm.

curves it is evident that the absorption of nitric oxide did not approach two moles, required for the formation of N-nitrosodiphenylamine, but stopped at 75–95% of this value. We were first inclined to attribute this apparent incomplete

absorption to redissociation of the N-nitrosodiphenylamine and attainment of equilibrium (Equation 2). Although Wieland has established the dissociation of N-nitrosodiphenylamine into nitric oxide at 130°, a sample of the reaction product dissolved in *o*-dichlorobenzene at 100° proved perfectly stable and no nitric oxide was evolved.

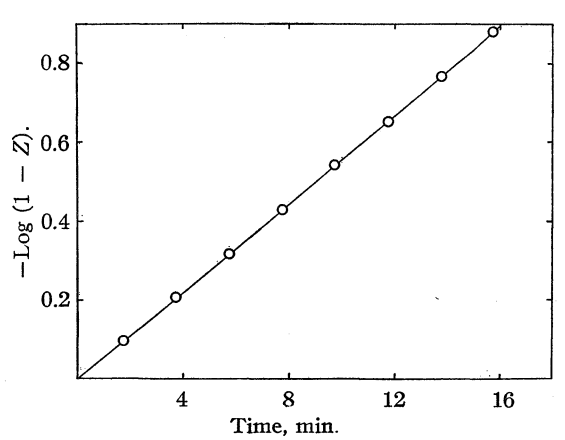

Fig. 3.—Rate of nitric oxide absorption by tetraphenylhydrazine. A plot of data in Table I.

Moreover, the fraction of the theoretical absorption of nitric oxide decreased as the time increased between the introduction of the sealed sample into the reaction flask and the beginning of the reaction. In an extreme case a bulb containing solid tetraphenylhydrazine in a nitrogen atmosphere was maintained at 100° for one hour; at the end of this period the sample was colored dark green and had partially liquefied, indicating extensive decomposition. When the bulb was broken in the absorption flask and the sample dissolved, the total absorption of nitric oxide was only 5.7% of the theoretical. It is evident, therefore, that tetraphenylhydrazine in the solid state undergoes extensive thermal decomposition at 100° to give products which do not react with nitric oxide.

That the reaction between nitric oxide and tetraphenylhydrazine was quantitative was shown in another experiment by dissolving a weighed sample of tetraphenylhydrazine in *o*-dichlorobenzene at 18°, a temperature at which no reaction took place; the solution, in the presence of nitric oxide, was warmed to 100° and maintained at this temperature for one hour. When the reaction mixture was again cooled to 18° the decrease in volume indicated an absorption of 99% of the theoretical amount of nitric oxide. A 94% yield of N-nitrosodiphenylamine was isolated from the reaction mixture on removal of the solvent; the product was identified through a determination of the melting point of a mixture with an authentic sample prepared from diphenylamine.

The reaction between tetraphenylhydrazine and nitric oxide, therefore, is stoichiometric and irreversible at temperatures up to 100°; moreover, the rate of absorption of nitric oxide, at 1 atm. pressure, is greater than the rate of thermal decomposition in *o*-dichlorobenzene. Because solid tetraphenylhydrazine also undergoes a fairly rapid pyrolysis, however, the true concentration of material present at the start of the reaction, *i. e.*, when the bulb was broken, was considerably less than that calculated from the weight of the sample. This initial concentration of tetraphenylhydrazine was calculated from the total absorption of nitric oxide at the completion of the reaction, using the equation given in the experimental section for calculating the theoretical absorption.

It was, of course, impossible to prevent the undesired pyrolysis of the solid tetraphenylhydrazine in our rate experiments but we reduced to a minimum the time between the introduction of the sample and the breaking of the bulb. This

period was rarely more than twenty minutes and under these conditions the absorption approached 85–95% of the theoretical at the higher temperatures and 100% of the theoretical at the lower temperatures.

Mechanism of the Reaction.—If the rate-controlling step involves a direct reaction between tetraphenylhydrazine and nitric oxide, regardless of the mechanism, then the rate must be a function of the nitric oxide concentration. Conversely, if the rate of absorption proves to be independent of the nitric oxide concentration, the nitric oxide cannot be involved in the rate-controlling step. Under the conditions of our experiments the partial pressure of nitric oxide was maintained constant throughout a run; the concentration of dissolved nitric oxide, proportional to the partial pressure, also remained constant since the gas–solution equilibrium was maintained by vigorous shaking. In order to determine the effect of changing the concentration of nitric oxide, therefore, several runs were made at different nitric oxide pressures.

From an inspection of the curves A and B of Fig. 2 it is apparent that the initial rate of absorption is independent of the nitric oxide pressure if this is greater than 0.2 atm. At these relatively high pressures, therefore, the rate-controlling step is a first-order reaction and a direct reaction between tetraphenylhydrazine and nitric oxide is precluded. For very low pressures, however, both the rate and extent of absorption of nitric oxide decrease (Curve C, Fig. 2).

These data, then, parallel those obtained by Ziegler, Orth and Weber for the reaction between hexaphenylethane and nitric oxide at 0°[7]; we believe the mechanisms in the two cases are analogous. The first step in the formation of N-nitrosodiphenylamine is a slow, unimolecular dissociation of tetraphenylhydrazine into free radicals (Equation 4).

$$(C_6H_5)_2N{-}N(C_6H_5)_2 \xrightarrow{\text{slow}} 2(C_6H_5)_2N{-} \quad (4)$$

In the absence of any reagent these radicals may undergo recombination to form tetraphenylhydrazine (Equation 5) or they may undergo an irreversible thermal decomposition (Equation 6). In

$$2(C_6H_5)_2N{-} \longrightarrow (C_6H_5)_2N{-}N(C_6H_5)_2 \quad (5)$$

$$x(C_6H_5)_2N{-} \xrightarrow{\text{fast}} \text{disproportionation products} \quad (6)$$

the presence of nitric oxide at pressures above 0.2 atm., however, the radicals react exclusively with nitric oxide as fast as they are formed (Equation 7). The rate of absorption of nitric

$$(C_6H_5)_2N{-} + NO \xrightarrow{\text{very fast}} (C_6H_5)_2N{-}NO \quad (7)$$

oxide, therefore, depends only upon the rate of formation of the diphenylnitrogen radicals and the over-all reaction is of the first order with respect to tetraphenylhydrazine.

At low partial pressures the small concentration of dissolved nitric oxide results in a decrease in the rate of formation of N-nitrosodiphenylamine (Equation 7); diphenylnitrogen radicals accumulate in the solution and may undergo reactions (5) and (6) as well as (7); the over-all rate becomes a function of the nitric oxide pressure and is less than the rate of dissociation.

For a first-order reaction the time rate of change of concentration may be expressed in the form: $-\log(1 - Z) = kt/2.3$, where Z is the fraction of tetraphenylhydrazine or nitric oxide reacted in time, t, and k is the specific reaction rate constant. In our work the fraction, Z, was determined by dividing the decrease in volume at time t by the total decrease in volume at the completion of the reaction. For such a reaction a plot of $-\log(1 - Z)$ against t should give a straight line the slope of which multiplied by 2.3 is the rate constant. Figure 3 shows such a plot from the data of Table I, and represents a typical evaluation of the rate constant. The precision of the data may be evaluated by comparing columns 5 and 6 of Table I.

Table II shows the effect of changing conditions on the rate constant at 95.15°. It will be noted that the rate constant is independent of the concentration of tetraphenylhydrazine, and of the partial pressure of nitric oxide except at very low values.

TABLE II

VELOCITY OF NITRIC OXIDE ABSORPTION BY TETRAPHENYLHYDRAZINE AT 95.15°

Concn. of tetraphenylhydrazine in moles per liter	Nitric oxide pressure, atm.	Per cent. of theoretical absorption	Rate constant k
0.046	1	82	0.131
.033	1	76	.132
.025	1	89	.127
.042	0.2	90	.128
.019	.2	88	.114
.028	.1	74	.088
Average of all reliable runs made			.130

We have repeated the absorption rate studies at five-degree intervals from 75 to 100° and have

verified this unimolecular character of the rate-controlling step at all temperatures; the results are collected in Table III. At the lower temperatures it was inconvenient to allow the reaction to proceed to completion and a more practicable method was adopted for calculating the rate constant. The reaction was carried to approximately 75% of completion and the total absorption of nitric oxide at infinite time was used as a parameter in plotting $-\log (1 - Z)$ against t; that value was chosen which gave no appreciable departure from a straight line and the rate constant was calculated from the slope of this line. This method is illustrated in Fig. 4 where three curves are plotted selecting values for the total absorption 2.5% too high and too low from the value which gave the best straight line. In a few experiments the two methods were compared; the agreement of the rate constants was usually within 2%.

TABLE III

VELOCITY OF NITRIC OXIDE ABSORPTION BY TETRAPHENYLHYDRAZINE

Temp., °C.	Av. vel. constant k, min.$^{-1}$	Half-life, min.	No. of runs	Mean error of mean, %
75.20	0.0119	58.3	2	1.7
80.20	.0230	30.2	4	1.7
85.20	.0397	17.5	4	2.5
90.2	.0670	10.4	4	1.8
95.15	.130	5.35	4	1.0
100.10	.222	3.13	5	2.0

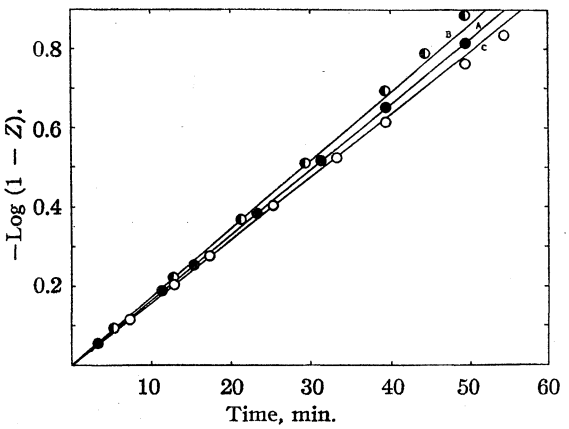

Fig. 4.—Rate of absorption of a 0.04 molar solution of tetraphenylhydrazine in *o*-dichlorobenzene at 85.20° showing alternative method of calculating rate constant: pNO = 1.0 atm.; Curve A, filled circles, total absorption assumed to be 40.0 cc.; Curve B, half-filled circles, total absorption assumed to be 39.0 cc.; Curve C, open circles, total absorption assumed to be 41.0 cc. It is apparent that the curves on either side of A diverge; rate "constants" for the three curves are: for C, 0.0365; for A, 0.0382; for B, 0.0401. The curves are exaggerated to illustrate the principle of the method; in practice absorptions of 39.5 cc. and 40.5 cc. would be assumed. The rate constant was determined from the slope of curve A, which shows no perceptible deviation from a straight line.

The energy of activation, E, for the rate-controlling step was calculated from the Arrhenius equation, $\log k = E/2.3RT + C$, where R is the gas constant, T the absolute temperature and C the integration constant. A plot of $\log k$ against the reciprocal of the absolute temperature gave a straight line (Fig. 5) the slope of which multiplied by 2.3 R gave 30 kcal. as the heat of activation. We consider that this value is accurate to ±1.5 kcal.

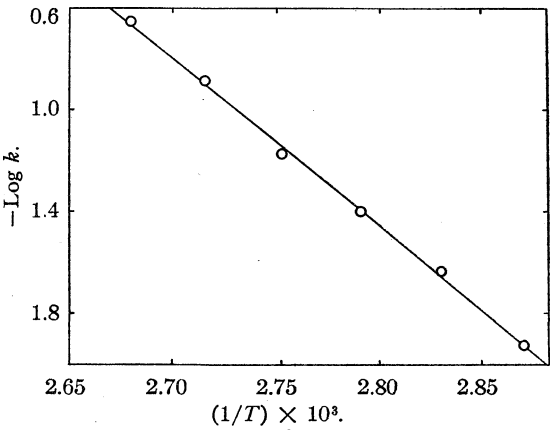

Fig. 5.—The rate of dissociation of tetraphenylhydrazine at different temperatures.

The energy of activation for a dissociation process, E_d, is of considerable significance since it represents a maximum value for the strength of the bond broken and is related to the bond strength, ΔH, by the equation $\Delta H = E_d - E_a$, where E_a is the activation energy for the association of the resulting radicals. The carbon–carbon bond strength in hexaphenylethane, 11.5 kcal.,[9] represents a marked decrease from the normal carbon–carbon bond strength of ethane, 58.6 kcal.,[10] an average reduction of 8 kcal. per phenyl group. The activation energy for the dissociation process likewise decreases as phenyl groups are substituted for hydrogen atoms. The activation energies for the dissociation of pentaphenylethane and hexaphenylethane are, respectively, 27.6 kcal.[11] and 19.5 kcal.[6] It will be noted that the difference, 8 kcal., is identical with

(9) Ziegler and Ewald, *Ann.*, **473**, 163 (1929).

(10) Pauling, "The Nature of the Chemical Bond," Cornell University Press, Ithaca, N. Y., 1939.

(11) Bachmann and Wiselogle, *J. Org. Chem.*, **1**, 359 (1936).

the average effect on the bond strength of replacing a hydrogen atom by a phenyl group.

Recently Hughes, Corruccini and Gilbert[12] have redetermined the heat of combustion of hydrazine, H_2N-NH_2, making possible a calculation of the strength of the normal N–N bond from thermochemical data. From the energy of formation of gaseous hydrazine from the elements, 22.25 kcal., the energy of dissociation of hydrogen, 103.8 kcal.,[13] and the energy of dissociation of nitrogen, 170.2 kcal., the energy of formation of gaseous hydrazine from the atoms may be calculated. This energy, 355.6 kcal., may be considered to be composed of two terms, one involving four N–H bonds and the other involving the N–N bond. If we assume that the average N–H bond strength in hydrazine is the same as in ammonia, 83.9 kcal., the energy of dissociation of hydrazine into divalent nitrogen radicals is 20 kcal. (Equation 8).[14]

$$N_2H_4(g) \longrightarrow 2NH_2^{\cdot}(g) \qquad \Delta H = 20 \text{ kcal.} \quad (8)$$

The energy of activation for the dissociation of tetraphenylhydrazine is greater than the energy of dissociation of hydrazine, in marked contrast to the lowering of bond strength and activation energy by substituting phenyl groups for hydrogen atoms in the ethane series. If the substitution of an aryl group for a hydrogen atom in hydrazine lowers the bond strength, then the energy of activation for the coupling of two divalent nitrogen radicals must be inordinately high. A rigorous test of this must await a determination of the energy of dissociation of tetraphenylhydrazine.

Acknowledgment.—We are indebted to E. I. du Pont de Nemours and Company for a fellowship held by one of us (C. K. C.) and to the Hynson, Westcott and Dunning Research Fund for a grant-in-aid covering a part of the cost of this research.

Summary

A study has been made of the kinetics of the reaction between tetraphenylhydrazine and nitric oxide at 75 to 100°. Although solid tetraphenylhydrazine undergoes rapid decomposition at 100°, solutions in *o*-dichlorobenzene absorb nitric oxide quantitatively and irreversibly to give N-nitrosodiphenylamine. For nitric oxide pressures above 0.2 atm. the rate-controlling step is independent of the nitric oxide pressure and is undoubtedly the dissociation of tetraphenylhydrazine into free diphenylnitrogen radicals. The half-life of tetraphenylhydrazine at 100° is 3.1 minutes and the energy of activation for the dissociation is 30 ± 1.5 kcal. This activation energy is 10 kcal. greater than the energy of dissociation of hydrazine calculated from recent thermochemical measurements.

BALTIMORE, MD. RECEIVED FEBRUARY 17, 1940

(12) Hughes, Corruccini and Gilbert, THIS JOURNAL, **61**, 2639 (1939).

(13) The data for the bond strengths in ammonia and for the heats of dissociation of hydrogen and nitrogen were taken from Pauling, "The Nature of the Chemical Bond," Cornell University Press, Ithaca, 1939, and Bichowsky and Rossini, "The Thermochemistry of the Chemical Substances," Reinhold Publishing Corp., New York, N. Y., 1936.

(14) This N–N bond strength is 4 kcal. less than that calculated by Pauling who used the average value for the heat of combustion of hydrazine cited in Bichowsky and Rossini (*loc. cit.*). It should be noted that the assumption of the equality of the N–H bond strengths in ammonia and in hydrazine has not received the empirical support which is available for other bonds such as C–H and O–H. We do know that the successive removal of hydrogen atoms from ammonia requires widely different energies. Thus the heat of dissociation of NH, 102.2 kcal., which is accurately known from spectroscopic data is much greater than the average strength of the N–H bonds in ammonia.

The Mechanism of the Esterification of Strong Organic Acids. The Esterification of Neopentyl Alcohol with the Chloroacetic Acids[1,2]

BY OSBORNE R. QUAYLE AND HARRY M. NORTON[3]

The origin of the hydrogen and hydroxyl groups which form water in esterification has been the subject of much investigation. Since the work of Reid[4,5] with the sulfur analogs of both alcohols and acids, it has been conceded that in the case of weak organic acids the hydrogen only is from the alcohol. This has been confirmed by the esterification of methyl alcohol containing a high percentage of heavy oxygen.[6] The question has remained as to whether the course of the reaction with strong organic acids is the same or whether these acids provide only the hydrogen, acting similarly to the strong mineral acids such as hydrochloric.

Neopentyl alcohol was esterified with a series of carboxylic acids varying widely in strength.

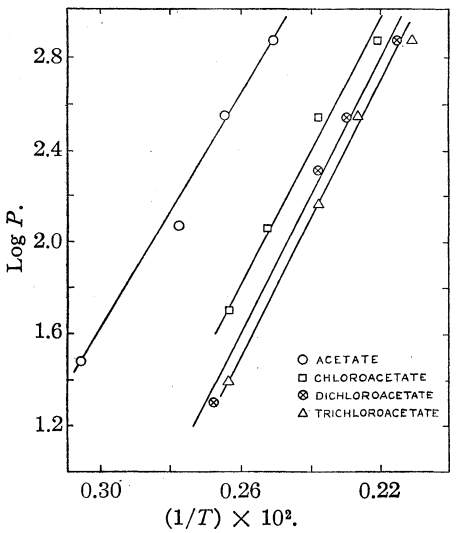

Fig. 1.—Vapor pressure of neopentyl esters.

This alcohol was chosen because of its unique property of rearranging if the electronic structure

$$CH_3:\ddot{C}:\ddot{C}:H$$
$$\quad\ddot{C}H_3\ddot{H}$$

is destroyed.[7,8,9,10] The removal of the hydroxyl group would break this structure; the removal of only hydrogen would not. Rearrangement of the neopentyl system yields *t*-amyl derivatives and is accompanied by the formation of unsaturated derivatives.

The neopentyl esters were made of chloroacetic, dichloroacetic and trichloroacetic acids, in addition to that of acetic acid previously discussed by Whitmore.[7] These esters when treated with bromine in a quantitative manner showed no evidence of the unsaturation which accompanies rearrangement.

Small portions of each ester (10 g.) were saponified and the resulting alcohol was identified in each case as neopentyl alcohol. Identification was established by mixed melting point determinations on the original alcohol with the alcohol obtained on saponification and on the *p*-nitrobenzoate derivatives. Since neopentyl alcohol was obtained from each ester, the neopentyl con-

figuration had been maintained throughout all esterifications and saponifications. The linkage between the oxygen and carbon of the alcohol had been maintained at all times and the mechanism of the reaction is the same regardless of the strength of the acid.

Experimental

The neopentyl alcohol was prepared by the Grignard reaction from *t*-butyl chloride and formaldehyde gas. The latter was prepared by heating paraformaldehyde dried *in vacuo* over concentrated sulfuric acid for five days. Satisfactory yields of the acetates were obtained by standard methods.

The esters were hydrolyzed by 25% potassium hydroxide. The alcohol produced in each case was dried and the *p*-nitrobenzoate and the 3,5-dinitrobenzoate were made. No depressions in mixed melting point determinations were found, indicating that the alcohol obtained upon saponification was in each case neopentyl alcohol.

Table I and Fig. 1 summarize the experimental data obtained.

Summary

Neopentyl acetate, chloroacetate, dichloroacetate and trichloroacetate have been prepared, hydrolyzed and the resulting alcohol identified as neopentyl alcohol. No evidence of any rearrangement of the neopentyl group was obtained.

The refractive index, specific gravity at three temperatures, and boiling points at four pressures have been determined for each of the esters prepared.

The melting points of the 3,5-dinitrobenzoate and the *p*-nitrobenzoate of neopentyl alcohol are reported.

The conclusions are drawn (1) that in the esterification of alcohols by carboxylic acids varying in strength from that of glacial acetic to that of trichloroacetic, the water removed is composed of the hydrogen from the alcohol and the hydroxyl from the acid; (2) that in the hydrolysis of these esters the rupture of the carbon–oxygen linkage occurs between the oxygen of the alcohol residue and the carbon of the acid group.

The Action of Elementary Fluorine Upon Organic Compounds. VIII. The Influence of Dilution on the Vapor Phase Fluorination of Ethane[1]

BY DEWALT S. YOUNG, NOBUKAZU FUKUHARA AND LUCIUS A. BIGELOW

In a previous paper of this series[2] we have described the vapor phase fluorination of ethane, using the pure gases in progressively varying proportions. The chief products were carbon tetrafluoride and hexafluoroethane, together with some higher boiling, partially fluorinated material, the liquid volume of which never exceeded 30% of the total condensate. This paper presents the results obtained when the fluorine was diluted progressively with nitrogen. They showed that the yield of the desired fluoroethanes could be raised to 90% of the total condensate under appropriate conditions.

The fluorinations were run in a metal apparatus, over copper gauze, as described before,[2] except that nitrogen, measured by a flowmeter, was introduced into the fluorine line. Two reaction chambers were used in series at the three highest dilutions, and adequate precautions taken throughout to avoid back pressure. The products were subsequently rectified in a Booth–Podbielniak low temperature fractionating unit,[2] and the higher boiling constituents divided into a number of empirically chosen cuts, from which pentafluoroethane CF_3CHF_2, *sym*-tetrafluoroethane CHF_2CHF_2, and 1,1,2-trifluoroethane CHF_2CH_2F were later isolated. However, no mono- or difluoroethanes were found, even when the fluorine was highly diluted.

Since it is known that alkyl monofluorides such as ethyl fluoride tend to be unstable, and also that ethylene fluoride decomposes spontaneously at 0°,[3] it seemed possible that these compounds, if formed at all, might have been decomposed immediately over the catalyst at the temperature of the reaction zone. Granting this, the fluorination

(1) This paper has been constructed in part from portions of Mr. Young's Doctorate Thesis, presented to the Graduate School of Duke University in October, 1939.

Total vol. of condensate for 10 hr. in ml.	20	23	23	22	22	14	14	14	12	9[b]	8[b]	10

[a] From ref. 2 for comparison. [b] After the removal of SiF_4.

of ethane may perhaps be represented simply as follows.

$$C_2H_6 \xrightarrow{F_2} CH_3CH_2F \xrightarrow{-HF} CH_2{=}CH_2 \xrightarrow{F_2}$$
$$CH_2F{-}CH_2F \xrightarrow{-HF} CHF{=}CH_2 \xrightarrow{F_2}$$
$$CHF_2{-}CH_2F \xrightarrow{F_2} CHF_2{-}CHF_2 \xrightarrow{F_2}$$
$$CF_3CHF_2 \xrightarrow{F_2} C_2F_6$$

This formulation, naturally, is to be regarded as subject to further experimental confirmation, but it is supported to some extent by the observations of Hass, McBee and Weber, working with vapor-phase chlorination.[4] They noted that such thermal decompositions took place to a greater extent in the presence of free chlorine than when the corresponding alkyl halides were heated alone. This was in accord with their free radical, chain mechanism for chlorination, which would seem to apply equally well to fluorination. They also state that in vapor phase chlorinations, there is a tendency against the formation of dihalides with two chlorine atoms attached to the same carbon atom. Correspondingly, the suggested scheme does not predict the formation of the compound CH_3CHF_2, or even of CH_3CF_3, and actually neither of these was found.

Table I shows the quantities of the original fractions produced, expressed in liquid volume per cent. of the total condensate in the same run, as compared with the gas volume ratios of the reactants. In order to make the recorded values really significant, the figures have been rounded off to the nearest 5%, but naturally this increased considerably the deviation of the total from one hundred in some cases.

Two series of runs were made, in which the volume ratios of fluorine to ethane were 2:1 and 4:1, respectively. In the first case, the proportion of the product boiling higher than hexafluoroethane ($-78°$) rose progressively to 45% when the ratio of fluorine to nitrogen was 1:2; after which further dilution had but little effect, and much of the ethane was being recovered unchanged. When the figures were recalculated on the basis of the ethane actually fluorinated, this value continued to rise to 95%, when the fluorine to nitrogen ratio was 1:4. In the second series, it should be noted that when the dilution ratio exceeded 1:3, essentially no organic product boiling below $-50°$ was obtained. However, due to the incomplete absorption of hydrogen fluoride under these conditions, the material contained a considerable amount of silicon tetrafluoride. This compound has no liquid range at atmospheric pressure, sublimes at $-90°$, and was difficult to handle in the still. In this series, in which most of the ethane reacted, the proportion boiling above $-78°$ rose to 90% when the dilution ratio was 1:3, after which there was little further change even when the ratio was increased to 1:20. From these results it was clear that the higher boiling, partially fluorinated ethanes readily could be formed in excellent yield by diluting the fluorine appropriately with nitrogen. It will be seen also that as the dilution was increased, distinct accumulations of material, amounting under favorable conditions to 30–40% of the total condensate were formed in the boiling ranges of -50 to $-40°$, -28 to $-19°$, and above $-19°$; while less and less of the product boiled below $-50°$, as would be expected. The sudden disappearance of hexafluoroethane, and the corresponding increase in the fraction boiling from -28 to $-19°$ when the dilution ratio was increased above 1:2, are worthy of note. Also, in considering the results it should be recognized that in these experiments no attempt has been made to control either

(4) Hass, McBee and Weber, *Ind. Eng. Chem.*, **28**, 333 (1936).

the temperature of the reaction zone or the time required for the gases to pass through it. We hope to make a study of the influence of these important factors later on.

Although a constant boiling fraction (b. p. about −48°) had been observed from the first,[5] repeated distillation of the product boiling from −50 to −40° at atmospheric pressure failed to separate it into pure components. However, on redistillation at elevated pressure, a pure compound was isolated, boiling at −38° at 1200 mm., and −48.5° at atmospheric pressure. It froze sharply at −103°, and had a molecular weight of 119. This was the hitherto unknown pentafluoroethane, CF_3CHF_2 (mol. wt. 120).

Anal. Calcd. for C_2HF_5: F, 79.2. Found: F, 79.0, 79.1.

When the material boiling in the range from −28 to −19° was distilled at reduced pressure, a fraction was isolated, boiling at −46 to −50° at 200 mm., which on redistillation at atmospheric pressure yielded another pure compound boiling from −23.5 to −22.5° with a molecular weight of 101–102. This was *sym*-tetrafluoroethane (b. p. −23°,[6] mol. wt. 102).

Anal. Calcd. for $C_2H_2F_4$: F, 74.5. Found: F, 74.5, 74.2.

Most of the product boiling above −19° consisted of a third pure compound, boiling at 3°, and freezing at −84°, with a constant molecular weight of 84. This was undoubtedly 1,1,2-trifluoroethane (b. p. 5°,[6] mol. wt. 84).

Anal. Calcd. for $C_2H_3F_3$: F, 67.8. Found: F, 67.8, 67.9.

(5) Calfee and Bigelow, THIS JOURNAL, **59**, 2072 (1937).
(6) Henne and Renoll, *ibid.*, **58**, 887, 889 (1936).

In addition to these compounds, a small amount of material was isolated boiling at −56 to −55°, and freezing at −132°, with a molecular weight of 103, but the quantity obtained was insufficient for analysis. Also, a constant boiling mixture, b. p. −19°, mol. wt. 92–98, was obtained, at times in considerable amounts, as well as small quantities of other materials, but these were not separated. No trace of ethyl fluoride (b. p. −38°) was found, even in a special run in which the ratio of fluorine to ethane was 2:6, although in this case over a quarter of the product boiled in the vicinity of 26° with a molecular weight of 70–75.

The writers are glad to express here their appreciation to Mr. Elbert H. Hadley for valuable assistance, and to the Duke University Research Council for a grant.

Summary

A study has been made of the influence of nitrogen dilution on the vapor-phase fluorination of ethane, and it has been found that a mixture of partially fluorinated ethanes can be obtained in excellent yield under suitable conditions.

Pentafluoroethane CF_3CHF_2, *sym*-tetrafluoroethane CHF_2CHF_2 and 1,1,2-trifluoroethane CHF_2CH_2F have been isolated from the reaction products boiling above −78°. The first of these is a new compound, and the others have not been prepared previously by direct fluorination.

The Synthesis of Some New Pyrimidines and Uric Acids fom Cystamine[1]

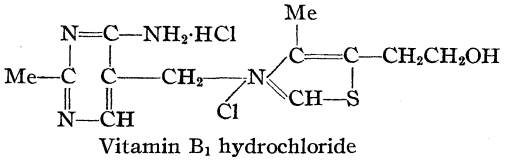
BY EDWARD JAMES MILLS, JR.,[2] AND MARSTON TAYLOR BOGERT

Attention recently has been directed increasingly to the important role played by various organic sulfur compounds concerned with vital physiological processes, and the present paper is a contribution in a field whose exploration seems to hold promise of interesting and perhaps useful results.

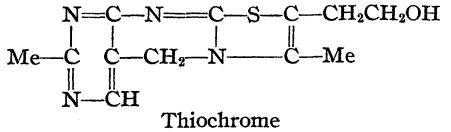
The great therapeutic value of Vitamin B_1, and its structural relationship to thiochrome, suggests the possibility of discovering other remedial drugs containing both the pyrimidine and thiazole nuclei, perhaps even when these two cycles have coalesced to a single bicyclic system with two atoms common to each of its constituent rings.

(1) Presented before the Organic Division at the Cincinnati Meeting of the American Chemical Society, April 8, 1940.
(2) E. R. Squibb & Sons Research Fellow at Columbia University, 1937–1939; present address, Department of Anatomy, College of Physicians and Surgeons, Columbia University, New York.

Fusion of the pyrimidine and thiazole, or of the purine and thiazole, cycles obviously will result in different structures depending upon the points of attachment of the two rings.

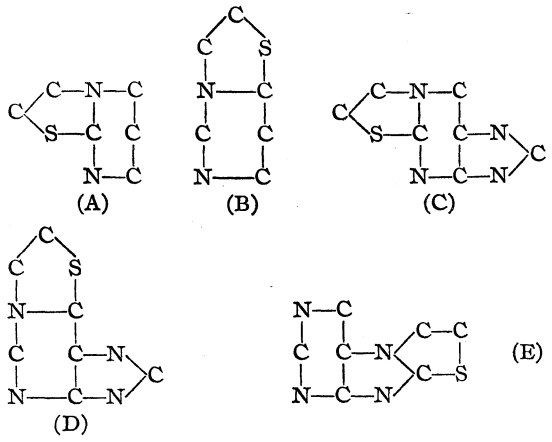


Vitamin B_1 hydrochloride



Thiochrome

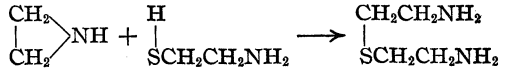
The polycyclic systems with which this communication deals are represented by skeletons (A), (B), (C) and (D):



For the synthesis of derivatives of (A), (B), (C) or (D), a convenient initial material is *beta*-mercaptoethylamine, and the Flow Sheets beyond show the progress made by utilizing that compound.

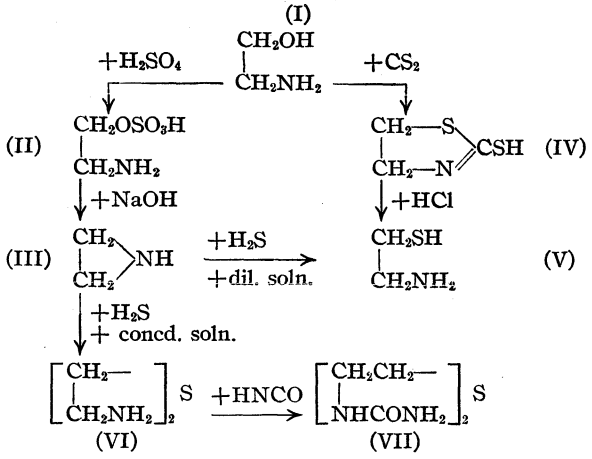
In 1936, Ochiai,[3] and Ochiai and Kitagawa,[4] prepared compounds containing the skeleton (E), but gave no information concerning their pharmacological properties.

The *beta*-mercaptoethylamine (V) required for our experiments was prepared by the hydrolysis of 2-mercaptothiazoline (IV), and also by the action of hydrogen sulfide upon a dilute solution of ethyleneimine (III). Of the two processes, the latter was the more satisfactory. The reaction in this case, as shown on Flow Sheet A, is a simple one, whether the cyclic (III), or the acyclic formula (CH_2=$CHNH_2$), be assigned to the imine. It was attempted by Gabriel and Eschenbach[5] many years ago, by passing hydrogen sulfide through ethyleneimine cooled to 0°, but their product was the sulfide (VI) and not the mercaptan (V) or its oxidation product the disulfide (VIII). It seems likely that this was due to a secondary reaction between the mercaptan first formed and the remaining unaltered imine.



A study of this problem and some preliminary experiments, convinced us that the conditions for optimum yields of the mercaptan (V) desired, or of the disulfide (VIII), would be (1) high concentration of hydrogen sulfide, (2) low concentration of the imine (III), and (3) low local concentration of the mercaptan (V) formed, to avoid the production of the monosulfide (VI). As described in detail beyond, the application of these conclusions resulted in yields of the mercaptoethylamine amounting to 85–95% of that calculated.

FLOW SHEET A



By oxidation, the mercaptan was easily converted into the disulfide (VIII) (cystamine or decarboxycystine), whose urea derivative (IX) may prove of interest if it should be found to possess hypoglycemic properties resembling those reported by Ackerman and Heinsen[6] for the analogously constituted diguanidino-diethyldisulfide. It is hoped that it also can be examined, together with its disulfoxide, to determine the effect, if any, upon the regulation of growth by cell proliferation, that phenomenon of natural chemical control of growth by sulfhydryl-disulfide–disulfoxide systems which has been studied so extensively and so ably by Hammett and his co-workers.[7]

The disulfide uric acid (XVII) also may merit attention in connection with cell proliferation studies, since it is structurally a uric acid with an alkyl disulfide side chain, or a cystamine in which the terminal nitrogen atoms form a part of two purine nuclei.

As will be observed, all of these compounds, as shown on Flow Sheet B, were retained in the stable disulfide form, to simplify purification and to avoid complications which would arise were a free mercapto group present. The reduction of the disulfide to the mercaptan was postponed purposely until it became necessary to reduce the disulfide uric acid (XVII) for the preparation of the *beta*-mercaptoethyl derivative and its cyclization product the thiazolidinouric acid.

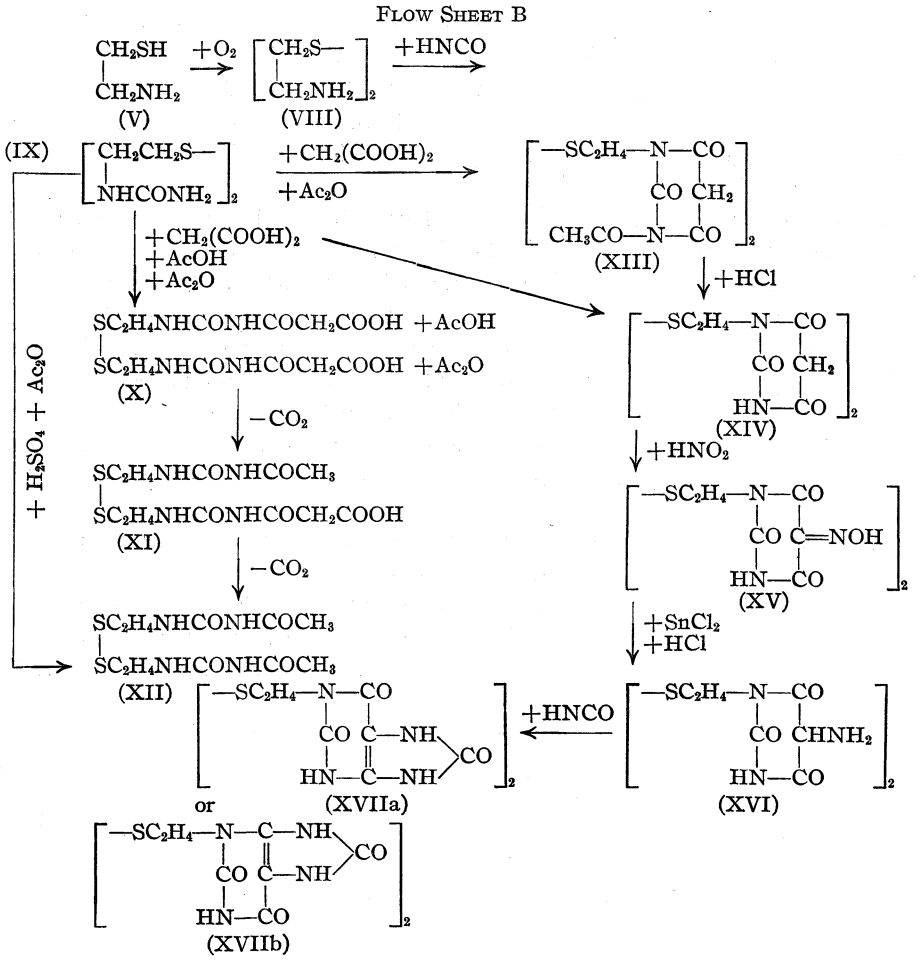
FLOW SHEET B



It has been learned that pyrimidines of type XIV, carrying either a *beta*-mercaptoethyl or an alkyldisulfide side chain in position 1, are very sensitive to alkaline solutions, the cycle tending to break open between positions 1 and 6, with formation of malonuric acids of the structure $RNHCONHCOCH_2COOH$. For this reason, the use of sodium ethylate as a condensing agent[8] in the preparation of these barbituric acids was not satisfactory.

This is in line with the findings of Aspelund and Skoglund,[9] who reported that 5,5,-1-trisubstituted barbituric acids were split by alkalies into both $RNHCONHCOCR_2COOH$ and $H_2NCONRCOCR_2COOH$, the former being produced in the larger quantity.

On the other hand, such pyrimidines are quite stable to acid solutions. The 3-acetyl derivative (XIII), for example, could be hydrolyzed readily to the unacetylated compound (XIV) by the action of hot 30% hydrochloric or sulfuric acid, without any apparent rupture of the pyrimidine cycle.

From the cystamine urea (IX), by condensation with malonic acid, in the presence of acetic acid and acetic anhydride, according to the method of Biltz and Wittek,[10] and Hepner and Frenkenberg,[11] the barbituric acid (XIV) was obtained, together with its acetyl derivative (XIII) and the dimalonuric acid (X). The latter (X) yielded the barbituric acid (XIV) when digested in glacial acetic acid solution with acetic anhydride; and the same product resulted when the acetyl derivative (XIII) of the barbituric acid was hydrolyzed by mineral acid.

Treatment of a mixture of the cystamine urea and malonic acid (IX) with acetic anhydride at 85–90°, also gave the acetylated barbituric acid (XIII).

The dimalonuric acid (X), when heated alone or with weakly acid solutions, lost first one and then a second mole of carbon dioxide, yielding successively the acetyl malonuric acid (XI) and then the diacetyl derivative (XII). The latter was also formed when the diureido disulfide (IX) was dissolved in acetic anhydride, a few drops of concentrated sulfuric acid added, and the mixture heated for three hours at 100°.

Grimaux[12] reported that when a mixture of urea and malonic acid was treated with phosphorus oxychloride, there resulted barbituric acid and an unidentified by-product, which latter was also formed when pure barbituric acid was

subjected to the action of phosphorus oxychloride. Conrad and Guthzeit,[13] repeating this work, concluded that this by-product was probably the 5-acetylbarbituric acid, arising from the decomposition of the malonic acid into carbon dioxide and acetic acid.

Sembritzky[14] has described a 1,3-diethyl-5-acetylbarbituric acid, produced by heating a mixture of diethylurea, malonic acid and phosphorus oxychloride in sealed tubes at 100°. Biltz and Wittek,[10] in developing their method of preparing N-alkylated barbituric acids from substituted ureas, malonic acid, and acetic anhydride, found that an excess of the latter led to the formation of acetylated barbituric acids. Using monomethylurea, malonic acid, acetic anhydride and sulfuric acid, they obtained what they believed to be the 1-methyl-5-acetylbarbituric acid, and prepared therefrom an oxime, a hydrazone and a phenylhydrazone. Further, acid hydrolysis of this acetyl derivative yielded no 1-methylbarbituric acid. These experimental observations led them to assign position 5 to the acetyl group. While such proof would be acceptable in the case of a 1,3-dialkylbarbituric acid, it is not so convincing for a monoalkylated acid, since the remaining NH group is easily acetylated and the resulting acetyl derivative is fairly resistant to de-acetylation by acids.

The acetyl derivative (XIII) obtained by us, when refluxed for six to eight hours with concentrated hydrochloric acid, gave the expected disulfide barbituric acid (XIV), while its sodium violurate was deep red. Based upon these experiments, and upon the analytical results for both (XIII) and (XIV), we believe that compound (XIII) carries its acetyl group in position 3 and not 5.

From the barbituric acid (XIV), the violuric acid (XV) was secured either by the action of sodium nitrite or, better, by treatment with isoamyl nitrite in acid solution.

For the reduction of violuric acids to uramils, such reagents as hydriodic acid,[10,15] hydrogen sulfide,[15] ammonium sulfide,[16,17] and sodium hydrosulfite,[18] have been used. Inasmuch as the uramil derivative was to be treated with cyanic acid, for conversion into the corresponding uric acid, the reducing agent employed had to be one which would attack only the isonitroso group and not the disulfide linkage. Such a selective reduction was accomplished by using stannous chloride and hydrochloric acid, with yields of the uramil about 50% of that calculated.

The experiments of Fruton and Clarke[19] have shown that, in solutions of *p*H 7, the reaction $RSSR \rightleftarrows 2RSH$ is a thermodynamically reversible system, the oxidation–reduction potential being a function thereof, independent of the substituents and equal to −0.23 volt for the reaction as written. Since the normal oxidation–reduction potential for the $Sn^{++++} \rightleftarrows Sn^{++}$ system equals +0.13 volt,[20] and since oximes and isonitroso compounds are irreversibly reduced to the amines by stannous chloride in hydrochloric acid solution,[21] it was concluded that no considerable reduction of the disulfide linkage would occur unless this reagent were used in large excess.

From this uramil (XVI), the uric acid derivative (XVII) was produced by the action of nitrourea, as a white crystalline solid, which remained unmelted at 350°. No intermediate pseudouric acid was detected. Apparently the urea group in position 5 of the pyrimidine cycle closed to the glyoxaline ring as soon as formed.

Manifestly, the method of synthesis does not enable us to decide whether the correct structure for the final product should be represented by (XVIIa) or (XVIIb). The synthesis of one or the other of these by a method which will resolve this uncertainty is now under way and the results will be reported later.

Preliminary experiments for the reduction of the disulfide uric acid (XVII) to the corresponding *beta*-mercaptoethyl derivative have been disappointing and, as it will be sometime before an additional supply of the disulfide can be synthesized, it has seemed to us desirable to record the results of our work to date. It remains to be ascertained also whether the *beta*-mercaptoethyl derivative so formed will close up spontaneously to a thiazolidinouric acid of (C) or (D) structure, or can be so cyclized by appropriate treatment.

Acknowledgments.—We are indebted to Drs. A. Wilbur Duryee and J. Nybor, of the New York Post Graduate Medical School, for the physiological tests with ethyleneimine reported in this

paper; and to Mr. Saul Gottlieb of our own Organic Laboratories, for the microanalyses which appear in the Experimental Part.

Experimental

beta-**Mercaptoethylamine** (V) was prepared from commercial ethanolamine (I) by two different routes: (a) *via* 2-mercaptothiazoline (IV), and (b) *via* ethyleneimine (III).

(a). **2-Mercaptothiazoline** was obtained from ethanolamine and carbon disulfide essentially as described by Knorr and Rössler,[22] and this in turn hydrolyzed to the mercaptoethylamine by the action of concentrated hydrochloric acid, as recorded by Gabriel and Leupold.[23] This gave a yield of hydrochloride practically equal to that calculated; white crystals, m. p. 70.2–70.7° (cor.); m. p. in the literature,[24] 70–72°. The free base, sublimed *in vacuo*, melted at 97–98.5°. Gabriel and Colman[25] gave the m. p. as 99–100°. It was further identified by oxidation in aqueous solution, with 30% hydrogen dioxide, to taurine.

Ethyleneimine (III) was prepared from commercial ethanolamine (I), by the process of Wenker.[26] The total yield of the intermediate *beta*-aminoethylsulfuric acid (II) was 85.9%; of the ethyleneimine from this, 25–30%, b. p. 54–56°. Wenker gives the b. p. as 55–56.5°.

This imine is strongly caustic and burns the skin. Inhalation of the vapors causes acute inflammation of the eyes, nose and throat, with symptoms resembling those of bronchitis. After two to three days, the irritation subsides and the tissues return to normal, without suffering any apparent permanent injury. Danehy and Pflaum[27] also have called attention to the toxicity of this compound.

Through the courtesy of Drs. A. Wilbur Duryee and J. Nybor, of the New York Post Graduate Medical School, some physiological experiments were carried out on a white rabbit, weighing 5.4 lb., to ascertain the effect of ethyleneimine upon the heart, since one of the authors (Mills) suffered some cardiac disorders while working with this substance.

The rabbit was subjected to an abdominal injection of 1 cc. of a $M/6$ solution of the imine in water (0.89 cc./100 cc. water). Electrocardiographic studies of this animal showed no marked cardiac changes.

After ten days, an intra-peritoneal injection of 2 cc. of a solution of 1.8 cc. of the imine in 100 cc. of water (*ca.* $M/3$) was given, and still no marked heart damage was detected. But within three days the rabbit died, and the post-mortem examination disclosed a gross hemorrhage of the lungs, congested and swollen kidneys, a flabby heart and a severe peritonitis.

A cooled solution of 91.1 g. (2.1 mols) of ethyleneimine in 819 cc. of absolute ethanol was added dropwise (three to four hours) to 200 cc. of chilled absolute ethanol surrounded by an ice pack, while a current of hydrogen sulfide was passed through the well stirred mixture. The solution was concentrated under reduced pressure to 50–75 cc., in the absence of air, to avoid oxidation of the mercaptan, and the concentrate well cooled. The mercapto amine separated as a white solid, which was air-dried, washed with petroleum ether and dried again, when it melted at 97–98.5° (cor.); yield, 139 g., or 85.5%. The free base had a disagreeable odor, and oxidized to the disulfide on standing in the air.

beta,beta'-**Diamino-ethylsulfide (Thioethylamine)** (**VI**).—When a 25% (or stronger) solution of ethyleneimine in 95% ethanol was treated with a stream of hydrogen sulfide, without either cooling or stirring, and the mixture was then concentrated under diminished pressure, the *beta, beta'*-diamino-ethylsulfide separated as a yellowish oil. It has been described by Gabriel and his collaborators.[28] Our product was identified by conversion into the corresponding compound, VII.

beta,beta'-**Diureido-ethylsulfide** (**VII**).—The crude thioethylamine (VI), in aqueous solution, was subjected to the action of nitrourea in excess.[29,30,31] After heating the solution at 100°, it was evaporated to dryness under reduced pressure, and the diureide (VII) crystallized from water. It formed white crystals, m. p. 221–222° (cor.).

Anal. Calcd. for $C_6H_{14}O_2N_4S$: C, 34.9; H, 6.8; N, 27.2. Found: C, 34.6; H, 6.5; N, 27.7.

Cystamine (*beta,beta'*-**Diamino-ethyldisulfide, Dithioethylamine**) (**VIII**).—The mercaptoethylamine was dissolved in slightly more than sufficient water, or 95% ethanol, to effect solution, and a current of oxygen was bubbled through until the solution no longer reduced a solution of iodine in potassium iodide, by which time the characteristic unpleasant odor of the mercaptan had disappeared. Concentration of this solution under reduced pressure yielded a thick oil. This was dehydrated by repeated addition of absolute ethanol and evaporated *in vacuo*, since the oil could not be distilled without decomposition.

Dihydrochloride.—An aqueous or alcoholic solution of the disulfide was mixed with an excess of alcoholic hydrochloric acid and the mixture evaporated to a small volume of viscous material under diminished pressure. Addition of a small amount of methanol, or ethanol (95% or absolute), precipitated the dihydrochloride as a white solid, which was removed and washed with a little chilled alcohol. More of the salt was recovered from the filtrate by similar treatment. The yield from the mercaptan was practically that calculated from the original imine, about 65%.

Anal. Calcd. for $C_4H_{14}N_2S_2Cl_2$: C, 21.3; H, 6.3; N, 12.4. Found: C, 21.6; H, 6.3; N, 12.2.

This salt when heated began to shrink at about 206° (cor.), and melted at 212–212.5° (cor.). Coblentz and Gabriel,[32] and Coblentz,[33] reported its m. p. as 203°, whereas Fruton and Clarke[19] found 214°.

beta,beta'-**Diureido-ethyldisulfide** (**IX**).—To one mol of the cystamine (VIII), in aqueous or alcoholic solution, 2.2 mols of nitrourea was added slowly, while heating care-

fully to control the reaction. After about an hour at 100°, the gas evolution ceased, and the solution was evaporated to dryness *in vacuo*. The residual solid was crystallized repeatedly from water or alcohol, in both of which it was quite soluble hot and very difficultly soluble cold. The pure compound formed white crystals, m. p. 166–167° (cor.).

Anal. Calcd. for $C_6H_{14}O_2N_4S_2$: C, 30.2; H, 5.9; N, 23.5. Found: C, 30.3; H, 5.8; N, 23.6.

Ethyldisulfide-*beta,beta'*-dimalonuric Acid (X).—By the usual sodium ethylate condensation of the diureido disulfide (IX) with malonic ester, in absolute ethanol solution at 105–110°, this dimalonuric acid was obtained, with small amounts (2–3%) of the dibarbituryl disulfide (XIV). A better method of preparing the dimalonuric acid follows.

A mixture of 4.7 g. of the diureido disulfide and 4.2 g. of malonic acid was dissolved in 25 cc. of glacial acetic acid at 50° and to this mixture, stirred under a reflux and protected from ingress of moisture, there was added slowly (thirty to sixty minutes) 9.2 g. of acetic anhydride, while the mixture was heated to 65–70°. This was followed by four hours of heating at 70–80°, and three hours at 80–90°, after which the mixture was permitted to cool. The yellowish precipitate of the dibarbituryl disulfide (XIV) (3%), m. p. 208.5–212.5° (cor.), was filtered out, and the filtrate concentrated *in vacuo* to a reddish oil. Treatment of this oil with hot absolute ethanol precipitated more of (XIV), but extracted the dimalonuric acid (X). The alcohol extract was concentrated *in vacuo* and the residual red oil crystallized repeatedly from hot water. A white crystalline solid was thus obtained, in a yield of 25–30%.

Anal. Calcd. for $C_{12}H_{18}O_8N_4S_2$: C, 35.1; H, 4.4. Found: C, 35.4; H, 4.6.

The behavior of this product on heating was significant. At 141–142° (cor.), it melted with evolution of carbon dioxide, recongealed, remelted at 150–151° (cor.), with evolution of a second mole of carbon dioxide, congealed again and finally melted with decomposition at 197.5–199° (cor.). With sodium nitrite, the compound gave a red salt.

***beta*-Acetylureido-ethyldisulfide-*beta'*-malonuric Acid (XI).**—When the dimalonuric acid (X) was warmed for a short time in slightly acidulated water, a white crystalline solid was obtained which, after recrystallization from warm water, melted at 150–151° (cor.), with evolution of gas, recongealed and then melted with decomposition at 197.5–199° (cor.). With sodium nitrite, it formed a red salt.

Anal. (of XI). Calcd. for $C_{11}H_{18}O_6N_4S_2$: C, 36.0; H, 4.9. Found: C, 35.5; H, 4.9.

***beta,beta'*-Diacetylureido-ethyldisulfide (XII).**—When an aqueous solution of (XI) was boiled, carbon dioxide was split out and a white solid obtained, which was repeatedly crystallized from boiling water, in which it was very difficultly soluble. The product began to shrink at 206° (cor.) and melted at 209–210° (cor.).

Another method of preparing the same compound consisted in dissolving the diureido disulfide (IX) in excess of acetic anhydride, adding a few drops of concentrated sulfuric acid, and heating the mixture for three hours at 100°, followed by removal of acetic acid and excess of acetic anhydride by concentration *in vacuo*. After repeated crystallization from water, the white powder began to shrink at 206° (cor.) and melted at 209–210° (cor.).

Anal. Calcd. for $C_{10}H_{18}O_4N_4S_2$: C, 37.2; H, 5.6; N, 17.4. Found: C, 37.8; H, 5.4; N, 17.0.

With sodium nitrite, the compound gave no color reaction, thus indicating the absence of a reactive malonic methylene group.

***beta,beta'*-Di-(1-barbituryl)-ethyldisulfide (XIV)** was prepared by three different methods.

(1) To a solution of 23.8 g. of the diureido disulfide (IX) and 20.9 g. of malonic acid in 100 cc. of glacial acetic acid at 50°, there was added dropwise, under a reflux, 40.8 g. of acetic anhydride, in the course of an hour, while the mixture was well stirred and protected from moisture. After eight hours of heating at 80–90°, the solution was concentrated *in vacuo* to a thick red oil, which was extracted with 200 cc. of boiling absolute ethanol. As the extract cooled, the dibarbituryl disulfide (XIV) separated as a pale yellow crystalline solid. It was filtered out, washed with chilled absolute ethanol, dried in a vacuum desiccator, and crystallized from water; yield, 9.8 g., or 26.2%; m. p. 216.8–218.8° (cor.).

Anal. Calcd. for $C_{12}H_{14}O_6N_4S_2$: C, 38.5; H, 3.8; N, 15.0. Found: C, 38.6; H, 4.0; N, 14.9.

Concentration *in vacuo* of the alcoholic filtrate from (XIV), yielded a large quantity of the dimalonuric acid (X), which was used in the preparation of (XIV) by the third method as noted beyond. Another by-product was the acetylated barbituric acid (XIII) described in the following pages.

The above process is based upon that of Biltz and Wittek[10] for the preparation of N-alkylated barbituric acids from substituted ureas, malonic acid, and acetic anhydride.

(2) A mixture of 1.9 g. of *beta,beta'*-di-(1-[3-acetylbarbituryl])-ethyldisulfide (XIII) with 25 cc. of concentrated hydrochloric acid was refluxed for two and one-half hours. The insoluble material was removed and refluxed for another two and one-half hours with a fresh 25-cc. lot of concentrated hydrochloric acid. The combined hydrochloric acid extracts were evaporated *in vacuo* to a pale yellow powder. This was crystallized four times from water, using Norit as a decolorizing agent, and then melted at 215.5–216.5° (uncor.); yield, 0.3 g., equivalent to 33%, after deducting the 0.9 g. of initial material (XIII) unaltered by the hydrochloric acid.

(3) To a solution of 1.9 g. of the dimalonuric acid (X), recovered from Method (1) above, in 25 cc. of glacial acetic acid, there was added slowly, with protection against absorption of moisture, 1.5 g. of acetic anhydride, while the mixture was heated under a reflux. After three hours of further heating at 80°, the warm solution was diluted with two volumes of water, which gave a solution sufficiently acid to precipitate the barbituric acid (XIV) desired, but not the initial dimalonuric acid (X). After standing for eighteen to twenty-four hours, the white precipitate was collected, washed free from acid, and crystallized twice from water, m. p. 211.5–214.5° (cor.). The mixed m. p. with an authentic sample of the barbituric acid (XIV), m. p. 216.8–218.8° (cor.), was 213–216.5°

(cor.); mixed m. p. with an authentic sample of the diacetylureido compound (XII), m. p. 209–210° (cor.), was 188–193° (uncor.); yield, 1 g., or 78.4%, after deducting 0.5 g. of unchanged initial material isolated from the acetic acid solution by evaporation *in vacuo*.

***beta,beta'*-Di-(1-[3-acetylbarbituryl])-ethyldisulfide (XIII).**—The diureidodisulfide (IX) was mixed with slightly more than the calculated amount of malonic acid, a small excess of acetic anhydride was added, and the mixture was heated at 70° for four hours. Acetic acid and excess of acetic anhydride were distilled off *in vacuo*, the residue treated with half the original quantity of acetic anhydride, the mixture heated for an hour at 70°, and acetic acid and acetic anhydride distilled off *in vacuo*. The oily residue was dissolved in 10% sodium hydroxide, and 10% hydrochloric acid added until the solution was acid to Congo-red. The orange-red precipitate was collected and purified by further precipitation from sodium carbonate and sodium bicarbonate solutions with 10% hydrochloric acid. A pale yellow product was thus obtained, in 80% yield, which was very slightly soluble in the usual neutral organic solvents. By reprecipitation with 10% hydrochloric acid from sodium bicarbonate solutions, and drying at 111° *in vacuo* for two and one-half hours, a pure compound was secured, which shrank at 214–217° (cor.) and melted at 219–223° (cor.).

Anal. Calcd. for $C_{16}H_{18}O_8N_4S_2$: C, 41.9; H, 4.0; N, 12.2. Found: C, 41.7; H, 4.3; N, 12.2.

***beta,beta'*-Di-(1-(violuryl)-ethyldisulfide (XV).**—A suspension of 1.1 g. of the barbituryl disulfide (XIV) in 20 cc. of water was treated slowly with 0.5 g. of sodium nitrite, with vigorous stirring. Upon completion of the addition, the pinkish solution was heated at 100° for thirty minutes, which changed its color to a purple, then cooled to room temperature, 1 cc. of concentrated sulfuric acid added, the mixture heated for an hour at 100° and then over a free flame until the red color was discharged. As the solution cooled, a yellow precipitate separated, which was filtered out, washed with cold water until acid-free, and dried *in vacuo* for twenty-four hours. There was thus obtained 1.1 g. (91% yield) of a yellow powder, which turned red at about 200°, and melted at 218.5–219.5° (cor.) with decomposition to a deep red liquid.

Difficulty was experienced in getting an analytically pure sample by this method, since inorganic salts or the sodium salt of the violurate, were carried down with the precipitate. Repeated crystallization from water, however, gave a practically pure product.

Anal. Calcd. for $C_{12}H_{12}O_8N_6S_2$: C, 33.3; H, 2.8. Found: C, 33.1; H, 3.0.

When the red solution of the sodium violurate stood for two to four days, the pyrimidine ring apparently broke open between positions 1 and 6, and no violuric acid (XV) could be recovered.

This violuric derivative (XV) was prepared also by the following process. A suspension of 2.4 g. of the barbituryl disulfide (XIV) in 50 cc. of 95% ethanol was cooled in an ice-bath, and 15 g. of isomamyl nitrite stirred in. After the careful addition of 0.5 cc. of concentrated hydrochloric acid, the mixture was stirred for fifteen to thirty minutes at 0°, one hour while warming up to room temperature, and thirty minutes at 40°. The solution was concentrated *in vacuo* to a small volume, cooled, the precipitate filtered out, washed twice with chilled 95% ethanol, and dried to a pale yellow powder, identical in m. p., and other respects, with the product of the first process; yield, 2.4 g., or 89%, and more was recovered from the filtrates. With sodium hydroxide or potassium hydroxide, it formed a purple isonitroso salt.

***beta,beta'*-Di-(1-uramilyl)-ethyldisulfide (XVI).**—To a solution of 1.1 g. of the violuric acid (XV) in 25 cc. of concentrated hydrochloric acid, there was added 1.9 g. of stannous chloride, and the mixture was heated at 100° for five hours. When the solution no longer reduced an iodine–potassium iodide solution, it was either evaporated to dryness at 100°, extracted with 60% ethanol, and precipitated by the addition of absolute ethanol; or absolute ethanol was added directly to the reduced solution. Cooling of either of these solutions gave a precipitate, which was filtered out and crystallized by dissolving it in a small amount of concentrated hydrochloric acid, reprecipitating with absolute ethanol and cooling to 0°. This precipitate was collected, washed with chilled absolute ethanol and dried *in vacuo* at 75° over phosphorus pentoxide for two hours. The pale yellow product shrank at 145°, turned reddish-brown at 155–160°, sintered at 170–171.5° and finally turned red and decomposed without showing any definite m. p.; yield, 55–60%.

Anal. Calcd. for $C_{12}H_{16}O_6N_6S_2$: C, 35.6; H, 4.0. Found: C, 35.2; H, 4.1.

With potassium hydroxide or sodium hydroxide, no color indicative of an isonitroso salt was obtained. The compound gave a positive murexide reaction.

1 (or 3)-(*beta*-Ethyldisulfide)-uric Acid (XVII).—A suspension of 0.4 g. of the above uramil (XVI) in 20 cc. of water was made faintly alkaline to litmus by the addition of dilute (10%) potassium hydroxide. To this there was added 0.25 g. of nitrourea, and the mixture was heated at 100° until the evolution of gas ceased. The nitrourea used contained sufficient sulfuric acid to change the reaction of the solution to the acid side, so it was filtered hot and cooled. The solid which precipitated was removed and crystallized from water. A white crystalline compound resulted, which was not melted, but only slightly charred, at 350°. Ignited on platinum foil, it left no ash. It dissolved in 5% sodium bicarbonate solution, was reprecipitated by hydrochloric acid, and gave a positive murexide reaction. For analysis, it was crystallized thrice from water and dried over phosphorus pentoxide *in vacuo* for two hours at 76°.

Anal. Calcd. for $C_{14}H_{14}O_6N_8S_2$: C, 37.0; H, 3.1; N, 24.7. Found: C, 36.9; H, 3.2; N, 24.9.

Summary

1. *beta*-Mercaptoethylamine is prepared most conveniently by passing hydrogen sulfide through an alcoholic solution of ethyleneimine. Some physiological tests on the toxicity of ethyleneimine are reported.

2. This mercaptan is easily oxidized to the corresponding disulfide (cystamine) by the action of air or oxygen upon its aqueous or alcoholic solution.

3. Cystamine is converted into the diurea by treatment with nitrourea.

4. This diurea when condensed with malonic acid, in the presence of acetic anhydride, yields the corresponding barbituric acid, as well as malonuric acid derivatives of cystamine and acetylation products.

5. From the disulfide barbituric acid, there have been obtained the corresponding violuric acid, uramil, and uric acid.

6. The latter is to be used as initial material for the preparation of *beta*-mercaptoethyl and thiazolidino uric acids.

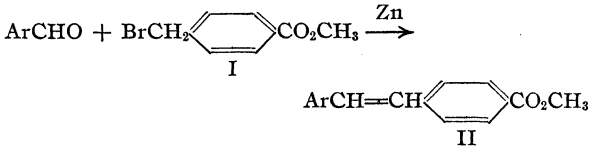
The Synthesis of Certain Carbalkoxystilbenes

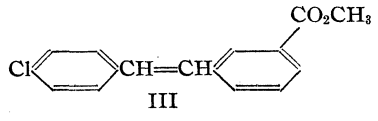
BY REYNOLD C. FUSON AND H. G. COOKE, JR.

Carbalkoxystilbenes of the type $ArCH{=}CHC_6H_4CO_2R$, needed for certain studies on the reversibility of the Friedel–Crafts condensation, could not be found in the literature. It was necessary, therefore, to devise ways for synthesizing them. The present paper reports three such methods.

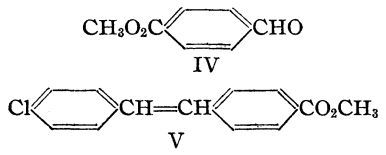
The first to be studied was the condensation of aromatic aldehydes with methyl α-bromo-*p*-toluate (I) by an adaptation of the Reformatsky reaction. This method was suggested by the vinylogous relationship between the α-bromo-*p*-toluates and bromoacetic esters. Experiments showed that the method could be used. Benzaldehyde, *p*-chlorobenzaldehyde and *p*-bromobenzaldehyde were condensed with methyl α-bromo-*p*-toluate to give the corresponding *p*-carbomethoxystilbenes (II).



The activation of the bromine atom by the carbomethoxy group proved, however, not to be essential. Similar results were obtained with the *meta* isomer of the bromotoluate. *p*-Chlorobenzaldehyde condensed with methyl α-bromo-*m*-toluate to give 4-chloro-3′-carbomethoxystilbene (III).



This type of condensation was found to take place also with simple benzyl halides. Thus *p*-chlorobenzyl bromide condensed with methyl terephthalaldehydate (IV) to give 4-chloro-4′-carbomethoxystilbene, the product (V) being identical with that from methyl α-bromo-*p*-toluate and *p*-chlorobenzaldehyde. These two



methods give about the same yields: approximately 20% of the theoretical. The former is preferable because the starting materials are less difficult to obtain.

The preparation of the α-bromotoluates[1] was accomplished by the method of Davis and Perkin.[2] The terephthalaldehydate was much more difficult to prepare. It was found that Mayer and Sieglitz's method[3] for α-naphthaldehyde could be applied successfully to methyl α-bromo-*p*-toluate to give methyl terephthalaldehydate.

After this work was completed Meerwein, Büchner and Emster[4] reported a new method for making substituted stilbenes from cinnamic acids and primary aromatic amines. For certain carbalkoxystilbenes this procedure proved to be superior to the methods already worked out. Applied to cinnamic acid and *p*-aminobenzoic esters it gave yields of 36 to 52%. The method gives low yields when applied to chlorocinnamic acids and consequently is not very helpful in making the halogen substituted stilbenes required in this work.

Experimental

Methyl α-Bromo-*p*-toluate.—Eighty-three grams of bromine was added slowly, with stirring, to 80 g. of *p*-

(1) Zal'kind, *J. Russ. Phys.-Chem. Soc.*, **46**, 508 (1914).
(2) Davis and Perkin, *J. Chem. Soc.*, **121**, 2202 (1922).

(4) Meerwein, Büchner and Emster, *J. prakt. Chem.*, **152**, 237 (1939).

toluyl chloride heated to approximately 180°.[2] The bromination mixture was allowed to cool and 50 cc. of methanol was added dropwise. Distillation of this reaction mixture under reduced pressure gave 72 g. of methyl α-bromo-*p*-toluate; b. p. 115–117 (3 mm.). After crystallization from methanol or low-boiling petroleum ether the ester melted at 54–55°. This melting point agrees with that reported by Zal'kind,[1] who made the ester by direct esterification of α-bromo-*p*-toluic acid.

Methyl α-Iodo-*p*-toluate.—To a solution of 50 g. of methyl α-bromo-*p*-toluate in 100 cc. of acetone was added a solution of 33 g. of sodium iodide in 150 cc. of acetone, and the mixture was refluxed for fifteen minutes. The sodium bromide was removed by filtration, the acetone was distilled and the residue was taken up in ether. The ether solution was washed with 1% sodium thiosulfate solution and dried over anhydrous magnesium sulfate. The ether was distilled, and the iodo ester was crystallized from methanol; m. p. 76–77°, yield 51 g.

Anal. Calcd. for $C_9H_9O_2I$: C, 39.13; H, 3.29. Found: C, 39.12; H, 3.35.

Methyl α-Bromo-*m*-toluate.—The method of synthesis was similar to that outlined for the para isomer. Distillation of the reaction mixture under reduced pressure gave 68 g. of the methyl α-bromo-*m*-toluate; b. p. 112–114° (3 mm.). After recrystallization from methanol or low-boiling petroleum ether the ester melted at 46–47°.

Anal. Calcd. for $C_9H_9O_2Br$: C, 47.16; H, 3.93; Br, 35.02. Found: C, 47.37; H, 4.09; Br, 35.08.

Methyl α-Iodo-*m*-toluate.—The conversion of the bromo ester to the corresponding iodo ester was found to proceed in the manner described for the para isomer. The iodo ester was recrystallized from methanol and low-boiling petroleum ether; m. p. 52–53°; yield 78%.

Anal. Calcd. for $C_9H_9O_2I$: C, 39.13; H, 3.29. Found: C, 39.38; H, 3.44.

The Condensation of Methyl α-Bromo-*p*-toluate with *p*-Chlorobenzaldehyde.—Twenty-five grams of methyl α-bromo-*p*-toluate in 100 cc. of dry benzene was added dropwise to a refluxing mixture of 21 g. of *p*-chlorobenzaldehyde, 50 cc. of dry benzene and 8 g. of zinc dust. The mixture was refluxed with stirring for eighteen hours, then decomposed with 100 cc. of dilute hydrochloric acid. The solid was removed by filtration, and the benzene layer was separated, washed with a 5% solution of sodium carbonate, and dried over anhydrous magnesium sulfate. The dry benzene solution was refluxed for two hours with 15 cc. of acetic anhydride. The solution was then concentrated under reduced pressure to a thick sirup. The 4-chloro-4′-carbomethoxystilbene solidified on cooling and was recrystallized from methanol.

Numerous attempts were made to increase the yield by using such solvents as toluene, ethyl ether and butyl ether in place of benzene. The iodo ester was used in place of the bromo ester and magnesium was substituted for zinc, but the above conditions were the most successful.

4-Chloro-4′-carbomethoxystilbene Bromide.—An excess of a 5% solution of bromine in carbon tetrachloride was added to a solution of 1 g. of 4-chloro-4′-carbomethoxystilbene in 25 cc. of carbon tetrachloride. The reaction mixture was heated to a temperature of 70° for twenty minutes. The carbon tetrachloride was removed by distillation and the 4-chloro-4′-carbomethoxystilbene bromide was recrystallized from methanol.

Debromination of 4-Chloro-4′-carbomethoxystilbene Bromide.—A solution of 1 g. of sodium iodide in 30 cc. of acetone was added to a solution of 1 g. of 4-chloro-4′-carbomethoxystilbene bromide in 30 cc. of acetone. This mixture was refluxed for fifteen minutes, the precipitate of sodium bromide removed by filtration and the acetone distilled. The residue was dissolved in ether and washed with a 1% solution of sodium thiosulfate. After the ether solution had been dried over anhydrous calcium chloride, the ether was distilled, and the 4-chloro-4′-carbomethoxystilbene crystallized from methanol; m. p. 161–162°, yield 95%. There was no depression of melting point when this product was mixed with the parent stilbene.

The condensation of other aromatic aldehydes and benzyl halides was carried out in the manner given for the synthesis of 4-chloro-4′-carbomethoxystilbene. The stilbene in each case was transformed into the corresponding dibromide which in turn was reconverted to the parent stilbene by treatment with sodium iodide in acetone. The results of these syntheses are collected in Table I. The yields in the debromination reactions varied from 86 to 92%. Purification of the stilbenes and their bromides was carried out in each case by recrystallization from methanol.

Attempted Condensation of Methyl α-Iodotoluates with Acetone.—When the meta and para α-iodotoluates were treated with zinc and acetone the only products were the corresponding methyl toluates and the bibenzyls produced by coupling. The 4,4′-dicarbomethoxybibenzyl melted at 118–119°.[5] The 3,3′-dicarbomethoxybibenzyl was a new compound. It was recrystallized from methanol, m. p. 84–85°.

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.51; H, 6.05. Found: C, 72.79; H, 5.86.

The Condensation of Benzyl Chloride with Benzaldehyde.—A solution of 45 g. of benzyl chloride in 200 cc. of dry benzene was added dropwise to a refluxing mixture of 38 g. of benzaldehyde, 100 cc. of dry benzene and 25 g. of zinc dust. The mixture was refluxed for twenty-four hours and decomposed with dilute hydrochloric acid. The solid was removed by filtration and the benzene layer was separated, washed and dried. The dry benzene solution was fractionally distilled to give 12 g. of diphenylmethane, b. p. 260–265°, and 16 g. of stilbene, b. p. 300–310°. Diphenylmethane is known to form when benzyl chloride is heated in the presence of zinc[6]; the structure of this hydrocarbon was proved by its oxidation to benzophenone. By the method of mixed melting points the high-boiling compound was shown to be *trans*-stilbene, m. p. 123–124° (from methanol); yield, 24%.

Preparation of Methyl Terephthalaldehyde.—This aldehyde was prepared by the same method that Mayer and Sieglitz[3] used for the preparation of α-naphthaldehyde. A solution of 28 g. of hexamethylenetetramine in 300 cc. of water was added to 44 g. of methyl α-bromo-*p*-toluate dissolved in 500 cc. of methanol. The solution was refluxed for seven hours, and the methanol was distilled.

			Found	40.78	2.95

The aqueous residue was extracted with 1000 cc. of ether, and the ether solution was washed with a dilute solution of sodium bicarbonate and dried over anhydrous calcium chloride. The ether was removed by distillation and the residue distilled under diminished pressure in an atmosphere of nitrogen. Eighteen grams of methyl terephthalaldehydate was obtained, b. p. 95–97° (2 mm.), m. p. 61–62° (from low-boiling petroleum ether). This melting point agrees with that observed by Simonis,[7] who prepared the ester by direct esterification of terephthalaldehydic acid.

The Condensation of *p*-Chlorobenzyl Bromide with Methyl Terephthalaldehydate.—A solution of 14 g. of *p*-chlorobenzyl bromide in 75 cc. of dry benzene was added dropwise to a refluxing mixture of 10 g. of methyl terephthalaldehydate, 50 cc. of dry benzene and 6 g. of zinc dust. The mixture was refluxed for ten hours and decomposed with dilute hydrochloric acid. The solid was removed by filtration, and the benzene layer was washed and dried over anhydrous magnesium sulfate. The dry benzene solution was refluxed for two hours with 15 cc. of acetic anhydride. The solution was concentrated to a thick sirup under reduced pressure, and the residue was allowed to cool. The partially solidified residue was washed with methanol, and the solid was crystallized from methanol to give 3.2 g. of 4-chloro-4′-carbomethoxystilbene melting at 158–160°. By the method of mixed melting points this compound was shown to be identical with the stilbene obtained from methyl α-bromo-*p*-toluate and *p*-chlorobenzaldehyde. A bromide was prepared from this product which was shown by the method of mixed melting points to be identical with the 4-chloro-4′-carbomethoxystilbene bromide which had been previously prepared.

(7) Simonis, *Ber.*, **45**, 1585 (1912).

Distillation of the oil gave a compound which distilled at 160–170° (2 mm.) and melted at 100° (from methanol). Its composition corresponded to that of *p,p′*-dichlorobibenzyl.

Anal. Calcd. for $C_{14}H_{12}Cl_2$: C, 66.91; H, 4.82. Found: C, 66.71; H, 5.01.

Preparation of 4-Carbomethoxystilbene from Cinnamic Acid and Methyl *p*-Aminobenzoate.—The general directions used by Meerwein[4] for the preparation of substituted stilbenes were used in this synthesis of 4-carbomethoxystilbene. The diazonium salt of methyl *p*-aminobenzoate was made by adding a solution of 9 g. of sodium nitrite in 15 cc. of water to a mixture of 50 cc. of 25% hydrochloric acid, 19 g. of methyl *p*-aminobenzoate and 50 g. of ice. Throughout this experiment the reaction mixture was well stirred. An ice-bath was placed around the reaction flask and 27.5 g. of sodium acetate was added. A solution of 18.5 g. of cinnamic acid in 150 cc. of acetone was added and the ice-bath was removed. Five minutes later a solution of 5.3 g. of cupric chloride in 15 cc. of water was added and the mixture was stirred for one hour at room temperature. The 4-carbomethoxystilbene was removed, washed with methanol and crystallized from methanol, m. p. 158–159°; yield, 52%.

By the method of mixed melting points this compound was shown to be identical with the stilbene prepared from methyl α-bromo-*p*-toluate and benzaldehyde. The bromide prepared from this stilbene was shown to be identical with the previously prepared 4-carbomethoxystilbene bromide.

4-Carbethoxystilbene.—By use of the foregoing procedure a 36% yield of 4-carbethoxystilbene was obtained from ethyl *p*-aminobenzoate. It was crystallized from ethanol, m. p. 105–106°.

Anal. Calcd. for $C_{17}H_{16}O_2$: C, 80.92; H, 6.38. Found: C, 80.77; H, 6.43.

The **bromide** was recrystallized from absolute ethanol, m. p. 180–181°; yield 90%.

Anal. Calcd. for $C_{17}H_{16}O_2Br_2$: C, 49.51; H, 3.91. Found: C, 49.89; H, 4.07.

Treatment of the bromide with sodium iodide in acetone gave an 85% yield of the parent stilbene.

Summary

Carbomethoxystilbenes of the type $ArCH{=}CHC_6H_4CO_2CH_3$ have been prepared from aromatic aldehydes and the appropriate methyl α-bromotoluates by the action of zinc.

Similar results have been obtained by condensing benzyl halides with methyl terephthalaldehydate.

For the unsubstituted carbalkoxystilbenes the method of Meerwein, Büchner and Emster was found to be excellent.

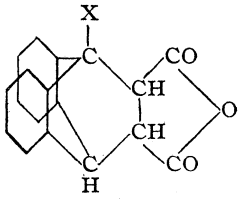
Bicyclic Structures Prohibiting the Walden Inversion. Some Bicyclo[2,2,2]octane Derivatives with Substituents at the Bridge-Head[1]

BY PAUL D. BARTLETT AND SAUL G. COHEN

It has been shown in the laboratories of Barnett[2] and of Bachmann[3] that maleic anhydride readily undergoes addition to 9-substitution products of anthracene, yielding dibenzobicyclooctadiene derivatives such as I with substituents at the bridge-head position. These are among the few compounds known which are structurally incapable of replacement reactions with Walden inversion. In connection with our study of such compounds in the apocamphane series[4] the substances I, II and III, in which X is Br, NH_2 and OH are of special interest.



I	X = Br
Ia	X = H
II	X = NH_2
III	X = OH
IV	X = $OOCCH_3$
V	X = NO_2
VI	X = $NHCOCH_3$
VII	X = $NHCOOC_2H_5$

These compounds have three principal features not found in the apocamphanes. The bridge-head carbon atom is directly bound to two phenyl groups, which in the acyclic analogs means an enhanced reactivity of the group X. The presence of two potential acid groups provides water-solubility in the salts, making these compounds quite different in manipulation from the apocamphanes. Finally, the dibasic acids show geometrical isomerism.

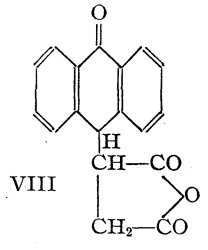
(4) Bartlett and Knox, THIS JOURNAL, **61**, 3184 (1939).

Barnett and his co-workers[2] observed that the addition product from 9-bromoanthracene (I) withstood treatment with alcoholic alkali for forty minutes without any replacement of the bromine. They also obtained only decomposition products from attempts to hydrolyze the corresponding acetate (IV). The direct reaction of maleic anhydride with anthranol or anthrone occurred only in the sense of a Michael condensation with the latter, yielding an uncyclized addition product (VIII).

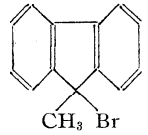


VIII

From these results Barnett concluded that the compound III must be incapable of existence.

Where our experiments have duplicated those of Barnett and his co-workers, there is complete agreement. We subjected the bromo compound, I, in different experiments, to treatment for fifteen to eighteen hours with boiling 15 to 30% potassium hydroxide, with no other effect than to open the anhydride ring and isomerize the *cis*- into the *trans*-dibasic acid. The aqueous extract of the product, after acidification and shaking with ether, gave no precipitate with silver nitrate. As the nearest analogous compound without the bridged ring structure we

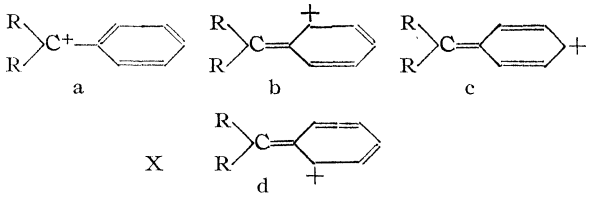
selected 9-methyl-9-bromofluorene (IX) for comparison. This compound, dissolved in ethyl alcohol at 25°, formed bromide ion at a unimolecular rate with a half-period of about five minutes. Although there is a possibility of elimination of hydrogen bromide from this compound, the isolation of impure 9-methyl-9-ethoxyfluorene in 52% yield shows that replacement of the bromine also was occurring. The corresponding half-period of the bridgehead bromine compound (I) at 83° is surely more than 1200 hours, since otherwise an easily detectable quantity of bromide ion would have been present in our experiments. Assuming a temperature coefficient of two for a ten degree rise in temperature, we find that at the same temperature there is at least a million-fold difference in reactivity between the bromine of I and that of IX. The difference is surely much greater than this, since the 50% aqueous medium in which the bicyclic compound was tested is much more favorable to bromine replacement reactions than the pure alcohol used for IX.[5]



IX

This inertness of the bromine in I is subject to interpretation along the same lines as indicated by Bartlett and Knox,[4] but the special structural features of this bromo compound make possible a new perspective on the problem. There is little opposition to the view that true and comparatively stable carbonium ions can be formed by the dissociation in appropriate solvents of diaryl and triarylmethyl bromides. The work of Walden[6] has shown this by conductivity methods, and indeed Ziegler and Wollschitt[7] have found that triphenylmethyl bromide is a completely strong electrolyte in liquid sulfur dioxide. Therefore even those who are unwilling to consider the ionization mechanism for the solvolysis of purely aliphatic tertiary halides must take it into account for highly arylated methyl bromides.

The source of the stabilization which facilitates such ionization in the arylated methyl halides is now well recognized in the contribution of the various bond structures Xa-d to the total (resonance) structure of the carbonium ion. It will be noted that three of these structures have double bonds to the central carbon atom and hence cannot be expected to contribute significantly to the resonance unless the geometry of the ion as a whole can be made compatible with such structures. This means that the central carbon atom, the three atoms directly connected to it, and in fact all the atoms of the phenyl group, must lie in the



X

same plane. This is obviously impossible in any carbonium ion that might be formed by the removal of Br^- from the compound I.

We thus derive, for carbonium ions stabilized by aromatic resonance, the generalization that the ion must approach a planar structure to be stable, and that any stereochemical conditions prohibiting a planar structure will markedly raise the energy barrier to the formation of the ion. Bartlett and Knox proposed that this might be the case for all carbonium ions, even those without aromatic resonance, taking the planar structure of trimethylborane (which, like the *t*-butyl cation, has a central atom with only six electrons) as an analogy.

With respect to reaction with metallic sodium, the bromine at the bridge-head is not wholly inert. In the reduction of 0.1 g. of I with a total of 4 g. of sodium in the presence of alcohol, 0.01 g. of the *trans*-reduction product was isolated and identified by mixed melting point with a synthetic sample prepared by boiling the addition product of maleic anhydride and anthracene with alkali. This seems to indicate that the hindrance to the momentary formation of a free radical at the bridge-head position is not as great as the hindrance to the formation of a carbonium ion. It is not purely the difference between a reagent which attacks the carbon and one which attacks the halogen, for the silver ion, which also must attack the bromine atom directly, fails to produce any silver bromide from this compound. Silver powder likewise gave no detectable reaction.

Experience in the apocamphane series suggested attempting the preparation of the hydroxy compound III or its *cis*- or *trans*-dibasic acid from the corresponding amino compound. Two

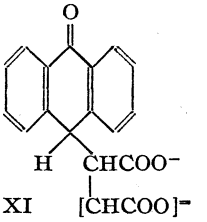
possible sources of this amino compound, the corresponding nitro and acetamino compounds (V and VI), were prepared with ease by the addition of maleic anhydride to 9-nitro- and 9-acetaminoanthracene, respectively. In neither case was the conversion into the amino compound achieved. The addition of maleic anhydride to ethyl N-9-anthrylcarbamate gave a bridge-head urethan (VII) which, as in the apocamphane series, was much more amenable to hydrolysis than the corresponding amide (VI). Sixteen hours of boiling with 35% alkali only converted the latter into the still acetylated *trans*-acid (in 80% yield), while the urethan was hydrolyzed in about an hour by 20% sodium hydroxide. Purification through the copper salt gave an amino-acid, m. p. 260–262°, of unknown configuration with respect to the two carboxyl groups.

When an acidified solution of this amino-acid was treated with sodium nitrite under controlled conditions, a variable yield of a white solid melting at 174–175° was obtained. Its analysis was correct for the dibasic acid from III, and although stable to heat its behavior in the presence of alkali was that to be expected from Barnett's results. In the presence of 10% sodium hydroxide it immediately acquired a deep orange color, and after thirty minutes of boiling, acidification and ether extraction, there resulted a mixture melting over a wide range above 130°. The results in preparing this compound were not reproducible and several other compounds were encountered in isolated runs but not satisfactorily identified.

The instability of the hydroxy compound to alkali probably is not uniquely related to the bicyclic ring structure. It is seen readily from the formula that III is a beta-hydroxy-anhydride, and its acid is an internal ketol condensation product of the acid of Barnett's compound, VIII. In the presence of a base this ketol condensation should be mobilized, and the equilibrium undoubtedly would be in favor of the uncyclized product. This is because the salt related to VIII can be enolized and converted into the alkali derivative of the corresponding anthranol. Actually, the compound VIII was never obtained from our hydroxy compound nor from Barnett's acetoxy compound (IV) with the bicyclic ring system. The only identifiable compounds which we obtained from the treatment of III with alkali were anthraquinone (obtained in the presence of oxygen) and dihydrodianthrone[8] obtained from a reaction in the absence of air. Both these products were identified by mixed melting points. The compound VIII does not yield these products on similar treatment, and hence is not intermediate in their formation from III. The mechanism of the deketolization of the cyclic compound may be such as to yield an ionic modification of VIII especially well adapted to the Michael retrogression to anthrone and maleate or fumarate ion. The molecular species XI would be of this kind.



XI

Experimental

Anthracene was brominated according to the directions of Barnett and Cook.[9] The crude product was distilled *in vacuo* as was done by Bachmann and Kloetzel[3] and crystallized several times from ligroin (b. p. 90–120°) and then from alcohol. The product was obtained as fine yellow needles melting at 101–103°.

9-Bromo-anthracene-9,10-endo-α,β-succinic Anhydride. (I).—The addition of maleic anhydride to 9-bromo-anthracene was carried out by refluxing equivalent quantities of the two reactants in dry xylene (5 cc. per gram of bromo-anthracene) for two and one-half hours. The product crystallized from the cooled solution in 94% yield, as white prisms, melting at 253–254°.[2]

Treatment of I with Alkali.—One-half gram of I was dissolved in 14 cc. of 21% aqueous potassium hydroxide and the solution was boiled for eighteen hours. The solution was acidified with chloride-free nitric acid, filtered and extracted with ether. Addition of a solution of silver nitrate to the water layer gave no precipitate or opalescence. Similar results were obtained when 50% aqueous alcohol was used as the solvent in this alkali treatment.

From this experiment a solid was recovered from the ether extract weighing 0.4 g., sintering at 210° and melting at 231°. Recrystallization from ether–petroleum ether gave white prisms melting at 238–240°; melting point, mixed with starting material, 224°. This product, not identical with either the starting material or the acid obtained from it by gentle treatment with alkali and acidification, is evidently the *trans*-dibasic acid.

(10) Analysis was performed by H. S. Wight.

of this anhydride, which may have been produced by a slow isomerization to the *cis*-form followed by dehydration, or it may have been present as an impurity in the *trans*-acid.

In an attempt to carry the alkali treatment still farther, we boiled 0.2659 g. of the anhydride with 10 cc. of 50% aqueous potassium hydroxide in a copper vessel. On the ninth day a hole had been eaten through the vessel and the material ran out. From an extract of the bench-top we recovered 35% of the bromine-containing *trans*-acid.

The *cis*-acid from I was obtained in practically quantitative yield when 0.1 g. of the anhydride was dissolved in 10 cc. of 10% potassium hydroxide by boiling and the solution cooled and acidified. This acid melted at 106°, re-solidified and melted again at 253–254°, both alone and when mixed with the original anhydride. When this *cis*-acid was dissolved in warm acetic anhydride, the original anhydride immediately crystallized quantitatively.

***cis–trans*-Isomerism of the Acid from Ia.**—The anhydride Ia, m. p. 258–260°, prepared according to Clar,[11] when boiled four hours with 2% potassium hydroxide, yielded a product which, after drying *in vacuo*, melted at 258–260° alone, and when mixed with the starting material. However, on boiling for sixteen hours with 3 g. of potassium hydroxide in 14 cc. of water, a product was obtained melting at 241°, which depressed the melting point of the original anhydride to 223°. Diels and Alder[12] prepared the *trans*-acid, m. p. 241–242°, by boiling 5 g. of the *cis*-dimethyl ester for twenty minutes in a solution of 0.5 g. of sodium in 100 cc. of alcohol. Treatment with the concentrated alkali for intermediate lengths of time gave mixtures of the *cis*- and *trans*-acids.

Treatment of I with Silver Nitrate.—A solution of 1.0226 g. of the anhydride and 1 g. of silver nitrate in 70 cc. of alcohol was heated to boiling for two and one-half hours on the steam-bath and allowed to stand for three days. There was a precipitate weighing 0.0248 g. Of this, 0.0118 g. was ignited in a porcelain crucible, leaving a residue of 0.0044 g. of silver which, after a second ignition, weighed 0.0042 g. These figures correspond to 37.3 and 35.5% of silver, respectively. Solution in nitric acid and precipitation gave 0.0054 g. of silver chloride. On the basis of 35.5% of silver the equivalent weight of the silver-containing precipitate was 304; calculated for $C_{18}H_{11}O_4BrAg_2$, 293.5. The precipitate is therefore accounted for as the silver salt of the bromine-containing dibasic acid, and not as silver bromide.

Treatment of the Bromo Compound I with Silver Powder.—Four-tenths gram of silver powder was added to a solution of 0.1779 g. of the compound I in 25 cc. of acetone. The solution was kept at room temperature for two days, and was boiled for sixteen days. The mixture was filtered and the solvent was removed. The residue weighed 0.16 g. and was identical with the starting material. When this procedure was carried out in boiling xylene, again only starting material was recovered.

Reduction of I with Sodium.—The bromo-anhydride (0.1 g.) was dissolved in about 20 cc. of alcohol containing a little sodium ethoxide, and 1 g. of sodium was added. When this had dissolved, the solution was acidified, diluted with water and extracted with ether. The ether was evaporated and the residue again dissolved in alcohol and treated with sodium. After four such treatments with a gram of sodium each time, 0.01 g. of *trans*-reduction product was recovered, m. p. 234–235°. Mixed with synthetic material of melting point 241°, the melting point was 234–237°, while a large depression was obtained on mixture with the *trans*-bromo-acid. In a number of such reduction runs, silver bromide was precipitated from the aqueous extract of the product, the maximum amount obtained being 95.4% of the theoretical, from a run in which the reaction mixture was boiled during the reduction. The reduction in most of the runs was less than 50%, and the organic product consisted of difficultly separable mixtures.

9-Methylfluorenol was made in 94% yield of crude product by the method of Ullmann and von Wurstemberger[13] and melted at 172° after crystallization from benzene.

9-Methyl-9-bromofluorene.—0.87 g. of 9-methylfluorenol was dissolved in 20 cc. of anhydrous ether. At 0°, hydrogen bromide was passed into this solution until it was fuming strongly, with anhydrous magnesium sulfate present to remove the water formed. After two hours at 0°, a yellow color had developed. The solution was then filtered and the ether was removed under reduced pressure in a stream of dry nitrogen. The oil residue was extracted with 10 cc. of petroleum–ether at room temperature, and a small quantity of red oil which did not dissolve readily was discarded. The solution was cooled in dry-ice and nearly colorless crystals were deposited, 0.92 g., 80% yield, melting at 48.5–49.5°. The recrystallized product melted at 50°. It has been reported previously by Keizo Nakamura.[14] It was kept in dry-ice until used, since on standing at room temperature in the light, it was converted into a red oil with loss of hydrogen bromide.

Reaction of 9-Methyl-9-bromofluorene with Alcohol.—0.92 g. of 9-bromo-9-methylfluorene was dissolved in 10 cc. of absolute alcohol. After eleven hours at room temperature, the solution was poured into twice its volume of water. The mixture was cooled in an ice-bath, and the solid which formed was filtered off, 0.65 g., melting nearly completely at 75°, but with a small quantity of solid persisting until a much higher temperature. The solid was taken up in 25 cc. of ether, giving a yellow solution and a white insoluble solid, 0.10 g., which turned yellow on exposure to air, and decomposed over a wide range to about 250°. Evaporation of the ether gave a solid, 0.55 g., melting poorly to 77°. This was dissolved in petroleum ether (35–60°) and the solution was filtered from a small quantity of insoluble material, 0.02 g., decomposing over a range to 110°. Concentration of the petroleum ether gave 0.3 g. of solid melting 75–80°, and 0.11 g. melting 72–79°. Recrystallization from dilute alcohol gave fine white needles, melting at 82–83°.

reaction mixture against standard base: 0.6949 g. of 9-methyl-9-bromofluorene was dissolved in 50 cc. of absolute ethyl alcohol at 25.0° and 5-cc. portions were withdrawn at intervals. Each portion was pipetted into a 125-cc. glass-stoppered Erlenmeyer flask containing 50 cc. of water and 5 cc. of chloroform. By quick shaking the solution was cleared and the acid was then neutralized with 0.5525 *N* sodium hydroxide. The end-points were sharp.

TABLE I

Time in minutes	Cc. of base
4.5	2.29
22.08	3.73
33.33	4.21
51.17	4.56
∞	4.90

When the logarithms of the concentrations of bromo compound were plotted against time, the slope of the line gave a rate constant of 0.0442 min.$^{-1}$.

9-Nitroanthracene was made by the nitration of anthracene according to the directions of Dimroth.[15] From 50 g. of anthracene was obtained 35 g. of 9-nitroanthracene, a 56% yield, orange needles, melting at 145–146°.

The nitrobicyclo compound V was obtained when a solution of 1.5 g. of 9-nitroanthracene and 1 g. of maleic anhydride in 5 cc. of xylene was boiled for two hours. The product, twice crystallized from xylene, weighed 1.2 g. (56% yield) and melted at 244–245°.

Anal. Calcd. for $C_{18}H_{11}NO_5$: C, 67.30; H, 3.45. Found: C, 67.54; H, 3.84.

Attempts to reduce this to the amino compound (II) by stannous chloride did not lead to the desired product.

9-Aminoanthracene was made by the reduction of 9-nitroanthracene with stannous chloride, the method of Meisenheimer and Connerade.[16] We obtained, in 91% yield, a yellow product which rapidly became brown on exposure to air. It melted unsharply at 135–140°, after softening at 120°. The highest reported melting point is 145–150° after softening at 135°[16] and it has also been reported as decomposing upward from 115°.[17] On long standing in a desiccator it was converted to a compound melting at 216–217°. A solution of 9-aminoanthracene in benzene, on standing for several months, also deposited crystals of this high melting compound. We did not characterize it further.

The reactions of maleic anhydride with 9-aminoanthracene, and with 9-aminoanthracene hydrochloride, did not lead to the desired product.

N-9-Anthrylacetamide was made by the action of acetic anhydride on 9-aminoanthracene at room temperature, the method of Goldmann.[17] The product is obtained, in practically quantitative yield, as slightly colored needles, melting at 272–274°.

The addition of maleic anhydride to N-9-anthryl acetamide was carried out by boiling a solution of 2.7 g. of the former and 4 g. of the latter in 20 cc. of xylene for four and one-half hours. The product (VI) was deposited from the cooled reaction solution in 91% yield, as white prisms, melting unsharply at 268°, after sintering from 257°.

Anal.[10] Calcd. for $C_{20}H_{15}O_4N$: C, 72.05; H, 4.54. Found: C, 71.95; H, 4.51.

The bridge-head amide (VI) proved resistant to acid or base hydrolysis, and the bridge-head amine could not be prepared from it.

One-half gram of the amide was dissolved in a solution of 5 g. of sodium hydroxide in 14 cc. of water, and boiled for sixteen hours. Acidification of the black reaction solution gave 0.4 g., 76% yield, of a white solid, sintering at 250°, and melting at 253°, and depressed to 242° on mixture with the starting material. Analysis indicated that it was the dibasic acid, and the melting point depression that it was the *trans*-isomer.

Anal.[10] Calcd. for $C_{20}H_{17}O_4N$: C, 68.38; H, 4.88. Found: C, 68.10, 68.39; H, 4.91, 4.87.

A solution of 0.2 g. of the amide VI in 10 cc. of concentrated sulfuric acid was allowed to stand at room temperature for one hour. Water was added until a slight turbidity formed, and the solution was warmed for one-half hour on the steam-bath. Color began to develop, so the heating was stopped. The solution was poured into water, and the product was extracted with benzene. We obtained 0.17 g., 85% yield, of starting material, sintering at 250° and melting at 263°. Its melting point was elevated on mixture with the starting material. Little or no hydrolysis had taken place.

Ethyl 9-Anthrylcarbamate.—Twenty-one grams of 9-nitroanthracene was reduced with stannous chloride as directed by Meisenheimer and Connerade.[16] The tin double salt was decomposed with dilute ammonia, and the amine was extracted with ether. The amine was not isolated, but this ether solution was dried over magnesium sulfate, and treated with 20 cc. of ethyl chloroformate. The reaction was allowed to run for thirty-six hours at room temperature, and a precipitate of the urethan and the amine hydrochloride formed. This solid was filtered off, and evaporation of the filtrate gave a small quantity of the urethan. The solid was boiled for a few minutes in 500 cc. of xylene and filtered, and from the cooled filtrate the urethan crystallized. Combined with that obtained from the mother liquor, the yield was 9.4 g., 75%. The solid filtered from the boiling xylene was suspended in dilute alkali and extracted with ether. The ether extract was treated with ethyl chloroformate and more of the urethan was made. The urethan was crystallized twice from xylene, and was obtained as fine, light yellow needles, melting at 224–225°.

Anal.[10] Calcd. for $C_{17}H_{15}O_2N$: C, 76.96; H, 5.70. Found: C, 77.15; H, 5.77.

The addition compound VII was obtained in 95% yield when 15 g. of maleic anhydride and 4.2 g. of ethyl 9-anthrylcarbamate were boiled in 60 cc. of dry xylene for 2.75 hours. There was a rapid development of an orange-red color, which slowly faded during the progress of the reaction. The product crystallized from the cooled reaction medium in colorless prisms, melting at 252–254°, with decomposition. It was washed with benzene and hexane, dried *in vacuo* and analyzed.

Anal.[10] Calcd. for $C_{21}H_{17}O_5N$: C, 69.38; H, 4.72. Found: C, 69.38; H, 4.49.

Bridge-head Amine (II) Hydrolysis of the Urethan VII.—In one of a series of preparations, 0.3 g. of the bridge-

head urethan was boiled for 1.25 hours in 20 cc. of 20% sodium hydroxide. A yellow color developed. The solution was filtered, acidified and warmed until the carbon dioxide was removed. The solution was made neutral, the silica which formed was filtered off, and a solution of 1 g. of cupric acetate in a little water was added. The mixture was warmed for a few minutes, and the precipitated copper salt was filtered off. The calcium and mercuric salts were soluble, whereas the copper salt precipitated from even a weakly acidic solution. When the reaction is run on a larger scale, the copper salt is rather to be centrifuged than filtered. The copper salt was suspended in a little water and dissolved by addition of a few drops of concentrated hydrochloric acid. Hydrochloric acid was added, so that the solution was about 6 normal. The solution was cooled in ice and the product slowly crystallized. The product also crystallizes out if the copper salt is merely dissolved in concentrated hydrochloric acid. We obtained 0.15 g. of crude product, 51% yield. It was purified by solution in water and precipitation by addition of hydrochloric acid. It melted at 260–262° with decomposition.

Anal.[10] Calcd. for $C_{18}H_{16}NClO_4$: C, 62.53; H, 4.66; N, 4.05. Found: C, 62.28; H, 4.74; N, 3.94.

Treatment of the Amine II with Nitrous Acid.—To a solution of 0.62 g. of the amine II in 40 cc. of 20% hydrochloric acid, a solution of 0.7 g. of sodium nitrite was added and the mixture allowed to stand at room temperature for several hours. A white turbidity appeared immediately. The mixture was extracted with ether, the ether dried and concentrated and petroleum ether added. There was obtained 0.37 g. (65% yield) of a product giving the correct analysis for the hydroxy compound III, m. p. 174–175°.

Anal.[10] Calcd. for $C_{18}H_{14}O_5$: C, 69.68; H, 4.55. Found: C, 69.54; H, 4.83.

This product was later obtained without prior isolation of the amine II. A solution of 0.3 g. of the bridge-head urethan VII in 20 cc. of 20% sodium hydroxide was boiled for thirty minutes. The solution was acidified, and to the clear acidic solution 0.5 g. of sodium nitrite was added. After standing one-half hour at 0° and at room temperature for sixteen hours, the mixture was saturated with hydrogen chloride gas and extracted with ether. The ether was dried and concentrated, and on addition of petroleum ether this product was obtained in 62% yield.

Measurement of the Nitrogen Evolved in the Nitrous Acid Reaction.—One-half gram of the bridge-head urethan VII was hydrolyzed by boiling for one hour in 25 cc. of 20% sodium hydroxide. The solution was neutralized and 3 cc. excess of concentrated hydrochloric acid was added. The flask was immersed in an ice-bath, and a solution of 0.5 g. of sodium nitrite was admitted. The nitrogen, carried on a stream of carbon dioxide, was passed through alkaline permanganate and collected over 50% potassium hydroxide. The reaction was complete in a few hours at 0°.

TABLE II

Time, hours	Vol. N_2 (unlevelled), cc. t = 30°
2	28
3.5	35
4	36
4.5	36.3, levelled vol. 34 cc.

Corrected for temperature, 30.6 cc.
Calculated, 31 cc.

The gas gave no test for oxides of nitrogen with starch-iodide paper and it did not support combustion.

While the reaction was proceeding at 0°, a white solid precipitated. However, it turned to a yellow oil when it was filtered off, or when the solution was allowed to warm up to room temperature. In one instance, we filtered off the solid which formed, but could isolate from it only an impure compound (1.5%) melting 160–200°. From the filtrate, worked up as usual, we obtained, in 4% yield, an impure product, melting 175–200°, and, in 19% yield, the compound melting at 174–175°, and an oil residue.

The results of this nitrous acid reaction were not strictly reproducible, the yields varying over a wide range. Several other compounds, none of them identical with any prepared by Barnett and his co-workers,[2] were found in different runs, usually in small yields, but they have not yet been satisfactorily identified.

Behavior of the Product of the Nitrous Acid Reaction.—Thirteen milligrams was boiled in 0.8 cc. of xylene for fifteen minutes. The compound was slightly soluble and stable, and was recovered both from the undissolved residue and from the filtrate.

Treatment with Alkali.—(a) The orange solution of 0.2 g. of the hydroxy compound in 20 cc. of 10% sodium hydroxide was boiled for one-half hour. A red color developed and the solution became turbid. Acidification discharged most of the color, and precipitated 0.1 g. of a yellow solid which melted at 258–269°. After crystallization from acetic acid and from xylene it darkened at 270° and melted at 277–280°, and on mixture with anthraquinone it melted at 279°. The product was apparently anthraquinone, obtained in 75% yield.

(b) The solution of 0.1 g. of the hydroxy compound in 10 cc. of 10% sodium hydroxide was boiled for thirty minutes in a stream of nitrogen. The orange solution was cooled and acidified. The color was discharged and a yellow solid formed, weighing 0.06 g. This sintered at 130°, melted to a large extent at 160°, and completely at 198°. After standing in ether solution for several weeks, it was converted to a compound melting at 240–250°.

These same compounds were obtained from anthrone. One-fourth gram of anthrone was boiled for thirty minutes in 50 cc. of 10% sodium hydroxide. On acidification a yellow compound, sintering at 145°, melting to a large extent at 155° and fully molten at 198°, was obtained. This melting range was not affected on mixture with the compound obtained above. Oxidation of this by ferric chloride in acetic acid solution, the method of Dimroth,[18] yielded dihydrodianthrone, melting at 245–257°, and at 242–257° on mixture with the compound obtained above.

Summary

The addition product (I) of maleic anhydride to 9-bromoanthracene, which is structurally incapable of a Walden inversion in the replacement of the bromine, shows no replacement of this bromine on boiling for eighteen hours with 30%

(18) Dimroth, *Ber.*, **34**, 222 (1901).

potassium hydroxide in 50% aqueous ethyl alcohol. This extends the observations of Barnett and his co-workers to more drastic conditions.

Two interpretations of this and similar facts are considered, that a Walden inversion must attend such a replacement reaction, or that a carbonium ion must be formed in which the central carbon atom and the three atoms directly combined with it lie in a common plane. The latter concept, advocated previously by Bartlett and Knox by analogy to boron compounds, is here correlated with the resonance normally present in an arylated carbonium ion. This interpretation is favored but not conclusively proved.

The bromine can be replaced by hydrogen by means of reduction with sodium and alcohol.

Maleic anhydride has been added to ethyl N-9-anthrylcarbamate to yield a bridged-ring urethan (VII) which is readily hydrolyzed to the aminodibasic acid related to II. Nitrous acid converts this into a compound which is probably the dibasic acid with hydroxyl on the bridge-head. As expected by Barnett, this compound is very unstable to alkali. Its decomposition is interpreted as ketol cleavage.

The Partial Pressure of Hydrogen Chloride from its Solutions in *o*-Nitrotoluene, *m*-Nitrotoluene and *n*-Hexane at 25°

BY S. JAMES O'BRIEN AND CHRISTOPHER L. KENNY

In an earlier paper[1] the partial pressure of hydrogen chloride from its solutions in various solvents was interpreted in terms of an acid–solvent reaction. The results so obtained may be taken as a measure of the relative basicities of the solvents used. It also has been pointed out[2,3,4] that the problem of solvent basicity can be attacked by means of infrared absorption studies. In work of this type the position of a certain absorption band, which is attributed to the formation of a hydrogen bond and which shifts to longer wave lengths in the more basic solvents, is considered a measure of the basicity of the solvent. It seemed of interest to determine to what extent the conclusions concerning the basicities of solvents obtained from such infrared absorption data parallel those obtained from partial pressure experiments. It was decided, then, to measure the partial pressure of hydrogen chloride from its solutions at 25° in the ortho and meta isomers of nitrotoluene in order to compare these and other similar available data with those obtained from infrared absorption investigations.[5]

Also, a few measurements of the partial pressure of hydrogen chloride from *n*-hexane solutions at the same temperature were made in order to determine whether the deviation of hydrogen chloride from the law of Raoult in this solvent is positive, as might be anticipated from the results obtained with haloforms in hydrocarbon solutions,[6] and from the fact that the rate of addition of hydrogen chloride to ethylenes is so very much greater in aliphatic than in aromatic hydrocarbons.[7]

Experimental

Apparatus and Method.—The apparatus and method were in general the same as those employed in the previous work.[1,8] The time allowed for the establishment of the solution–vapor equilibria ranged from two to five days. In the analysis of the solutions of the nitrotoluenes it was found to be advantageous to add a drop or two of capryl alcohol to the solutions before titration with sodium hydroxide. The constant temperature bath was regulated at 25.00 ± 0.02°.

Materials.—The liquids used were Eastman Kodak Company products. The *m*-nitrotoluene and *n*-hexane were not further purified. Since the *o*-nitrotoluene had a slightly pink color which turned to a deep purple on the

(5) Since this paper was written, an article by W. Gordy and S. C. Stanford, *J. Chem. Physics*, **8**, 170 (1940), has appeared in which a study of this kind has been made. Gordy and Stanford relate the basicities of solvents as derived from shifts of the OD vibrational band of CH_3OD in these solvents, to those derived from measurements of the solubilities of monofluorodichloromethane. This comparison seems to be in accord with the opinion, stated later in this paper, concerning the discrepancies between the basicities of solvents as intimated by infrared absorption and solubility studies.

addition of hydrogen chloride, it was purified by allowing it to stand over calcium oxide and distilling it from phosphorus pentoxide. The liquid obtained was yellow in color and maintained this color when hydrogen chloride was added. Results obtained using the unpurified *o*-nitrotoluene were, however, not significantly different from those obtained using the purified material as is shown in Table I. The physical constants of the liquids, taken as an index of purity, are as follows: *n*-hexane, $n^{20}D$ 1.3741; *o*-nitrotoluene, $n^{20}D$ 1.5476; *m*-nitrotoluene, $n^{20}D$ 1.5479; m. p. 15.35°.

The hydrogen chloride was generated and introduced into the liquids as in the previous work.[1]

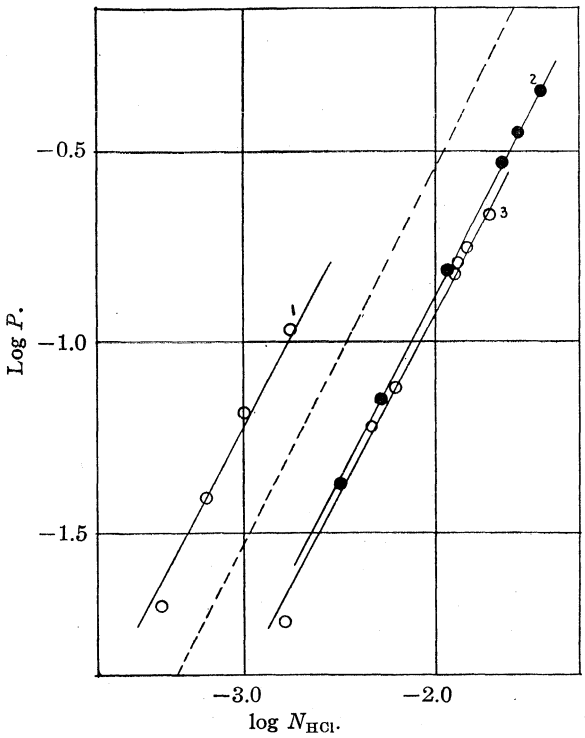

Fig. 1.—The partial pressure of hydrogen chloride from solutions in (1) *n*-hexane, (2) *o*-nitrotoluene and (3) *m*-nitrotoluene. The broken line represents Raoult's law.

Results

The results obtained are given in Tables I, II and III, in which the first column gives the molal concentration of hydrogen chloride in the solutions, the second gives the partial pressure of hydrogen chloride from the solutions in mm. of mercury, and the third column gives the Henry law constant, $k = p/m$, in atmospheres per mole per 1000 g. of solvent.

TABLE I

THE PARTIAL PRESSURE OF HYDROGEN CHLORIDE FROM ITS SOLUTIONS IN *o*-NITROTOLUENE AT 25°

TABLE III

THE PARTIAL PRESSURE OF HYDROGEN CHLORIDE FROM ITS SOLUTIONS IN *n*-HEXANE AT 25°

m	*p*, mm.	*k*
0.020	81.5	5.4
.0111	49.2	5.8
.0073	28.3	5.1
.0042	15.7	4.9
		Mean 5.3 ± 0.3

The mean value of the Henry law constant was taken as the slope of the best straight line, intersecting the origin, that could be drawn through a plot of pressure against molality. The deviation indicated is the average deviation from this mean.

The data listed in the tables are also shown graphically in Fig. 1, where the logarithm of the pressure is plotted against the logarithm of the mole fraction of the solutions. The theoretical curve was obtained using the value of 30.3 atm., calculated in the previous paper[1] for the fugacity of hydrogen chloride from the pure liquid at 25°.

Discussion

In Table IV, the reciprocals of the Henry law constants (molal solubility at 1 atm.) for hydrogen chloride in benzene, nitrobenzene, the nitrotoluenes, ethyl acetate and diethyl ether are compared with the positions in these solutions of the hydrogen chloride infrared absorption band which occurs at 3.46 μ in the pure hydrogen chloride. From this it will be seen that with the exception of the two nitrotoluenes the order of basicities as suggested by the two types of measurement is, in general, the same. The greater solubility of hydrogen chloride in the meta compound is, however, in accord with the assumption of a greater tend-

TABLE IV

Solvent	Position of band (microns)	$1/k$

ency for chelation in the ortho compound,[9] since chelation has been shown to result in a reduction of solubility if that property depends on the formation of a hydrogen bond.[10] That a chelate bond of this type should be stable in the presence of hydrogen chloride seems, however, contrary to the interpretation of the results obtained in the preceding paper[1] (p. 2507).[11] There, the high solubility of hydrogen chloride in ethylene glycol in comparison with that of monofluorodichloromethane in this solvent was explained in terms of a reduction of the association of the glycol molecules by the presence of hydrogen chloride.[12] This point is being further investigated, by similar partial pressure studies in progress in this Laboratory. If the solubility of hydrogen chloride can be taken as an index of the basic character of the solvent, it seems that the intensity, as well as the position of the absorption band must be taken into consideration when this property is to be interpreted not only in terms of the occurrence but also the extent of the solvent–solute reaction.[13]

Since hydrogen chloride solutions in the nitrotoluenes correspond with the law of Henry, and since the deviations from the law of Raoult are negative, the data may be interpreted in terms of the reaction between the solute and solvent represented by the equation

$$S + HCl = S \longrightarrow H—Cl$$

where S represents the solvent and S ⟶ H—Cl a compound formed by means of a hydrogen bond, some atom in the solvent acting as the electron donor. The equilibrium constant for this reaction is given by the equation[1]

$$K_a = f_0 - km_s/km_s \qquad (1)$$

where f_0 is the fugacity of liquid hydrogen chloride (30.3 atm. at 25°), k the Henry law constant and m_s the number of moles of solvent in 1000 g. Values of K_a calculated from the above data are 1.35 and 1.53 for ortho- and meta-nitrotoluene, respectively. As a measure of the basicity of the solvent, K_a should be more suitable than the molal solubility used in Table IV. This equilibrium constant was not used in the table, however, due to the inclusion of ethyl acetate and ether solutions, for which the existing data are not sufficient to show whether equation (1) is applicable.

While the value being used for the fugacity of liquid hydrogen chloride is far from satisfactory, there can be little doubt that the data obtained for the *n*-hexane solutions demonstrate a positive deviation from the law of Raoult, since the vapor pressure of hydrogen chloride from the solutions is greater than that required by the law even if the fugacity of liquid hydrogen chloride were equal to its vapor pressure (46.8 atm. at 25°). Treatment of these results in terms of association of the solvent seems to be out of the question for a liquid like hexane. Solutions which show a positive deviation from the law of Raoult can, no doubt, be better interpreted through a consideration of the internal pressures of the liquids involved.[14] However, it seems best to postpone further discussion along these lines until additional data can be presented.

Summary

1. Measurements are reported of the partial pressure of hydrogen chloride at 25° from its solutions in *o*-nitrotoluene, *m*-nitrotoluene and *n*-hexane over the concentration ranges 0.023–0.259, 0.012–0.139 and 0.004–0.02 molal, respectively.

2. The conclusions concerning the basicity of liquids derived from these measurements are compared with those obtained from the infrared absorption spectra of hydrogen chloride in various solvents. The comparison seems to show that

(10) M. J. Copley, G. F. Zellhoefer and C. S. Marvel, THIS JOURNAL, **60**, 2672 (1938).

(11) It should be pointed out that J. J. Fox and A. E. Martin, *Proc. Roy Soc.* (London), **A162**, 437 (1937), suggested a similar interpretation of the infrared absorption of phenol in chloroform solutions as compared with its absorption in carbon tetrachloride solutions. The high "concentration" of the solvent, chloroform, would favor a phenol–chloroform reaction in such solutions, although this is a reaction which may not occur when the haloform is the solute, as intimated by solubility measurements[9] (pp. 2667–2668).

intensities as well as position of infrared absorption bands are required for an accurate estimate of the basicity of solvents.

3. In the nitrotoluene solutions, hydrogen chloride corresponds with the law of Henry and shows negative deviations from the law of Raoult. The data in these solutions are interpreted in terms of a reaction between solute and solvent. In the hexane solutions hydrogen chloride also corresponds with the law of Henry, but the deviation from the law of Raoult is positive.

Preparation of Cobalt Carbonyl, Cobalt Nitrosyl Carbonyl and Cobalt Carbonyl Hydride by the Cyanide Method

BY ARTHUR A. BLANCHARD AND PAUL GILMONT

Brockway and Anderson[1] have prepared cobalt nitrosyl carbonyl for the purpose of electron diffraction studies by the method of Blanchard, Rafter and Adams,[2] saturating an alkaline suspension of cobaltous cyanide with carbon monoxide, but they state that on passing nitric oxide into the still alkaline solution no nitrosyl carbonyl is formed. They obtain this product only after acidification. This is contrary to the findings of Blanchard, Rafter and Adams, who found that cobalt nitrosyl carbonyl vapor could be swept from the still alkaline solution. The present studies confirm the latter statement. Furthermore, the product obtained by treating the alkaline solution with nitric oxide is undoubtedly purer than that obtained from the acidified solution.

Ewens and Lister[3] prepared cobalt carbonyl hydride, also for electron diffraction studies, by a modification of the method of Coleman and Blanchard[4] by saturating an alkaline suspension of cobaltous cyanide with carbon monoxide, then acidifying and sweeping the volatile hydride from the solution. The fact that the volatile hydride $HCo(CO)_4$ is obtained when cyanide is used as a carrier makes it seem probable that the fundamental reaction of oxidation and reduction is the same as when cysteine is the carrier, namely: $2CoCl_2 + 11CO + 12KOH \rightarrow 3K_2CO_3 + 2KCo(CO)_4 + 4KCl$. In absence of the carrier, no absorption of carbon monoxide takes place. The carrier, whether cysteine or cyanide, forms an intermediate complex containing carbon monoxide and cobalt; the latter reacts further to yield the salt of $HCo(CO)_4$ and the carrier is regenerated. Schubert[5] has very beautifully identified the intermediate complexes in the case of cysteine. Acidification liberates the volatile acid $HCo(CO)_4$ from its salt. Treatment with NO produces the volatile nitrosyl carbonyl, probably according to the reaction: $KCo(CO)_4 + NO + H_2O \rightarrow CO(CO)_3NO + CO + KOH + {}^1/_2 H_2$.

(4) Coleman and Blanchard, THIS JOURNAL, **58**, 2160 (1936).

Experimental

A large number of runs with varying proportions of cyanide and alkali were carried out and the proportions given in the following statements were found to produce the best results in the shortest time.

A shaking apparatus capable of keeping the liquid in the condition of a fine spray and yet allowing the passage of gases during the shaking is provided. It is swept out with carbon monoxide and approximately 50 ml. of a solution about 0.5 formal in cobalt nitrate, 0.5 formal in potassium cyanide and 4.0 formal in potassium hydroxide is introduced as follows: 7.3 g. of $Co(NO_3)_2 \cdot 6H_2O$ in 15 ml. of water is allowed to enter through a side arm, then 5 cc. of water to wash the arm, then 11.2 g. of potassium hydroxide in 11 ml. of water, then 5 cc. of water, then 1.6 g. of potassium cyanide in 3 ml. of water and lastly, 5 cc. of water.

The exit stopcock is closed and the solution shaken. A total absorption of 2200 to 2600 cc. of carbon monoxide takes place in about seven hours, 2 liters in the first two to three hours, the rate falling during the next three to five hours. During this absorption the solution changes from a blue suspension, through a pink suspension, to a yellow solution almost free of suspended matter.

Cobalt Nitrosyl Carbonyl.—The yellow liquid is a solution of the potassium salt of cobalt carbonyl hydride. The carbon monoxide is displaced from the shaker by nitric oxide and the shaker is started. Soon the solution turns red and after a while a deep yellow gas begins to show in

(5) Schubert, *ibid.*, **55**, 1877 (1933).

the shaker. This is the cobalt nitrosyl carbonyl and it is swept from the shaker by a very slow stream of nitric oxide, dried by passing through calcium chloride and phosphorus pentoxide, and frozen in a trap cooled with solid carbon dioxide and alcohol. Sweeping with nitric oxide at the rate of 2 liters per hour until no further product is obtained takes about five hours. A yield of 2.5 g. of $Co(NO)(CO)_3$ can be obtained or 58%.

Cobalt Carbonyl Hydride.—A solution of the potassium salt of cobalt carbonyl hydride is prepared as in the foregoing directions. A 500-ml. distilling flask fitted with an inlet tube reaching to the bottom and another short inlet tube and a drying train and trap leading from the side arm is provided. The long inlet tube is attached to the shaker and the apparatus is filled with carbon monoxide. The shaker is tilted and the solution is run into the flask. The flask is cooled with ice water and 30 ml. of 12 *N* hydrochloric acid is added slowly with hand shaking through the short tube. The surplus of hydrochloric acid after the surplus potassium hydroxide, potassium carbonate, potassium cyanide and $KCo(CO)_4$ have reacted gives a concentration of approximately 2.3 *N*. With a slow stream of carbon monoxide passing, the flask is allowed to come to room temperature, but care must be taken that the evolution of gas (carbon dioxide and $Co(CO)_4H$) does not carry the foam into the drying train. A slow stream of carbon monoxide is continued for ten hours to sweep the hydride from the solution. Sweeping at a lower temperature (10–15°) takes a longer time but produces a better yield of a cleaner product.

The cobalt carbonyl hydride condenses in the trap at −79° to a nearly white to light yellow solid. It melts at −33° to a light yellow liquid and begins to decompose above that temperature into cobalt tetracarbonyl and hydrogen. If it is sealed in a tube and brought to room temperature a high pressure results which will burst an ordinary tube. It is true that the presence of hydrogen tends to reverse the reaction.[6] The cobalt carbonyl hydride vapor in the tube has a deep yellow color. A yield of 2.2 g. of $Co(CO)_4H$[7,8] can be obtained or 44%.

Cobalt Tetracarbonyl $[Co(CO)_4]_2$.—The trap in which the hydride is collected should be connected through a tube of perhaps 100-ml. capacity with a sample tube and the system evacuated. Cooling the sample tube to −79° and removing the trap from the carbon dioxide ice, the hydride is distilled into the sample tube. The latter is allowed to come to room temperature and the hydride to decompose. The trap is again cooled to −79°, the hydrogen is pumped out and the remaining yellow cobalt carbonyl hydride vapor is condensed in the trap. The hydride is again distilled back into the sample tube and this process is repeated until, when no more yellow vapors appear after several days of standing, the sample tube is sealed off.

Summary

Carbon monoxide is absorbed almost quantitatively by an alkaline suspension of a cobalt salt to form $KCo(CO)_4$, but only when a carrier such as a small amount of a cyanide is present.

Nitric oxide displaces the volatile cobalt nitrosyl carbonyl $Co(NO)(CO)_3$ from the resulting solution even when the solution is distinctly alkaline.

Acids displace the volatile cobalt carbonyl hydride, $HCo(CO)_4$.

Cobalt tetracarbonyl $[Co(CO)_4]_2$ is obtained by allowing the hydride to decompose spontaneously at room temperature.

CAMBRIDGE, MASSACHUSETTS RECEIVED JANUARY 25, 1940

(6) Hieber, Schulten and Marin, *Z. anorg. allgem. Chem.*, **240**, 261 (1939).

(7) It is noteworthy that cobalt carbonyl hydride vapor mixed with a large amount of carbon monoxide at room temperature can be carried through long connections and a drying train without showing any sign of decomposition.

(8) The odor of cobalt carbonyl hydride is so intolerable that the danger from inhaling it is much less than from nickel carbonyl. It is, however, probably equally poisonous and since there is no antidote and the injury resulting from inhaling it is permanent, the utmost caution should be used to keep it from escaping into the laboratory.

The Physical Chemical Investigation of Certain Nucleoproteins. I. Preparation and General Properties

BY R. OWEN CARTER[1,2] AND JAMES L. HALL[1,3]

Nucleoproteins are present in all cells, occurring in highest concentration in the nucleoplasm. Since no systematic investigation of the physicochemical properties of this class of proteins has been made, it has been selected by us as the first class of tissue proteins to be studied. This report describes the preparation and some properties of two members of this group, the nucleohistone of the calf thymus, and the nucleoprotein of the hog thyroid. For the first of these are given the phosphorus and nitrogen contents, the apparent specific volume, and the refractive index increment, along with viscosity studies of its solutions and a titration curve.

Calf Thymus Nucleohistone

Preparation.—The calf thymus nucleohistone was prepared by a modification of the method of Huiskamp.[4] The glands, obtained directly from the animal carcasses, were reduced to a pulp, suspended in two to three times their volume of pure water, and extracted at 5° for twenty-four to thirty-six hours. The extract was filtered and clarified and the nucleohistone precipitated as the corresponding salt by addition of an equal volume of either 2% sodium chloride solution, or 0.2% calcium chloride solution. All work was done near the freezing temperature.

The sodium salt is a dense gel-like material which dissolves either in pure water or 5% sodium chloride solution. The calcium salt is insoluble in pure water but dissolves easily in solutions of 2% calcium chloride or 5% sodium chloride, though in the last case it is converted to the sodium salt.

Phosphorus Content of Sodium Nucleohistone.—Sodium nucleohistone which had been dialyzed against distilled water until the dialyzate gave no chloride test was frozen and dried to constant weight in a vacuum over phosphorus pentoxide. Samples of this dried protein were completely ashed with alcoholic magnesium nitrate and phosphate determinations were made colorimetrically with a small Duboscq calorimeter following the method of Fiske and Subbarow.[5] These colored solutions do not absorb light as required by Beer's law. The corrections for this deviation given by Bodansky[6] were found to apply and were used in the calculations.

TABLE I

PHOSPHORUS CONTENT OF CALF THYMUS NUCLEOHISTONE

Sample, g.	Color. reading,[a] mm.	Vol. of solution, cc.	Wt. P, g.	Per cent. P
0.0309	15.3	250	0.00137	4.43
.0510	9.3	250	.00238	4.67
.0241	18.6	250	.00109	4.52
.0174	10.8	100	.00081	4.66
			Average	4.6 ± 0.1

[a] The standard containing 0.02 mg. P in 5 cc. was set at 20 mm.

Nitrogen Content of Sodium Nucleohistone.—This value was determined by the micro-Kjeldahl method of Pregl. Because of the deliquescence of the dried protein, these determinations were performed on aliquots of solutions.

TABLE II

NITROGEN CONTENT OF CALF THYMUS NUCLEOHISTONE

				Average 16.73 ± 0.02

Apparent Specific Volume of Sodium Nucleohistone.—For this determination a double bulb pycnometer of the Ostwald type was used. All measurements were made at 25 ± 0.005°. The protein solution was sterilized with merthiolate and completely dialyzed against distilled water. In two determinations made at a protein concentration of 1.7805%, the result was $V = 0.6575 \pm 0.003$. This is in contrast to the usual protein value of 0.73 to 0.75. Such a low value is reasonable, however, since nucleic acid, which makes up a large part of the nucleohistone molecule, has a density of about 2.15 g. per cc.[7] as compared to the usual protein density of 1.33 g. per cc.

Refractive Index Increment.—The refractive index of solutions of nucleohistone is a linear function of the protein concentration, permitting the use of refractive index methods for following concentration. As determined by use of a Bausch and Lomb immersion refractometer at 25.0°, the difference between the refractive indices of the protein solution and solvent, divided by the concentration of the protein, was found to be $(1.76 \pm 0.02) \times 10^{-3}$ per g. per 100 cc.

Viscosity of Sodium Nucleohistone Solutions.—Three series of viscosity measurements were made with the sodium nucleohistone solutions, (a) in dilute buffer,

Titration Curve for Sodium Nucleohistone.—A titration curve was obtained by using nucleohistone which had been twice precipitated with sodium chloride and then dissolved in and dialyzed against distilled water until the dialyzate was chloride free. The initial *p*H of this dialyzed solution was about 5.4. Either 0.1 *N* sodium hydroxide or hydrochloric acid was continuously titrated into a 4% protein solution. The *p*H was measured at intervals by means of a glass electrode. The results, calculated on the basis of moles of acid or base bound per gram of protein are shown in Fig. 1.

The curve is completely reproducible although the characteristics of the glass electrode make the *p*H values beyond *p*H 9.5 very doubtful. The apparent break in the curve just below *p*H 2 is possibly genuine, since the nucleohistone hydrolyzes in acid solution and releases the comparatively strong nucleic acid. The entire acid combining capacity may be accounted for on the basis of the phosphorus present in the protein molecule. Because of the insolubility of the protein over part of the range, and because it was not possible to determine an exact isoelectric point, no attempt is made to estimate individual amino acids from the curve.

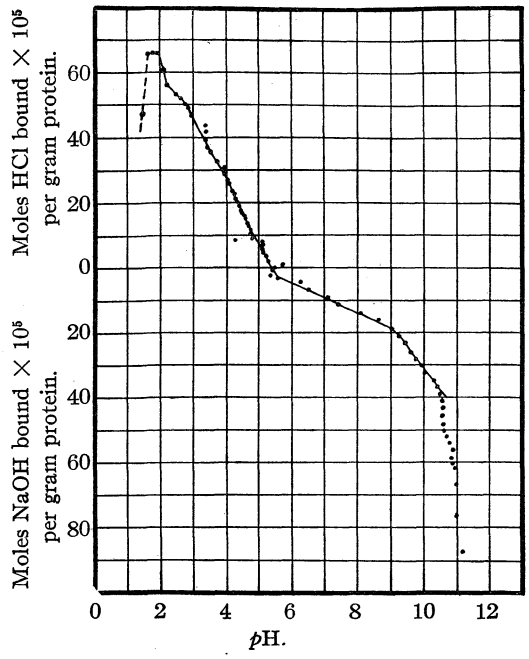

Fig. 1.—Titration curve of thymus nucleohistone: acid and base combining capacity.

Nucleoprotein from the Hog Thyroid

The nucleoprotein of the hog thyroid gland was prepared after the method of Heidelberger and Palmer.[8] It was found quite impossible to separate the thyroglobulin from the nucleoprotein by salting out at various concentrations of ammonium or sodium sulfates, thus completely confirming the work of Heidelberger and Palmer in this respect. Accordingly the nucleoprotein was precipitated and purified by precipitation at *p*H 4.9 with either 0.1 *N* hydrochloric or acetic acid. In the purification of the nucleoprotein a negative iodine test was used as a criterion of the absence of thyroglobulin.

Free diffusion and sedimentation velocity experiments indicate that the protein so prepared is more or less polydisperse, but electrophoretic studies indicate that the amount of nucleic acid present is independent of the preparational method. When the diffusion curves are analyzed by a statistical method, an average diffusion constant can be calculated. This value depends upon the previous treatment of the protein. Material prepared with acetic acid gives a much lower diffusion constant than that prepared with hydrochloric acid. Precipitation of purified nucleoprotein with ammonium sulfate also gives a material having a low diffusion constant.

The sedimentation, diffusion, and electrophoretic studies of these substances will be reported in later papers of this series.

Acknowledgments.—The writers wish to express their gratitude for the helpful advice of J. W. Williams throughout the course of their work and to acknowledge the suggestions of Dr. H. P. Lundgren in connection with the prepa-

ration of the nucleoprotein of the hog thyroid. One of us (R. O. C.) wishes to acknowledge financial assistance received from the Wisconsin Alumni Research Foundation.

Summary

1. Certain striking physical and chemical properties of the calf thymus nucleohistone protein have been presented. The phosphorus and nitrogen contents were accurately determined. The specific volume, refractive index increment, and viscosity of this protein in solution, as well as a titration curve are given.

2. The effect of certain preparational methods on the centrifugal and diffusion properties of the hog thyroid nucleoprotein has been briefly discussed.

The Calculation of Weight Average Molecular Weights during the Course of Decomposition of Homogeneous Linear Polymers

BY WALTER H. DURFEE[1] AND Z. I. KERTESZ[2]

For materials that occur naturally and that are composed of large molecules (in whatever sense the word molecule may be understood), some degree of heterogeneity as regards size of the individual molecules must be assumed. This natural heterogeneity is further increased upon progressing degradation until the lower polymers become dominant and, finally, by complete depolymerization, homogeneity is attained.

Such heterogeneity is obvious in any pectin isolated from plant material.[3] Its heterogeneity is increased by the chemical manipulations necessary for its isolation. On the other hand, there is ample evidence to show[4] that by extracting the crude pectic materials with 50% ethanol the lower polymers originally present (or formed during preparation) are removed, together with some other materials, usually accompanying pectins in nature. It is obvious, however, that even material prepared by this latter method contains a certain range of the various polymers and is not entirely homogeneous.

For several years one of us (Z. I. K.) has been engaged in research on the chemical and physical structure of the pectin molecule. One method of approach to this problem is through a study of the changes which take place in the chemical and physical structure of pectin upon enzymic hydrolysis. It is hoped that by such a study information can be gained concerning the naturally occurring pectic materials.

It has been reported recently[5] that when the decomposition of pectin is followed by various methods, the conclusions drawn concerning the average degree of polymerization are not in agreement. This led to an investigation of the number and weight averages[6] (M_n, M_w) for the "molecular weight" during the course of decomposition. During this work a formula was developed for the calculation of the M_w for any stage of progressive decomposition of a homogeneous linear polymer which, the authors feel, may also be useful to other workers dealing with such materials.

Several articles dealing with similar calculations already have appeared in the literature. W. Kuhn[7] made a study of the kinetics of the decomposition of chain-like polymers and calculated the proportions of various fission products occurring during the course of the hydrolysis. Dostal and Mark[8] investigated the heterogeneity of materials composed of macromolecules and proposed a method for the determination of the distribution of the proportion of fractions having various molecular weights in the mixture. More recently Lassatre[9] considered the degree of polymerization of cellulose during hydrolysis. All these authors approached the problem from the kinetical point of view and we feel that there is need to consider the basic relation between

M_n and M_w in a more general manner, without considering the rate at which the progressive decomposition proceeds. In the present work it has been assumed that the number of broken linkages can be chemically determined (as is mostly the case) and thus the progress of the decomposition may be followed in that manner. The purpose of the calculations was to determine the M_w (and M_n) corresponding to any definite extent of hydrolysis as measured by the number of linkages broken irrespective of the velocity of the reaction.

Methods Used and Results Obtained.—Some assumptions have been made in order to increase the general validity of the results as well as for the purpose of defining their limitations. The question whether these assumptions hold in the case of pectins is not the subject of this paper and will be dealt with elsewhere. The molecules have been assumed to be composed of n identical units coupled by $n-1$ linkages to form a chain-like compound. The original material (composed of n units each of the molecular weight m, so that $M = mn$) has been assumed to be homogeneous in its molecular weight. It has been assumed that fission occurs as easily in a linkage of two units as in a long chain and furthermore that each step in the fission occurs simultaneously in all pieces of all chains, thus ignoring the impossibility of fission occurring in single units.

The calculation of the M_n at any degree of hydrolysis is obvious and simple. It will always equal M (original)$/p = mn/p$, where p is the number of groups or pieces into which the original chain of n units has split. The number of linkages opened is always $p-1$.

In the calculation of the M_w the size of each of the p groups, as well as all of the various possible ways in which the original chain of n units may be split into p groups, must be considered. In order to take all possibilities into consideration, it is necessary to assume the presence of a large number of molecules. While it is true that if a chain is split progressively in such a way that all the resulting groups are composed of the same number of units, the values of M_n and M_w will be equal, these values will differ considerably from each other when an average of all possible splittings is calculated, as can be done by formula (4).

We denote by $K(n,p)$ the number of ways that the n units of a chain may be split into p groups, each containing one or more units. (Obviously, $1 \leqq p \leqq n$). There being $n-1$ linkages and $p-1$ partitions between groups, $K(n,p)$ is the number of ways that the $p-1$ partitions may be distributed among the $n-1$ linkages

$$K(n,p) = {}_{n-1}C_{p-1} = \frac{(n-1)!}{(n-p)!\,(p-1)!} = \frac{(n-1)(n-2)\ldots(n-p+1)}{1\cdot 2\ldots(p-1)} \qquad (1)$$

Now $M_w = \sum_i f_i M_i$, where f_i is "the fractional weight of the constituent of molecular weight M_i," and the summation extends over all "constituents."[6] A "constituent" is one of the p groups: if it contains n_i units its f_i is n_i/n, and its $M_i = mn_i$. Thus $f_i = M_i/mn$, and for a single chain we have

$$M_w = \sum_{i=1}^{p} f_i M_i = \sum_{i=1}^{p} \frac{M_i^2}{mn} = \frac{1}{mn}\sum_{i=1}^{p} M_i^2 \qquad (2)$$

This must be averaged over all $K(n,p)$ possible arrangements of n units in p groups. To do this, suppose $K(n,p)$ chains arranged one below another. There being p groups in each chain, there will be p columns, and in each column a group of r units will occur as many times as the number of ways in which the remaining $n-r$ units can be split into $p-1$ groups, namely

$$K(n-r, p-1) = {}_{n-r-2}C_{p-2}$$

Hence, considering all p columns, a group of r units, each with $f_i = r/n$, $M_i = mr$, occurs $p\cdot{}_{n-r-1}C_{p-2}$ times, contributing to the total $f_i M_i$ the amount $\frac{mpr^2}{n}\cdot{}_{n-r-1}C_{p-2}$. Summing this for all values of r from 1 to $n-p+1$, and dividing by $K(n,p)$ for the average, we have

$$M_w = \sum_{r=1}^{n-p+1} \frac{mpr^2}{n}\cdot{}_{n-r-1}C_{p-2}/{}_{n-1}C_{p-1} \qquad (3)$$

This expression reduces without difficulty to

$$M_w = \frac{2n-p+1}{p+1}\,m \qquad (4)$$

The ratio of M_n to M_w is, therefore

$$\frac{M_n}{M_w} = \frac{n(p+1)}{p(2n-p+1)} \qquad (5)$$

which is less than unity for $1 < n < p$.

This ratio has a minimum value for $p = \sqrt{2n+2} - 1$, namely, $n/(\sqrt{2n+2}-1)^2$.

Consider, as an example, a chain of ten units split into seven groups. We may assume $m = 1$. We may analyze this situation as follows

(a) 6 groups of 1 unit each, 1 group of 4 units

Units	1	1	1	1	1	1	4	
f_i	.1	.1	.1	.1	.1	.1	.4	
M_i	1	1	1	1	1	1	4	
f_iM_i	.1	.1	.1	.1	.1	.1	1.6	$\Sigma f_iM_i = 2.2$

There are seven such arrangements, corresponding to the seven places in which the 4-group may fall; hence, we have a total $\Sigma f_iM_i = 7 \times 2.2 = 15.4$.

(b) 5 groups of 1 unit each, 1 group of 2 units and 1 of 3 units

Units	1	1	1	1	1	2	3	
f_i	.1	.1	.1	.1	.1	.2	.3	
M_i	1	1	1	1	1	2	3	
f_iM_i	.1	.1	.1	.1	.1	.4	.9	$\Sigma f_iM_i = 1.8$

There are 42 such arrangements obtainable by placing the 2-group and 3-group in all possible positions, giving a total $\Sigma f_iM_i = 42 \times 1.8 = 75.6$.

(c) 4 groups of 1 unit each, 3 groups of 2 units each

Units	1	1	1	1	2	2	2	
f_i	.1	.1	.1	.1	.2	.2	.2	
M_i	1	1	1	1	2	2	2	
f_iM_i	.1	.1	.1	.1	.4	.4	.4	$\Sigma f_iM_i = 1.6$

There are 35 such arrangements obtainable by placing the three 2-groups in all possible positions, giving a total $\Sigma f_iM_i = 35 \times 1.6 = 56.0$.

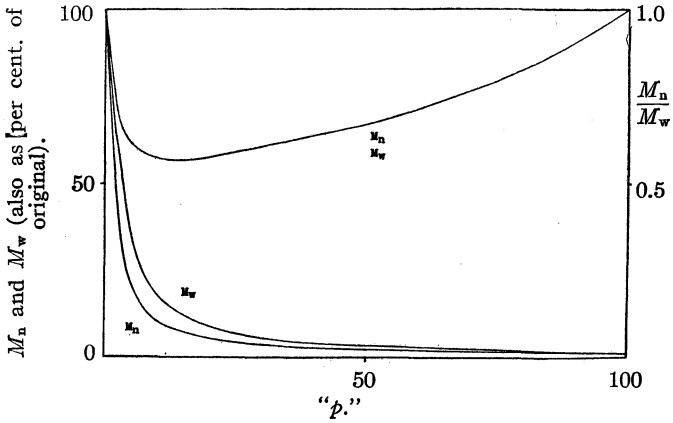

Fig. 1.—The weight average molecular weight (M_w), number average molecular weight (M_n) and the ratio M_n/M_w in case of progressive splitting of a 100 unit chain ($n = 100$, $m = 1$).

Adding these results we have $\Sigma f_iM_i = 147.0$, obtained by using a total of 84 arrangements. The average is 147.0/84 = 1.75, which is the value of M_w.

This method of analysis quickly becomes impracticable as the value of n increases. The results may be obtained directly, however, from formulas (1) and (4). In the example considered, $n = 10$ and $p = 7$, hence

$$K(10,7) = {}_9C_6 = 84; \quad M_w = \frac{20 - 7 + 1}{7 + 1} = \frac{14}{8} = 1.75$$

Figure 1 shows the values of M_n and M_w, again assuming $m = 1$, for a chain originally of 100 units progressively hydrolyzed, that is, for values of p from 1 to 100. In addition, the values of the ratio M_n/M_w are plotted. This ratio is a minimum for $p = 13$. At this point, we have $M_n = 7.7$, $M_w = 13.4$, and $M_n/M_w = 0.57$. To the right of this point, the curves slowly converge again, meeting at the point ($p = 100$), indicating complete hydrolysis.

It is realized that in order to have a sufficient number of the various early split-products present the number of molecules required from the starting material is very high; but assuming a *random* distribution in the size of those chains available for the various steps in the fission, the values obtained for the M_w will not be influenced.

Summary

A formula has been developed for the calculation of the weight average molecular weight of a linear polymer undergoing progressive splitting. An example is given to show the validity of the formula obtained. By the use of the formula the trend of average number and weight molecular weights for a polymer containing 100 units was calculated and is shown in Fig. 1. At the point representing 13% of complete hydrolysis the ratio between the two averages reaches a minimum, 0.57.

Substituted Vinyl Barbituric Acids. IV. Derivatives Containing a Primary 1-Alkenyl Group

BY ARTHUR C. COPE, WALTER H. HARTUNG,[1,2] EVELYN M. HANCOCK AND FRANK S. CROSSLEY[2]

Previous papers in this series have described the preparation and properties of barbituric acids substituted in the 5-position by (1-alkylvinyl) groups, RCH=C(R')—. This paper concerns barbituric acids containing "primary 1-alkenyl" groups, RCH=CH—, or R_2C=CH, in the 5-position.

The 5-(primary 1-alkenyl)-5-alkylbarbituric acids were prepared by condensing (primary 1-alkenyl)-alkylmalonic esters[3] with urea in the presence of alcoholic sodium ethoxide. Appreciable quantities of the substituted malonic esters underwent cleavage during the condensation, producing monocarboxylic esters and amides derived from them.[4] The yields of purified barbituric acid derivatives, which are recorded in Table I, were low in several cases, due partly to the occurrence of cleavage as a side reaction during the condensations, and partly to difficulties encountered in purification of the products. Most of the substituted barbituric acids did not crystallize readily, and in several cases a number of recrystallizations were required. Only one of the two possible geometric isomers was isolated in each case.

The structures of the barbituric acid derivatives must be those indicated in Table I, since there is no other position in the alkenyl groups which the double bond can take, unless the extremely improbable assumption is made that the double bond can migrate farther into the carbon chain. In the case of the first three compounds listed in Table I, which are 5-propenyl-5-alkyl-barbituric acids, such a migration would produce the corresponding 5-allyl-5-alkyl-barbituric acids, which are known.[5]

The three 5-propenyl-5-alkyl-barbituric acids (Table I) were proved to be different from the corresponding 5-allyl-5-alkyl derivatives by direct comparison in two cases, and by a divergence of physical properties in the third. Moreover, the position of the double bond in 5-propenyl-5-butyl-barbituric acid was definitely established by ozonization, which produced acetaldehyde.

The purity of two of the (primary 1-alkenyl)-alkyl-barbituric acids was established by quantitative reduction. One of the compounds reduced was 5-(1-butenyl)-5-ethyl-barbituric acid, and the reduction product was proved to be 5-butyl-5-ethyl-barbituric acid by direct comparison with a commercial sample of the latter (Neonal).

Experimental Part

The barbituric acid condensations were carried out in the manner previously described.[4a] The properties of the products and the yields of material purified by recrystallization to constant melting point are recorded in Table I.

In each preparation the neutral by-products were separated by ether extraction of the aqueous alkaline solutions containing the substituted barbituric acids, before acidification (as in ref. 4a). In all but two cases, distillation of these extracts gave a mixture of the original substituted malonic ester, the monocarboxylic ester formed by cleavage of a carbethoxy group from the dicarboxylic ester (see ref. 4a), and a small quantity of a solid amide. The quantity of this mixture varied from 10 to 30% of the weight of the original substituted malonic ester.

The amide formed as a by-product in the preparation of 5-isopropyl-5-(1-butenyl)-barbituric acid was present in sufficient quantity to permit isolation and purification, by washing free from ester with hexane and recrystallization from ether and hexane; m. p. 123–124°. Analysis indicated that this amide was 2-isopropyl-2-hexenamide, as expected by analogy with similar cases (ref. 4; the position of the double bond is assumed by analogy).

Anal. Calcd. for $C_9H_{17}ON$: N, 9.03. Found: N, 8.92.

Approximately 40% of the substituted malonic esters, free from cleavage products, were recovered from the condensations which produced 5-(1-isobutenyl)-5-ethyl-barbituric acid and 5-propenyl-5-isopropyl-barbituric acid, respectively.

Structure of 5-(Primary 1-alkenyl)-5-alkyl-barbituric Acids. Quantitative Reductions.—5-(1-Butenyl)-5-ethyl-barbituric acid (3.00 g.) was dissolved in 25 cc. of alcohol and shaken with hydrogen in the presence of 1 g. of palladinized charcoal catalyst. Reduction was complete in thirty minutes, and 98.5% of the theoretical quantity of hydrogen was required (within experimental error of one molar equivalent). The reduction product was isolated by filtering the catalyst and crystallizing from dilute alcohol; yield 2.6 g. (87%); m. p. 122–123°. It was proved to be

[a] Recrystallized from dilute alcohol. [b] Recrystallized from benzene and pentane. [c] Distilled in vacuum; b. p. 185–190 (1.5 mm.); then crystallized from benzene and pentane. [d] Recrystallized from ether and pentane. [e] Distilled in vacuum; b. p. 138–142 (1.5 mm.) [f] Geometric isomerism is not possible for this compound. [g] These two compounds are 5-(secondary 1-alkenyl)-5-alkyl-barbituric acids, related in structure to a series previously described in THIS JOURNAL, **61**, 776 (1939). They were prepared by the method used for their homologs, from esters described in THIS JOURNAL, **60**, 2903 (1938). [h] Distilled in vacuum, b. p. 154–158 (1 mm.), then crystallized from ether and pentane. [i] Using two equivalents of sodium ethoxide in a procedure otherwise similar to that described in ref. 4a. [j] Using one equivalent of sodium ethoxide. [k] We are indebted to Mr. C. S. Miller for semi-micro Kjeldahl analyses.

5-butyl-5-ethyl-barbituric acid by determining the mixed m. p. with a commercial sample of Neonal, which gave no depression.

A similar reduction of 3.00 g. of 5-(1-butenyl)-5-isopropyl-barbituric acid required 99.0% of one molar equivalent of hydrogen, and 2.8 g. (93%) of 5-butyl-5-isopropyl-barbituric acid, m. p. 154–155°, was isolated as the reduction product in the same manner.

Anal. Calcd. for $C_{11}H_{18}O_3N_2$: N, 12.39. Found: N, 12.37.

The identity of this sample of 5-butyl-5-isopropyl-barbituric acid was established by the fact that it did not depress the m. p. of a known sample (m. p. also 154–155°) prepared by the reduction of 5-butyl-5-isopropenyl barbituric acid.[4a] Another known sample prepared by the condensation of ethyl butyl-isopropylmalonate with urea had the same m. p.[6]

Comparison of Propenyl and Allyl Alkyl-barbituric Acids.—A mixed m. p. of 5-propenyl-5-isopropyl-barbituric acid (m. p. 140–141°) and 5-allyl-5-isopropyl-barbituric acid (m. p. 136–137°) was 121–127°. A mixture of 5-propenyl-5-butyl-barbituric acid (m. p. 127.5–128.5°) and 5-allyl-5-butyl-barbituric acid (m. p. 126–127°) had m. p. 106–120°.

Ozonization.—The ozonization of 5-propenyl-5-butyl-barbituric acid[7] produced acetaldehyde, m. p. of the 2,4-dinitrophenylhydrazone and mixed m. p. with a known sample 166–168° (cor.).[8]

Pharmacological Data

The results of pharmacological tests of the 5-(primary 1-alkenyl)-5-alkyl-barbituric acids are recorded in Table II. The 1-butenyl and 1-isopentenyl derivatives, particularly those in which the total number of carbon atoms in the groups attached to the barbituric acid nucleus is seven or eight, are the most effective hypnotics with the highest therapeutic ratios of the series. The compounds in which isopropyl is the alkyl group substituted in the 5-position are particularly effective.

The most noteworthy fact about the pharmacological action of these barbiturates is the very short duration of narcosis produced by several of them, particularly the 5-(1-butenyl)-5-isopropyl and 5-(1-isopentenyl)-5-isopropyl derivatives. These substances are short acting even at relatively high dose levels. We have observed similar durations of action heretofore only with N-substituted barbituric acids.

(6) The m. p. of 209–210° recorded by Shonle and Moment, THIS JOURNAL, **45**, 248 (1923), for 5-butyl-5-isopropyl-barbituric acid must be in error.

(7) By a procedure described by Cope and Hancock, *ibid.*, **61**, 358 (1939).

(8) Campbell, *Analyst*, **61**, 392 (1936).

Summary

A series of fifteen substituted vinyl alkyl barbituric acids has been prepared in which the substituted vinyl groups are of the type RCH=CH— or $R_2C{=}CH-$. The chemical and pharmacological properties of the compounds are recorded.

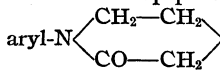
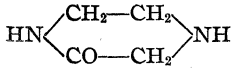
A Synthesis of Monoketopiperazines

BY SAMUEL R. ASPINALL

Monoketopiperazines of the type

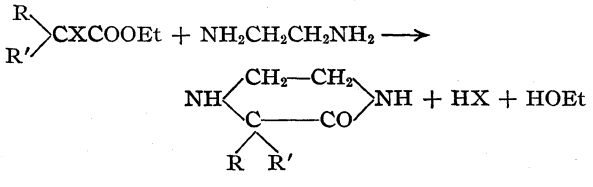


were prepared by Bischoff and Nastvogel in 1889[1] by condensing N,N′-diarylethylenediamines with chloroacetic acid in the presence of sodium acetate; and in 1892 Bischoff and Trapesonzjanz[2] prepared the same compounds by reducing 1,4-diaryl-2,3-diketopiperazines[3] using various metal–acid combinations. The 2,3-diketopiperazines had been obtained by heating N,N′-diarylethylenediamines with oxalic acid. No significant information in regard to yields is given in any of this work. No further synthetic work on monoketopiperazines has been carried out and the non-arylated type

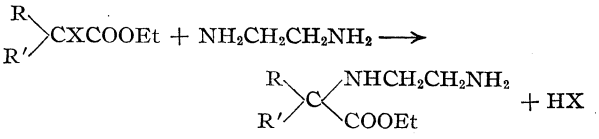


never has been reported.

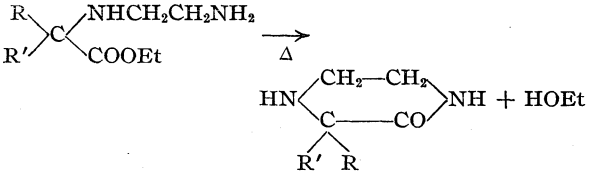
In connection with a more extended study of the interaction of ethylenediamine and various organic esters,[4] it has now been found that α-halogen esters react with ethylenediamine to give satisfactory yields of the non-arylated type of monoketopiperazines according to the following equation, where R and R′ may be alkyl or hydrogen.



That the first phase of the reaction is alkylation of the ethylenediamine is evidenced by the fact that when the two reactants are mixed there is a violent reaction with evolution of heat and the simultaneous liberation of ionic halogen. This is consistent with the usual behavior of aliphatic amines with α-halogen compounds; furthermore, it is generally true that an amidation at room temperature by means of an ester is not a fast, violent reaction. It is then obvious that the reaction should be carried out under conditions favorable to the formation of a monoalkylethylenediamine, as follows



This requires slow addition of the halogen ester to an excess of ethylenediamine diluted as much as feasible with some inert solvent. The liberated halogen acid, which is absorbed by the reaction mixture, is destroyed by sodium ethylate, the sodium halide so produced is filtered off and the solvent and excess ethylenediamine are removed by distillation at the water pump. When the residual monoalkylethylenediamine is heated at 200° under high vacuum, cyclization occurs and the monoketopiperazine distils over as a pale yellow oil. After solidification, it is obtained as a pure white, well-defined solid by recrystallization.



Experimental

The following description of the synthesis of 2-ketopiperazine is typical also of its 3-alkyl and 3,3,-dialkyl derivatives.

2-Ketopiperazine.—One-sixth of a mole (20.4 g.) of ethyl chloroacetate dissolved in 100 cc. of absolute alcohol is slowly added at room temperature to a well-stirred solution of one mole (60 g.) of anhydrous ethylenediamine in 300 cc. of absolute alcohol. The addition requires about three hours and the mixture is allowed to stand for an additional two hours. One-sixth of a mole (11.3 g.) of sodium ethylate in alcohol solution is added, the precipitated sodium chloride filtered off and the alcohol and excess ethylenediamine removed by distillation at the water pump. Upon heating the residual reaction mass at 200° under 5 mm. pressure, 2-ketopiperazine is formed and distils at about 165° (uncor.) as a pale yellow oil. After solidification, it is obtained as well-defined white crystals melting at 136° (cor.) by recrystallization from acetone–petroleum ether. The yield is 45% of the theoretical.

The effects of using other reaction temperatures, other concentrations of reactants and replacement

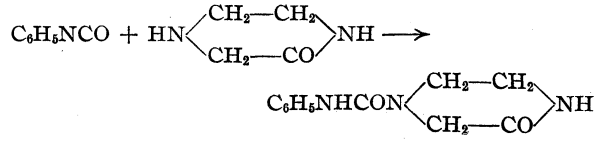
α-Bromo-*n*-butyrate	$C_2H_5C_4H_7ON_2$	60	60	EtOAc	21.88	21.97	148	10.45	10.50
α-Bromo-isobutyrate	$(CH_3)_2C_4H_6ON_2$	134	40	EtOAc	21.88	21.89	206	10.45	10.54

[a] Precipitation of the ketopiperazines is more complete if petroleum ether is added to the solvent. [b] Reported analytical results are the averages of two determinations, neither of which differs from the calculated by more than 0.15% absolute error.

of chloroacetic ester by bromoacetic ester were studied. 1. Syntheses carried out at −15°, 0° and +80° gave the same yields as those at room temperature. 2. The extent to which ethylenediamine is present in excess profoundly affects the yield of end-product, because a large excess of ethylenediamine favors the monoalkylation essential to the eventual formation of monoketopiperazine. When one mole of ethylenediamine is treated with one mole of ethyl chloroacetate under the conditions described above, there is a quantitative precipitation of one-half mole of ethylenediamine dihydrochloride which is insoluble in the absolute alcohol medium. The remaining one-half mole of ethylenediamine was necessarily dialkylated and it is found that no monoketopiperazine is obtained. When one mole of ethylenediamine is treated with one-third mole of ethyl chloroacetate, there is no precipitation of ethylenediamine dihydrochloride (which is soluble in the alcohol–ethylenediamine medium) and the yield of monoketopiperazine is 25% of the theoretical. It is probable that the yield of monoketopiperazine could be increased to any desired amount if a sufficient excess of ethylenediamine were used. 3. The replacement of the chloroester by the bromoester has no effect on the yield, but has the disadvantage that the sodium bromide formed by the addition of sodium ethylate is soluble in the reaction mixture and special steps must be taken for its removal before a smooth distillation is possible. The method adopted was as follows. After addition of the bromoester in the usual way, the alcohol and most of the ethylenediamine were removed by distillation at the water pump and a dilute benzene solution of one equivalent of sodium ethylate was added. The sodium bromide, which is insoluble in benzene, was filtered off, the benzene and remaining ethylenediamine removed and the product distilled as before. 3-Ethyl-2-ketopiperazine and 3,3-dimethyl-2-ketopiperazine were prepared by this procedure from ethyl α-bromo-*n*-butyrate and ethyl α-bromo-isobutyrate, respectively.[5]

The ketopiperazines, which are extremely soluble in cold water and alcohol and insoluble in ether and petroleum ether, are best recrystallized from ethyl acetate or acetone, with or without the addition of petroleum ether. The compounds react strongly basic in water solution and give the usual diagnostic reactions of amines. For purposes of further characterization the ketopiperazines were converted to crystalline benzene sulfonamides by shaking an aqueous solution of 2.5 equivalents of the base with benzenesulfonyl chloride. The sulfonamides precipitated immediately with evolution of heat, and were recrystallized from water. Monoketopiperazine itself was more thoroughly characterized by preparing and analyzing the following derivatives. (1) The picrate was made in alcohol and recrystallized from water. (2) The hydrochloride was prepared by passing dry hydrogen chloride into an absolute alcohol solution of the base, and recrystallizing from absolute alcohol. It is extremely soluble in water. (3) The phenyl ureido derivative, which precipitated immediately with evolution of heat when an acetone solution of the base was treated with one equivalent of phenyl isocyanate, was recrystallized from absolute alcohol.



The phenyl thioureido derivative, similarly prepared from phenyl isothiocyanate, was recrystallized from 95% alcohol. Further investigation of this synthesis is in progress.

(5) The low solubility reported for potassium bromide in alcohol and alcohol–water mixtures indicates that potassium ethylate or even potassium hydroxide could be advantageously used to precipitate hydrogen bromide from the original reaction mixture without the use of benzene.

TABLE II
DERIVATIVES OF 2-KETOPIPERAZINE

	M. p., °C. cor.	N, % Calcd.	Kjeld.[a]
Picrate	180	21.28	21.19
Hydrochloride	208	20.51	20.65
Phenylurea	171	19.18	19.18
Phenylthiourea	199	17.87	17.85

[a] Reported analytical results are the averages of two determinations, neither of which differs from the calculated by more than 0.15% absolute error.

Summary

1. A practical synthesis for the hitherto unknown 2-ketopiperazine and its 3-alkyl and 3,3-dialkyl derivatives has been developed.

2. A study of the reaction between ethylenediamine and α-halogen esters under different conditions has been carried out.

3. The piperazines prepared in this study have been fully characterized by reaction with such typical amine reagents as benzenesulfonyl chloride, picric acid, hydrogen chloride, phenyl isocyanate and phenyl isothiocyanate.

The Relationship of Inositol, Thiamin, Biotin, Pantothenic Acid and Vitamin B_6 to the Growth of Yeasts

BY ROGER J. WILLIAMS, ROBERT E. EAKIN AND ESMOND E. SNELL

The specific chemical substances found to be effective constituents of culture media for promoting the growth of yeasts are of general biological interest. Inositol, found to be a growth factor for yeast in the laboratory of W. Lash Miller,[1] is of widespread occurrence in the tissues of plants and animals. Thiamin (vitamin B_1), first found to be effective for yeast in the author's laboratory,[2] was a recognized vitamin long before and has since proved to be of widespread significance in cellular physiology, functioning as the organic moiety of co-carboxylase (and perhaps in other ways). Biotin, discovered in the laboratories of F. Kögl,[3] is widely distributed and is physiologically effective for a number of organisms.[4,5,6] Pantothenic acid, discovered and concentrated in the author's laboratory,[7,8] is now recognized as identical to the filtrate factor or the chick antidermatitis vitamin,[9,10] and probably stimulates the growth of rats.[11] It is of ubiquitous occurrence and has been found essential for the growth of many bacteria[12,13] and to stimulate the growth of green plants[14] and the respiration of widely different tissues. It appears to be an essential constituent of some important enzyme systems.[15] β-Alanine is a component part of pantothenic acid[16] and may itself serve as a precursor of pantothenic acid both for yeasts and for certain bacteria.[13,16,17] Vitamin B_6 (adermin), recently found to be a growth factor for yeast,[18,19] bacteria,[20] and higher plants,[21] has for some time been recognized as a vitamin essential for rats.

Through the kindness of Professor Kögl, who has placed a sample of biotin at our disposal, we are now in a position to study the interaction of all of the factors enumerated above in promoting the growth of yeasts. The results of such studies may prove of great interest both from the standpoint of yeast physiology and because of the light which they may throw on the interplay of these

physiological principles in biological phenomena in general.

While aspartic acid[22] (placed in our basal medium), leucine,[23] ethanolamine, riboflavin, nicotinamide, carotene and doubtless other recognized compounds may under suitable conditions increase growth or respiration of yeast, the effects are relatively small and these effects are not included in the present study.

The "optimal" concentration of any specific substance in a nutrient medium depends upon the strain of yeast, the cultural conditions, and particularly upon the other constituents of the medium. For practical reasons, however, we have fixed the concentration of each nutrilite at a level somewhat above that required to produce a "maximum" response when tested alone and have studied the growth curves of three distinct (and highly different) strains of "*Saccharomyces cerevisiae*" under the influence of the five more significant substances mentioned above.

The basal medium used throughout was similar to that used in other studies from the author's laboratory[16,24] and contained as the source of organic nitrogen 0.1 g. of *l*-aspartic acid per liter. This has the general effect of increasing yeast crops, though experiments have shown that it can be omitted (in some cases at least) without changing the general trend of the results in any major way.

Experimental

The carefully sterilized media (50 ml. batches in 250 ml. Erlenmeyer flasks) were each seeded with 0.2 mg. of the yeast under investigation and allowed to grow for one hundred to one hundred and sixty hours at 30°. At intervals the cultures were shaken and samples aseptically withdrawn and their yeast content determined with a thermocouple turbidimeter.[25,26]

The media used were composed as indicated below. An addendum when used was always in the same concentration, as follows: inositol 5 γ per ml. of the final medium; thiamin 0.04 γ per ml.; biotin 0.0001 γ per ml.; pantothenic acid 0.006 γ per ml.; β-alanine 1 γ per ml.; vitamin B_6 0.04 γ per ml. Since previous experiments had shown that β-alanine could serve as a precursor of pantothenic acid, this substance was substituted for pantothenic acid in some of the media as indicated. The amount of β-alanine used is much more than equivalent on a stoichiometric basis to the pantothenic acid addendum.

(1) Basal alone.
(2) Basal + pantothenic acid (p. a.).
(3) Basal + β-alanine.
(4) Basal + biotin.
(5) Basal + inositol, thiamin, biotin and B_6 (no p. a.).
(6) Basal + inositol, thiamin, biotin and β-alanine (no B_6).
(7) Basal + inositol, biotin, β-alanine and B_6 (no thiamin).
(8) Basal + thiamin, biotin, β-alanine, and B_6 (no inositol).
(9) Basal + inositol, thiamin, β-alanine and B_6 (no biotin).
(10) Basal + inositol, thiamin, biotin, p. a. and B_6 (complete p. a.).
(11) Basal + inositol, thiamin, biotin, β-alanine and B_6 (complete β-alanine).
(12) Same as 11 above + 0.2 mg./ml. crude liver extract.

The strains of yeast used were (1) Gebrüder Mayer (G. M.), (2) "Old Process" (O. P.), and (3) yeast isolated (repeatedly) from Fleischmann baker's yeast (pound goods) (F. B.).[27]

The results of the tests are presented in Figs. 1, 2 and 3.

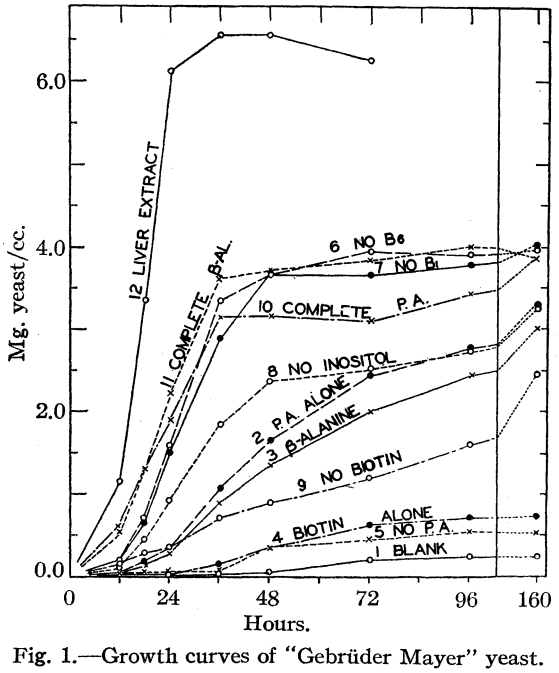

Fig. 1.—Growth curves of "Gebrüder Mayer" yeast.

Discussion of Results

In order to conserve space, separate curves are not given showing in more detail the growth during the first twenty-four hours. From many standpoints this is the most interesting period, since in the practical utilization of yeasts in the fermentation industries, the immediate response to the medium is often of much greater importance than what may happen after a long time interval. The great majority of studies of yeast growth have

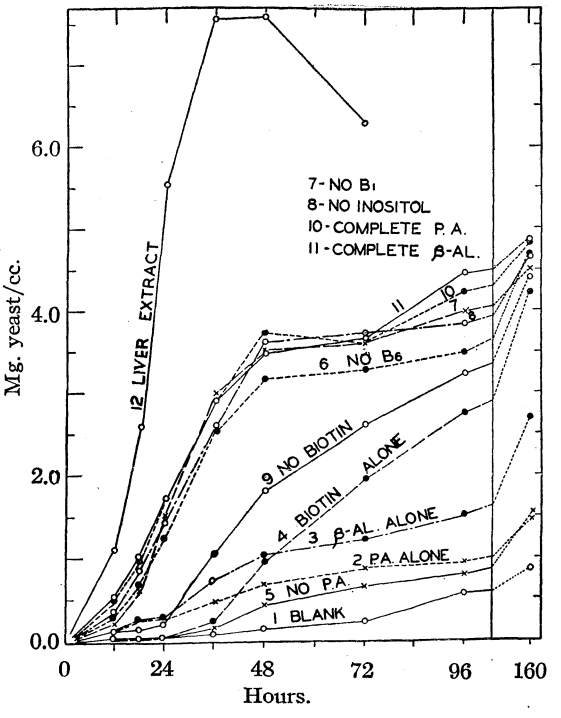

Fig. 3.—Growth curves of Fleischmann baker's yeast.

also involved a comparatively short period of incubation. The problem of whether and to what extent yeast is able to grow in a medium after many days of incubation is of scientific and academic, rather than practical interest.

It is obvious that when continued growth takes place in a medium devoid of a particular substance the substance is either dispensable or can be synthesized by the yeast from other constituents of the medium. On the basis of available evidence we shall assume tentatively in such cases that synthesis is taking place.

Inositol.—F. B. yeast grows at only a slightly diminished rate, and up to high levels in the absence of inositol. G. M. yeast is more dependent upon an exogenous source of inositol, and O. P. yeast most dependent. There is a question in view of the fact that the growth curve of the O. P. yeast flattens after seventy-two hours, whether it is capable of indefinite growth in the absence of inositol.

Thiamin.—Both F. B. and G. M. yeasts are able to grow to high levels in the absence of thiamin, but O. P. yeast is dependent on an external source for rapid growth. It appears that O. P. yeast may develop an ability to synthesize thiamin, because after thirty-six hours the growth curve rises more rapidly; growth continued throughout the period of observation.

Biotin.—In no case does biotin alone induce an appreciable increase in growth during the first twenty-four hours (under our conditions, light seeding etc.). F. B. yeast is markedly affected by biotin (alone) after this period; other yeasts are less affected. When biotin is left out and the other nutrilites are put in, each yeast grows less than the maximum (with all five nutrilites), but F. B. yeast curiously yields most nearly maximum growth.

Pantothenic Acid (and β-Alanine).—The close correspondence between curves 2 and 3, Figs. 1, 2 and 3, and curves 10 and 11, Figs. 1, 2, and 3, in which pantothenic acid and β-alanine are interchanged, shows that for the purpose of these experiments pantothenic acid and β-alanine are practically equivalent physiologically. This is in line with the known fact that β-alanine is a precursor of pantothenic acid.[16]

None of the yeasts grow, except very slowly, during the first twenty-four hours in the absence of an exogenous source of pantothenic acid. Each yeast appears to be able to grow continuously in the synthetic medium when pantothenic acid or β-alanine is present. When the other four nutrilites are present and pantothenic acid is absent, growth continues at a low rate with F. B. and O. P. yeast, but with G. M. yeast growth ceases after a few days. This is in line with the previous observation that this yeast is apparently unable to bring about the synthesis of pantothenic acid.[17]

Vitamin B_6.—This vitamin appears dispensable for all three yeasts, yet its physiological effects

are noticeable in each case. Its absence from the medium is most noticeable in the case of G. M. yeast at the end of a twelve-hour growth period. In this case the "complete" medium yielded about three times the amount of yeast as the same medium lacking B_6.

Unknown Factors.—That unknown factors play an important part in stimulating the rapid growth of yeasts is evidenced by the fact that each yeast is strikingly stimulated when a liver extract is added to the medium containing all five of the nutrilites. Extracts of yeast also contain these additional stimulatory substances, which cannot be replaced by a higher concentration of the five nutrilites under consideration. For some yeasts at least biotic acid[28] is an important nutrilite.

Growth over Long Periods.—Although biotin and pantothenic acid are unlike chemically and are tested for under entirely different conditions, it does appear that when growth over a long period is concerned, they are in a measure interchangeable. Thus in the case of the F. B. and O. P. yeasts either biotin alone or pantothenic acid (or β-alanine) alone causes a substantial increase (100% or more) over the blank. For G. M. yeast biotin alone was relatively ineffective even after one hundred and sixty hours (*cf.* curves 1–4, Figs. 1, 2, 3). The same apparent replaceability of one nutrilite by others is observed in some cases where only one nutrilite is omitted from the medium. Similar phenomena have been observed in the senior author's laboratory when the mold *Trichophyton interdigitale* failed to grow on an amino acid medium but did grow appreciably when *any one* of three nutrilites (inositol, thiamin or pantothenic acid) was furnished.[29]

These results suggest that when one nutrilite alone is furnished it leads to the more ready synthesis of those which are lacking in the medium. It may be that the one nutrilite by furnishing the means of completing one of several enzyme systems enables the organism to derive energy for metabolic and synthetic activity.

Ability to Grow in a Synthetic Medium.—From the growth curves it appears that F. B. and O. P. yeasts are eventually able to grow continuously, though very slowly, in a medium containing none of the nutrilites. The growth of G. M. yeast, however, ceases after about three days, at which time about a 60-fold increase has taken place. The original yeast seeding of course has in it all of the requisites for growth. The extent to which growth can take place in a synthetic medium seems to depend on how far these original substances can be "diluted" by passage to the daughter cells and to what extent the yeast is able to synthesize the substances. G. M. yeast seems to be limited in its ability to grow in a synthetic medium by the fact that synthesis of pantothenic acid cannot take place. Whether G. M. yeast can through long "training" be induced to synthesize pantothenic acid is, again, unknown.

This work has been generously supported by grants from the Rockefeller Foundation and from Standard Brands, Inc., of New York.

Summary

The growth curves of three distinct (and highly different) strains of "*Saccharomyces cerevisiae*" were studied in media containing different combinations of inositol, thiamin, biotin, pantothenic acid (or β-alanine) and vitamin B_6. Among the conclusions drawn are the following. At least two of the yeasts can grow continuously without inositol. Thiamin is especially important for one yeast only. Biotin alone will not immediately stimulate the yeast growth from small seedings but in proper combination its effect is striking and evident at very minute doses. Pantothenic acid (or its precursor β-alanine) is highly essential for the immediate growth of all of the yeasts and when added alone is able to induce continued growth of all the yeasts tested. B_6 is relatively unimportant as a constituent of the culture media. Substances of unknown nature present in liver and yeast extracts play an important role in promoting rapid growth. Yeasts during a long incubation period show considerable ability to grow in the absence of various nutrilites, and under such conditions one nutrilite alone may serve whereas for rapid growth several are required.

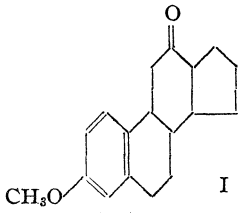
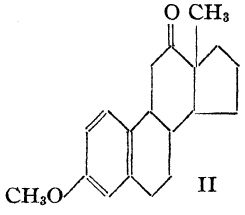
The Direct Introduction of the Angular-Methyl Group

BY ROBERT BURNS WOODWARD*

As a result of the great interest in the chemistry of the sterols and related substances, considerable effort has been expended in the past six years to elaborate methods for the synthesis of substances containing methyl groups at the bridgeheads of bicyclo-(0,3,4)-nonanes and bicyclo-(0,4,4)-decanes, the so-called angular-methyl groups. Several elegant methods have been evolved, notably those of Linstead[1a] and Robinson.[1b] With one exception, these procedures are in essence syntheses of the bicyclic systems involved from simpler compounds containing appositely substituted methyl groups. Only Robinson has in a few isolated instances introduced with difficulty an angular-methyl group in a compound already containing the bicyclic system. For example, 7-methoxy-3-keto-1,2,3,4,9,10,11,12-octahydro-1,2-cyclopentenophenanthrene[2] (I) on vigorous



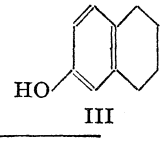
I



II

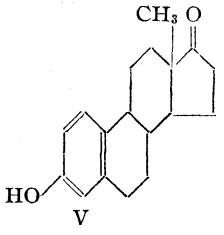
treatment with potassium *t*-butylate, followed by methyl iodide, is transformed into a methyl derivative in which the substituted group is presumed to be in the angular position (II).

In this communication is described a method for the direct production of substances having the carbon skeleton of 9-methyl-bicyclo-(0,4,4)-decane (IV) from 6-hydroxy-1,2,3,4-tetrahydronaphthalene (III). It is at once apparent that the relationship of compounds having the skeleton (IV) to the tetralol (III) is also that which androsterone (VI) and the other male hormones bear to oestrone (V), and that these experiments may be

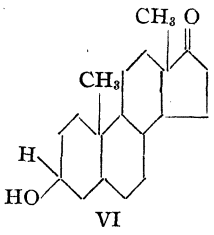


III

IV



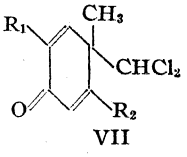
V



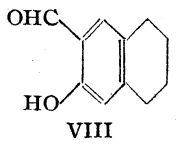
VI

considered as models for the conversion of oestrone into one or more of the androgenic hormones.

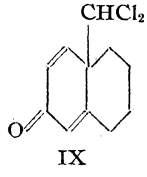
It has been shown by von Auwers[3a,b,c] and collaborators in a brilliant series of investigations that *o*- and *p*-alkyl substituted phenols, on treatment with chloroform and alkali under the conditions of the Reimer–Tiemann synthesis, are converted only in part into the expected aldehydes, the remainder being used in the formation of cyclohexadienones, the ratio of normal to abnormal products varying strikingly with the structure of the phenol. From *p*-cresol, for example, 2-hydroxy-5-methylbenzaldehyde is formed almost to the exclusion of 4-methyl-4-dichloromethyl-$\Delta^{2,5}$-cyclohexadienone-1 (VII, $R_1 = R_2 = H$), while ψ-cumenol, on the other hand, gives over 80% of the abnormal product, 2,4,5-trimethyl-4-dichloro-



VII



VIII



IX

methyl-$\Delta^{2,5}$-cyclohexadienone-1 (VII, $R_1 = R_2 = CH_3$). We were led by these results to undertake the investigation of the Reimer–Tiemann reaction with 6-hydroxy-1,2,3,4-tetrahydronaphthalene (III).

The latter, on treatment with chloroform and 10% aqueous sodium hydroxide, was mainly converted into two products. The first, representing about 50% of the tetralol consumed in the reaction, was an aldehyde, m. p. 82°, which was found to be identical with the aldehyde obtained from the same phenol by Thom and Kross[4] through the Gattermann synthesis. Previous work[4,5] on

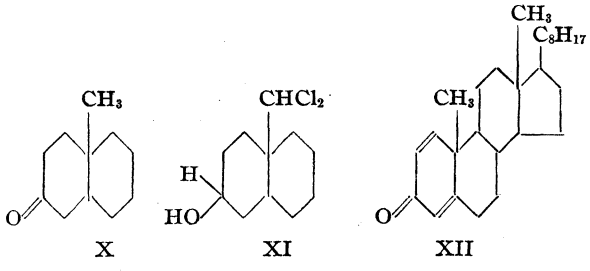
the orientation of (*ar*)-2-tetralol makes it highly probable that this aldehyde is 6-hydroxy-1,2,3,4-tetrahydronaphthalene-7-aldehyde (VIII). In our work the substance was characterized through its semicarbazone. This compound on heating undergoes an interesting change for which analogy is found in the behavior of the semicarbazone of salicylic aldehyde,[6] in that above the melting point it resolidifies in beautiful long yellow needles of the corresponding azine.

The second product of the reaction was a beautifully crystalline, non-acidic substance, m. p. 167.5–168.5°, having the formula $C_{11}H_{12}OCl_2$. While the analogy with the work of von Auwers lends strong presumptive support to the formulation of this compound as 10-dichloromethyl-2-keto-$\Delta^{1,9;\ 3,4}$-hexahydronaphthalene (IX), our work proves unambiguously that this formulation is correct.

On hydrogenation in methyl alcohol with Adams catalyst, the substance smoothly adds three moles of hydrogen with the formation of an alcohol, $C_{11}H_{18}OCl_2$, m. p. 92.5–93°, characterized by an α-naphthylurethan, m. p. 152.5–153°. Under the above conditions, it was not possible either to stop the reaction at the tetrahydro stage, or to remove the halogen atoms to an appreciable extent. However, under more drastic conditions, *viz.*, hydrogenation of the dichloro-alcohol in 10% alcoholic potassium hydroxide over palladinized barium sulfate, it was possible to remove both halogen atoms with the formation of a methyldecalol which on oxidation with chromate mixture was transformed into 10-methyl-decalone-2 (X), identical with an authentic sample prepared by the method of Robinson.[1b]



X XI XII

These transformations indicate clearly that the alcohol $C_{11}H_{18}OCl_2$ must be formulated as 10-dichloromethyl - 2 - hydroxydecahydronaphthalene (XI), and that the abnormal Reimer–Tiemann product from which it was obtained is 10-dichloromethyl-1-keto-$\Delta^{1,9;3,4}$-hexahydronaphthalene (IX).

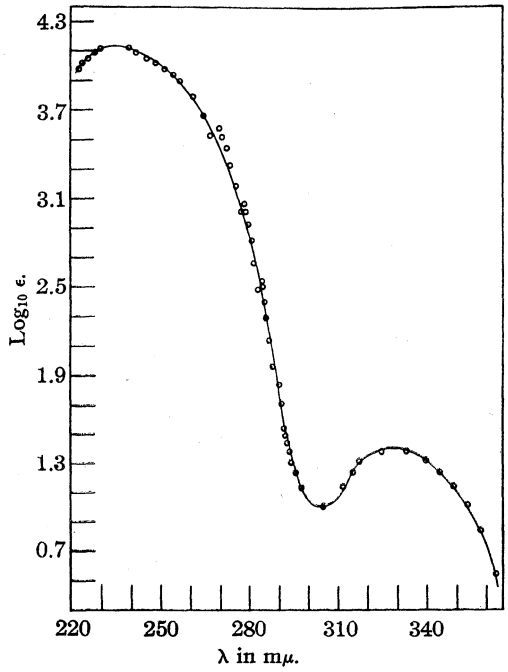

Fig. 1.—Ultraviolet absorption spectrum of 10-dichloromethyl-2-keto-$\Delta^{1,9;\ 3,4}$-hexahydronaphthalene in alcohol.

The ultraviolet absorption spectrum[7] (Fig. 1) of the latter substance gives confirmatory evidence of its structure. The maximum at 235 mμ (log ϵ = 4.14) is clearly a consequence of the conjugation of carbonyl and ethylenic double bonds, while the less intense maximum at 329 mμ (log ϵ = 1.38) must be ascribed to the carbonyl group. In this connection, it is instructive to note that cholestadiene-1,4-one-3 (XII), the only other cyclohexadienone for which ultraviolet absorption data are known, is reported by Inhoffen and Huang-Minlon[8] to have an intense band at 235 mμ (log ϵ = 4.1). It is a striking fact that both these compounds exhibit strong absorption in the same region as do those substances containing but one ethylenic bond in conjugation with the carbonyl group, as will be apparent from an inspection of Table I.

On the other hand phorone,[9] which likewise contains a cross-conjugated system, shows the expected shift of the intense band toward the red. This observation might well lead one to question the validity of the assumption of cross-conjugated systems in Inhoffen's compound and in ours. Inhoffen's degradative work,[10] however, as well as

the hydrogenation of his substance to compounds of the coprostane, rather than the cholestane, series, proves beyond doubt that his material has in fact the structure (XII).

These considerations lead us to suggest that the rule of Menschick, Page and Bossert,[11] *viz.*, that substances exhibiting strong absorption (log ε = 4.0–5.0) in the vicinity of 235–250 mμ contain an α,β-unsaturated carbonyl system, be extended to include the possibility that such absorption is a consequence of cross-conjugation of two ethylenic bonds with a carbonyl group.

Experimental

6-Hydroxy-1,2,3,4-tetrahydronaphthalene-7-aldehyde (VIII) and 10-Dichloromethyl-2-keto-$\Delta^{1,9;3,4}$-hexahydronaphthalene (IX).—3.5 grams of 6-hydroxy-1,2,3,4-tetrahydronaphthalene was dissolved in 80 cc. of 10% aqueous sodium hydroxide in a flask equipped with an efficient reflux condenser and a dropping funnel. After the reaction mixture had been immersed in a water-bath at 75°, pure chloroform was dropped in slowly from the funnel. With the addition of the first few drops of chloroform, the solution turned yellow; as more was added the color gradually deepened to orange. In the course of three hours, 13.0 g. of chloroform was added. The reaction was then allowed to continue for one-half to three-quarters of an hour, when the water-bath was removed and the reaction mixture allowed to cool. More chloroform was now added, the mixture was well shaken, and the two layers separated, the neutral aqueous layer being discarded. The chloroform was evaporated on the steam-bath and the residual red oil, which crystallized partially on cooling, distilled *in vacuo* from a 10-cc. Claisen flask, b. p. 4–5 mm., *ca.* 130–150°. The distillate, a clear yellow, very sirupy liquid which deposited crystals on scratching, was triturated with 5% aqueous sodium hydroxide, the resulting solid was filtered at the pump, and washed with water until the sparingly soluble sodium salt of the hydroxy-aldehyde had been completely dissolved. The bright yellow filtrate was made neutral with dilute hydrochloric acid, the precipitated oil taken up in ether and recovered in the usual way. The oil thus obtained weighed 1.8 g., and crystallized slowly on standing as octagonal prisms, m. p. 80–82°; mixed with an authentic sample of 6-hydroxy-1,2,3,4-tetrahydronaphthalene-7-aldehyde,[4] m. p. 80–82°.

The solid remaining on the funnel after the removal of the sodium salt by washing was dissolved in methanol, the reddish solution was filtered from a small amount of amorphous material, and evaporated to a very small volume. The crystals which separated were recrystallized from cyclohexane, 0.8 g. of colorless stout hexagonal prisms, m. p. 167.5–168.5°, being obtained. (Occasionally long needles of the same m. p. were obtained on crystallization from methyl alcohol, but the above form is more common from either solvent.) Further recrystallization failed to change the melting point.

Anal. Calcd. for $C_{11}H_{12}OCl_2$: C, 57.2; H, 5.2; Cl, 30.5. Found: C, 57.15; H, 4.91; Cl, 30.3.

10-Dichloromethyl-2-hydroxydecahydronaphthalene (XI).—150 mg. of 10-dichloromethyl-2-keto-$\Delta^{1,9;3,4}$-hexahydronaphthalene was dissolved in 20 cc. of absolute methanol, a small amount of platinum oxide catalyst added, and the reaction mixture shaken with hydrogen at 30.5° and 755 mm. In five minutes 57 cc. (3.5 mols) of hydrogen had been taken up, and there was no further absorption. The clear solution was filtered to remove catalyst, evaporated to a small volume on the hot-plate, and then to "dryness" in a current of warm air. A clear, viscous oil of camphoraceous odor remained. Since it could not be crystallized on trituration with cyclohexane or petroleum ether, it was allowed to stand overnight, when it crystallized partially in waxy prisms, sintering at 67°, melting at 73–76°. The oil was then dissolved in a small amount of methanol, and the solution was allowed to stand for a few hours after enough water had been added to cause strong turbidity. At the end of this time the material had crystallized in beautiful rosets of needles. This process was repeated five times, the period necessary for crystallization becoming shorter with each repetition. 10-Dichloromethyl-2-hydroxydecahydronaphthalene finally was obtained as beautiful silky needles, m. p. 92.5–93°, extremely soluble in methanol, and giving a strong Beilstein test. The material sublimed easily in colorless rosets in high vacuum at 64°.

Anal. Calcd. for $C_{11}H_{18}OCl_2$: C, 55.70; H, 7.66. Found: C, 55.90; H, 7.73.

α-Naphthylurethan of 10-Dichloromethyl-2-hydroxydecahydronaphthalene.—The clear colorless oil obtained on hydrogenation of 130 mg. of 10-dichloromethyl-2-keto-$\Delta^{1,9;3,4}$-hexahydronaphthalene in the manner described above was allowed to stand overnight over phosphorus pentoxide in the vacuum desiccator. An approximately equivalent amount of freshly distilled α-naphthylisocyanate was added, the two substances were mixed completely, and the reaction mixture placed in the vacuum desiccator over phosphorus pentoxide. After six days, the flask contained a mass of prisms, and a small amount of oil. The reaction mixture was dissolved in 6–8 cc. of hot middle-boiling ligroin, and the solution filtered from a small amount of insoluble tarry material. After concentrating to 2–3 cc. on the hot-plate, the solution was allowed to stand overnight. The stout hard prisms which had separated were filtered, washed with a small amount of petroleum ether, and recrystallized twice from hot ligroin.

(11) Menschick, Page and Bossert, *Ann.*, **495**, 233 (1932).

Hard, compact glistening aggregates of plates, m. p. 152.5–153°, were formed.

Anal. Calcd. for $C_{22}H_{25}O_2NCl_2$: C, 65.0; H, 6.21. Found: C, 64.99; H, 6.42.

10-Methyl-decalone-2 (X).—220 mg. of 10-dichloromethyl-2-hydroxy-decahydronaphthalene was dissolved in 20 cc. of 10% methanolic potassium hydroxide, 0.5 g. of palladinized barium sulfate added, and the reaction mixture shaken with hydrogen for six hours at 29° and 759 mm. At the end of this time 42 cc. (1.9 mols) of hydrogen had been taken up. The reaction mixture was then poured into 60 cc. of water and extracted exhaustively with ether (6 hand extractions). The combined ethereal extracts were dried over sodium sulfate, the ether was removed, and the residual colorless viscous oil allowed to stand in the vacuum desiccator over phosphorus pentoxide. Since it did not crystallize on standing overnight, it was dissolved in 5 cc. of glacial acetic acid and oxidized directly by dropping in slowly a solution of 100 mg. of chromic oxide in 4 cc. of glacial acetic acid and 1 cc. of water. After stirring for four hours, the reaction mixture was poured into water, extracted exhaustively with ether, and the combined ethereal extracts dried over anhydrous sodium sulfate. The residual oil obtained on evaporating the ether was converted into the 2,4-dinitrophenylhydrazone in the usual manner, pale yellow needles from methyl alcohol, m. p. 151–152°, mixed with an authentic sample prepared by Robinson's method, m. p. 151–152°. On hydrolyzing this derivative with 5% sulfuric acid and working up in the usual manner, 100 mg. of a colorless oil of camphoraceous odor was obtained which solidified on standing, m. p. 46°, mixed with Robinson's ketone, m. p. 45–46°.

Summary

A novel method for the direct introduction of the angular-methyl group is described. These experiments may be considered as models for the transformation of oestrone or oestradiol into substances of the testosterone–androsterone group.

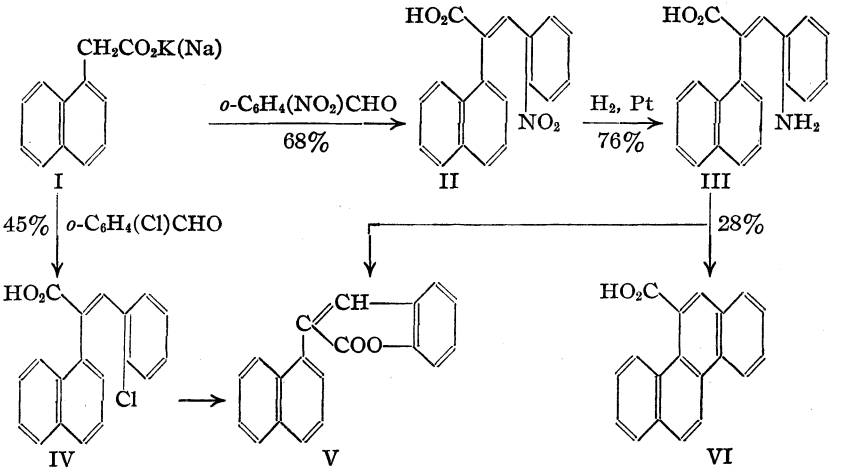
5-Methylchrysene

BY LOUIS F. FIESER AND LLOYD M. JOSHEL[1]

In a previous attempt to synthesize 5-methylchrysene a rearrangement was encountered in a final dehydrogenation step and the product, isolated in small yield, proved to be the 6-methyl isomer.[2] Another route not requiring a dehydrogenation now has been investigated, the plan being to obtain the 5-methyl compound from the corresponding carboxylic acid.

One scheme for obtaining the desired intermediate consisted in the condensation of α-naphthylacetic acid with *o*-chlorobenzaldehyde and fusion of the product IV with potassium hydroxide, following the synthetic method employed by Hewett.[3] The only crystalline product isolated proved to be the lactone of α-(1-naphthyl)-*o*-hydroxycinnamic acid, V. We then turned to the Pschorr synthesis, which already has been carried to the stage of the 5-acid VI by Weitzenböck and Lieb.[4] The condensation product II was obtained in improved yield and was conveniently reduced to the amine III by catalytic hydrogenation. Weitzenböck and Lieb state that the Pschorr ring closure afforded in about 20% yield a crude product which was purified with difficulty. A number of variations were tried in the present work and the best result was a 28% yield of pure chrysene-5-carboxylic acid by a procedure



(1) Fellow of the Finney-Howell Research Foundation.

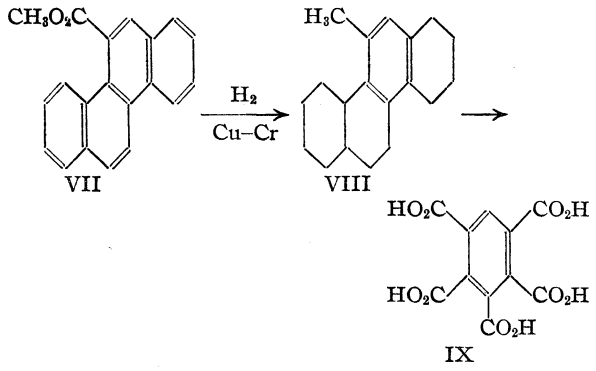
using copper bronze and sodium hypophosphite.[5] A neutral by-product of the reaction had the composition of the lactone V.

On attempting to obtain either the 5-methyl or 5-hydroxymethyl compound by the direct reduction of the 5-carbomethoxy derivative VII it became apparent that the nucleus is reduced about as easily as the ester group. Reduction with sodium and ethanol gave a non-crystalline product having approximately eight hydrogen atoms more than the expected carbinol. The only crystalline reaction product isolated in various attempted hydrogenations over copper chromite catalyst was obtained on conducting the reaction at 250° for seventeen hours and proved to be 5-methyl-1,2,3,4,7,8,9,10,11,12,13,14-dodecahydrochrysene (VIII), for it gave benzene-pentacarboxylic acid (IX) on oxidation with dilute nitric acid.



With a shorter reaction period the product was a glass having approximately the composition of an octahydride. On attempting to prevent over-hydrogenation at 250° by using a nitrogen–hydrogen mixture containing just the required amount of the latter gas[6] we recovered the ester unchanged. Hydrogenation in the usual way at 160° gave a glassy mixture having the composition of a dihydro derivative of the ester VII.

The preparation of the desired 5-methyl derivative was accomplished satisfactorily by converting the acid VI by the Sonn and Müller reaction to the aldehyde, which was isolated as the semicarbazone, and reducing this by the Wolff–Kishner method. The hydrocarbon, m. p. 116.8–117.6°, proved identical with the 5-methylchrysene synthesized by Dr. M. S. Newman by a different method.[7]

Experimental Part[8]

α-(1-Naphthyl)-o-chlorocinnamic Acid (IV).—A mixture of 6.4 g. of the sodium salt of α-naphthylacetic acid, 4.5 g. of freshly distilled *o*-chlorobenzaldehyde, and 50 cc. of acetic anhydride was heated in a bath at 135° for twenty-five hours and poured into water. After standing overnight the orange-yellow resin was separated by decantation and extracted with boiling aqueous potassium carbonate. After clarification with Norit and cooling the potassium salt of IV separated as colorless plates (washed with potassium carbonate solution). From the filtrate, by acidification and crystallization of the precipitate from benzene, there was obtained 1 g. of *o*-chlorocinnamic acid, m. p. 209–211°. The acid liberated from the potassium salt on crystallization from benzene–ligroin was obtained as colorless prisms which partially melted at 160°, solidified, and remelted at 171–172.5°; yield 4.3 g. (45%). The behavior on melting was not altered by recrystallization as such or as the potassium salt.

Anal.[9] Calcd. for $C_{19}H_{13}O_2Cl$: Cl, 11.48. Found: Cl, 11.29.

In a typical attempted cyclization 4.5 g. of the chloro acid IV was fused with 25 g. of potassium hydroxide at 200–235° for five minutes and the temperature was raised to 245° in ten minutes. The crude acidic material was refluxed overnight with alcoholic hydrogen chloride and the neutral fraction separated and distilled in vacuum. The glassy distillate yielded no crystalline trinitrobenzene derivative, but after saponification and acidification a crystalline product was obtained from benzene–ligroin. This formed needles, m. p. 241–243°, dec., amounting to 0.15 g. (4%). On recrystallization the substance formed light buff needles, m. p. 244–245°, and did not depress the m. p. of the sample of the lactone V obtained as a by-product in the Pschorr synthesis.

α-(1-Naphthyl)-o-nitrocinnamic Acid (II).—The potassium salt of α-naphthylacetic acid was prepared by exactly neutralizing the acid in methanol with methyl alcoholic potassium hydroxide and evaporating to dryness. A solution of 25 g. of the salt and 20 g. of *o*-nitrobenzaldehyde in 200 cc. of acetic anhydride was heated in a bath at 125–130° for one hour and poured into excess dilute hydrochloric acid. After standing overnight the aqueous layer was decanted and the residue extracted with boiling potassium carbonate solution. The clarified filtrate when treated with more potassium carbonate and cooled deposited the salt of II in glistening plates. The alkaline mother liquor afforded 2.5 g. of *o*-nitrocinnamic acid, m. p. 245–247° (from acetone). The acid liberated from the salt crystallized from benzene–ligroin as yellow prisms, m. p. 181–182°; yield 24.2 g. (68%). A recrystallized sample melted at 181.8–182.8°.

Weitzenböck and Lieb[4] obtained a product, m. p. 173–174°, in 40% yield after a reaction period of eight to nine hours. In the present work it was found advantageous to shorten the period of heating and to separate the two acidic products through the salts rather than by crystallization as such.

(8) All melting points are corrected. Microanalyses by Lyon Southworth except as noted.

(9) Analysis by Herbert S. Wight.

α-(1-Naphthyl)-o-aminocinnamic Acid (III).—While the nitro compound II can be reduced in good yield on a small scale with ferrous sulfate,[4] hydrogenation seemed more satisfactory with larger amounts. With 32 g. of acid in 250 cc. of absolute ethanol and 0.2 g. of Adams catalyst, 90% of the theoretical amount of hydrogen was absorbed in two hours and the reaction then stopped. On two crystallizations from dilute alcohol the amino acid formed silvery white plates, m. p. 175–176°; yield 22 g. (76%).

Chrysene-5-carboxylic Acid (VI).—A solution of 4.5 g. of the amino acid III in 175 cc. of alcohol was treated with 1.8 cc. of concentrated sulfuric acid, followed by 3.6 cc. of amyl nitrite. After being stirred at room temperature for one-half hour the deep orange solution was added from a dropping funnel during forty-five minutes to a stirred suspension of 0.2 g. of copper bronze in 15 cc. of water and 15 g. of sodium hypophosphite at 45–50°. A test for diazonium salt with β-naphthol was negative within five minutes after the addition. The mixture was poured into excess potassium carbonate solution, the alcohol was distilled, and the hot solution was clarified with Norit and acidified. The light brown, granular precipitate was dried and allowed to stand in solution in 100 cc. of 3–5% methyl alcoholic hydrogen chloride for twelve hours. The solution was diluted with water, extracted with ether, and the acid VI, which is not esterified under these conditions, was extracted with aqueous sodium carbonate solution. The carbonate extract was clarified with Norit and the liberated acid crystallized twice from acetone–benzene, furnishing 1.2 g. (28%) of satisfactory product as buff needles, m. p. 225–226°, dec.

The neutral fraction was distilled in vacuum and crystallized three times from acetone–benzene, yielding 0.1–0.2 g. of yellow needles, m. p. 244.5–245.5°, dec., having the composition of the **lactone of α-(1-naphthyl)-o-hydroxycinnamic acid (V).**

Anal. Calcd. for $C_{19}H_{12}O_2$: C, 83.80; H, 4.44. Found: C, 83.59; H, 4.42.

As solvent in the Pschorr reaction dioxane[10] or acetic acid proved less satisfactory.

Methyl 5-chrysene carboxylate was prepared from 2.5 g. of the acid in 50 cc. of acetone, treated with an ethereal solution of diazomethane from 5 cc. of nitrosomethylurethan. On distillation in vacuum and crystallization from benzene the ester formed colorless prisms, m. p. 159–160° (90% yield).

Anal. Calcd. for $C_{20}H_{14}O_2$: C, 83.89; H, 4.93. Found: C, 83.85; H, 5.04.

Bouveault Reduction.—After treatment in benzene with the calculated amount of ethanol and sodium, the ester was largely recovered unchanged. In another experiment 0.4 g. of powdered sodium was added in two portions to 0.3 g. of the ester in 5 cc. of benzene and 20 cc. of absolute ethanol and the mixture was refluxed for a few minutes, when all the sodium had reacted. After dilution, acidification and removal of the solvents with steam, the product was distilled in vacuum. A small amount (10 mg.) of the starting ester crystallized from the distillate and the main product was a light yellow glass probably consisting mainly of 5-hydroxymethyloctahydrochrysene (calcd. for $C_{19}H_{22}O$: C, 85.67; H, 8.33. Found: C, 84.99; H, 7.77).

5 - Methyl - 1,2,3,4,7,8,9,10,11,12,13,14 - dodecahydrochrysene (VIII).—Hydrogenation of 1 g. of the ester in 8 cc. of dioxane with 0.1 g. of copper-chromite catalyst 37KAF was conducted at 250° and 2100 lb. (140 atm.) pressure for seventeen hours. Distillation in vacuum and crystallization from benzene–alcohol furnished 0.52 g. (58.5%) of colorless needles, m. p. 95–99°. On recrystallization the hydrocarbon melted at 98.8–99.8° (0.35 g.).

Anal. Calcd. for $C_{19}H_{26}$: C, 89.70; H, 10.30. Found: C, 89.90; H, 10.56.

For oxidation 0.3 g. of the hydrocarbon was heated with 1.5 cc. of concentrated nitric acid and 3 cc. of water at 195–200° for twenty-two hours. The clear yellow solution was taken to dryness and the residue allowed to stand for several hours with diazomethane solution. After sublimation of the ester at 2 mm. pressure, crystallization from ether–ligroin gave 0.05 g. of prisms and after recrystallization the sample of **pentacarbomethoxybenzene** melted at 146–149.5°.

Anal. Calcd. for $C_{16}H_{16}O_{10}$: C, 52.18; H, 4.38. Found: C, 52.28; H, 4.73.

Pentacarbomethoxybenzene is described as melting at 150.5° with previous sintering.[11] The ester of prehnitic acid (1,2,3,4), which would be the expected product if the alternate non-terminal ring were aromatic, melts at 131–133°.

Other Hydrogenations.—On hydrogenation of the ester as above but for only four hours there was obtained a small amount of the crystalline dodecahydride and a colorless glass of composition corresponding approximately to an octahydride (calcd. for $C_{19}H_{22}$: C, 91.15; H, 8.85. Found: C, 90.50; H, 8.35). On conducting the reaction at 160° for four hours the non-crystalline product corresponded most closely to a dihydro ester (calcd. for $C_{20}H_{16}O_2$: C, 83.31; H, 5.59. Found: C, 83.10; H, 5.83.

Chrysene-5-aldehyde Semicarbazone.—A mixture of 0.56 g. of chrysene-5-carboxylic acid, 0.5 cc. of phosphorus pentachloride, and 10 cc. of benzene was refluxed for ten minutes and the resulting solution was evaporated to dryness at reduced pressure. The residue was taken into 15 cc. of dry acetone and treated with 2 cc. of aniline, and after boiling for a few minutes the anilide which separated was collected, washed with benzene, and heated with 0.5 g. of phosphorus pentachloride in 5 cc. of benzene for one-half hour. Evaporation in vacuum left the chloroanilide as a bright red oil. This was dissolved in 5 cc. of ethylene chloride and added to a solution prepared by passing hydrogen chloride into 1.5 g. of anhydrous stannous chloride suspended in 15 cc. of dry ether. After sixteen hours at 0°, 15 cc. of water was added and the mixture refluxed for two hours and steam distilled. The residue was extracted with benzene, the solvent was replaced by absolute alcohol, 5 cc. of pyridine and 0.3 g. of semicarbazide hydrochloride were added and the solution was refluxed for one hour and diluted with water. The semicarbazone crystallized as light yellow microprisms, m. p. 260–263°, dec.; yield 0.34 g. (53%). Recrystallized from acetic acid, the substance melted at 266–268°, dec.

Anal. Calcd. for $C_{20}H_{15}ON_3$: N, 13.41. Found: N, 13.21.

5-Methylchrysene.—The semicarbazone (0.23 g.) was heated with a solution from 0.3 g. of sodium and 10 cc. of absolute alcohol in a sealed tube at 200° for nine hours. After dilution and acidification the product was extracted with benzene and the washed and dried solution was passed through a tower of alumina. After vacuum distillation the product was fractionally crystallized from alcohol to remove a small amount of chrysene. The 5-methyl compound then crystallized from alcohol in colorless needles, m. p. 116.8–117.6°; yield 0.03 g. (17%).

Anal. Calcd. for $C_{19}H_{14}$: C, 94.18; H, 5.82. Found: C. 94.35; H, 5.61.

The hydrocarbon shows strong blue-violet fluorescence in ultraviolet light. The substance did not depress the m. p. of a sample kindly supplied by Dr. M. S. Newman. The **picrate** formed red needles, m. p. 141.6–142.4°, from alcohol.

Anal. Calcd. for $C_{25}H_{17}O_7N_3$: N, 8.91. Found: N, 8.80.

Summary

Chrysene-5-carboxylic acid, obtained by the Pschorr synthesis, has been converted through the aldehyde (Sonn–Müller reaction) to the 5-methyl compound. In attempts to reduce the ester with sodium and ethanol or by high pressure hydrogenation, the aromatic nucleus was invariably attacked.

Oxidation Products of Sulfanilamide

BY MARGARET K. SEIKEL[1]

Sulfanilamide (I) oxidizes with ordinary oxidizing agents either to azobenzene-4,4′-disulfonamide (II) or to azoxybenzene-4,4′-disulfonamide (III). Both II and III can be reduced to I and to hydrazobenzene-4,4′-disulfonamide (IV).[2] Oxidation of sulfanilamide with cold alkaline ferricyanide produced a 20% yield of the azo compound II.[3] A better method for preparing II, with the over-all yield of brighter colored product as high as 46%, comprises the series of reactions I→III→IV→II. II could be converted into III by heating for several hours with hydrogen peroxide in glacial acetic acid.[4]

When I was oxidized in glacial acetic acid with 30% hydrogen peroxide, the azoxy compound III was obtained in 70% yields after only half an hour's heating. The speed with which III was obtained from I in comparison with the slow conversion of II to III indicated that II is probably not an intermediate in the former reaction; likewise IV yielded mainly II by the same treatment.[5] However, with this reagent *p*-toluidine is oxidized first to the corresponding azo compound so undoubtedly the sulfonamido group affects the course of the reaction.

If I was oxidized by hydrogen peroxide in dilute sulfuric acid, the product was a mixture of II and III. If hydrochloric acid was employed as the acidifying agent, partial chlorination yielded mixtures of products. Oxidations by hydrogen peroxide in neutral or basic solutions were too slow to be practical.

Reductions of II, III or material believed to be a mixture of the two by stannous chloride in hydrochloric acid regenerated sulfanilamide in 35–50% yields.[3a] Reductions with hydrosulfite in alkaline solution produced quantitative yields of IV.

Reoxidation of IV to II occurred very readily with various oxidizing agents, but 1 *N* ferric chloride was preferable because it yielded instantaneous and quantitative results.

Sulfanilamide may be chlorinated in the cold by treatment with a great excess of hydrochloric acid and only a moderate excess of hydrogen peroxide, the previously unreported 3,5-dichloro-4-amino-benzenesulfonamide (V) separating in fair yields. The reaction undoubtedly occurs through an intermediate chloramide.

Experimental

All melting points are uncorrected and were taken by the method described in Mulliken's "Identification of

Pure Organic Compounds," Vol. I, page 218, on a 360° thermometer immersed in a mixture of sulfuric acid and potassium acid sulfate to the 0° point. Analytical values represent averages of closely agreeing duplicate determinations.

Oxidation Procedures: Ferricyanide.—Sulfanilamide (0.85 g., 0.005 mole) dissolved in 5 ml. of water containing 1.4 g. (0.025 mole) of potassium hydroxide was treated at room temperature with an aqueous solution of 6.58 g. (0.02 mole) of potassium ferricyanide. The precipitated potassium derivative of II was filtered off after ten to thirty minutes and converted to the free amide. The 17–25% yield of tan product was most readily purified by several recrystallizations from 30–40% pyridine (its solubility in alcohol is low) from which it separated in fronds of dull apricot hair-like needles, m. p. 312° dec. after sintering above 300°.

Anal. Calcd. for $C_{12}H_{12}N_4O_4S_2$: C, 42.3; H, 3.55; N, 16.5. Found: C, 42.2; H, 3.63; N, 16.6.

It forms a vivid yellow solution in concentrated sulfuric acid and dissolves fairly readily in dilute alkali.

Hydrogen Peroxide–Acetic Acid.—A solution of 5 g. of sulfanilamide in 30 ml. of 30% hydrogen peroxide and 120 ml. of glacial acetic acid was heated for one-half hour at 100°. A 58% yield (3.0 g.) of the 6-mm. shining orange needles of III was filtered from the hot solution, and on cooling the mother liquor deposited an additional 14% yield. The same reaction occurs slowly at room temperature, a 64% yield being obtained in one day. III was easily purified by one or two recrystallizations from 30% pyridine from which it separated as yellow-orange plate-needles, m. p. 289–290° with violent evolution of gas.

Anal. Calcd. for $C_{12}H_{12}N_4O_6S_2$: C, 40.4; H, 3.39; N, 15.7. Found: C, 40.4; H, 3.49; N, 15.3.

The compound gave an orange-yellow solution in concentrated sulfuric acid. It did not free iodine from potassium iodide in acetic acid.

Hydrogen Peroxide–Sulfuric Acid.—When sulfanilamide was oxidized by 30% hydrogen peroxide in the presence of 6 *N* sulfuric acid, slower precipitation of a product occurred. After recrystallization, the vivid orange needles representing a mixture of II and III generally melted around 296° with violent evolution of gas.

Anal. Calcd. for $C_{12}H_{12}N_4O_4S_2$: C, 42.3; H, 3.55; N, 16.5. Calcd. for $C_{12}H_{12}N_4O_5S_2$: C, 40.4; H, 3.39; N, 15.7. Found: C, 41.2; H, 3.31; N, 16.0.

The mixture gave a yellow-orange solution in concentrated sulfuric acid.

Reduction Procedures: Stannous Chloride.—II, III and the mixture of the two were reduced by heating 0.25 g. of material with 1.0 g. of stannous chloride and 4 ml. of 10 *N* hydrochloric acid for ten minutes at 100°. After being made basic with bicarbonate, the reaction mixtures were evaporated to dryness by air and extracted twice with acetone. The residues obtained by evaporating the acetone were either recrystallized from or extracted with boiling water depending on the amount of high melting insoluble impurity present. From the aqueous solutions 35–50% yields of sulfanilamide melting around 160° were isolated. After further purification, material from any of the initial sources did not lower the melting point of an authentic sample.

Hydrosulfite.—Solutions of 0.10 g. of II, III and the mixture of the two in 5 ml. of 0.2 *N* sodium hydroxide were heated to boiling and treated with solid practical sodium hydrosulfite until decolorization was complete, the separation of an intermediate precipitate being disregarded. The amounts of hydrosulfite used were as follows: for II, 0.08, 0.08 g. or 0.27 g. per millimole; for III, 0.15, 0.15, 0.15 g. or 0.54 g. per millimole; for the mixture, 0.13, 0.13, 0.13 g. After boiling five minutes and cooling, the solutions deposited 100% yields of IV, m. p. 224–224.5° to a red melt which resolidified. Recrystallization from water containing a trace of hydrosulfite to prevent reoxidation produced white fronds with the melting point unchanged. Samples from the various initial materials did not lower each other's melting points.

Anal. Calcd. for $C_{12}H_{14}N_4O_4S_2$: C, 42.1; H, 4.12. Found: from II, C, 42.1; H, 4.17; from III, C, 42.1; H, 4.10; from mixture, C, 42.1; H, 3.91.

Oxidation of Hydrazo Compound IV.—When an aqueous solution of IV was heated on the steam-bath, it soon assumed a yellow tinge and in two hours the rust colored needles of II separated, m. p. 308° dec. If IV was heated with enough 30% hydrogen peroxide to dissolve it, a 70% yield of II, m. p. 311° dec., could be obtained in an hour. When hydrogen peroxide and acetic acid were used in the proportions employed in the preparation of III, a 95% yield of II, m. p. 307° dec., was obtained after five minutes of heating. The speediest reoxidation resulted when a hot aqueous solution of IV (0.10 g. in 5–7 ml.) was treated with 1.0 ml. of 1 *N* ferric chloride; 90–100% yields of II separated instantaneously.[6]

After two recrystallizations from 30% pyridine, II was obtained as pure orange opaque flat needles, m. p. 314° dec., and it did not lower the melting point of II obtained by ferricyanide oxidation of I.

Anal. Calcd. for $C_{12}H_{12}N_4O_4S_2$: C, 42.3; H, 3.55. Found: C, 42.2; H, 3.41.

Oxidation of II to III.—When II was dissolved in hot 30% hydrogen peroxide and glacial acetic acid in the proportions used for the oxidation of I, the product isolated after at least three hours of heating melted at 291° with violent evolution of gas; it did not lower the melting point of III but did lower that of II.

Chlorination.—Sulfanilamide (0.43 g., 0.0025 mole) was dissolved in 15 ml. of 6 *N* hydrochloric acid (0.08 mole) and treated with 2 ml. of 30% hydrogen peroxide (0.02 mole) at room temperature. It was found most advantageous to filter off the precipitate when the mixture first assumed a yellow tinge (thirty to forty-five minutes); the product would then be practically colorless. The 60–80% yield of V was recrystallized twice from large volumes of water (200–300 ml. per gram) producing shining colorless needles, m. p. 205–205.5°.

Anal. Calcd. for $C_6H_6Cl_2N_2O_2S$: Cl, 29.7. Found: Cl, 29.5.

The proportions of acid and peroxide suggested were

(6) The high yields and speed of the reduction and reoxidation steps allows II to be prepared quickly and in good yields by way of III and IV. Experimentally a 46% yield, m. p. 308–309° dec., was obtained when the intermediate products were not purified.

determined empirically to be the best for a speedy reaction and a pure product.

Proof of Structure of V.—When V was desulfamidated by 75% sulfuric acid in the manner described for the analogous dibromo compound,[7] a 51% yield of 2,6-dichloroaniline, m. p. 38–39° (recorded 39°), could be steam distilled from the reaction mixture. This was acetylated with acetic acid and acetyl chloride,[8] m. p. 178.5–179°, recorded 175°, after recrystallization from 25% acetic acid.

(8) Beilstein and Kurbatow, *Ann.*, **196**, 215, 219–220 (1879).

Summary

1. On oxidation sulfanilamide yields the corresponding azo- and azoxy-benzenes which may be reduced to the hydrazo compound.

2. It can be chlorinated readily by a mixture of hydrogen peroxide and hydrochloric acid.

The Mutarotation and Rotatory Dispersion of Derivatives of Aldehydo-*d*-galacturonic Acid[1]

BY ROBERT J. DIMLER AND KARL PAUL LINK

Aldehydo tetraacetyl methyl-*d*-galacturonate and one of its ethyl hemiacetals were prepared by Link and Campbell[2] as the first derivatives of the aldehydo form of a hexuronic acid. Prior to this work on *d*-galacturonic acid Wolfrom and Morgan[3] had prepared the corresponding derivatives of the parent sugar *d*-galactose. They also reported[4,5] on the optical properties of aldehydo-*d*-galactose pentaacetate and its hemiacetals. In this communication we have extended the mutarotation and rotatory dispersion study to the aldehydo derivatives of *d*-galacturonic acid.

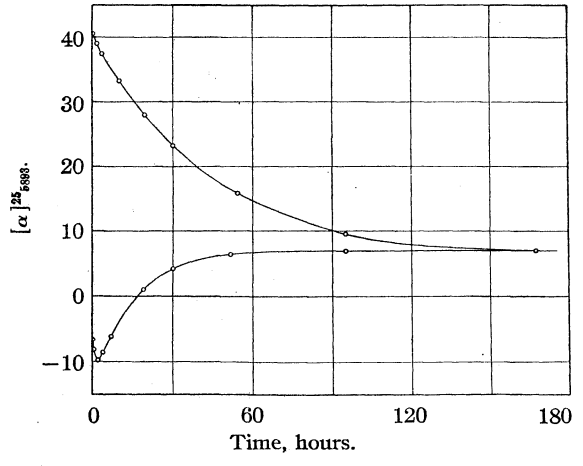

Fig. 1.—Mutarotation of α- and β-ethyl hemiacetal tetraacetyl methyl *d*-galacturonate in alcohol-free chloroform.

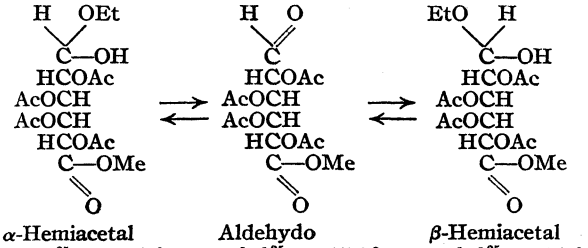
The isomeric α- and β-ethyl hemiacetals of tetraacetyl methyl-*d*-galacturonate have been obtained by variation of the method of preparation and fractional crystallization. This is the first member of the hemiacetal series for which both of the predictable forms have been realized. The designation of the isomers as α- and β- is based on the usage proposed by Hudson,[6] in which that derivative in the *d*-series having the more positive rotation is assigned the prefix α. The β-ethyl hemiacetal exhibits a mutarotation (Fig. 1) similar to that of the compounds of galactose studied by Wolfrom.[5] The α-ethyl hemiacetal shows a regular mutarotation without a minimum as seen in Fig. 1.

The mutarotation of the α- and β-ethyl hemiacetals involves the establishing of an equilibrium among the three compounds.



α-Hemiacetal $[\alpha]^{25}_{5893}$ +40.7° Aldehydo $[\alpha]^{25}_{5893}$ −15.6° β-Hemiacetal $[\alpha]^{25}_{5893}$ −6.7°

The minimum in the mutarotation curve for the β-ethyl hemiacetal is attributed to the primary rapid formation of the free aldehydo compound. The resulting aldehyde and alcohol recombine

in a second order reaction to form either of the isomeric hemiacetals. Since the concentration of the reactants in this reaction is low, the ratio of the aldehydo form will be high, as shown by the rotation of the equilibrium mixture. While differences in the *rate* of mutarotation for independent determinations can be noted, the curves obtained are of reproducible form. These variations are probably due to catalysts arising in the chloroform on standing. The nature of the compounds involved has not been investigated.[7]

The ethyl ester of ethyl hemiacetal tetraacetyl *d*-galacturonic acid, prepared in order that a compound might be used in which both alkyl groups were the same, was obtained only in the form of the β-isomer. The mutarotation, as shown in Fig. 2, is typical of the β-hemiacetals.

The rotatory dispersion of aldehydo pentaacetyl *d*-galactose was shown by Hudson, Wolfrom and Lowry[8] to be attributable to the induced dissymmetry of the aldehyde group, with only a small contribution from the other asymmetric centers of the molecule. The galacturonic acid structure contains another possible source of induced activity, namely, the carboxyl group (as the ester).

(7) Wolfrom[4] has suggested that hydrogen chloride is the responsible agent. We have observed that dry or moist hydrogen chloride or absolute alcohol in chloroform has no effect on the rate. However, alcoholic hydrogen chloride produces immediate equilibrium.

(8) Hudson, Wolfrom and Lowry, *J. Chem. Soc.*, 1179 (1933).

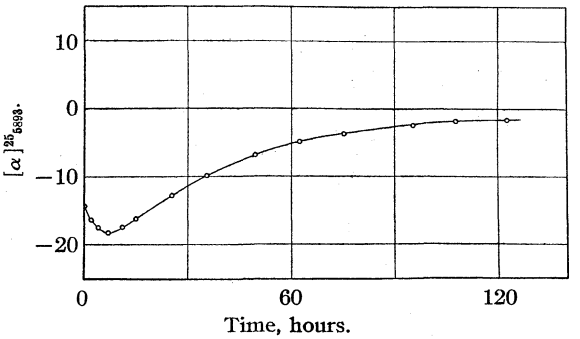

Fig. 2.—Mutarotation of β-ethyl hemiacetal tetraacetyl ethyl *d*-galacturonate in alcohol-free chloroform.

The methyl and ethyl esters of aldehydo tetraacetyl *d*-galacturonic acid were shown to have a complex rotatory dispersion by a preliminary plotting of the reciprocal of the specific rotation against the square of the wave length, the points lying on a curve instead of a straight line. Two-term Drude equations were then determined for the dispersions. These equations, with the difference between the observed rotations and those calculated from the equations, are given in Tables I and II. Since the observations were made only in the visible region of the spectrum the significance of the Drude equations is more qualitative than quantitative.

6708	−16.5	+0.1

[a] O − C is the difference between the observed specific rotation and the rotation calculated from the Drude equation.

The rotatory dispersion of the methyl and ethyl esters of aldehydo tetraacetyl *d*-galacturonic acid is complex but normal. The rotation is

dominated by the activity due to the induced dissymmetry of the aldehyde group, with an active band at about 2900 Å. A comparison of rotation constants of the two different esters and also the galactose derivative studied by Hudson, *et al.*,[8] shows that the groups on the terminal carbon remote from the aldehyde group have little influence on the magnitude of the activity induced in the carbonyl group. This is in accord with the present conception of induced dissymmetry.

The remaining active groups contribute a rotation of opposite sign and smaller magnitude. The dispersion constant may be assigned to the induced dissymmetry of the carboxyl group, with an active absorption band in the region of 2300 Å. While the carboxyl group often shows another active band at about 1700 Å., the limited range of dispersion studied in this case does not permit consideration of the possibility of such a contribution. Similarly, the small contribution of the other asymmetric centers, demonstrated for galactose, cannot be detected in this study. It may be concluded that the dispersion is probably more complex than is implied by a two-term Drude equation. The equations obtained indicate only the dominant sources of optical activity.

Experimental

Standardization of the Polarimeter.—The rotatory dispersions were studied with the use of a Franz Schmidt and Haensch polarimeter No. 52B with a monochromator attachment. The instrument was standardized by a modification of the method of Bencowitz.[9] A spectroscope was set with a sodium light and checked against a mercury arc. This spectroscope was then used to determine the wave length of the light transmitted by the monochromator. The settings were thus determined for the monochromator which would give the desired wave lengths. The results were checked by determining the rotatory dispersion of a 26% solution of Bureau of Standards sucrose, for which the dispersion formula is known.

Ethylmercaptal Methyl-*d*-galacturonate.—The method used by Campbell and Link[2] was modified to permit simultaneous mercaptalation and esterification. To a solution of 10 g. of *d*-galacturonic acid in 60 cc. of approximately 1 *N* hydrogen chloride–methanol (dry), was added 15 cc. of ethyl mercaptan. After standing at room temperature for one and one-half hours, the solution was refluxed gently for one-half hour. Concentration of the solution under reduced pressure gave a mass of crystals which was removed by filtration and washed with cold methanol. The mother liquors were concentrated to obtain another crop of crystals. In this way about four crops of crystals were obtained; yield of the crude product was 9.2 g. (57%). For acetylation it is sufficient to dry the crude preparation in a vacuum desiccator. If the product is to be kept for any length of time it should be recrystallized since the hydrogen chloride adhering to the crystals may cause decomposition.

Ethylmercaptal Tetraacetyl Methyl-*d*-galacturonate.—The method used was that described by Campbell and Link.[2] From the 9.2 g. of ethylmercaptal methyl-*d*-galacturonate prepared as above about 11.5 g. (71%) of the acetate (recrystallized once, m. p. 109–110°) was obtained.

Aldehydo Tetraacetyl Methyl-*d*-galacturonate.—This compound was prepared by the method of Wolfrom and Morgan.[3] The crude product was recrystallized several times to obtain the pure aldehydo tetraacetyl methyl-*d*-galacturonate; m. p. 135–136°; $[\alpha]^{25}_{5893}$ −15.6° (*c*, 4; $CHCl_3$).

The rotatory dispersion in alcohol-free chloroform was determined in a 4-dm. semi-micro jacketed tube at 25°. The rotations obtained with a comparison to the values calculated from the two-term Drude equation, are given in Table I.

Anal. Calcd. for $C_{15}H_{20}O_{11}$: $-OCH_3$, 8.25. Found: $-OCH_3$, 8.29.

β-Ethylhemiacetal Tetraacetyl Methyl-*d*-galacturonate.—Without fractionation the first time, 2.5 g. of the crude aldehydo compound was crystallized from 8 cc. of boiling absolute ethanol. The resulting 1.8 g. of crude ethyl hemiacetal was recrystallized with fractionation from 8 cc. of boiling ethanol. The first crop obtained from quiescent crystallization was 0.8 g.; initial $[\alpha]^{25}_{5893}$ −5.9°. The second crop, obtained by vigorous stirring of the mother liquor, was 0.2 g.; initial $[\alpha]^{25}_{5893}$ +3.0°. Repeated fractional crystallizations of the first fractions yielded the apparently pure β-isomer; m. p. 127–130° (on the Kofler microscope stage[10] with crossed nicols one observes the loss of ethyl alcohol at about 127° and the sharp melting of the remaining aldehydo compound at 135–136°); $[\alpha]^{25}_{5893}$ −6.7° initial, with equilibrium value of +7.1° (*c*, 4; $CHCl_3$).

The mutarotation of the ethyl hemiacetal in alcohol-free chloroform is shown by the curve in Fig. 1. Independent determinations showed differences in the length of time required to reach equilibrium, but the form of the curve was the same for all. The differences in rate probably are due to catalysts formed in the chloroform on standing.

Anal. Calcd. for $C_{17}H_{26}O_{12}$: alkoxyl, 18.06. Found: alkoxyl, 18.2.

α-Ethyl Hemiacetal Tetraacetyl Methyl-*d*-galacturonate.—The ethyl hemiacetal was prepared directly from the mercaptal by the method of Campbell and Link.[2] The 5.3 g. of crude product was recrystallized first without fractionation from absolute alcohol. On fractional crystallization of the 3.7 g. from 10 cc. of boiling absolute alcohol, as above, the first crop was 0.5 g., initial $[\alpha]^{25}_{5893}$ −2.2°; the second crop was 2.1 g., initial $[\alpha]^{25}_{5893}$ +15.8°. Further fractionation of second crops yielded the apparently pure α-isomer; m. p. 105–107° (on the Kofler microscope stage loss of ethyl alcohol is observed at about 105° and melting of the aldehydo compound at 135–

(9) Bencowitz, *J. Phys. Chem.*, **32**, 1163 (1928).

(10) Pregl–Roth, "Die quantitative organische Mikroanalyse," Berlin, 1935.

136°); $[\alpha]^{25}_{5893}$ +40.7° initial, changing to a final value of +7.1° (*c*, 4; $CHCl_3$).

The mutarotation, observed in alcohol-free chloroform, is shown by the curve in Fig. 1.

Anal. Calcd. for $C_{17}H_{26}O_{12}$: alkoxyl, 18.06. Found: alkoxyl, 18.1.

Ethylmercaptal Ethyl-*d*-galacturonate.—This compound was prepared from *d*-galacturonic acid in the same manner as the methyl ester. A dry hydrogen chloride–ethanol solution (approx. 1 *N*) was used as the solvent. The ethyl ester did not crystallize as readily as the methyl ester. By the repeated addition of absolute ethanol and removal under reduced pressure crystallization was induced. The concentrate was placed in a refrigerator for twenty-four hours to permit more complete crystallization.

From 10 g. of *d*-galacturonic acid, the yield was 9.6 g. (57%). Recrystallization from absolute ethanol gave a pure product; m. p. 128–129°; $[\alpha]^{25}_{5893}$ +15.7° (*c*, 2; EtOH).

Anal. Calcd. for $C_{12}H_{24}O_6S_2$: S, 19.53. Found: S, 19.62.

Ethylmercaptal Tetraacetyl Ethyl-*d*-galacturonate.—This acetyl derivative was prepared by the same method used for the corresponding methyl ester. From 9.6 g. of crude ethyl mercaptal ethyl ester the yield after one recrystallization was 11.5 g. (79%); m. p. 80–81°; $[\alpha]^{25}_{5893}$ +11.0° (*c*, 4; $CHCl_3$).

Anal. Calcd. for $C_{20}H_{32}O_{10}S_2$: S, 12.92. Found: S, 12.93.

Aldehydo Tetraacetyl Ethyl-*d*-galacturonate.—The preparation is similar to that of the corresponding methyl ester. The compound is quite soluble in toluene; m. p. 95–97°; $[\alpha]^{25}_{5893}$ −24.0° (*c*, 4; $CHCl_3$).

The rotations obtained in the study of the rotatory dispersion with a comparison to the values calculated from the two-term Drude equation, are given in Table II.

Anal. Calcd. for $C_{16}H_{22}O_{11}$: —OEt, 11.54. Found: —OEt, 11.7.

β-Ethylhemiacetal Tetraacetyl Ethyl-*d*-galacturonate.—The hemiacetal was prepared by both of the methods which were used for the methyl ester. The resulting compounds were apparently identical and could not be fractionated; m. p. 105–106°; $[\alpha]^{25}_{5893}$ −14.4° initial, reaching equilibrium at −1.6° (*c*, 4; $CHCl_3$). The course of the mutarotation, observed in alcohol-free chloroform, is shown by the curve in Fig. 2.

Anal. Calcd. for $C_{18}H_{28}O_{12}$: —OEt, 20.70. Found: —OEt, 20.8.

Summary

1. The α- and β-ethyl hemiacetals of aldehydo tetraacetyl methyl-*d*-galacturonate have been prepared. The mutarotation of the two compounds in chloroform indicates an interconversion over the aldehydo form.

2. The ethyl ester of ethyl mercaptal, ethyl mercaptal tetraacetyl, aldehydo tetraacetyl and ethyl hemiacetal tetraacetyl *d*-galacturonic acid have been prepared. Through mutarotation studies the ethyl hemiacetal tetraacetyl ethyl-*d*-galacturonate obtained is characterized as a β-hemiacetal.

3. The rotatory dispersions of the aldehydo tetraacetyl methyl- and ethyl-*d*-galacturonate have been shown to be complex but normal. Two-term Drude equations have been calculated for the dispersions to obtain a qualitative interpretation of the results.

The Dipole Moments and Structures of Certain Compounds of Sulfur, Selenium and Phosphorus

BY C. P. SMYTH, G. L. LEWIS, A. J. GROSSMAN AND F. B. JENNINGS, III

The dipole moments of hydrogen disulfide and sulfur and selenium monochlorides have been measured with a view to obtaining evidence as to the two possible structures, the Y-shaped or irregular tetrahedral such as S—SCl_2 and the more extended structures such as Cl—S—S—Cl, as well as getting some information bearing on the magnitudes of the bond moments. Selenium oxychloride and phosphoryl and thiophosphoryl chlorides have been investigated for the sake of the bond moments involved. Indeed, bond moment values obtained from the measurements on the two latter compounds already have been published,[1] and electron diffraction measurements have been made upon the more volatile of these several substances. The moments were obtained with the apparatus and methods previously described,[2,3] the dielectric constants and densities of solutions of the substances in benzene or heptane being determined.

Preparation of Materials.—Benzene and heptane were purified as in previous work.[4]

Hydrogen Disulfide.—The material was prepared from sodium polysulfide and purified in the manner described

by Butler and Maass[5]; d^{25}_4 1.3279, $n^{25}D$ 1.62635, $n^{22}D$ 1.63237.

Sulfur Monochloride.—Material previously prepared in this Laboratory was fractionally distilled at 10 mm. over sulfur; b. p. (10 mm.) 39°.

Selenium Monochloride.—The material was prepared from selenium and purified by methods described in the literature.[6,7] In spite of all precautions, it could not be regarded as very pure.

Selenium Oxychloride.—Material from the Eastman Kodak Company was vacuum distilled seven times in a glass apparatus which had been acidified with dry hydrogen chloride and completely sealed except for the outlet to the pump. It was then recrystallized and the third recrystallization crop was quickly filtered through a sintered glass crucible. After another vacuum distillation, this material was used for the measurements; $n^{20}D$ 1.65159.

Phosphoryl Chloride.—Material from the Baker and Adamson General Chemical Company was fractionally distilled twice; b. p. 107.0–107.1°, $n^{25}D$ 1.45816, d^{25}_4 1.6659. As this fractionation did not alter the boiling point and raised the refractive index by only 0.0001, a second sample of refractive index 1.45797 was used without purification for a second series of measurements, which agreed well with the first.

Thiophosphoryl Chloride.—Material from the Eastman Kodak Company was dried with calcium chloride and fractionally distilled twice; b. p. 125.0°, $n^{25}D$ 1.5432, d^{25}_4 1.6271.

Experimental Results.—The dielectric constants ϵ and the densities d of benzene or heptane solutions containing mole fraction c_2 of solute are given in Table I, the polarizations P_2 being listed in the last column. The polarization of the pure solvent is given as P_1. The measurements were carried out at 25° with the exception of those on a second set of solutions of phosphoryl chloride in benzene at 10, 40 and 60°, which agreed well with the results on the first set measured at 25°. Table II lists in the second column the values of MR_D, the molar refraction for the D sodium line, calculated for the colored sulfur monochloride and selenium monochloride as the sums of the atomic refractions given in the literature,[8] and for the other substances from the data in the present paper, the density of selenium oxychloride being taken from the literature.[9] A value obtained from the data of Lenher and Kao[7] for selenium monochloride is practically identical with that calculated for the corresponding sulfur compound and is, therefore, to be regarded as too

$PSCl_3$	32.8	74.3(25°)	1.41 (in benzene)
		74.4(25°)	1.41 (in heptane)

low. The difference of 7.9 in the two values makes a difference of only 0.09 in the moment values. The last two columns of Table II give the polarization P_∞ obtained by extrapolation to $c_2 = 0$ of the values of P_2 in Table I and the dipole moments.

Discussion of Results

The moment of diphenyl disulfide,[10] which is apparently an extended structure C_6H_5—S—S—C_6H_5, is 1.81. The C–S bond moment was calculated[1] on the reasonable assumption of an 112° C–S–C angle. If it is assumed that the greater separation of the attached groups in the disulfide prevents widening of the C–S–S angle by repulsion, this may be taken as 90°. Complete freedom of rotation around the S–S bond would then give a calculated moment[11] = 1.414 × 1.3 = 1.84 in excellent agreement with the observed 1.81. If the C–S–C angle used in calculating the bond moment were really less than 112° or if the C–S–S angle were much widened by repulsion, the calculated moment would be lower than the observed. It would appear, however, that the observed moment is consistent with the extended structure with all positions of rotation around the S–S bond equally probable. A 90° azimuthal angle as suggested in the case of hydrogen peroxide[12] would lead to the same calculated value.

An analogous extended structure, H–S–S–H, for hydrogen disulfide, which is indicated by the electron diffraction measurements made in this Laboratory,[13] leads to a calculated moment value 1.41 × the H–S bond moment 0.68, if the H–S–S valence angle is 90°, as seems highly probable, and if all positions of rotation around the S–S bond are equally probable or if the azimuthal angle is 90°. The value thus calculated 0.96 is 0.21 lower than the observed value 1.17, which cannot be more than 0.05 high because of neglect of atomic polarization. The discrepancy might arise from differences in the inductive effects in this molecule from those in the hydrogen sulfide molecule, from the moment of which the H–S bond moment is calculated. It would, however, be accounted for if the hydrogen disulfide contained a small proportion of Y-shaped molecules $H_2S^+ - S^-$, in which the large moment of the semipolar bond between the sulfur atoms could easily raise the mean moment to the observed value. It appears highly probable, however, that the largely predominant structure is H–S–S–H.

The problem of the structures of sulfur and selenium monochlorides is analogous to that of the disulfides. Raman spectra investigations have led Matossi and Aderhold[14] to ascribe a Y-shaped structure $SSCl_2$ to sulfur monochloride, while Morino and Mizushima[15] have concluded the structure to be Cl–S–S–Cl. Palmer's[16] electron diffraction measurements are interpreted as indicating an extended Cl–S–S–Cl structure. The dipole moment 1.0 found by Morino and Mizushima[15] for sulfur monochloride in heptane solution is much lower than the value 1.60 found here in benzene solution. If the bond moment value 0.5 calculated[1] from a somewhat doubtful moment value for SCl_2 but consistent with the sulfur and chlorine electronegativities is correct, the two chlorines would have to be on the same side of the extended structure of the molecule with a 90° Cl–S–S angle and a zero azimuthal angle to account for the moment value observed by Morino and Mizushima. Even this structure would fail to account for the much higher moment found in benzene solution. If the molecule had the bent Y-shaped or tetrahedral structure $^-S—^+SCl_2$, the large moment of the semipolar bond between the sulfurs should exceed the small opposing S–Cl moments by an amount sufficient to give a resultant moment, at least, as large as 1.6. The moment 1.6 found for thionyl chloride,[17] which has been shown by electron

diffraction[16] to have a similar bent Y-shaped or irregular tetrahedral structure is identical with that here found for S_2Cl_2, although the more accurate vapor value 1.44 found by Coop and Sutton[18] is slightly lower.

The moment of selenium monochloride is 0.5 higher than that of the corresponding sulfur compound and the moment of selenium oxychloride is 1.0 higher than that reported for thionyl chloride. An increase in moment is to be expected from the more positive character of selenium as compared to sulfur, but, as in the cases of other bonds involving atoms of considerable size,[19] the increase is greater than would be anticipated from the difference 0.1 in the electronegativities of the two elements.[1,20] If moments 1.1 and 1.55 are assigned to the S—Cl and Se—Cl bonds, respectively, the moments of the two monochlorides can be reproduced by the unbranched structures  and  with 90° sulfur or selenium valence angles and freedom of rotation around the S–S or Se–Se bond when the molecules are surrounded by benzene but with much reduced freedom when the molecules are in heptane, somewhat as observed in the case of the ethylene halides.[11,21] However, this necessitates the assumption of the incorrectness of the SCl_2 moment value from which the S–Cl moment was previously calculated and gives a value higher than those of the P–Cl and I–Cl bonds, than which it should be lower. Also, the Se–Cl value is closer to that of As–Cl, 1.6, than the electronegativity difference 0.4 between Se and As would lead one to expect. If the Cl–S–S angle in S_2Cl_2 were 103° as reported by Palmer[16] instead of 90° as roughly assumed here, a still higher value would have to be assigned to the S–Cl moment. The moments of the monochlorides can be accounted for without the assumption of these seemingly too high bond moments if the molecules have the branched structures with semipolar bonds or if the substances, under the conditions of measurement, contained a considerable proportion of the branched molecules. The coexistence of the extended and the branched structures would thus be consistent with the moments observed for hydrogen disulfide as well as for the two monochlorides. If this is the correct explanation of the moments, a moment of about 0.8 is to be assigned to the Se–Cl bond.

Coop and Sutton[18] have used the moments of thionyl chloride 1.44 and sulfuryl chloride 1.795 together with the assumption of tetrahedral structures to calculate approximate moment values, 0.61 for the S–Cl bond and 2.16 for the S–O bond. Use of the bond moment 0.5 for S–Cl together with the valence angles of the somewhat distorted tetrahedral structures reported by Palmer[16] for these two molecules gives an S–O value 1.64 in thionyl chloride and 2.36 in sulfuryl chloride. All of these values are lower than the value 2.5 for S–O calculated by Coop and Sutton from the moments of dimethylsulfone and dimethyl sulfide, but are not far from the S–O bond values calculated previously by one of the writers[1] from earlier values of the moments of these compounds. In this previous work the moment of the semipolar $S^+—O^-$ bond was concluded to be about 3.0, of the magnitude usually found for semipolar bonds. While the discrepancies in the values calculated above arise in part from uncertainties in the valence angles used, it appears fairly certain that the S—O bond moment in thionyl chloride is lower than the usual semipolar $S^+—O^-$ moment. Palmer attributes the abnormally short S–O bond distance found in these compounds to contributions from triply-bonded structures. The contributions from such structures as $^-S\equiv{}^+O$ would, of course, oppose the normal bond moment and reduce the value observed for it. Lister and Sutton[22] regard the bond as predominantly double in character, which would involve a moment lower than that of a semipolar bond. In either case, a moment lower than that of the usual hybridized semipolar bond is to be expected.

If it is assumed that the valence angles in selenium oxychloride are identical with those in thionyl chloride and the Se–Cl moment is taken as 0.8, the Se–O moment obtained is 2.95. Raising of the Se–Cl value to 1.5 would increase the Se–O value obtained only to 3.04. The Se–O bond value 3.0 thus obtained is typical of the somewhat hybridized semipolar bond. The more positive character of the selenium evidently reduces the contributions from the doubly-bonded and the much less probable triply-bonded structures.

The data on phosphoryl chloride and thiophosphoryl chloride have already been used[1] to calculate the moments of the semipolar $P^+—O^-$ and $P^+—S^-$ bonds. As each of these bonds lies in the axis of symmetry of its molecule[23,24] with its moment acting in the opposite direction to the resultant of the three P–Cl bond moments, the semipolar bond moment was calculated by adding the moment of the PCl_3 molecule 1.1 to the moment observed for the whole molecule. A slight revision of the data on thiophosphoryl chloride raises the $P^+—S^-$ moment value from 2.4 to 2.5, the $P^+—O^-$ value 3.5 remaining unchanged. It was recognized that, as usual in the case of such bonds, neither of these was a pure semipolar bond as other resonating forms, particularly double-bonded structures, contributed to the structures of the molecules. The difference 1.0 between the $P^+—S^-$ and $P^+—O^-$ bonds appears surprisingly large, especially in view of the fact that the C=S bond moment is greater by 0.3 than the C=O moment.[1] Coop and Sutton[18] suggest that their low value for thiophosgene 0.28 as compared to 1.18 for phosgene[25] may be due to the inductive effects of the two C–Cl moments upon the very polarizable sulfur. In $PSCl_3$, the three P–Cl dipoles are farther from the S than are the two C–Cl dipoles in $CSCl_2$, but there are three of them instead of two. It appears quite reasonable, therefore, to attribute the lower moment value obtained for the $P^+—S^-$ bond as compared to the $P^+—O^-$ bond less to any inherent structural difference or even to the lower electronegativity of sulfur as compared to oxygen, than to the greater opposing moments induced by the P–Cl dipoles in the sulfur atom, which is much more polarizable than the oxygen.[26] The inherent moment of the $P^+—S^-$ bond is presumably not appreciably different from that of the $P^+—O^-$, the two lying in the neighborhood of 3.5, where most of the more or less hybrid semipolar bonds seem to lie.

Summary

The dielectric constants and densities of solutions of hydrogen disulfide, sulfur monochloride, selenium monochloride, selenium oxychloride, phosphoryl chloride and thiophosphoryl chloride in benzene or heptane have been measured and used to calculate the dipole moments of the molecules of the solutes.

The hydrogen disulfide moment may be explained by an extended structure H–S–S–H, but may be best explained if the substance contains also a small proportion of branched molecules H_2S–S. The sulfur monochloride and selenium monochloride moments may be explained with difficulty by extended structures, Cl–S–S–Cl and Cl–Se–Se–Cl, but correspond better to branched structures, S–SCl_2 and Se–$SeCl_2$, in the form of an irregular tetrahedron like that of $SOCl_2$ and $SeOCl_2$, or to a mixture of the extended and the branched structures.

The value 3.0 is calculated for the moment of the Se–O bond in selenium oxychloride which has more polar character than the S–O bond in thionyl chloride. The moments of phosphoryl chloride and thiophosphoryl chloride have been used to calculate the values 3.5 and 2.5 for the moments of the semipolar bonds $P^+—O^-$ and $P^+—S^-$, the latter of which is lowered more than the former by induction.

The Thermodynamics of *n*-Heptane and 2,2,4-Trimethylpentane, Including Heat Capacities, Heats of Fusion and Vaporization and Entropies

BY KENNETH S. PITZER

Thermodynamic functions for the saturated hydrocarbons through the butanes and tetramethylmethane were given by the writer in 1937.[1] More recent experimental work[2] has confirmed the general scheme used at that time, and the numerical values there listed within their respective limits of error. This paper represents the beginning of an attempt to extend this work through the octanes. The researches of Parks and co-workers[3] have included most of the hydrocarbons in this range; however, their entropies are based on long extrapolations of the heat capacity curve from 90°K. Thus, while accurate enough for their original purpose, these data are of doubtful value for the more precise work now at hand. It would be nice if lower temperature measurements on a few compounds should confirm the accuracy of Parks' extrapolations. The results presented below tend to support this hope for the normal paraffins but indicate that the branched chain compounds may deviate by large amounts.

Apparatus.—The calorimeter used for the condensed phases already has been described.[4] A calorimeter, somewhat similar to the one described by Bennewitz and Rossner[5] was used to measure the heats of vaporization. Data also were obtained on the heat capacity of the vapors. However, since work is continuing on certain aspects of the design and operation of the heat capacity calorimeter, a detailed description seems hardly worthwhile at present.

The parts used for heat of vaporization measurements may be described briefly as comprising a dewar with electrical heater inside in which the liquid is vaporized, and a condenser system in which the amount vaporized in a given time can be measured accurately. The dewar is rather tall and narrow (40 cm. long by 4.2 cm. diameter) with the heater near the bottom. During measurements a considerable height of liquid is present above the heater, tending to bring the vapor temperature to equilibrium and to prevent heat loss through the lead-in wires. The heater has a resistance of about 30 ohms and the lead wires are of no. 18 copper. A White potentiometer is used for measuring the heating energy, readings being taken across a 0.01-ohm standard resistance for the current, and across a suitable volt box for the potential. The error of these measurements is much less than 0.1%. The batteries supplying the heating current are steady within about 0.1% for the period of a measurement, which ranges from ten minutes to nearly an hour. The vaporizer dewar is jacketed with a bath of boiling liquid so as to maintain a temperature a few tenths of a degree higher outside than inside. The heat leak through the dewar is usually insignificant under these conditions, which further assure that no reflux can occur in the tube carrying vapor from the dewar. This tube of course passes through the jacket.

After leaving the vaporizer the gas passes through the specific heat calorimeter and then goes to the condensers. These comprise first a permanent condenser and reservoir and second a removable sample bulb. The latter is immersed in cold water, and the gas is condensed in a small tube before entering the bottom of the bulb. A second connection equalizes the pressure between the sample bulb and the reservoir so that practically no disturbance occurs when a change is made from one to the other. The sample bulb is connected with ground glass joints and has stopcocks on both openings.

A heat of vaporization measurement involves the following operations: 1. The jacket around the vaporizing dewar is adjusted to the proper temperature. 2. The current in the vaporizing heater is started and adjusted. 3. When a steady state has been attained, the flow is turned into the sample bulb for an accurately timed interval. 4. During this interval numerous precise readings are taken on the heater current and potential.

As a check on the accuracy of this calorimeter the heat of vaporization of water was measured. Three runs at different rates of heating gave 9730, 9740 and 9720 cal. per mole. In a recent paper Osborne, Stimson and Ginnings[6] report 9723 cal. per mole at the boiling point. The agreement is thus perfect, considering the experimental error of the present work.

Materials.—The 2,2,4-trimethylpentane had been recovered from other experiments in this University. The boiling point was remarkably constant and the heat capacity immediately below the melting point indicated less than 0.01% of solid insoluble, liquid soluble impurity. The *n*-heptane was obtained from the Eastman Kodak Co. After two fractionations its premelting heat capacity indicated 0.15% impurity. This impurity cannot have any large effect on the results reported below, and very probably is of no consequence at all. The melting point and heat of fusion were appropriately corrected assuming Raoult's law.

Melting and Boiling Points.—Since precise measurements of these physical constants have been reported by several workers, no attempt was made to obtain exact values in the course of this work. Approximate values were observed which are in agreement within 0.1° or less in each case. We shall adopt the results obtained by Smith and Matheson[7] and by Brooks,[8] which are for *n*-heptane, m. p. 182.52° and b. p. 371.51°, and for 2,2,4-trimethylpentane, m. p. 165.79° and b. p. 372.33°K. (273.10°K. = 0°C.).

Solid and Liquid Heat Capacities.—The heat capacities were measured by the usual methods and are reported in Tables I and II. The unit is the defined calorie, equal to 4.1833 Int. joules, which is used throughout this paper. Above 90°K. the heat capacities of both substances were measured by Parks, Huffman and Thomas.[3] The agreement is reasonably satisfactory, and is better at the lower temperatures than near room temperature. The largest differences are about 1%, the values of Parks being lower in these cases. Over considerable regions the agreement is within 0.2%, which is approximately the accuracy claimed for the present investigation. The points at the highest and lowest temperatures are somewhat more uncertain than the others.

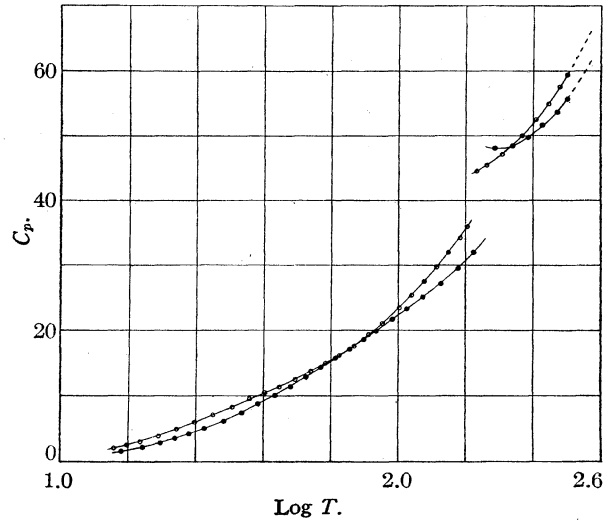

Fig. 1.—The molal heat capacity of solid and liquid *n*-heptane (solid circles) and 2,2,4-trimethylpentane (open circles) in cal. per degree.

Figure 1 shows the two heat capacity curves graphically. Although the two substances never differ very greatly, the curves are by no means parallel. In particular, at 90°K. (log T = 1.95) where Parks began measurements, the heat capacities are almost equal and the 2,2,4-trimethylpentane has the greater slope. Thus almost any reasonable extrapolation would have the curves cross, and give the heptane the larger entropy at 90°K. However, this is not correct, and it illustrates the danger of heat capacity extrapolations from such a high temperature.

Heats of Fusion.—Table III presents the heat of fusion results. The agreement between the individual results is remarkable, particularly when one considers that the temperature intervals and rates of heating were varied considerably. The

uncertainties given are based on estimates of the various constant errors.

It is quite possible that the heats of fusion reported by Parks, Huffman and Thomas[3] are calorimetrically in better agreement than would appear from Table III. The differences may arise from their treatment of the premelting heat for the less pure samples that they had available. The lack of any appreciable impurity precludes such an error in the 2,2,4-trimethylpentane value from this research. If Raoult's law is not even approximately followed the *n*-heptane result may be in error by somewhat more than the uncertainty listed. Any error of this nature will, however, be approximately compensated in the heat capacities just below the melting point and therefore does not appreciably affect the final entropy value.

15.01	0.02899	7420
14.89	.02886	7410
9.96	.01936	7380
6.06	.01166	7450
	Weighted average	7410 ± 20

Heats of Vaporization.—The apparatus and procedure in measuring heats of vaporization were described above, where the check measurements with water were also mentioned. The results for the hydrocarbons are given in Table IV, together with those from other observers. The result for *n*-heptane reported by Mathews[9] is in excellent agreement with the value obtained in this research. Bennewitz and Rossner's result differs, however, by about 3%.

Smith and Matheson[7] have reported accurate vapor pressure–temperature curves for both of these substances. If the true molal volumes of the saturated vapors were known, good heats of vaporization could be calculated. Careful measurements of these volumes were carried out, using the Dumas method. While these results were not as accurate as the calorimetric values, they agree within the 1% uncertainty to be assigned to the former. The volumes at the boiling points for both substances are approximately 4.5% lower than would be calculated from the perfect gas law.

Gas Heat Capacities.—Measurements of the heat capacity of these hydrocarbons as gases were made in connection with the heat of vaporization work. The calorimeter was mentioned above, but, as was stated there, a complete description will be postponed until developments now in progress have been more nearly completed. The present results are to be regarded as less accurate than results to be obtained in the near future. The values obtained are for 423°K. except in the case of steam which was measured at 432°K. All are at a constant pressure of one atmosphere. The results are: for H_2O, 8.4; for CCl_4, 22.7; for *n*-heptane, 53.9; and for 2,2,4-trimethylpentane, 61.6 cal. per degree per mole.

From the work of Gordon,[10] Wilson,[11] and Keyes and co-workers,[12] one may calculate an accurate heat capacity for steam to compare with that obtained in this work. The value obtained is 8.49 cal. per degree. For carbon tetrachloride a complete calculation is not possible, but using the approximate (rigid rotator–harmonic oscillator) spectroscopic calculations of Vold[13] and assuming the Berthelot equation of state one obtains 22.5 cal. per degree. The true value would be expected to be a little larger. The agreement on the two "knowns" is thus to within about 1%. Probably the values for the hydrocarbons are not in error

by much more than this amount. The value for *n*-heptane (45.1 cal. per degree at 410°K.) reported by Bennewitz and Rossner[5] seems definitely too low.

For thermodynamic calculations it would be desirable at least to estimate the temperature variation of the heat capacity. On the basis of statistical calculations to be published soon, the following equations are suggested. They should not err grossly in the range 300–600°K.

$$n\text{-heptane};\ C_p = -235.0 + 110 \log T$$
$$2,2,4\text{-Trimethylpentane};\ C_p = -227.3 + 110 \log T$$

It is suggested that these equations be used in preference to constant heat capacities for these gases until accurate data are available. They agree with the experiments at 423°K., of course.

TABLE V

THE MOLAL ENTROPY OF *n*-HEPTANE

0–15.14°K.	Debye extrapolation	0.535 cal./deg.
15.14–182.52	Graphical–solid	35.186
182.52	Fusion (3355.8/182.52)	18.386
182.52–298.10	Graphical–liquid	24.488
	Entropy at 298.10°K. (liquid)	78.60 ± 0.2
298.10–371.51	Graphical–liquid	12.55
371.51	Vaporization (7660/371.51)	20.62
	Entropy at 371.51°K. (gas)	111.77 ± 0.3

TABLE VI

THE MOLAL ENTROPY OF 2,2,4-TRIMETHYLPENTANE

0–14.13°K.	Debye extrapolation	0.683
14.13–165.79	Graphical–solid	35.309
165.79	Fusion (2201.6/165.79)	13.279
165.79–298.10	Graphical–liquid	29.132
	Entropy at 298.10°K. (liquid)	78.40 ± 0.2
298.10–372.33	Graphical–liquid	13.75
372.33	Vaporization (7410/372.33)	19.90
	Entropy at 372.33°K. (gas)	112.05 ± 0.3

Entropies.—The entropy calculations are summarized in Tables V and VI. The Debye extrapolations are for six degrees of freedom to include torsional as well as compressional waves in the crystal, and to obtain better agreement with the first few experimental points.[14] All the other contributions are based on experimental data of this research except for short ranges of the liquids just below their boiling points. These regions are shown dotted in Fig. 1. The uncertainty from this source can hardly be very large considering the regularity of heat capacity curves for liquid substances of this type.

(14) See Lord, Ahlberg and Andrews, *J. Chem. Phys.*, **5**, 649 (1937), for a fuller discussion of this matter.

It already has been mentioned that any reasonable extrapolation method starting from 90°K. cannot give the correct answer for both of these compounds. Thus the results of Parks, Huffman, and Thomas[3] can at best agree in only one case. Actually their *n*-heptane value agrees very well (78.9 cal. per degree at 298.1°K.) while their result for 2,2,4-trimethylpentane is too small (75.2 cal. per degree at 298.1°K.). When one considers that the crystals of all normal paraffins must be very similar it seems likely that a method of extrapolation from 90°K. may have a fair accuracy for this limited group of compounds. Since Parks' original[15] values for *n*-butane and *n*-heptane appear to be nearly correct,[16] the corresponding values for other normal paraffins can be used with some confidence. On the other hand it seems that crystals of branch chain compounds will possess no such similarity and that in consequence entropies based on long extrapolations may be considerably in error in these cases.

Statistical calculations in terms of molecular structure data will be presented elsewhere. It suffices to say here that these experimental entropies and gas heat capacities are consistent with internal rotation potential barriers of the same order of magnitude as have been found for simpler molecules.[1]

Summary

The thermal behavior of *n*-heptane and of 2,2,4-trimethylpentane has been investigated from 15 to 423°K. for which range heat capacities of the solid, liquid or gas are given. The following heats of fusion and vaporization were obtained: *n*-heptane, 3355.8 ± 4 and 7660 ± 20; 2,2,4-trimethylpentane, 2201.6 ± 2, 7410 ± 20 cal. per mole. The entropies were calculated for the liquid at 298.1°K. and for the gas at the boiling point respectively to be: *n*-heptane 78.60 ± 0.2 and 111.77 ± 0.3 and 2,2,4-trimethylpentane 78.40 ± 0.2 and 112.05 ± 0.3. A discussion of these results in terms of statistically calculated entropies will be presented elsewhere.

BERKELEY, CALIF. RECEIVED FEBRUARY 28, 1940

(15) Those given in ref. 3 not the revised values given or suggested by Parks, Shomate, Kennedy and Crawford, *ibid.*, **5**, 359 (1937).

(16) For *n*-butane at its b. p. Parks obtained originally 72.5 but revision of his entropy of vaporization data will lower this a few tenths. Aston (personal communication) has recently obtained 72.0 cal. per degree.

The Configuration of Some Cupric, Nickelous and Cobaltous Complexes by Means of Magnetic Measurements

BY G. N. TYSON, JR., AND S. C. ADAMS

A large number of organo-metallic compounds, in which a transition metal is found in the quadricovalent state, have been prepared. In particular, the preparation of organic complexes of several metals was described by Zetzsche and co-workers,[1] and more recently by Pfeiffer and colleagues.[2] The compounds cupric, nickelous, and cobaltous disalicylaldehyde have been synthesized for this study, as well as the disalicylaldimine complexes of divalent copper and nickel. The magnetic susceptibilities of these complexes have been determined, and on the basis of these results alone, except in the case of the cupric compounds, the most probable configurations have been assigned to the molecules.

Experimental

Synthesis.—The cupric (I), nickelous (II), and cobaltous (III) disalicylaldehydes were prepared by treating approximately half saturated solutions of J. T. Baker Co. C. P. metal acetate salts in 50% alcohol with the stoichiometric amounts of carefully purified salicylaldehyde. The reactants were thoroughly mixed and allowed to stand at room temperature until the reactions were complete. The precipitated products were filtered, washed successively with water, alcohol and ether, and finally dried in a vacuum desiccator over concentrated sulfuric acid.

The cupric (IV) and nickelous (V) disalicylaldimines were prepared by suspending the corresponding disalicylaldehyde compounds in 10% solutions of aqueous ammonia and stirring vigorously until the reactions were completed. A definite color change indicated the completeness of the reaction in both cases. It has not been found possible to prepare the cobaltous disalicylaldimine compound by this method. The purification of the two salicylaldimine compounds was effected by the method as given above for the salicylaldehyde complexes.

Analytical Results.—Analyses for metal, carbon, hydrogen, and nitrogen, using standard electrolytic deposition methods for the metals, and standard micro and semi-micro methods for C, H, and N, gave the results listed in Table I.

All of the compounds were sparingly soluble in water, ether, and alcohol, and slightly soluble in solvents such as chloroform and carbon tetrachloride. No definite melting points were shown, but all compounds slowly decomposed when heated above 100°.

TABLE I

Cpd.	Metal, % Calcd.	Metal, % Found	Carbon, % Calcd.	Carbon, % Found	Hydrogen, % Calcd.	Hydrogen, % Found	Nitrogen, % Calcd.	Nitrogen, % Found	Color

[a] Calculated percentages based on two molecules of water of crystallization.

Magnetic Measurements.—The results of magnetic measurements on the solid crystals by the Gouy method are shown in Table II. In the column listing the Bohr magnetons, the calculations have been made assuming complete quenching of the orbital contribution to the magnetic moment. In the conversion of the experimental data into Bohr magnetons, a correction has been made for the diamagnetism of the non-metal portion of the molecule.

TABLE II

Cpd.	$X_s \times 10^6$	$X_m \times 10^6$	Temp., °C.	Bohr magnetons Exptl.	Bohr magnetons Calcd.	Unpaired electrons present
I	4.11	1256	22	1.9	1.73	1

III	24.26	8180	23	4.5	3.88	3
IV	4.14	1236	20	1.9	1.73	1
V	Diamagnetic					0

Discussion.—It is seen from Table II that the cupric disalicylaldehyde compound (I) exhibits a magnetic moment close to the theoretical value of 1.73 Bohr magnetons for one unpaired electron. However, from this datum it is not possible to decide whether the molecule is tetrahedral (sp^3 bonds) or coplanar (dsp^2 bonds) as the unpaired electron can occupy a $3d$ or $4p$ orbital. Cox and Webster,[3] in a study of analogous quadricovalent cupric complexes of β-diketones, have found a planar configuration by means of X-ray analysis. This result is in accord with the theoretical prediction of the greater strength of the planar bonds.[4] Accordingly, compound (I)

(1) Zetzsche, Silbermann and Vieli, *Helv. Chim. Acta*, **8**, 569 (1925).
(2) Pfeiffer, *et al.*, *Ann.*, **84**, 503 (1933).

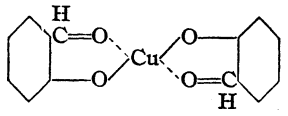
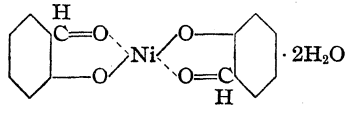
(4) Pauling, "The Nature of the Chemical Bond," Cornell University Press., Ithaca, New York, 1939, p. 100.

is considered to have a planar configuration, and the formula is written as

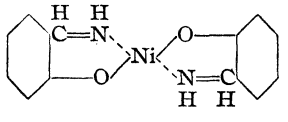


From Table II it is seen that the nickelous disalicylaldehyde compound (II) has a magnetic moment corresponding approximately to that given by two unpaired electrons. The twenty-six electrons of the nickel are in the $1s2s2p^3 3s3p^33d^3$ orbitals as completed pairs, while the two remaining $3d$ orbitals each contain an unpaired electron to account for the observed magnetic moment. The quadricovalent bonding should therefore occur in the $4s$ and three $4p$ orbitals, with the formation of the tetrahedral configuration. Thus, tetrahedral nickelous disalicylaldehyde (II) is written



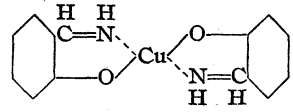
The formation of a planar configuration for this compound is also a reasonable interpretation of the data. It is possible that an unpaired electron might occupy a $4p$ in place of a $3d$ orbital, as previously noted in the copper compound. There would then be available a $3d$, $4s$, and two $4p$ orbitals for bond formation, and the planar configuration is seen to be possible.

The nickelous disalicylaldimine compound (V) is found to be diamagnetic, indicating the formation of the planar (dsp^2 bonds) configuration. It is assumed that the electrons in the two $3d$ orbitals have paired, leaving one $3d$ orbital available for bond formation together with the $4s$ and two of the $4p$ orbitals. Thus, the planar compound (V) is written

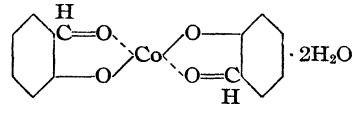


It is interesting to note that in the case of the nickelous compounds, the formation of the disalicylaldimine from the disalicylaldehyde results in the change of the probable tetrahedral configuration of the aldehyde complex to a planar structure in the aldimine compound. A marked color change also is noted, as shown in Table I.

The same reasoning is applied to cupric salicylaldimine (IV) as in the case of cupric salicylaldehyde (I). A magnetic moment corresponding to one unpaired electron is also given by (IV), so that until evidence to the contrary is obtained, the configuration of this molecule is to be considered as planar. The structural formula is



It is assumed that the twenty-five electrons in the cobalt of the cobaltous disalicylaldehyde have the electronic configuration of electron pairs in the $1s2s2p^33s3p^33d^2$ orbitals, and one unpaired electron in each of the three remaining $3d$ orbitals. The quadricovalent bonding of the cobalt would then use the $4s$ and three $4p$ orbitals, resulting in a tetrahedral configuration. Thus cobaltous disalicylaldehyde is considered to be tetrahedral, and the formula is written as



The possibility of this compound having a planar configuration must be considered as in the case of the nickel disalicylaldehyde discussed previously.

An attempt is currently being made to correlate the colors shown by these compounds, together with additional complexes of the transitional elements to be obtained, with the configuration of the molecules.[5]

Acknowledgment.—The authors desire to thank Professor Linus Pauling of the California Institute of Technology for the use of the magnetic equipment for preliminary measurements of these compounds.

Summary

From magnetic measurements made on the salicylaldehyde complexes of copper, nickel and cobalt, and the salicylaldimine complexes of copper and nickel (the synthesis and analysis of which have been given), it has been possible to assign the following configurations to the compounds: (1) cobaltous and nickelous disalicylaldehyde probably have tetrahedral configurations; (2) nickelous disalicylaldimine has a planar configuration; (3) cupric disalicylaldehyde and cupric disalicylaldimine are probably both planar in configuration.

The Rates of Formation of Sulfoaliphatic Acids*

BY T. F. MURRAY, JR., AND W. O. KENYON

Anhydrides of aliphatic acids are in common use as acylating agents, often in conjunction with sulfuric acid as the catalyst. Little attention apparently has been given to the fate of sulfuric acid when employed as an acylation catalyst, though Franchimont[1] as early as 1881 showed that sulfoacetic acid,  , forms when acetic anhydride and sulfuric acid react. He suggested that the reaction mechanism involved the primary formation of a mixed anhydride of sulfuric and acetic acids, 
(sometimes called acetyl sulfuric acid), which subsequently rearranges to the sulfo-acid. Anhydrides of aliphatic acids of three or more carbon atoms produce α-sulfo-acids by this method,[1] which have been resolved into their optical isomers.[2]

alpha-Sulfoaliphatic acids have been produced by other methods including the action of sulfur trioxide[3] or chlorosulfonic acid[4] on aliphatic acids, the oxidation of isethionic acid with chromic acid,[5] the action of alkali sulfites on the α-halogen acids,[6] the reaction of acetyl chloride with silver sulfate,[7] and the reaction of potassium or ammonium bisulfite with crotonic acid to form α-sulfobutyric acid.[8]

Russell and Cameron[9] have studied the acidity of sulfuric acid in mixtures of acetic anhydride with acetic acid and conclude that acetic anhydride and sulfuric acid react to form an ultra-acidic mixed anhydride which undergoes rearrangement to form sulfoacetic acid, which does not show ultra-acidic behavior. Beer[10] has suggested the formation of a compound designated as "diacetylium sulfate" from which the mixed anhydride of acetic and sulfuric acid can be formed.

In the work of Franchimont,[1] molar ratios of sulfuric acid to acetic anhydride of one to one and one to two were employed and the resulting exothermic reactions were vigorous. In view of the common use of sulfuric acid as a catalyst, it appeared of interest to determine whether sulfuric acid also reacted with anhydrides under the general conditions of esterification reactions and, if so, to ascertain the rate. In these experiments, the reaction of sulfuric acid with acetic, propionic and *n*-butyric anhydrides at various concentrations in the corresponding acids was followed, using low sulfuric acid/anhydride ratios.

Experimental

The aliphatic anhydrides were obtained by distilling C. P. grades and utilizing the following fractions: acetic anhydride 138 to 140°, propionic anhydride 166 to 168°, *n*-butyric anhydride 76 to 78° at 11 mm. Chemically pure grades of the aliphatic acids were employed as the diluents.

Specially designed reaction flasks of the Erlenmeyer type with glass-stoppered side arms through which samples could be removed periodically were used. The flasks were closed with glass stoppers carrying glass bearings through which glass stirrers were introduced. A reaction temperature of 40 ± 0.1° was chosen in order that the reactions would run practically to completion within convenient times.

Stock solutions of sulfuric acid were prepared by diluting 12.5 cc. of 95% sulfuric acid to 250 cc. with the aliphatic acid corresponding to the anhydride to be studied. These were kept in glass-stoppered flasks in the constant temperature bath. Twenty-five cc. portions of the sulfuric acid–aliphatic acid solutions were added to mixtures of calculated amounts of the aliphatic anhydrides and the additional amounts of the aliphatic acids required to produce the desired anhydride concentrations as shown in Table I. The aliphatic acid–aliphatic anhydride mixtures were brought to a temperature of 40° before the sulfuric acid solution was added.

In the percentages shown, no correction is made for any change in volume due to mixing.

As soon after mixing as possible, duplicate 5-cc. samples were removed for determination of the sulfuric acid content at the start of the experiments. Additional duplicate samples were removed at the designated periods of time and analyzed to determine the amount of precipitable sulfate ion present. The 5-cc. samples were added to approximately 200 cc. of distilled water containing 4 cc. of 6 *N* hydrochloric acid. The solutions were heated to boiling and the sulfate ion precipitated with 10 cc. of 10% barium chloride solution. The barium sulfate was digested in the usual manner, isolated, ignited and weighed. The barium salts of the sulfoaliphatic acids are comparatively soluble in water and were not precipitated under the conditions employed. The mixed anhydrides of the aliphatic acids with sulfuric acid quickly decomposed in the presence of water to form the corresponding acids.

In order to determine whether sulfuric acid would react with the aliphatic acid, a solution of sulfuric acid in acetic acid was prepared of approximately the concentration used in these experiments and allowed to stand for eleven days at room temperature. Samples removed at the beginning and at the end of this period gave analytical values of 0.0417 and 0.0416 g. sulfuric acid per 5 cc., respectively, which indicated that little if any sulfoacetic acid was formed.

The experimental results obtained using 50% concentrations of the three anhydrides are tabulated in Table II. In order to conserve space, the analytical data for the other anhydride concentrations are not included.

The analytical results are expressed in terms of sulfuric acid though they include the sulfate which may be present as acetyl sulfuric as well as free sulfuric acid. In these experiments we are interested in the amount of sulfuric acid which has been converted into the sulfoaliphatic acid and not in the state of the residual sulfate ion. The values given are the averages of duplicate determinations.

When the experimental data are employed in the usual equation for a first-order reaction

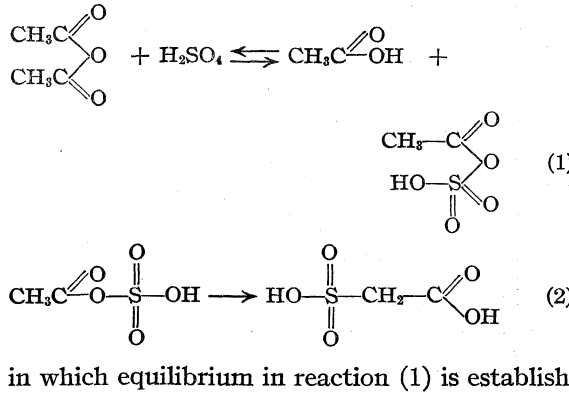
$$k^1 = \frac{1}{t} 2.303 \log \frac{a}{a - x}$$

reasonably constant values for k^1 are obtained. In these calculations, a is the amount of precipitable sulfate ion at the start of the experiment and $a - x$ is the amount of precipitable sulfate ion at time t. The average k^1 values for the various experiments are tabulated in Table III.

Discussion

Since the principal purpose of the work was to demonstrate the disappearance of sulfuric acid under conditions which simulate those prevailing in esterification reactions, the rate measurements were necessarily made over a very wide range of solvent conditions. For this reason, it is impossible to draw, in some particulars, rigorous conclusions concerning the mechanism of reaction. In spite of this fact, it is believed that a reasonably accurate formulation of the course of the reaction can be deduced in at least a semi-quantitative manner.

On the basis of independent evidence concerning the same type of reaction, Franchimont[1] and others[9] have postulated the following mechanism for the production of sulfoacetic acid



in which equilibrium in reaction (1) is established rapidly, and reaction (2) is the slow or rate-de-

TABLE III

CALCULATED FIRST-ORDER REACTION CONSTANTS

Anhydride, %	Acid, %	Acetic k^1/min.$^{-1}$ (av.)	Acetic Number of k^1 values averaged	Propionic k^1/min.$^{-1}$ (av.)	Propionic Number of k^1 values averaged	*n*-Butyric k^1/min.$^{-1}$ (av.)	*n*-Butyric Number of k^1 values averaged
90	10	0.053	3	0.021	4	0.023	5

25	75	.00049	15	.00033	12	.00085	10

termining step. By the well-known steady state treatment, the instantaneous concentration of the intermediate, acetylsulfuric acid, is given by the expression

$$\left[\mathrm{CH_3C(=O)OS(=O)(=O)OH}\right] = \frac{\left[\mathrm{(CH_3CO)_2O}\right]\left[\mathrm{H_2SO_4}\right]}{K_e\left[\mathrm{CH_3COOH}\right]} \qquad (3)$$

where K_e is the equilibrium constant in reaction (1). The differential rate expression for the over-all process is thus given as follows

$$\frac{-\,d[H_2SO_4]}{dt} = \frac{K_2}{K_e}\,\frac{\left[\mathrm{(CH_3CO)_2O}\right]\left[\mathrm{H_2SO_4}\right]}{[HAc]} \qquad (4)$$

The velocity of the over-all reaction should accordingly be proportional to the first power of the sulfuric acid concentration and to the first power of the ratio Organic anhydride/Organic acid. When the log of $\frac{a}{a-x}$ is plotted against the time, linear relationships are obtained in each experiment. Since the concentration of the anhydride and its hydrate in each case was so much greater than that of the sulfuric acid, only the latter changes appreciably in concentration throughout the course of reaction. Linearity in these relationships indicates that the sulfuric acid concentration enters to the first power as demanded by expression (4). Figure 1, in which the average apparent rate constants of the over-all reaction at various values of anhydride concentration, as tabulated in Table III, are plotted against the ratio Organic anhydride/Organic acid, shows a considerable non-random departure from linearity. The approximation is, however, about as good as can be expected, considering the change in character of the solvent in the four separate measurements. It will be observed, also, from Fig. 1, that the deviations from linearity appear to become less serious with increasing length of the chain attached to the carboxyl group, further suggesting the importance of solvent effects. It thus appears that the data obtained in this investigation are compatible with the mechanism previously proposed and, indeed, appear to afford it considerable substantiation.

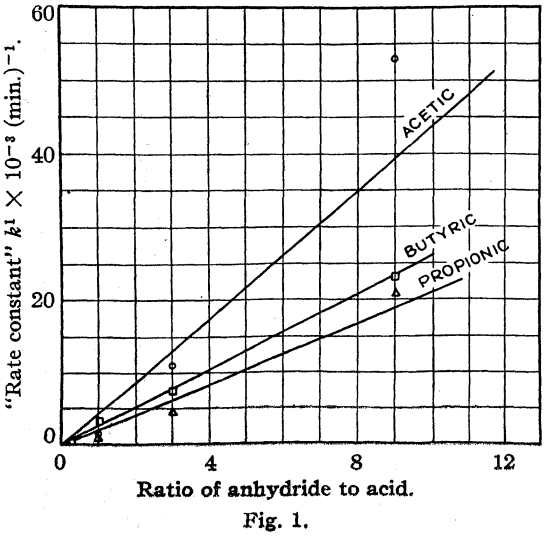

Fig. 1.

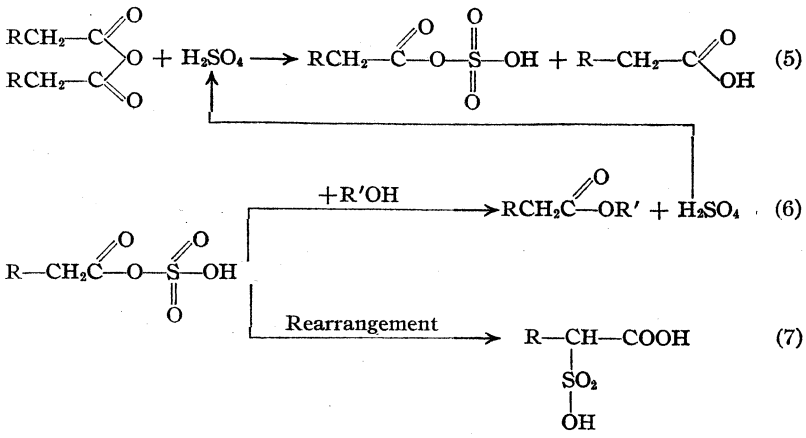
The data indicate that sulfuric acid reacts with the lower aliphatic anhydrides to form sulfoaliphatic acids even when the sulfuric acid is present in the small amounts employed to catalyze acylation reactions. In esterification processes, the reaction which produces sulfoaliphatic acids may proceed concurrently with the esterification reaction, and the rate of disappearance of the sulfate ion should depend on the original concentration of the anhydride in the reaction mixture as well as the rate at which the anhydride is withdrawn from the reaction by esterification. Since the mixed anhydride of sulfuric acid and the aliphatic acid appears to be formed quickly in esterification mixtures,[9] this compound may be the active acylating agent in many reactions as was suggested by Franchimont.[1] The possible mechanism is indicated in the following series of reactions.



The mixed anhydride of sulfuric and the aliphatic acid may react with the material to be acylated, liberating a molecule of sulfuric acid which again may react with a molecule of aliphatic anhydride, and the acylation cycle may be repeated or the mixed anhydride may rearrange to a sulfoaliphatic acid, thus removing the sulfuric acid from further participation in the acylation.

The authors wish to express their appreciation to Dr. William J. Priest of these Laboratories for his assistance in the kinetic interpretation of these data.

Summary

The rate of formation of sulfoaliphatic acids by reaction of sulfuric acid with aliphatic anhydrides at 40° has been measured, using small amounts of sulfuric acid in various concentrations of acetic, propionic and *n*-butyric anhydrides in the corresponding acids.

The rate of disappearance of sulfate ion follows the first-order reaction equation and is related to the concentration of the aliphatic anhydride. The relation between the experimental results and the mechanism of the reaction is discussed.

A mechanism of acylation in the presence of sulfuric acid catalyst is suggested.

Diene Addition Products to Diaroylethylenes and their Transformation Products. II

BY ROGER ADAMS AND R. B. WEARN[1]

In a recently published article[2] it was shown that butadiene, 2,3-dimethylbutadiene and cyclopentadiene undergo an essentially quantitative addition to dibenzoylethylene with formation of dibenzoylcyclohexenes (I). Syntheses from these adducts were developed for the corresponding dibromo addition products (II), dihydroisobenzofurans (V), isobenzofurans (IV), *o*-dibenzoylbenzenes (VI), oxido-tetrahydronaphthalenes (VII) and substituted naphthalenes (VIII). A comparison of the procedures used with those previously known for the same compounds was discussed. The series of reactions is illustrated by formulas I–VIII.

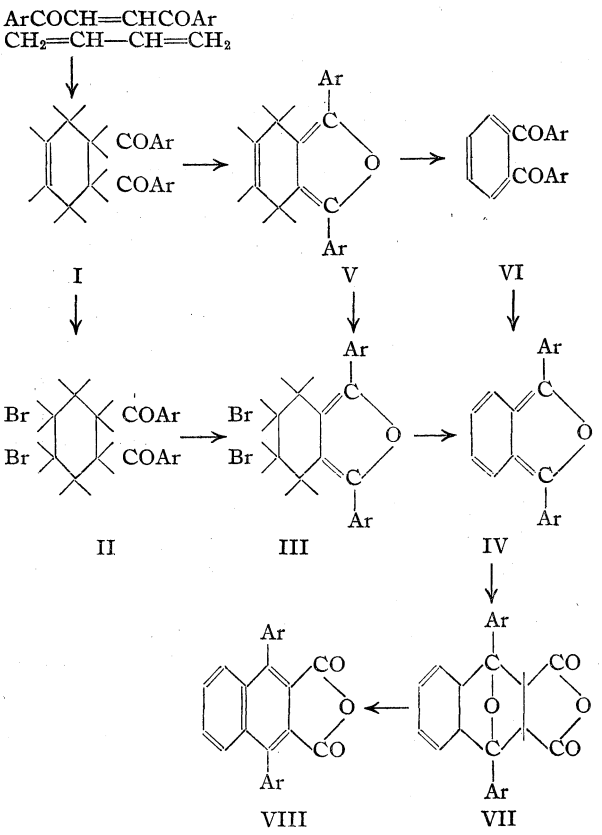
In this paper, analogous reactions between the *trans* forms of di-*p*-chlorobenzoyl, di-*p*-toluyl and dimesitoyl ethylenes and butadiene, 2,3-dimethylbutadiene and cyclopentadiene are reported in order to demonstrate the extent of applicability of these methods in preparative work Butadiene and cyclopentadiene added quantitatively to all three of the diaroyl ethylenes with formation of 4,5-diaroyl cyclohexenes (I). 2,3-Dimethylbutadiene also added to all except the dimesitoylethylene. Apparently, in this case, steric influences prevent the addition from taking place.

The cyclopentadiene addition products could in no case be converted to furans, possibly on account of the strains involved. Similarly, the dimesitoylethylene and butadiene adduct did not form a furan, due probably to steric influences.

The reactions discussed below, except for the addition of bromine to the original adducts, the 4,5-diaroyl cyclohexenes (I), apply merely to the products formed from di-*p*-chlorobenzoylethylene and di-*p*-toluylethylene with butadiene and 2,3-dimethylbutadiene.

(1) An abstract of a thesis submitted in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry.

(2) Adams and Gold, THIS JOURNAL, **62**, 56 (1940). See also Adams and Geissman, *ibid.*, **61**, 2083 (1939).



The 4,5-diaroyl cyclohexenes (I) add bromine quantitatively in chloroform solution to give 1,2-dibromo-4,5-diaroyl cyclohexanes (II).

The 4,5-diaroyl cyclohexenes (I) are converted quantitatively by means of acetic anhydride and a little phosphoric acid to 1,3-diaryl-4,7-dihydroisobenzofurans (V).

The 1,2-dibromo-4,5-diaroyl cyclohexanes (II) are unaffected by treatment with acetic anhydride and phosphoric acid but by means of acetyl chloride containing a little sulfuric acid, a reagent shown by Lutz[3] to be more effective than the former, are converted to the corresponding 1,3-diaryl-5,6-dibromo-4,5,6,7-tetrahydroisobenzofurans (III). These latter products when derived from 2,3-dimethylbutadiene derivatives are stable but when derived from butadiene derivatives partially decompose and oxidize upon attempts to recrystallize with formation of *o*-diaroyl benzenes. It is worthy of note that the dibromo compounds formed by addition of bromine to the adducts from butadiene or 2,3-dimethylbutadiene and unsubstituted dibenzoylethylene are not closed to furans by acetyl chloride and sulfuric acid.

(3) Lutz, THIS JOURNAL, **48**, 2916 (1926).

The 1,3-diaryl-5,6-dibromo-4,5,6,7-tetrahydroisobenzofurans (III) also could be prepared by direct addition of bromine to the 1,3-diaryl-4,7-dihydroisobenzofurans but the yields were poor.

o-Diaroyl benzenes (VI) are formed quantitatively from the 1,3-diaryl-4,7-dihydroisobenzofurans (V) by treatment of the latter with two moles of bromine followed immediately by sodium acetate in acetic acid and then with water.

Activated zinc and alkali convert the *o*-diaroyl benzenes (VI) to 1,3-diarylisobenzofurans (IV). The yields are usually excellent but depend upon the length of time of reduction, which varies from compound to compound. If the reduction is carried too far, the yield falls. The derivatives of butadiene in all cases reduce more rapidly than those from dimethylbutadiene.

The 1,3-diarylisobenzofurans (IV) when derived from 2,3-dimethylbutadiene also can be formed from the 1,3-diaryl-5,6-dibromo-4,5,6,7-tetrahydroisobenzofurans (III) merely by treatment with sodium acetate, acetic acid and acetic anhydride. The dibromotetrahydroisobenzofurans derived from butadiene, however, do not undergo this reaction

The addition of maleic anhydride to the 1,3-diarylisobenzofurans (IV) proceeds very smoothly to give 1,4-diaryl-1,4-oxido-1,2,3,4-tetrahydronaphthalene-2,3-dicarboxylic anhydrides (VII). The 1,3-diarylisobenzofurans containing 5,6-dimethyl groups give two isomeric oxido compounds. One is stable only in cold benzene and changes to a lower melting form when crystallized from hot benzene.

Dehydration of the 1,4-diaryl-1,4-oxido-1,2,3,4-tetrahydronaphthalene-2,3-dicarboxylic anhydrides (VII) with dry hydrogen chloride yields 1,4-diaryl-2,3-naphthalic anhydrides (VIII).

The dihydroisobenzofurans (V) and the isobenzofurans (IV) produce a blue-green fluorescence in solution.

The compounds prepared, with the methods of purification, melting points, yields and analyses are given in Tables I–IV.

Experimental

Addition of Diaroylethylenes to Dienes—General Procedure for Preparing Dibenzoyl Cyclohexenes (I).—To a solution of 40 g. (1 mole) of di-*p*-chlorobenzoylethylene in 1 liter of dry benzene was added 21.5 g. (2 moles) of crude 2,3-dimethylbutadiene (prepared by distilling pinacol from a small amount of hydrobromic acid). After refluxing overnight, the solvent was evaporated

[a] Bloc Maquenne.

until the resulting volume was 70 cc. On cooling the 1,2-dimethyl-4,5-di-*p*-chlorobenzoylcyclohexene crystallized.

By this procedure, di-*p*-chlorobenzoyl and di-*p*-toluyl ethylenes were added to butadiene, 2,3-dimethylbutadiene, and cyclopentadiene. Dimesitoylethylene was added to butadiene and cyclopentadiene but did not react (even under pressure in a sealed tube) with 2,3-dimethylbutadiene (see Table I).

Bromination of Dibenzoyl Cyclohexenes.—One mole of bromine was added to a saturated chloroform solution of 4,5-di-*p*-chlorobenzoylcyclohexene at 0°. The crude 1,2-dibromo-4,5-di-*p*-chlorobenzoylcyclohexane separated from a benzene–ligroin mixture.

By this procedure, the dibromo derivatives (II) of all the diaroyl cyclohexenes derived from butadiene and 2,3-dimethylbutadiene were prepared (see Table II).

Conversion of *o*-Diaroyl Cyclohexenes to the Corresponding Dihydroisobenzofurans (V).—To a suspension of 25 g. of 1,2-dimethyl-4,5-di-*p*-chlorobenzoylcyclohexene in 200 cc. of hot acetic anhydride was added 0.5 g. of sirupy phosphoric acid. The insoluble furan began to crystallize immediately, but the mixture was refluxed for five minutes. On cooling, the 1,3-di-*p*-chlorophenyl-5,6-dimethyl-4,7-dihydroisobenzofuran crystallized quantitatively.

By this method 1,3-di-*p*-tolyl-, 1,3-di-*p*-chlorophenyl-, and 1,3-di-*p*-tolyl-5,6-dimethyl dihydroisobenzofurans were also prepared. Under the same conditions, 1,3-dimesitoylcyclohexene and the 3,6-endomethylene-4,5-diaroyl cyclohexenes would not close to form furans (see Table II).

Preparation of 1,3-Diaryl-5,6-dibromo-4,5,6,7-tetrahydroisobenzofurans (III).—(a) A saturated solution of 9.2 g. of 1,2-dimethyl-1,2-dibromo-4,5-di-*p*-chlorobenzoylcyclohexane in acetyl chloride was heated to boiling. Several drops of concentrated sulfuric acid was added, and the solution was boiled for several minutes. It became dark colored, due to charring by the acid. The sides of the flask were scratched vigorously with a glass rod, and greenish needles of the 1,3-di-*p*-chlorophenyl-5,6-dibromo-5,6-dimethyl-4,5,6,7-tetrahydroisobenzofuran separated.

By this method, the corresponding di-*p*-tolyl compound also was prepared. The 1,2-dibromo-4,5-diaroylcyclohexanes (II) (without the 1,2-methyl groups) were closed to the furans under the same conditions, but pure products could not be isolated on account of their ready oxidation in solution to the *o*-dibenzoyl benzenes (VI) (see Table II).

(b) To a saturated solution of 1 g. (1 mol) of 1,3-di-*p*-chlorophenyl-4,7-dihydroisobenzofuran in chloroform at 0° was added slowly a solution of 0.49 g. (1 mol) of bromine in 2 cc. of chloroform. The product was isolated by concentrating the solvent to small volume.

By this procedure the corresponding di-*p*-tolyl compound was prepared. Due to unsatisfactory yields in both cases, this method was discarded in favor of the above (a).

Conversion of Diaryl-dihydroisobenzofurans to Corresponding *o*-Dibenzoyl Benzenes (VI).—To a suspension of 10 g. (1 mol) of 1,3-di-*p*-chlorophenyl-5,6-dimethyl-4,7-dihydroisobenzofuran in a hot solution of 20 g. of sodium acetate (anhydrous) in 400 cc. of glacial acetic acid was slowly added 8.7 g. (2 mols) of bromine. The mixture was kept boiling throughout this addition (ten minutes) and then refluxed for twenty minutes longer. Water was added until a considerable precipitate was formed in the boiling solution, and the mixture was allowed to cool. The crude 1,2-dimethyl-4,5-di-*p*-chlorobenzoylbenzene was filtered and recrystallized.

By the same method 1,2-dimethyl-4,5-di-*p*-toluyl, *o*-di-*p*-chlorobenzoyl-, and *o*-di-*p*-toluyl benzenes were prepared (see Table III).

Conversion of *o*-Diaroyl Benzenes to the Corresponding Isobenzofurans (IV).—A suspension of 5 g. (1 mol) of 1,2-dimethyl-4,5-di-*p*-chlorobenzoylbenzene in 200 cc. of absolute ethanol was heated to boiling. A solution of 5 g. of sodium hydroxide in 5 cc. of water was added to the mixture. Refluxing was continued until the solution became dark reddish-brown (from one-half to one and one-half hours). At this point, 5 g. of active zinc dust (prepared by washing with dilute hydrochloric acid followed by water) was added and refluxing continued for twenty minutes. At the end of this time, the color changed from

dark red to bright fluorescent yellow. The hot solution was then filtered, 50 cc. of acetic acid was added, and the mixture was heated to boiling. Hot water was added until crystals began to form. Boiling was continued for several minutes, and then the solution was cooled. The product was 1,3-di-*p*-chlorophenyl-5,6-dimethylisobenzofuran.

By the same method the 1,3-di-*p*-tolyl-5,6-dimethyl-, 1,3-di-*p*-tolyl-, and 1,3-di-*p*-chlorophenyl-substituted isobenzofurans were prepared. The change of color at the end of the reduction did not always take place, so the length of time for reduction, which apparently varied with the activity of the zinc, had to be estimated in each case.

Addition of Maleic Anhydride to Isobenzofurans (VII).—To a solution of 6 g. (1 mol) of 1,3-di-*p*-chlorophenyl-5,6-dimethylisobenzofuran in 200 cc. of benzene was added 1.8 g. (1.1 mols) of maleic anhydride. The reaction was complete in about five minutes in cold solution, as indicated by the sudden disappearance of fluorescence. The solvent was evaporated at room temperature under reduced pressure, and crystals of 1,4-di-*p*-chlorophenyl-1,4-oxido - 6,7 - dimethyl - 1,2,3,4 - tetrahydronaphthalene-2,3-dicarboxylic anhydride separated.

When this compound was crystallized from hot benzene solution, a lower melting isomer was obtained. This isomer was also obtained when the original addition was carried out in hot solution.

By this method the maleic anhydride adducts of 1,3-di-*p*-tolyl-5,6-dimethyl-, 1,3-di-*p*-chlorophenyl-, and 1,3-di-*p*-tolyl-substituted isobenzofurans were also prepared. These products were crystallized from hot solutions and no attempt was made to isolate the higher melting isomers except in the case of 1,3-di-*p*-tolyl-5,6-dimethylisobenzofuran (see Table IV).

Dehydration of Oxido Tetrahydro Naphthalic Anhydrides (VII) to Form the Corresponding Naphthalic Anhydrides (VIII).—A suspension of 2 g. of 1,4-di-*p*-chlorophenyl - 1,4 - oxido - 6,7 - dimethyl - 1,2,3,4 - tetrahydronaphthalene-2,3-dicarboxylic anhydride in 200 cc. of absolute methanol was saturated with dry hydrogen chloride gas. The gas was bubbled through the solution slowly to keep it saturated while it was refluxed for two hours. The mixture was then evaporated to dryness. After addition of 50 cc. of 30% aqueous potassium hydroxide and 200 cc. of ethanol, the mixture was refluxed for six hours. The solution was then cooled and acidified. The precipitate was filtered off and purified by dissolving in potassium hydroxide, followed by reprecipitation by acid. The crude 1,4-di-*p*-chlorophenyl-6,7-dimethyl-2,3-naphthalic anhydride was crystallized from hot acetic acid.

By the same method the 1,4-di-*p*-tolyl-6,7-dimethyl-, 1,4-di-*p*-chlorophenyl-, and 1,4-di-*p*-tolyl-substituted 2,3-naphthalic anhydrides were also prepared (see Table IV). Benzene was a more suitable solvent for crystallization of the last two compounds.

Summary

The new methods reported in a previous paper[2] for the preparation of dihydroisobenzofurans, isobenzofurans, *o*-dibenzoyl benzenes, and aryl- and alkyl-substituted naphthalenes from the butadiene and dimethylbutadiene adducts of dibenzoylethylene were shown to work equally well for the di-*p*-chlorobenzoyl and di-*p*-toluyl ethylenes.

Cyclopentadiene added in good yield to di-*p*-chlorobenzoyl, di-*p*-toluyl, and dimesitoyl ethylenes.

Dimesitoylethylene formed an adduct with butadiene, but did not react with 2,3-dimethylbutadiene.

The dimesitoylethylene adduct to butadiene and all of the adducts from cyclopentadiene could not be converted to furans by the usual procedures.

The Halogenation of Salicylic Acid

BY LARKIN HUNDLEY FARINHOLT, A. P. STUART* AND DANIEL TWISS

The preparation of polyhalogenated salicylic acids was attempted for several reasons. In the first place, the compounds might have valuable physiological properties and, in the second place, the order in which the halogen atoms enter the available positions is interesting from a theoretical point of view.

The mono- and disubstituted halogen derivatives of salicylic acid have been prepared by previous investigators by the addition of the free halogens to a solution of salicylic acid in a suitable medium. Nothing is known, however, concerning the tri- and tetrahalogenated salicylic acids which form the subject of this investigation.

Starting with 3,5-diiodosalicylic acid prepared according to Woollett and Johnson,[1] numerous methods were applied with the object of obtaining higher iodinated derivatives, but with negative results in each case. The following methods were attempted: (I) refluxing diiodosalicylic acid

* Present address: University of Delaware, Newark, Delaware.

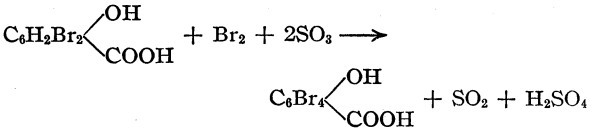
(1) "Organic Syntheses," Vol. XIV, 1934, p. 52.

with iodine in ethyl alcohol, as well as in other solvents, according to Lautemann[2]; (II) using iodine chloride, based on the method of Cofman[3]; (III) following the method of Weselsky,[4] who iodinated in the presence of mercuric oxide; (IV) by the effective method of Likhosherstov and Tzimbalist[5] using dichlorourea and potassium iodide. These methods also were tested on the acetyl derivative of 3,5-diiodosalicylic acid but with equally negative results.

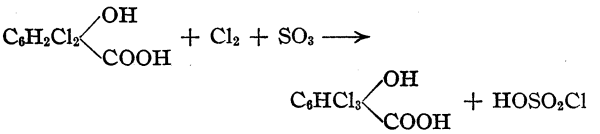
3,5-Dichloro- and 3,5-dibromosalicylic acids were prepared by the method of Earle and Jackson.[6] Attempts to substitute in these compounds more chlorine and bromine, respectively, resulted either in a replacement of the carboxyl group by halogen or no reaction at all.

Juvalta,[7] Rupp[8] and Pratt and Shupp[9] prepared polyhalogenated phthalic anhydrides by halogenating phthalic anhydride in solution in fuming sulfuric acid and Twiss and Farinholt[10] showed that *o*-sulfobenzoic anhydride may be halogenated in the same manner. The present investigation is concerned with the application of this method to salicylic acid and dihalogenosalicylic acids. The experiments with salicylic acid were not successful. The reaction yielded a water-soluble product, indicating substitution of sulfonic acid groups which, apparently, were too firmly bound to the nucleus to be replaced by halogen atoms under the conditions of the reaction. It was found necessary first to prepare the dihalogenosalicylic acids by known methods and use them as the starting materials for further halogenations. No iodine derivatives could be prepared by this method since both diiodosalicylic acid and its acetyl derivative decomposed on contact with fuming sulfuric acid, even in the cold, with liberation of iodine.

Good results were obtained with dibromo- and dichlorosalicylic acids. No attempt was made to interpret the mechanism of the process but it seems likely that the dihalogenosalicylic acids form some sort of unstable addition complex with sulfur trioxide or sulfuric acid which facilitates the substitution of the halogen atoms. According to the amount of bromine, one or two bromine atoms may be introduced into dibromosalicylic acid. The hydrogen bromide evolved in the reaction is oxidized by the sulfur trioxide and the resulting bromine made available again for further substitution. The net result of the formation of tetrabromosalicylic acid may be represented by the equation

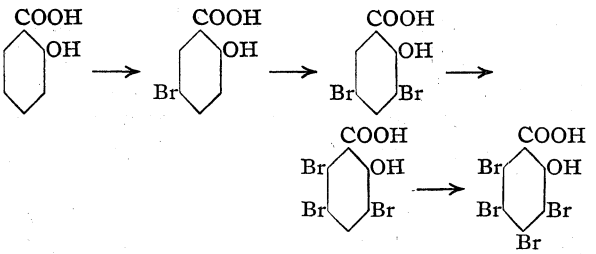


In the chlorination, the hydrogen chloride is not oxidized but combines with sulfur trioxide to form chlorosulfonic acid. It is worthy of note that the trichlorosalicylic acid cannot be chlorinated further but that a bromine atom may be substituted in the remaining free position. The formation of trichlorosalicylic acid follows the equation



The position of the third halogen in trichloro- and tribromosalicylic acids was determined by heating the acid thus formed with soda lime and identifying the resulting trihalogenophenol. It was shown that the substitution takes place in position 6, adjacent to the carboxyl group, presumably under the influence of the two halogen atoms already present. No evidence was found of the formation of isomers. The introduction of a fourth bromine atom in tribromosalicylic acid and of a bromine atom in trichlorosalicylic acid occurs without difficulty.

The order in which bromine atoms, for example, substitute in salicylic acid is represented by the scheme below. The first atom enters mainly in the position meta to the carboxyl and para to the hydroxyl group.



The replacement of the carboxyl group by a halogen atom served as a further check on the

configurations of the halogenated salicylic acids. The combined action of bromine and water on all these acids produced halogenated phenols of known constitution. In this way tetrabromosalicylic acid gave pentabromophenol, 3,5,6-tribromosalicylic acid yielded 2,3,4,6-tetrabromophenol, while 3,5,6-trichlorosalicylic acid gave 2-bromo-3,4,6-trichlorophenol and 4-bromo-3,5,6-trichlorosalicylic acid formed 2,5-dibromo-3,4,6-trichlorophenol. Similarly, 3,5,6-trichlorosalicylic acid was converted into 2,3,4,6-tetrachlorophenol by the action of chlorine in the presence of water. For complete identification, acetyl and benzoyl derivatives were prepared and the melting points compared with those given in the literature.

Experimental

Halogenation of Salicylic Acid

The preparation of the following polyhalogenated salicylic acids was carried out in a three-necked Pyrex flask, fitted with a reflux condenser and a monel metal stirrer. The flask was heated by means of an oil- or water-bath; the temperatures given refer to the bath.

3,4,5,6-Tetrabromosalicylic Acid.—In 275 ml. of 60% fuming sulfuric acid, 50 g. of 3,5-dibromosalicylic acid[11] was dissolved and 28 g. (9 ml.) of bromine slowly added through a dropping funnel under the surface of the liquid while stirring vigorously. The addition took place over a period of four hours and during this time the flask was kept in a water-bath at about 30°. Toward the latter part of the reaction a crystalline solid separated. After stirring for two more hours and standing overnight, the tetrabromosalicylic acid was filtered off on a sintered glass funnel. The filtrate gave more tetrabromosalicylic acid by pouring on ice. The yield of the crude product was nearly quantitative.

3,4,5,6-Tetrabromosalicylic acid was purified by crystallization from dilute alcohol, forming clusters of white crystals which gradually decomposed at about 235–240°.

Anal. Calcd. for $C_7H_2O_3Br_4$: Br, 70.46. Found: Br, 70.33.

Acetyl 3,4,5,6-Tetrabromosalicylic Acid.—In order to furnish a check on the results above and to prepare a suitable derivative for identification, 3,4,5,6-tetrabromosalicylic acid was acetylated by heating a small amount with acetic anhydride and several drops of concentrated sulfuric acid. The solution was then carefully diluted with water, the solid filtered off and allowed to dry spontaneously on a porous plate. The acetyl derivative of 3,4,5,6-tetrabromosalicylic acid crystallizes in needles from ligroin containing a little toluene, m. p. 162.5°.

Anal. Calcd. for $C_9H_4O_4Br_4$: Br, 64.49. Found: Br, 64.34.

3,5,6-Tribromosalicylic Acid.—After dissolving 30 g. of 3,5-dibromosalicylic acid in 200 ml. of 60% fuming sulfuric acid, 8.1 g. (2.7 ml.) of bromine was added, while stirring, over a period of one and one-half hours. After the addition of the bromine, stirring was continued for another hour. The temperature was kept at about 30° throughout the reaction. Some tribromosalicylic acid precipitated from the oleum solution and was filtered off. The filtrate was diluted by pouring on ice and more of the acid thus obtained. The yield of the crude product was nearly quantitative. 3,5,6-Tribromosalicylic acid crystallizes from toluene in rectangular plates, m. p. 210.5°.

Anal. Calcd. for $C_7H_3O_3Br_3$: Br, 63.98. Found: Br, 63.70.

Acetyl 3,5,6-Tribromosalicylic Acid.—The compound was prepared following the same procedure as for the tetrabromosalicylic acid. On dilution of the acetic anhydride solution, the acetyl derivative of 3,5,6-tribromosalicylic acid separated as an oil which, after scratching and shaking, was converted into a solid. The product crystallized from ligroin in needles, m. p. 145°.

Anal. Calcd. for $C_9H_5O_4Br_3$: Br, 57.52. Found: Br, 57.73.

3,5,6-Trichlorosalicylic Acid.—3,5-Dichlorosalicylic acid was first prepared by the method of Earle and Jackson.[6] A solution of 83 g. of this material in 200 ml. of 60% fuming sulfuric acid was heated in an oil-bath to 80–90°. While stirring vigorously, a slow stream of chlorine was passed through the solution for about fifteen hours. On cooling, crystals of trichlorosalicylic acid separated and were filtered off on a sintered glass funnel. A second crop was obtained by pouring the filtrate on ice. Based on the crude product, the yield was about 70%. 3,5,6-Trichlorosalicylic acid may be crystallized from benzene, toluene, dilute acetic acid or dilute ethyl alcohol. It forms white plates, m. p. 207°.

Anal. Calcd. for $C_7H_3O_3Cl_3$: Cl, 44.08. Found: Cl, 44.06.

Acetyl 3,5,6-Trichlorosalicylic Acid.—Prepared by the procedure described above, this compound crystallizes from ligroin in needles, m. p. 129.5°.

Anal. Calcd. for $C_9H_5O_4Cl_3$: Cl, 37.53. Found: Cl, 37.77.

Attempted Preparation of Tetrachlorosalicylic Acid.—A solution of 60 g. of 3,5-dichlorosalicylic acid in 250 ml. of 60% fuming sulfuric acid was chlorinated for six hours at 40–45°, then for six hours at 65–75° and finally for seventeen hours at 100°. The resulting compound was not the anticipated tetrachloro derivative but was 3,5,6-trichlorosalicylic acid. The addition of iodine as a catalyst did not produce different results, while an attempt to chlorinate trichlorosalicylic acid with dichlorourea, according to Likhosherstov,[5] left the starting material unaltered.

4-Bromo-3,5,6-trichlorosalicylic Acid.—To a solution of 25 g. of recrystallized 3,5,6-trichlorosalicylic acid in 175 ml. of 60% fuming sulfuric acid was added 8.1 g. [2.7 ml.] of bromine through a dropping funnel over a period of about two hours while stirring. The temperature was kept at about 30°. After the addition, the solution was stirred for another hour and then diluted by pouring over ice. The white solid which separated was obtained in nearly a quantitative yield. 4-Bromo-3,5,6-trichlorosalicylic acid crystallizes from dilute alcohol in clusters of white crystals, m. p. 213°.

(11) This compound was prepared by the method of Earle and Jackson.[6] A pure product was obtained in an 87% yield.

Anal. Calcd. amount of silver to precipitate all halogen in a 0.3181 g. sample of $C_7H_2O_3BrCl_3$: 3.971 milliequivalents. Found: 3.962.

Acetyl 4-Bromo-3,5,6-trichlorosalicylic Acid.—The acetyl derivative of 4-bromo-3,5,6-trichlorosalicylic acid was prepared in the usual manner. It separates from ligroin in white crystals, m. p. 144°.

Anal. Calcd. amount of silver to precipitate all halogen in a 0.3236 g. sample of $C_9H_4O_4BrCl_3$: 3.572 milliequivalents. Found: 3.579.

Attempted Preparation of 3,5-Dichloro-4,6-diiodosalicylic Acid.—As the instability of 3,5-diiodosalicylic acid in fuming sulfuric acid may be due to the fact that the iodine atoms are in the activated positions, ortho and para to the phenolic hydroxyl, an attempt was made to iodinate 3,5-dichlorosalicylic acid in the less reactive positions 4 and 6.

To a solution of 60 g. of 3,5-dichlorosalicylic acid in 200 ml. of 60% fuming sulfuric acid, 74.5 g. of iodine was added gradually over a period of sixteen hours. The temperature was kept at 50–60° and the mixture was stirred continuously. The procedure was marked by foaming which ceased at the end of this time. Heating was then continued at 100° with 100 ml. additional fuming sulfuric acid until the foaming subsided and the cooled reaction mixture poured on ice. A dark colored solid separated and this was shown to be free iodine. No other solid precipitated and no dichlorosalicylic acid could be recovered.

Establishment of the Positions of the Halogen Atoms by Decarboxylation

The determination of the positions of the halogen atoms in the halogenosalicylic acids was accomplished by two methods. The first consisted in decarboxylating the acid, to form the corresponding phenol, by heating in a retort with an excess of dry soda lime. The desired phenol sublimed into the neck of the retort and was removed by dissolving in alkali, then reprecipitated with acid and recrystallized from a suitable solvent. As an additional check, a functional derivative was prepared and, if already known, its melting point compared with that recorded in the literature.

2,3,4,5-Tetrabromophenol was formed by heating 2,3,4,5-tetrabromosalicylic acid with powdered soda lime in a retort at 195°. It crystallizes in white needles from dilute alcohol, m. p. 123°, and has not been reported previously in the literature.

Anal. Calcd. for $C_6H_2OBr_4$: Br, 78.03. Found: Br, 78.08.

2,3,4,5-Tetrabromophenyl acetate was prepared in the usual manner with acetic anhydride and a drop of concentrated sulfuric acid. It crystallizes from dilute acetic acid in white needles, m. p. 110.5°.

Anal. Calcd. for $C_8H_4O_2Br_4$: Br, 70.78. Found: Br, 70.93.

2,3,4,5-Tetrabromophenyl benzoate was prepared by the Schotten–Baumann reaction. It crystallizes from ethyl alcohol in clusters of white needles, m. p. 133°.

Anal. Calcd. for $C_{13}H_6O_2Br_4$: Br, 62.24. Found: Br, 62.23.

2,4,5-Tribromophenol[12] (m. p. 80°) was obtained by decarboxylating 3,5,6-tribromosalicylic acid with soda lime at 200°; benzoate, m. p. 97–98°.

2,4,5-Trichlorophenol[13] (m. p. 67.5°) was obtained by decarboxylating 3,5,6-trichlorosalicylic acid with soda lime at 185°; benzoate, m. p. 89–90°.

3-Bromo-2,4,5-trichlorophenol was obtained by heating 4-bromo-3,5,6-trichlorosalicylic acid with soda lime in a retort at 185°. This compound, which has not been prepared previously, crystallizes from ligroin in clusters of white needles, m. p. 126°.

Anal. Calcd. amount of silver to precipitate all halogen in a 0.3055 g. sample of $C_6H_2OBrCl_3$: 4.421 milliequivalents. Found: 4.399.

3-Bromo-2,4,5-trichlorophenyl benzoate was prepared by the usual method. It crystallizes from dilute alcohol in clusters of needles, m. p. 125°.

Anal. Calcd. amount of silver to precipitate all halogen in a 0.1313 g. sample of $C_{13}H_6O_2BrCl_3$: 1.381 milliequivalents. Found: 1.372.

Action of Bromine and Chlorine Water on the Halogenated Salicylic Acids

Another aid in determining the position of the halogen atoms in the halogenated salicylic acids was the replacement of the carboxyl group by bromine or chlorine, thus obtaining known halogenated phenols. For complete identification, the acetyl or benzoyl derivatives were prepared and compared with the literature.

2,3,4,5,6-Pentabromophenol.—A solution of bromine in acetic acid was added to a suspension of 2,3,4,5-tetrabromosalicylic acid in 30% acetic acid. Carbon dioxide was evolved slowly. Excess bromine solution was added, the mixture was warmed to about 60° and stirred at that temperature until no more carbon dioxide was liberated. More water was added, the mixture shaken and the solid filtered off and washed thoroughly. The yield of the phenol was nearly quantitative. 2,3,4,5,6-Pentabromophenol[14] crystallizes from dilute acetic acid in white needles, m. p. 229–230°. The acetyl derivative crystallizes from acetic acid in prisms, m. p. 198–199°.

2,3,4,6-Tetrabromophenol.—Following the same procedure as in the preparation of pentabromophenol, 3,5,6-tribromosalicylic acid in dilute acetic acid was treated with bromine to give a nearly quantitative yield of 2,3,4,6-tetrabromophenol.[15] It crystallizes from dilute alcohol in clusters of needles, m. p. 112–113°. Its acetyl derivative separates from dilute acetic acid in flat plates, m. p. 105°.

2-Bromo-3,4,6-trichlorophenol.—In the same manner as above, 3,5,6-trichlorosalicylic acid was treated with bromine water. The crude phenol thus obtained was dissolved in 5% sodium hydroxide solution, filtered from a small amount of insoluble material of unknown composition, and precipitated with hydrochloric acid. 2-Bromo-

(15) *Cf.* Hodgson, Walker and Nixon, *J. Chem. Soc.*, 1054 (1933); Zincke, *Ann.*, **363**, 262–263 (1908).

3,4,6-trichlorophenol crystallizes from dilute acetic acid in white needles, m. p. 83–84°. The melting point is several degrees higher than that given by previous investigators[13b,16] but there seems to be little doubt concerning its constitution since the benzoyl derivative is identical with that prepared by Kohn and Fink. This compound crystallizes from acetic acid in prisms, m. p. 116–117°.

2,5-Dibromo-3,4,6-trichlorophenol.—Following the same procedure, 4-bromo-3,5,6-trichlorosalicylic acid was treated with bromine water. The resulting 2,5-dibromo-3,4,6-trichlorophenol[13b] crystallizes from dilute alcohol in clusters of needles, m. p. 195°. The benzoyl derivative separates from glacial acetic acid in prisms, m. p. 177–178°.

2,3,4,6-Tetrachlorophenol.—Chlorine was passed through a suspension of 3,5,6-trichlorosalicylic acid in 30% acetic acid for several hours. A heavy oil precipitated. It was washed with water several times and treated with 5% sodium hydroxide solution, in which most of the material dissolved. The alkaline solution was filtered and then acidified with hydrochloric acid. The oil which separated soon solidified. On recrystallizing several times from ligroin, the resulting needles melted at 68–69°, the melting point of 2,3,4,6-tetrachlorophenol.[17] Its acetyl derivative[18] crystallizes from dilute alcohol, and melts at 66°.

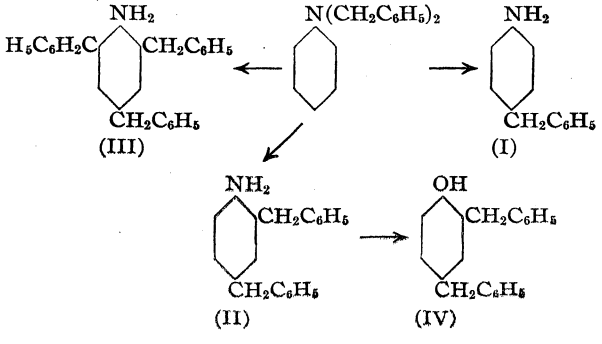
The Molecular Rearrangement of Tertiary Aryl Alkyl Anilines

BY PETER J. DRUMM, W. F. O'CONNOR AND J. REILLY

The well-known Hofmann–Martius reaction involving the rearrangement of N-substitution products of the arylamines to C-substitution compounds has, in recent years, received considerable attention. Three theories which have been put forward are that the rearrangement, which is admittedly intermolecular, consists in the migration of the alkyl group, (1) as alkyl halide, (2) as a free radical and (3) as an olefin.

It seems to the present authors, in certain cases at any rate, that another possibility may be envisaged, *viz.*, a combination of the free radical and olefin mechanisms, in which the free radical is first produced and then dissociates to give an olefin. In support of this view F. O. Rice[1] from his work on propyl radicals has concluded that all radicals higher than ethyl dissociate to give olefins. It would seem possible, therefore, in certain cases, such as in the rearrangement of isoamylaniline, where trimethylethylene has been obtained,[2] that the first step is the splitting off of the free radical isoamyl which then loses a hydrogen atom to yield the olefin trimethylethylene.

To obtain further evidence, if possible, of the mechanism involved, the authors studied the rearrangement of dibenzylaniline hydrochloride. The products isolated were *p*-aminodiphenylmethane (I), 1-amino-2,4-dibenzylbenzene (II) and an aminotribenzylbenzene which is probably 1-amino-2,4,6-tribenzylbenzene (III). The orientation of the benzyl groups in (II) was determined by its conversion into 2,4-dibenzylphenol (IV).



(1) Rice, "Annual Reports on the Progress of Chemistry," The Chemical Society, London, 1937, p. 268.

(2) Hickinbottom, *J. Chem. Soc.*, 2396 (1932).

The authors were unable to obtain evidence of the formation of dibenzyl which might be expected to occur on the basis of the "free radical" theory. An olefin mechanism is also excluded for obvious reasons. It would appear, therefore, that under the conditions employed the theory of primary dissociation into aniline and benzyl halide may be an intermediate step in the rearrangement and in support of this view it was found that on heating dibenzylaniline hydrobromide in a current of nitrogen and so removing volatile products from the sphere of reaction benzyl bromide was obtained and identified as the benzyl ester of *p*-nitrobenzoic acid. It was found that dibenzylaniline undergoes rearrangement at temperatures below 200° which is considerably lower than that necessary in the case of the alkylanilines. A similar facility of migration has been observed by Hickinbottom[3] in the case of alkylanilines with heavy groups such as the cetyl and octyl groups. A further point of interest in connection with this work is the formation of aminotribenzylbenzene. This is the first instance so far as the authors are aware where more than two groups have been introduced into the aniline ring during the molecular rearrangement of either secondary or tertiary aniline bases.

Experimental

Seventy-eight grams of dry dibenzylaniline hydrochloride was heated in a sealed tube for seven hours at 200–220°. The viscous amber-colored product was treated with dilute sodium carbonate solution, and the liberated bases extracted with ether. The ethereal solution was dried over anhydrous sodium sulfate, the ether distilled off and the residual oil fractionated. The following fractions were collected: I, 15.6 g., b. p. 180–220° at 20 mm.; II, 24.2 g., b. p. 250–285° at 20 mm.; III, 15.0 g., b. p. 290–300° at 20 mm.

p-Aminodiphenylmethane.—Fraction I was redistilled and yielded 14.1 g. of an oil boiling at 185–190° at 14 mm. This oil readily dissolved, on heating, in dilute hydrochloric acid. On cooling the hydrochloride was deposited as colorless plates melting at 219°.

Anal. Calcd. for $C_{13}H_{14}NCl$: Cl, 16.17. Found: Cl, 16.26.

On conversion of this hydrochloride into the base, the latter was obtained as a solid which separated from ligroin in the form of colorless plates which melted at 36° alone or when mixed with a specimen of pure *p*-aminodiphenylmethane.[4] Benzoyl-*p*-aminodiphenylmethane crystallizes from alcohol in long, thin, prismatic needles, m. p. 165°.

Anal. Calcd. for $C_{20}H_{17}ON$: N, 4.88. Found: N, 4.82.

Diphenylmethane-4-azo-β-naphthol forms scarlet needles from alcohol, m. p. 141°.

Anal. Calcd. for $C_{23}H_{18}ON_2$: N, 8.28. Found: N, 8.34.

Fraction II.—This fraction on redistillation gave 22.8 g. of a light-yellow colored viscous oil, b. p. 250–260° at 11 mm. On dissolving in hot aqueous alcoholic hydrochloric acid and allowing the solution to cool slowly the hydrochloride separated and was subsequently crystallized from a mixture of chloroform and light petroleum (b. p. 60–80°) from which it separated in the form of needles melting at 171°.

Anal. Calcd. for $C_{20}H_{20}NCl$: Cl, 11.47. Found: Cl, 11.69.

The free base crystallizes from light petroleum (b. p. 40–60°) in colorless needles melting at 50°.[3]

Anal. Calcd. for $C_{20}H_{19}N$: C, 87.91; H, 6.96; N, 5.12. Found: C, 87.83; H, 7.08; N, 5.13.

Identification of above Base as 1-Amino-2,4-dibenzylbenzene.—Twenty-two grams of the above base was dissolved in dilute sulfuric acid. The solution was cooled to 5° and diazotized by the addition of an aqueous solution of 5.6 g. of sodium nitrite. The whole was then heated slowly to 60° and maintained at this temperature until evolution of nitrogen was complete. The product was extracted with ether and the residue after evaporation of the latter was distilled under reduced pressure giving a pale-yellow oil, b. p. 250–255° at 10 mm. This oil which was phenolic in character was still contaminated with traces of unchanged amine which interfered with its subsequent characterization. To remove the last traces of amine the oil was boiled with tin and hydrochloric acid and the cold acid solution extracted with ether. On removal of the latter the phenol was obtained as a colorless oil, b. p. 252–254° at 10 mm. It was converted into its α-naphthyl urethan derivative by heating with α-naphthyl carbimide almost to the boiling point for a few minutes. The oily product was extracted repeatedly with hot ligroin and filtered from the di-α-naphthyl carbamide. From the filtrate the α-naphthyl urethan separated in light yellow crystals m. p. 143–144°. A mixture of this substance with the α-naphthyl urethan of 2,4-dibenzylphenol[5] melted at 143–144°, with which substance it was identical. The base melting at 50°, obtained from fraction II above, is therefore 1-amino-2,4-dibenzylbenzene.

1-Benzoylamino-2,4-dibenzylbenzene separates as long, colorless needles from alcohol, m. p. 158°.

Anal. Calcd. for $C_{27}H_{23}ON$: N, 3.71. Found: N, 3.66.

2,4-Dibenzylbenzene-1-azo-β-naphthol.—It was found advantageous to carry out the diazotization of the amine in glacial acetic acid solution. The azo-β-naphthol was obtained from alcohol–chloroform in long red needles melting at 154°.

Anal. Calcd. for $C_{30}H_{24}ON_2$: N, 6.54. Found: N, 6.73.

Fraction III.—This oil, b. p. 290–300° at 20 mm., was dissolved in warm glacial acetic acid and concentrated hydrochloric acid added. The precipitated hydrochloride

was collected and recrystallized several times from ethyl acetate from which solvent it was obtained in clusters of needles melting at 186°.

Anal. Calcd. for $C_{27}H_{26}ClN$: Cl, 8.89. Found: Cl, 8.94.

The free base from the above hydrochloride crystallizes from ligroin in colorless, prismatic plates, m. p. 61–62°.

Anal. Calcd. for $C_{27}H_{25}N$: N, 3.86. Found: N, 3.78.

This substance is a primary amine and the results of analysis of itself and its derivatives agree with its formulation as an aminotribenzylbenzene. Hofmann, in his study of the molecular rearrangement of phenyltrimethylammonium iodide, obtained mesidine.[6] By analogy it is probable that the above aminotribenzylbenzene is 1-amino-2,4,6-tribenzylbenzene.

Benzoylaminotribenzylbenzene.—This compound crystallizes from alcohol in needles, m. p. 149°. *Anal.* Calcd. for $C_{34}H_{29}ON$: N, 3.00. Found: N, 3.01.

(6) Hofmann, *Ber.*, **5**, 715 (1872).

Tribenzylbenzene-azo-β-naphthol.—Crystallizes from alcohol in scarlet prisms with copper glance, m. p. 146°. *Anal.* Calcd. for $C_{37}H_{30}ON_2$: N, 5.41. Found: N, 5.61.

Summary

The molecular rearrangement of dibenzylaniline hydrochloride has been studied. The rearrangement proceeded at a comparatively low temperature with formation of *p*-aminodiphenylmethane, 1-amino-2,4-dibenzylbenzene and a third amine which is probably 1-amino-2,4,6-tribenzylbenzene. This would appear to be the first instance where three migrating groups have been introduced into the aniline ring during the rearrangement of a secondary or tertiary aniline base.

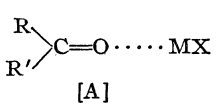
Coördinate Compounds in the Color Test for Organometallic Compounds[1]

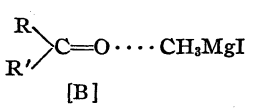
BY HENRY GILMAN AND R. G. JONES

The color test[2] is probably the most useful laboratory tool in studies on organometallic compounds. However, because Michler ketone, the essential compound in the color test, can form coördinate compounds with Grignard reagents, it is necessary to examine the possible interference effects of coördinate compounds.

The formal relationship of organometallic compounds to salts, made it a relatively short step from Werner's[3] coördination structures of the carbonyl type with salts [A], to the suggestion, which probably first was proposed by Straus,[4] for coördination compounds of ketones with the



[A]



[B]

Grignard reagent [B]. Later, v. Braun[5] and then, particularly, Meisenheimer and co-workers[6] and Hess and Rheinboldt[7] used the coördination structures as a basis for interpreting some reactions of carbonyl compounds with the Grignard reagent.[8]

There is no doubt that coördination complexes of some sort are formed with many ketones and Grignard reagents. Not only have some of the complexes been isolated and analyzed, but they have been hydrolyzed to the original ketones.[9] The most interesting and suggestive recent study is by Pfeiffer and Blank.[10] They examined the molecular compounds derived by interaction of some Grignard reagents with benzophenone, *p*-aminobenzophenone, *p*-dimethylaminobenzophenone, and, of especial interest at this time, *p,p'*-tetramethyldiaminobenzophenone or Michler ketone. In each case, the complex formed by a 1:1 ratio of ketone and Grignard reagent regenerated the ketone on hydrolysis. With benzo-

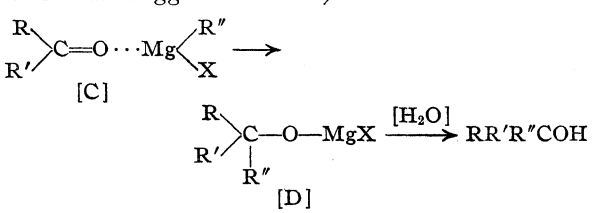
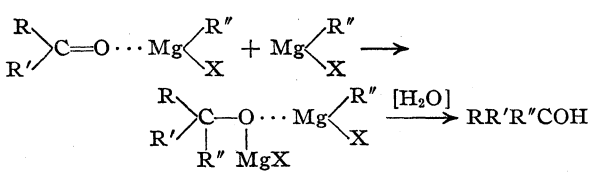
phenone a 1:2 ratio of ketone to RMgX compound produced intramolecular reaction resulting in the alcohol, triphenylcarbinol. With *p*-aminobenzophenone and *p*-dimethylaminobenzophenone it was found that a ratio of 1:3 of ketone to RMgX compound was necessary to obtain the carbinol under comparable conditions. With Michler ketone, a 1:4 ratio of ketone to RMgX compound gave *p,p'*-tetramethyldiaminodiphenylpropene, $[(CH_3)_2NC_6H_4]_2C{=}CHCH_3$, the dehydration product of the carbinol to be expected from Michler ketone and ethylmagnesium bromide.

Pfeiffer interpreted the reactions in accordance with his halochrome theory, stating that the unsaturated carbonyl carbon atom in complex [C] can become saturated in two ways. Either the R″ group wanders from the magnesium atom to the carbonyl carbon atom (as Meisenheimer[6] and Hess[7] suggested earlier)



or the R″ group of a second Grignard molecule attaches itself to the unsaturated carbon.



In accordance with the observations of Pfeiffer and Blank[10] we find that a complex is formed between Michler ketone and phenylmagnesium bromide in a 1:1 ratio in ether, and that this complex on hydrolysis yields Michler ketone. However, even though the ratio was as low as 1:1, the recovery of ketone was only 88%. Of greater significance is the fact that this mixture gave a color test. One may conclude then that the complexes from Michler ketone and Grignard reagent are not so stable but what they rearrange sufficiently to a true valence type of carbinol salt [D] to give a color test.

The stability of such complexes appears to be influenced by solvents. When the experiment with a 1:1 ratio of Michler ketone to phenylmagnesium bromide was carried out not in ether alone, but in a solution containing mostly benzene, the yield of ketone recovered was only 45%, and there was actually isolated a 42% yield of the carbinol (*p,p'*-tetramethyldiaminotriphenylcarbinol) which is the intermediate compound in the color test for phenylmetallic compounds. From the work mentioned later in this paper on the etherate of triethylgallium, one might expect that compounds like ethers would dampen the reactivity of some organometallic compounds by the formation of coördinate compounds. Fortunately, the color test is always carried out with a benzene solution of Michler ketone and this may help to give the high degree of sensitivity reported[2] for the color tests. In this connection, there is no essential difference in the sensitivity of the color tests for ethylmagnesium bromide and phenylmagnesium bromide.[2c]

Relative Reactivities of Organometallic Compounds.—There appears to be some correlation between the tendency of organometallic compounds to form coördinate compounds with ketones and the relative reactivities of organometallic compounds. We observed no stable complex with Michler ketone, in ether or in benzene, in reactions carried out with phenyllithium at room temperature with equivalent quantities of reactants. The yields of *p,p'*-tetramethyldiaminotriphenylcarbinol were 78% and 92.5%, respectively, and no Michler ketone was recovered. We reported recently[11] that a liberal excess of triphenylgallium was necessary for a color test. This is very probably due to the pronounced tendency of gallium compounds to form complexes. For example, Dennis and Patnode[12] have shown that the simple triethylgallium $[(C_2H_5)_3Ga]$ reacts violently with water; the etherate $[(C_2H_5)_3Ga{\cdot}(C_2H_5)_2O]$ vigorously; and the ammine $[(C_2H_5)_3Ga{\cdot}NH_3]$ only very slowly.

With the three arylmetallic compounds mentioned, the order of decrease in relative reactivities and increase in tendency to form coördinate compounds with ketones is: C_6H_5Li, C_6H_5MgBr, $(C_6H_5)_3Ga$.

Relative Reactivities of Functional Groups.—In a study of the relative reactivities of some functional groups with phenylmagnesium bromide, Entemann and Johnson[13] observed that benzophenone and benzoyl chloride were of about the same reactivity. It has been shown that benzoyl chloride is decidedly more reactive than benzophenone when other less reactive or-

(11) Gilman and Jones, THIS JOURNAL, **62**, 980 (1940).
(12) Dennis and Patnode, *ibid.*, **54**, 182 (1932).
(13) Entemann and Johnson, *ibid.*, **55**, 2900 (1933).

ganometallic compounds like those of mercury,[14a] thallium[14b] and gallium[11] are used. It is quite likely that all organometallic compounds which react with carbonyl containing compounds first form coördinate compounds or complexes of varying stabilities. The less reactive RM compounds may form more stable coördinate linkages with the carbonyl group in ketones than with the carbonyl group in acid halides; and the coördinate complexes with the less reactive RM compounds may stabilize themselves by the direct removal of halogen to form a metal halide rather than by prior addition of the R of the RM compound to the unsaturated carbonyl carbon atom. Varying coördination effects of solvents may influence significantly the relative reactivities of RM compounds.

Steric Hindrance.—It now appears reasonable to suggest that the absence of reaction or very slow reaction observed with some ketones and Grignard reagents may be due appreciably to the formation of coördinate compounds rather than to steric hindrance. Von Braun and coworkers[5,15] observed that $C_6H_5N(CH_3)CH_2CH_2MgX$ reacted with aldehydes but not with ketones; but did find that $C_6H_5N(CH_3)CH_2CH_2CH_2MgX$ reacted with both aldehydes and ketones. These results appear to present an excellent case for steric hindrance for not only is there less steric hindrance with aldehydes than with ketones, but the further removal of the MgX group from the nitrogen in the γ-propyl Grignard reagent should give less steric hindrance than the homologous β-ethyl Grignard reagent. However, not only do aldehydes form less stable complexes than ketones,[6,7] but Heck[2e] showed later that the β-ethyl Grignard reagent did undergo a slower than usual reaction with Michler ketone and color tests were obtained. It is possible that more stable coördination compounds are formed in such cases because of the amino groups present in both the Grignard reagent and the Michler ketone, if one may carry over the analogy from the relatively less reactive ammines of triethylgallium[12] mentioned previously. Furthermore, the experiments of Pfeiffer and Blank[10] illustrate in a striking fashion that the tendency to form coördinate complexes with the Grignard reagent increases progressively with the introduction of amino groups in the ketone: $(C_6H_5)_2CO <$ $(NH_2C_6H_4)(C_6H_5)CO$; $[(CH_3)_2NC_6H_4](C_6H_5)CO <$ $[(CH_3)_2NC_6H_4]_2CO$.

However, these authors[10] have misinterpreted the experiments of Klages[16] on the reaction of acetomesitylene with ethylmagnesium iodide. These two reactants gave a product which on hydrolysis yielded the original acetomesitylene. The product, however, was not a coördination complex stabilized in some way by steric hindrance, for reaction with the Grignard reagent was not inhibited. Actually, as Kohler and Baltzly[17] have demonstrated, Klages had in hand an iodomagnesium enolate, which on hydrolysis yields the acetomesitylene

$$(CH_3)_3C_6H_2COCH_3 \xrightarrow{[C_2H_5MgI]} (CH_3)_3C_6H_2C(OMgI)=CH_2 \xrightarrow{[H_2O]} (CH_3)_3C_6H_2COCH_3$$

Not only is there no stabilization of a complex with acetomesitylene because of steric hindrance, but an equally sterically hindered Grignard reagent (mesitylmagnesium bromide) gives a strong color test.[2e] Also, color tests are obtained with sterically hindered aliphatic Grignard reagents like the *t*-butylmagnesium halides, *t*-amylmagnesium chloride, and methyldiethylmethylmagnesium chloride.[2b]

Dimorphism with *p,p'*-Tetramethyldiaminotriphenylcarbinol.—Two forms of this carbinol were first reported[18]: a higher melting one from petroleum ether, and a lower melting one from methanol. Later,[19] only the lower melting form was isolated from several solvents including petroleum ether. In our work, we obtained both forms and showed that they could be interchanged by selection of the appropriate solvent.

Experimental Part

Phenylmagnesium Bromide and Michler Ketone.—The Grignard reagent was prepared in a nitrogen atmosphere, and its concentration was determined by the acid-titration procedure.[20]

A 0.5-cc. sample of the 1.06 molar solution of phenylmagnesium bromide was added dropwise to a rapidly stirred suspension of 1.34 g. (0.005 mole) of Michler ketone

in 50 cc. of dry ether. The resulting solution gave a strong positive color test when a 1-cc. sample was removed, hydrolyzed and treated with the iodine–acetic acid solution used to complete the color test.[2a] Another 4.5 cc. of the Grignard solution was then added to the Michler ketone suspension, the several operations being carried out in nitrogen, at room temperature, and with rapid stirring. A bright orange precipitate quickly formed as the phenylmagnesium bromide was added. Stirring was continued for fifteen minutes, and then the mixture was hydrolyzed by the addition of 75 cc. of dilute aqueous ammonium chloride solution. The solid which was insoluble in both the ether and water layers was filtered off, washed with ether and water, and shown by the method of mixed melting points to be Michler ketone (1.11 g.). The ether layer was separated and dried, and the ether removed by distillation. The residue was extracted with 20 cc. of hot petroleum ether (b. p. 60–68°) and the insoluble portion (0.08 g.) was shown to be Michler ketone. The total yield of ketone recovered was 1.19 g. or 88%. The experiment was repeated, again using a 1:1 ratio of phenylmagnesium bromide and Michler ketone, and the same results were obtained.

Another reaction was carried out in which 6.8 cc. of 0.73 molar phenylmagnesium bromide solution (0.005 mole of RMgX compound) was added to a stirred solution of 1.34 g. (0.005 mole) of Michler ketone in 40 cc. of dry benzene. A heavy orange precipitate formed quickly, but most of it soon went into solution. After stirring for fifteen minutes at room temperature in an atmosphere of nitrogen, the mixture was hydrolyzed with 75 cc. of dilute ammonium chloride solution. The benzene layer was separated, dried, and then the benzene removed by distillation. The residue was extracted with two 25-cc. portions of hot petroleum ether (b. p. 60–68°). The insoluble portion, after filtering and drying, weighed 0.6 g. and melted between 162 and 165°. After one crystallization from 95% ethanol, the melting point and mixed melting point with an authentic specimen of Michler ketone was 172–173°. The petroleum ether solution deposited, on cooling, 0.72 g. of granular crystals, which after crystallization from methanol melted at 106°, and were shown by the method of mixed melting points to be *p,p'*-tetramethyldiaminotriphenylcarbinol. The yield of recovered Michler ketone was 45% and the yield of carbinol was 42%. This experiment was repeated and the results were practically the same.

Color Tests with Dilute Solutions of Phenylmagnesium Bromide. [A].—A solution of phenylmagnesium bromide was diluted with dry ether and a resulting 0.238 molar solution was used in the following tests. Various quantities of this Grignard solution were added to dry test-tubes containing 2.0-cc. portions of a 0.067 molar benzene solution of Michler ketone. After about one minute, the mixtures were hydrolyzed with 1-cc. portions of water, and then 3 drops of the iodine–glacial acetic acid reagent[2a] were added. The smallest volume of the Grignard solution which would produce a positive color test was 0.07 cc. A good test was obtained when 0.1 cc. was used, and more than 0.2 cc. gave a very strong color test. The ratio of reactants in the case requiring the least quantity of Grignard reagent to give a positive test is 1.7×10^{-5} mole of phenylmagnesium bromide to 1.3×10^{-4} mole of Michler ketone in 2 cc. of solution, or a 13-fold excess of Michler ketone.

[B]. The Grignard solution was again diluted, and this time to a concentration of 0.053 molar. A 5-cc. portion of this solution was required to give a faint positive test with 1 cc. of 0.067 molar Michler ketone solution. The concentrations in this case are equivalent to 8.8×10^{-5} mole of Grignard reagent and 2.2×10^{-5} mole of Michler ketone in 2 cc. of solution, or a four-fold excess of Grignard reagent.

It will be noted that in experiment [A] the relatively high initial ratio of Grignard reagent to ketone together with the presence of much benzene combine to favor a color test. In experiment [B] the situation is reversed for not only is the initial ratio of Grignard reagent to ketone sharply decreased, but the medium is also largely ether.

Phenyllithium and Michler Ketone.—An ether solution of phenyllithium, 0.744 molar in concentration, was prepared in the usual manner from bromobenzene and lithium.[21] To a rapidly stirred suspension of 1.34 g. (0.005 mole) of Michler ketone in 50 cc. of ether was added dropwise 6.8 cc. of the 0.744 molar phenyllithium solution or 0.005 mole of phenyllithium. The suspended material quickly dissolved, and the clear brown solution was stirred at room temperature for fifteen minutes. Hydrolysis was effected by distilled water; the ether layer was separated and dried, and the ether was removed by distillation. The residue was crystallized from petroleum ether, and the white crystalline product weighed 1.35 g. and melted at 121–122°. It was then recrystallized from methanol, and found to melt at 107–107.5°. An authentic sample of *p,p'*-tetramethyldiaminotriphenylcarbinol was obtained by dissolving Merck malachite green in water, precipitating the carbinol with dilute potassium carbonate and crystallizing twice from methanol to give a product melting at 107°. A mixed melting point of the two different samples (one melting at 107–107.5° and the other at 107°) was 107–108°.

The carbinol obtained from phenyllithium (m. p. 107–107.5°) was crystallized twice from petroleum ether (b. p. 60–68°) and again melted at 120°.

No unreacted ketone was recovered, and the yield of carbinol was 78%.

The experiment with phenyllithium was repeated except that benzene was used as the solvent for the ketone. In this case the yield of carbinol melting at 105–107° (mixed melting point) was 1.6 g. or 92.5%. No Michler ketone was recovered.

Summary

A 1:1 mixture of Michler ketone and phenylmagnesium bromide in ether forms a coördination compound, which on hydrolysis gives an 88% recovery of ketone. However, the coördination compound is sufficiently unstable so that there is no interference with the color test for organometallic compounds. The stability of the complex is markedly decreased in an ether–benzene mixture, and in addition to a 45% recovery of ke-

(21) Gilman, Zoellner and Selby, THIS JOURNAL, 55, 1252 (1933).

tone there was isolated a 42% yield of *p,p'*-tetramethyldiaminotriphenylcarbinol.

A 1:1 mixture of Michler ketone and phenyllithium, in either benzene or ether, forms no stable complex and the only product isolated in excellent yields is the carbinol, which is an intermediate in the color test.

Other aspects of coördination compounds in organometallic chemistry are considered.

Spectroscopic Evidence for Hydrogen Bonds: The Hexyl Alcohols. I[1]

BY SPENCER C. STANFORD[2] AND WALTER GORDY[3]

Many papers dealing with the infrared absorption spectra of the alcohols have appeared since the discovery that such spectra give direct evidence of the linkage involved in association through hydrogen bonding. The work on the alcohols through 1938 has been summarized by Freymann.[4]

Previous work, pertinent to the present discussion, may be summarized briefly as follows. In the region of the —OH fundamental vibration band, there is found, in the pure liquid at ordinary temperatures, a broad, intense band with its center at 2.95–3.00 μ. On dilution with an inert solvent such as carbon tetrachloride, or on increasing the temperature, the broad band begins to decrease in intensity. Because of this behavior the band is attributed to the presence of associated molecules. As the broad band diminishes in intensity a sharp band appears at 2.75 μ. This band increases in intensity with increased dilution or temperature and is attributed to single alcohol molecules.

Work on the overtones gives results similar to those on the fundamental. However, in the overtone regions, traces of the monomer bands are found, even in the pure liquids at ordinary temperatures, in alcohols above methyl alcohol. The increased symmetry of the potential energy curve of the proton due to hydrogen bonding causes the overtone association bands to be weak in comparison to the fundamental association band, hence the monomer band is not overlapped as much by the association band.[5]

So far as the authors know, no research has been done on a complete series of isomeric alcohols. It appeared of interest to us to study one such series to see if there are detectable differences in association due to variations in structure. Fortunately the hexyl alcohols were available to us, through the courtesy of Dr. Frank Hovorka, of Western Reserve University. The present paper reports the results of the investigation of eight of the seventeen possible hexyl alcohols.

Experimental Technique.—The preparation and purification of hexanol-1, -2, -3, 2-methylpentanol-1, -2, and -4 has been described in the literature.[6] The preparation of 3-methylpentanol-1 and 2-ethylbutanol-1 will be described in publications soon to appear. The boiling point range did not exceed $\pm 0.02°$ in any of the alcohols studied. The spectrometer and experimental method have been described in a previous paper of this series.[7]

Results and Discussion

The transmission curves for the pure liquids are given in Fig. 1. There is no trace of the monomer band at 2.75 μ. The minimum of the association band is at 2.97 μ for hexanol-1 and 3-methylpentanol-1, the other bands have their minima at 2.95 μ. This slight shift appears to be real, since we were able to reproduce the position of the minima.

There is a gradual increase in the per cent. transmission at the minimum and a decrease in the breadth of the band as one goes from hexanol-1 to hexanol-3. These and differences in intensity among the other pure liquid curves could possibly be due to error in reproducing cell thickness with such thin cells. It is probable, however, that

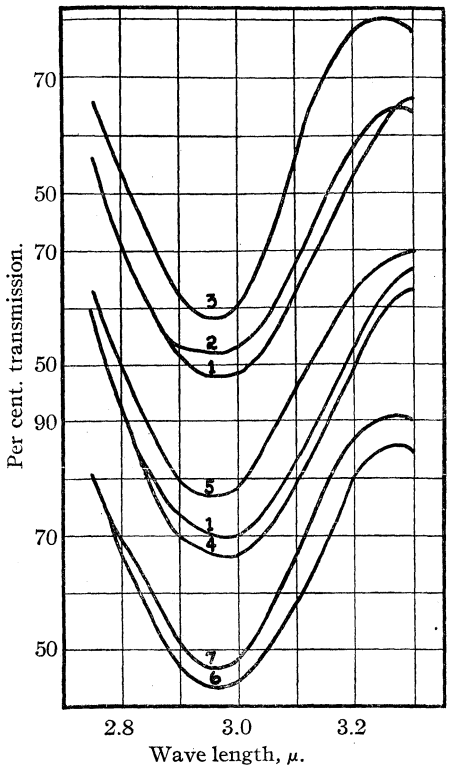

Fig. 1.—Pure liquids, cell thickness, 0.015 mm.: (1) hexanol-1; (2) hexanol-2; 2-methylpentanol-2; (3) hexanol-3; (4) 3-methylpentanol-1; (5) 2-methylpentanol-1; (6) 2-ethylbutanol-1; (7) 2-methylpentanol-4.

they are caused partly by structural differences since similar differences are noted in the solution curves where cell thicknesses are accurate.

For the solutions we have plotted molecular extinction coefficients as a function of wave length. Figure 2 shows the curves for the 0.291 molar solutions. At this concentration there is a distinct monomer band. This band is at 2.75 μ, within the limits of experimental error, for all the alcohols studied. This fact shows that there is no detectable interaction between the —OH and adjacent groups; consequently differences in the association bands may be attributed entirely to differences in association caused by variations in the structure of the alcohol molecules.

The slight differences in the bands of the pure liquids become much more pronounced in the 0.291 molar solutions. Figure 2A shows that there is a marked change in intensity and band position as the hydroxyl is moved from the 1- to the 3-position. The center of the association band for hexanol-2 is at a slightly shorter wave length (2.95 μ) than for hexanol-1 (2.97 μ). The center of the hexanol-3 band is at 2.88 μ. Figure 2B shows that the primary alcohols with side chains fall in a single group having smaller intensity and maxima at shorter wave lengths than is the case with hexanol-1. The curves for these alcohols are identical, within the limits of experimental error, so only the curve for 2-methylpentanol-1 is given. The secondary alcohol, 2-methylpentanol-4, and the tertiary alcohol, 2-methylpentanol-2, give similar curves. The maxima for these alcohols are at the same wave length (2.95 μ) as for the primary branched chain compounds but the intensity is somewhat less.

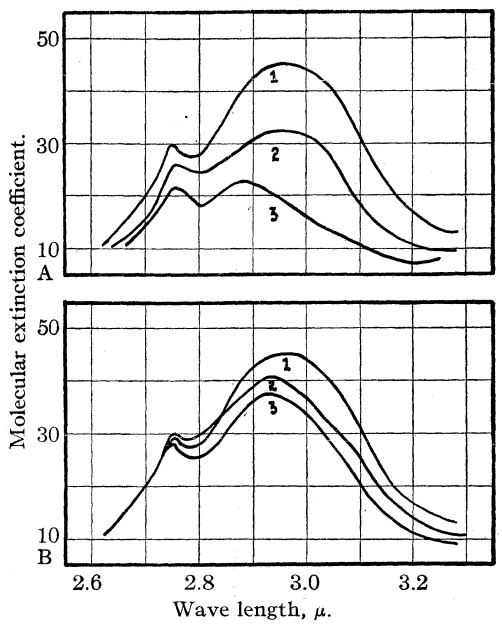

Fig. 2.—Concentration, 0.291 molar; cell thickness, 0.56 mm.: A.—(1) hexanol-1; (2) hexanol-2; (3) hexanol-3. B.—(1) hexanol-1; (2) 2-methylpentanol-1; 2-ethylbutanol-1; 3-methylpentanol-1; (3) 2-methylpentanol-4; 2-methylpentanol-2.

The curves for the 0.1 molar solutions are shown in Fig. 3. The primary alcohols, hexanol-1 and 3-methylpentanol-1 show two well defined components in the association band at 2.91 and 3.03 μ. In hexanol-2 the longer wave length component is not as pronounced and the short wave length component is at 2.89 μ. In hexanol-3 the long wave length component has completely disappeared and the short wave length component is at 2.86 μ. The remainder of the alcohols give very similar curves. The short wave length component is at 2.86 μ and the long wave length component is extremely weak and poorly defined.

The results for the 0.05 molar solutions are plotted in Fig. 4. At this concentration the long

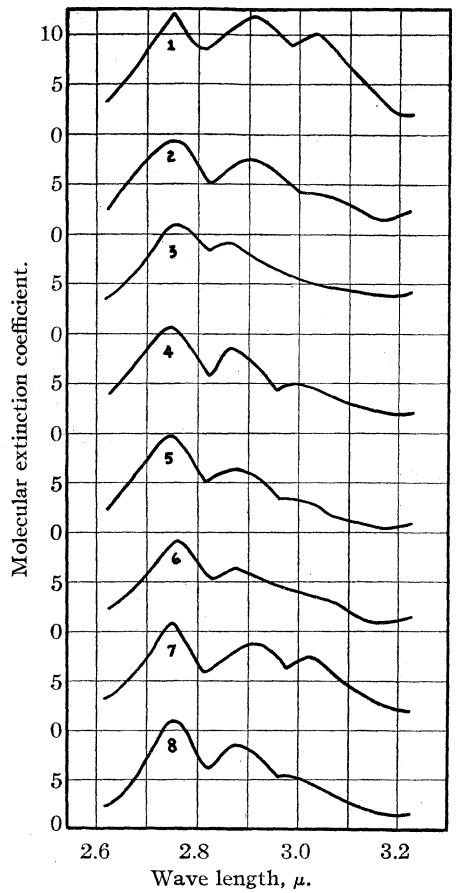

Fig. 3.—Concentration, 0.1 molar; cell thickness, 1.63 mm.: (1) hexanol-1; (2) hexanol-2; (3) hexanol-3; (4) 2-methylpentanol-1; (5) 2-methylpentanol-2; (6) 2-methylpentanol-4; (7) 3-methylpentanol-1; (8) 2-ethylbutanol-1.

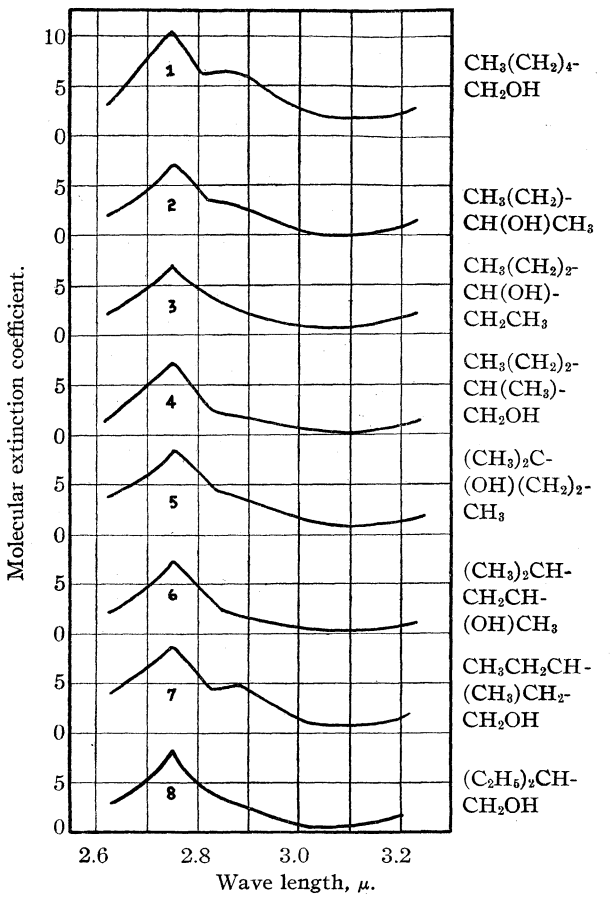

Fig. 4.—Concentration, 0.05 molar; cell thickness, 3.31 mm.: (1) hexanol-1; (2) hexanol-2; (3) hexanol-3; (4) 2-methylpentanol-1; (5) 2-methylpentanol-2; (6) 2-methylpentanol-4; (7) 3-methylpentanol-1; (8) 2-ethylbutanol-1.

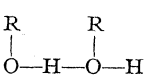
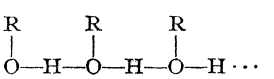
wave length component of the association band has disappeared. The curves fall into the same groups found with the 0.1 molar solutions. In hexanol-1 and 3-methylpentanol-1 there is a distinct band at about 2.86 μ. Hexanol-3 shows only the monomer band at 2.75 μ. In the remaining curves there is a slight indication of absorption in the region of the association band, showing that at this concentration these alcohols are not completely broken down into monomers.

Fox and Martin,[8] studying aliphatic alcohols in carbon tetrachloride at a concentration of 0.112 molar, resolved the association band into two components. Their results were similar to ours, in that they found the long wave length component predominant in the primary alcohols, and the short wave length component predominant in tertiary butyl alcohol. They suggested that the two components might be due to dimers and higher polymers.

In the dimer association



the energy of a single hydrogen bond is supplied by two separate —OH groups of different molecules. Here neither —OH group acts both as a proton donor and as a proton acceptor, as do the —OH groups (with the exception of the end group) of long chain polymers,



where the number of hydrogen bonds per —OH group approaches one as the chain increases in length. If the hydrogen bonds in the dimer are of the same order of strength as those in the higher

(8) Fox and Martin, *Proc. Roy. Soc.* (London), **A162**, 419 (1937).

polymer, one for the above reasons would expect the dimer association to produce less disturbance of the —OH band than the longer chain polymerization. Thus for alcohols which form long chain polymers, one would expect, as is observed, a shift to shorter wave lengths of the —OH band as the length of the chains is diminished either by dilution in an inert solvent or by an increase of temperature. When the dimer stage is reached further breaking down of the polymer would of course cause a sudden jump of the band to the position of monomeric absorption.

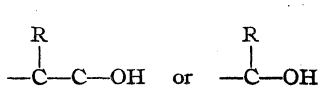
Application of this hypothesis suggests that hexanol-3 in the liquid state (Fig. 1) consists chiefly of lower polymers, possibly dimers, since the band is less intense than that for hexanol-1 and the maximum occurs at the shorter wave length. The other alcohols give curves which are more difficult of interpretation, but the results indicate that these compounds tend to form more dimers than hexanol-1.

Apparently hexanol-3, in 0.291 molar solution in carbon tetrachloride, consists almost entirely of dimers. The rest of the alcohols, at this concentration, appear to form a group intermediate between hexanol-1 and hexanol-3.

In 0.1 molar solution three well-defined groups are found. The primary alcohols, hexanol-1 and 3-methylpentanol-1, show two distinct bands with the short wave length component predominant, indicating that at this concentration more of the molecules exist as dimers than as higher polymers. Hexanol-3 is in a class by itself, with only a weak dimer band. The remainder of the alcohols form a group with very similar bands. In these alcohols there is still a trace of the higher polymer band.

In 0.05 molar solution hexanol-3 is present entirely as monomer. Hexanol-1 and 3-methylpentanol-1 still contain an appreciable amount of dimers. The rest of the alcohols show slight absorption in the region of the association band, indicating that the associated molecules are not completely broken down in these compounds.

It is evident that in all the alcohols studied, with the exception of hexanol-1 and 3-methylpentanol-1, there is something which tends to hinder the formation of polymers higher than dimers. These alcohols have the structure



hence it appears probable that the R groups tend to prevent orientations which are favorable to the production of the higher polymers.

These results are in substantial agreement with those obtained from X-ray work.[9] This seems to confirm the validity of the interpretation of the two components of the association band as being due to dimers and higher polymers.

Some time ago, Hovorka, Lankelma and Stanford[6a] measured the viscosity and density of five of the alcohols over a wide temperature range. It was found that the density and viscosity of hexanol-1 changed rather slowly with temperature. These properties varied much more rapidly in the case of hexanol-3. Hexanol-2, 2-methylpentanol-1, and -4 showed density and viscosity changes intermediate between those of the above two alcohols. The slope of the curves was nearly the same for the last three compounds. The results were interpreted as being due to different types of association and to different rates of dissociation of the associated molecules. The data of the present research are in excellent agreement with this interpretation.

The results obtained thus far indicate that the type and extent of association of a member of an isomeric series of alcohols depends chiefly on the immediate environment of the —OH group rather than on the length of the carbon chain. One would, therefore, expect to find rather similar bands in other alcohols in which the —OH group has a like environment.

In conclusion the authors wish to express their appreciation to Dr. H. H. Nielson and Dr. Alpheus W. Smith for the use of their equipment and for their constant interest in this work, and to Dr. Frank Hovorka of Western Reserve University for providing the alcohols, which made this study possible. They also wish to acknowledge a very helpful conversation with G. B. B. M. Sutherland of Cambridge University.

Summary

1. The infrared absorption spectra of hexanol-1, -2, -3, 2-methylpentanol-1, -2, -4, 3-methylpentanol-1 and 2-ethylbutanol-1 have been determined in the 3 μ region, for the pure liquids and for 0.291, 0.1 and 0.05 molar solutions in carbon tetrachloride.

2. From the behavior of the —OH band of the different liquids upon dilution in carbon tetra-

(9) Stewart, *Chem. Rev.*, **6**, 483 (1929); *Phys. Rev.*, **35**, 726 (1930); Pierce and MacMillan, THIS JOURNAL, **60**, 779 (1938).

chloride, something of the nature of association can be ascertained.

3. It was found that hexanol-3 in concentrated solutions consists chiefly of dimers and that its rate of dissociation with dilution is greater than that for the other alcohols. Hexanol-1 and 3-methylpentanol-1 show the presence of higher polymers down to and including a concentration of 0.1 molar. The rate of change of association with dilution is least for hexanol-1. The remainder of the alcohols form intermediate cases between hexanol-1 and hexanol-3, both in respect to the presence of higher polymers and rate of dissociation with dilution.

4. The difference in behavior of the hexyl alcohols has been interpreted in terms of the structural environment of the —OH group.

The Equilibrium Constants for the Systems Alkyl Formates and Alkyl Acetates with Stearic Acid

BY CHAS. BARKENBUS, C. A. ROSWELL AND A. ELEANOR MITTS

Ester interchange with alcohols or alcoholysis has received considerable attention in the last few years. A similar type of interchange between ester and acid and called acidolysis has not been so extensively studied. Since very little work has been done from a quantitative viewpoint it was thought advisable to determine the equilibrium constants for a series of alkyl esters with stearic acid and to see how these constants varied with change of alkyl group.

The general reaction, *i. e.*

$$RCO_2R + R'CO_2H \longleftrightarrow R'CO_2R + RCO_2H$$

has been used to prepare certain esters where the conditions were favorable.[1] The first quantitative study of acidolysis was made by Reid[2] who determined the equilibrium constants for the systems benzoic acid–benzyl acetate and *p*-bromobenzoic acid–ethyl benzoate. The equilibrium mixture was analyzed by determining the density and the constants obtained checked within 5% with those calculated from the esterification constants.

Sudborough and Karve[3] obtained an equilibrium constant of unity for the two systems trichloroacetic acid–methyl acetate and trichloroacetic acid–ethyl acetate.

Gault and Chablay[4] have recently studied the system methyl palmitate–acetic acid. They determined the time needed to reach equilibrium and found that fifty hours were necessary at 100° when sulfuric acid was used as a catalyst. In their latest paper they give the equilibrium constants for methyl palmitate with acetic acid, propionic acid, *n*-butyric acid, *n*-valeric acid, and *n*-caproic acid. The analysis of equilibrium mixtures of this type is simplified by the determination of the water soluble or water insoluble acids.

Sowa[5] has determined the rate of reaction using acetic acid with various alkyl esters of propionic, benzoic and salicylic acids. He was able to show that the main reaction was one of straight interchange but that larger normal alkyl groups of esters rearrange to secondary alkyl groups when changing to the other acid. This is probably due to the intermediate formation of an olefin. It was stated that only 4% of the new ester was due to this type of reaction. To see whether this observation held for the higher fatty acids, a large scale run was made using *n*-butyl stearate and acetic acid. The butyl acetates when separated and fractionally distilled through a ten-plate Podbielniak column showed that only 2% of the esters was *s*-butyl acetate.

In this work the equilibrium was obtained by heating in a sealed glass tube at 100° about 0.02 mole of stearic acid, 0.1 mole of the ester and 0.1 g. of *p*-toluenesulfonic acid as a catalyst. The tubes were heated at various lengths of time and equilibrium was considered established when the tubes heated the longest checked with those heated next in length of time. From seventy-two to one hundred and twenty hours were usually required.

(5) Sowa, THIS JOURNAL, **60**, 654 (1938).

The contents were dissolved in benzene and extracted at least ten times with cold water to remove the water soluble acids. It was rather difficult to completely remove acetic acid from the benzene solution. The time consumed in the extraction caused some hydrolysis of the lower esters which made it impossible to determine the water soluble acids produced by the acidolysis. The stearate esters due to their insolubility in water were not hydrolyzed during the extraction, as was determined by running blanks.

After extraction, the benzene was evaporated and the last traces of the more volatile ester were removed under vacuum. The residue was then taken up in neutral hot alcohol and titrated. It was found that the most consistent and accurate results were obtained by titrating the insoluble acid instead of the water soluble acid. The equilibrium constants obtained never varied more than 2% and most of them checked within less than 1%.

It was found that formic acid could be more readily extracted with water and a few of the constants were determined by the quantitative oxidation of formic acid with potassium permanganate. In this case the small amount of formate esters dissolved in the water had to be removed by aeration before oxidation. This made the analysis long and great care had to be used in keeping the solutions cold to prevent hydrolysis.

The stearic acid used was a highly purified product obtained by fractional distillation of methyl stearate and by crystallization of the acid. All the esters used were fractionally distilled through a Widmer column and only those fractions having indices corresponding to those in the literature were used. The *p*-toluenesulfonic acid was prepared in the usual way except that stirring was used during the sulfonation, which gave a whiter product. The acid was not crystallized but was triturated several times with toluene and filtered. This last procedure gave a product which was completely soluble in water and, after drying in a desiccator over phosphorus pentoxide, analyzed for approximately one water of hydration.

Gault and Chablay[4] have shown for the reversible reaction $CH_3COOH + CH_3(CH_2)_{14}COOCH_3 \rightleftarrows CH_3COOCH_3 + CH_3(CH_2)_{14}COOH$ that the equilibrium can be approached from both directions. They determined the time necessary to obtain equilibrium starting from both sides and, though the time varied, the concentrations at equilibrium were the same. It was also necessary to have some comparison between the systems using palmitic acid with those using stearic acid. The equilibrium constant for methyl palmitate–acetic acid was redetermined and an average value of 1.034 for four determinations was obtained. The average value obtained by Gault and Chablay,[4] who approached the equilibrium from the other side, was 1.070. Since the above data indicate clearly that a true equilibrium is obtained in acidolysis reactions, the equilibrium constants reported in this paper were obtained by approaching the equilibrium from one direction only.

The equilibrium constants

$$K = \frac{[CH_3(CH_2)_{16}COOR][RCOOH]}{[R—COOR][CH_3(CH_2)_{16}COOH]}$$

are collected in Table I. The values all represent the mean of three independent measurements.

TABLE I

EQUILIBRIUM CONSTANT K IN THE PRESENCE OF STEARIC ACID

	Formates		Acetates	
Esters	K	Av. dev. ±%	K	Av. dev. ±%
Methyl	1.287	0.1	1.019	0.4
Ethyl	0.845	.2	0.902	.5
n-Propyl	.794	.0	.912	.6
s-Propyl	.693	.9	...	...
n-Butyl	.869	.5	.964	.5
i-Butyl	.782	.4	...	...
n-Amyl	.750	.9	.731	.6

Similar measurements were made with methyl acetate using palmitic acid instead of stearic. The corresponding value of K for this system was 1.034 ± 0.4%. This is interesting in showing that there is no significant difference between the palmitate and the stearate system.

We have also calculated similar equilibrium constants from the data of Gault and Chablay.[4] The values thus obtained were for methyl propionate, *n*-butyrate, *n*-valerate and *n*-caproate, 1.12 ± 4, 1.17 ± 10, 1.04 ± 4 and 1.02 ± 3%, respectively. These constants show a diminishing trend with increasing molecular weight of the acid, but the deviations of the individual measurements from the mean are so great as to raise some questions as to whether there was any real difference in these values of K.

It can be seen readily that the methyl group of an ester is more readily replaced by the acid hydrogen of stearic acid than are the other alkyl groups listed. The normal alkyl groups are more readily exchanged than the secondary alkyl groups or branched chain alkyl groups. Esters containing a tertiary alkyl group could not be used as they were decomposed by the acid catalyst. The extent of displacement decreases slowly with length of normal alkyl group at least as far as the normal amyl group. The only exception to this is the *n*-butyl group, which is higher.

From the data of Gault and Chablay and from Table I it can be seen that the length of the fatty acid which forms the ester does not affect the reactivity as much as does the alkyl group of the

ester. The formates are considerably more active than the acetates and from then on the decrease in activity is much smaller as the length of acid increases. In this series the exception to the above statement is methyl *n*-butyrate.

It is interesting to note that esters having a total of five carbons have higher equilibrium constants. Methyl *n*-butyrate and *n*-butyl formate have constants much higher than would be expected. *n*-Propyl acetate does not vary as much but even here the constant is the same as the preceding ester instead of decreasing. The one exception to this observation is *n*-butyl acetate, which is even higher than *n*-propyl acetate. No equilibrium constant has been run for ethyl propionate.

Hatch and Adkins[6] in their displacement series for alcoholysis observed that the values decreased until the normal amyl group was reached. A marked increase was then noticed which gradually decreased in going up the series, but all values were higher than those preceding the normal amyl group. They rationalized these anomalies by the assumption that the effect of a methyl or methylene group may be transferred directly as well as through the chain. By stereochemical considerations the methyl group of the amyl group should be close to the oxygen and act directly.

This explanation might be used for the above anomalies but it is difficult to see why *n*-amyl formate should have a smaller constant than *n*-butyl formate. If the activation is due to both ends of the ester being close together, then the observation that it occurs only in esters having five carbons would be logical. This, however, does not explain why *n*-butyl acetate should have a large constant.

(6) Hatch and Adkins, THIS JOURNAL, **59**, 1694 (1937).

Summary

The equilibrium constants for the reaction of several alkyl formates and alkyl acetates with stearic acid have been determined. Increasing the length of the alkyl group of the ester decreases the value of the constant. However, when the total number of carbons in the ester reaches five, higher values are obtained. Secondary and branched-chain alkyl esters give lower values than the normal alkyl esters.

Optical Constants of Benzamide, its Homologs, and Some Aliphatic Amides[1]

BY M. L. WILLARD AND CHARLES MARESH[2]

Two homologous series of organic amides, namely, an aromatic series based on benzamide and an aliphatic series based on acetamide, were studied optically by means of the petrographic microscope and the Fedorow universal stage as modified by R. C. Emmons.

Materials.—The derivatives and reagents used in this study were obtained from the Eastman Kodak Company. **Acetamide** was recrystallized from 95% alcohol. **Propionamide** and **butyramide** were used as obtained. ***n*-Valeramide** was recrystallized from fusion giving flat plates suitable for optical study. **Isovaleramide** was prepared from isovaleryl chloride and concentrated ammonia solution and purified by sublimation.

Benzamide, *o*-, *m*-, and *p*-toluamides were prepared by the hydrogen peroxide hydrolysis[3] of the corresponding nitriles. ***o*-Ethylbenzamide, *p*-ethylbenzamide,** and **1,3-dimethylbenzamide-2** were prepared from the corresponding amines, using the method of Clarke and Read[4] in the preparation of the nitriles followed by the hydrolysis to the amides. The dimethyl compound, however, required refluxing for seventy-two hours with a saturated alcoholic potassium hydroxide solution for the hydrolysis to the amide.

The melting point of *p*-ethylbenzamide (see Table I) was found to be different from that reported in the literature. Upon hydrolysis, the acid was obtained melting at 112–113.5°. The amide was likewise prepared from the acid by treating with thionyl chloride followed by treatment with concentrated ammonia solution. The amide so obtained melted at 162.9–164.4°.

The amides, ***p*-propylbenzamide, *p*-*n*-butylbenzamide,** and ***p*-isobutylbenzamide** were prepared from bromobenzene and the corresponding bromides (obtained from the alcohols) by means of the Wurtz–Fittig synthesis. The alkyl benzenes were nitrated and reduced according to the method of R. R. Read and D. B. Mullin.[5] The

amines were then diazotized, the nitriles prepared, and the amides formed by the hydrogen peroxide hydrolysis.

The Wurtz–Fittig synthesis was not successful in the preparation of *s*-butylbenzamide, and Eastman Kodak Co. *s*-butylbenzene was the starting material in the preparation of **secondary butyl benzamide.** The melting points from water and petroleum ether differed, and there is a possibility that the optical activity of the secondary butyl group is the explanation. The product from water was studied.

In nitrating, the position of the nitro group was in all cases checked by the preparation of the corresponding nitrobenzoic acid. The amides, *p*-propylbenzamide, *p*-butylbenzamide, *p*-isobutylbenzamide, and *p*-*s*-butylbenzamide, have not been reported in the literature.

The fractionations of the intermediates in the preparation of the aromatic amides were carried out with two columns packed with glass helices of the total condensing variable take-off type with electrically heated jackets 40 and 64 cm. long.

Apparatus and Technique.—A Spencer 35 petrographic microscope was used in all of the work except that involving the universal stage. In addition to the usual accessories, the microscope was fitted with a 1.8-mm. oil immersion (N. A. = 1.25) objective used in conjunction with an aplanatic wide angle condenser (N. A. = 1.40). A removable ocular micrometer in a Spencer 8x ocular was calibrated with both the 4-mm. and 1.8-mm. objectives for optic axial angle measurement against standardized mineral thin sections. As illustrated by W. M. D. Bryant,[6] the use of an oil immersion objective permits the measurement of the entire range of acute axial angles as well as smaller obtuse axial angles.

A Bausch and Lomb modified Fedorow universal stage was fitted on a Bausch and Lomb LC petrographic microscope for the measurement of optic axial angles and indices of refraction beyond the limit of the index oils as well as n_α in the case of the platy aliphatic amides. The universal stage was fitted with three pairs of hemispheres of refractive indices, 1.649, 1.559, and 1.516.

The indices of the liquids beyond the limit of the Abbé refractometer were determined by the method of minimum deviation using a constant temperature hollow prism[7] in conjunction with a single circle reflecting goniometer made by the R. Fuess Company. Monochromatic light was furnished by an 85-watt high intensity Westinghouse mercury vapor lamp Type H-3 along with suitable Corning filters (λ = 5461 Å.).

(6) W. M. D. Bryant, THIS JOURNAL, **60**, 1394 (1938).

(7) M. S. Buerger, *Am. Mineral.*, **18**, 325 (1933).

The principal refractive indices, α, β, and γ at 25° ±3° for λ = 5461 Å. were determined by the immersion method with axial illumination using interference figures in selecting the correct orientation for a given index.[8]

The optical study involved the examination of the crystals obtained from various solvents and from xylene–Canada balsam. In some cases crushed material was mixed with powdered glass preparatory to the examination. The determination of the optic axial angles by means of the universal stage was done on preparations made up in Canada balsam.

The universal stage was used in the determination of n_γ in the case of benzamide and n_α in the case of the platy aliphatic amides using the methods worked out by R. C. Emmons.[9] In the determination of the optic axial angles, the graphical method of T. A. Dodge[10] was used.

Optical Data.—Although metastable forms were encountered in this research, no attempt was made to determine their optical constants. $2V$ values were (a) obtained from melatope distances, (b) measured on the universal stage, and (c) calculated from the indices of refraction. The accuracy of the $2V$ values is given by the agreement of the values obtained by the three methods. The indices of refraction are given with an accuracy of ± 0.003 except where indicated.

Table I gives the data for the aliphatic amides. All of the aliphatic amides listed have been measured crystallographically, but only acetamide in its stable and metastable forms has been studied optically. The values recorded for the stable modification[11] (n_ϵ = 1.46, n_ω = 1.54) are not entirely in accordance with those reported here. The stable form of acetamide is trigonal uniaxial giving short prismatic needles from alcohol and does not fit in with the remainder of the series. The amides from propionamide through isovaleramide crystallize out in mica-like flakes which make it difficult to measure the lowest index.

E. Kahrs[12] states that the amides show good cleavage parallel to the front pinacoid (100), and the obtuse bisectrix is perpendicular to the prominent face of the crystals in the case of propionamide and butyramide, and leaning slightly toward (101) in the case of the two valeramides.

The first value for n_α given has been calculated from $2V$ values. The birefringence being small gives good results for the calculated index. The values given in footnotes are index values obtained on the universal stage by the method of R. C. Emmons.[9] They are good to ±0.01 except where noted.

In Table I are given the data for the aromatic amides studied. Only benzamide has been measured crystallographically. According to Groth[13] benzamide forms monoclinic prismatic crystals, β = 90° 38′; the acute bisectrix forms an angle of 40° with the c axis; and 2H = 100° 15′ (red), 2H = 102° 10′ (violet).

The plates obtained from water give beautifully centered optic axis figures which are practically straight. Twinning is prominent on this face. Rapid cooling during crystallization causes the formation of the metastable triclinic needles having $2V$ = 44°.

o-Toluamide from water gives tablets exhibiting oblique extinction, good cleavage, and off-centered Bx_0 figures. *m*-Toluamide from water crystallizes as monoclinic prisms with a maximum extinction angle of *ca.* 43°. They are elongated parallel to the c axis. The material used for optical determinations was fused beneath a cover glass, then crushed, and mixed with powdered glass. *p*-Toluamide from water crystallizes on the microscope slide as monoclinic square plates showing very good rectangular cleavage. Careful recrystallization from water gives monoclinic crystals elongated parallel to γ. *o*-Ethylbenzamide gives crystals showing both parallel and oblique extinction. From the melt a metastable form giving a well centered Bx_a figure rapidly reverts to the stable monoclinic form. *p*-Ethylbenzamide from water forms monoclinic tablets giving good Bx_0 figures and parallel extinction. *p*-Propylbenzamide from water shows very prominent cleavage parallel to the plane of the optic axes. *p-n*-Butylbenzamide from xylene–Canada balsam forms monoclinic prisms elongated parallel to the c axis. From water the prominent face is parallel to the plane of the optic axes with an extinction angle of 40°. *p*-Isobutyl benzamide from xylene–Canada balsam forms monoclinic prisms elongated parallel to the c axis. From water small plates representing sections parallel to the plane of the optic axes with an extinction angle of *ca.* 37° and with v-shaped cavities running in from the two ends are formed. The interference figure usually obtained for *p-s*-butylbenzamide is that of the optic axis section, not centered, however. Although 2-cyano-1,3-dimethylbenzene crystals

(13) P. Groth, "Chemische Krystallographie," Vol. IV, Leipzig, 1917, p. 523.

show only parallel extinction, they are monoclinic. The monoclinic needles are elongated parallel to the c axis and give perfectly centered Bx_a figures. 1,3-Dimethylbenzamide-2 from water forms needle-like plates giving Bx_a figures, and elongated parallel to c.

In Fig. 1 are given the optic axial angles of the aromatic and aliphatic amides. The aromatic amides plotted are para-substituted homologs of benzamide, and the abscissa gives the length of the carbon chain in the para position. In the case of the aliphatic amides the abscissa gives the length of the carbon chain attached to the $-CONH_2$ group.

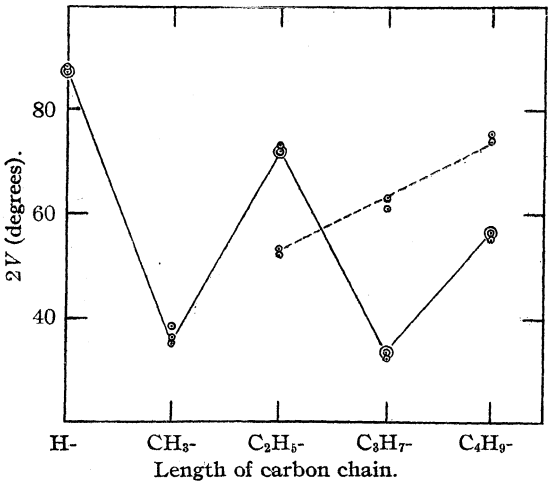

Fig. 1.—Optic axial angles: full lines represent $2V$ values of aromatic amides as a function of the carbon chain in the para position; dotted lines represent $2V$ values of aliphatic amides as function of the carbon chain.

The $2V$ value of acetamide has been omitted. Whereas the $2V$ values of the aliphatic amides vary in a regular manner, there is noted a fluctuation in the case of the aromatic para-substituted amides. The one with the odd number of carbon atoms in the aliphatic chain has a $2V$ value lower than the homolog containing the even number of carbon atoms. From the compounds investigated it appears that the evens and odds vary in a regular manner.

According to Müller and Shearer[14] the natural saturated alcohols have a zigzag structure while the carbon atoms in the natural saturated aliphatic acids have the alternate structure. It appears that the same two types of structure are present in the aromatic and aliphatic amides. Possibly the benzene ring is the cause of the alternate structure.

(14) A. Müller and G. Shearer, *J. Chem. Soc.*, **123**, 3156 (1923).

In Fig. 2 are plotted the refractive indices of the para-substituted normal aromatic amides as a function of the carbon content. As can be seen from the curves, there is a step-like decrease in the birefringence with an increase of the carbon chain which is what would be expected. The substance takes on an aliphatic character as the aliphatic chain is increased, a low birefringence being associated with the aliphatic amides and a higher birefringence with the aromatic amides.

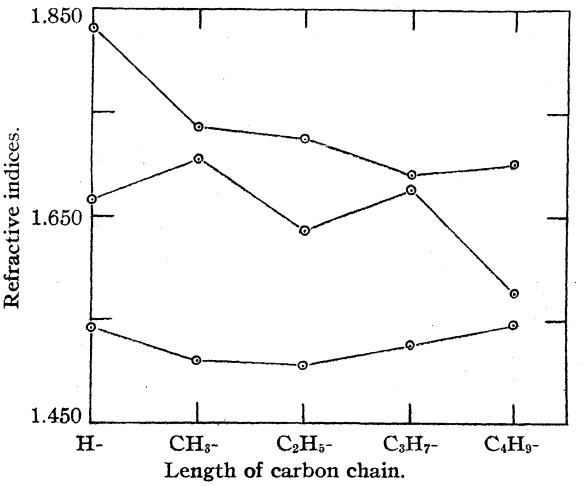

Fig. 2.—Refractive indices of benzamide and its para-substituted homologs: from top to bottom the lines represent n_γ, n_β and n_α; the length of the carbon chain in the para position is plotted as the abscissa.

It is noted from the figure that it is n_β which causes the fluctuation of the $2V$ values.

Acknowledgment.—The authors thank Dr. C. D. Jeffries of the Agronomy Laboratory for his counsel in the use of the universal stage and Mr. E. F. Williams of the Geology Department for the use of the universal stage and his counsel with its application. Thanks are also due The Research Council of this College for making a part of this research possible.

Summary

1. A homologous series of aromatic acid amides based on benzamide was prepared. Four of these have not been reported in the literature and another was reported incorrectly.

2. The optical data including the principal refractive indices, $2V$ values, optical character, crystal system, etc., was worked out for the aromatic amides as well as for a homologous series of amides based on acetamide.

3. The applicability of petrographic methods

including the use of the universal stage was shown.

4. Some attempt was made to explain the data in terms of structure and chemical constitution.

The Reaction of Boron Fluoride with Aluminum Chloride or Bromide

BY E. LEE GAMBLE, PAUL GILMONT AND JOHN F. STIFF

Discussion

The comparative lack of volatility of aluminum fluoride (melting point 1040°) with respect to the other halides of aluminum may be taken advantage of for the preparation of various volatile halides. For example, this paper describes the preparation of boron chloride and of boron bromide by the action of boron fluoride on the corresponding aluminum halide.

$$BF_3 + AlX_3 = AlF_3 + BX_3$$

The ease with which the reactants are obtainable and the differences in volatility make this a simple means of preparation. It is possible that mixed fluorohalides of aluminum are intermediate products of this reaction, but they have not been isolated in a state of purity. The action of boron fluoride on aluminum iodide has produced small amounts of boron iodide but as yet the yields have been quite low. The development of this preparation is to be continued. Boron chloride or bromide is also produced when potassium fluoborate is heated with aluminum chloride or bromide but the yields obtained are not as satisfactory as when boron fluoride is used.

No fluorochlorides or fluorobromides of boron have ever been reported, nor have any been detected in this investigation. To determine whether the known fluorochlorides of silicon[1] could be prepared by this type of reaction, sodium fluosilicate was heated with aluminum chloride, the volatile products obtained proved to be only silicon tetrachloride and tetrafluoride, containing none of the fluorochlorosilanes.

The conversion of volatile fluorides into chlorides or bromides by means of aluminum chloride or bromide should prove to be somewhat general. From one point of view, the results of this reaction may be looked upon as the reverse of those of the Swarts reaction for the production of fluorides or mixed fluorohalides by means of antimony fluoride.[2]

Many of the methods described in the literature for the preparation of the boron halides have been repeated in this Laboratory.[3] It is felt that the preparation of boron bromide from boron fluoride and aluminum bromide is a simpler method than any hitherto described. Also, the preparation of boron chloride by this method may prove convenient.

Experimental

Reagents.—Potassium fluoborate was prepared by dissolving boric acid in 48% hydrofluoric acid and adding potassium carbonate. The product was recrystallized from hot water and dried at 110°.[4] Boron fluoride was prepared by the action of hot concentrated sulfuric acid on a mixture of potassium fluoborate and boric oxide.[5] The aluminum bromide was prepared by slowly adding bromine to an excess of aluminum, in an ordinary distilling flask cooled by water.

Reactions with Boron Fluoride.—The flask in which the reactions were carried on was dumbbell-like in appearance and was constructed by sealing a 1-liter round-bottomed flask to the bottom of a half-liter distilling flask by means of 25 cm. of 30-mm. tubing. The tube for the introduction of the boron fluoride passed through a one-hole cork stopper in the distilling flask and extended to the middle of the larger flask. The smaller flask served as a condenser to prevent large quantities of the aluminum halide from distilling over with the product. A weighed quantity of aluminum chloride was poured into the reaction flask, or aluminum bromide was distilled in from the flask in which it was prepared, and its weight determined by difference. The boron fluoride generator was connected to the reaction flask by means of a small bubbler containing concentrated sulfuric acid. The rate of flow of the boron fluoride was comparatively rapid, about thirty minutes for 2 moles of gas. After the apparatus was swept out with boron fluoride, the large flask containing the

(3) An effort was made to see whether, in the preparation of boron trichloride [BCl_3] by relatively low temperature reactions, some B_2Cl_4 was not formed at the same time. Careful distillation of the reaction products produced only negative results.

(4) "Inorganic Syntheses," Vol. I, McGraw-Hill Book Co., Inc., New York, N. Y., 1939, p. 24.

(5) Ref. 4, p. 23.

aluminum halide was heated gently by means of a free flame whereupon the reaction soon started. For the preparation of boron chloride gentle heating was found desirable as long as the reaction took place. Then, using two burners, both flasks were heated strongly with a stream of boron fluoride still passing through the reaction flasks. After continued heating, the aluminum fluoride fell from the sides of the flask as a light white powder. For the preparation of the boron bromide the aluminum bromide was refluxed gently in a stream of boron fluoride. The contents of the flask soon solidified and again the mass was strongly heated in boron fluoride. The effluent gases were passed into a U-tube cooled with solid carbon dioxide and alcohol, protected by a drying tube. When the reaction was over the U-tube was sealed off and its contents distilled. In the preparation of boron bromide small amounts of bromine were obtained but were readily removed by shaking with mercury. A little metallic aluminum added to the preparation flask decreased the amount of bromine formed. In order completely to remove boron fluoride from boron chloride or bromide, distillation in a good column was desirable. From one-half a mole of aluminum chloride and two moles of boron fluoride 80% yields of boron chloride have been obtained. Using comparable amounts of reactants, 70% yields of boron bromide have been obtained.

Pure aluminum fluoride was not obtained as the by-product of the reaction, appreciable amounts of chloride or bromide being present. Analysis has shown the amount of bromine to be as high as 40% (theoretical for AlF_2Br is 55%); but this was decreased very markedly when the solid product was heated strongly in a stream of boron fluoride.

Reaction with Potassium Fluoborate.—When either aluminum chloride or bromide was heated with potassium fluoborate, some boron chloride or bromide, together with boron fluoride, was formed. An excess of the aluminum halide increases the percentage conversion of the fluoborate.
